Differential Diagnosis. Porphyria shows deposits of hyalin-like material around the superficial dermal capillaries that are indistinguishable from the perivascular deposits of hyalin-like material seen in lipoid proteinosis. However, involvement of the membrana propria of the sweat glands is rare, and no true dermal hyalin is present. In addition, the cutaneous lesions in porphyria are limited to sun-exposed areas.

PORPHYRIA

Seven types of porphyria are recognized (Table 17-1). The light sensitivity in the six types with cutaneous lesions is caused by wavelengths that are absorbed by the porphyrin molecule. These wavelengths lie in the 400-nm range, representing long-wave ultraviolet light (UVA) and visible light (88).

In *erythropoietic porphyria*, a very rare disease that typically develops during infancy or childhood, recurrent vesiculobullous eruptions in sun-exposed areas of the skin gradually result in mutilating ulcerations and scarring. It is inherited in an autosomal recessive pattern (89). Hypertrichosis and brown-stained teeth that fluoresce are additional features (90,91).

TABLE 17-1 Classification of the Porphyrias

Porphyrias	Type; heredity; onset	Cutaneous manifestations	Extra-cutaneous manifestations	Urine	Feces	Erythrocytes	Enzymatic defect
Erythropoietic porphyria	Ery; Rec; Infancy	Blisters, severe scarring	Red teeth; hemolytic anemia	Uro I	Copro I	Uro I, stable fluorescence	Uroporphyrinogen cosynthase
Erythropoietic protoporphyria	Ery; Dom; Childhood	Burning, edema, thickening, rarely blisters	Rarely fatal liver disease	Negative	Protoporphyrin continuously	Protoporphyrin, transient fluoresence	Ferrochelatase (Heme synthase)
Acute intermittent porphyria (AIP)	Hep; Dom; Young adulthood	Negative	Abdominal pain, neuropathy, psychoses	ALA, PBG continuously	Negative	Negative	Uroporphyrinogen synthase
Porphyria variegata	Hep; Dom; Young adulthood	Same as PCT	Same as AIP	ALA, PBG during attacks	Protoporphyrin continuously	Negative	Protoporphyrinogin oxidase
Porphyria cutanea tarda (PCT)	Hep; Dom; Middle age	Blisters, scarring, thickening	Decreased liver function, siderosis	Uro III, continuous fluorescence		Negative	Uroporphyrinogen decarboxylase
Hepatoerythrocytic porphyria (homozygous form of PCT)	Ery and Hep; Dom; Childhood	Blisters, severe scarring, thickening	Decreased liver function	Uro I, Uro III	Copro I, Copro III	Protoporphyrin	Uroporphyrinogen decarboxylase
Hereditary coproporphyria	Hep; Dom; Young adulthood	Same as PCT	Same as AIP	Copro, ALA, PBG during attacks	Copro continuously	Negative	Coproporphynnogen oxidase

Ery, erythropoietic; Rec, autosomal recessive; Uro, uroporphyrin; Copro, coproporphyrin; Dom, autosomal dominant; Hep, hepatic; ALA, delta-aminolevulinic acid; PBG, porphobilinogen; PCT, porphyria cutanea tarda; AIP, acute intermittent porphyria.

In *erythropoietic protoporphyria*, the usual reaction to light is erythema and edema followed by thickening and superficial scarring of the skin (92). In rare instances, vesicles are present that may resemble those seen in hydroa vacciniforme (93–95). It is an autosomal dominant disorder that results from a mutation in the gene that codes for ferrochelatase, which is the final enzyme in the heme synthesis chain (96). The protoporphyrin is formed in reticulocytes in the bone marrow and is then carried in circulating erythrocytes and in the plasma. When a smear of blood from a patient is examined under a fluorescence microscope, large numbers of red-fluorescing erythrocytes are observed. The protoporphyrin is cleared from the plasma by the liver and excreted into the bile and feces (97). It is not found in the urine. In rare instances, fatal liver disease develops quite suddenly, usually in persons of middle age (98) but occasionally in patients only in the second decade of life (99,100).

In *porphyria variegata*, different members of the same family may have either cutaneous manifestations identical to those of porphyria cutanea tarda or systemic involvement analogous to acute intermittent porphyria, or both, or the condition may remain latent (95,101). The presence of protoporphyrin in the feces distinguishes porphyria variegata from porphyria cutanea tarda (102) (see Table 17-1). Also, a sharp fluorescence emission peak at 626 nm is specific for the plasma of porphyria variegata (103,104).

Three forms of *porphyria cutanea tarda* can be distinguished: sporadic, familial, and hepatoerythropoietic (105). In the *sporadic form*, only the hepatic activity of uroporphyrinogen decarboxylase is decreased. Almost all patients are adults, and no clinical evidence of porphyria cutanea tarda is found in other members of the patient's family. Although the sporadic form can occur without any precipitating factor, in most instances, in addition to the inherited enzymatic defect, an

acquired damaging factor to liver function is needed. The damaging agent most commonly is ethanol, but iron supplements, estrogen treatment, and hepatitis are also implicated (106,107).

In the *familial form*, a dominantly inherited disorder, in addition to the hepatic activity, the extrahepatic activity of uroporphyrinogen decarboxylase is decreased to about 50% of normal. The enzymatic activity usually is determined on the erythrocytes. The familial form may occur at any age, including childhood, and often, but not always, there is a family history of overt porphyria cutanea tarda. A reliable laboratory method for the diagnosis of the porphyrias is now provided by molecular genetics (106).

In the very rare *hepatoerythropoietic form*, the skin lesions appear in childhood and the activity of uroporphyrinogen decarboxylase in all organs is decreased to <10% of normal. Family studies suggest that these patients are homozygous for the gene that causes porphyria cutanea tarda (105).

Clinically, the sporadic form of porphyria cutanea tarda, by far the most common type of porphyria, shows blisters that arise through a combination of sun exposure and minor trauma, mainly on the dorsa of the hands but sometimes also on the face (Fig. 17-9). Mild scarring may result. The skin of the face and the dorsa of the hands often is thickened and sclerotic. Hypertrichosis of the face is common. Evidence of hepatic cirrhosis with siderosis is regularly present but generally is mild (108). In rare instances, hepatocellular carcinoma or a carcinoma metastatic to the liver induces porphyria cutanea tarda (109). In the familial form of porphyria cutanea tarda, the clinical picture is similar to that of the sporadic form, but the changes are more pronounced. In the hepatoerythropoietic form, the manifestations are even more severe. On clinical grounds, the symptoms of most patients resemble those of erythropoietic porphyria, but when symptoms are milder, they resemble those of erythropoietic protoporphyria (110). Vesicular eruptions lead to ulceration, severe scarring, partial alopecia, and sclerosis (111). Erythrocytes and teeth may show fluorescence (112). Liver damage develops with increasing age (113).

FIGURE 17-9. Porphyria cutanea tarda. There are crusts from healing vesicles scattered over the dorsal hand. Scars and milia are present on the mid-dorsal hand.

In *hereditary coproporphyria*, a very rare disorder, there are episodic attacks of abdominal pain and a variety of neurologic and psychiatric disturbances analogous to those observed in acute intermittent porphyria and porphyria variegata (114). In some cases, there are also cutaneous manifestations indistinguishable from those of porphyria cutanea tarda and porphyria variegata (114,115).

Histopathology. The histologic changes in the skin lesions are the same in all six types of porphyria with cutaneous lesions. Differences are based on the severity rather than on the type of porphyria. Homogeneous, eosinophilic material is regularly observed, and bullae are present in some instances. In addition, sclerosis of the collagen is present in old lesions (116,117).

In mild cases, homogeneous, pale, eosinophilic deposits are limited to the immediate vicinity of the blood vessels in the papillary dermis (117). These deposits are best visualized with a PAS stain, being PAS positive and diastase resistant.

In severely involved areas, which are most common in erythropoietic protoporphyria, the perivascular mantles of homogeneous material are wide enough in the papillary dermis to coalesce with those of adjoining capillaries. In addition, deeper blood vessels may show homogeneous material around them, and similar homogeneous material may be found occasionally around eccrine glands (118). PAS staining demonstrates this material particularly well. In some instances, it also contains acid mucopolysaccharides, shown with Alcian blue or the colloidal iron stain (117), or lipids, demonstrable with Sudan IV or Sudan black B (93,118). In addition, the PAS-positive dermal–epidermal basement membrane zone may be thickened (117).

In areas of sclerosis, which occur especially in porphyria cutanea tarda, the collagen bundles are thickened. In contrast to scleroderma, PAS-positive, diastase-resistant material is often present in the dermis in perivascular locations (117).

The bullae, which are most common in porphyria cutanea tarda and least common in erythropoietic protoporphyria, arise subepidermally (Fig. 17-10). Some blisters are dermolytic and arise beneath the PAS-positive basement membrane zone (119); others form in the lamina lucida and are situated above the PAS-positive basement membrane zone (120) (Fig. 17-11). It has been suggested that the blisters in porphyria cutanea tarda in mild cases arise within the junctional zone but that in severe cases they form beneath the PAS-positive basement membrane zone and thus heal with scarring (121). It is quite characteristic of the bullae of porphyria cutanea tarda that the

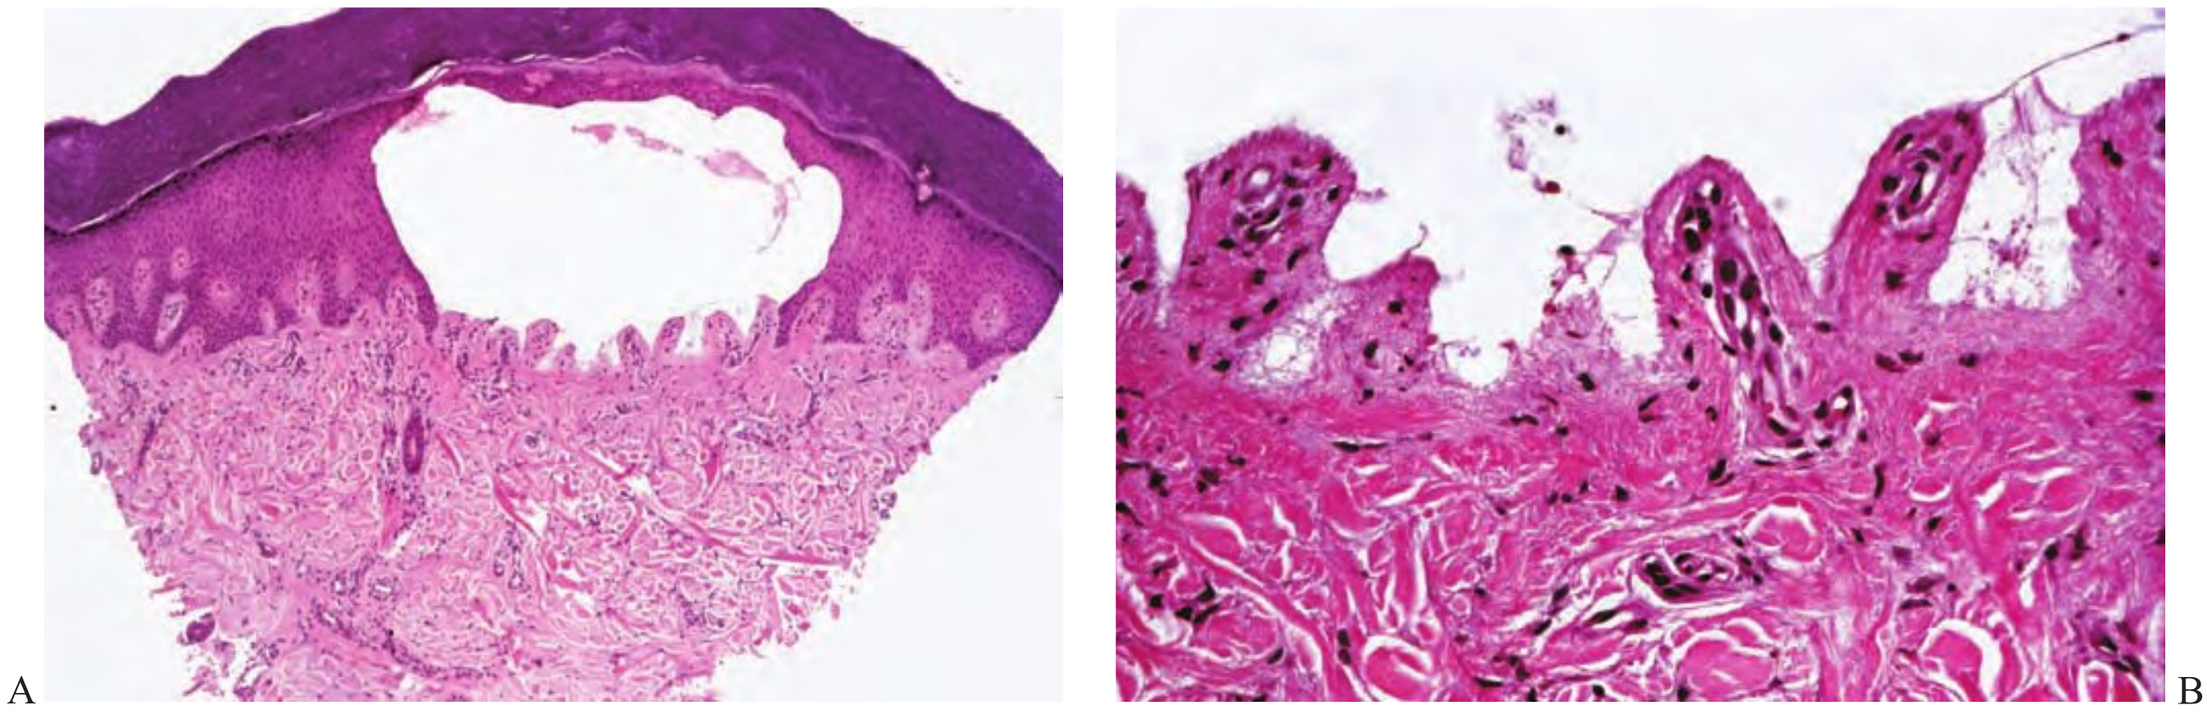

FIGURE 17-10. Porphyria cutanea tarda. A: There is a subepidermal blister. The architecture of the dermal papillae remains intact. The dermis contains no significant inflammatory infiltrate (H&E). B: Vessels within preserved dermal papillae at the blister base are surrounded by PAS-positive, diastase-resistant deposits.

dermal papillae often extend irregularly from the floor of the bulla into the bulla cavity (104,122). This phenomenon, referred to as *festooning*, is explained by the rigidity of the upper dermis induced by the presence of eosinophilic material within and around the capillary walls in the papillae and the papillary dermis.

The epidermis forming the roof of the blister often contains eosinophilic bodies that are elongate and sometimes segmented (123). These "caterpillar bodies" are PAS positive and diastase resistant. Ultrastructurally, they have been found to contain three components: (a) cellular organelles, including melanosomes, desmosomes, and mitochondria; (b) colloid that may be located intracellularly or extracellularly; and (c) electron-dense material thought to be of basement membrane origin (124).

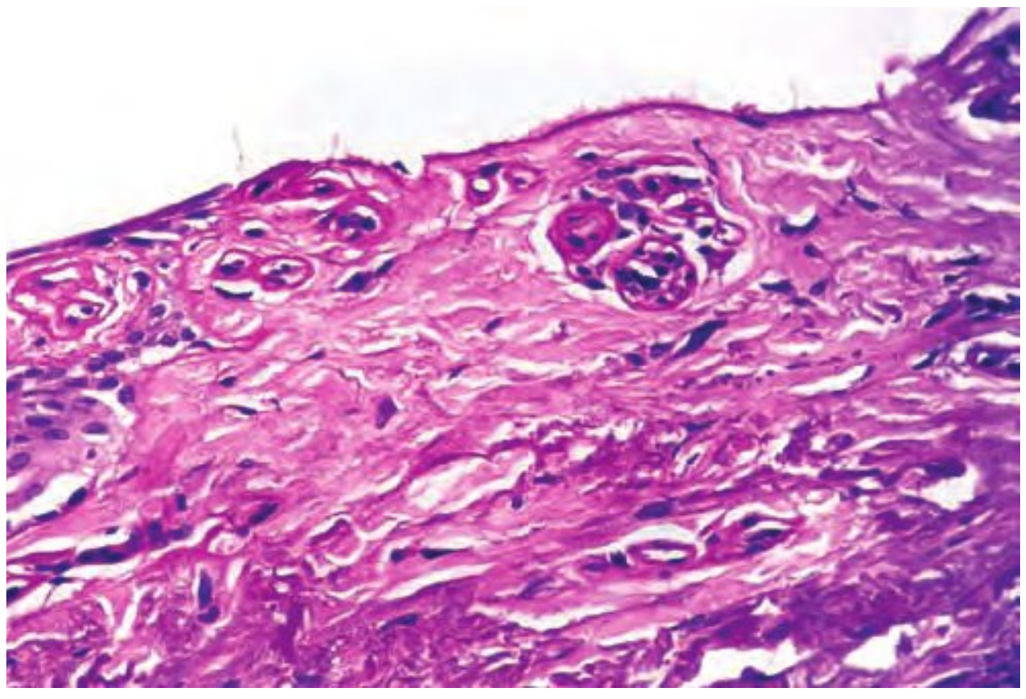

FIGURE 17-11. Porphyria cutanea tarda. On staining with the PAS reaction after diastase digestion, the PAS-positive basement membrane zone is observed at the floor of the blister. PAS-positive hyalin-like material is present in the walls of capillaries in the upper dermis.

Pathogenesis. The substance around dermal vessels has the appearance of hyalin because it consists of homogeneous, eosinophilic material and is PAS positive and diastase resistant. However, just as the perivascular material in lipoid proteinosis, it is only hyalin-like and consists of multiplications of basal laminae (125). True hyalin, which is present in large amounts in the dermis of lipoid proteinosis and produced by fibroblasts as amorphous material, is absent.

On electron microscopic examination, concentric duplications of the basement membrane around the dermal blood vessels are observed. Peripheral to this multilayered basement membrane, one observes a thick mantle of unlayered material with the same filamentous and amorphous composition as that of the basement membrane. Often, a gradual transition from the layered to the unlayered zone can be observed (125,126). Scattered through the thick, unlayered zone are solitary collagen fibrils with an average diameter of only 35 nm, in contrast to the 100 nm of mature collagen (116,125). In cases with severe involvement, intermingled filamentous and amorphous material is seen throughout the upper dermis and even in the mid dermis.

Proof that the perivascular material in porphyria represents excessively synthesized basement membrane material and as such contains type IV collagen is provided by positive immunofluorescence staining with anti–type IV collagen monospecific antibody (127). The presence of small collagen fibrils analogous to reticulum fibrils suggests the presence also of type III collagen.

In the majority of patients, direct immunofluorescence testing has revealed the presence of immunoglobulins, particularly immunoglobulin G (IgG) (117), and occasionally also of complement (128), in the walls of blood vessels and at the dermal–epidermal junction of light-exposed skin. It is unlikely that these deposits indicate an immunologic phenomenon; rather, they are the result of "trapping" of immunoglobulins and complement in the filamentous material.

The *enzymatic defect* that causes each form of porphyria is known (see Table 17-1). Enzyme determinations may be carried out on cultured skin fibroblasts, erythrocytes, or liver tissue.

Liver damage is generally mild and chronic in porphyria cutanea tarda. In erythropoietic protoporphyria, however, liver function tests are usually normal, even though microscopic deposits of protoporphyrin in the liver are found frequently (94). Yet, in rare instances, death occurs from liver failure developing swiftly after the initial detection of hepatic dysfunction (98). Patients with liver failure have very high levels of protoporphyrin in the erythrocytes and at the time of death show extensive deposits of protoporphyrin in a cirrhotic liver. The protoporphyrin in hepatocytes and Kupffer cells appears as dark brown granules (100). This pigment exhibits birefringence on polariscopic examination and in unstained sections viewed with ultraviolet light shows red autofluorescence (98). In patients with normal liver function tests, biopsy of the liver may or may not show portal and periportal fibrosis (99).

Pseudoporphyria Cutanea Tarda

In patients with chronic renal failure who are receiving maintenance hemodialysis, an eruption indistinguishable from that of porphyria cutanea tarda may develop on the dorsa of the hands and fingers during the summer months (129). Rarely, blisters are seen also on the face, and atrophic scarring develops (130). In a series of 180 patients receiving hemodialysis, 28 (16%) showed this type of eruption (131). Normal porphyrin levels in urine, stool, and plasma are the rule in hemodialyzed patients developing clinical signs of porphyria cutanea tarda. However, in a few patients receiving hemodialysis for chronic renal failure, a true porphyria cutanea tarda coexists (132,133). In such patients, if a certain degree of diuresis persists, urinalysis may not be representative of the porphyria metabolism, and the plasma and fecal porphyrins should always be measured (134).

Pseudoporphyria cutanea tarda may also occur following the ingestion of certain drugs, such as furosemide, nalidixic acid, tetracycline hydrochloride, and naproxen (135). Because many patients on hemodialysis for renal failure also are receiving furosemide, withdrawal of the drug can determine whether the dialysis or the medication is the cause of the pseudoporphyria, because in drug-induced cases, withdrawal of the drug is curative (135).

Histopathology. In patients with pseudoporphyria, the histologic picture is indistinguishable from that seen in mild cases of porphyria. The superficial blood vessels show thickened walls, and the PAS-positive basement membrane zone is often thickened as well. Blisters are subepidermal, with festooned dermal papillae. The blisters usually are situated above the PAS-positive basement membrane zone (130–135).

Pathogenesis. Electron microscopic findings are identical to those of porphyria (131). As in porphyria, immunoglobulins are often observed in vessel walls and at the dermal–epidermal junction. Complement is also occasionally present (129,131).

CALCINOSIS CUTIS

There are four forms of calcinosis cutis: metastatic calcinosis cutis, dystrophic calcinosis cutis, idiopathic calcinosis cutis, and subepidermal calcified nodule.

Metastatic Calcinosis Cutis

Metastatic calcification develops as the result of hypercalcemia or hyperphosphatemia. Hypercalcemia may result from (a) primary hyperparathyroidism, (b) excessive intake of vitamin D (136), (c) excessive intake of milk and alkali (137), or (d) extensive destruction of bone through osteomyelitis or metastases of a carcinoma (138). Hyperphosphatemia occurs in chronic renal failure as the result of a decrease in renal clearance of phosphorus and is associated with a compensatory drop in the serum calcium level. The low level of ionized calcium in the serum stimulates parathyroid secretion, leading to secondary hyperparathyroidism and to resorption of calcium and phosphorus from bone. The demineralization of bone causes both osteodystrophy and metastatic calcification (139,140).

Metastatic calcification most commonly affects the media of the arteries and the kidneys. In addition, other visceral organs, such as the myocardium, the stomach, and the lungs (139,141), may be involved.

Metastatic calcification in the subcutaneous tissue is occasionally observed in association with renal hyperparathyroidism (139), in uremia (142), in hypervitaminosis D (136), and as the result of excessive intake of milk and alkali (137) but rarely in primary hyperparathyroidism (138). Palpable, hard nodules, occasionally of considerable size, are located mainly in the vicinity of the large joints (139). With an increase in size, the nodules may become fluctuant (143).

Calciphylaxis is a life-threatening condition in which there is progressive calcification of small- and medium-sized vessels of the subcutis often accompanied by necrosis. It most frequently arises in the setting of hyperparathyroidism associated with chronic renal failure. Calciphylaxis is often, but not always, associated with an elevated serum calcium/phosphate product, with other factors, including several glycoproteins (matrix G1a protein and glycopontin) likely playing a role in the development of vascular calcification (144).

Clinically, the lesions present as a panniculitis or vasculitis. Bullae, ulcerations, or a livedo reticularis–like eruption can be present (145). Potential complications of gangrene, sepsis, pancreatitis, and multisystem organ failure contribute to an overall mortality of >60% (146).

Instances of *cutaneous metastatic calcinosis* are rare. Most reports have concerned patients with renal hyperparathyroidism and osteodystrophy. The cutaneous lesions may consist of firm, white papules (147); papules in a linear arrangement (143); symmetric, nodular plaques (140); or papules and nodules from which a granular, white substance can be expressed (148).

Mural calcification of arteries and arterioles in the deep dermis or subcutaneous tissue occurs rarely in primary

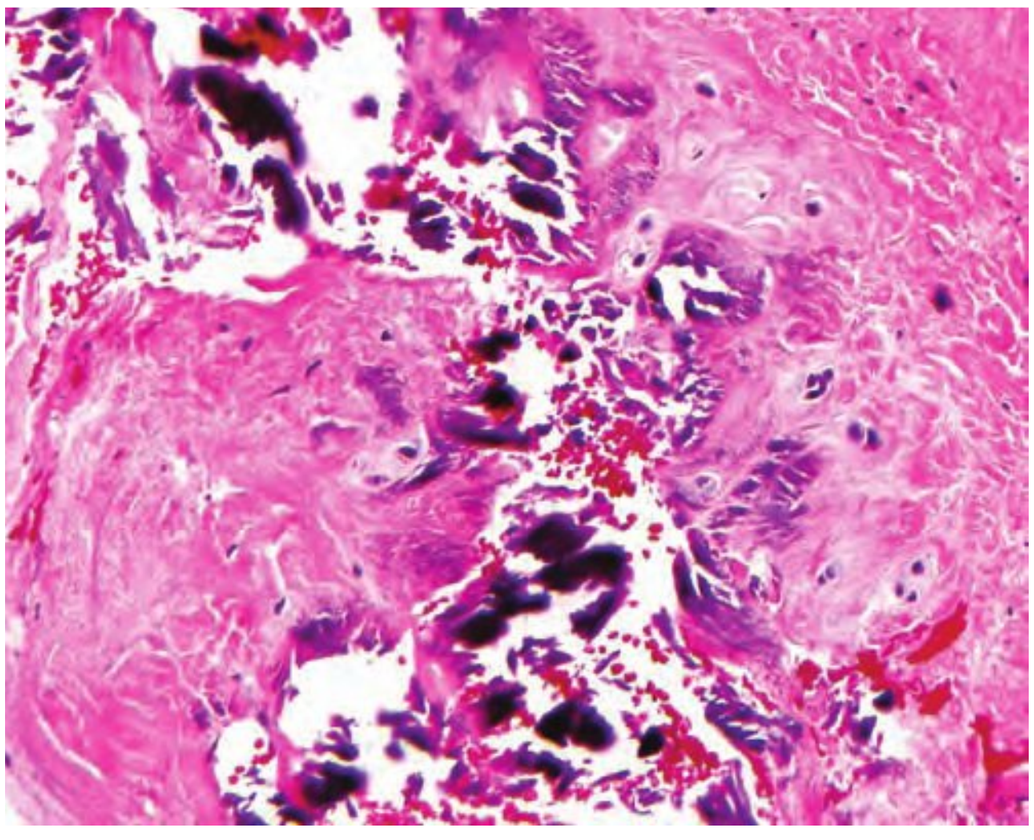

FIGURE 17-12. Metastatic calcinosis cutis. Amorphous deposits of basophilic material are present in the dermis.

hyperparathyroidism (149) but somewhat more frequently in secondary hyperparathyroidism subsequent to renal disease and particularly if subsequent to dialysis for chronic renal disease or to renal allograft (150,151). This may lead to occlusion of these vessels and to infarctive ulcerations, especially on the legs.

Histopathology. Calcium deposits are recognized easily in histologic sections, because they stain deep blue with H&E. They stain black with the von Kossa stain for calcium phosphate. As a rule, the calcium occurs as massive deposits when located in the subcutaneous fat and usually as granules and small deposits when located in the dermis (Fig. 17-12). Large deposits of calcium often evoke a foreign body reaction; thus, giant cells, an inflammatory infiltrate, and fibrosis may be present around them (140).

In areas of infarctive necrosis, as a result of calcification of dermal or subcutaneous arteries or arterioles, the involved vessels show calcification of their walls and intravascular fibrosis with attempts at recanalization of the obstructed lumina (149). Mural calcification often is most pronounced in the internal elastic membranes of arteries or arterioles (150).

The histologic changes in calciphylaxis include calcium deposits in the subcutis, chiefly within the walls of small- and medium-sized vessels (Fig. 17-13). These deposits can be associated with endovascular fibrosis, thrombosis, or global calcific obliteration (152). The fully evolved disease process shows, in addition, areas of necrosis with a clean background or accompanied by neutrophils (146).

It is particularly important that these findings be recognized in order that appropriate therapy, which often includes parathyroidectomy, might be instituted immediately.

Dystrophic Calcinosis Cutis

In dystrophic calcinosis cutis, the calcium is deposited in previously damaged tissue. The values for serum calcium and phosphorus are normal, and the internal organs are spared. There may be numerous large deposits of calcium (calcinosis universalis) or only a few deposits (calcinosis circumscripta).

Calcinosis universalis occurs as a rule in patients with dermatomyositis (Fig. 17-14), but exceptionally it has also been observed in patients with systemic scleroderma (153). Large deposits of calcium are found in the skin and subcutaneous tissue and often in muscles and tendons (154). In dermatomyositis, if the patient survives, the nodules of dystrophic calcinosis gradually resolve.

Calcinosis circumscripta occurs as a rule in patients with systemic scleroderma; rarely, however, it may be observed in patients with widespread morphea (155,156). Generally, in the presence of calcinosis, systemic scleroderma manifests itself as acrosclerosis. The association of acrosclerosis and calcinosis is

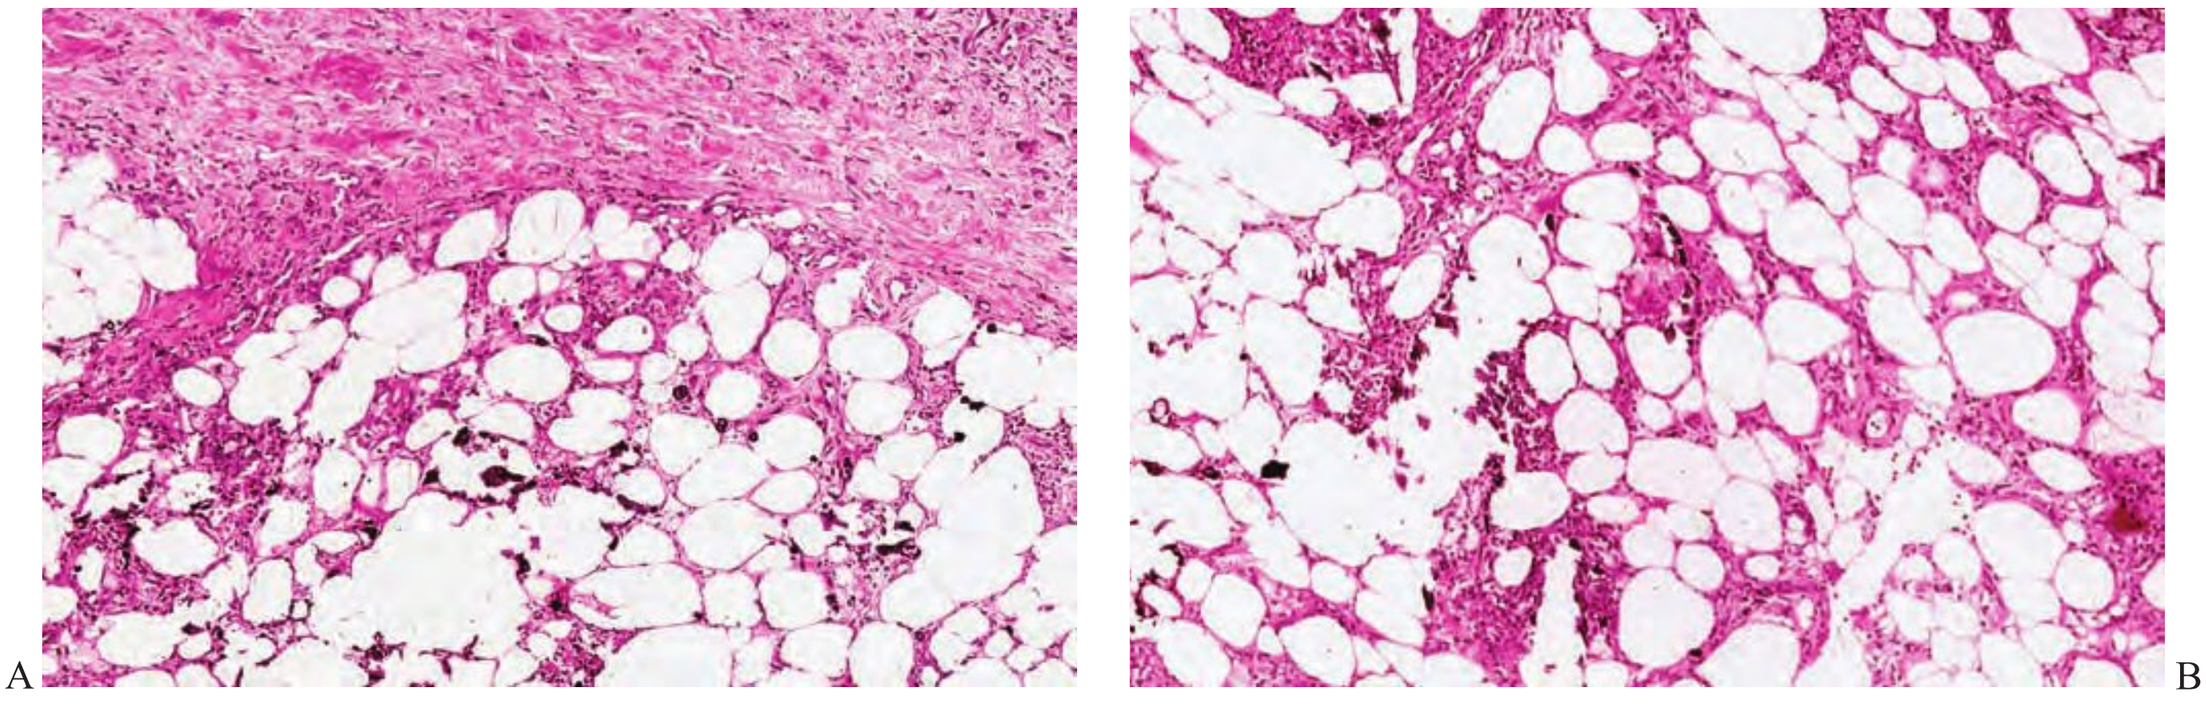

FIGURE 17-13. Calciphylaxis. There is a panniculitis with associated calcification of soft tissues in the walls of small vessels (A: H&E, original magnification ×20; B: H&E, original magnification ×100.)

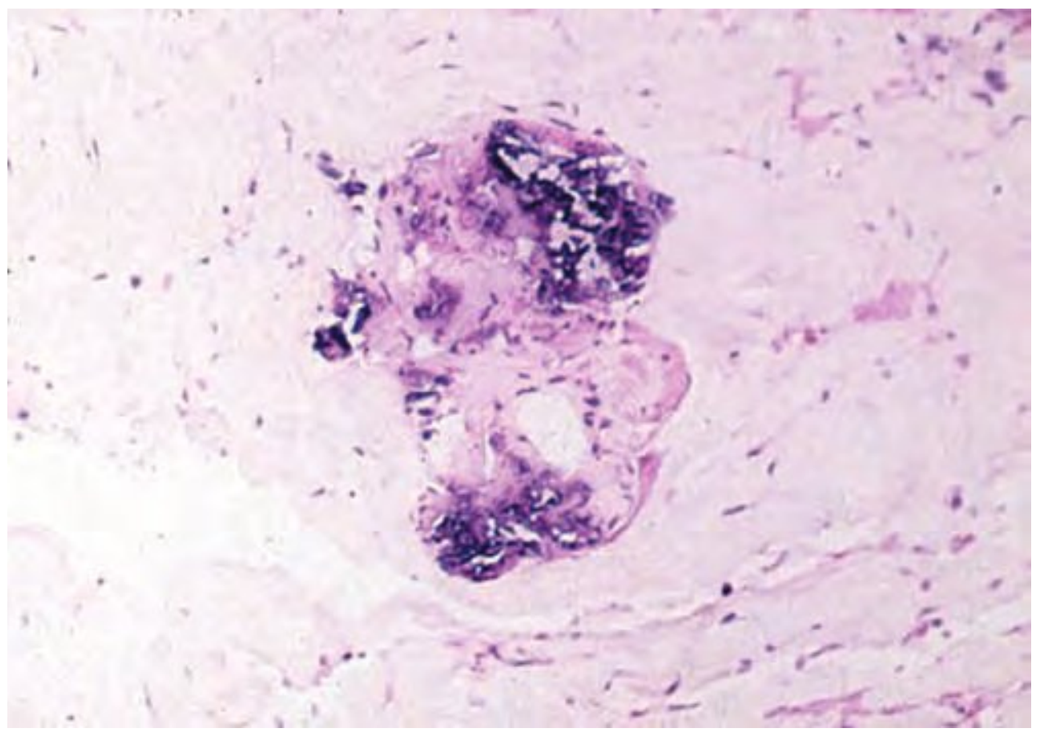

FIGURE 17-14. Dystrophic calcinosis cutis. Granules and globules of calcium are located beneath the epidermis. This biopsy is from the buttock of a child with dermatomyositis who had extensive calcification also of muscles and tendons.

often referred to as the *Thibierge-Weissenbach syndrome* or as the *CREST syndrome*, because the manifestations usually consist of calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia (153,155,157). Patients with this syndrome often have a better prognosis than those with generalized scleroderma or systemic sclerosis. Clinically, calcinosis circumscripta shows successively appearing areas of induration that often break down and extrude white, chalky material.

Lupus erythematosus is only rarely associated with dystrophic calcinosis cutis (158). In addition to occurring in the connective tissue diseases, dystrophic calcinosis is often seen in subcutaneous fat necrosis of the newborn and, rarely, in the subcutaneous nodules occurring in Ehlers-Danlos disease.

Histopathology. As in metastatic calcinosis cutis, the calcium in dystrophic calcinosis cutis usually is present as granules or small deposits in the dermis and as massive deposits in the subcutaneous tissue (156). A foreign-body giant cell reaction is often found around large deposits of calcium (159). The calcium deposits usually are located in areas in which the collagen or fatty tissue appears degenerated as a result of the disease preceding the calcinosis.

Idiopathic Calcinosis Cutis

Even though the underlying connective tissue disease in some instances of dystrophic calcinosis cutis may be mild and can be overlooked unless specifically searched for, there remain cases of idiopathic calcinosis cutis that resemble dystrophic calcinosis cutis but show no underlying disease (160–162).

One entity is regarded as a special manifestation of idiopathic calcinosis cutis: tumoral calcinosis. It consists of numerous large, subcutaneous, calcified masses that may be associated with papular and nodular skin lesions of calcinosis (163,164). The disease usually is familial and is associated with hyperphosphatemia (164,165). Otherwise, the resemblance of tumoral calcinosis to the dystrophic calcinosis universalis observed with dermatomyositis is great.

Histopathology. Tumoral calcinosis shows in the subcutaneous tissue large masses of calcium surrounded by a foreign body reaction (159). Intradermal aggregates are present in some cases. Discharge of calcium may take place through areas of ulceration or by means of transepidermal elimination (164).

Pathogenesis. Two authors have studied lesions of idiopathic calcinosis cutis by electron microscopy (160,161). They agree that the deposits consist of pleomorphic calcium phosphate (apatite) crystals. However, according to one opinion, the earliest deposits of calcium are situated in the ground substance (160), whereas according to the other, the earliest calcium deposits lie within collagen fibrils and subsequently extend into the ground substance as the apatite crystals grow (161).

Idiopathic Calcinosis of the Scrotum

Idiopathic calcinosis of the scrotum consists of multiple asymptomatic nodules of the scrotal skin. The nodules begin to appear in childhood or in early adult life, increase in size and number, and sometimes break down to discharge their chalky contents (166).

Histopathology. At one time, the accepted view was that some of the calcific masses in calcinosis of the scrotum were surrounded by a granulomatous foreign body reaction and others were not (166,167). However, in recent publications in which numerous scrotal nodules were examined, some of the lesions were epidermal cysts, whereas other cystic lesions showed calcification of their keratin contents, and still others showed ruptures of their epithelial walls. The cyst wall was eventually destroyed, leaving only dermal collections of calcium. Thus, according to this view, calcinosis of the scrotum represents the end stage of dystrophic calcification of scrotal epidermal cysts (168,169). Other authors who also had examined either several patients or multiple nodules agreed that the lesions originated from cysts. One author favored eccrine duct milia as the origin because of a positive reaction for carcinoembryonic antigen, which is a marker of eccrine sweat glands (170). Another author found various types of cysts—epidermal, pilar, and indeterminate cysts showing various degrees of calcification (171). It can be assumed that early lesions start out as cysts but, as they age and calcify, lose their cyst walls. It is likely that authors who found no cyst walls were examining old lesions.

Subepidermal Calcified Nodule

In subepidermal calcified nodule, also referred to as *cutaneous calculi*, usually a single small, raised, hard nodule is present. Occasionally, however, there are two or three nodules (172,173), and in some instances, there are numerous (174) or even innumerable (175) nodules. Most patients are children; however, in some patients, a nodule is present at birth (176) or

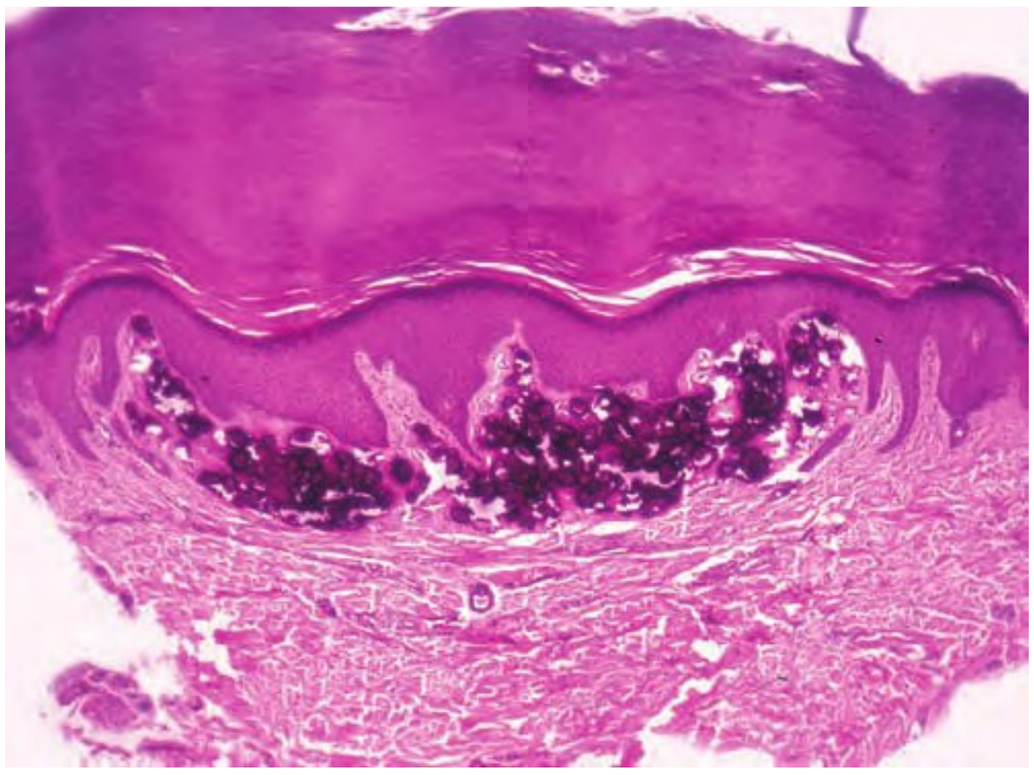

FIGURE 17-15. Subepidermal calcified nodule. A large deposit of calcium in the dermis distorts the overlying epidermis (H&E).

FIGURE 17-16. Gouty tophi. There are yellow-white urate deposits on the elbow.

does not appear until adulthood (177). In most instances, the surface of the nodule is verrucous, but it may be smooth. The most common location of the nodule is the face.

Histopathology. The calcified material is located predominantly in the uppermost dermis, although in large nodules, it may extend into the deep layers of the dermis. The calcium is present largely as closely aggregated globules (Fig. 17-15). In some instances, however, there are also one or several large, homogeneous masses of calcified material (172,173). Both the globules and the homogeneous masses occasionally contain well-preserved nuclei (172). Macrophages and foreign body giant cells may be arranged around the large, homogeneous masses (172). The epidermis is often hypertrophic. Calcium granules may be observed within the epidermis, which is indicative of transepidermal elimination (175,178).

Pathogenesis. The primary event seems to be the formation of large, homogeneous masses that undergo calcification and break up into numerous calcified globules (173). The origin of the homogeneous masses is obscure. It is not likely that they originate from a specific preexisting structure, such as sweat ducts (176) or nevus cells (177), as has been assumed.

GOUT

In the early stage of gout, there usually are irregularly recurring attacks of acute arthritis. In the late stage, deposits of monosodium urate form within and around various joints, leading to chronic arthritis with destruction in the joints and the adjoining bone. During this late stage, urate deposits, called *tophi*, may occur in the dermis and subcutaneous tissue. The incidence of tophaceous lesions in gout has significantly decreased since 1950, from 14% to 3%, even though the incidence of gout has remained unchanged. Improved methods of treatment account for this decrease (179).

Tophi are observed most commonly on the helix of the ears, over the bursae of the elbows, and on the fingers and toes (180) (Fig. 17-16). They may attain a diameter of several centimeters. When large, tophi may discharge a chalky material. In rare instances, gout may present as tophi on the fingertips or as panniculitis on the legs without the coexistence of a gouty arthritis (181–183).

Histopathology. For the histologic examination of tophi, fixation in absolute ethanol or an ethanol-based fixative, such as Carnoy's fluid, is preferable to fixation in formalin; it has been stated that aqueous fixatives such as formalin dissolve the characteristic urate crystals, leaving only amorphous material (184). However, some authors contend that formalin-fixed, paraffin-embedded tissue that is sectioned, floated in alcohol (as opposed to a water bath), and then placed onto a slide without staining will display refractile crystals when examined under polarized light (185). An alternate staining protocol to preserve any urate crystals remaining in formalin-fixed tissue after processing also has been forwarded (186).

On fixation in alcohol, tophi can be seen to consist of variously sized, sharply demarcated aggregates of needle-shaped urate crystals lying closely packed in the form of bundles or sheaves (Fig. 17-17). The crystals often have a brownish color and are doubly refractile on polariscopic examination (Fig. 17-18). If a red compensator is used along with polarizing filters in tissue that has been processed to preserve crystals, the crystals will appear yellow when they are parallel to the direction of the compensator and blue when perpendicular to it (187). The aggregates of urate crystals are often surrounded by a palisaded granulomatous infiltrate containing many foreign body giant cells (Fig. 17-17). The urate crystals appear black and the surrounding tissue yellow when the sections are stained with 20% silver nitrate solution (188).

Even when the specimen has been fixed in formalin, the diagnosis of gout can be made without difficulty because of the

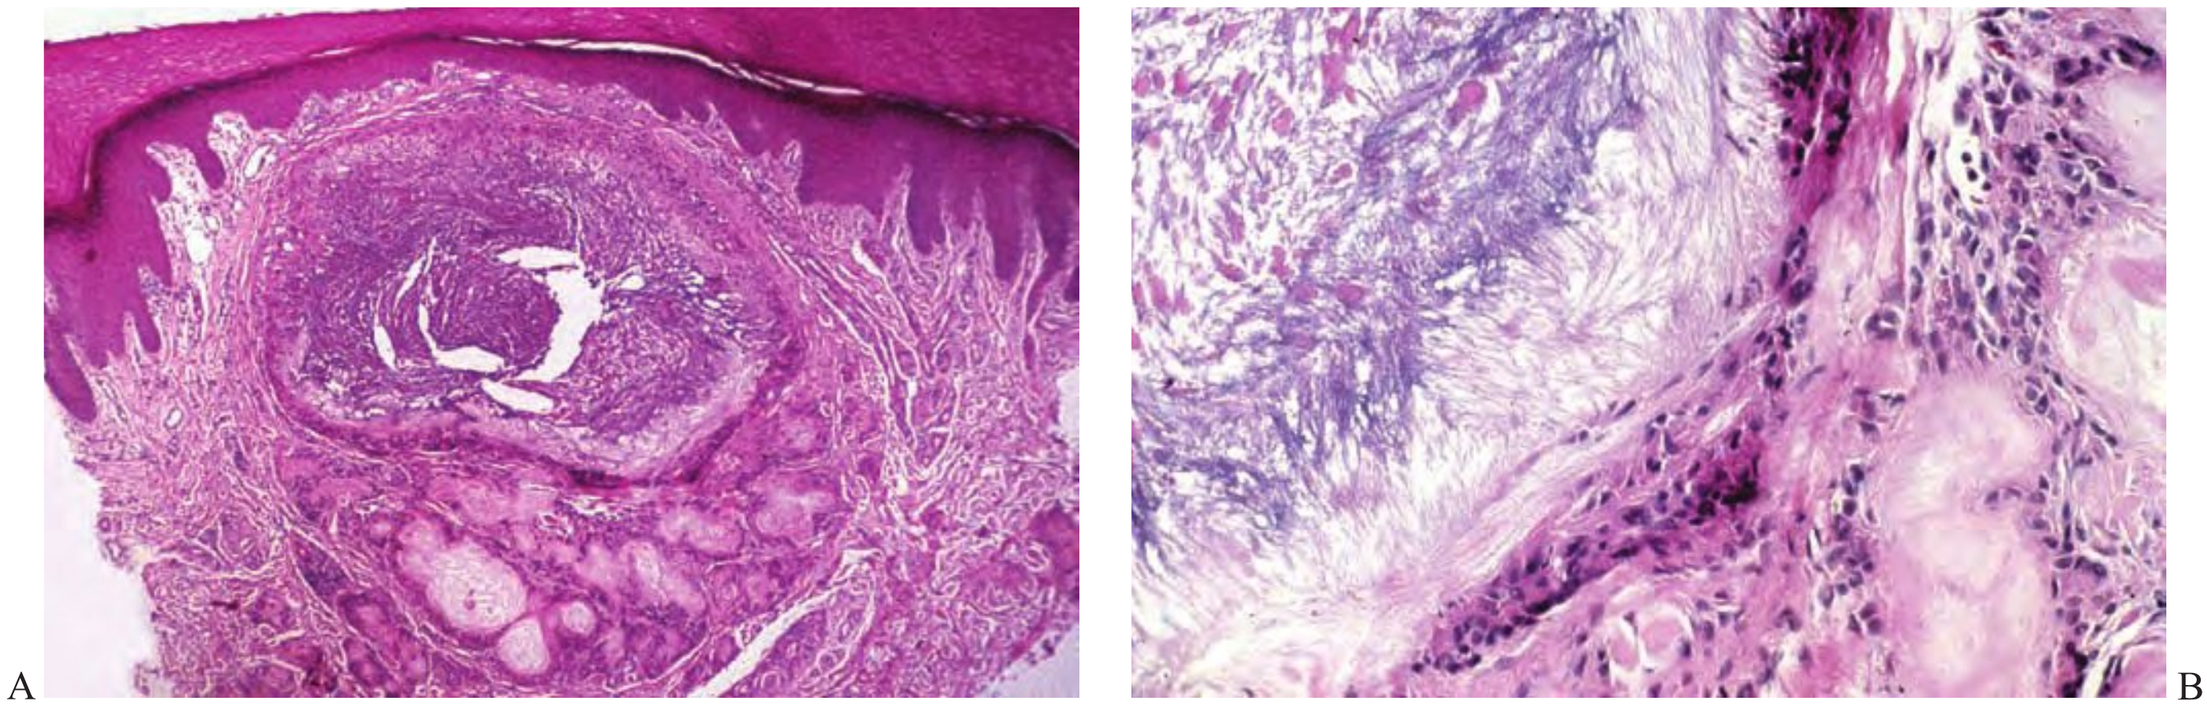

FIGURE 17-17. Gouty tophus. A: There are deposits of urate crystals in the reticular dermis that have a radial array. The lucent areas show where some urate crystals were removed during processing of the tissue (H&E). B: There are macrophages and multinucleated giant cells surrounding the urate deposits in the dermis (H&E).

characteristic rim of foreign body giant cells and macrophages surrounding the aggregates of amorphous material. As a secondary phenomenon, calcification, and occasionally ossification, may take place in the sodium urate aggregates.

Histogenesis. Gout, a dominantly inherited disorder, is characterized by hyperuricemia. An asymptomatic stage of hyperuricemia precedes the development of gouty arthritis by many years. Patients with gout are a heterogeneous group. In some patients, diminished renal excretion of uric acid accounts for the hyperuricemia; in others, an excessive production of uric acid from increased purine biosynthesis is found. In still other patients with gout, both excessive synthesis of uric acid and decreased renal excretion of uric acid are found (189). The deposits of urate crystals stimulate cytokine production, chiefly interleukin-1 (IL-1). IL-1 is a central mediator of the neutrophil recruitment and activation that is characteristic of joint disease (but not a feature in dermal disease) (190).

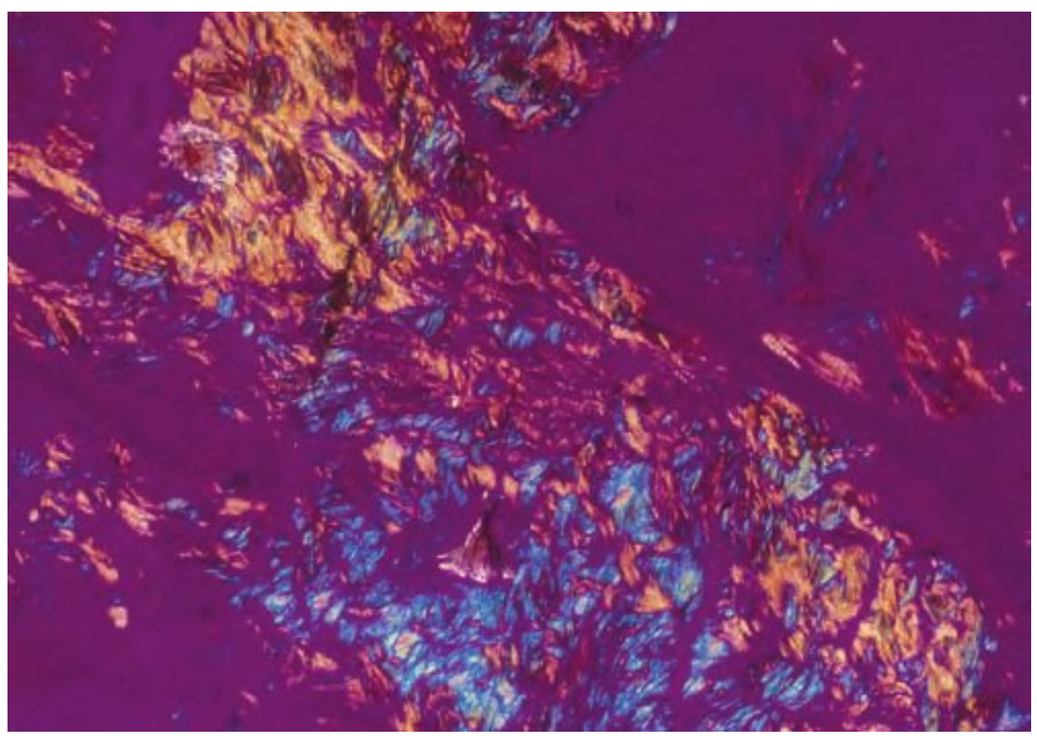

FIGURE 17-18. Gouty tophus. Polarization with a red filter reveals birefringent blue urate crystals in a gouty tophus.

OCHRONOSIS

There are two types of ochronosis: endogenous ochronosis (alkaptonuria), which is inherited as an autosomal recessive trait, and localized exogenous ochronosis, which is prototypically caused by the topical application of a hydroquinone cream to exposed parts of the skin in order to lighten the color of dark skin.

As the result of the lack of homogentisic acid oxidase in endogenous ochronosis, homogentisic acid accumulates over the course of years in many tissues—especially in the cartilages of the joints, the ears, and the nose; in ligaments and tendons; and in the sclerae. This results in osteoarthritis; in blackening of cartilages, ligaments, and tendons; and in patchy pigmentation of the sclerae. In one unusual case, the presenting complaint was pigmentation of the palms and soles with overlying hyperkeratosis and pitting (191). Intervertebral calcification is a characteristic x-ray finding (191–193). In the course of time, homogentisic acid accumulates in the dermis in sufficient amounts to cause patchy brown pigmentation of the skin. The gene for homogentisic acid oxidase maps to chromosome 3q (193,194).

In localized exogenous ochronosis, there is a macular blue-black hyperpigmentation of portions of the face to which the hydroquinone cream or other responsible agent was applied (195) (Fig. 17-19). In more severely involved areas, blue-black papules, milia, and nodules can occur. A condition termed *pseudo-ochronosis* has been recently described as a histopathologic finding in localized argyria occurring primarily in jewelry workers. Clinically, these patients present with blue-black macules ("blue nevus-like") typically on the upper extremities (196).

Histopathology. Involvement of the skin is essentially identical in endogenous and exogenous ochronosis, although it is often more pronounced in exogenous ochronosis (197). The ochronotic pigment, as seen in sections of the dermis stained

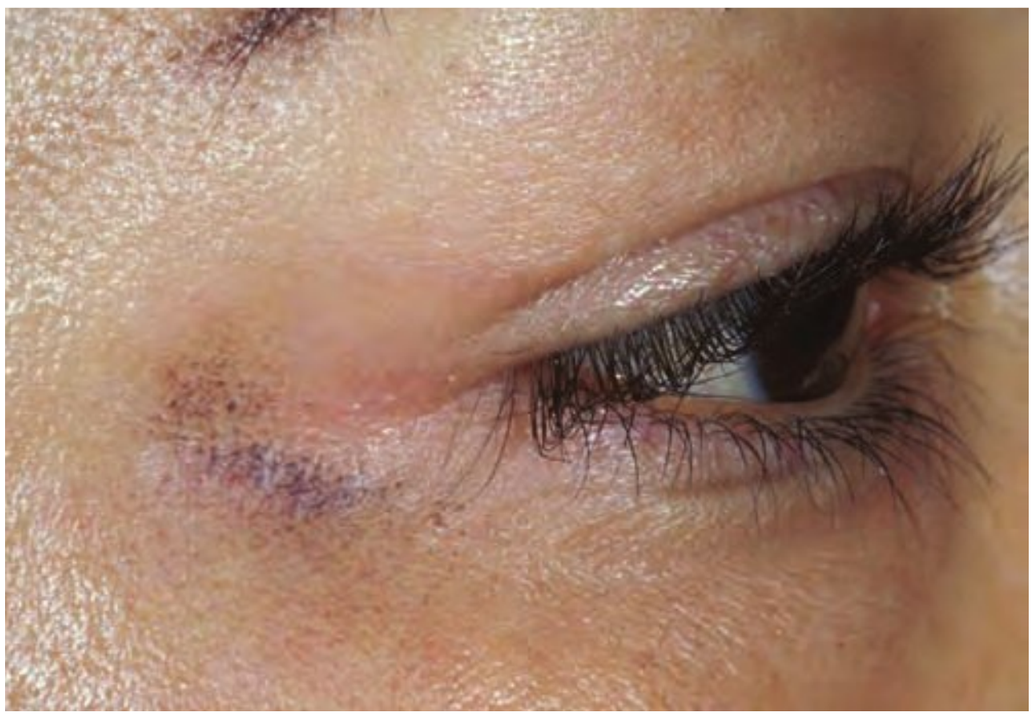

FIGURE 17-19. Exogenous ochronosis. There is stippled, blue-gray pigmentation following long-term use of topical hydroquinone.

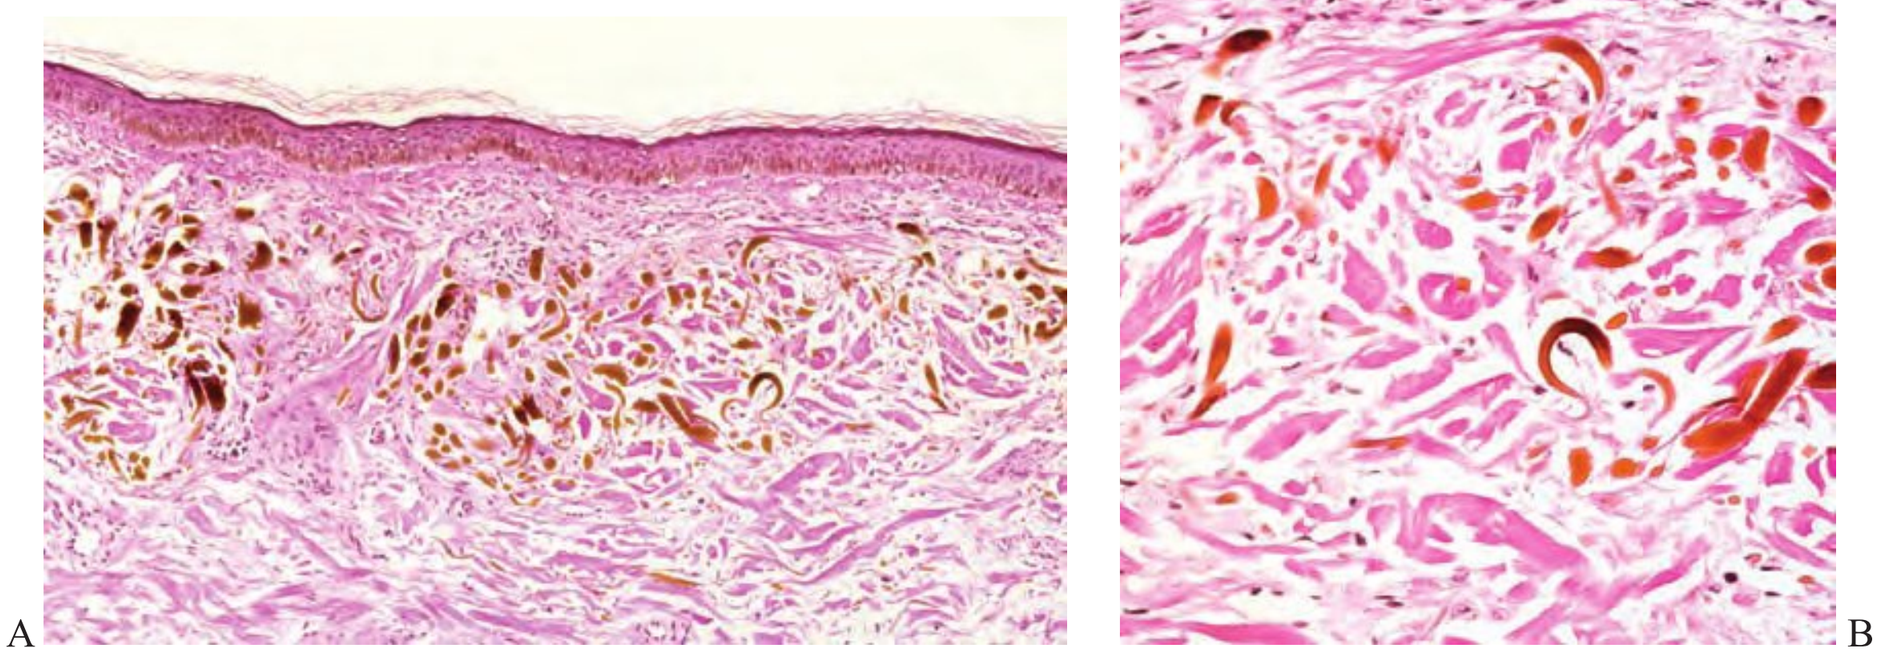
with H&E, has a yellow-brown or ochre color; thus, the name *ochronosis*.



The skin shows ochronotic pigment as fine granules free in the tissue and in the endothelial cells of blood vessels, in the basement membrane and the secretory cells of sweat glands, and within scattered macrophages (198). The most striking finding, however, is the ochronotic pigment within collagen bundles, causing homogenization and swelling of the bundles. Some collagen bundles assume a bizarre shape; they appear rigid and tend to fracture transversely with jagged or pointed ends (199) (Fig. 17-20). As the result of the breaking up of degenerated collagen bundles, irregular, homogeneous, light brown clumps lie free in the tissue. The altered dermal connective tissue does not stain with silver nitrate as melanin does but becomes black when stained with cresyl violet or methylene blue (200). In addition, ochronotic pigment can be found within elastic fibers (201). In nodular ochronosis, a granulomatous response surrounds this material (202). Transfollicular elimination of ochronotic fibers may occur in patients with severe disease (203).

In pseudo-ochronosis, features similar to ochronosis are present in the form of prominent collagen bundles that are yellow-brown in color. In addition, most cases have shown "ellipsoid black globules" of silver within the dermis (196).

Pathogenesis. In *endogenous ochronosis*, because of an inborn lack of homogentisic acid oxidase, the two amino acids tyrosine and phenylalanine cannot be catabolized beyond homogentisic acid. Most of the homogentisic acid is excreted in the urine. The urine, on standing or after the addition of sodium hydroxide, turns black (alkaptonuria) because, through oxidation and polymerization, homogentisic acid is converted into a dark-colored insoluble product. However, some of the homogentisic acid gradually accumulates in certain tissues. It is bound irreversibly to collagen fibers as a polymer after oxidation to benzoquinone-acetic acid (190,204).

In *exogenous ochronosis*, a topical agent such as hydroquinone, resorcinol, phenol, mercury, picric acid or benzene, or a systemic medication such as quinine or antimalarials inhibits the activity of homogentisic acid oxidase in the skin, resulting in the local accumulation of homogentisic acid, which polymerizes to form ochronotic pigment (205,206). In effect, this process mimics the cutaneous manifestation of endogenous ochronosis (197).

Pseudo-ochronosis appears to be due to deposits of traumatically implanted silver onto collagen bundles (196).

A B

FIGURE 17-20. Exogenous ochronosis. Yellowish orange–colored collagen bundles are present in the superficial reticular dermis. Some are abnormally thickened (A: H&E, original magnification ×100; B: H&E, original magnification ×200.)

On electron microscopic examination of early lesions, deposition of amorphous, electron-dense ochronotic pigment around individual collagen fibrils within collagen fibers is observed (192). This causes the collagen fibrils to lose their periodicity and to degenerate. Gradually, the collagen fibrils disappear as they are replaced by ochronotic pigment. Ultimately, the ochronotic pigment occupies entire collagen fibers and, by fusion, entire collagen bundles (207). Cross-sections of the bundles then reveal a large, homogeneous, electron-dense aggregate that in some instances shows remnants of collagen fibrils at its periphery as well as macrophages containing particles of ochronotic pigment (201,208). Particles of ochronotic pigment can also be found in elastic fibers (201). In pseudoochronosis, scanning electron microscopy demonstrates silver deposited on collagen fibers (196).

MUCINOSES

There are six types of cutaneous mucinosis: (a) generalized myxedema, (b) pretibial myxedema, (c) lichen myxedematosus or papular mucinosis, (d) reticular erythematous mucinosis or plaquelike mucinosis, (e) self-healing juvenile cutaneous mucinosis, and (f) scleredema.

Regular demonstration of the presence of mucin in the dermis is possible only in pretibial myxedema, self-healing juvenile cutaneous mucinosis, and lichen myxedematosus. In reticular erythematous mucinosis, it is possible in most cases. In generalized myxedema, the amount of mucin usually is too small to be demonstrable, and in scleredema, mucin may be present only in the early stage.

The mucin found in these six diseases represents an increase in the mucin that is normally present in the ground substance of the dermis. It consists of proteins bound to hyaluronic acid (hyaluronan), which is an acid mucopolysaccharide or glycosaminoglycan. As a result of the great water-binding capacity of hyaluronic acid, dermal mucin contains a considerable amount of water. This water is largely removed during the process of dehydration of the specimen; consequently, in routine sections, the mucin, because of its marked shrinkage, appears largely as threads and granules.

The mucin present in the six types of mucinosis stains a light blue in sections stained with H&E. It also stains with colloidal iron. It is Alcian blue–positive at pH 2.5 but negative at pH 0.5 and shows metachromasia with toluidine blue at pH 7.0 and 4.0 but no metachromasia below pH 2.0 (209). It is PAS negative (indicating the absence of neutral mucopolysaccharides) and aldehyde fuchsin negative (indicating the absence of sulfated acid mucopolysaccharides). The mucin is completely removed on incubation of histologic sections with testicular hyaluronidase for 1 hour at 37°C (210).

Generalized Myxedema

In generalized myxedema, caused by hypothyroidism, the entire skin appears swollen, dry, pale, and waxy. It is firm to the touch. Despite its edematous appearance, the skin does not pit on pressure. There is often a characteristic facial appearance: the nose is broad, the lips are swollen, and the eyelids are puffy.

Histopathology. The epidermis may show slight orthohyperkeratosis and follicular plugging. Usually, routinely stained sections show no abnormality in the dermis, except in severe cases, in which one may observe swelling of the collagen bundles with splitting up of the bundles into individual fibers with some blue threads and granules of mucin interspersed (211). However, with histochemical stains, such as colloidal iron, Alcian blue, or toluidine blue, it is possible, at least in severe cases, to demonstrate small amounts of mucin, mainly in the vicinity of the blood vessels and hair follicles.

Pretibial Myxedema

Usually, the lesions are limited to the anterior aspects of the legs, but they may extend to the dorsa of the feet. They consist of raised, nodular, yellow, waxy plaques with prominent follicular openings that give a peau d'orange appearance (Fig. 17-21). Similar lesions rarely occur on the radial aspect of the forearms (212).

Pretibial myxedema usually occurs in association with thyrotoxicosis and not infrequently becomes more pronounced after treatment of the thyrotoxicosis. It nearly always occurs in association with exophthalmos, and 15% to 20% also have acropachy (213). Complete remission occurs in about 25% of cases (213). Rarely, pretibial myxedema, with or without exophthalmos, occurs in nonthyrotoxic thyroid disease such as chronic lymphocytic thyroiditis; the patient is then either euthyroid or hypothyroid (214).

Histopathology. The epidermis and papillary dermis are usually normal. Mucin in large amounts is present in the dermis,

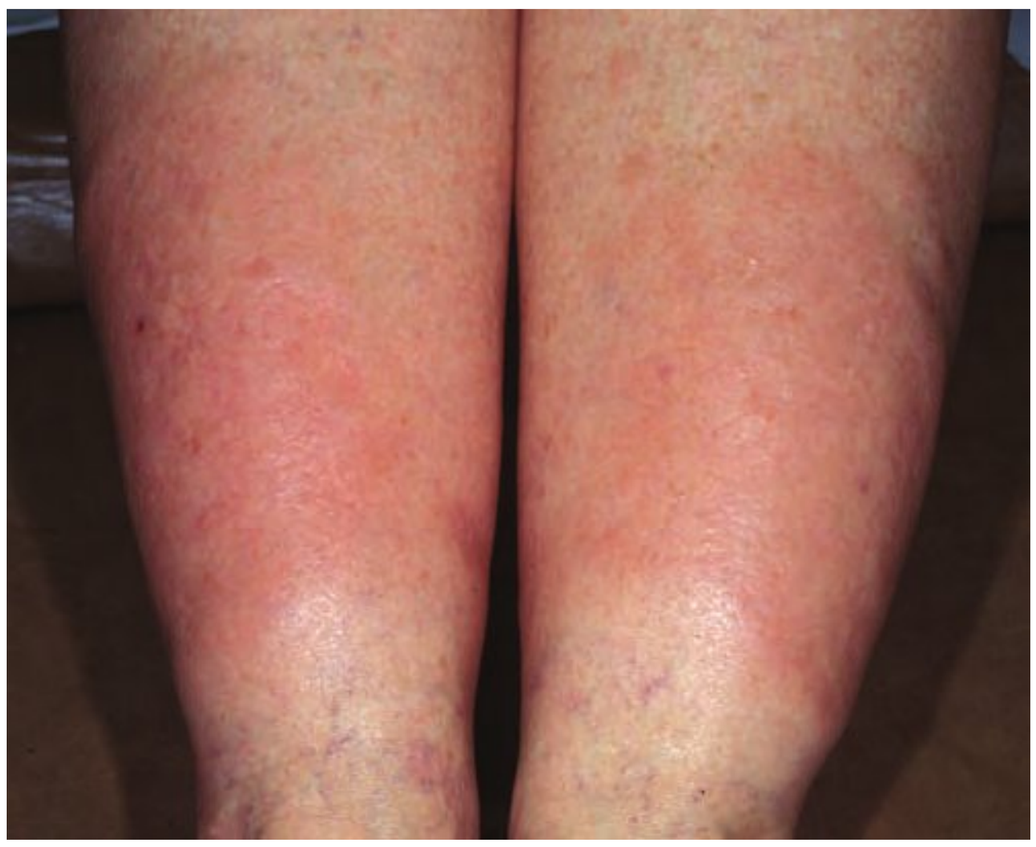


FIGURE 17-21. Pretibial myxedema. There are waxy infiltrated yellow-erythematous plaques on the anterior lower legs.

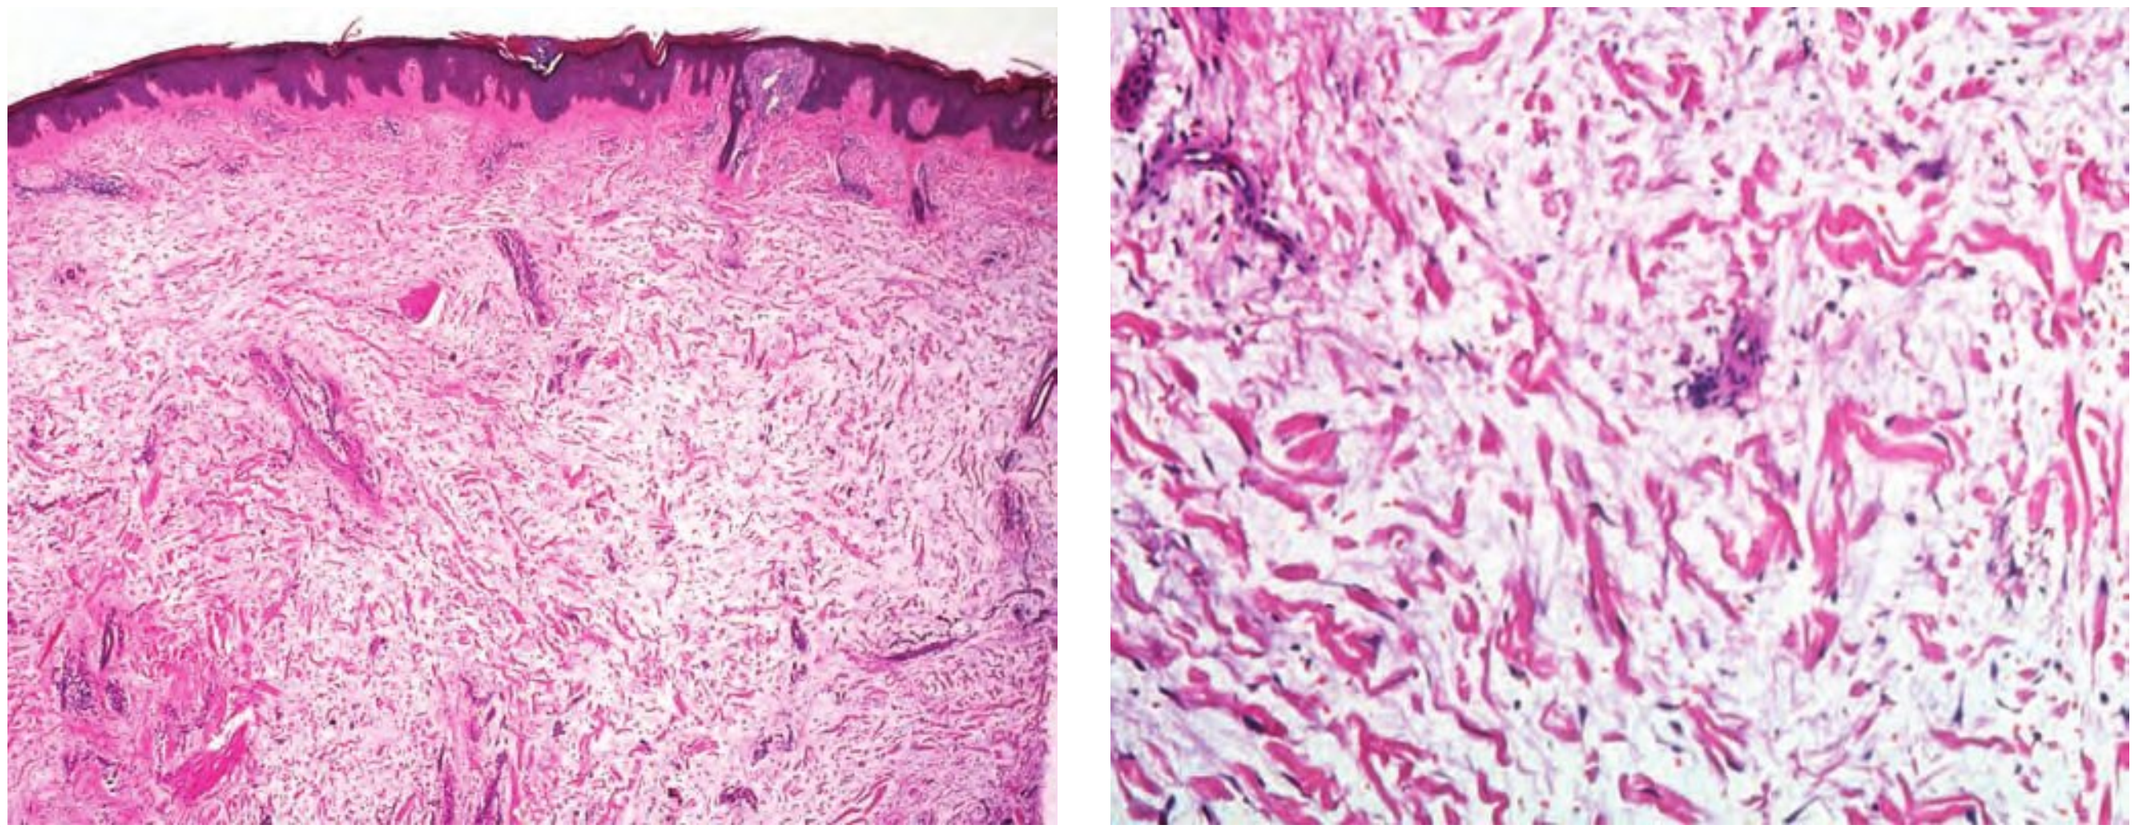

FIGURE 17-22. Pretibial myxedema. A: At scanning magnification, the epidermis and papillary dermis are normal. The collagen fibers in the reticular dermis are widely separated by deposits of mucin (H&E). B: At higher magnification, stellate fibroblasts are evident among the separated collagen fibers (H&E).

particularly in the upper half (Fig. 17-22). As a result, the dermis is greatly thickened. The mucin occurs not only as individual threads and granules but also as extensive deposits resulting in the splitting up of collagen bundles into fibers and wide separation of the fibers. As a result of shrinkage of the mucin during the process of fixation and dehydration, there are empty spaces within the mucin deposits. The number of fibroblasts is not increased as a rule, but in areas where there is much mucin, some fibroblasts have a stellate shape and are then referred to as *mucoblasts* (213,215). A perivascular infiltrate of lymphocytes may be seen in some cases, and mast cells are moderately increased in number (213,215).

Pathogenesis. On electron microscopic examination, the collagen bundles and fibers are separated by wide, electron-lucent, empty spaces. The fibroblasts that produce the mucin are stellate shaped with long, thin cytoplasmic processes and exhibit dilated cisternae of the rough endoplasmic reticulum. An amorphous, moderately electron-dense material coats the surface of the fibroblasts. This material is also present in small, irregular clumps within the otherwise empty-appearing spaces (216). At high magnification, the amorphous material appears as a complex of microfibrils and granules, forming a network (217).

Of interest is the almost invariable presence of long-acting thyroid stimulator (LATS) in the serum of patients with pretibial myxedema. There is, however, a rather poor correlation between the severity of the skin lesions and the level of serum LATS; furthermore, LATS is detected in 40% to 60% of patients with an active exophthalmic goiter but without pretibial myxedema. Thus, LATS cannot be regarded as the cause of pretibial myxedema (218). It is likely that the IgG LATS represents an autoantibody that is produced by lymphocytes in thyroid disease, especially in thyrotoxicosis, and is a reflection rather than a cause of the underlying disease (214).

The restriction of the myxedema largely to the pretibial area may be explained by the finding that fibroblasts from the pretibial area synthesize two to three times more hyaluronic acid than do fibroblasts from other areas when incubated with serum from patients with pretibial myxedema (219). The receptor for thyroid-stimulating hormone (TSH-R) is a candidate as the common tissue antigen in Grave's disease, exophthalmos, and pretibial myxedema. TSH-R immunoreactivity has been detected on fibroblasts in the dermis of control patients without thyroid disease (216).

Differential Diagnosis. Pretibial myxedema must be differentiated from pretibial mucinosis associated with venous stasis. In pretibial mucinosis, the excess mucin is localized to the thickened papillary dermis and is accompanied by angioplasia and siderophages (220).

Lichen Myxedematosus

Lichen myxedematosus, or papular mucinosis, is characterized by a more or less extensive eruption of asymptomatic, soft papules generally 2 to 3 mm in diameter, associated with a monoclonal gammopathy. Although densely grouped, they usually do not coalesce. The face and arms are the most commonly affected areas (Fig. 17-23). In some instances, in addition to papules, large nodules may be present, especially on the face (221). Although the disease is very chronic, spontaneous resolution has been reported (222).

In a variant of lichen myxedematosus called *scleromyxedema*, a generalized eruption of papules as in lichen myxedematosus and, in addition, diffuse thickening of the skin associated with

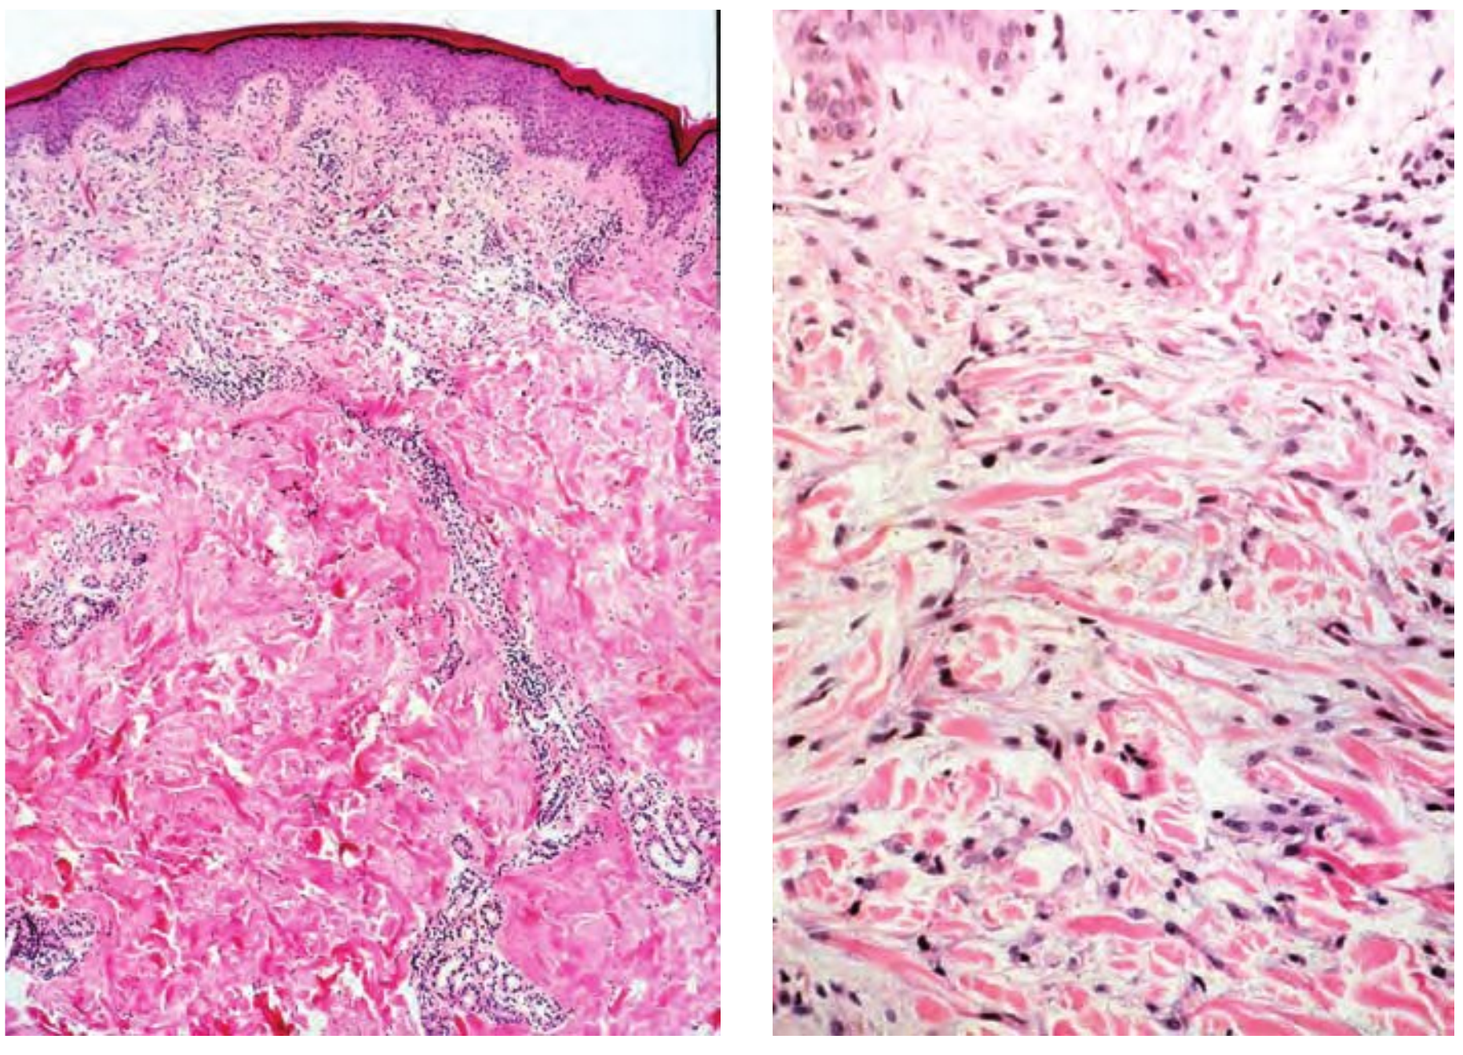

FIGURE 17-23. Lichen myxedematosus. There are numerous firm papules on the face and ear. Note the linear arrangement of the papules near the angle of the jaw.

erythema are found. There is marked accentuation of the skin folds, particularly on the face. Scleromyxedema can be differentiated from scleroderma clinically by the papular component and the absence of telangiectasias. Transitions of lichen myxedematosus to scleromyxedema do occur. Acral persistent papular mucinosis presents multiple small papular lesions on the hands and forearms (223). The clinical and histopathologic features resemble the discrete papular form of lichen myxedematosus (224). The detection of immunoglobulin A (IgA) monoclonal gammopathy in one case also suggests that it is a localized variant of lichen myxedematosus (225). Cutaneous mucinosis of infancy may also represent a localized form of papular mucinosis on the upper extremities unassociated with monoclonal gammopathy (226). It may remit spontaneously (227).

Multiple dome-shaped papules with histopathologic features suggestive of papular mucinosis have been noted in Birt-Hogg-Dube syndrome (228).

Histopathology. In lichen myxedematosus, fairly large amounts of mucin are present. In contrast with pretibial myxedema, however, the mucinous infiltration is found only in circumscribed areas, is most pronounced in the upper dermis, and is associated with an increase in fibroblasts and collagen (229,230) (Fig. 17-24). The collagen bundles may show a rather irregular arrangement.

A B

FIGURE 17-24. Lichen myxedematosus. A: At scanning power, a dome-shaped papule is evident. The papillary and superficial reticular dermis contain abundant mucin (H&E). B: In addition to mucin, there is an increased number of plump fibroblasts in the upper dermis (H&E).

Scleromyxedema

The histologic picture found in the papules in scleromyxedema resembles that observed in lichen myxedematosus. In the diffusely thickened skin, there is extensive proliferation of fibroblasts throughout the dermis associated with irregularly arranged bundles of collagen. In many areas, the collagen bundles are split into individual fibers by mucin. As a rule, the amount of mucin is greater in the upper half than in the lower half of the dermis.

Scleromyxedema may be difficult to distinguish from nephrogenic fibrosing dermopathy without clinicopathologic correlation. Both conditions are characterized by a dermal infiltrate of spindle cells with increased mucin and collagen. In both conditions, the spindle cells label for either factor XIIIa or CD34 and procollagen1 without demonstrating a pattern that could be utilized to discriminate between these diseases (231). However, in scleromyxedema, the infiltrate is limited to the dermis whereas in nephrogenic fibrosing dermopathy the infiltrate usually also extends down the subcutaneous septa (231).

Autopsy examination of patients with lichen myxedematosus and scleromyxedema usually has not shown mucinous deposits in any internal organs (230,232). However, in one case, mucin was detected in renal papillae, and in others, it was found in the adventitia and media of blood vessels in several organs (233–235).

Pathogenesis. Electron microscopic examination of scleromyxedema reveals an increase in the number of fibroblasts. They show considerable activity, as indicated by the presence of a markedly dilated rough endoplasmic reticulum and long cytoplasmic processes. These fibroblasts produce both collagen and ground substance. The presence of many collagen fibrils with reduced diameter, similar to those in scleroderma, indicates that it is young collagen. In many areas, there are small bundles of young collagen fibrils, with each fibril richly coated with ground substance (236).

The presence of a *monoclonal component* (M component) or paraprotein in the sera of patients with lichen myxedematosus and scleromyxedema has been noted in nearly all cases that have been adequately tested. Its absence has been noted in a few cases (237); in another case, it was absent at first but present later on (238).

In nearly all instances, the paraprotein is an IgG, although other immunoglobulin classes occur on rare occasions (232,239). The IgG paraprotein is a very basic protein because of an increased lysine content in its light chains (240). Thus, in most instances, it migrates more slowly than gamma globulin on serum electrophoresis and may even migrate toward the cathode rather than toward the anode (241). In instances in which it migrates with the same speed as gamma globulin, immunoelectrophoresis is required for its recognition (242). The IgG of lichen myxedematosus differs from the IgG of multiple myeloma not only by usually showing slower electrophoretic migration but also by the fact that its IgG molecules nearly always possess light chains of the lambda type, although light chains of the kappa type have occasionally been found (243,244). In contrast, in multiple myeloma with elevated values for IgG, only about one third of the reported cases with IgG molecules have lambda light chains, and two thirds have kappa light chains (245). In addition to showing a monoclonal IgG, many cases of lichen myxedematosus show hyperplasia of plasma cells in the bone marrow (232,233,242,246). These plasma cells have been shown to synthesize the monoclonal IgG (244). In some cases, the plasma cells in the bone marrow have been regarded as atypical in appearance (247). However, only one case fulfilling the criteria for coexisting multiple myeloma has been documented (248).

The role of the monoclonal IgG in lichen myxedematosus is not clear. Its presence in the dermal mucin has been demonstrated by direct immunofluorescence (247,249,250). Furthermore, the serum containing the paraprotein stimulates the production of hyaluronic acid and prostaglandin E by fibroblasts *in vitro* (251). However, although the serum from patients with lichen myxedematosus stimulates fibroblast proliferation *in vitro*, the purified IgG paraprotein itself has no direct effect on fibroblast proliferation (252).

Reticular Erythematous Mucinosis

Erythematous, reticulated areas with irregular but well-defined margins are present, usually in the center of the chest and of the upper back (Fig. 17-25). This disorder was first described in 1960 as being composed of confluent papules and was called *plaquelike mucinosis*, but similar cases showing coalescent macules, rather than papules, were designated as *reticular erythematous mucinosis* in 1974 (253,254). It has since become apparent that macular and papular lesions can coexist (255). In rare instances, lesions spare the trunk and are present on the arms and face (256). The eruption is asymptomatic. It is chronic but usually responds well to small doses of antimalarial drugs of the 4-aminoquinoline group, such as chloroquine. It may be a presenting sign of systemic lupus erythematosus (257).

Histopathology. Two histologic features are usually present: small amounts of dermal mucin and a mild or moderately pronounced mononuclear infiltrate situated predominantly

FIGURE 17-25. Reticular erythematous mucinosis. There is a netlike (reticulated) pattern of erythema involving the neck and upper chest.

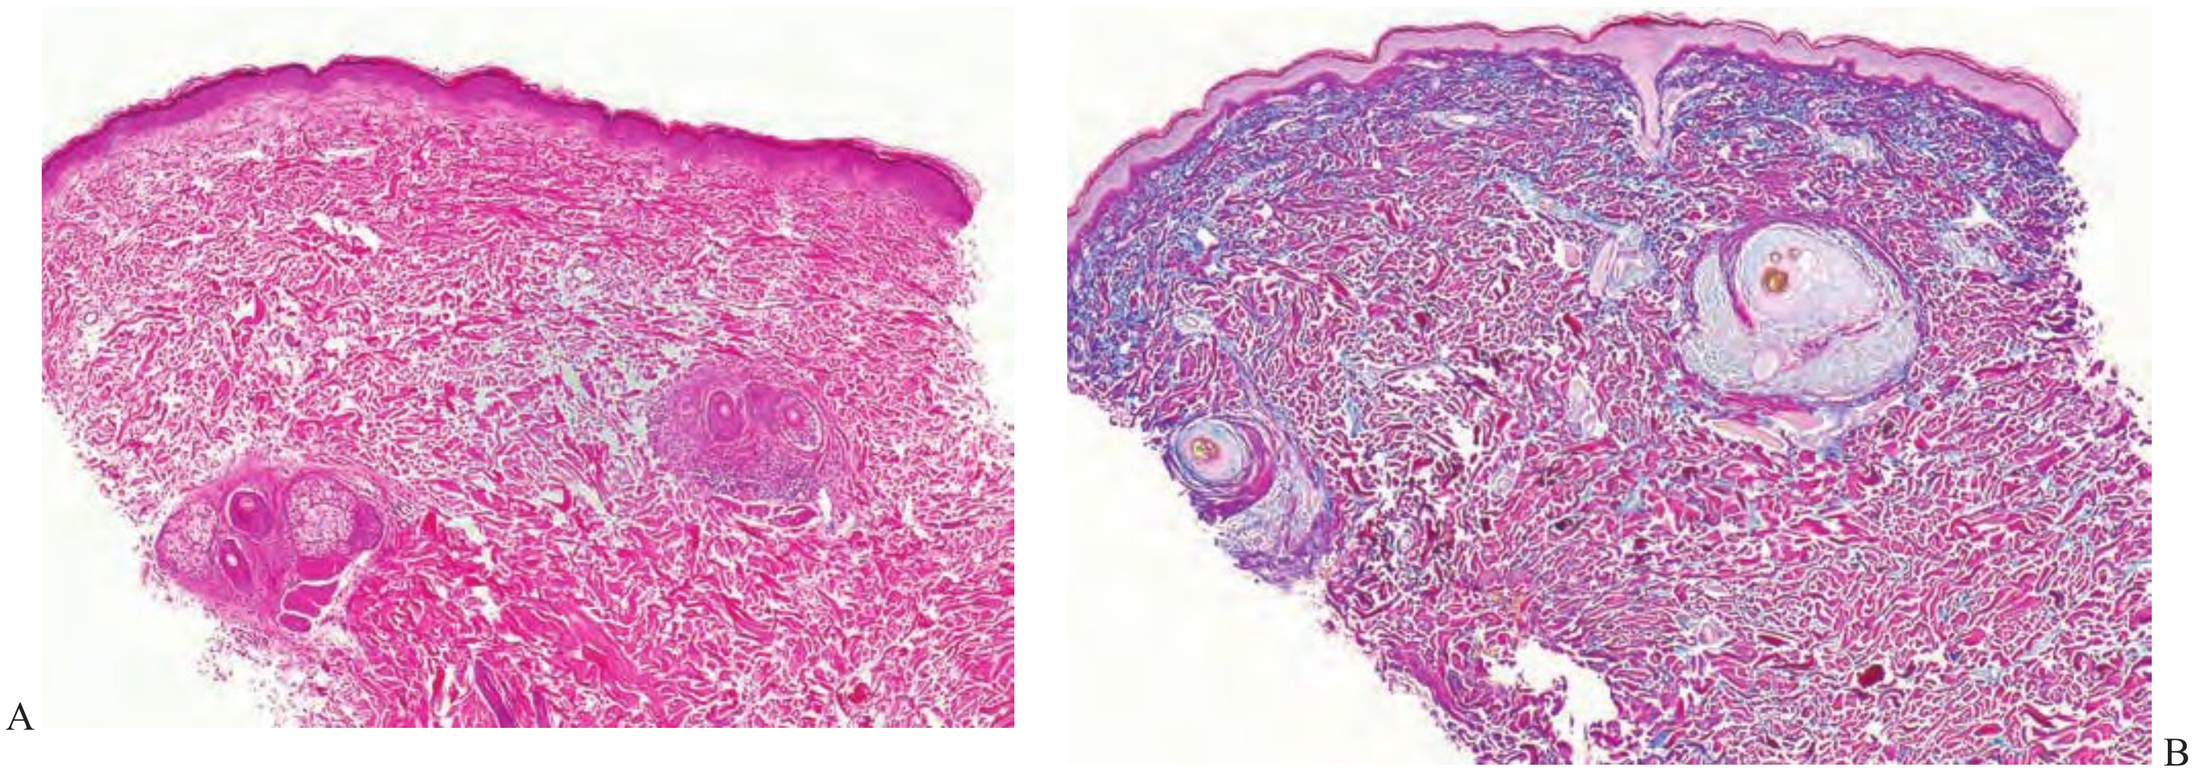

FIGURE 17-26. Reticular erythematous mucinosis. A: There is a sparse superficial perivascular and perifollicular infiltrate of lymphocytes around blood vessels in the dermis (H&E). B: Colloidal iron staining reveals abundant mucin among collagen fibers.

around blood vessels and hair follicles (253,254). The infiltrate is composed of helper T cells (258).

In papular lesions, the mucin usually is fairly conspicuous. As a rule, mucin can be recognized even in routinely stained sections (Fig. 17-26). The mucin stains with Alcian blue and usually also with mucicarmine. In addition, there often is metachromasia on staining with toluidine blue or with the Giemsa stain (253,254). Fibroblasts with bipolar processes are located in the mucinous deposits (259). Immunohistochemistry has revealed a significantly increased number of factor XIIIa dendritic cells in the lesional skin of a patient with reticular erythematosus mucinosis but not in the patient's uninvolved skin or normal control skin samples (260). These same cells also demonstrated immunoreactivity for one isoform of hyaluronan synthase (260).

In macular lesions, the mucin may be missed in routinely stained sections and become apparent only on staining with Alcian blue. In some instances, no mucin is found, even on staining with Alcian blue (261), but if an Alcian blue stain is negative in paraffin-embedded sections, it may be positive in unfixed, frozen sections (262). If this is negative as well, the diagnosis depends on the presence of the mononuclear infiltrate, the clinical appearance, and the response of the patient to treatment with antimalarial drugs.

Differential Diagnosis. Reticular erythematous mucinosis, Jessner's lymphocytic infiltrate of skin, and lupus erythematosus may share in common a perivascular and perifollicular lymphocytic infiltrate and increased mucin among collagen bundles. In Jessner's lymphocytic infiltrate, the lymphocytic infiltrate is usually much denser than that in reticular erythematous mucinosis. Lupus erythematosus almost always shows vacuolar changes in the basal layer of the epidermis and follicular units, but in the rare tumid lesions, vacuolar changes may be inconspicuous. Thus, it may not be possible to distinguish between the tumid lesions of lupus erythematosus and reticular erythematous mucinosis by conventional microscopy. Furthermore, flesh-colored papules and nodules situated on the trunk and demonstrating increased dermal mucin may precede or accompany systemic lupus erythematosus or progressive systemic sclerosis (263). Clinicopathologic correlation is essential in distinguishing these conditions.

Self-Healing Juvenile Cutaneous Mucinosis

Self-healing juvenile cutaneous mucinosis is a rare dermatosis that has been described only in children. It has a sudden onset and undergoes spontaneous resolution within a few months. Infiltrated plaques with a corrugated surface are observed on the torso, and nodules occur on the face and in the periarticular region. Nontender ivory papules in a linear configuration may also occur. There may be associated fever, arthralgias, muscle tenderness, and weakness (264).

Histopathology. Abundant mucinous material, which is Alcian blue positive at pH 2.5, is present mainly in the upper reticular dermis. There may be a superficial perivascular lymphocytic infiltrate and a slight increase in the number of mast cells and fibroblasts in the zone of mucin deposition. Nodular lesions may show a septolobular panniculitis-like pattern with abundant mucin in the expanded fat lobules (265). There may be a proliferation of delicate spindle cells and an infiltrate of lymphocytes. Epithelioid gangliocyte-like mononuclear cells may be present. The histopathologic changes can be confused with proliferative fasciitis. The presence of increased mucin in the papillary and reticular dermis favors self-healing mucinosis.

Scleredema

Scleredema, occasionally called *scleredema adultorum* even though it may occur in children and infants, is characterized by diffuse, nonpitting swelling and induration of the skin (266,267). Three groups can be recognized (268): one with abrupt onset, one with insidious onset, and one preceded by diabetes. In the first group, the scleredema starts abruptly during or within a few weeks after an upper respiratory tract infection. The

skin lesions may clear within a few months, or the disease may take a prolonged course. In the second group, the scleredema starts insidiously, for no apparent reason; spreads gradually; and takes a chronic course. The disease in the third group is preceded by diabetes for years, starts insidiously, and persists indefinitely. Usually, the scleredema starts on the face and extends to the neck and upper trunk. Unlike scleroderma, the hands and feet are always spared. In about 75% of patients, complete resolution takes place within a few months; in the remaining 25%, the disease may persist for as long as 40 years (269). Although visceral lesions may occur, death from scleredema is rare.

Diabetes is commonly associated with persistent scleredema and in most of these instances is quite resistant to antidiabetic therapy (269). It has been suggested that the association of persistent scleredema with maturity-onset diabetes be recognized as a special form of scleredema (270).

Histopathology. The dermis in scleredema is about three times thicker than normal (Fig. 17-27). The collagen bundles are thickened and separated by clear spaces, causing "fenestration" of the collagen. The secretory coils of the sweat glands, surrounded by fat tissue, are located in the upper dermis or mid dermis rather than, as normally, in the lower dermis or at the junction of the dermis and the subcutaneous fat. Because the distance between the epidermis and the sweat glands is unchanged, it can be concluded that much of the subcutaneous fat in scleredema has been replaced by dense collagenous bundles (271). No increase in the number of fibroblasts is noted in association with the hyperplasia of the collagen; in fact, their number may be strikingly decreased (272).

In many instances, especially in early cases, histochemical staining reveals the presence of hyaluronic acid between the bundles of collagen, particularly in the areas of fenestration. Staining with toluidine blue usually reveals metachromasia, which is most evident at pH 7.0, weaker at pH 5.0, and absent at pH 1.5, indicating the presence of only nonsulfated acid mucopolysaccharides (209). Although the hyaluronic acid is usually present throughout the dermis, it may be present only in the deeper portion of the dermis (273) (Fig. 17-28).

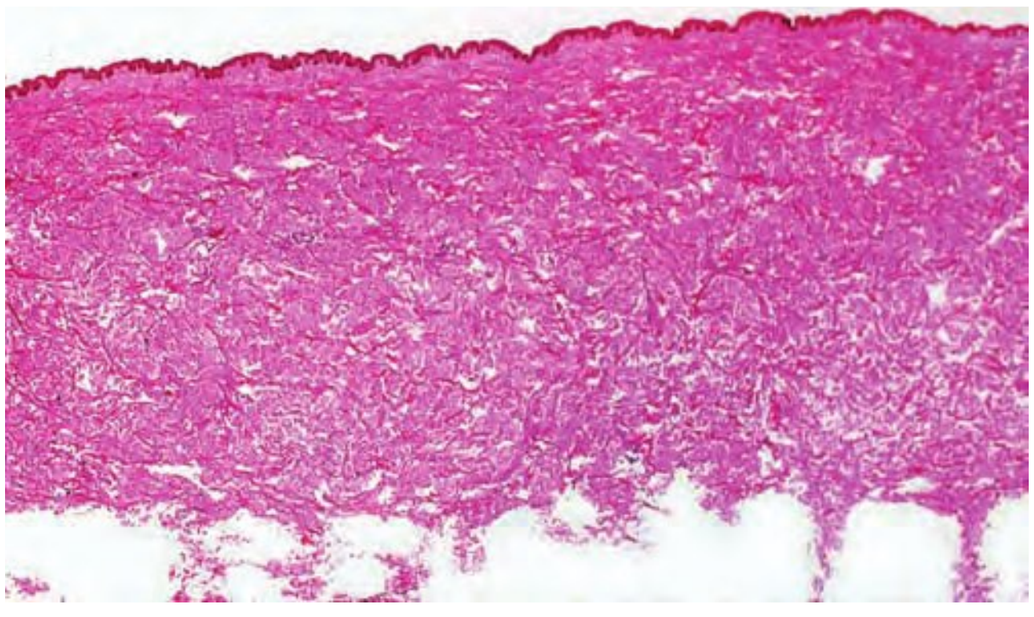

FIGURE 17-27. Scleredema. Panoramic view showing only a greatly thickened reticular dermis. The subcutis is not involved as in scleroderma (H&E).

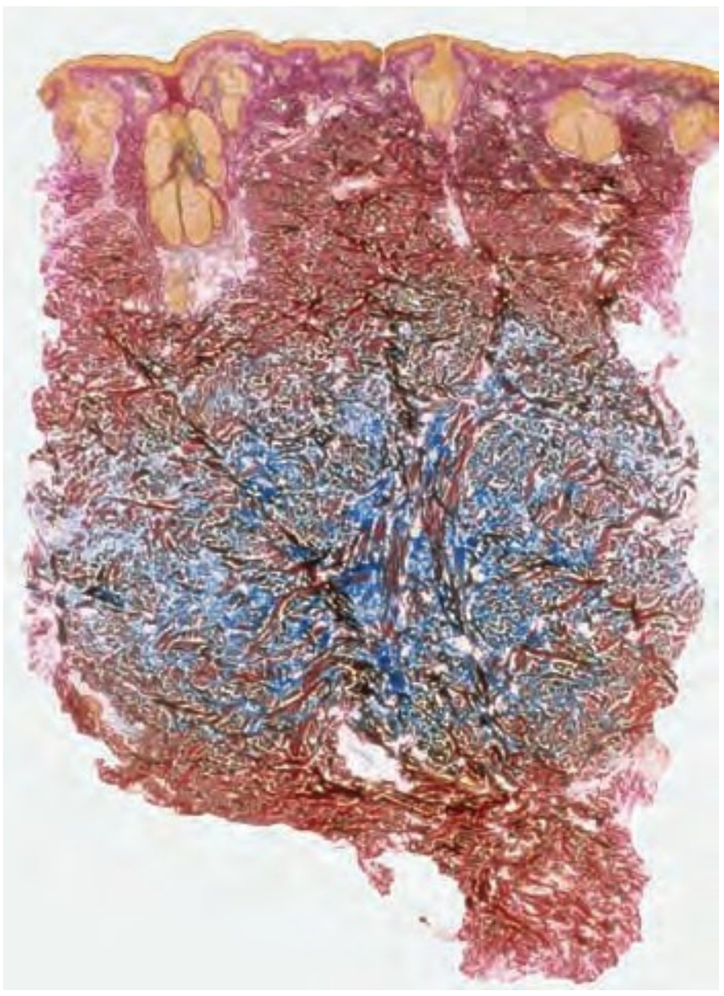

FIGURE 17-28. Scleredema. Colloidal iron staining of an early case reveals increased mucin in the middle and lower dermis.

In some instances, staining with toluidine blue at pH 7.0 is more intense if unfixed cryostat sections are used in place of formalin-fixed material (274). In some cases, even frozen sections have failed to stain with Alcian blue or toluidine blue (275). It may be postulated that in long-standing cases in which the disease has reached a steady stage of collagen turnover, staining for hyaluronic acid may give negative results (271). In cases of scleredema in which formaldehyde-fixed specimens fail to show acid mucopolysaccharides, they may show them on fixation in 0.05% cetylpyridinium chloride solution and staining with Alcian blue at pH 2.5 (267). It has been stated that fixation with 1% cetylpyridinium chloride solution in standard formalin fixative combined with colloidal iron staining gives the best results (276).

Systemic Lesions. Occasionally, the tongue and some skeletal muscles are involved, and on histologic examination, the muscle bundles show edema and loss of striation (275,277). In a few reported cases, pleural and pericardial effusions were present (275,278). In one case, the disease terminated in death, and autopsy revealed diffuse edema of the heart, liver, and spleen in addition to pleural and pericardial effusions (279).

Pathogenesis. In many patients with long-standing scleredema, a monoclonal gammopathy is found in the serum. Usually, the paraprotein is either IgG kappa or IgG lambda (272). In other cases, it has been IgA kappa, IgA lambda, or IgM lambda (280). There can be coexistence of scleredema with multiple myeloma (281). No immunoglobulin deposits have been found in involved skin sites (272). A marked increase in type 1 collagen gene expression occurs in scleroderma, leading to increased collagen synthesis (282).

Differential Diagnosis. It can be difficult to differentiate between end-stage scleroderma in which inflammation is no

longer present and scleredema. As a rule, however, in scleroderma, the collagen in the reticular dermis and subcutaneous tissue appears homogenized and hyalinized and stains only lightly with eosin and with the Masson trichrome stain, but in scleredema, the collagen bundles are thickened without being hyalinized and stain normally with eosin and the trichrome stain (271). A marked increase in type 1 collagen gene expression occurs in scleroderma, leading to increased collagen synthesis (282).

MUCOPOLYSACCHARIDOSIS

Mucopolysaccharidosis (MPS) comprises a group of storage diseases in which, as the result of a deficiency of specific lysosomal enzymes, there is inadequate degradation of mucopolysaccharides, or glycosaminoglycans. Consequently, this material accumulates within lysosomes of various cells in many organs, including the skin. Greatly elevated levels of mucopolysaccharides are present in the blood, serum, and urine. There are 11 different enzyme deficiencies implicated in development of the 7 major types of MPS (283). Thus, there is marked variation in the manifestations not only from type to type but also within the same type (284). The most common features, any or all of which may be present or absent, include dwarfism, skeletal deformities, hepatosplenomegaly, corneal clouding, and progressive mental deterioration with premature death from cardiorespiratory complications. In many instances, there is a characteristic facial appearance—thick lips, flattened nose, and hirsutism—referred to as *gargoylism*. The mode of transmission is autosomal recessive in all types of MPS except type II, the Hunter syndrome, which is X-linked recessive.

Only MPS types I to III will be discussed in this chapter. MPS I presents as three distinctive variants, even though they are all caused by a deficiency of the same enzyme. MPS I H, Hurler's syndrome, causes severe mental retardation and death, usually within the first decade of life (285). In contrast, persons with MPS I S, Scheie's syndrome, have normal intelligence, no dwarfism, and a normal life expectancy (286). MPS I H/S, the Hurler-Scheie syndrome, is intermediate between MPS I H and MPS I S. MPS II, Hunter's syndrome, occurs in a severe form, with mental retardation and early death, and in a mild form, in which mental function is normal and survival to adult life is the rule (287). MPS III, Sanfilippo's syndrome, has mild somatic changes but severe mental retardation (288).

The skin in all types of MPS usually appears thickened and inelastic. However, the only type in which distinctive cutaneous lesions are found frequently, although not invariably, is MPS II, Hunter's syndrome. These lesions consist of ivory white papules or small nodules, usually 3 to 4 mm in diameter, that may coalesce to form ridges in a reticular pattern on the upper trunk, especially in the scapular region (287,289). This condition has been referred to as *pebbling of the skin*. Grouped papules on the extensor surfaces at the upper portions of the arms and legs has been noted in one patient with the Hurler-Scheie syndrome (MPS I H/S) (290).

Histopathology. In all types of MPS, the normal-appearing or slightly thickened skin, on staining with the Giemsa stain or toluidine blue, shows metachromatic granules within fibroblasts, so the fibroblasts resemble mast cells (285). The granules also stain with Alcian blue and with colloidal iron (286). Fixation in absolute alcohol in some instances demonstrates the metachromasia better than fixation in formalin (291). In addition, metachromatic granules are occasionally present in some epidermal cells and in the secretory and ductal cells of eccrine glands (285,292,293).

The cutaneous papules observed only in Hunter's syndrome show not only metachromatic granules within dermal fibroblasts but also extracellular deposits of metachromatic material between collagen bundles and fibers (289,291).

In all types of MPS, metachromatic granules are visible also in the cytoplasm of circulating lymphocytes when smears of them are stained with toluidine blue after fixation in absolute methanol, a finding that aids in the rapid diagnosis of MPS (294).

Histogenesis. Biochemical studies have shown that in MPS I, as a result of a deficiency in alpha-l-iduronidase, there is an accumulation of heparan sulfate and dermatan sulfate (chondroitin sulfate) (283). Accumulation of dermatan sulfate but not heparan sulfate is linked to impaired elastic fiber assembly, which is thought to contribute to the clinical phenotype in Hurler disease (295). In MPS II, the same two substances are excessively accumulated owing to a deficiency in iduronate sulfatase. In MPS III, there is excessive accumulation of heparan sulfate. Successful bone marrow transplantation in children with Hurler's syndrome can restore the previously deficient alpha-1-iduronidase level (296).

By staining for acid phosphatase and by electron microscopy, the metachromatic granules in the skin and in the lymphocytes have been identified as lysosomes that contain acid mucopolysaccharides, which they are incapable of degrading (293,294).

Electron microscopic examination of the skin reveals in most fibroblasts numerous electron-lucent, greatly dilated, membrane-bound vacuoles representing lysosomes. Some of the vacuoles contain granular material or, less commonly, myelin-like structures representing residual bodies (286). Lysosomes are present also in macrophages, showing the same characteristics as in fibroblasts (288). In addition, from 5% to 20% of the epidermal cells contain lysosomal vacuoles, with acid phosphatase activity, varying from a solitary vacuole to 20 or 30 vacuoles per cell (292).

The dermal Schwann cells also contain electron-lucent lysosomes. In addition, some Schwann cells occasionally show laminated membranous structures ("zebra bodies"). These structures resemble those found in the brains of some patients with MPS. In the brain, they contain gangliosides as the result of a deficiency in the lysosomal hydrolase beta-d-galactosidase (292). The deposition of gangliosides in the brain leads to mental deterioration through the degeneration and loss of neurons.

ACANTHOSIS NIGRICANS

Acanthosis nigricans can be seen in multiple clinical settings: malignancy associated, benign, inherited, obesity associated, syndromic, drug induced, and mixed (297). The malignant

type differs from the benign types by showing more extensive and more pronounced lesions, by its progressiveness, and by its onset usually after 40 years of age. The histologic picture is essentially the same in all types.

The *malignant* type is associated with a malignant tumor—most commonly an abdominal, and particularly a gastric, carcinoma (298). However, it may also occur with squamous cell carcinoma, with sarcomas, and with Hodgkin and non-Hodgkin's lymphomas (297). In some cases, the skin lesions precede the symptoms of malignancy. The sign of Leser-Trélat, which is characterized by the sudden appearance of numerous seborrheic keratoses in association with a malignant tumor, may be an early stage or incomplete form of the malignant type of acanthosis nigricans. The seborrheic keratoses observed in this sign may be accompanied or followed by lesions of acanthosis nigricans (297).

The *benign inherited* type usually has its onset during infancy or early childhood. It is an autosomal dominant trait (299).

Syndromic acanthosis nigricans is especially linked to syndromes associated with insulin resistance (300). In the HAIR-AN syndrome, which affects younger women, there is hyperandrogenemia (HA), insulin resistance (IR), and acanthosis nigricans (AN) (297). Another subset links autoimmune states such as lupus erythematosus with uncontrolled diabetes mellitus, acanthosis nigricans, and ovarian hyperandrogenism. These patients have antibodies to the insulin receptor. Acanthosis nigricans has also been associated with insulin resistance in obesity, hypothyroidism, and congenital generalized lipodystrophy (301–303).

Acanthosis nigricans–like lesions have been induced by high dosages of nicotinic acid (304). Acanthosis nigricans has also occurred following use of oral contraceptives, following use of the folic acid antagonist triazinate, and as a localized reaction to insulin (299,305,306).

Clinically, acanthosis nigricans presents as papillomatous brown patches, predominantly in the intertriginous areas such as the axillae, the neck, and the genital and submammary regions (Fig. 17-29). In extensive cases of acanthosis nigricans of the malignant type, mucosal surfaces, such as the mouth, the vulva, and the palpebral conjunctivae, may be involved (298). In the acral type, there is velvety hyperpigmentation of the dorsa of the hands and feet.

FIGURE 17-29. Acanthosis nigricans. There is a velvety, hyperpigmented plaque in the axillary fossa.

Histopathology. Histologic examination reveals hyperkeratosis and papillomatosis but only slight, irregular acanthosis and usually no hyperpigmentation. Thus, the term *acanthosis nigricans* has little histologic justification.

In a typical lesion, the dermal papillae project upward as finger-like projections. The valleys between the papillae show mild to moderate acanthosis and are filled with keratotic material (Fig. 17-30). Horn pseudocysts can occur in some cases (307). The epidermis at the tips of the papillae and often also on the sides of the protruding papillae appears thinned.

Slight hyperpigmentation of the basal layer is demonstrable with silver nitrate staining in some cases but not in others (308). The brown color of the lesions is caused more by hyperkeratosis than by melanin.

In the acanthosis nigricans lesions of the polycystic ovary syndrome, there are prominent deposits of glycosaminoglycan consisting mostly of hyaluronic acid in the papillary dermis (309).

Histogenesis. The inherited type of acanthosis nigricans can be classified as a type of epidermal nevus. In persons who have acanthosis associated with insulin resistance, high levels of insulin may activate insulin-like growth factor-1 receptors and thereby mediate epidermal proliferation (310). Malignant acanthosis nigricans most likely is mediated by growth factors that are secreted by the associated neoplasm, such as transforming growth factor-alpha (311,312). The basal cells from one patient with syndromic acanthosis nigricans demonstrated unusually high expression of the rare keratins 18 and 19 (307).

Differential Diagnosis. Differentiation of acanthosis nigricans from other benign papillomas, particularly from linear epidermal nevi and from the hyperkeratotic type of seborrheic keratosis, may be difficult. As a rule, however, linear epidermal nevi show more marked acanthosis than acanthosis nigricans and have a more compact orthokeratotic stratum corneum. Furthermore, the pilosebaceous units in linear epidermal nevi are rudimentary. Acanthosis nigricans cannot be distinguished histologically from confluent and reticulated papillomatosis.

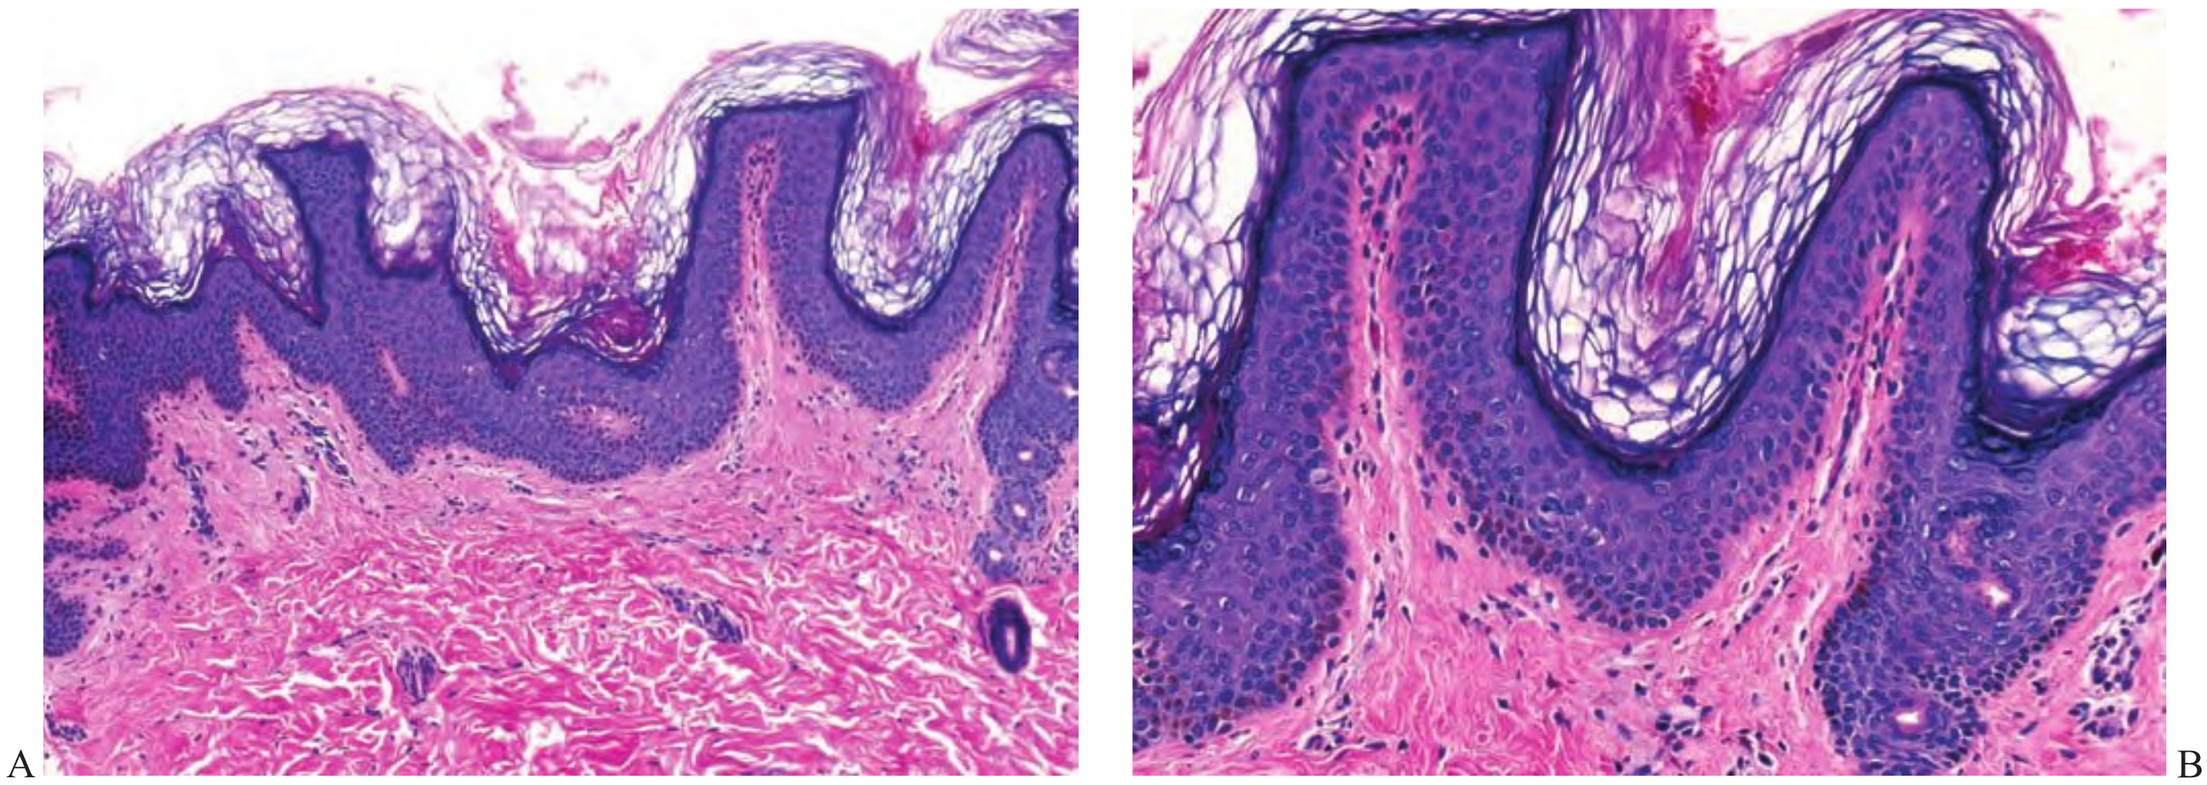

FIGURE 17-30. Acanthosis nigricans. A: There are papillomatous projections of the dermis (H&E). B: The epidermis is not increased in thickness above the papillomatous projections. The stratum corneum shows loose, basket-weave orthokeratosis (H&E).

Confluent and Reticulated Papillomatosis

Confluent and reticulated papillomatosis shows slightly hyperkeratotic and papillomatous pigmented papules that are confluent in the center and reticulated at the periphery (313). The site of predilection is the sternal region (Fig. 17-31). In the view of some authors, this disorder represents a variant of acanthosis nigricans (314). However, its location and reticulated pattern are distinctive.

Histopathology. Mild hyperkeratosis and papillomatosis are present, as is focal acanthosis, limited largely to the valleys between elongated papillae (314). Thus, the histologic changes are similar to but milder than those of acanthosis nigricans.

Histogenesis. Heavy colonization with *Pityrosporum orbiculare* has been observed in patients with confluent and reticulated papillomatosis; thus, this disorder has been regarded as a peculiar host reaction to *P. orbiculare* (315,316). However, in a review of the literature, it was found that even though potassium hydroxide preparations had yielded positive findings for yeast in 10 cases, there were positive findings for yeast and hyphae in only one case and negative results in 20 cases (317). Considering the common presence of the yeast phase as a nonpathogen, the role of *Malassezia* (*Pityrosporum*) as the cause of confluent and reticulated papillomatosis can be discounted. Reports of a variety of antibiotics that have been used successfully in the treatment of this condition raise the possibility that bacteria play a role in inducing the observed changes, although this is speculative (318).

FIGURE 17-31. Confluent and reticulated papillomatosis. There are discrete, flat, brown papules distributed over the sternal region, a characteristic location. Note the coalescence of papules into plaques in some areas and the reticulated appearance inferiorly.

HEREDITARY HEMOCHROMATOSIS

In hereditary hemochromatosis, large amounts of iron are deposited in various organs of the body, especially in the parenchymal cells of the liver and pancreas and in the myocardial fibers. The classic tetrad of hereditary hemochromatosis consists of hepatic cirrhosis, diabetes, hyperpigmentation of the skin, and cardiac failure.

Unless there is early recognition and adequate treatment by phlebotomy, hemochromatosis is a fatal disorder as the result of liver failure, heart disease, or hepatocellular carcinoma, which occurs in about one third of patients with advanced hemochromatosis (319).

Pigmentation of the skin is present in more than 90% of patients with hereditary hemochromatosis at the time the diagnosis is made, but it is often so mild as to attract little attention (320,321). The pigmentation is most pronounced in exposed

areas, especially on the face. Its color usually is brown or bronze but may be blue-gray. The pigmentation is caused largely by melanin and not by iron. In addition to pigmentation, ichthyosis-like changes, koilonychia, and hair loss are common.

Histopathology. Histologic examination of pigmented skin, especially from exposed areas, shows melanin to be present in increased amounts in the basal layer of the epidermis (320,322). Hemosiderin can be demonstrated in the skin of most patients with the aid of an iron stain, such as Perls' stain. It is found as blue-staining granules, mainly around blood vessels, both extracellularly and within macrophages, and in the basement membrane zone of the sweat glands and within cells of the connective tissue surrounding these glands (322). Siderosis around eccrine glands appears specific for hereditary hemochromatosis (320). In rare instances, some iron is present in the epidermis, particularly in the basal cell layer, and in the epithelial cells of the sweat glands (323).

In selecting a site for biopsy, it is not necessary to choose a pigmented area, because if deposits of iron are present in the skin, they are not limited to the areas of pigmentation. However, it is important not to take a specimen from the legs, where deposits of iron are frequently found in association with even minor venous stasis or as a consequence of a preceding inflammation that may no longer be evident.

A skin biopsy no longer represents an important test for establishing the diagnosis of hereditary hemochromatosis; it is merely of confirmatory value. Determinations in the serum of the level of iron, of the iron-binding capacity, as measured by the degree of saturation of transferrin with iron, of the plasma ferritin concentration, and, above all, biopsy of the liver, have replaced the skin biopsy in importance (321). Before liver biopsy, however, genotyping of patients who have abnormal screening exams for iron overload is now being performed. If the person is homozygous for the most common mutation in the hemochromatosis gene (HFE) and has persistently elevated transaminase levels, a biopsy of the liver is considered to evaluate whether fibrosis is present. Phlebotomy can prevent iron overload and development of fibrosis or can prevent further hepatic injury (324).

Histogenesis. Hereditary hemochromatosis is an autosomal recessive disease caused by mutation in the HFE gene. It is the most common genetically inherited disease in people of northern European ancestry (325). About 10% of the U.S. population are carriers of the disease (326). This figure implies a homozygote frequency of 2 or 3 per 1,000 persons. The gene for hemochromatosis is located on chromosome 6 and is most commonly altered by a point mutation that results in a cysteine to tyrosine switch at amino acid position 282 of the HFE protein (327). Homozygosity is present in approximately 90% of affected persons (327).

The amino acid substitution responsible for the vast majority of cases results in the inability of HFE to bind to β-2 microglobulin, a required step in the shuttling of HFE to the cell surface, the site of interaction of HFE and transferrin. The precise role of HFE in regulating iron stores is not known (324). Although iron absorption through duodenal mucosa is excessive, it is not known if this is the primary event. The degree of saturation of transferrin with iron is very high. Consequently, not all of the iron passing from the intestinal tract can be bound to transferrin, and it is therefore deposited in a variety of organs. Iron accumulates particularly in the parenchyma of the liver and pancreas and in the myocardium, and by damaging the cells in which it accumulates, it causes hepatic cirrhosis, diabetes, and cardiac insufficiency.

Two observations indicate that the cutaneous pigmentation in hereditary hemochromatosis is caused by melanin and not by hemosiderin. The first observation concerns a patient who in addition to having hemochromatosis had vitiligo. The areas of vitiligo were fully depigmented despite the finding on histologic examination that they contained just as much iron as deeply pigmented areas (322). The second observation was made in a black patient with idiopathic hemochromatosis who had three epidermal cysts. Although the patient had noticed no change in his skin color, he had observed progressive darkening of the cysts, and histologic examination revealed considerable amounts of melanin both in the walls of the cysts and in their keratinous contents (328). Although pigmented epidermoid cysts have been attributed to hemochromatosis, in a series of 125 epidermal cysts in Indian patients, pigmentation was found in 79 of them, none of which was attributed to hemochromatosis or iron deposition (329).

The increase in the amount of melanin found in the skin of patients with hemochromatosis is brought about by iron in the skin. The iron stimulates melanocytic activity either by increasing oxidative processes or by reacting with epidermal sulfhydryl groups and reducing their inhibitory effect on the enzyme system governing melanin synthesis (330,331).

VITAMIN A DEFICIENCY (PHRYNODERMA)

Deficiency of vitamin A is very rare in the United States, occurring mainly in Asia and Africa. It has been described, however, as occurring after small bowel bypass surgery for obesity (332,333). Vitamin A deficiency results in cutaneous changes to which the name *phrynoderma* (toad skin) has been given. These changes consist of dryness and roughness of the skin and the presence of conical, follicular keratotic lesions usually most prominent in the elbows and knees. Clinically, phrynoderma may at times simulate a perforating disorder (334). In addition to causing cutaneous changes, deficiency of vitamin A may cause night blindness, xerophthalmia, and keratomalacia.

Histopathology. The skin shows moderate hyperkeratosis with marked distention of the upper parts of the hair follicles by large, horny plugs (332,335). The horny plugs may perforate the follicular epithelium (333). The sebaceous gland lobules are greatly reduced in size. There may also be atrophy of the sweat glands, such as flattening of the secretory cells (336).

In severe cases, the sweat glands and sebaceous glands may undergo keratinizing metaplasia (337).

Differential Diagnosis. Histologic differentiation of phrynoderma from ichthyosis vulgaris and keratosis pilaris is impossible, except in very severe cases of phrynoderma, in which the sweat glands and the sebaceous glands show keratinizing metaplasia. Pityriasis rubra pilaris differs from phrynoderma by showing, in addition to hyperkeratosis and follicular plugging, stuttering parakeratosis, irregular epidermal hyperplasia, and an inflammatory infiltrate in the upper dermis.

PELLAGRA

Pellagra is caused by a deficiency of nicotinic acid (niacin) or its precursor, the essential amino acid tryptophan. As a dietary deficiency disease, it may occur in chronic alcoholics and patients with anorexia nervosa (338). It may also occur in patients with the carcinoid syndrome; the tumor cells divert tryptophan toward serotonin, thus depressing endogenous niacin production (339). In addition, pellagra is a well-recognized complication of isoniazid therapy for tuberculosis. Because isoniazid is a structural analog of niacin, it can cause the suppression of endogenous niacin production (340). Because 5-fluorouracil inhibits the conversion of tryptophan to nicotinic acid, it also may precipitate pellagra (341). Recently, multiple anticonvulsants have been reported to induce pellagra as well, although the precise mechanism for this is not known (342,343). Deficiencies of other vitamins such as B_6 and thiamine that are involved in the synthesis or utilization of niacin or excess dietary intake of substances (e.g., leucine) that directly inhibit niacin synthesis can result in clinical symptoms as well (342).

Pellagra presents with cutaneous lesions, gastrointestinal symptoms, and mental changes, resulting in the triad of the three Ds: dermatitis, diarrhea, and dementia.

The cutaneous lesions are precipitated by sunlight. A symmetrical photosensitive dermatitis predominantly involves the dorsa of the hands, wrists, and forearms; the face; and the nape of the neck. In the early stage, there is erythema, which usually is sharply demarcated; in severe cases, it may be accompanied by vesicles or bullae. Later, the skin becomes thickened, scaly, and pigmented.

Histopathology. The histologic changes of the skin are nonspecific. Early lesions present a superficial perivascular lymphocytic inflammatory infiltrate in the upper dermis. Vesicles, if present, arise as in erythema multiforme either subepidermally, owing to vacuolar degeneration of the basal layer and edema in the papillary dermis, or intraepidermally, owing to degenerative changes in the epidermis (344). Sometimes, there is a distinct pallor of the upper layers of the epidermis with or without an infiltrate of neutrophils. The differential diagnosis of this pattern includes acrodermatitis enteropathica (zinc deficiency), necrolytic migratory erythema of the glucagonoma syndrome, and occasionally psoriasis (345). There is one report of a contact dermatitis due to topical application of a eutectic mixture of local anesthetics (EMLA cream) that resembled pellagra microscopically (346).

In older lesions, hyperkeratosis with areas of parakeratosis and prominent but irregular epidermal hyperplasia is observed. The amount of melanin in the basal layer of the epidermis often is increased. Late lesions may show epidermal atrophy, and the dermis may show fibrosis in addition to chronic inflammation (344).

Hartnup Disease

First described in 1956 and named in 1957 after the family in which it was first observed, Hartnup disease is transmitted as an autosomal recessive trait (347,348). It first manifests itself in early childhood and often improves with advancing age. A photosensitivity eruption is present that usually is indistinguishable from pellagra (349). However, in some cases, the cutaneous reaction to sun exposure resembles poikiloderma atrophicans vasculare or, because of the prominence of vesicles, hydroa vacciniforme (350,351). In addition, there may be cerebellar ataxia and mental retardation. Niacin is used to treat Hartnup disease (349).

Histopathology. The cutaneous eruption in Hartnup disease usually shows the same histologic changes observed in pellagra (see previous section) (345). In patients with poikiloderma-like changes, atrophy of the epidermis and the presence of a chronic inflammatory infiltrate and of melanophages in the upper dermis are observed (350).

Histogenesis. The sun-sensitivity eruption with its resemblance to pellagra is caused by an enzymatic defect in the transport of tryptophan and a resultant decrease in the endogenous production of niacin. Specifically, the defective transporter is a transporter of monoamino-monocarboxylic acids, which is encoded by a gene which maps to chromosome 5p (352). The defect in tryptophan transport consists of both an intestinal defect in tryptophan absorption and a renal tubular defect causing inadequate reabsorption of amino acids, including tryptophan. Chromatographic study of the urine shows a constant aminoaciduria, particularly the presence of tryptophan and of indolic substances derived from tryptophan—a finding that establishes the diagnosis (350).

TYROSINEMIA TYPE II (OCULOCUTANEOUS TYROSINOSIS)

Tyrosinemia type II, also referred to as the *Richner-Hanhart syndrome* and *oculocutaneous tyrosinosis*, is transmitted as an autosomal recessive trait. It is characterized by very tender hyperkeratotic papules and plaques on the palms and soles arising in infancy or childhood; bilateral keratitis, which may lead to corneal opacities; and mental retardation. Palmoplantar lesions may begin as bullae and erosions (353). Ocular changes

are absent in some families (354). A diet low in tyrosine and phenylalanine improves the disease manifestations.

Histopathology. In most instances, the histologic findings in the keratotic lesions are not diagnostic, showing merely orthokeratotic hyperkeratosis with hypergranulosis and acanthosis (355). In one reported case, vertical parakeratotic columns were present over the openings of the acrosyringia. Multinucleated keratinocytes and dyskeratotic cells were noted in the spinous layer (356). A large intraepidermal bulla seen in another patient probably was also the result of irritation (357).

Histogenesis. Tyrosinemia maps to chromosome 16q 22.1 to 16q 22.2 (349). As a result of a genetic deficiency in hepatic tyrosine aminotransferase, excessive amounts of tyrosine are found in the blood, urine, and tissues. It can be assumed that excessive amounts of intracellular tyrosine enhance cross-links between aggregated tonofilaments. On electron microscopic examination, aggregations of tonofilaments and needle-shaped tyrosine crystalline inclusions are found in keratinocytes (356).

CHAPTER 18

Michael D. Ioffreda

Inflammatory Diseases of Hair Follicles, Sweat Glands, and Cartilage

INFLAMMATORY DISEASES OF HAIR FOLLICLES: FOLLICULITIS

There are various types of folliculitis, or inflammation of the hair follicle, many of which are covered in other areas of this book. Folliculitis can have an infectious etiology due to bacteria (see Chapter 21), viruses such as herpes (see Chapter 25), and fungi (see Chapter 23), including dermatophytes (tinea capitis, tinea barbae, Majocchi's granuloma) and yeast (*Pityrosporum*). Chapter 21 discusses pseudofolliculitis barbae, folliculitis ("*acne*") keloidalis nuchae, and the follicular occlusion triad. Perforating folliculitis is discussed with the other perforating disorders in Chapter 15. The present chapter reviews the types of acneiform folliculitis and miscellaneous follicular disorders.

Acne Vulgaris

Acne vulgaris is a disease of adolescence and early adulthood that only occasionally persists into later adult life, when it is found more often in women (1). Chiefly affecting the face, upper back, and chest, it manifests as two types of lesions—comedones and inflammatory lesions, both of which are follicular based. Comedones may be closed ("whiteheads") or open ("blackheads"). Inflammatory lesions evolve from ruptured comedones or microcomedones, which are not clinically apparent, and they originate more frequently from closed than open comedones. Once developed, inflammatory papules may become pustules or nodules, which develop from cysts. Cystic acne can result in severe scarring. In acne fulminans—a rare variant occurring mainly in young male patients—lesions rapidly become tender, ulcerated, and crusted, and eventually scar. It may be associated with fever and polyarthralgia (2).

Histopathology. The development of a comedone involves a complex but incompletely understood process that results in infundibular dilation and thinning of the follicular wall. A plug composed of loosely arranged keratinized cells and sebum forms (Fig. 18-1). Sebum is made up of sebaceous lipids that empty into the follicular lumen and microorganisms. Solvents used in histologic processing remove these lipids.

In closed comedones, the follicular orifice remains more or less normal in size, but when the follicular ostium widens, an open comedone results. Both types of comedones are associated with mild mononuclear inflammation around vessels in the adjacent papillary dermis. Attenuation of the follicular wall may be so extreme as to lead to rupture (3). Release of follicular contents into the dermis generates an inflammatory response initially mediated by neutrophils and later by histiocytes and foreign-body giant cells. When rupture occurs superficially, it tends to lead to the development of a clinical pustule (Fig. 18-2), but when it occurs in the deeper dermis, an inflammatory nodule forms (Fig. 18-3). If the follicular damage and inflammatory response are severe, scarring can result. This is the norm in severe forms of acne (cystic acne and acne fulminans), in which extensive inflammation can result in dermal necrosis with large abscesses.

Pathogenesis. Several reviews highlight important advances that have affected our understanding of acne (4,5). Acne is a multifactorial condition, initially requiring sex hormone release during puberty and activation of the sebaceous glands. The major factors contributing to acne development are follicular hyperkeratinization, androgens, sebum, *Propionibacterium acnes*, and inflammation.

Comedones exhibit hyperkeratinization, and the keratin is bound more avidly as a result of increased levels of intercellular adhesion materials (6). Follicular linoleic acid deficiency, androgens, and interleukin-1 may all play a role in follicular hyperkeratinization (5,7). Ultrastructurally, follicular keratinocytes in comedones possess increased numbers of desmosomes and tonofilaments, which contribute to hypercornification (8). The black color of open comedones ("blackheads") appears to be related to densely packed keratinocytes, bacteria, and bacterial breakdown products located at the surface. If dilation of the follicular orifice does not occur (closed comedone), continued thinning and ultimate rupture of the infundibular wall becomes more probable.

Comedone development is associated with increased epithelial cell proliferation in the lower portion of the infundibulum, as measured by tritium-labeling techniques (9). Based on the use of Ki-67, increased keratinocyte proliferation was demonstrated in normal follicles from acne-affected areas (as compared to areas free of acne), suggesting that some follicles may be "acne-prone" (10). Ki-67 was also increased in comedones.

Generation of inflammation in acne lesions is also a complex process. Potential instigators of inflammation may be

FIGURE 18-1. Comedone, open. A dilated follicular infundibulum with an attenuated wall is plugged with keratin and sebum. The follicular orifice is widened.

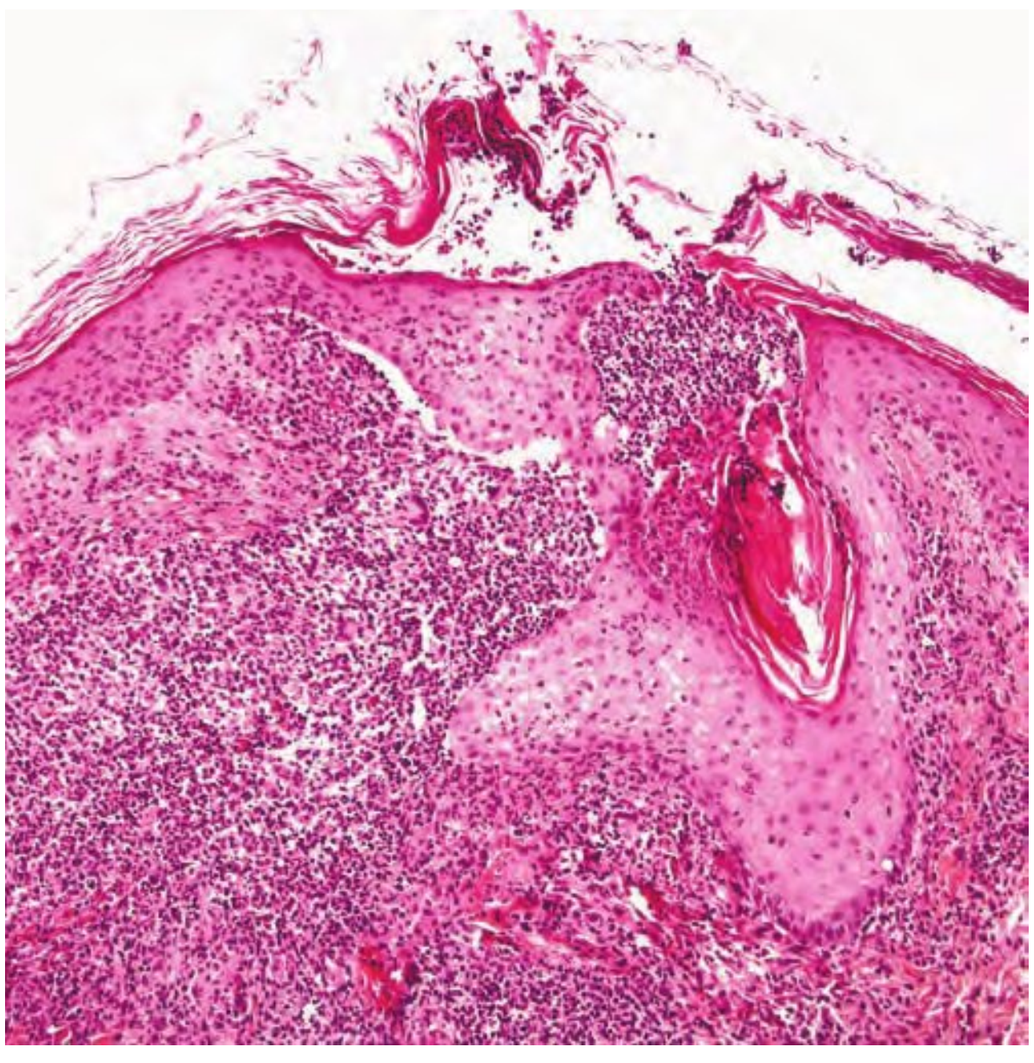

FIGURE 18-2. Acne vulgaris, pustule. Superficial follicular rupture incites suppurative and granulomatous inflammation, with neutrophils predominating in early lesions.

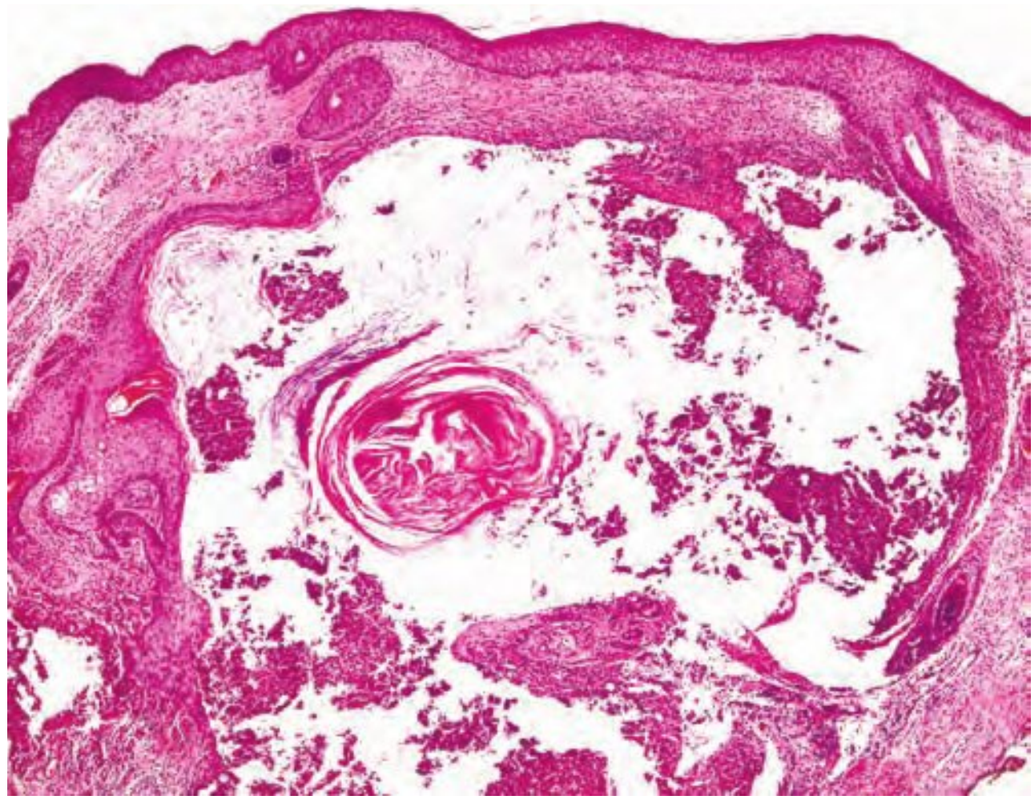

FIGURE 18-3. Acne vulgaris, nodule. Cystlike follicular dilation with deep rupture leads to neutrophilic and granulomatous inflammation throughout the dermis.

derived from the breakdown products of sebaceous lipids, from byproducts derived from *P. acnes*, and from various immunologic mechanisms directed against this organism (11). The expression of adhesion molecules and inflammatory infiltrates was studied by immunohistochemistry in evolving lesions of acne vulgaris (12). There was vascular expression of intercellular adhesion molecule-1, E-selectin, vascular cell adhesion molecule-1, and human leukocyte antigen (HLA)-DR, and the inflammatory cells consisted of $CD4^+$ T lymphocytes.

There is substantial evidence linking the activation of sebum production to androgens, specifically testosterone and dihydrotestosterone (DHT) (13). Circulating testosterone is converted in tissues to the more potent DHT by the enzyme 5α-reductase (14). The type 1 isoform of 5α-reductase is located primarily in sebocytes [but is also found in the epidermis, infundibular hair follicle keratinocytes (15), dermal papilla cells, sweat glands, and fibroblasts]. The gene encoding the type 1 isozyme is found on chromosome 5p (16). Activity of the type 1 isoform of 5α-reductase was greater in sebaceous glands from acne-prone areas of the skin than in those from non–acne-prone areas, suggesting that regional differences in pilosebaceous production of DHT may play a role in acne (17).

The precise role of androgenic hormones in the production of acne lesions is controversial. Androgens are derived from two sources: precursor serum androgens of glandular origin (gonadal and adrenal) and target tissue androgens derived from conversion of circulating precursors. It has been suggested that in patients with mild acne the serum levels of precursor androgens are normal and that in these circumstances only tissue androgen levels are elevated (18). In severe cystic acne, increased serum androgen levels have been found, although the majority of acne patients—especially male patients—do not show abnormal levels. Elevated serum

androgen levels occur more frequently in women with acne, but similar elevations have been found in hirsute women without acne (19). Another study found significantly higher mean serum androgen levels in females with acne than in those without acne, although values were in the range of normal; in addition, sebaceous glands from the women with acne showed higher mean 5α-reductase type 1 activity, although the difference was not statistically significant (20). This study suggests that women with acne may have higher serum androgen levels and perhaps a greater capacity to produce DHT within sebaceous glands.

One author emphasized the importance of sebum in acne with a simple statement: "remove sebum and you remove acne" (21). Sebum production in acne is elevated and appears to correlate with disease severity. An *in vitro* study of sebaceous gland ultrastructure after exposure to substance P found that this stress-induced neuropeptide promoted the proliferation and differentiation of sebaceous glands, implicating a role for stress in acne (8). The beneficial effect of isotretinoin (13-*cis*-retinoic acid) appears to result largely from reduction in sebum production, although a substantial decrease in *P. acnes* levels was detected in one study (22) and follicular hyperkeratinization was found to be reduced in another study (23). After 2 months of treatment with oral isotretinoin, a 70% reduction in sebum excretion is achieved (22), and after 4 months a reduction of 88% may be attained (24). These changes are associated histologically with a marked reduction in sebaceous gland size (24).

Of all the microorganisms identified in the follicular infundibulum, only *P. acnes* appears to be consistently involved in the pathogenesis of acne lesions (25). Nevertheless, levels of this organism may not be consistently greater in lesional skin than in normal skin (26). Immunologic reactivity to this organism may contribute to the inflammation in acne lesions. In response to *P. acnes*, acne patients may exhibit elevated serum antibody levels, increased immediate hypersensitivity, and augmented cell-mediated immunity (27). The beneficial effects of systemic and topical antibiotics in acne patients are generally attributed to their suppression of *P. acnes*, although some studies suggest that oral tetracycline and topical erythromycin may improve acne without reducing the population of *P. acnes*.

Peroxisomal proliferator activator receptors (PPARs) may play a role in acne. PPARs modulate various functions of peroxisomes (small organelles that are important in regulating cell proliferation, differentiation, metabolism, and inflammation) (28,29). In addition, *P. acnes* has been shown to elicit inflammatory cytokines in acne through activation of Toll-like receptor 2; Toll-like receptors initiate immune reactions in response to pathogen-associated molecular patterns (30).

Steroid Acne

Steroid acne is a folliculitis caused by the use of corticosteroids, including systemic, topical, inhaled (31), and intranasal (32) steroids. Despite its well-known existence, steroid acne has become more prevalent with the creation of increasingly potent topical preparations and the introduction of organ transplant surgery and various treatment regimens for cancer (33). Although other medications have been implicated in acneiform eruptions, steroid acne results in a distinctive clinical picture characterized by the sudden appearance of monomorphous papulopustules predominantly on the upper trunck and arms but also on the face (34). Comedones are not apparent. The underlying rash for which topical steroids are used initially improves, followed by exacerbation of the rash (35). The exacerbation is controlled only by continued use of topical steroids (physical dependence). Resolution typically occurs without scarring. Perioral dermatitis may be caused by topical corticosteroids (see the later discussion of perioral dermatitis).

Histopathology. Acne due to both topical and systemic corticosteroids shows similar histologic features. Despite the apparent absence of comedones clinically, Hurwitz described histologic features that resembled those of acne vulgaris (Fig. 18-4), albeit with an accelerated rate of development (33). In chronologic order, biopsied flesh-colored papules that measured 1 mm showed infundibular spongiosis, hyperkeratosis, perifollicular edema, microcomedo formation, and infundibular wall thinning, sometimes with infundibular rupture. It was more common, however, to see only infundibular dilation with compact hyperkeratosis. Biopsied lesions that were 2 mm or greater and clinically inflamed frequently showed infundibular rupture, necrotic keratinocytes, and surrounding suppurative and granulomatous inflammation that included multinucleated giant cells amid keratinous debris. Dilated blood vessels were also seen.

Pathogenesis. Although the exact pathogenesis is not known, three phases of lesion development have been described as a result of "addiction" to topical steroids (35): (a) initial improvement of the rash is due to the antiinflammatory properties of topical corticosteroids, (b) local immunosuppressive

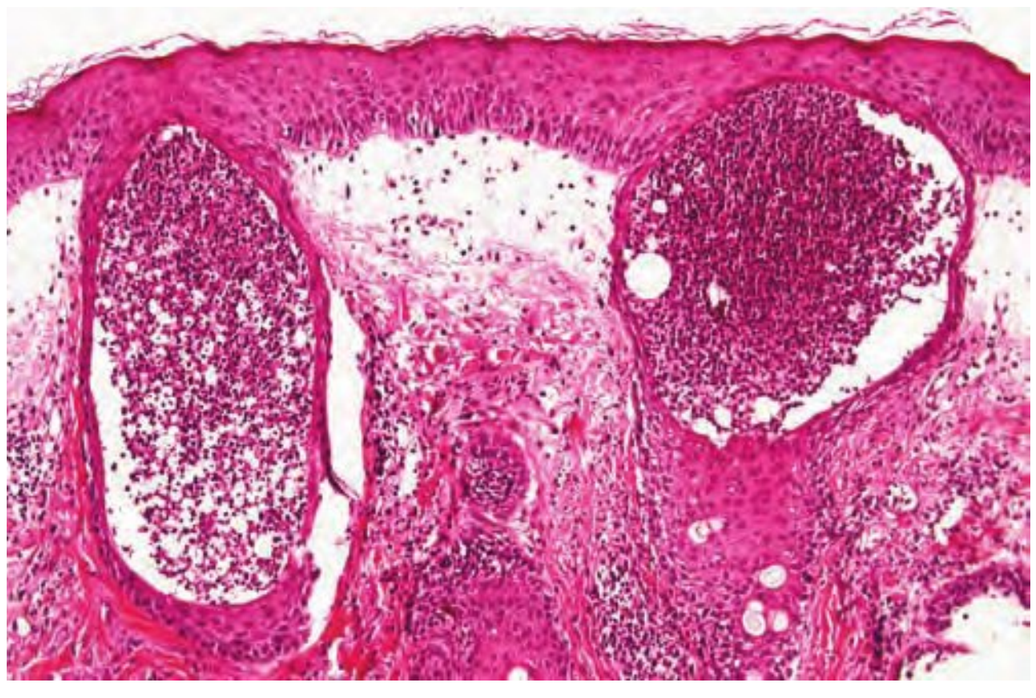

FIGURE 18-4. Steroid acne. Pustules in steroid acne are monomorphous and are indistinguishable from acne vulgaris.

effects of the steroids result in bacterial overgrowth, and (c) on withdrawal of steroids there is rebound and flaring secondary to bacterial overgrowth. In addition to the chronologic sequence described under Histopathology, some authors have described a pathologic process that is the reverse of acne vulgaris, beginning with folliculitis that proceeds to rupture and concludes with comedone formation (a so-called "secondary" comedone) (36). In a study of steroid acne due to systemic therapy, 80% of 125 patients showed significant numbers of *Pityrosporum ovale* in lesional follicles, and itraconazole, an oral antifungal agent, proved more efficacious than other medications (37).

Perioral Dermatitis

Recognition of this relatively common facial eruption is important because of its resemblance to rosacea, seborrheic dermatitis, and occasionally lupus erythematosus. Predominantly affecting white women of European extraction ranging in age from the mid teens into middle age, it results in fine, follicular-based papules perioral and, more rarely, in a periocular distribution (*periocular dermatitis*) (38,39). The papules are single, grouped, or confluent, with minimal scaling. Pinhead-sized pustules may occur in more severe cases. There is sparing of a 5-mm zone around the vermilion border (34). The condition lacks significant telangiectasia. It is commonly associated with topically applied preparations, especially topical corticosteroids and cosmetics. Perioral dermatitis in children occurs primarily as a result of topical steroid use and is almost identical to the disease in adults (40–43).

Childhood granulomatous periorificial dermatitis is an acneiform facial eruption that shows some similarity to granulomatous rosacea and perioral dermatitis in children but does have some distinctive features (44–46). The current terminology was first coined in 1989 (44), although other terms have been proposed, such as facial Afro-Caribbean childhood eruption, reflecting its usual incidence on the face of black children (47). Other features that distinguish childhood granulomatous periorificial dermatitis from childhood perioral dermatitis and acne vulgaris include (a) exclusive incidence in healthy prepubertal children and (b) absence of pustules and lack of circumoral sparing. Another entity producing clinically similar lesions—lupus miliaris disseminatus faciei—has not been reported in children (47). Clinical lesions may be flesh colored, hypopigmented, or reddish yellow; are small (1 to 3 mm); are monomorphous; and occur periorally, perinasally, and periorbitally. Lesions are asymptomatic and self-limited but may last for years, typically healing without residual except for some small, pitted scars in a small number of patients (48). Cases with extrafacial and generalized lesions have been reported (48).

Histopathology. Some authors consider perioral dermatitis to be a variant of rosacea, with indistinguishable histologic features (42,49), whereas others consider the two entities to be distinct (50,51), with some histologic overlap. A proposed clinical classification scheme for rosacea published in 2002 did not classify steroid-induced acneiform eruptions or perioral dermatitis as rosacea variants, citing insufficient evidence (51).

The following histologic characteristics of perioral dermatitis have been described (50). Fully developed lesions show spongiosis of the follicular infundibulum with mild mononuclear cell exocytosis (Fig. 18-5), with similar changes sometimes observed in the epidermis adjacent to the involved follicle. The epidermis may show mild acanthosis and parakeratosis, particularly about follicular ostia. The perifollicular dermis shows lymphohistiocytic inflammation around vessels, and in rare cases plasma cells may be prominent. Less developed lesions may exhibit only dermal inflammation. Lesions tend to lack the dermal edema and telangiectasias characteristic of rosacea and show more noticeable epidermal changes. Acute folliculitis is uncommon.

Lesions of *childhood granulomatous periorificial dermatitis* often resemble granulomatous rosacea, with noncaseating perifollicular granulomas with some giant cells (44,48). Other features include epidermal changes consisting of mild hyperkeratosis and spongiosis, as well as dermal inflammation, composed of lymphocytes and histiocytes, that is mild to moderate, perivascular, and perifollicular. The granulomatous component is variable; some biopsies lacked granuloma formation or follicular involvement altogether. Some cases showed focal follicular rupture with inflammation to the released contents (44). Special stains for fungi and mycobacteria have been negative (48).

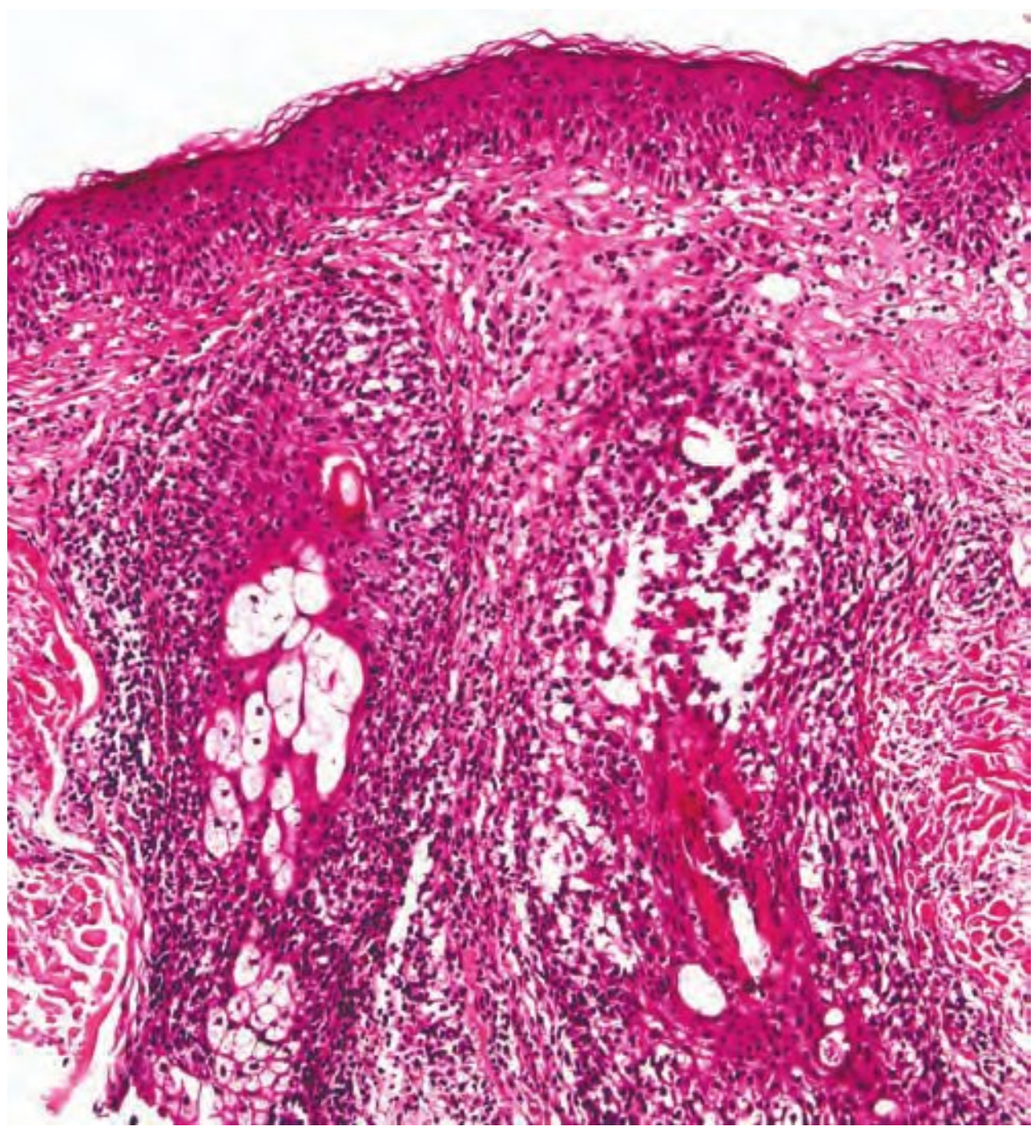

FIGURE 18-5. Perioral dermatitis. There is perifollicular mononuclear inflammation with infundibular spongiosis and exocytosis of lymphocytes.

Pathogenesis. Many possible etiologies for *perioral dermatitis* have been proposed, including *Candida* organisms, bacteria, particularly of the fusiform type, *Demodex* mites, a wide range of contactants, both irritant and allergic (including cosmetics and fluoride-containing toothpaste), hormones (including birth control pills), topical corticosteroids (particularly potent ones), and emotional as well as systemic conditions. An Australian survey found an increased risk of developing perioral dermatitis with use of foundation makeup along with moisturizer and night cream (52). Periocular dermatitis has been reported with the use of a steroid eye ointment (53).

The etiology of *childhood granulomatous periorificial dermatitis* is not known, but an external contactant has been implicated in some cases, with various agents, including topical fluorinated corticosteroids, reported (48).

Rosacea

Rosacea is an acneiform inflammatory condition that primarily affects the face and is more common after the age of 30 years. It is characterized by background erythema within which scattered telangiectasias, papules, and occasional pustules develop (Fig. 18-6). It typically affects the nose, cheeks, glabella, and chin, and it is usually bilateral but occasionally unilateral or focal. If it is severe, lesions may spread to the neck and, rarely, become disseminated. Rhinophyma, a bulbous swelling of the soft tissue of the nose, is a late complication that occurs almost exclusively in men. Eye changes—especially blepharitis and conjunctivitis—are quite common in rosacea, and in 5% of cases a painful keratitis can develop (54). Rosacea can precipitate persistent facial lymphedema.

A recently proposed clinical classification scheme for rosacea delineated four subtypes: (a) erythematotelangiectatic, (b) papulopustular, (c) phymatous, and (d) ocular (51,55). In this classification, a single rosacea variant was defined, *granulomatous rosacea*, that did not show morphology of one of the subtypes.

FIGURE 18-6. Rosacea. Scattered erythematous papules with background telangiectasias that give the face a "ruddy" appearance.

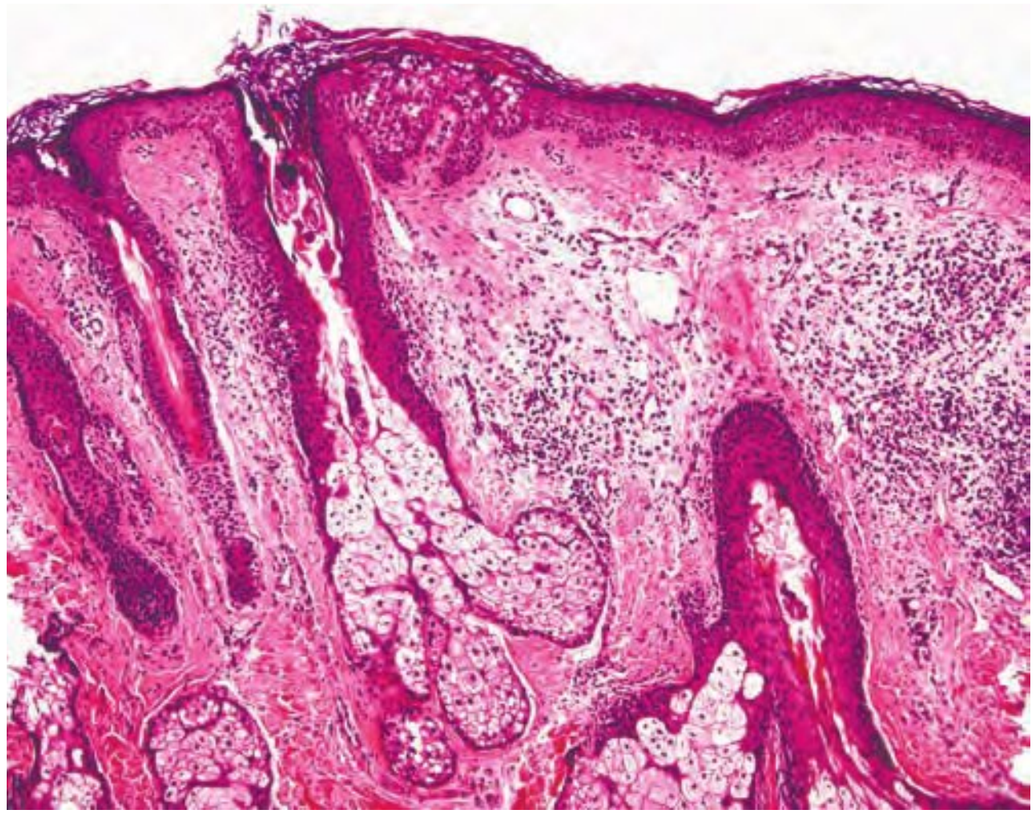

FIGURE 18-7. Rosacea. Patchy lymphocytic inflammation surrounds vellus hair follicles, which contain Demodex mites, as well as some blood vessels. Telangiectasias are present.

Histopathology. Vascular dilation of upper and middermal vessels with perivascular and perifollicular lymphohistiocytic inflammation (and occasional plasma cells) is generally present in all cases (Fig. 18-7). Lymphatic dilation is also common and may be prominent. With mild follicular involvement, there is infundibular spongiosis and lymphocyte exocytosis. With more extensive follicular involvement, neutrophils accumulate, resulting in a superficial pustule. Reflecting the clinical presentation, various other pathologic changes can be seen from case to case, including organization of dermal lymphocytes into small nodular aggregates (56).

Granulomatous infiltrates are reported to occur in about 10% of all cases of rosacea (56) (Fig. 18-8), and caseation necrosis has been identified in about 10% of these patients

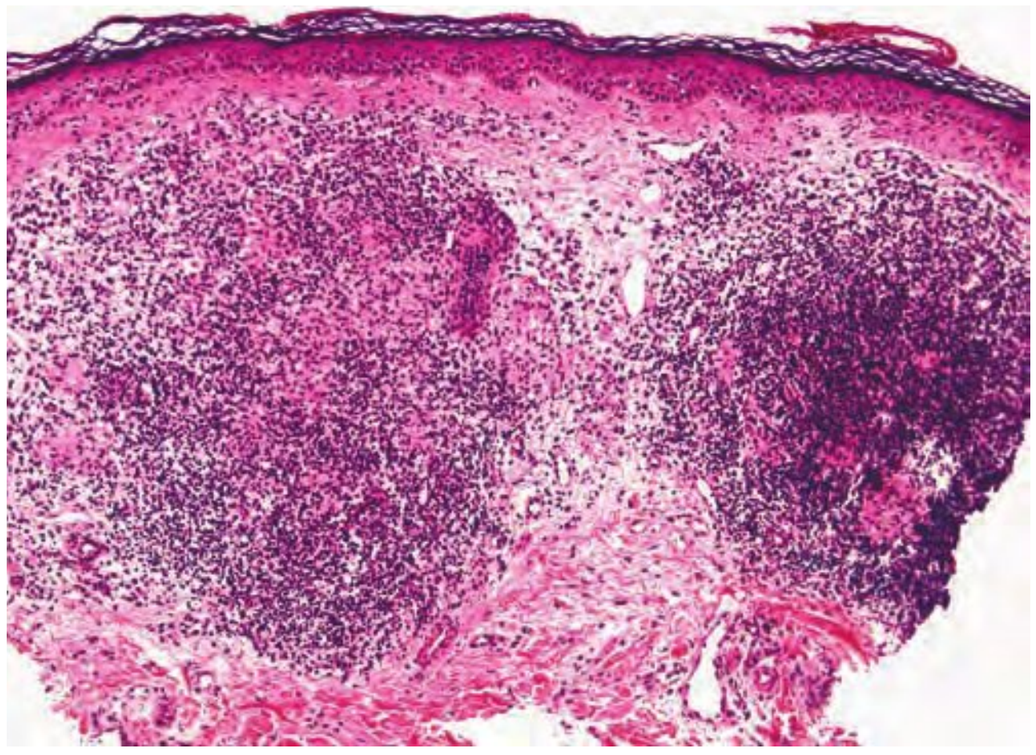

FIGURE 18-8. Granulomatous rosacea. The infiltrate is dense and has a prominent histiocytic component, clustered into granulomas. Telangiectatic blood vessels are present.

(57). *Granulomatous rosacea* can histologically mimic mycobacterial infections, with epithelioid histiocytes forming a tuberculoid pattern. In such cases, other investigative procedures, including tissue cultures, may be necessary. Less frequently, the changes resemble cutaneous sarcoidosis. Multinucleated giant cells of the foreign-body type may aggregate around follicular contents spilled from a ruptured follicle.

In a study of rhinophyma, the classic or common type showed histologic features of fully developed rosacea, except for sebaceous gland hyperplasia, which can be prominent (58). The sebaceous ducts become dilated and filled with keratin and sebum. The same study showed that in patients with the severe form of rhinophyma, there is marked dermal thickening with sclerotic collagen bundles and large amounts of mucin, an absence of pilosebaceous structures, sparse inflammation, and telangiectasias (58). Many spindle-shaped and "bizarre" cells staining for factor XIIIa were seen in the interstitium. It was noted that the microscopic findings in the severe form of rhinophyma demonstrate many similarities to elephantiasis nostras caused by chronic lower-extremity lymphedema.

Pathogenesis. Although triggers of rosacea are well known, the pathogenesis of the disease is unknown. It is probable that the etiology of rosacea is multifactorial (59), but sun damage appears to be a constant feature. Rosacea is not associated with an increase in sebum excretion. Dahl proposed that the vascular dilation leads to dermal edema, which in turn promotes the inflammation that is ultimately responsible for the sequelae of rosacea (60). In this model, warm facial skin from increased blood flow may modify the behavior of bacteria and/or *Demodex* or change the enzymatic activity of keratinocytes or other skin cells, leading to altered metabolism and inciting inflammation.

The role of *Demodex* organisms has been debated for decades. Some reports claimed a significant association of mites in rosacea biopsies (61–65), but other studies did not support this claim (66). Although a definitive causative role for *Demodex* in rosacea is uncertain, the mites may represent an important cofactor in heightening disease severity (65).

An association with gastrointestinal *Helicobacter pylori* infection has been the subject of investigation. In one study, a number of rosacea patients had gastrointestinal symptoms related to gastritis; the prevalence of *H. pylori* in those patients with rosacea was 88%, compared to 65% in the control group without rosacea (but with nonulcer dyspepsia) (67). Furthermore, eradication of *H. pylori* with 1 week of therapy that included oral metronidazole, omeprazole, clarithromycin, and topical intraoral metronidazole resulted in marked improvement or resolution of rosacea symptoms after 2 to 4 weeks. In another report, a man with intractable rosacea for 4 years was treated with a similar treatment regimen directed against *H. pylori*, which had been documented by gastroscopy and serologic testing. His skin began to improve with treatment and cleared completely 2 months later, remaining clear for at least 3 years thereafter (68). Attempts to find *H. pylori* in the skin have been unsuccessful. A proposed pathogenesis is increased flushing due to vasodilators such as nitric oxide and gastrin, and inflammatory cytokines such as tissue necrosis factor-α and interleukin-8 (IL-8), all produced by *H. pylori* (69). Nevertheless, definitive studies validating an association of *H. pylori* with rosacea have yet to be done (70).

Immunoglobulins and complement components have been identified at the dermal–epidermal junction in patients with rosacea (71), but others have disputed these findings (72). Immune deposits in the skin of rosacea patients may be a reflection of chronic actinic injury.

Demodicidosis

Demodicidosis is the term for cutaneous disease caused by mites of the genus *Demodex*. Despite more than 65 years of investigation into the role of *Demodex* mites in human skin disease, questions remain. Aside from their controversial role in rosacea, *Demodex* mites have been implicated in follicular-based skin eruptions resembling rosacea, albeit with some unique features that warrant consideration as distinct entities (73). There are at least three clinical forms of demodicidosis (73). The first, *pityriasis folliculorum*, is characterized by facial erythema with fine follicular plugs and scale producing a "nutmeg-grater" or "sandpaper-like" appearance. It usually affects women and may be associated with itching and burning. The second, *rosacea-like demodicidosis*, resembles rosacea, in that there are papules and pustules. In contrast to rosacea, however, there is follicular scaling, sudden onset, rapid progression, and no history of flushing. There may be eyelid involvement (demodectic blepharitis) and poor general health, such as diabetes mellitus (73). Lastly, "*demodicidosis gravis*" resembles severe granulomatous rosacea. These forms may represent a spectrum of disease in which the clinical expression depends on the degree and duration of *Demodex* infestation and the individual's age and overall health (73). *Demodex* may also be important in the pathogenesis of nonclassic presentations involving facial pruritus and erythema and nonspecific acneiform lesions (74).

Demodex are obligatory parasites frequently found in mammalian pilosebaceous units, and colonization is usually asymptomatic (64). The mites found in humans are of the species *D. folliculorum* and *D. brevis*. *D. folliculorum,* the predominant mite, has a longer body, inhabits the infundibulum of hair follicles, and is found almost exclusively on the face (75,76). *D. brevis* is smaller and lives exclusively within sebaceous glands on the face and trunk (75,76).

Demodicidosis has also been classified as *primary* or *secondary*, with the latter occurring on diseased skin (77). The primary form affects nondiseased skin, is caused by *D. folliculorum*, and causes an eruption in the T-zone of the face, involving 8% to 15% of the face. Secondary demodicidosis is characterized by a symmetric eruption of the malar region, covering 30% to 40% of the face, and is caused by *D. brevis*. There are other distinguishing features, such as onset of erythema, pruritus, and seasonality (77).

A study of consecutive biopsies submitted to one dermatopathology laboratory showed *Demodex* mites in 10% of all biopsies and 12% of all follicles (75). Their prevalence increased with age, and males were more heavily infested. In another study, there was a nonrandom association between histologic folliculitis and presence of *Demodex* in the follicles (76); mites were found in 42% of inflamed follicles but in only 10% of noninflamed follicles, whereas 83% of follicles containing *Demodex* showed inflammation. This demonstrated a strong association but not a cause-and-effect relation because the possibility that *Demodex* could preferentially select inflamed follicles was raised. Additional support for a pathogenic role was provided by reports of sudden facial eruptions in which numerous *Demodex* mites were identified and the eruption failed to respond to therapy for rosacea but cleared quickly with treatments directed against *Demodex*, such as crotamiton or ivermectin and permethrin (78).

Some believe that *Demodex* mites are pathogenic only in large numbers (78), but an individual's overall health also appears to be important, as demonstrated by reports in immunocompromised children (79–81) and multiple reports in patients with HIV and AIDS, in which the eruption may also involve the neck, upper trunk, and extremities (80,82,83). One study stated that demodicidosis is prevalent even in immunocompetent individuals (61), and it has been reported in immunocompetent children (84). Patients with HLA types Cw2 and Cw4 are more likely to develop clinical symptoms of demodicidosis, whereas HLA-A2 individuals appear to be more resistant (85). There is a coassociation with immune response, including subtypes and functional activity of lymphocytes, and circulating levels of immune complexes (86).

Human demodectic alopecia may be a real entity characterized by alopecia, erythema, and scale, with numerous *Demodex* mites in affected follicles (87). It resembles canine demodectic mange and has been successfully treated with permethrin. *Demodex* may also cause a refractory scalp folliculitis (88).

Histopathology. The diagnosis can be made in the clinical setting by examining scale with 40% KOH (89) or by standardized skin surface biopsy (SSSB), in which cyanoacrylate glue is used to sample the horny layer and follicular contents (90). The presence of five or more mites in a single low-power field by KOH or more than 5/cm^2 by SSSB is considered significant.

Biopsies of *pityriasis folliculorum* show a perivascular and diffuse dermal lymphocytic infiltrate without granuloma formation (73). *Demodex* mites are present within pilosebaceous units. Biopsies of *rosacea-like demodicidosis* (Fig. 18-9) show a primarily perifollicular infiltrate of mononuclear cells with possible granulomatous inflammation (73). The infiltrate is composed predominantly of CD4$^+$ T lymphocytes (65), and perifollicular Langerhans cells may be found. "*Demodicidosis gravis*" shows granulomas with central necrosis (caseation) and foreign-body-type multinucleated giant cells (91).

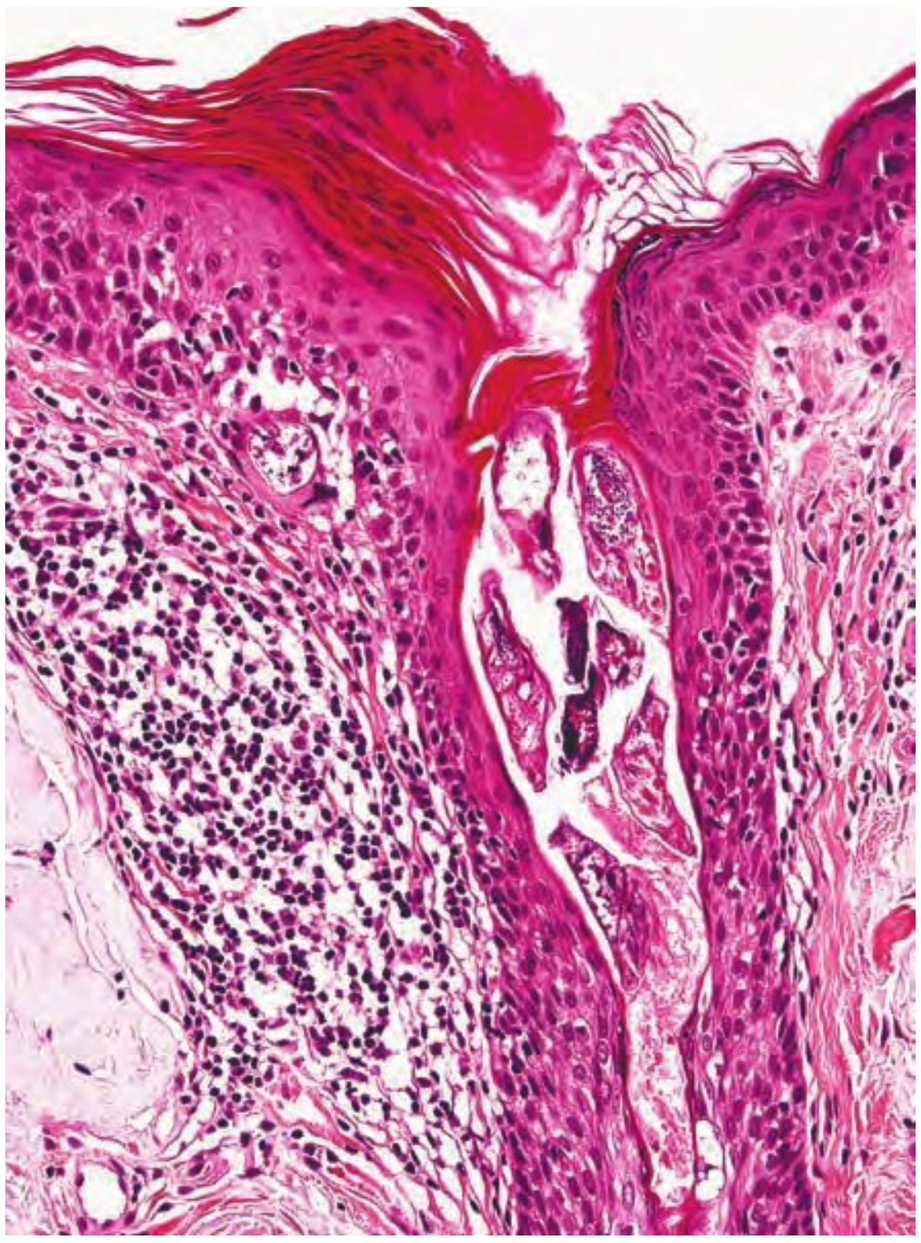

FIGURE 18-9. Demodicidosis. The follicular infundibulum contains multiple Demodex mites, and there is perifollicular lymphohistiocytic inflammation. Where the left side of the follicular epithelium meets the epidermis, an organism appears to be perforating through to the dermis.

Pathogenesis. The pathogenesis of *Demodex*-related disease may be linked to one of the following: (a) blockage of hair follicles and sebaceous ducts due to reactive epithelial hyperplasia and hyperkeratinization, (b) mites serving as vectors for bacteria, (c) a foreign-body reaction to the mite, or (d) induction of host immunity by the mites and their waste (64). Some mite antigens may also elicit a delayed hypersensitivity reaction (65). One paper suggested that a mite-derived lipase could potentially release fatty acids from serum triglycerides, producing an irritant reaction (92).

Lupus Miliaris Disseminatus Faciei

Lupus miliaris disseminatus faciei (acne agminata) is considered by some to be a granulomatous variant of rosacea, but other authors consider it to be a distinctive rosacea-like syndrome (93). The clinical presentation is distinctive, with discrete, flesh-colored or mildly erythematous papules—arranged singly or in small groups—involving the eyelids and upper lip, areas where rosacea lesions are not commonly found (94). The background erythema and telangiectasias of rosacea are lacking. Papules frequently persist for 12 to 24 months and are resistant to standard rosacea therapy, although spontaneous

healing can occur. Unusual presentations have included axillary lesions (95,96) and during pregnancy in a patient with cutaneous lupus erythematosus (97). One group proposed the use of equally cumbersome terminology, "facial idiopathic granulomas with regressive evolution" (F.I.GU.R.E.) (98). Clinically similar lesions due to metastatic silicone granulomas were reported in a patient with silicone breast implants (99).

Histopathology. Biopsy specimens sectioned through the central portion of a papular lesion demonstrate one of the most highly characteristic patterns of cutaneous histopathology. Surrounding a usually large area of caseous necrosis, aggregates of epithelioid histiocytes and occasional multinucleate giant cells form a "tubercle" with sparse lymphoid inflammation at the periphery (Fig. 18-10).

In one study, this characteristic histology was only found in a minority of patients in fully developed lesions, and an attempt was made to describe the histologic features of early, fully developed, and late lesions (100,101). Early, developing lesions show perivascular and perifollicular lymphocytes and some histiocytes. Fully developed lesions show a sarcoidal granuloma (first stage), sometimes accompanied by an abscess (second stage) or surrounding an area of caseation necrosis (third stage). The granuloma may be perifollicular and involve one or more hairs, and the follicle may be "ruptured" with a neutrophilic response. Granulomas may also be compact or loose and may occupy the upper or lower dermis, and some hug the epidermis. Late lesions demonstrate scattered lymphocytes, histiocytes, and neutrophils and perifollicular fibrosis. Additional findings include follicular dilation, hyperkeratosis, sometimes combined with follicular plugging, and pigment incontinence (100).

Despite the histologic picture, no direct relationship with tuberculosis has been documented, including testing using polymerase chain reaction with DNA fragments specific for *Mycobacterium tuberculosis* complex (102).

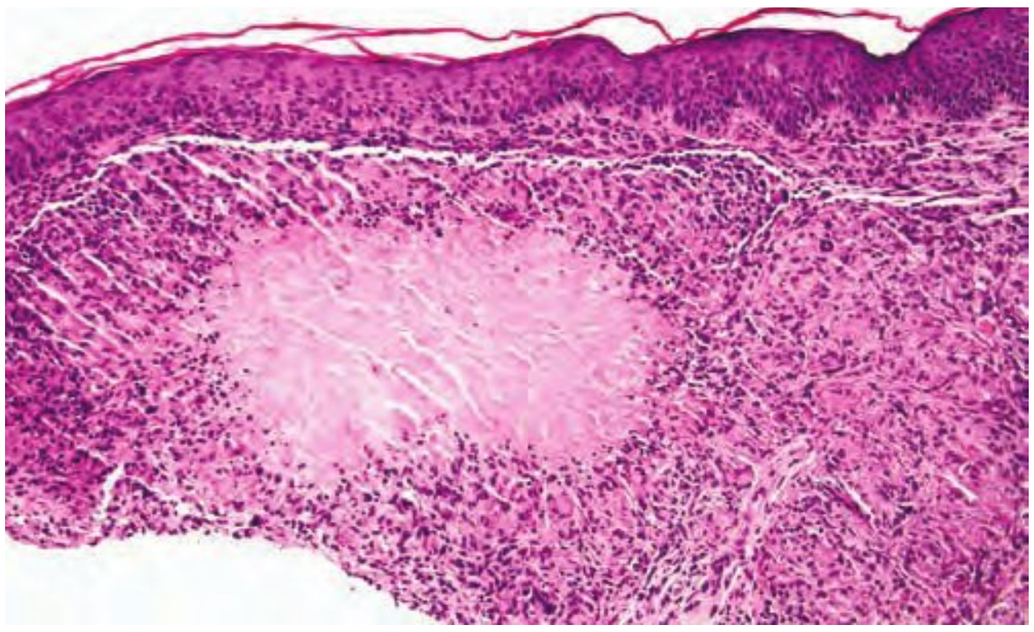

FIGURE 18-10. Lupus miliaris disseminatus faciei. Caseous necrosis is surrounded by epithelioid histiocytes and peripheral lymphocytes, forming a "tubercle" that mimics Mycobacterium tuberculosis infection.

Eosinophilic Pustular Folliculitis

Ofuji originally described *eosinophilic pustular folliculitis* (EPF) in immunocompetent Japanese patients as itchy follicular papules and pustules arranged in arcuate plaques with central healing and peripheral spread (103,104). Although most reported cases have been from Japan, the condition is now known to be geographically more widespread. Lesions typically involve seborrheic areas, including the face, trunk, and upper arms, with documented reports of extrafollicular lesions of the palms and soles (105,106). Moderate leukocytosis and eosinophilia in the peripheral blood may be present. There is usually spontaneous healing over months to years (107). There are reports of the eruption in children (108), including neonates (109), and in this subset lesions occur predominantly on the scalp. Scarring alopecia of the scalp in an adult has been reported (110). Although a cause has not been identified, rare medication-induced cases have been described due to carbamazepine (111) and allopurinol (112), after patch testing with minocycline (113) and indeloxazine hydrochloride (114), and after prolonged treatment with oral corticosteroids in a patient with pustulosis palmoplantaris (115). Cases have been associated with nevoid basal cell carcinoma syndrome (116), hepatitis C infection (117), and infestations (118).

Lesions with similar histology are well documented in patients with HIV infection (119), including children with HIV (120), and other immunocompromised conditions, such as myelodysplastic syndrome (121), non-Hodgkin's lymphoma (122), B-cell chronic lymphatic leukemia (123), polycythemia vera (124), after bone marrow transplantation (125), and after autologous peripheral blood stem-cell transplantation (126). There appear to be enough clinical dissimilarities from the disorder described by Ofuji to consider HIV-associated disease a distinct entity, and use of the terms *eosinophilic folliculitis* or *HIV-associated eosinophilic folliculitis* was recommended to reflect this (119). Another classification scheme proposed the designations classical, infancy associated, and immunosuppression associated (mostly HIV) (104,127). In HIV patients, lesions tend to be urticarial papules with less tendency to become pustular, and leukocytosis is less common (128). They are most commonly found on the face, scalp, and upper trunk and often are excoriated.

Histopathology. In Ofuji's disease, there is exocytosis of eosinophils into a spongiotic follicular infundibulum and accompanying sebaceous gland, eventually forming eosinophilic micropustules (Fig. 18-11) (110,129,130). The epidermis adjacent to the affected follicle may contain lymphocytes and eosinophils, with the latter aggregating into small eosinophilic pustules that are subcorneal or intraepidermal; these epidermal changes reflect the histologic picture seen in palmoplantar lesions, where follicles are absent (105). In more inflamed lesions neutrophils may be present (105). In the dermis, there are perivascular and interstitial infiltrates of lymphocytes and numerous eosinophils, which may surround sweat glands. Associated follicular mucinosis has been reported (131).

FIGURE 18-11. Eosinophilic pustular folliculitis. Eosinophils and lymphocytes surround and infiltrate the follicle, forming intrafollicular eosinophilic micropustules.

A study of 52 biopsies in 50 HIV-positive patients best described the histology of *HIV-associated eosinophilic folliculitis* (128). Perifollicular and intrafollicular lymphocytes and eosinophils are concentrated about the isthmus, and may involve the sebaceous duct. There is spongiosis of the follicular epithelium. Eosinophils and lymphocytes may be seen aggregating in the hair canal, but neutrophils are rare. In early lesions, lymphocytes may predominate and be distributed perifollicularly and interstitially. In more developed lesions, dermal inflammation diminishes and perifollicular/follicular inflammation increases. Less common findings include inflammation of the sebaceous gland, eosinophilic pustules, and follicular rupture (128). Dense eosinophilic infiltrates with degranulation and flame figures, resembling Well's syndrome, may sometimes be seen. A small number of macrophages can be present. Bacteria, yeast, or *Demodex* may be identified, albeit away from the areas of inflammation. Because the disorder is highly pruritic, excoriation is a common secondary finding.

Features that may help to distinguish suppurative folliculitis in HIV-positive patients from *HIV-associated eosinophilic folliculitis* have been described; suppurative folliculitis in HIV-positive patients more commonly shows an infiltrate dominated by neutrophils and macrophages, the presence of microorganisms amid the inflammation, and rupture of the involved follicle. The use of transverse histologic sections has been advocated over vertical sections for increasing diagnostic sensitivity and demonstrating the key pathologic findings in HIV-associated eosinophilic folliculitis (132).

Pathogenesis. The cause of Ofuji's disease (EPF) is not known. Although the prevalence in Japan could not be explained by HLA patterns (110), the occurrence in brothers in the neonatal period hints at some inherited predisposition or possibly an infectious etiology (133).

The perivascular infiltrating cells in EPF were found to be mostly T lymphocytes, with some $CD68^+$ myelomonocytic cells, and most of the eosinophils were positive for eosinophil cationic protein (134). A moderate increase in the number of tryptase-positive, chymase-negative mast cells, the type predominantly found in lung and small intestine, was noted around hair follicles and sebaceous glands (129). A study of Ofuji's disease found markers of sebaceous differentiation to be decreased or absent, whereas follicular differentiation markers were expressed normally (107).

In another study of three patients with EPF, serum levels of interferon-γ and IL-2, -4, and -6 were measured before and after successful treatment with indomethacin (135). Investigators found elevated IL-4 in the EPF patients, which remained unchanged after treatment, and increased interferon-γ with disease remission. Decreased expression of IL-5 mRNA in peripheral blood mononuclear cells was demonstrated after the disease was controlled in two EPF patients undergoing treatment with interferon-γ (136); IL-5 is responsible for the growth and differentiation of eosinophils.

Ultrastructurally, in EPF lesions characterized by an infundibular pustule, acantholytic outer root sheath keratinocytes showed desmosomal cleavage with microvilli formation, and some contained sebaceous lipid droplets (137). Apposition of T lymphocytes and Langerhans cells was seen.

In the differential diagnosis, eosinophilic follicular pustules may be seen in erythema toxicum neonatorum, and intraepidermal eosinophilic vesicles can be seen both in acropustulosis and the vesicular phase of incontinentia pigmenti. However, the clinical presentation of these conditions would generally be significantly different than that in EPF, although it has been suggested that EPF in infants and infantile acropustulosis may be variants of the same disorder (138). Identical eosinophilic pustular eruptions have been described in association with *Pseudomonas* infection (139) and in fungal infections due to dermatophytes (140).

Follicular Mucinosis and Alopecia Mucinosa

Follicular mucinosis is characterized clinically by grouped erythematous papules and/or plaques that may be markedly indurated or nodular (Fig. 18-12) and histologically by mucin accumulation in hair follicles (141). It can be classified into two types: a primary (idiopathic) type and a secondary variety. The *primary* form tends to have a shorter but benign course. The *secondary* type has been associated with numerous benign and malignant conditions, including lymphomas, of which the majority are mycosis fungoides. A distinct variant of mycosis

FIGURE 18-12. Follicular mucinosis/alopecia mucinosa. This round, slightly elevated pink plaque in an adolescent boy has resulted in clinically apparent alopecia because the hairs at this site are coarser.

FIGURE 18-13. Alopecia mucinosa. Diffuse thinning of the scalp associated with slightly elevated, scaly plaques. The scalp erythema and poorly defined areas of alopecia distinguish this example from alopecia areata.

fungoides—follicular mycosis fungoides—may or may not be associated with follicular mucinosis (142,143).

The *primary* form tends to affect children and young adults more frequently and resolves spontaneously in several months (acute benign type) or several years (chronic benign type) (144). It is often confined to the head and neck but may be disseminated. The *secondary* type tends to form more widespread plaques and is almost always a disorder of adults.

The secondary type has been found in association with other lymphoproliferative disorders, including Hodgkin's disease (145–147), cutaneous B-cell lymphoma (148), acute myeloblastic leukemia (149), chronic lymphocytic leukemia (147), and syringolymphoid hyperplasia with cutaneous T-cell lymphoma (150), as well as a number of inflammatory cutaneous disorders such as chronic discoid lupus erythematosus (151), angiolymphoid hyperplasia (152), alopecia areata (153), eosinophilic pustular folliculitis (131), spongiotic dermatitis, lichen striatus, arthropod bites, sarcoidosis, Goodpasture's syndrome (154), leprosy (155), and growths such as verrucae (154), melanocytic nevi, and squamous cell carcinoma of the tongue (156). The numerous associations with production of follicular mucin certainly suggest that this is a relatively nonspecific reaction pattern.

There has been controversy about whether the histopathology allows for distinction between the primary and secondary forms. Initially it was considered that the histopathology could be predictive (157). Later, some researchers claimed that transition from the benign form to a lymphomatous type could occur (158,159), whereas others disputed this finding (154). In 1989 a study of 59 cases concluded that there was no clinical or pathologic pattern by which the ultimate outcome of the condition could be predicted (145).

Others have reported that adults older than the age of 40 years with widespread follicular mucinosis are at increased risk for mycosis fungoides or Sézary's syndrome (154,158), although Cerroni et al. claimed that criteria purported to differentiate lymphoma-associated follicular mucinosis from the idiopathic type were not effective (159). A long-term follow-up study (median 10 years) of seven patients younger than 40 years of with primary follicular mucinosis failed to demonstrate progression to cutaneous T-cell lymphoma, despite the presence of a T-cell clone in five of the patients (160).

In 1957, Pinkus described *alopecia mucinosa,* the term used when follicular mucinosis affects terminal hair-bearing areas and is associated with hair loss (161) (Fig. 18-13). Papules and plaques may be present or inconspicuous in this form, which may show only alopecia. Scarring is seen more commonly when alopecia mucinosa is associated with cutaneous T-cell lymphoma. Others claim that alopecia mucinosa is simply one of the many morphologic variants of mycosis fungoides (162), whereas LeBoit and LeBoit acknowledged the paradoxes of alopecia mucinosa that have led to the debate over classification (163).

Histopathology. Within the outer root sheath and sebaceous gland epithelium, there is reticular epithelial degeneration that sometimes evolves into more extensive cavitation within which mucin is deposited (Fig. 18-14). Occasionally, little mucin can be detected, perhaps because of removal of this water-soluble material in the processing procedure. The deposited mucin is an acid mucopolysaccharide that stains metachromatically with toluidine blue at pH 3.0, as well as with Alcian blue at acid pH. The fact that it can be substantially removed by digestion with hyaluronidase demonstrates that the mucin is predominantly hyaluronic acid. Colloidal iron stain may also be used for its detection.

Inflammation is composed of lymphocytes and histiocytes, but there can also be eosinophils. There may be exocytosis into the outer root sheath epithelium of the infundibulum and the sebaceous gland epithelium. Although individual pathologic criteria are not absolutely diagnostic of the type of

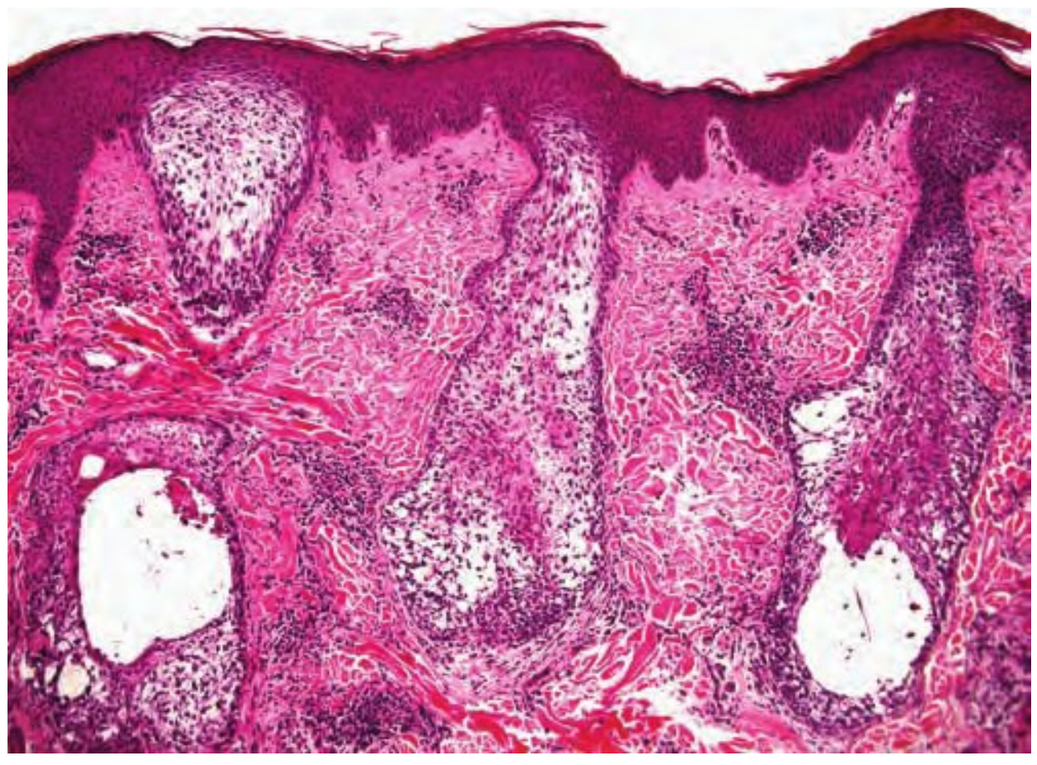

FIGURE 18-14. Follicular mucinosis. The outer root sheath epithelium of several follicles shows reticular degeneration with areas of cavitation. There are intercellular strands of bluish-staining mucin.

follicular mucinosis (primary or secondary), features that have been proposed as favoring a lymphoma-associated lesion include an atypical lymphocytic infiltrate or increased density of the perifollicular infiltrate with substantial folliculotropism (Fig. 18-15) (164). This study also suggested that a prominent eosinophilic infiltrate and more substantial mucin deposition tend to favor a benign process, but a subsequent study failed to substantiate these findings (145).

Pathogenesis. Electron microscopic studies have shown that the mucin is a product of the outer root sheath epithelial cells. The cytoplasm shows prominent, dilated, rough-surfaced endoplasmic reticulum containing fine, granular, filamentous material that is secreted into the intercellular spaces (165). In two of our patients with primary, idiopathic *alopecia mucinosa* with reversible alopecia, we found, using transverse sections, an increased number of resting-phase follicles, mostly catagen, ranging from 46% to 92% of all terminal follicles (unpublished observation).

Keratosis Pilaris

This common persistent condition characteristically affects the lateral aspect of the arms, thighs, and buttocks. Keratotic follicular papules, sometimes with surrounding erythema, are present. They are usually asymptomatic. Keratosis pilaris may be seen in association with ichthyosis vulgaris (166) and appears to be more common in patients with atopic dermatitis.

Similar lesions may form as part of a variety of more extensive erythematous keratinizing disorders. Keratosis pilaris rubra is a variant that shows more widespread skin involvement and more prominent erythema (167). Keratosis pilaris atrophicans represents a spectrum of clinical conditions, including keratosis follicularis spinulosa decalvans (168–170), in which the involved follicle becomes atrophic and destroyed, sometimes associated with scarring alopecia of the scalp.

Histopathology. An orthokeratotic keratin plug blocks and dilates the orifice and upper portion of the follicular infundibulum (Fig. 18-16). A twisted hair shaft may be trapped within this keratin material, and mild perivascular mononuclear cell infiltrates are usually present in the adjacent dermis.

A similar condition, lichen spinulosus (171), shows a very similar histologic picture except that the keratin plug may protrude more substantially above the skin surface and contain one or more hair shafts (172). Lesions similar to keratosis pilaris may also be seen in phrynoderma (vitamin A deficiency; see Chapter 16), but the follicular keratin plug is said to be parakeratotic (173).

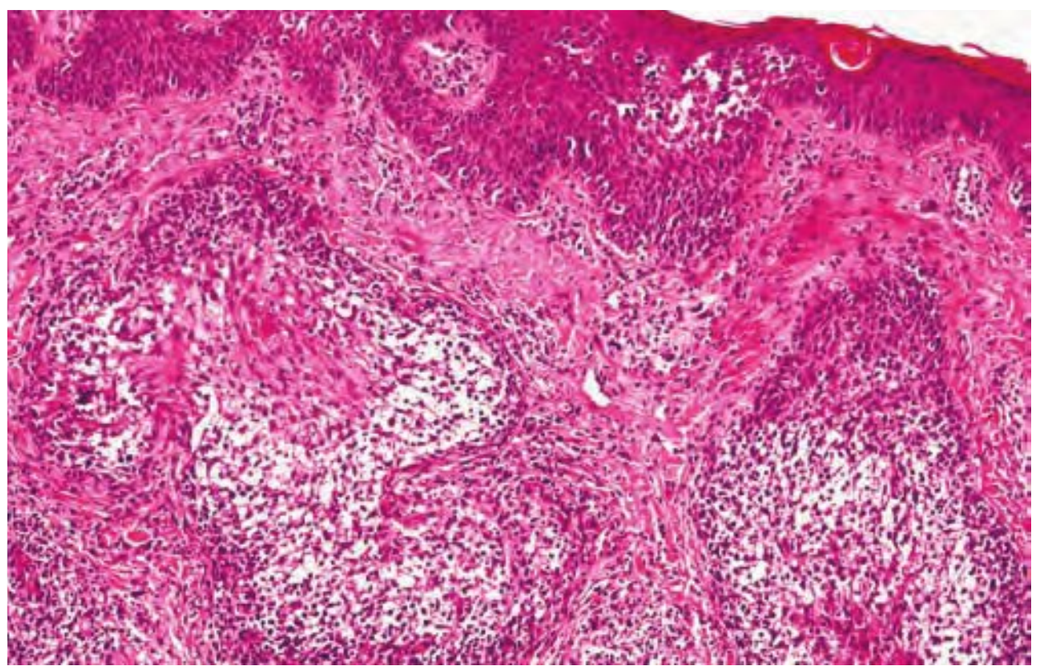

FIGURE 18-15. Follicular mucinosis associated with folliculotropic mycosis fungoides. In addition to changes of follicular mucinosis, there is extensive folliculotropism of lymphocytes. There is also epidermotropism of large lymphocytes.

FIGURE 18-16. Keratosis pilaris. The follicle is plugged with compact orthokeratin that protrudes above the skin surface.

Pathogenesis. Genetic factors may play a role in this condition. Patients with a generalized form of keratosis pilaris were found to have a chromosome 18p deletion, implicating a gene on the short arm of chromosome 18 (174).

Trichostasis Spinulosa

Trichostasis spinulosa is a fairly common condition that may present clinically as raised follicular spicules or as open comedones or be inapparent (175). It occurs predominantly on the face, nose, or cheeks of middle-aged and older individuals, but it has been reported in a pediatric patient (175). It may be pruritic. Generalized trichostasis spinulosa has been reported in a patient with chronic renal failure (176).

Histopathology. Affected hair follicles demonstrate retention of small hair shafts within a dilated infundibulum, sometimes enveloped in a keratinous sheath (Fig. 18-17). As many as 20 or more hair shafts may be trapped in this way, often projecting above the skin surface. A perifollicular mononuclear infiltrate may be present. In the clinical setting, the follicular plugs may be easily extracted with fine forceps or a comedone extractor and examined microscopically, demonstrating a cluster of vellus hairs within a keratinous plug.

Pathogenesis. The etiology of trichostasis spinulosa is not known for certain. The retained hairs are normal telogen hairs, which suggests a normally functioning follicle. Congenital dysplasia of the hair follicles and external factors such as dust, oils, ultraviolet light, heat, and irritants have been proposed (175). One hypothesis is that hair shaft entrapment is the result of hyperkeratosis in the follicular infundibulum, thus producing an obstruction to normal hair shedding (177).

FIGURE 18-17. Trichostasis spinulosa. A dilated follicular infundibulum with retention of multiple vellus hair shafts. The granular blue material represents resident bacteria of the follicle.

DISEASES OF HAIR FOLLICLES LEADING TO HAIR LOSS: ALOPECIA

A discussion of alopecia generally pertains to loss of hair on the scalp, although other body sites may be affected, as can be seen in alopecia areata, trichotillomania, telogen effluvium, and lichen planopilaris, to name a few. A useful way broadly to classify the alopecias is to divide them into nonscarring and scarring types depending on their (relative) propensity to culminate in permanent hair loss. An algorithmic approach to the alopecias was presented in an excellent paper by Solomon (178). Sometimes classification of an individual case of alopecia can be complicated by the coexistence of more than one process. For example, scarring alopecia can occur in a patient with underlying androgenetic alopecia.

Some types of alopecia are discussed elsewhere in this text, such as lichen planopilaris (see Chapter 7), lupus erythematosus (see Chapter 10), syphilitic alopecia (see Chapter 22), perifolliculitis capitis abscedens et suffodiens (see Chapter 21), folliculitis (*"acne"*) keloidalis nuchae (see Chapter 21), and alopecia neoplastica (see Chapter 36). Although hair shaft disorders result in alopecia, a diagnosis is often made on clinical grounds and based on examination of hair shafts rather than biopsy material; therefore, a discussion of hair shaft disorders is not included here but can be found in one of several review articles (179–181). Alopecia that is easily diagnosed in the clinical setting based on history, physical examination, and microscopic assessment of gently pulled hairs, thereby negating the need for a scalp biopsy, is also not discussed; these include postoperative pressure-induced alopecia, temporal triangular alopecia, and loose anagen syndrome.

General Considerations in Diagnosing Alopecia

The Scalp Biopsy

A punch biopsy or incisional biopsy extending into fat to include terminal hair bulbs is necessary for proper evaluation of alopecia. A punch biopsy is easier for the clinician to perform, and most scalp biopsies are submitted as such. It is generally accepted that at least a 4-mm punch be used to obtain a sufficient number of hairs for study. In addition, many of the published quantitative parameters for diagnosing different forms of alopecia are based on a 4-mm punch, so this is the one that is generally recommended (182).

Controversy exists regarding the manner in which the punch biopsy should be sectioned: vertically, where the cylinder of tissue is bisected longitudinally, which is the standard way of sectioning punched specimens procured for other

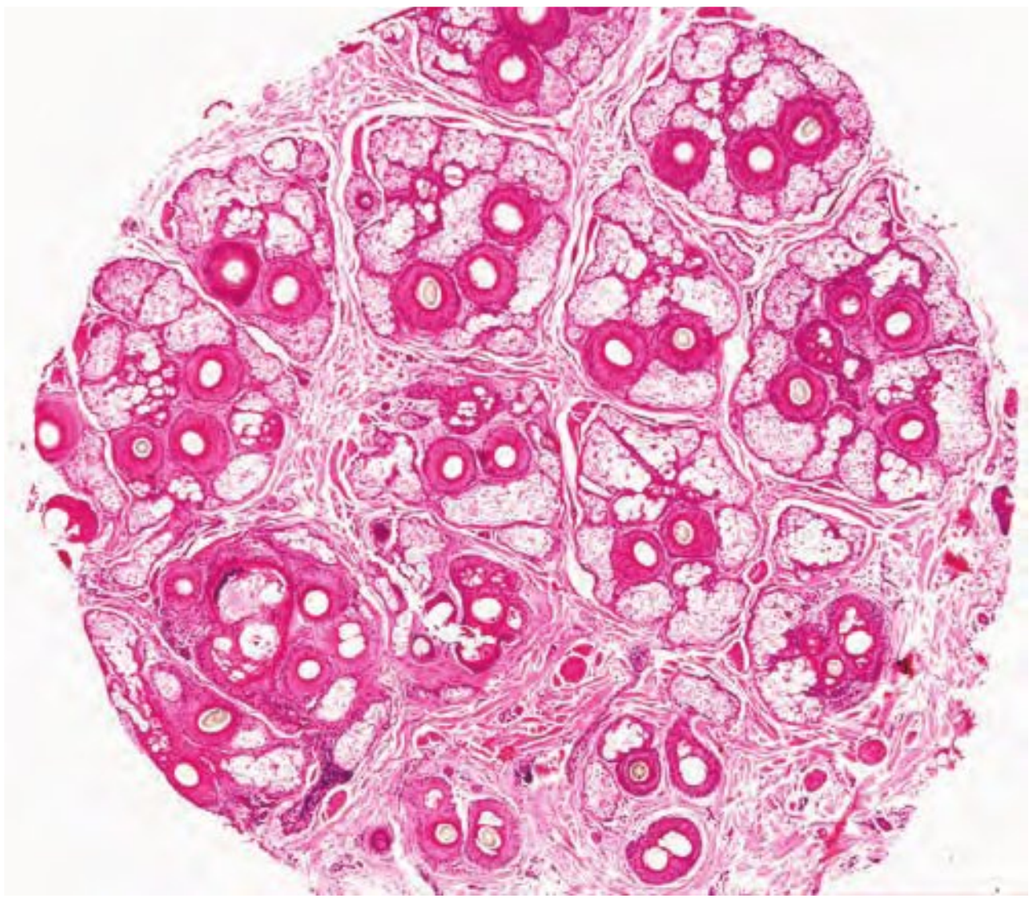

FIGURE 18-18. Horizontal section, scalp. This 4-mm punch biopsy was sectioned horizontally (a.k.a. transversely), enabling visualization of every follicle in the specimen. At this level, through the middermis near the isthmus, arrangement of pilosebaceous structures into "follicular units" is apparent.

cutaneous disorders, or horizontally (a.k.a. transversely), in which the skin cylinder is "bread-loafed," which is the method pioneered by Headington (183). Horizontal sectioning enables visualization of all the follicles in the specimen (Fig. 18-18), whereas it has been estimated that conventional vertical sections demonstrate only 10% to 15% of the follicles in the sample (183). Dermatopathologists appear to be polarized with regard to which method of sectioning is preferable. Of dermatopathologists who favor vertical sections, some feel that they can glean as much information if serial sections are obtained, and some feel uncomfortable interpreting hair follicle anatomy and pathology in a horizontal orientation. A notable disadvantage of transverse sections is the inability properly to evaluate the epidermis (178). However, when a transversely sectioned biopsy is cut through, a portion of the epidermis can usually be seen and evaluated, albeit tangentially.

Some authors have recommended that two 4-mm punch biopsies be performed from the area of disease activity, and that one biopsy be sectioned transversely and the other sectioned vertically. The latter is bisected at the time of the biopsy, with one half sent for routine histology (embedded with the two halves of the transversely sectioned specimen), and the other half processed for direct immunofluorescence (184). In some forms of nonscarring alopecia such as telogen effluvium or early androgenetic alopecia, in which the histologic findings may be subtle, it may be helpful to take one specimen from the involved vertex of the scalp and one specimen from the occiput; on comparing the two, one should find the occipital scalp to be relatively normal in androgenetic alopecia and equally involved in telogen effluvium. Certainly a single biopsy is preferable from a patient morbidity standpoint, and a single biopsy may be sufficient (185).

For diagnosing cicatricial alopecia, the recommendation is for one 4-mm punch biopsy specimen from the edge of an involved area where there is new hair loss, a positive hair pull test, or inflammation as evidenced by clinically apparent erythema (186). If the goal of the biopsy is to assess the potential for hair regrowth (prognosis), then the optimal area to sample is an older, more central area with a "burnt-out" appearance.

In the past, serial horizontal sections would result in numerous sections and multiple slides to review, typically 12 to 20 (185). A proposed method for improving the convenience of transverse processing recommended trisecting or quadrisecting the specimen, inking one side of each resultant disk of tissue in a consistent orientation, and then embedding them all in a single cassette so that several microanatomic levels can be viewed on a single slide (185). My experience with this technique is that, although convenient, it sometimes results in loss of tissue (sometimes critical tissue) because laboratory personnel significantly efface some of the tissue pieces to obtain a "good" slice of *all* of the tissue disks. This can occur particularly when the pieces of tissue are embedded at slightly different depths in the paraffin block.

I have found that a safer way to process the punch specimen to avoid loss of tissue is to bisect it once transversely, approximately 1 mm below the epidermal surface, ink the cut surfaces, and embed the two pieces so that the inked surfaces are cut first, a method previously advocated (178,183). Deeper levels from the block reveal sections that approach the epidermis for one piece of tissue and the subcutis for the other piece of tissue.

The ideal way to procure a punch biopsy for transverse processing is to orient the punch tool parallel to the direction of hair growth, decreasing the frequency that hairs are transected by the biopsy procedure. The result is a cylinder of scalp skin in which the sides of the cylinder are not exactly perpendicular to the epidermal surface. With this in mind, when the specimen is bisected 1 mm below the epidermis, the cut should be angled parallel to the epidermal surface (not perpendicular to the sides of the tissue cylinder), so that each histologic section will show all of the follicles at roughly the same microanatomic level, which facilitates their interpretation. As a consequence, however, follicles and hair shafts will appear ovoid in shape under the microscope rather than round.

I prefer to interpret transverse sections whenever possible, and this chapter emphasizes this method. Transversely sectioned scalp biopsies offer the following advantages (178): (a) *All* of the follicles in the biopsy specimen can be seen and studied, (b) it allows for rapid evaluation of hair density and follicular units, (c) it allows for accurate assessment of follicle size, (d) pathologic alterations at different levels of the follicle can easily be evaluated, and (e) it facilitates quantitative interpretation of the biopsy. In my experience, it is a more sensitive technique for detecting tinea capitis when only scattered follicles are involved. Horizontal sections are ideal for evaluating the

number of viable follicles and estimating prognosis for hair regrowth. As previously mentioned, interpretation of horizontal sections requires a thorough understanding of hair follicle microanatomy, as well as the normal hair cycle. These are superbly described in Chapter 3 and in other sources (178, 183,187) and are not reiterated here.

Recently introduced terms include *exogen*—a distinct phase of the hair cycle in which the hair shaft is actively shed, most likely by a proteolytic mechanism (188,189)—and *kenogen*—referring to the empty hair follicle after the telogen hair is shed (190). Kenogen is believed to represent a physiologic rest period for the follicle prior to initiation of a new growth phase.

Terminology Defined

Solomon and Templeton noted that "working definitions" are "important in the microscopic evaluation of alopecia," although "these definitions are arbitrary and therefore debatable" (191). Although authors differ in the definitions they use to characterize hair follicles, the following definitions are commonly employed. A terminal hair was designated by Headington as having a hair shaft diameter of 0.06 mm or greater and a vellus hair as having a hair shaft diameter of 0.03 mm or less (183). Between terminal and vellus hairs are intermediate hairs (a.k.a. indeterminate), whose shaft diameter, i, is defined as $0.06 > i > 0.03$ mm (Fig. 18-19). A micrometer is sometimes needed accurately to assess hair shaft diameter, although without actually measuring them, hair follicles can be classified by comparing the shaft size to the width of the inner root sheath; the diameter of a vellus hair shaft should be less than or equal to the thickness of the inner root sheath (Fig. 18-19). Qualitatively, terminal hairs have their bulbs anchored in the subcutaneous fat, whereas vellus hair bulbs are in the mid to upper dermis.

True vellus hairs lack melanin pigment and are small throughout their existence, whereas *miniaturized* vellus hairs are terminal hairs that have decreased in size. Because these are histologically identical, it is not necessary to distinguish them for the purpose of diagnosing alopecias; henceforth in this chapter, the term *vellus hairs* will encompass true vellus hairs *and* miniaturized terminal hairs. Although some authors group intermediate hairs with the terminal hair population for the purpose of quantification, I prefer to include them with the vellus group because more often they represent a transitional follicle undergoing the process of miniaturization to a vellus hair. Reversal of the process via therapy with minoxidil or finasteride can confuse the picture, however. A cross section at the lower infundibular level is optimal for visualizing vellus hairs, allowing one accurately to count terminal and vellus hair shafts to determine the terminal-to-vellus hair ratio.

In determining the telogen count or anagen-to-telogen ratio, the term "*telogen*" actually encompasses all phases of the nonanagen follicle, including telogen, catagen, and telogen germinal unit (Fig. 18-20), because they all represent stages in a continuum: the irreversible process of hair follicle regression and shedding. For instance, a catagen follicle, with an epithelial column in the subcutis and/or lower dermis, often shows a telogen hair near the isthmus. Although vellus hairs also cycle, only terminal-sized follicles in catagen and telogen are counted as part of the regressing/resting hair population. The telogen count derived histologically, using these definitions, reflects the count obtained in the clinical setting by forcible hair pluck (using a rubber-tipped hemostat) because this method is unsuccessful at dislodging the smaller, vellus hairs (187,192).

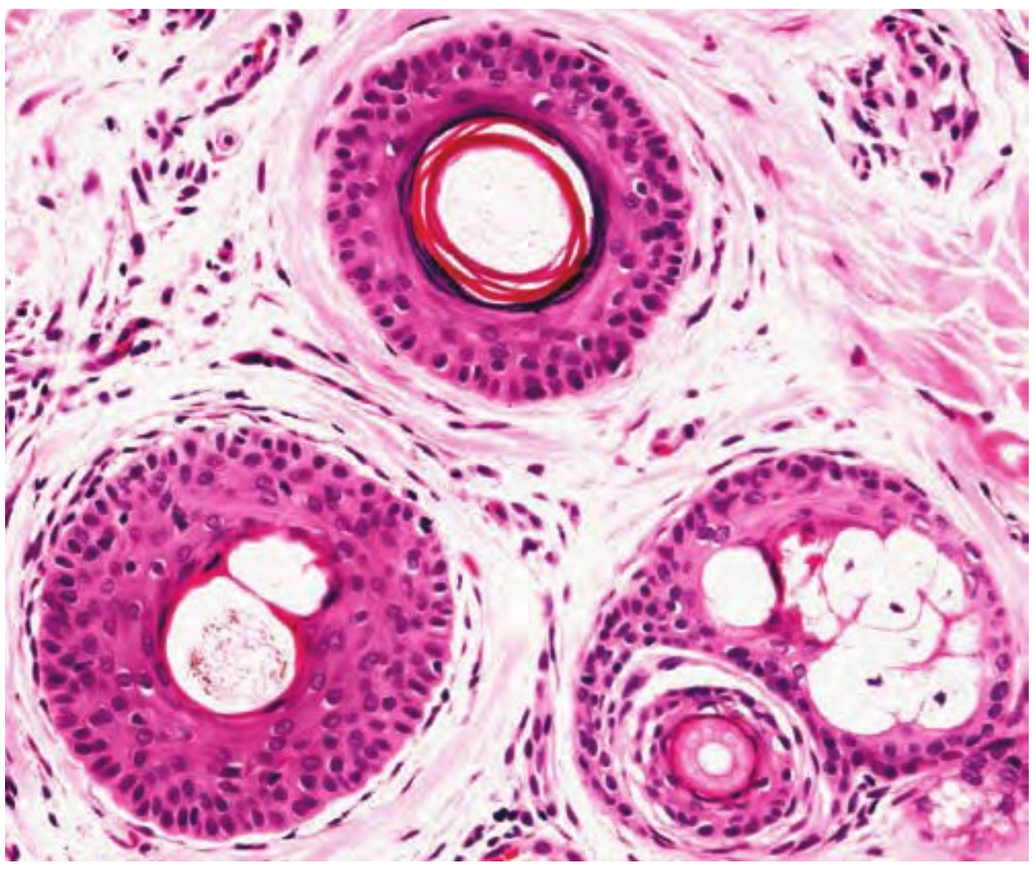

FIGURE 18-19. Normal variation in hair diameter (horizontal). This level is through the infundibulum of the terminal follicle, defined by a hair shaft diameter that is 0.06 mm or greater (top). The vellus hair (right) is readily identifiable by a shaft diameter that is equal to or less than the thickness of the inner root sheath (0.03 mm or less). An intermediate hair (lower left) has a shaft diameter that is between the other two.

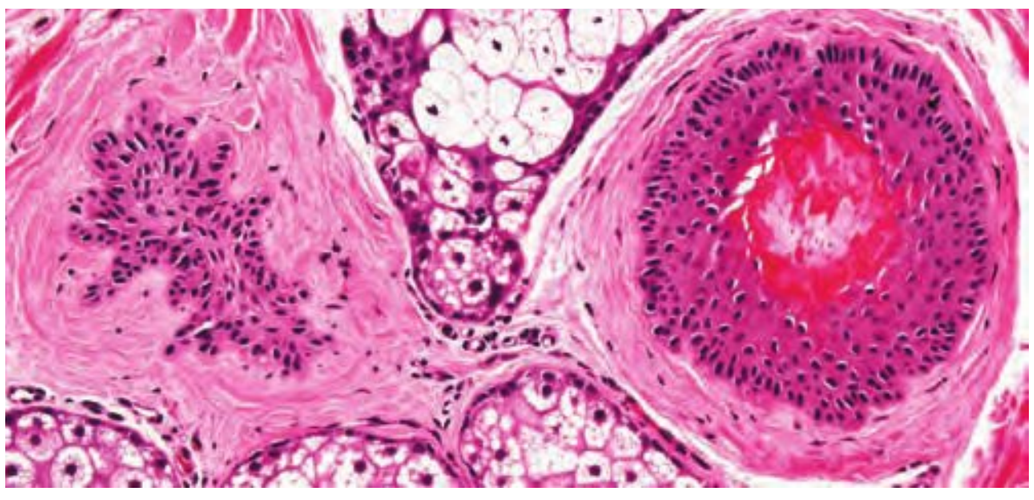

FIGURE 18-20. Normal resting follicles (horizontal). The follicle at right is a telogen follicle, identifiable by brightly eosinophilic trichilemmal keratinization of the proximal hair shaft. This structure is the histologic correlate of easily displaced telogen hairs viewed by microscopy in the clinical setting, so-called "club hairs." To the left is a telogen germinal unit, which represents the secondary hair germ. This structure is found in the mid to upper dermis and is characterized by follicular epithelium with radial projections. In vertical sections, it is sometimes visible just beneath the telogen hair.

A cross section through the isthmus is optimal for assessing the number of telogen and catagen hairs and telogen germinal units. This telogen count should be interpreted in the context of a second count at the infundibular level to assess terminal and vellus hairs because follicles in telogen or catagen according to their appearance near the isthmus show a shaft in the infundibulum that looks identical to that of a terminal anagen follicle; that is, a hair shaft with a diameter of 0.06 mm or greater situated in the infundibular hair canal. Often the infundibular portion of the hair shaft, untethered by the inner root sheath, is missing, presumably carried away by the microtome blade. In this situation, the pathologist must rely on the caliber of the follicular outer root sheath and the diameter of the empty hair canal to extrapolate the size of the hair shaft and obtain more accurate counts.

Miniaturization and conversion to catagen and telogen leave many collapsed fibrous root sheaths in the subcutis (Fig. 18-21). Also known as "stelae" and "fibrous streamers," they are found in conditions in which there is follicular miniaturization (i.e., androgenetic alopecia) or conditions with increased numbers of catagen and telogen hairs, such as telogen effluvium and trichotillomania.

Normal Parameters

Normal parameters as determined by examination of transversely sectioned scalp biopsies have been published in various sources and are typically based on a 4-mm punch biopsy. Most were from studies of white subjects, but ethnic differences in "normal" values have been demonstrated, and this must be taken into consideration when evaluating a scalp biopsy. Whites without alopecia should have approximately 40 total hairs in a 4-mm punch biopsy, with roughly 20 to 35 terminal hairs and 5 to 10 vellus hairs (182,183,192,193). The normal terminal-to-vellus hair ratio for adult scalp is 3:1 to 4:1 (183) but at least 2:1 (194). Another study found a value of 7:1 (193).

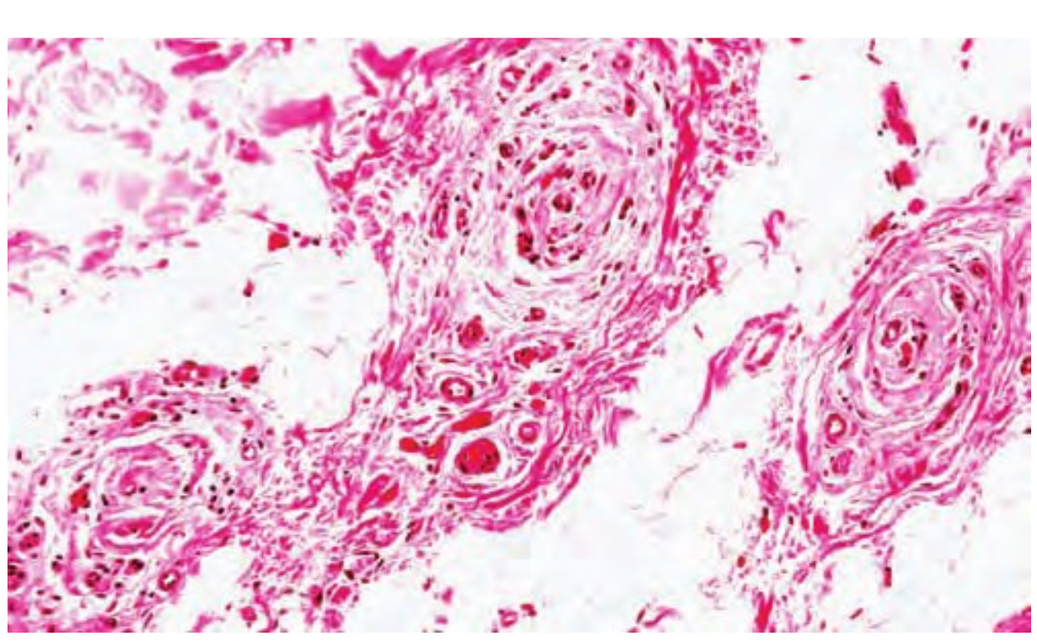

FIGURE 18-21. Fibrous streamers (horizontal). Also known as stelae, these collapsed fibrous sheaths are subcutaneous evidence of hairs that have moved upward through the process of miniaturization or conversion to telogen. They consist of concentrically arranged bands of collagen with numerous capillaries and an increased number of mast cells.

Hair density in African-Americans was found to be significantly lower than in whites, with an average of 18 terminal and 3 vellus hairs in a 4-mm punch biopsy (195). However, the follicles are typically larger (196). In Koreans, the follicular density was found to be significantly lower than in whites and blacks (197).

Hair follicles on the scalp are arranged in follicular units—bundles of hairs naturally found together. They form hexagonal modules separated from one another by intervening collagen and are best visualized by transverse sections through the upper dermis near the isthmus (Fig. 18-18) (198). There are typically 10 to 12 follicular units in a 4-mm punch (178). Each follicular unit normally contains 2 to 5 terminal hairs and 0 to 2 vellus hairs, along with sebaceous glands and arrector pili muscle (182).

Nonscarring Alopecia

Alopecia that is nonscarring clinically shows intact follicular ostia and histologically shows a normal density of hair follicles (199,200). Despite being categorized as "nonscarring," conditions such as androgenetic alopecia, longstanding alopecia areata, and traction alopecia can lead to irreversible loss of hair follicles. Transverse sections are particularly useful in the histologic diagnosis of nonscarring alopecias because the anagen-to-telogen ratio and terminal-to-vellus hair ratio may be crucial in making an accurate diagnosis. In particular, female patients with a fairly diffuse, nonscarring alopecia can be a diagnostic dilemma based on clinical grounds alone, and a biopsy can help. The main diagnostic possibilities in this setting are (a) female pattern hair loss, (b) acute and chronic telogen effluvium, (c) diffuse alopecia areata, and (d) loose anagen syndrome (201).

Alopecia Areata

Alopecia areata (AA) is characterized clinically by complete or nearly complete absence of hair in one or more circumscribed areas of the scalp (Figs. 18-22). Clinical inflammation, typically manifested by erythema, is not obvious, and the follicular openings are preserved, a clinical finding that allows the examiner to make the assessment of a nonscarring alopecia. In active areas of involvement, hair shedding is seen, as well as some short, fractured hair shafts, including the pathognomonic "exclamation point" hair. Complete scalp involvement (*alopecia totalis*) may occur suddenly or through prolonged, progressive disease. Complete or nearly complete loss of all body hair (*alopecia universalis*) can also occur. Involvement of the eyebrows and eyelashes and regularly spaced pits on the surface of the nails may be seen. The majority of patients with localized disease undergo spontaneous resolution, but others show persistent disease, and a few patients have permanent hair loss. "The only predictable thing about the progress of alopecia areata is that it is unpredictable" (202), which means essentially that one cannot reliably predict which patients will have limited disease with spontaneous resolution and which will have recurrent disease or chronic, severe disease.

FIGURE 18-22. Alopecia areata. A patch of alopecia with obvious follicular pores, indicating a nonscarring type of hair loss. Exclamation-point hairs are present at the edge of the patch to the right. Despite the microscopic lymphocytic infiltrate that is sometimes present, the areas lack clinical evidence of inflammation, namely erythema.

Histopathology: The diagnostic pathologic feature is peribulbar lymphocytic inflammation ("swarm of bees") affecting anagen follicles (Fig. 18-23) or follicles in early catagen. The inflammatory assault on anagen follicles induces a premature conversion to catagen (Fig. 18-24). Consequently, the number

FIGURE 18-23. Alopecia areata (horizontal). Classic peribulbar lymphocytic inflammation likened to a "swarm of bees."

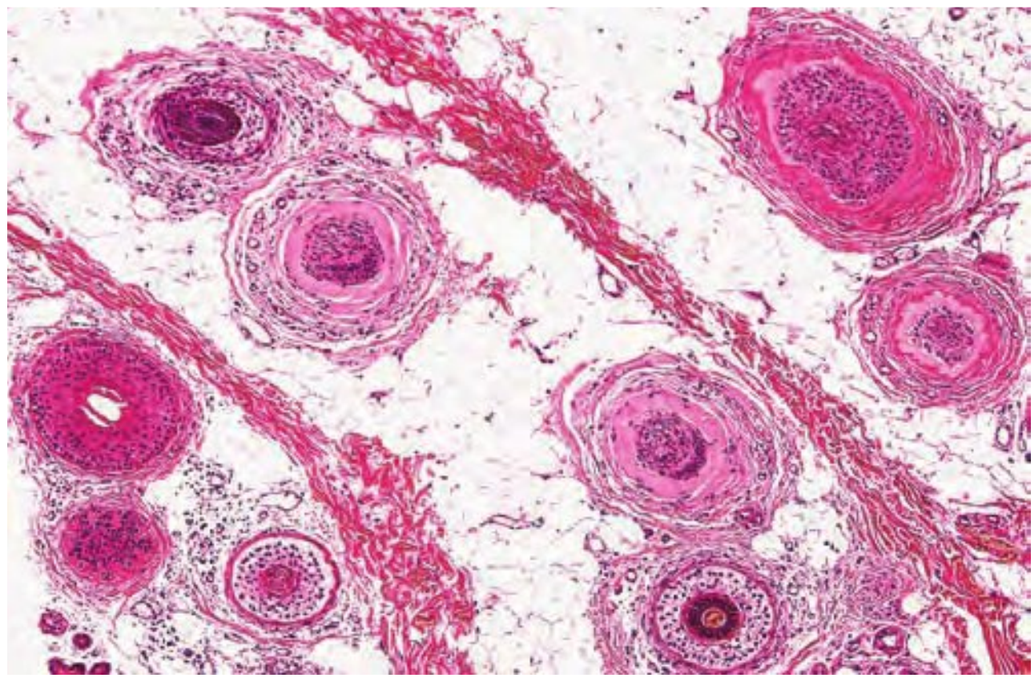

FIGURE 18-24. Alopecia areata (horizontal). Although peribulbar inflammation is not obvious here, the combination of an increased number of resting hairs and miniaturized hairs is characteristic of alopecia areata. Catagen follicles are notable by their eosinophilic "glassy" membrane and lack of a hair shaft.

of catagen and telogen follicles found may be marked, approaching 100% (203,204). Follicles may enter a persistent phase of telogen in which the hair shaft has already been shed, manifested by the *telogen germinal unit* (Fig. 18-20) (204). As follicles enter catagen, the lymphocytic infiltrate may persist around the epithelial remnant of the receding follicle and also within and surrounding the collapsed follicular sheaths. Telogen hairs show little to no perifollicular inflammation.

Lymphocytes may also be seen sparsely infiltrating the matrix epithelium of anagen follicles, inducing damage to the matrical cells that includes intra- and intercellular edema, cellular necrosis, and microvesicle formation. One of the earliest findings was shown to be a loss of structural integrity of bulbar keratinocytes in the central part of the supramatrical bulb and shrinkage of hair bulbs toward a club shape (205). As a result of injury to bulbar melanocytes and keratinocytes, pigment casts, which are clumps of melanin pigment, may be found within the dermal papilla, the sheath of miniaturizing or regressing follicles, or the follicular epithelium (194). Pigment casts are more often found in trichotillomania; one interpretation of their presence in the context of AA is that here too they represent external manipulation of the hair (49). Pigment casts have also been found in postoperative pressure-induced alopecia, leading those authors to postulate that they resulted from the sudden conversion of follicles from anagen to catagen, as occurs in trichotillomania and AA (206).

The inflammatory assault may produce dysmorphic follicles and shafts. Anagen hairs not sufficiently damaged so as to enter prematurely into catagen may continue to manufacture a hair shaft, one that may be small, distorted, and often nonpigmented (termed *trichomalacia*). The hair shaft may taper to a point so tiny and fragile that it fractures. Small, abnormal follicles called *nanogen* hairs are a distinctive finding in longstanding cases (Fig. 18-25) (196). They are difficult to categorize as anagen,

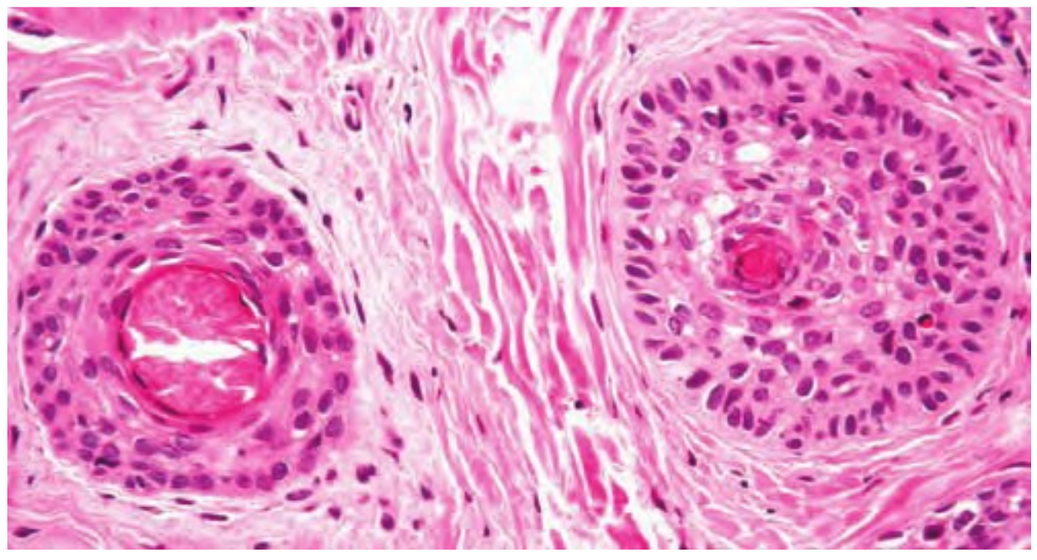

FIGURE 18-25. Alopecia areata (horizontal). Dystrophic hairs. The follicle at left has no shaft at all; the inner root sheath completely fills the canal. The follicle to the right is producing only a minute, "pencil-point" hair shaft that will break easily.

catagen, or telogen hairs, and in transverse sections they show only a minute, incompletely keratinized hair shaft or no shaft at all.

As telogen follicles reenter anagen, they again come under attack from pathogenic lymphocytes, which precipitate premature conversion to catagen once again, so that anagen duration becomes shorter and shorter and the follicles begin to miniaturize (Fig. 18-24). As the follicles decrease in size they become situated more superficially, although often deeper than normal vellus hairs, with their bulbs situated in the mid to lower dermis (194). With disease chronicity, most of the hairs become miniaturized. Miniaturization and conversion to catagen and telogen leave many collapsed fibrous root sheaths in the subcutis.

Whiting found that transversely sectioned scalp biopsies showed the diagnostic features of alopecia areata more often than vertically sectioned biopsies (207). He also published mean quantitative hair counts for horizontally sectioned scalp biopsies of alopecia areata. The mean terminal-to-vellus hair ratio was similar to that seen in androgenetic alopecia (1.1:1), reflecting extensive miniaturization. The mean anagen-to-telogen ratio was 73%:27%, and the total hair count (mean of 27 hairs) was 33% less than in the control group, with more severely affected patients (alopecia universalis) at the lower end of the spectrum. Others have also found that the follicular density can decrease in severe alopecia totalis and universalis of long duration (a decade or more), with scars replacing some of the follicular sheaths (208).

Whiting and others have emphasized the use of follicular counts to aid in the diagnosis of AA when the characteristic peribulbar inflammation is missing, with a high percentage of catagen or telogen hairs and miniaturized hairs as a strong sign of AA (Fig. 18-24) (209). In one study, the presence of eosinophils around the bulb and within fibrous tracts was found to be a helpful diagnostic feature of AA, identifying it in 38 of 71 patients. In biopsies lacking peribulbar lymphocytic inflammation, eosinophils were found approximately 50% of the time (210). Some plasma cells may also be present.

Some authors claim that in longstanding AA, the inflammatory infiltrates appear to diminish (203), whereas others believe that the degree of inflammation found on biopsy does not depend on disease duration, citing cases of longstanding AA that showed a great deal of inflammation (194). In a reappraisal of the histopathology of AA, Whiting suggested that the key factor in the histologic picture was the duration of the attack, with lymphocytes surrounding mainly terminal hair bulbs in acute episodes and involving mainly miniaturized hair bulbs in chronic, recurrent disease (211).

In the histologic differential diagnosis, alopecia syphilitica may closely mimic active AA (212). Features that help to distinguish syphilitic alopecia include lymphocytes situated near the isthmus, the presence of plasma cells, an endothelial reaction, interface dermatitis, and neutrophils in the stratum corneum (212,213). Alopecia areata may also look identical to the patchy, nonscarring alopecia that occurs in the setting of systemic lupus erythematosus, which shows mononuclear cell inflammation around terminal and miniaturized anagen hair bulbs, as well as an increased percentage of resting hairs, sometimes approaching 100% (196). Features favoring lupus erythematosus include increased dermal mucin, focal basal vacuolization of infundibular epithelium, and inflammation around blood vessels and eccrine glands, particularly when the infiltrate is dense. Although androgenetic alopecia shows diminution of follicular size, dermal infiltrates that are present in this condition are usually superficial, perivascular, and periinfundibular. Using a comparison of clinical and histologic features, one paper discussed problematic differential diagnoses with respect to AA (214).

Pathogenesis. The exact pathogenesis of AA is not known, but substantial evidence exists to support a role for genetic factors, nonspecific immune- and organ-specific autoimmune reactions, and environmental triggers (202,215–217). The antigenic stimulus for autoimmune attack may be the follicular keratinocyte, melanocyte, or dermal papilla. Advances in the understanding of alopecia areata in the last decade have benefited from animal models of the disease (218), including the C3H/HeJ mouse (219,220), the Dundee experimental bald rat (221), and the Smyth chicken (222). Quantitative and qualitative investigational guidelines for the study of AA were proposed in 1999 to facilitate collaboration among researchers, data comparison, and sharing of tissue specimens (223).

Familial cases of AA are well recognized, suggesting a genetic predisposition (224). A family history of AA reportedly ranges between 10% and 42% (225), with higher incidences in patients with disease onset early in life and in identical twins (226). Alopecia areata has been associated with both HLA class I and class II antigens, with different forms and severity of AA found to be associated with certain HLA types (202,227,228). AA has been associated with many conditions, including Down's syndrome, atopy, vitiligo, thyroid disease, pernicious anemia, diabetes, myasthenia gravis, lupus erythematosus, rheumatoid arthritis, ulcerative colitis, lichen planus, polymyalgia rheumatica, *Candida* endocrinopathy syndrome, and idiopathic thrombocytopenia purpura (202,229).

In a study using indirect immunofluorescence, autoantibodies to various parts of the anagen hair follicle were found in AA patients (230). Most commonly targeted were the outer root sheath, then the matrix, inner root sheath, and hair shaft. Tobin et al. also found serum autoantibodies to pigmented hair follicles in 100% of AA patients but in only 44% of control patients (231).

Earlier experiments showed the peribulbar infiltrate to be composed predominantly of $CD4^+$ cells (helper T lymphocytes) (232). Subsequently, $CD8^+$ cells (suppressor-cytotoxic T lymphocytes) were implicated in the pathogenesis of AA (233,234), with experiments supporting a cooperative role between $CD8^+$ and $CD4^+$ T cells (235). Expression of cell adhesion molecules in the matrix epithelium, dermal papilla, and adjacent vessels has been demonstrated, suggesting a mechanism for leukocyte binding (236,237).

The immune system of the hair follicle is unique and differs from that of the surrounding skin (238). The epithelial portion of the proximal anagen hair is immune privileged; the inner root sheath and hair matrix do not express major histocompatibility class (MHC) class I antigens (238–241). A theory put forth by Paus, an "immune privilege collapse model," suggests that in AA, the body's immune system may begin to recognize immune-privileged hair follicle antigens as a result of upregulated MHC molecules or downregulation of local immunosuppressive factors (238,242).

Cytokines may play an important role in AA. When serum cytokine levels were measured, it was found that IL-1α and IL-4 (Th2 cytokines) were elevated in patients with localized AA, whereas interferon-γ and IL-2 (Th1 cytokines) were significantly increased in AA patients with severe disease (alopecia universalis) (243). IL-1α, IL-1β, and tissue necrosis factor-α have been shown *in vitro* to produce changes in hair follicle morphology that resemble those in AA (244–246). In addition, a role for the peripheral nervous system has been postulated in AA, via neuropeptides with pro- and antiinflammatory properties released in the vicinity of critical areas of the hair follicle (247–250).

Trichotillomania

Trichotillomania is a condition in which patients pull or manipulate hair from the scalp or other body sites (251). For example, persistent rubbing of an area of the scalp that may be pruritic or compulsive avulsion of hair shafts can lead to zones of alopecia characterized by sparse, ragged, broken stubble. Hair shaft breakage and loss may be associated with damage to the scalp, as evidenced by erosions or crusts. Trichotillomania occurs most often in children and adolescent girls. In children under the age of 6 years, the disorder may be more benign and self-limited (252). In teens and adults, trichotillomania is more likely to be associated with psychopathology. It has features in common with obsessive-compulsive disorder (253,254), and in one study a large proportion of patients with trichotillomania also had comorbid self-injurious habits (255). Trichotillomania is part of the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, classification of psychiatric disorders (255). Treatment of this form is often difficult; conventional modalities that may be tried include antidepressant or psychotropic medications, topical adjunctive therapies, and psychotherapy (252). Concomitant alopecia areata has been reported (256).

FIGURE 18-26. Trichotillomania (vertical). The hair canal is distorted in a spiral configuration, most likely secondary to twisting of the hair. Pigment casts, derived from bulbar or hair shaft melanin, are present.

Histopathology. In horizontally sectioned biopsies of trichotillomania uncomplicated by the coexistence of other types of alopecia, the density of hair follicles is normal, as is the terminal-to-vellus hair ratio. The diagnostic finding, when seen, is distorted hair follicle anatomy, without inflammation (Fig. 18-26) (194). Specifically, the pulling of hairs can leave behind empty anagen follicles and "torn-away" follicles, the result of plucked hair shafts that retain parts of the hair matrix and root sheaths (Fig. 18-27) (194). Additional microscopic evidence of traumatic injury was published by Royer et al. as the "hamburger sign," describing a vertically oriented split in the hair shaft containing proteinaceous material and erythrocytes, resembling a hamburger within a bun (257). Damaged follicles enter the resting phase, leading to an increase in the percentage of catagen and telogen hairs, as high as 75% (Fig. 18-28) (258). Often the hairs do not become normal catagen hairs and appear distorted and abnormal (194).

Pigment casts, which are clumps of melanin pigment, may be seen in the hair papilla and peribulbar connective tissue. They are also commonly seen in the upper portion of the hair follicle (Fig. 18-26) as a result of pigmented matrical cells

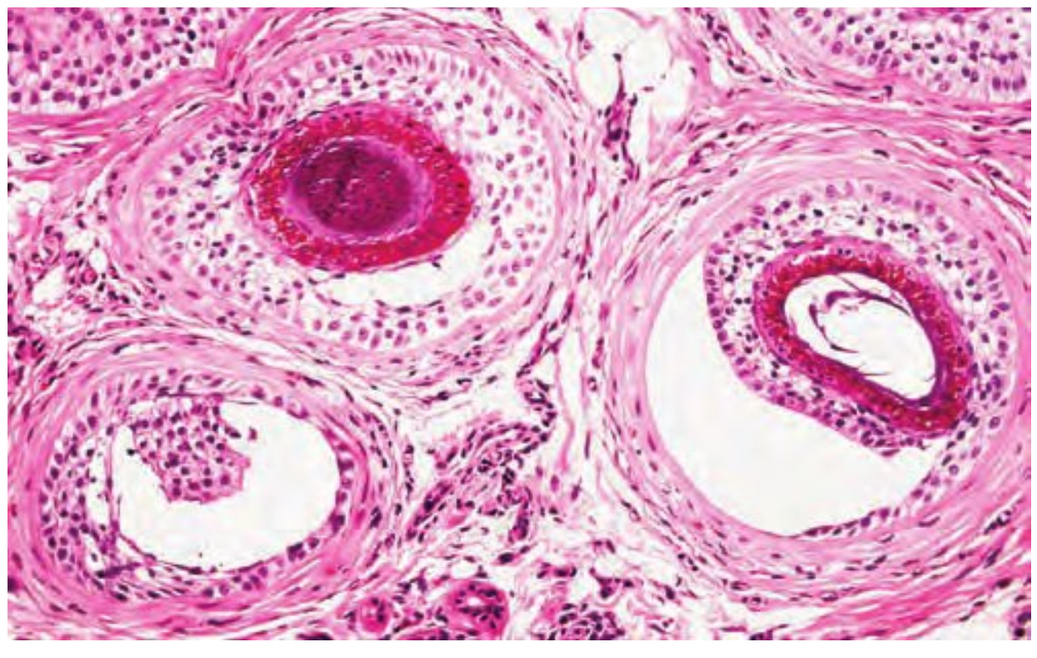

FIGURE 18-27. Trichotillomania (horizontal). At left is an empty anagen follicle, where a rim of outer root sheath epithelium remains after the hair was forcefully pulled, taking with it the inner root sheath and part of the outer sheath. At right, the follicle is partially avulsed and the shaft that is normally tightly anchored to the inner root sheath at this level is gone.

being deposited distally as the hair is plucked (194). Pigment casts are due to injury to the hair matrix, although some authors have theorized that they result from the sudden conversion of anagen to catagen (206). Hair shaft changes, termed *trichomalacia*, may be seen. Characterized by diminished size, distorted and odd shape, and irregular pigmentation of the shaft, trichomalacia is additional evidence of trauma to the matrix (194,258). Traumatized follicles can also show considerable distortion of the bulbar epithelium and conspicuous hemorrhage (258).

Because not all follicles in a given area are affected, transversely sectioned scalp biopsies may increase the yield of finding the diagnostic histologic features of trichotillomania, including increased numbers of catagen and telogen hairs (most cases) and empty or distorted follicles (greater than 50% of cases) (194). The same study found pigment casts and trichomalacia in less than 50% of cases. When the scalp is also rubbed persistently, epidermal changes of lichen simplex chronicus may be seen in vertical sections.

The histologic differential diagnosis of increased numbers of catagen and telogen hairs, characteristic of trichotillomania, includes alopecia areata and telogen effluvium. Trichotillomania also shares with early alopecia areata the features of normal hair density and occasional trichomalacia, but trichotillomania lacks the follicular miniaturization and peribulbar infiltrates. In telogen effluvium, evidence of trauma to follicles, as discussed earlier, is not seen. The histologic findings in early traction alopecia are said to be identical with those of trichotillomania, but fewer follicles are involved and the features are less prominent (see later discussion) (194).

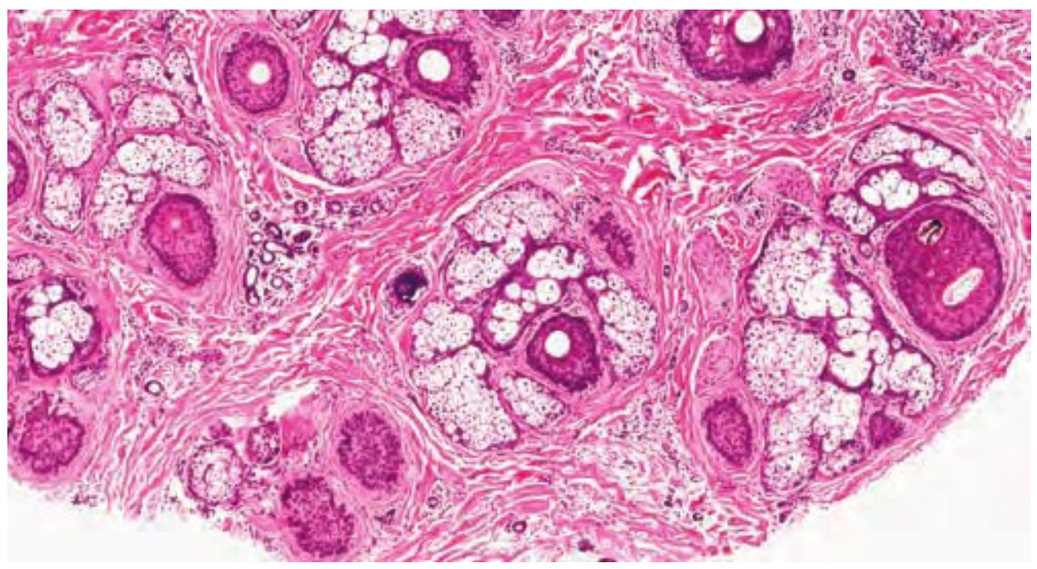

FIGURE 18-28. Trichotillomania (horizontal). Low-power view reveals an increased number of "resting" follicles, with catagen and telogen hairs, and telogen germinal units. A follicle to the far right contains a black pigment cast.

Traction Alopecia

Traction alopecia is another type of mechanical alopecia, usually resulting from a variety of hair-styling practices, particularly in African-Americans, that includes tight braids, corn rows, straightening, and the use of sponge rollers (259). Hair follicle injury is similar to that produced in trichotillomania, but in traction alopecia there are differences that relate to the use of less force over a greater period of time (194). Traction alopecia is often classified clinically and histologically as "early" and "late" disease (194). In early disease, tension on hair follicles exists over the course of months to a few years, sometimes presenting as a traction folliculitis with perifollicular erythema and pustules (260). In late disease, hair is subject to traction over many years. In early disease, discontinuation of the abnormal forces on the hair leads to regrowth of hair, but in late disease, follicles are lost, producing a permanent alopecia. Early and late disease are commonly found together in the same patient; as permanently scarred areas develop (late disease), terminal hairs at the periphery are used in styling, becoming the new target of traction (early disease) (194). Occupationally related traction alopecia has been reported due to wearing of a nurse's cap, occurring at the site of pin placement used to secure the cap (261).

Histopathology. In early traction alopecia, the histologic findings are similar to those of trichotillomania, albeit more subtle (194). For instance, the density of follicles is normal, with a normal number of vellus hairs. Premature conversion of anagen hairs to catagen occurs, resulting in an increased number of catagen and telogen follicles. Pigment casts and trichomalacia are sometimes found, although less often than in trichotillomania. Inflammation is absent.

In late disease, permanent loss of terminal follicles occurs, with replacement of follicular tracts by scar tissue (194) (Fig. 18-29). These "follicular scars" resemble columns of fibrous tissue; interfollicular areas are uninvolved. Because vellus hairs are not sufficiently large to be included in the method of styling and be affected by tractional forces, these hairs are preserved, and this is reflected in a normal absolute number of vellus follicles, often outnumbering terminal follicles. In late disease, the pathology shows an "end-stage" scarring alopecia, a

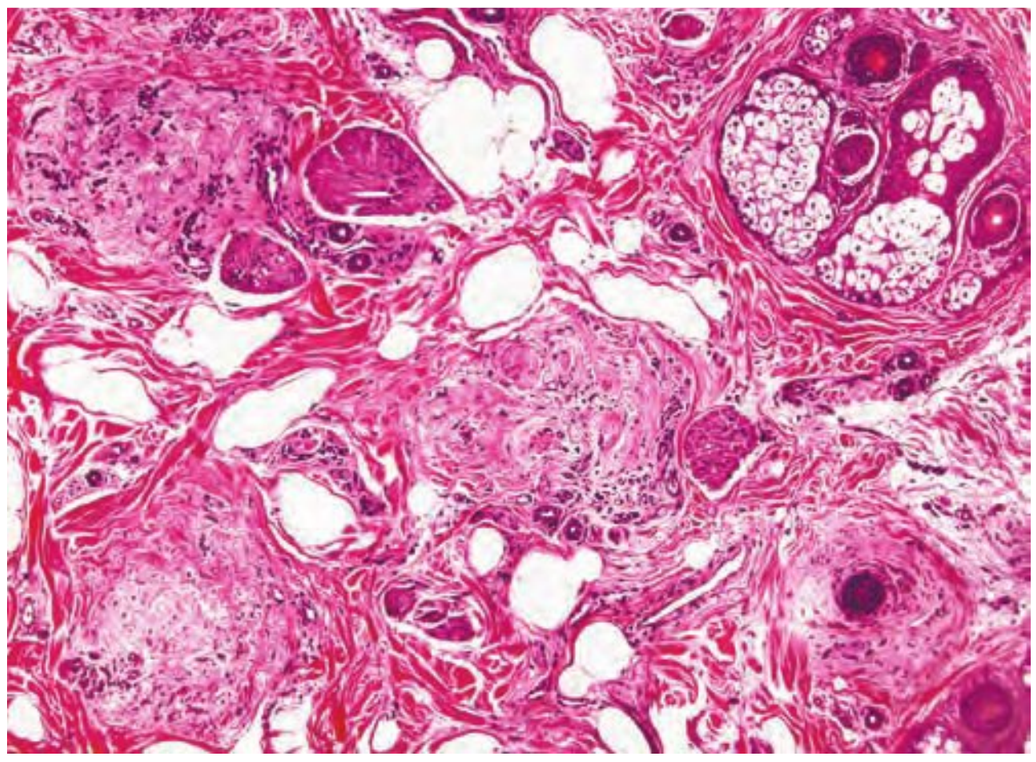

FIGURE 18-29. Traction alopecia, late stage (horizontal). The histologic picture is that of a burnt-out scarring alopecia. Several follicular scars are seen along with stranded arrector pili muscles and absent sebaceous glands. A few vellus follicles remain, at right. Their small size makes them immune to the mechanical forces that lead to hair follicle destruction.

histologic picture shared by many forms of permanent alopecia at an advanced stage. Pigment casts and trichomalacia are not seen in late traction alopecia.

Anagen Effluvium

Acute loss of actively growing (anagen) hairs occurs as a result of a severe insult that disrupts the mitotic activity of dividing cells in the hair matrix (262), with hair shaft production suffering greatly. The shaft becomes tapered proximally, breaks at the narrowest point, and is shed. The most commonly encountered forms of anagen effluvium are from chemotherapeutic agents and radiation therapy (192), although heavy metal poisoning and other toxins should be considered (262). Rapidly progressing alopecia totalis may present as anagen effluvium.

Microscopic Examination of Hairs. Diagnosis of anagen effluvium is usually made on clinical grounds with the aid of a trichogram or gentle hair pull, so that scalp biopsies are seldom done. Resting (telogen) hairs are immune to the metabolic insult, so that when sufficient anagen hairs are lost through shedding, a forcible hair pluck performed late in the course of disease will show almost all telogen hairs; a telogen count that approaches 100% on trichogram is a clue that a type of anagen effluvium is to blame. Early, a gentle hair pull demonstrates "pencil-point" tapered hairs with a pointed or frayed end (192).

In contrast, in loose anagen syndrome, the proximal portion of pulled anagen hairs shows a ruffled hair shaft cuticle because the inner and outer root sheaths are lost during extraction (192). One report described the loss of normal-appearing anagen hairs with an intact inner root sheath and partially intact outer root sheath in the setting of pemphigus vulgaris, in which the cleavage plane is in the outer root sheath (263).

Telogen Effluvium

Effluvium is a Latin term meaning "a flowing out" (264). Telogen effluvium results from "outflowing," or shedding, of hair shafts in the telogen phase of the hair growth cycle. The concept was originally delineated by Kligman (265). This condition has many precipitating causes or associated conditions, including childbirth, serious illness, including HIV infection, high fever, life-threatening trauma, major surgery, restrictive dieting and nutritional deficiencies, hypothyroidism, iron-deficiency anemia, medications, especially hormonal drugs, allergic contact dermatitis, the onset of androgenetic alopecia, and psychological stress (178,194,265–269). The shedding tends to occur diffusely throughout the scalp and may involve hair over the rest of the body.

Telogen hairs are recognizable by the club shape of their proximal end when visualized microscopically (*club hairs*). In conjunction with the history, physical examination of the scalp, and sometimes a *trichogram* (microscopic examination of shed, pulled, or plucked hairs), a diagnosis of telogen effluvium can often be made in the clinical setting. However, in difficult cases in which the differential diagnosis includes androgenetic alopecia and diffuse alopecia areata, a biopsy may be done.

Chronic telogen effluvium was a concept put forth by Whiting in 1996 after studying 355 patients with the disorder (270,271). Patients are usually middle-aged women 30 to 60 years of age with variable shedding that persists for years. Because hairs are replaced as fast as they are shed, patients do not become bald. An obvious cause is not identified (although an initiating factor may exist), hence the designation "idiopathic." In one long-term study, chronic telogen effluvium continued for 7 years in four of five women, and only one developed female pattern hair loss (272). Chronic telogen effluvium has rarely been reported in men (270,273). A scalp biopsy for horizontal sections is particularly helpful in distinguishing chronic telogen effluvium from androgenetic alopecia (274).

Histopathology. Only a subjective assessment of the proportion of follicles in telogen can be obtained with vertical sectioning of scalp punch biopsy specimens. More objective analysis can be obtained by examining horizontal sections (Fig. 18-30) (183). There is a normal number of hair follicles and an absence of follicular miniaturization, unless telogen effluvium occurs in patients with established androgenetic or another form of involutional alopecia. Inflammation is generally not seen.

Telogen follicles, characterized histologically by trichilemmal keratinization of the most proximal portion of the hair shaft, are increased. The number of catagen follicles or telogen germinal units also may be increased (Fig. 18-30). According to published data, the telogen count in normal scalp may range from 0% to 25% (265), with averages of 6% (193) and 13% (265) cited. Telogen follicles in excess of 15% are considered to be abnormal and suggest a diagnosis of telogen effluvium in the absence of significant inflammation and miniaturization (193,266). Others have suggested that a level of 25% is necessary for a definitive diagnosis of telogen effluvium (194,265),

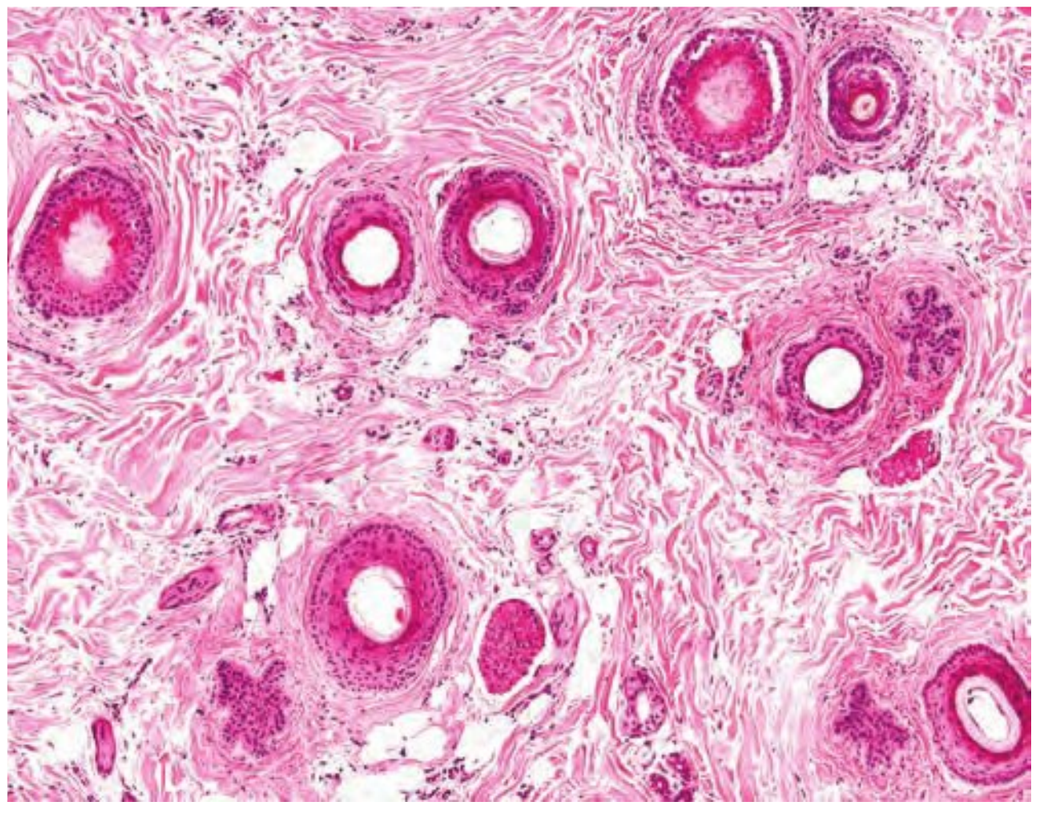

FIGURE 18-30. Telogen effluvium (horizontal). An increased number of telogen hairs is present. Forty-five percent of the 11 follicles in this field are in a stage of telogen; there are 2 typical telogen hairs and 3 telogen germinal units.

whereas a telogen count of 20% is "presumptive" evidence (265). Kligman also stated that telogen counts greater than 60% in telogen effluvium are rare. With a telogen count approaching 100% one should consider anagen effluvium or alopecia areata (192,194,204).

Biopsies from the crown/vertex and occiput yield similar findings because the process is diffuse. Timing of the biopsy clearly affects the pathologic changes observed. Should a biopsy be obtained in the very early stages of recovery, follicles in early anagen will be present in addition to elevated resting follicles, but if recovery is substantial, the histopathologic assessment may be entirely normal.

In a study of *chronic telogen effluvium* the average number of hairs in a 4-mm punch biopsy was normal at 39, the terminal-to-vellus hair ratio was normal, and the average telogen count was 11% (270). In comparison, the average telogen count was 16.8% in androgenetic alopecia and 6.5% in normal controls. Significant inflammation and fibrosis were present in only 10% to 12% of chronic telogen effluvium and control cases, as compared to 37% of androgenetic alopecia biopsies. Sinclair et al. found that when three horizontally sectioned, 4-mm punch biopsies from the scalp were performed instead of one, diagnostic distinction between chronic telogen effluvium and female pattern hair loss could be made more frequently (275).

Pathogenesis. In the acute form, increased shedding is noted approximately 3 months after the precipitating factor; this is the timetable for regressing anagen follicles to pass through catagen into telogen. Headington described five processes by which excessive telogen shedding may occur (266). Briefly, these processes depend on changes in the length of the anagen (growth) period and on the active release of hair shafts in telogen. Teloptosis is the termination of telogen with shedding of the hair, believed to be due to loss of adhesion between the club hair and cells of the surrounding epithelium (276). These authors distinguished two kinds of telogen hairs on trichogram—those with an epithelial sheath, suggesting early telogen, and those devoid of an epithelial sheath, indicating telogen termination or teloptosis. A transcription factor that is involved in physiologic cell death via apoptosis, p53, has been implicated in normal hair follicle regression in mice and may be important in disorders characterized by premature anagen-to-telogen conversion, such as telogen effluvium (277).

Androgenetic Alopecia

The hallmark of androgenetic alopecia (AGA) is follicular miniaturization, the process by which hair shafts become progressively finer and shorter. AGA results from an androgenic influence on hair follicles in certain areas of the scalp, and the pattern of involvement in the different sexes has led to use of the preferred terminology *male-pattern* or *female-pattern hair loss*. Some prefer this terminology over AGA because the etiologic role of androgens in women is not fully determined (278–280). AGA is the most common type of hair loss in males, affecting 50% of men by the age of 50 years and almost as many women, according to some reports (281,282), leading some to espouse that it is a physiologic process, not a pathologic one (283). AGA frequently shows a familial tendency, but inheritance does not follow simple Mendelian genetics and is most likely a polygenic trait (284,285).

In male patients, the process usually begins with bifrontal thinning, often with similar changes over the vertex. In full expression of the condition, there may be almost total baldness of the entire frontal/parietal scalp. The most common pattern seen in women is one of diffuse thinning over the crown and frontal scalp with preservation of the frontal hairline. The process occurs with less severity in women, so that significant balding is unusual.

Histopathology. Satisfactory evaluation of AGA can only be achieved from transverse sectioning of punch biopsy material (183,193,286), allowing for quantitative evaluation. Furthermore, samples smaller than 4 mm in diameter show an insufficient number of follicles for meaningful results.

Diminution of follicular size, or miniaturization, is the histologic hallmark of AGA. To fully appreciate the number of miniaturized follicles, horizontal sections at the level of the lower infundibulum of terminal hair follicles should be examined because sections below this may miss the vellus hairs whose bulbs are situated in the upper dermis (Fig. 18-31). Cursory inspection at low power reveals random variation in the caliber of hair follicles, consistent with a progressive miniaturization (Fig. 18-32) (287) , and absence of well-defined follicular units (286). Although vellus hairs can be quickly identified by the fact that their shaft diameter is equal to or greater than the thickness of their inner root sheath, they are quantitatively defined as having a shaft diameter of 0.03 mm or less (183). In his 1984 paper that laid the groundwork for horizontal

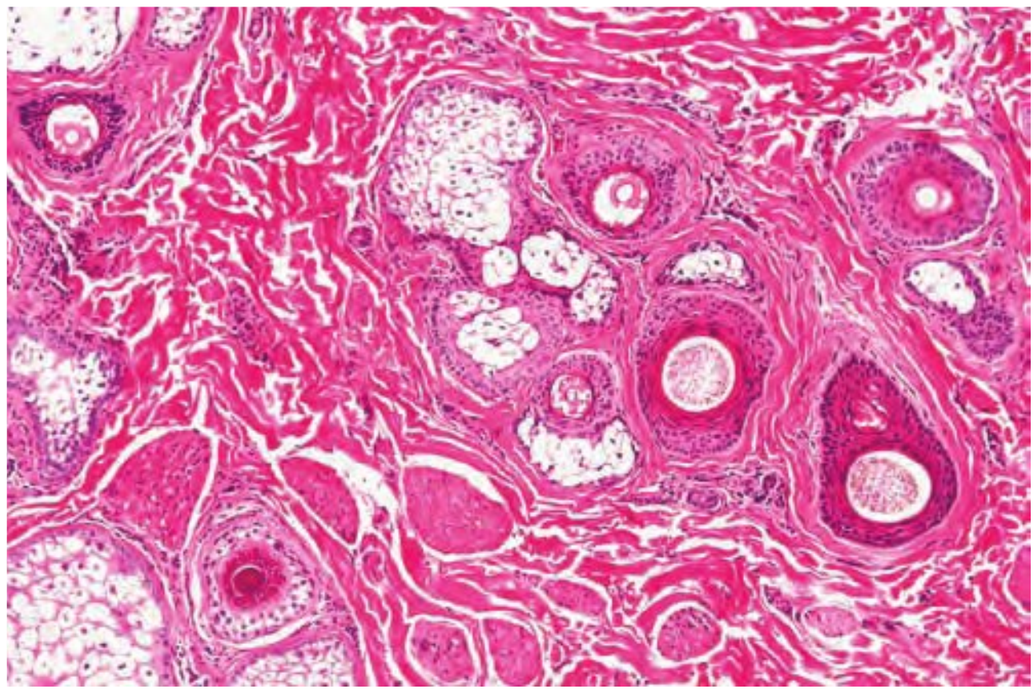

FIGURE 18-31. Androgenetic alopecia (horizontal). At a level through the lower infundibulum of terminal hairs, many vellus hairs become apparent, outnumbering the terminal follicles in this field.

interpretation of scalp biopsies, Headington also defined terminal hairs as having a shaft diameter of 0.06 mm or greater, thus recognizing an intermediate/indeterminate category in which the shaft diameter, i, measures $0.06 > i > 0.03$ mm, between terminal and vellus hairs (see Fig. 18-19) (183). An optical micrometer may be used to measure hair shaft diameter, if necessary.

However, slightly different definitions were used in subsequent articles on AGA, specifically with regard to the intermediate category. For example, Whiting classified terminal hairs as having a "shaft diameter exceeding 0.03 mm . . . . thicker than its inner root sheath," thereby grouping intermediate hairs with the terminal hair population (193). He then used a 3:1 (or less) terminal-to-vellus hair ratio as being diagnostic of male pattern AGA, although at other times he and others quoted a terminal-to-vellus hair ratio of less than or equal to 2:1 to diagnose AGA (193,194,288). Whiting found the *average* terminal-to-vellus ratio in AGA to be 1.7:1 (193). Using similar definitions of terminal and vellus hairs, Sperling and Winton reported finding an *average* terminal-to-vellus ratio of 1:6.1 (286), illustrating how, in advanced cases, miniaturized hairs outnumber terminal hairs (194). In my opinion, intermediate hairs should be grouped with the vellus hair population because more often they represent a transitional follicle undergoing miniaturization to a vellus hair (unless the patient is using agents such as minoxidil or finasteride to reverse the process); unfortunately, ratios for normal scalp and in AGA in which vellus and intermediate hairs are lumped together are not available in the literature and remain to be determined.

It is easy to undercount the number of vellus hairs, even with horizontal sections (286). Some vellus hairs may be so small as to be mistaken for keratinous debris. The use of toluidine blue stain was reported to be superior to the use of hematoxylin and eosin in identifying the tiniest of hairs because it stains the inner root sheath intensely blue (286).

The onset of AGA may be manifested by a telogen effluvium (289). Whiting found the telogen count in AGA to be 16.8%, as compared to 6.5% in controls (193), with telogen counts as high as 30% reported (286). Because the reduction in follicular size is associated with a shorter anagen phase (the smaller hairs do not grow as long), at a given point in time (for a histologic specimen this is the moment of biopsy harvest) a greater proportion of follicles will be found in telogen. There may be typical telogen hairs or, with increasing severity, telogen germinal units. A telogen germinal unit is the follicular epithelium that remains after the telogen hair shaft has been shed; it represents the secondary hair germ (Fig. 18-20) (183). Although vellus hairs continue to cycle through anagen and telogen in the papillary dermis, they are not considered to be part of the telogen count (198). Both miniaturization and increased conversion to telogen are associated with the finding of fewer terminal hair bulbs and more fibrous streamers in the deep dermis and subcutis (198). The fibrous streamers in AGA are thicker, more cellular, and possibly more fibrotic than those of normal follicles (194,290,291).

In advanced AGA there may be a reduced hair density with permanent loss of follicles, termed *cicatricial pattern hair loss* by Olsen and Olsen (193,286,292). Periinfundibular fibroplasia, ultimately leading to focal follicular scarring, may be responsible (193,293). In subtle cases, a second biopsy, taken from the occipital scalp, may be helpful for comparison because the occiput is typically uninvolved.

Lymphocytic infiltrates, defined as activated T cells in one study, are found around superficial vessels and in the vicinity of the lower infundibulum, sebaceous glands, and bulge in follicles transitioning to full miniaturization (294). The presence of inflammation has been reported in as many as 50% to 75% of cases (293) and has been linked to peripilar signs seen clinically (295). However, mild perifollicular and upper dermal inflammation can be observed in normal scalp with a similar frequency to AGA (287) and therefore is of no value in diagnosing AGA (194). Moderate inflammation, however, was

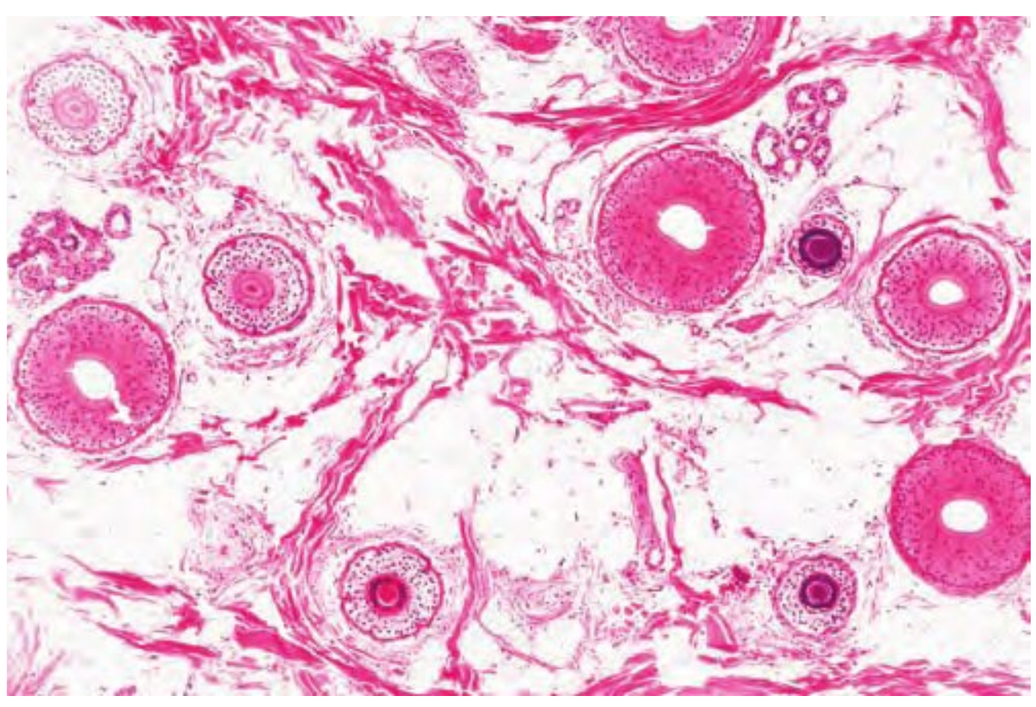

FIGURE 18-32. Androgenetic alopecia (horizontal). Even in the superficial subcutis, variability in the caliber of hair follicles, with an increased number of miniaturizing hairs, can be seen. Several fibrous streamers are also present.

seen more often in AGA than in normal individuals (193); the infiltrate was composed primarily of lymphocytes and histiocytes, with rare neutrophils, plasma cells, and giant cells. It has been suggested that inflammation in AGA may result from *Demodex*, seborrheic dermatitis, actinic damage, cosmetics, and grooming agents (193) and therefore should not be considered pathogenic (283). Nevertheless, its presence may have a bearing on the potential to respond to treatment; one study found that AGA patients with histologic inflammation or fibrosis showed less frequent regrowth on treatment with 2% minoxidil than AGA patients without inflammation (193), although the figures did not prove to be statistically significant. In conclusion, upper dermal inflammation can be seen in AGA, but it does not support or discount this diagnosis.

Pathogenesis. Androgens are the primary regulators of normal human hair growth. With the arrival of puberty, they transform vellus hairs in many sites, such as the axilla, to terminal hairs, while at the same time mediating the opposite effect on certain scalp follicles in predisposed individuals (296). The effects of androgens on the hair follicle are mediated via androgen receptors in the hair papilla (297). The primary androgen responsible for these effects is dihydrotestosterone (DHT), via androgen-receptor binding (298). Within the follicle, the enzyme 5α-reductase produces DHT from serum testosterone. Predisposed scalp displayed high levels of DHT and increased androgen-receptor expression in one study (298). In another study, frontal scalp follicles showed higher levels of androgen receptor and 5α-reductase than occipital scalp follicles, and men exhibited higher levels than women (299).

A group of investigators found that the predominant form of 5α-reductase in human scalp is type 1, concentrated in sebaceous glands (300). These same investigators found 5α-reductase type 2 to be present in the inner layer of the outer root sheath, the proximal inner root sheath, and the infundibulum and some in sebaceous ducts. The type 2 isozyme is responsible for AGA. It is preferentially inhibited by finasteride, which decreases scalp production of DHT and promotes hair growth in males with AGA (300).

Other serum hormones, such as adrenal-derived dehydroepiandrosterone, may also be converted to DHT by some hair follicles, and steroid sulfatase found in the dermal papilla may be the responsible enzyme (301). This may explain why males affected by X-linked recessive ichthyosis due to a defect in steroid sulfatase do not develop AGA or do so only mildly (302).

Apoptosis is an important part of hair follicle regression, and therefore factors that affect apoptosis may play a role in regulating the hair cycle (303). One study of apoptotic mechanisms in AGA suggested that levels of caspases, regulators of programmed cell death, and inhibitors of apoptosis may control hair follicle homeostasis (304,305). Another study found similar expression of bcl-2, p53, and other heat shock proteins in follicles from normal (occipital) scalp and follicles from scalp affected by AGA (frontal), whereas follicular expression of the proliferation marker Ki-67 was decreased in AGA (306). The authors concluded that abnormal regulation of apoptosis was not involved in AGA, but a lower proliferation rate may be. This contradicts an analysis of bcl-2 and TUNEL (terminal deoxynucleotidyltransferase–mediated deoxyuridine triphosphate-biotin nick end-labeling) staining—markers of apoptotic activity—in scalp of cadaveric males with AGA, in which significant differences were noted between normal and alopecic scalp follicles (307); the apoptotic "hot spot" was identified in the bulge-isthmus region.

Whiting postulated that the process of miniaturization cannot be explained simply by shortening of the anagen phase with repeated hair cycles (198). He suggested that miniaturization of some follicles occurred rapidly, over the course of a single hair cycle, possibly mediated by a change in the size of the dermal papilla, because vellus follicles have a smaller papilla than terminal follicles (289,308). In cell cultures of dermal papillae derived from balding scalp follicles, the cells were smaller and did not grow as well as those derived from nonbalding scalp follicles (309).

There is evidence that fibroplasia of the adventitial sheath surrounding the hair follicle is important to the pathogenesis of AGA (291,310). As previously noted, fibrous streamers in AGA may be more fibrotic than those of normal follicles (194,291). One study found *Demodex* to be present more frequently in patients with AGA and postulated that *Demodex*-induced inflammation could contribute to the process and possibly play a role in permanence (scarring) (311).

There exists a physiologic rest period during which the posttelogen follicle remains empty. This recently recognized phase of the hair cycle was termed *kenogen* (190). It may last longer and occur with greater frequency in AGA (312).

Scarring Alopecia

Various definitions exist for scarring (cicatricial) alopecia. A clinically relevant definition is the permanent loss of hair follicles, usually manifested on physical examination by absence of follicular ostia, sometimes with a porcelain-white appearance (313). Histology may or may not reveal true scar formation or inflammation, although most processes leading to permanent hair loss are inflammatory, at least initially. With this definition we can include disorders typically classified as "nonscarring" that in late stages lead to irreversible loss of hair follicles; this biphasic pattern can be seen in androgenetic alopecia, longstanding alopecia areata, and traction alopecia.

Processes that specifically target the hair follicle early in the course of the disease are *primary* scarring alopecias (314,315). *Secondary* scarring alopecias result from inflammatory or neoplastic processes that secondarily involve hair follicles. Secondary scarring alopecias are not discussed here, nor are primary scarring alopecias whose cutaneous manifestations are predominantly nonfollicular, such as lichen planopilaris and chronic cutaneous lupus erythematosus. The discussion of scarring alopecias that follows refers to *primary scarring alopecias*, as defined earlier in this paragraph.

There have been various classification schemes proposed for primary scarring alopecias, including inflammatory versus

noninflammatory, and neutrophil mediated versus lymphocyte mediated (316). The usefulness of these schemes is hampered by clinical and histologic overlap between the various types of scarring alopecia, as well as a lack of uniformity in the terminology used by clinicians and dermatopathologists (317). This is why clinical–pathologic correlation is so important in the interpretation of scarring alopecias. Future proposals for the definitive classification of scarring alopecias will require insight into pathogenic mechanisms or biological markers of disease, possibly provided by molecular research (182). A unifying concept of *central centrifugal scarring alopecia*, discussed later, was proposed in 2000 (318). In addition, based on a Workshop on Cicatricial Alopecia sponsored by the North American Hair Research Society, a working classification of scarring alopecia based on clinical and pathologic features was published with hopes for an improved classification scheme pending additional, collaborative investigation (186). More important, however, this workshop laid the groundwork for meaningful clinical–pathologic correlation by setting guidelines for the study of scarring alopecias to uncover etiologic factors, ultimately aiding in treatment, and facilitated collaboration between investigators. Needless to say, the problem of classifying scarring alopecias will not be solved in this chapter. The intent here is to present "classic" features of more commonly encountered disorders and some rarer, more recently described conditions.

In one published algorithm for classifying alopecia, emphasis was placed on the pattern of fibrosis (scarring), with a branch point separating follicular fibrosis from diffuse dermal fibrosis (319). The *pattern* of scarring is important in the permanent alopecias. For example, when a condition produces enough damage to completely destroy the follicle, there is replacement of the pilosebaceous structure by scar tissue (Fig. 18-33) (320). These "follicular scars" may occur without interfollicular fibrosis. Histologically the follicular epithelium is replaced by a column of thickened collagen, sometimes surrounded by a rim of connective tissue that stains faintly blue on hematoxylin and eosin–stained sections (Fig. 18-33).

The end stage of many forms of scarring alopecia may look similar, with the "final common pathway" characterized by decreased follicular density, absence of sebaceous glands, replacement of follicles by follicular scars that may extend into the subcutis, and sometimes tufting (see later discussion of *tufted folliculitis*). A study of elastic tissue in various forms of permanent alopecia showed distinctive staining patterns using Verhoeff-van Gieson stain (321). Fibrous tracts of normal follicles show an elastic tissue sheath, which may be destroyed or altered by scarring and inflammation (Fig. 18-34). Cases of end-stage lichen planopilaris showed a wedge-shaped scar involving the upper one third of the follicle where the elastic sheath was destroyed (Figs. 18-35). In addition, in well-developed lesions of lupus erythematosus, a broad pattern of scarring throughout the dermis was characteristic, with destruction of perifollicular elastic sheaths. In cases of "central progressive alopecia in black females" (*follicular degeneration syndrome*), the fibrous tracts were broad ("tree trunk") and out-

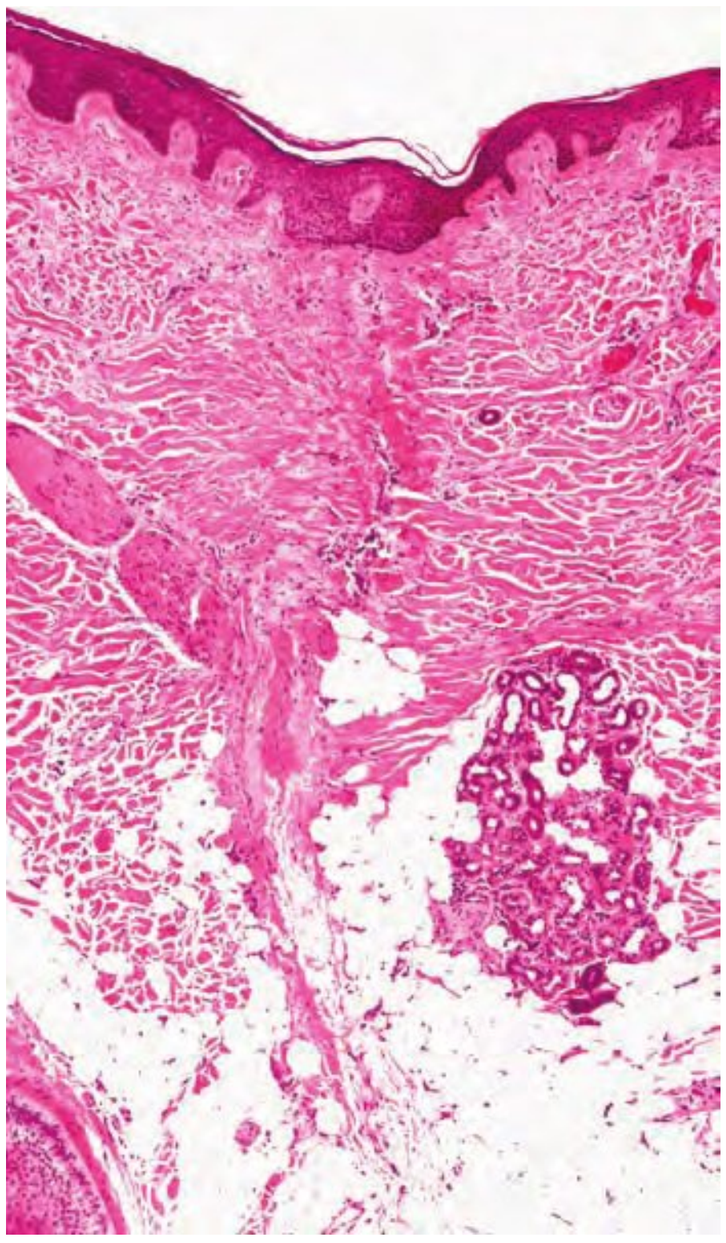

FIGURE 18-33. Follicular scar (vertical). A column of fibrosis replaces the hair follicle and extends into the subcutaneous fat. Note the stranded arrector pili muscle.

lined by an intact elastic sheath. Thickened elastic fibers were also found throughout the dermis, interpreted to be the result of "recoil" as the dermis became shrunken and hyalinized. "Idiopathic 'ivory white' pseudopelade" showed findings that were identical to this. In morphea, dermal elastic fibers were

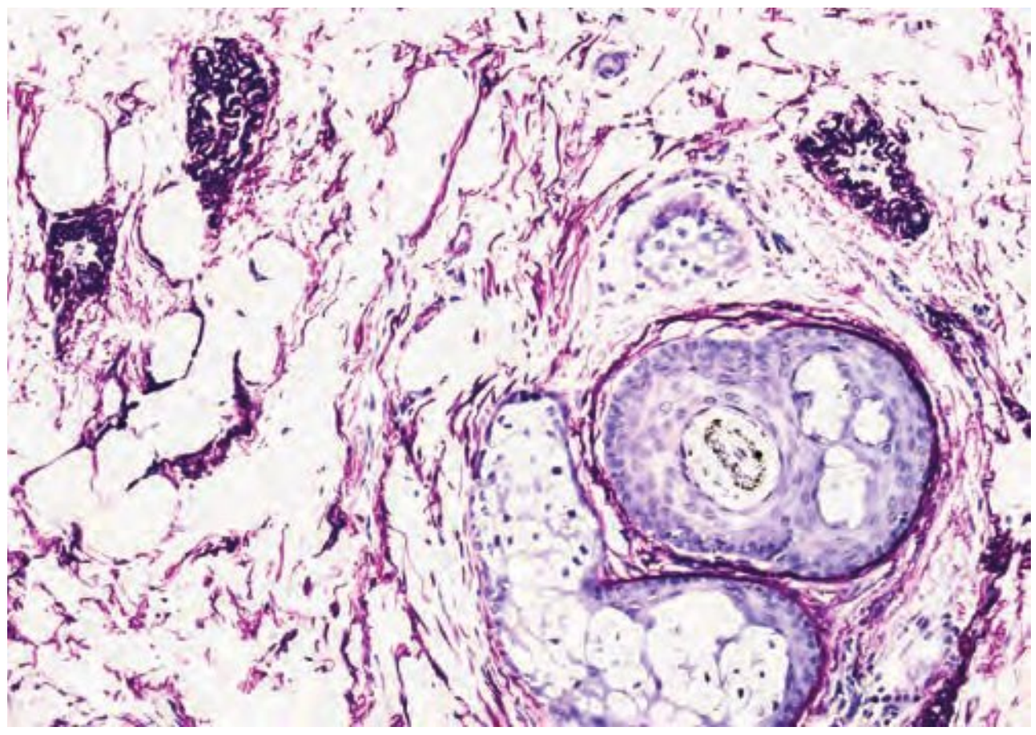

FIGURE 18-34. End-stage scarring alopecia, elastic stain (horizontal). Elastic fibers that encircle normal follicles stain purple with the Luna stain. Three destroyed follicles have left behind their elastic sheath, identifiable as purple rings with a corrugated appearance.

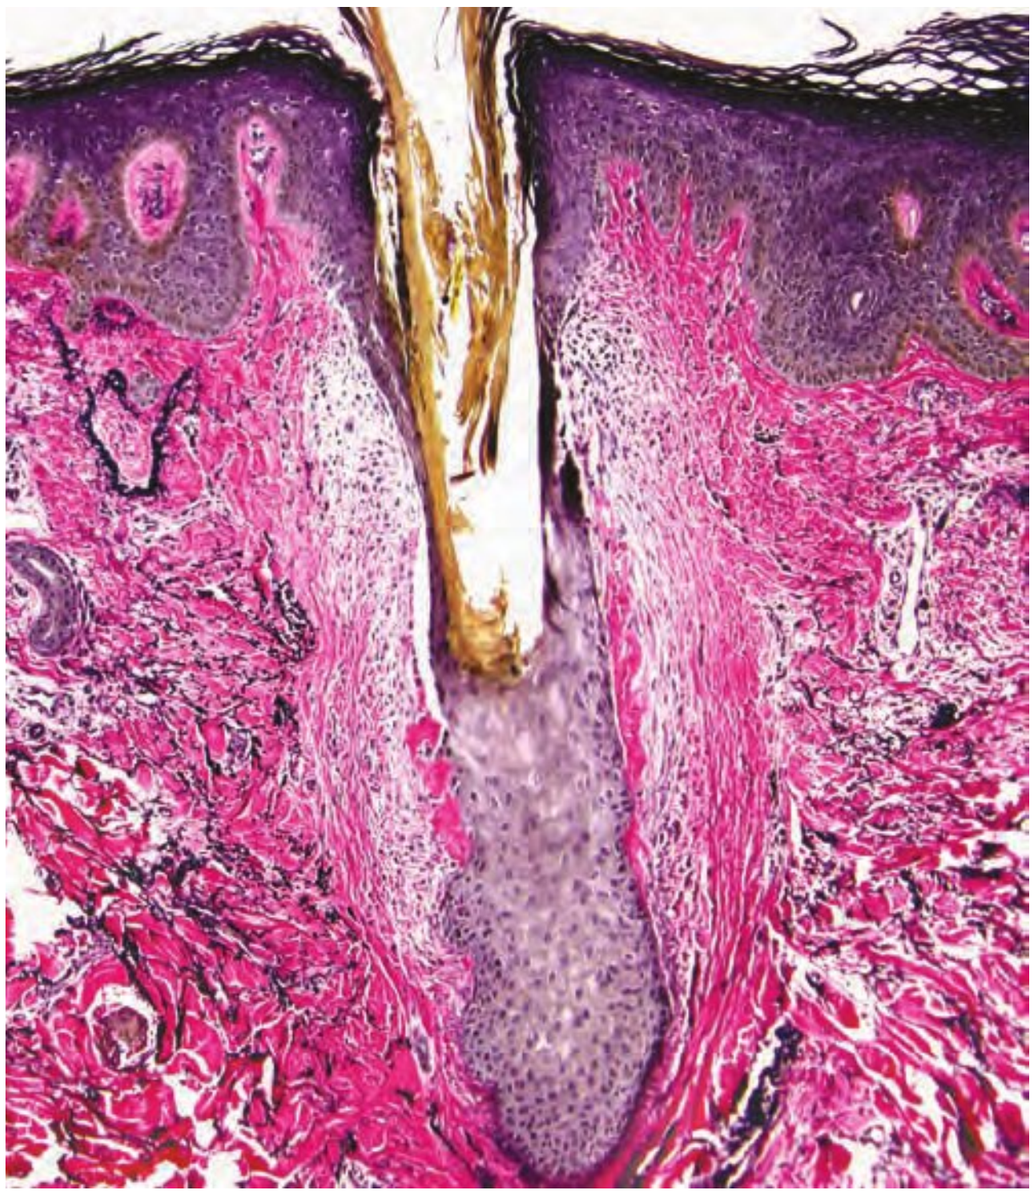

FIGURE 18-35. Scar in lichen planopilaris (vertical). Verhoeff-van Gieson elastic tissue stain shows a wedge-shaped perifollicular scar devoid of elastic fibers.

normal, and the fibrous tracts (with an intact elastic sheath) were narrow.

The value of transverse sections in the interpretation of nonscarring alopecias is well documented, but their value in scarring alopecias is less clear. This may be a matter of personal preference for the dermatopathologist, but one study found that when only one biopsy was available, the diagnosis made with vertical sections alone had a higher concordance rate with the original diagnosis than did transverse sections alone, although biopsies studied using vertical and transverse sections together had the highest concordance (322). A blinded, prospective study of primary cicatricial alopecia could only discriminate neutrophilic types from lymphocytic types on histology but could not further differentiate clinically distinct forms of primary cicatricial alopecia (323).

Although the exact pathogenesis of each type of permanent alopecia may be different, some general pathogenic mechanisms have been proposed. For instance, Headington believed that the basic pathogenesis common to cicatricial alopecias was hair follicle stem cell failure (324). Massive synchronous apoptosis was suggested in one study (325). In a commentary on scarring alopecias, the role of the sebaceous gland was emphasized, particularly its importance in the dissociation of the hair shaft from the inner root sheath (326); the asebia mouse is an animal model for scarring alopecia that is based on a sebaceous gland defect (327,328).

Pseudopelade of Brocq

This uncommon condition has arguably generated more controversy and confusion than any other type of alopecia. Many articles have been written about pseudopelade of Brocq (PPB), with some classifying it as a distinct clinical–pathologic entity ("classic" or "idiopathic" PPB) (329) and others defining it as an end-stage of scarring alopecia resulting from disorders such as lichen planopilaris, discoid lupus erythematosus, scleroderma, folliculitis decalvans, or chronic traction (330,331). Therefore, the term must be defined each time it is used anew. The salient clinical features that follow are similarly reported by both sides of the debate.

PPB in the classic definition is characterized by asymptomatic, discrete, scattered or clustered, irregularly shaped, ivory- or porcelain-white patches of alopecia predominantly over the parietal scalp and vertex (316) (Fig. 18-36) and rarely on nonscalp sites such as the beard (332). The patches are sometimes atrophic, producing an appearance often likened to "footprints in the snow" (324). Late-stage lesions of lichen planopilaris, lupus erythematosus, or scleroderma can produce this same clinical picture (333). Idiopathic PPB is found mostly in whites and in women more than men and occasionally in children (334). Disease progression occurs in "spurts," ultimately running its course and leaving areas of permanent alopecia. The key feature that supposedly makes idiopathic PPB distinctive is the lack of clinical inflammation throughout

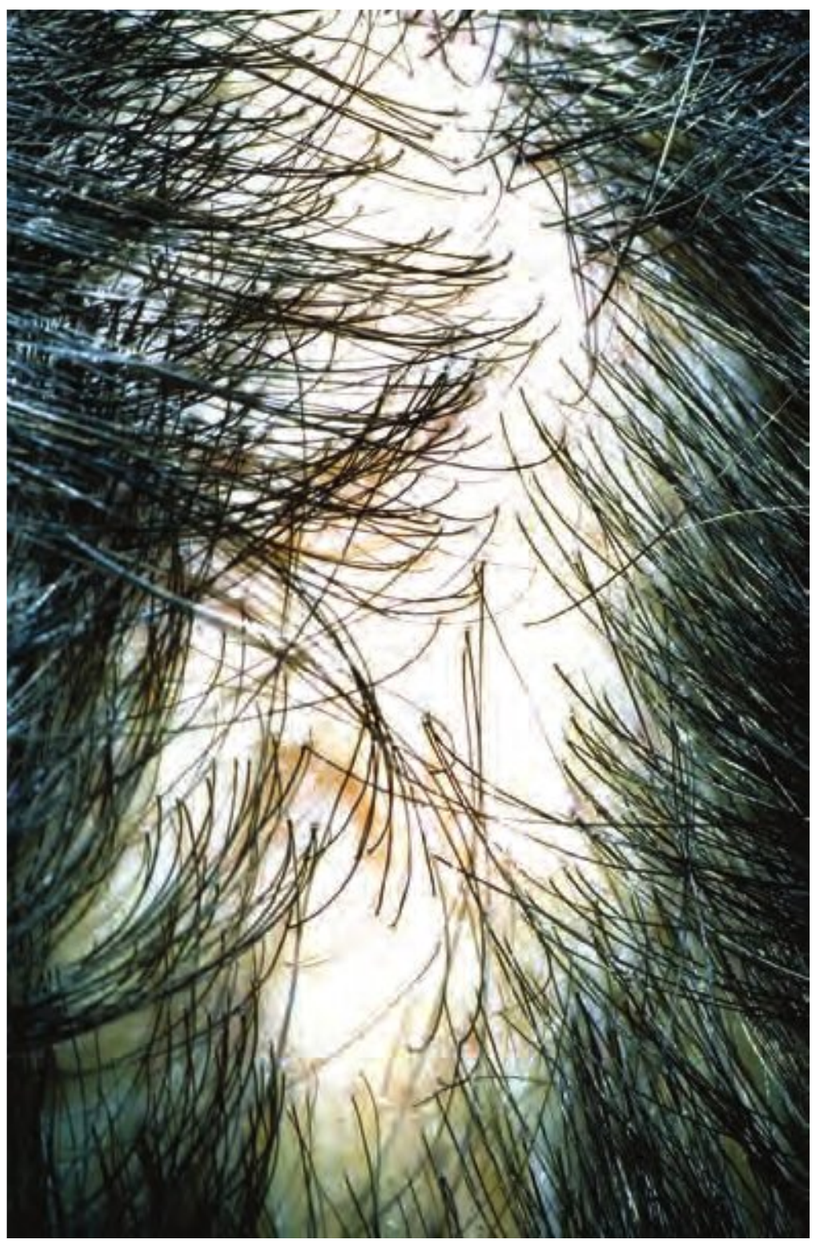

FIGURE 18-36. Pseudopelade of Brocq. "Ivory white," macular areas of hair loss without evidence of inflammation (erythema). This is distinguished from alopecia areata by the lack of follicular ostia.

its course, although some theorize that an inflammatory phase exists but is fleeting (335).

In 1885, Brocq first used the term pseudopelade, which literally means "pseudo alopecia areata" in French (336). Later, in 1905, Brocq characterized "pseudopelade" as a distinct entity (337). How the concept of PPB changed over the twentieth century was chronicled in an article by Dawber entitled "What is pseudopelade?" (338).

A major publication often cited in support of PPB as a separate disorder came from Pinkus in 1978 in which he noted a distinctive pattern of perifollicular and interfollicular elastic tissue in PPB and other forms of scarring alopecia, using acid orcein stain (339). In 180 cases that satisfied the histologic criteria for idiopathic PPB established by Brocq and others, Pinkus found that the site of destroyed hair follicles (above the level of the bulge) was marked by broad cords of collagenous and elastic fibers (Fig. 18-37). He further subdivided these 180 cases into classic PPB and fibrosing alopecia, the latter characterized by less perifollicular inflammation and, more important, the presence of prominent elastic fibers around the lower, cycling portion of the preexistent hair follicle. The major criticism of Pinkus' work is that his histologic criteria for PPB were not correlated with clinical findings (182).

Subsequently, elastic tissue staining patterns in various forms of permanent alopecia were examined using Verhoeff-van Gieson stain (321). Two cases of "idiopathic 'ivory white' pseudopelade" showed a hyalinized dermis with thickened elastic fibers and broad fibrous tracts with an intact elastic sheath, findings indistinguishable from "central progressive alopecia in black females" (*central centrifugal cicatricial alopecia*), and similar to the findings of Pinkus.

Braun-Falco et al. subsequently studied 26 cases believed to represent PPB (330) (cases of scarring alopecia due to known, identifiable causes were excluded) and concluded that the clinical and histologic criteria they proposed were distinctive enough to warrant designation as a separate disease (333).

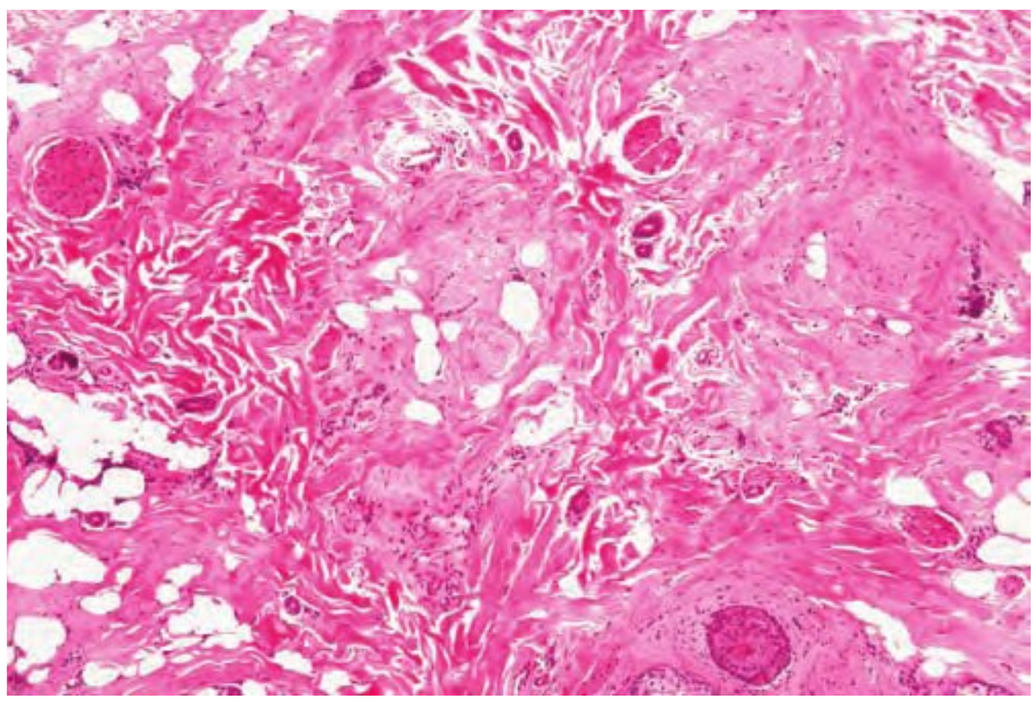

FIGURE 18-37. Pseudopelade of Brocq (horizontal). Viable pilosebaceous follicles are notably absent, replaced by follicular scars. Several unaffected arrector pili muscles remain.

On the other hand, many reports support idiopathic PPB as an end-stage scarring alopecia. In the 1950s, Degos noted that 70% of the time, a preceding or underlying disease could be found, so he called the typically described findings a "pseudopeladic" state (340). One study used criteria established by Braun-Falco to diagnose PPB in 33 patients. Because two thirds of these patients showed features of discoid lupus or lichen planopilaris, the authors concluded that PPB could not be considered a distinct entity (341). Some groups have published evidence that lichen planopilaris and PPB may be variants of the same disease. One of these groups presented 4 alopecic patients with clinical and histologic features of PPB who also had cutaneous and mucosal findings of lichen planus (342). The authors believed that PPB represented a less inflammatory stage in the disease spectrum of lichen planopilaris. In another study of 10 patients who underwent 28 biopsies, the histologic features were not distinctive enough to differentiate PPB from lichen planopilaris (343).

In summary, the diagnosis of idiopathic PPB is one of exclusion. The terminology has become so confusing that for cases in which an underlying disorder is not identifiable, Sperling et al. proposed an alternate, more descriptive term, "patchy, scarring alopecia of unknown etiology" (318).

Histopathology. Because the histologic findings of a typical lesion of PPB are those of a "burnt-out" scarring alopecia (182), clinical correlation is always necessary for accurate interpretation. The classic description of PPB is one of predominantly follicular scarring characterized by columns of fibrosis replacing hair follicles (Figs. 18-33 and 18-37), sometimes extending into the subcutaneous fat. This is accompanied by a loss or decrease of sebaceous glands and absence of widespread (interfollicular) scarring (192,330). Normal arrector pili muscles remain, isolated in the middermis or inserting on the vertically oriented fibrotic streams (Figs. 18-33 and 18-37). The epidermis may be normal or, rarely, atrophic, and sweat glands are normal. Marked inflammation is absent.

The apparent lack of inflammation in this disorder may be the result of a short, often missed, inflammatory phase. Such lesions were the target of one study that found massive folliculocentric lymphocytic infiltration associated with pronounced apoptosis (325). The fact that histologic inflammation exists in some cases has lead some authors to further subdivide PPB into inflammatory and noninflammatory subtypes based on histology (335).

In two sources, the findings of early inflammatory and more developed lesions of PPB are well described (178,324). Early lesions of PPB show variable lymphocytic inflammation in the superficial dermis that is perivascular or perifollicular, centered about the infundibulum or midpoint of the follicle. The infiltrates may extend into the follicular epithelium and occasionally into sebaceous glands, but deep perifollicular inflammation or interface alteration is not detected. With disease progression there is early loss of sebaceous glands. In later, well-developed lesions, inflammation becomes patchy, mild, and perivascular, and it eventually disappears. There may be

premature disintegration of the inner root sheath, and the infundibular epithelium may become eccentrically thinned. Concentric lamellar fibrosis may be present. Fusion of infundibular outer root sheaths ("tufting") may be seen (see *tufted folliculitis*). In time, follicles are destroyed, with naked hair shafts remaining and inciting a granulomatous response. Fibrous tracts mark the site of obliterated follicles. Even features of this often-missed inflammatory phase of PPB are shared by other forms of scarring alopecia (318).

Direct immunofluorescence in PPB is negative, with occasional immunoglobulin M at the basement membrane zone of the follicular infundibulum (330). Immunofluorescence changes of lupus erythematosus and lichen planopilaris should be absent (344).

Pathogenesis. As a theoretical basis for PPB, Sullivan and Kossard speculated that there could occur a noninflammatory focal loss of follicles, possibly due to premature exhaustion or inhibition of the stem cell compartment to recycle (331). Headington postulated that the pathogenesis of PPB is probably related to a T-cell–mediated inflammatory process involving the bulge region (324). An autoimmune etiology has also been hypothesized (345).

An ultrastructural study of hairs and follicles from scalp affected by pseudopelade found pili torti–like hairs with oblique or longitudinal grooves and ridges, a deformed hair cuticle and cortex, and an asymmetric inner root sheath (346).

Central Centrifugal Cicatricial Alopecia

Because many forms of scarring alopecia share clinical and histologic features that make them difficult to distinguish with certainty, a unifying concept of *central centrifugal cicatricial alopecia* was proposed to reflect the overlap (318). Central centrifugal cicatricial alopecia (CCCA) is a category that includes several types of cicatricial hair loss that have in common the following features (Fig. 18-38): (a) alopecia centered on the crown or vertex of the scalp, (b) progressive, chronic disease with eventual "burnout," the affected scalp becoming shiny and smooth, without follicular ostia, (c) fairly symmetric expansion, with the most active areas at the periphery, and (d) clinical evidence of inflammation (i.e., erythematous papules or pustules) in these active sites, corresponding to microscopic inflammation (182,318). Clinically, inflammatory lesions may be sparse to absent. CCCA encompasses three *patterns* of disease: follicular degeneration syndrome, pseudopelade pattern (a "modern" use of the term, *not* pseudopelade of Brocq), and folliculitis decalvans.

Histopathology. The earliest and most characteristic histologic finding of CCCA is premature desquamation of the inner root sheath (Fig. 18-39) (196), typically seen in only a few follicles. The inner root sheath normally degenerates at the isthmus, which is delimited below by the attachment point of the arrector pili muscle and above by the insertion of the sebaceous duct. "Crumbling" or absence of the inner root sheath below the isthmus, at a level through the deep dermis near the eccrine

FIGURE 18-38. Central centrifugal cicatricial alopecia. An area of permanent alopecia on the crown of the scalp characterized by absent follicular ostia.

coils or in the subcutis, characterizes this finding. This may the primary event in the pathophysiology of this condition, although some consider it to be a secondary phenomenon (347). Headington did not consider it to be specific, noting

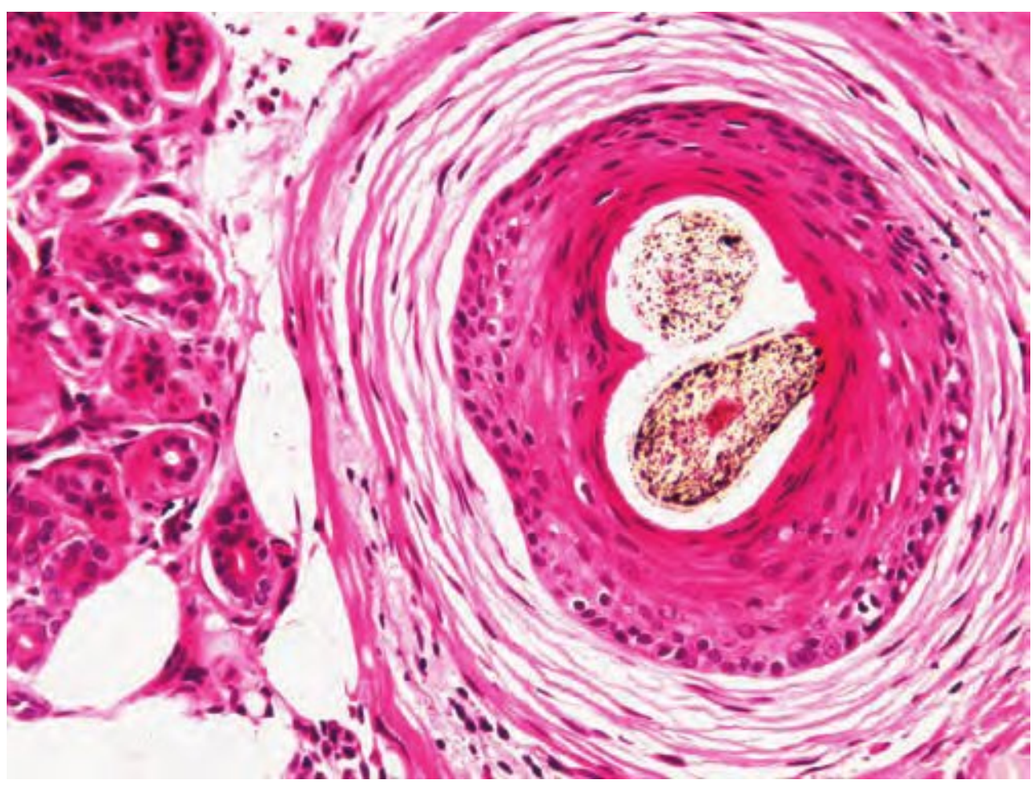

FIGURE 18-39. Central centrifugal cicatricial alopecia (horizontal). At a level through the superficial subcutis, the inner root sheath is missing. The outer root sheath is thinned, and there is already perifollicular fibrosis and polytrichia.

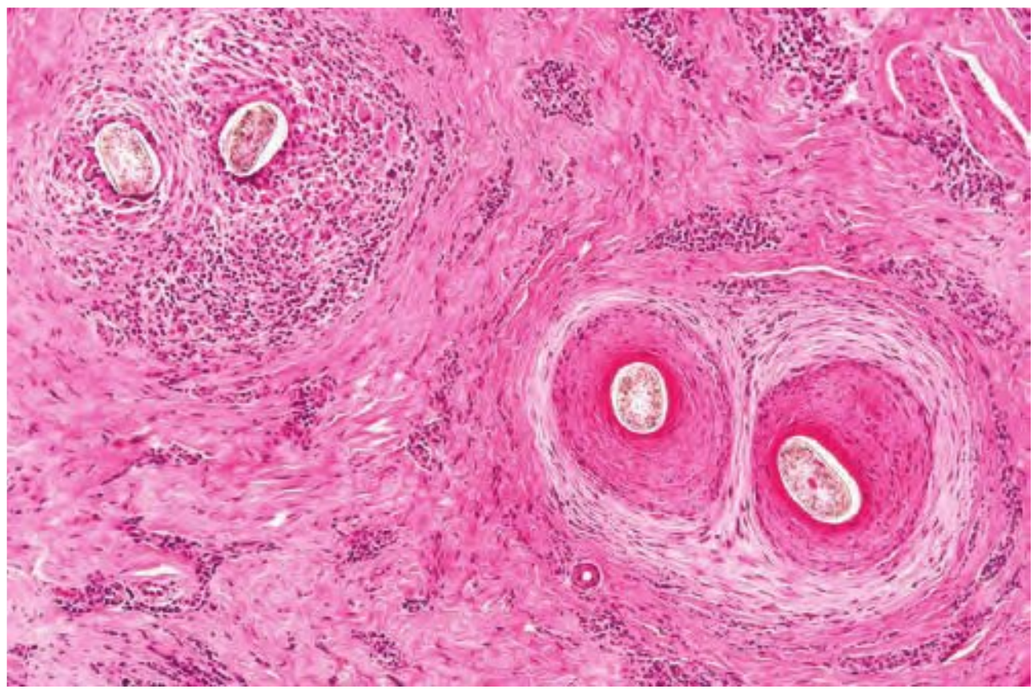

FIGURE 18-40. Central centrifugal cicatricial alopecia (horizontal). The following features are demonstrated: eccentric thinning of the follicular epithelium, concentric lamellar fibroplasia, lymphoplasmacytic inflammation, dermal fibrosis, and naked hair shafts inciting a granulomatous response.

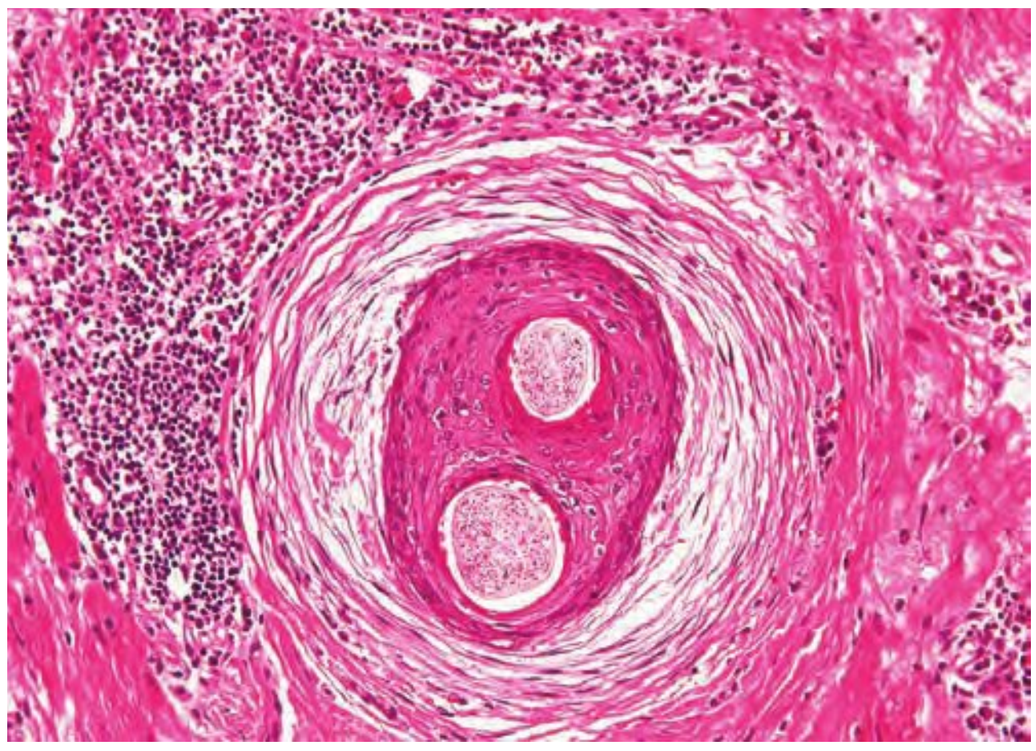

FIGURE 18-41. Central centrifugal cicatricial alopecia (horizontal). In the upper dermis, two follicles exhibit fusion of their outer root sheaths along with concentric fibrosis, focal thinning of the follicular epithelium, and perifollicular lymphocytic inflammation.

that premature desquamation of the inner root sheath could also be seen in chronic cutaneous lupus erythematosus and pseudopelade of Brocq (324). What is unique to CCCA, however, is its occurrence *early* in the disease process.

Most likely as a consequence of premature loss of the inner root sheath, CCCA exhibits some or all of the following histologic features in clinically involved scalp (Fig. 18-40) (182,318): (a) eccentric thinning of the outer root sheath follicular epithelium, most prominent at the level of the isthmus and lower infundibulum, associated with (b) close apposition of the hair shaft and follicular contents to the dermis, (c) concentric lamellar fibroplasia (resembling "onion skin"), and (d) chronic inflammation composed of lymphocytes and plasma cells surrounding the zone of fibroplasia. In addition, there is (e) eventual migration of the hair shaft into the dermis, inciting granulomatous inflammation and additional epithelial damage, and (f) replacement of the destroyed follicle by a vertical band of connective tissue, resulting in a "follicular scar." The lymphoplasmacytic inflammation is usually concentrated on the side opposite penetration of the shaft through the follicular epithelium. Singly, these six histologic features may be found in other types of scarring alopecia. As with all scarring alopecias, sebaceous glands are lost. There may also be polytrichia, whereby damaged follicles fuse their outer root sheaths at the infundibular level (Fig. 18-41).

If a clinical pustule from the expanding margin is biopsied (Fig. 18-42), there may be folliculocentric neutrophilic inflammation (Fig. 18-43), allowing for subclassification as the folliculitis decalvans pattern. Those cases classified as the pseudopelade pattern showed the histologic features described but typically were white patients with a clinical picture of indolent disease characterized by perifollicular scale and some papules (196).

I would like to make special mention of the *follicular degeneration syndrome* subtype of CCCA from a historical perspective, when it was considered a distinct clinicopathologic entity. This subtype of CCCA occurs almost exclusively in African-American patients, usually women, between the second and fourth decades (348,349). It was originally described as "hot comb" alopecia (350), but it was subsequently shown that use of a hot comb to straighten the hair was not requisite (348,349). Although the precise etiology is unknown, hair care practices that include heat, bleaching, pomades, and traction, as well as the predominance in African-Americans, suggest that environmental, cultural, and genetic factors, as well as possible

FIGURE 18-42. Folliculitis decalvans. The advancing edge of a scarred alopecic plaque shows the earliest lesions of folliculitis decalvans, follicular-based pustules with crusting.

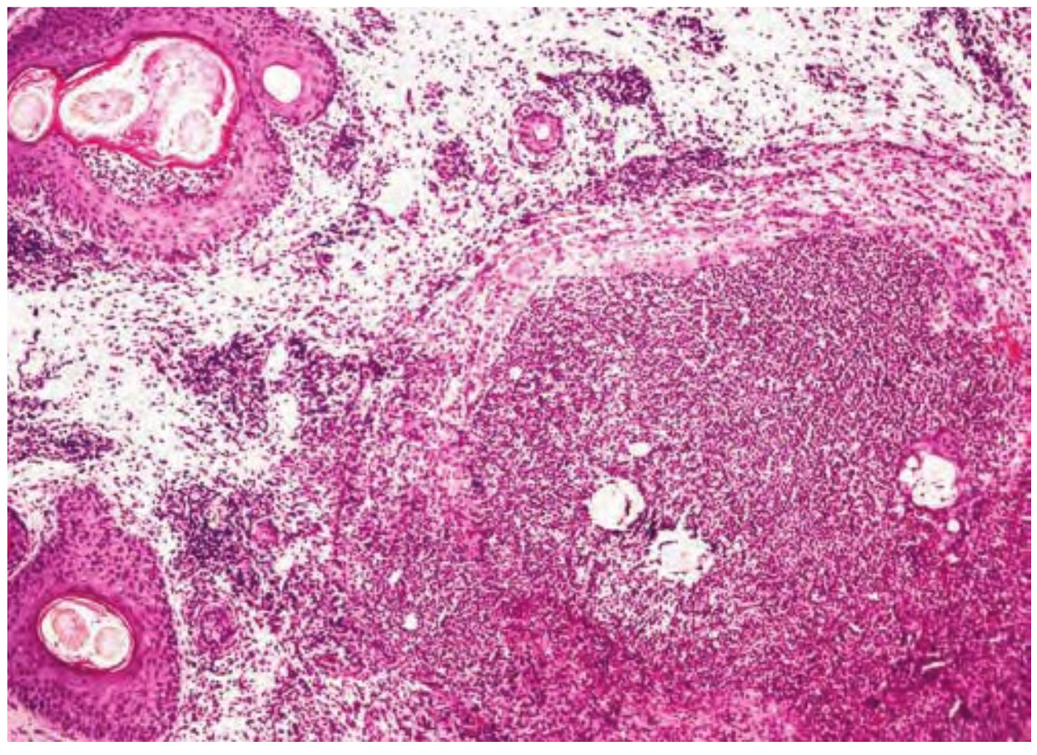

FIGURE 18-43. Folliculitis decalvans (horizontal). A dilated infundibulum containing several hairs is filled with neutrophils (follicular-based pustule). The follicular epithelium is partially destroyed by the inflammation. Other hairs in the left of this field exhibit polytrichia.

structural factors unique to hair follicles in blacks, may play a role (348).

Folliculitis Decalvans

Although some authors have equated folliculitis decalvans (FD) with erosive pustular dermatosis (351), since the last decade it has been considered to represent a highly inflammatory subtype of central centrifugal cicatricial alopecia (318). From a historical perspective, FD as a distinct entity has been described as a patchy pustular alopecia with recurrences (324) (Fig. 18-42). Later lesions show areas of scarring with pustules at the periphery (324). Cultures from the pustules usually reveal *Staphylococcus aureus*. Although some believe that the bacteria are pathogenic, others hold that they are the result of superinfection (318). When pustules are absent, the clinical picture resembles pseudopelade of Brocq (352). The finding of tufted hairs is common (353). FD has been reported in a patient with Darier's disease (354), in other areas besides the scalp, including the beard, face, and nape (355), and in 32-year-old identical twins, suggesting a possible genetic component (356).

Histopathology. Early, pustular lesions show an abscess centered about the affected follicle at the level of the lower to upper infundibulum (Fig. 18-43) (324), which may show comedonal dilation (352). Later lesions typically show perifollicular inflammation composed predominantly of lymphocytes, with fewer plasma cells, neutrophils, eosinophils, and giant cells (351,357). There may be hyperkeratosis, follicular plugging, and evidence of tufting. Late-stage lesions show follicular destruction secondary to diffuse dermal scarring (324). In such lesions the inflammation is less pronounced and is composed of lymphocytes, macrophages, and some giant cells in response to follicular remnants (357).

Pathogenesis. A number of authors believe that *S. aureus* is involved in the pathogenesis of FD (357), perhaps via bacterial superantigens that stimulate the immune system without intracellular processing (358) or an abnormal host response to *S. aureus* toxins in an otherwise straightforward infection (357). There have been reports of alterations in cell-mediated and humoral immunity, neutrophil chemotaxis, and low serum complement levels (359). Other investigators believe the presence of pustules is due to secondary infection with *S. aureus* or an immune response to disrupted follicles and their contents (318,360).

Tufted Hair Folliculitis

"Tufted folliculitis" is a finding that may be present in various forms of scarring alopecia and should not be considered a distinct entity, although some authors believe that it is, specifically characterizing it as a subset of folliculitis decalvans (353,361). Believing that it is a pattern that occurs in many forms of scarring alopecia and therefore is nonspecific, Sperling held that "the term tufted folliculitis should be purged from the lexicon of scarring alopecia" (182). It can be seen as a late process in several conditions, including central centrifugal scarring alopecia, folliculitis decalvans, inflammatory tinea capitis, *S. aureus* folliculitis, lichen planopilaris, dissecting cellulitis, follicular degeneration syndrome, and acne keloidalis nuchae (347,362,363). It has also been reported after traumatic scalp laceration (364) and after years of pemphigus vulgaris involvement of the scalp (365).

"Tufting" corresponds to the clinical finding of "doll's hair deformity," resembling the clustered hairs that are characteristic of a child's doll (Fig. 18-44). Another name for this finding is "polytrichia" (350). It has been reported in a 10-year old child (366). It should be distinguished from compound hairs, where two or three hairs exit from a single infundibulum, a normal finding on the occipital scalp.

FIGURE 18-44. Tufted folliculitis. Groups of hairs exit the scalp through a single opening (polytrichia), producing a clinical appearance that has been likened to "doll's hair." There is interfollicular scarring and erythema.

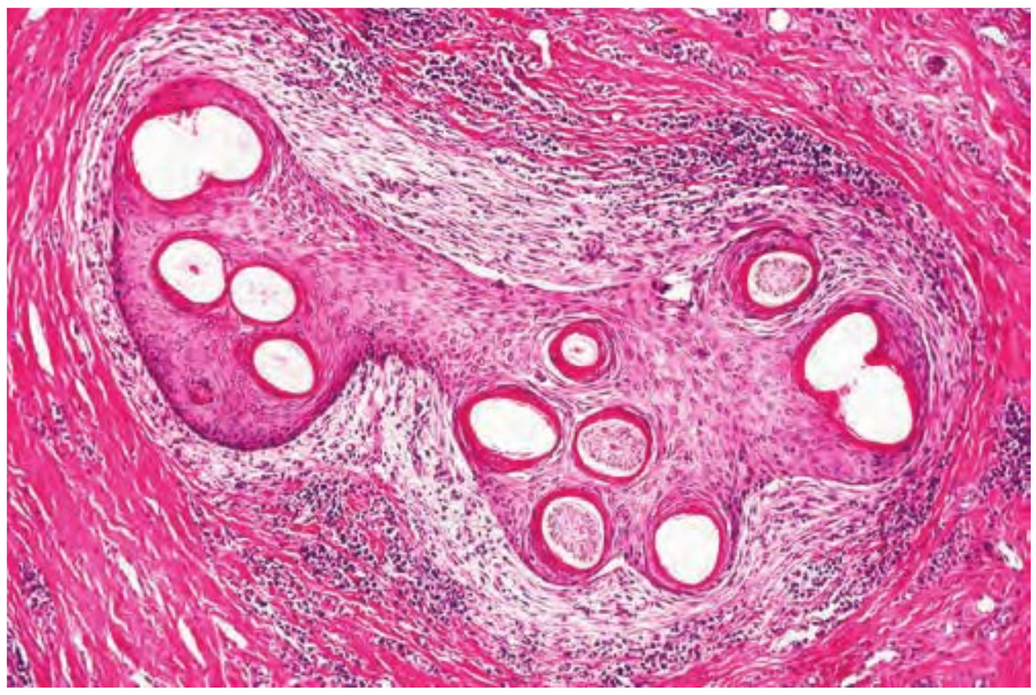

FIGURE 18-45. Tufted folliculitis (horizontal). In this extreme example, multiple hairs share a common outer root sheath and ultimately exit the scalp through a single opening. Perifollicular fibrosis and inflammation are present.

Histopathology. Histology shows a single group of three to five follicles, or several (two to four) such groups of follicles, in which the infundibular epithelium of the affected hair follicles is fused together (Fig. 18-45) so that the multiple hair shafts are situated in the infundibular hair canal and exit the skin through a shared ostium, which may show hyperkeratosis and parakeratosis (353). There is perifollicular fibroplasia superficially, as well as interfollicular fibrosis. The lower segments of the hairs are unaffected. The epidermis may be depressed from contraction of the fibrous tissue, forming a dell from which the hairs emerge. There may be variable infiltrates around the follicles and perivascularly that are composed of lymphocytes, histiocytes, and plasma cells, in addition to neutrophils when pustular lesions are biopsied. The hair tufts may eventually be destroyed by the process itself, and a foreign-body giant-cell reaction to free hair shafts may be seen. In one report, hairs were plucked from the tufts, revealing more than one-third telogen hairs (353).

Pathogenesis. Tufting results from injury to the outer root sheath epithelium of hairs in a single follicular unit or in several adjacent follicular units, possibly from a superficial suppurative folliculitis (353). There is accompanying perifollicular and interfollicular fibroplasia, leading to contraction of the involved skin and clustering of the follicular units. In healing, the outer root sheaths of the follicles grow together at the infundibular level. Other mechanistic theories include retention of telogen hairs (367), infection by *S. aureus* (361), and a congenital lesion, possibly a hair nevus, that became secondarily infected and scarred.

Postmenopausal Frontal Fibrosing Alopecia

This form of scarring alopecia is now considered a frontal variant of lichen planopilaris (368,369). It occurs in older women (mean age, 66.8 years), predominantly postmenopausal, with progressive recession of the frontal hairline (369,370). Other distinguishing features from typical lichen planopilaris include a marked decrease or complete loss of the eyebrows in most patients, a focal rather than multifocal pattern of alopecia, and lack of signs of lichen planus at other sites (369). There are rare exceptions, including one case with oral lichen planus (371) and another with cutaneous lichen planus in a premenopausal woman (372). Clinically the involved areas are pale, without sclerosis or induration, and show loss of follicular orifices (369). At the transition zone, follicles show perifollicular erythema and keratinization. Although frontotemporal recession can occur in postmenopausal women, mostly as a consequence of androgenetic alopecia, the follicular destruction in frontal fibrosing alopecia makes this condition unique (368,369).

Histopathology. Biopsies show histologic features of lichen planopilaris (Fig. 18-46), including perifollicular lymphocytic inflammation affecting the lower infundibulum and isthmus area near the bulge, hydropic degeneration of basal follicular keratinocytes with necrotic cells, concentric fibroplasia around the upper follicle, and absence of interfollicular changes (368,369). Naked hair shafts surrounded by granulomatous inflammation may be seen. Late lesions resemble burnt-out scarring alopecia, with noninflammatory fibrotic tracts replacing follicles and extending into the subcutis (373).

Pathogenesis. The infiltrate is predominantly composed of activated T-helper lymphocytes (368). The possibility that this

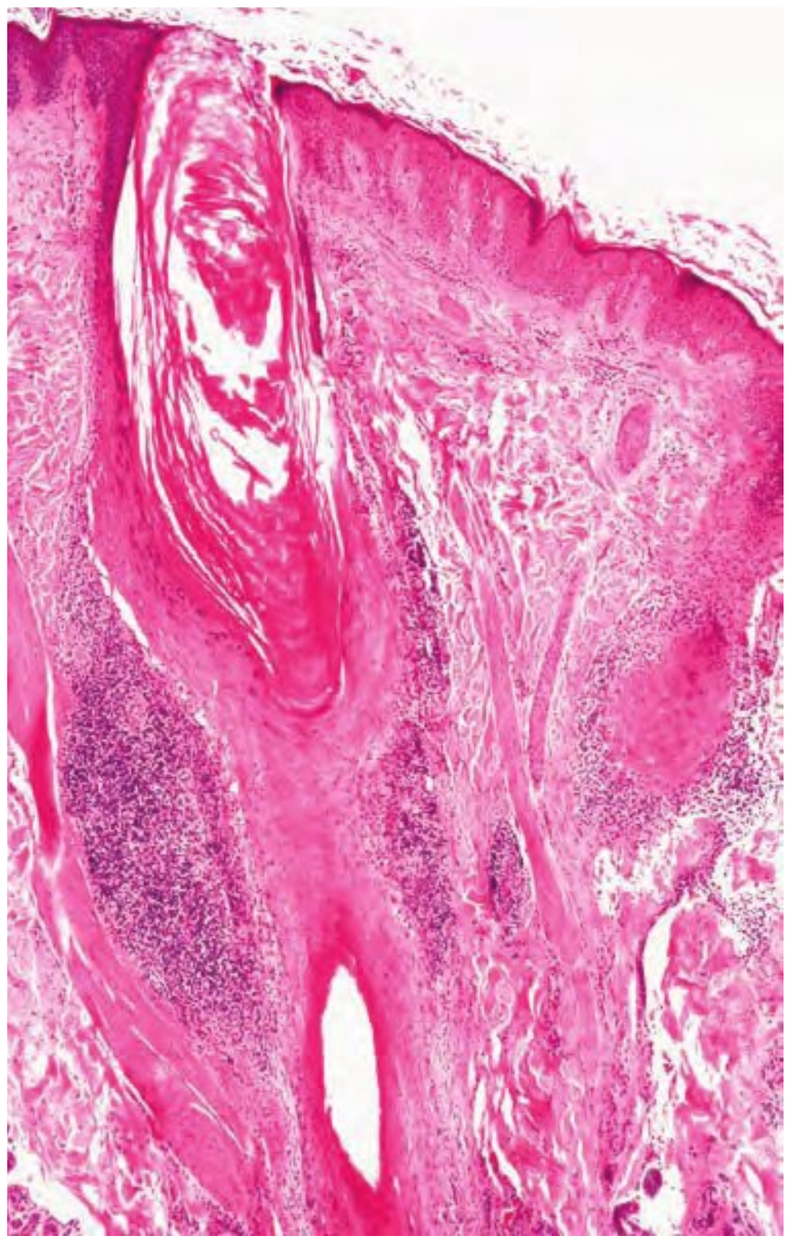

FIGURE 18-46. Postmenopausal frontal fibrosing alopecia (vertical). The changes are identical to those seen in lichen planopilaris, with lichenoid lymphocytic inflammation around the isthmus and lower infundibulum.

condition is triggered by androgenetic alopecia was considered, but some patients also displayed androgenetic alopecia over the central scalp that was unaffected by the fibrosing process (368,369). Despite the fact that most patients were postmenopausal, evidence to support a role for hormonal factors has not been demonstrated.

Fibrosing Alopecia in a Pattern Distribution

Fibrosing alopecia in a pattern distribution was described as another lichen planopilaris variant in which the clinically involved areas occur in a distribution characteristic of androgenetic alopecia (374). Both women and men were involved, but women outnumbered men with roughly a 4:1 ratio, and the mean age of affected patients was 59 years. Patients showed progressive fibrosing alopecia of the central scalp in the area of androgenetic alopecia. Affected follicles displayed perifollicular erythema and follicular keratinization. Multifocal lesions typical of lichen planopilaris or other mucocutaneous signs of lichen planus were not seen.

Histopathology. The histology of early and late lesions shows findings identical to those of early and end-stage lichen planopilaris (see the discussion of histopathology for postmenopausal frontal fibrosing alopecia), in conjunction with follicular miniaturization (374). Although both terminal and vellus hairs are affected by the inflammation, the miniaturized follicles appear to be preferentially targeted (318).

Miscellaneous Alopecia

Senescent Alopecia

Senescent or senile alopecia refers to the normal hair loss that occurs as a consequence of the aging process, with scalp hair becoming progressively and diffusely thinned starting at age 50 years but more typically by the seventh or eighth decade (294,331). Both sexes are affected. All elderly individuals exhibit thinning to some degree, but in severe cases, an individual may seek medical advice (192).

Histopathology. A 4-mm punch biopsy demonstrates the following: a decrease in the total number of hairs, from a normal of 35 to 45, to 25 to 35, a normal telogen count (less than 20%), a terminal-to-vellus hair ratio of at least 2:1, and a lack of deep inflammation (192,194). Horizontal sections are well suited to assess these parameters. The diameter of hairs may be diminished, and fibrous tracts may be seen (331). The occiput should show similar findings to those of other areas of the scalp (192).

Pathogenesis. Presumably follicles are lost forever; it is tempting to speculate that the regenerative capacity of follicular stem cells is restricted to a finite number of hair cycles.

Lipedematous Alopecia

Lipedematous scalp is localized or diffuse thickening of the scalp without hair loss, a result of thickening of the subcutaneous fat layer (375). This finding, in association with usually diffuse or patchy alopecia, has been termed *lipedematous alopecia* (376–378). It is a rare chronic condition, with relatively few cases being reported, that occurs most often in African-American females, although it has been reported in white women (379,380), as well as in men (381,382). The alopecia is characterized by short hairs that fail to grow longer than 2 cm in length. The scalp feels thick and boggy or spongy on palpation (378). It is smooth, without furrows, contrary to cutis verticis gyrata. Patients may complain of scalp pruritus, pain, or parasthesias. It was found in one patient with discoid lupus erythematosus (383).

Scalp thickness ranges from 10 to 15 mm, whereas normal scalp thickness averages 5.8 ± 0.12 mm, according to a study in which measurements were made at the bregma using skull x-rays (384). Scalp thickness may also be measured using computed tomography (375), magnetic resonance imaging (382), or ultrasound (377) or by introducing a sterile needle into the scalp (376).

Histopathology. The defining abnormality is increased thickness of the subcutaneous fat layer (385). To appreciate this on biopsy, the specimen must extend to the galea, and vertical sections are required. Superficial biopsies will not show the diagnostic finding. There is no evidence of adipose tissue hypertrophy or hyperplasia; instead, there is edema, with disruption of the normal subcutaneous architecture of lobules separated by collagenous septae (386). Degeneration of the adipose tissue into loosely associated collagenous strands, vessels, and aggregates of fat cells is also seen (386). Excess mucin deposition is not generally characteristic but was seen in some cases (377,379). There may be mild hyperkeratosis and acanthosis, as well as a sparse, superficial perivascular, interstitial, and perifollicular mononuclear infiltrate with occasional eosinophils (386).

A good explanation for the associated alopecia has not been found, although some researchers have noted a decrease in the number of follicles and focal bulbar atrophy (386). The hairs are in anagen and appear normal. In a study of lipedematous scalp and lipedematous alopecia, only the two cases with hair loss showed ectactic lymphatic vessels, believed to be potentially pathogenic (379). Scarring in the dermis or subcutis is generally absent, but perifollicular fibrosis has been noted (376,377). Follicular plugging and atrophic follicles have also been reported (376). Microscopic examination of hairs pulled in the clinical setting may show distal loss of the hair cuticle and changes of trichorrhexis nodosa, with hairs that break easily.

Pathogenesis. The etiology is unknown. The approximate doubling in scalp thickness is due entirely to thickening of the adipose layer. Free-floating lipid droplets along with adipocytes in various stages of degeneration were seen using electron microscopy (386). In addition to reduced follicular density, it is postulated that alopecia from aberrant hair shaft production may occur secondary to increased tissue oncotic pressure on hair bulbs (386).

Atrichia with Papular Lesions

Atrichia with papular lesions is a rare autosomal recessive condition characterized by total alopecia involving the scalp and body and usually the eyebrows (387), although eyelashes may be spared (388). Normal hair is present at birth but is shed within the ensuing months to years of life, never to be replaced (389). At around age 2 years, individuals start to develop generalized cystic papules. Unlike other forms of ectodermal dysplasia, defects in nails, sweat glands, or teeth are not seen (387).

Histopathology. A biopsy from affected scalp will demonstrate an absence of developed hair follicles (Fig. 18-47). Intact sebaceous glands may sometimes be seen (388). Follicular infundibula are present without the lower two thirds of hair follicles, which are often replaced by irregular epithelial structures or cysts (390). Consequently, hair shafts are not manufactured. Cysts develop from these abnormal follicles, producing clinical papules on the scalp and elsewhere that, when biopsied, reveal keratinous cysts with differentiation toward the follicular infundibulum (epidermoid, found in the upper dermis) and isthmus (trichilemmal, found in the middle and lower dermis) (388,390). The cysts may rupture, leading to foreign-body granulomas. Eccrine glands are normal in appearance.

Pathogenesis. Mutations in the human hairless (*HR*) gene on chromosome 8p12 produce the described clinical phenotype (391–393), although a patient with mutations in the vitamin D receptor gene has been reported (394). The hairless gene in humans is a homolog of the murine hairless gene (391,395). The human *HR* gene encodes a zinc-finger transcription factor protein that is expressed in the brain and skin (391).

Atrichia with papular lesions is recessively inherited, requiring two defective alleles; although most of the identified mutations have been homozygous within consanguineous families, compound heterozygous mutations have also been found (389). Possession of one allele with a *HR* gene mutation (heterozygous carrier) did not alter the expression of androgenetic alopecia in one study (396), and a significant association was not found in a group of men with androgenetic alopecia screened for *HR* gene mutations (397).

INFLAMMATORY DISEASES OF SWEAT GLANDS—ECCRINE

Syringolymphoid Hyperplasia with Alopecia

Originally described in 1969 (150,398), this rare dermatosis presents with localized or scattered, erythematous to red-brown patches, plaques, and hyperkeratotic follicular papules, sometimes producing anhidrosis (399). There may be an associated alopecia, most noticeable on the scalp, when there is follicular involvement (400). Most cases involve adult men.

Whereas some cases are considered idiopathic, others are associated with cutaneous T-cell lymphoma (CTCL) (400–402). "Idiopathic" cases should be followed closely to monitor for progression to clear-cut CTCL.

Histopathology. There are dense lymphocytic infiltrates surrounding superficial and deep vessels, hair follicles, and eccrine sweat glands. The sweat glands show epithelial hyperplasia, lymphocyte exocytosis, and sometimes obliteration of ductal lumina (Fig. 18-48) (401). Follicular mucinosis may be seen in some cases.

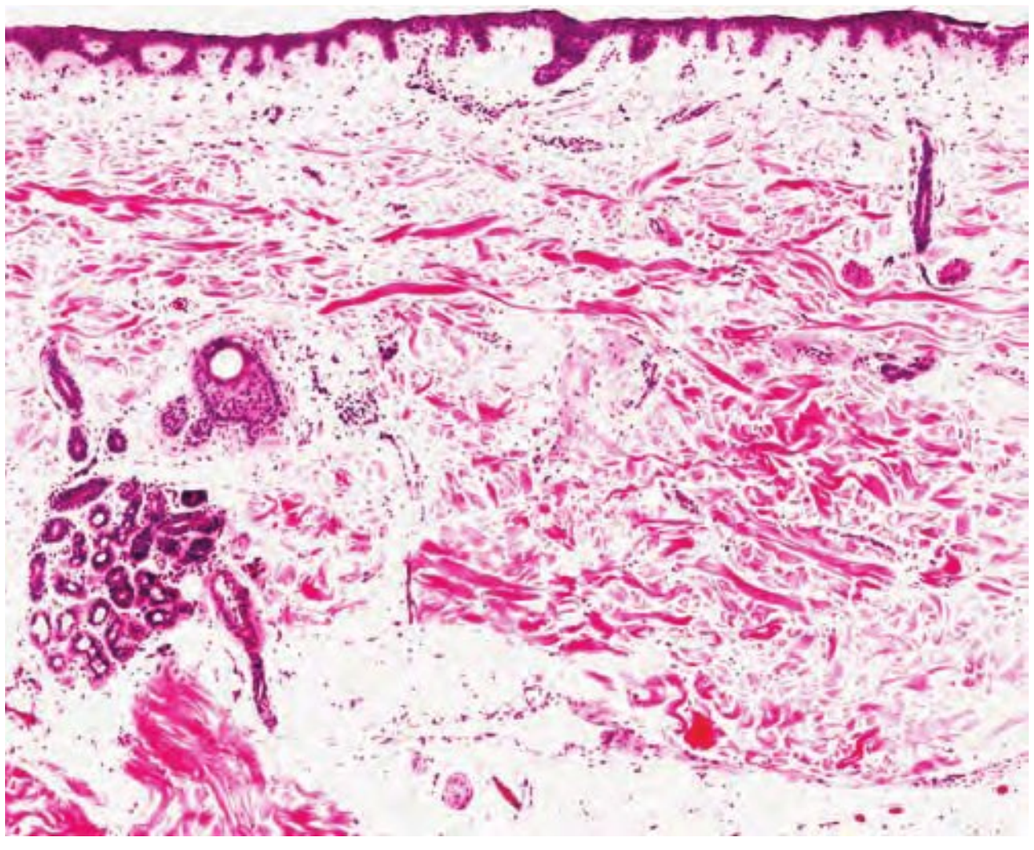

FIGURE 18-47. Atrichia with papular lesions (vertical). In this biopsy from the scalp, functional follicles are absent. Only a rudimentary follicle without a hair shaft is seen, near the eccrine gland, which is normal.

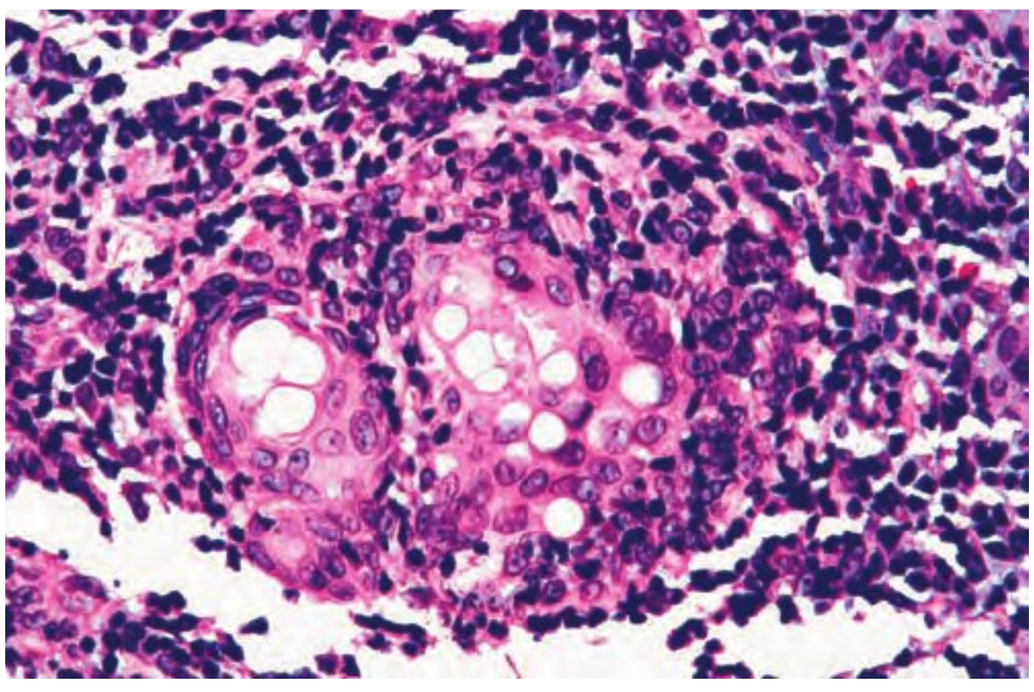

FIGURE 18-48. Syringolymphoid hyperplasia with alopecia. A mildly hyperplastic eccrine sweat gland shows partial obliteration of ductal lumina, a dense surrounding lymphocytic infiltrate, and lymphocyte exocytosis (syringotropism), findings that should prompt consideration of mycosis fungoides.

In cases associated with CTCL, early lesions may show features more akin to a "precursor" lesion, with psoriasiform epidermal hyperplasia, spongiosis, papillary dermal fibrosis, scattered eosinophils, and a lichenoid infiltrate composed of small lymphocytes and some larger ones with convoluted nuclei, without significant epidermotropism (150). Late lesions show epidermotropism with Pautrier's collections and denser perivascular and periadnexal infiltrates. Atypical lymphocytes infiltrate the eccrine gland epithelium (syringotropism) and also the follicular outer root sheath. The eccrine glands demonstrate hyperplasia with formation of complex, sometimes cribriform, structures (150). "Syringotropic variant of mycosis fungoides" was proposed as the preferred term for those cases associated with CTCL (403).

Neutrophilic Eccrine Hidradenitis

Neutrophilic eccrine hidradenitis (NEH) occurs in varied clinical settings (404). *Chemotherapy-associated NEH* is discussed in Chapter 11. NEH has been described in conjunction with infectious agents, including *Serratia marcescens* (405), *Enterobacter cloacae* (406), *Staphylococcus aureus* (407), streptococcal endocarditis (408), *Nocardia* (409), and HIV-1 (410–413), as well as miscellaneous associations that include granulocyte colony-stimulating factor (414), actinic reticuloid syndrome (415), Behçet's disease (416), acute myelogenous leukemia in the absence of chemotherapy (417), and one case in an otherwise healthy adult (418).

A subset of NEH that occurs in healthy children and young adults, *palmoplantar hidradenitis*, has been reported under many names, including "idiopathic palmoplantar eccrine hidradenitis," "juvenile neutrophilic eccrine hidradenitis," "recurrent eccrine hidradenitis," "idiopathic plantar hidradenitis," "traumatic plantar urticaria," and "plantar erythema nodosum" (419–426). Painful erythematous papules and nodules occur on the palms and soles. Constitutional symptoms are usually absent. In one study of 22 patients, occurrences were most frequent in the spring and fall, and almost half of the patients experienced more than one episode (427). The condition is benign and self-limited. Although the pathogenesis is unclear, temporal association with intense physical activity and exposure to cold, damp footwear have been reported (420,423).

A related condition has been described, the *Pseudomonas hot-foot syndrome* (428). Painful red-to-purple nodules developed on weight-bearing sites on the soles of 40 children within 1 to 2 days of using a community wading pool where the floor was covered with an abrasive grit (believed to be important to the pathogenesis). Lesions were cultured from some patients, yielding a strain of *Pseudomonas aeruginosa* identical to that found in the pool, and some of the children had associated *Pseudomonas* folliculitis. Previous reports of hot-tub folliculitis had noted similar plantar lesions (429) . Nevertheless, one group denied the existence of the *Pseudomonas* hot-foot syndrome, stating that the findings were consistent with idiopathic palmoplantar hidradenitis (430).

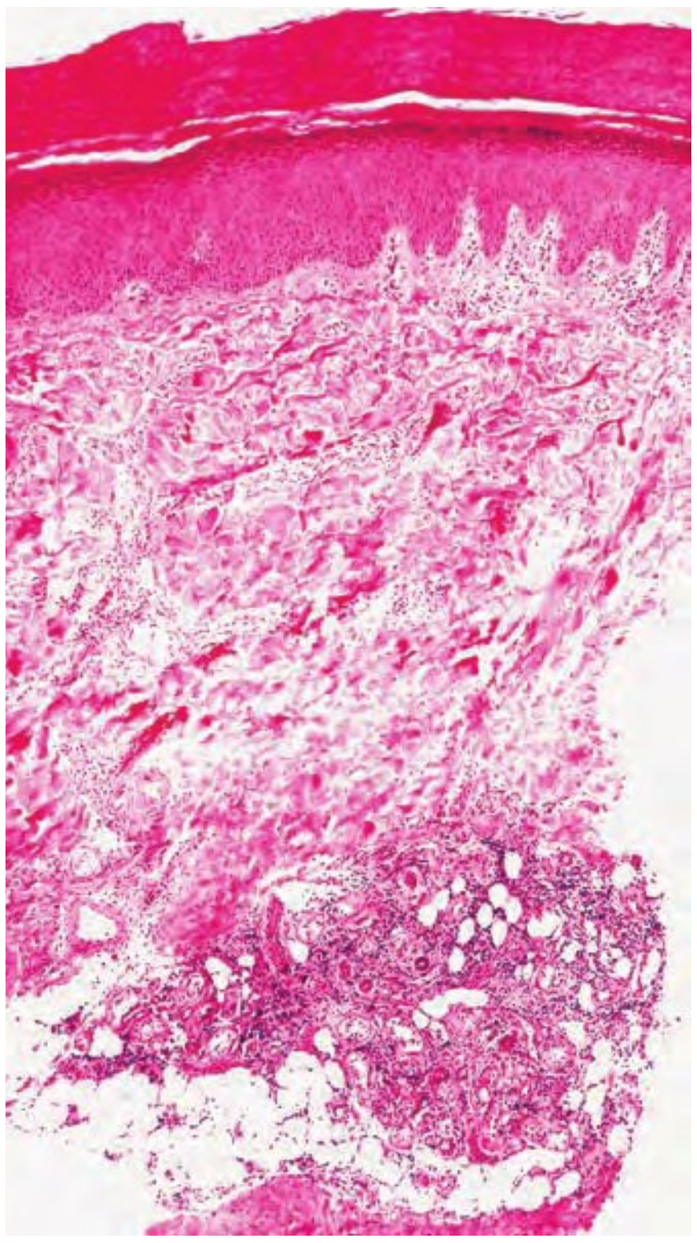

FIGURE 18-49. Palmoplantar hidradenitis. This biopsy from the plantar surface demonstrates an infiltrate around the eccrine gland coil.

Histopathology. The histology of *palmoplantar hidradenitis* occurring in children is similar to that of NEH induced by certain forms of chemotherapy (see Chapter 11), except that syringosquamous metaplasia is missing (431). A neutrophilic infiltrate is centered on the eccrine gland coils (Figs. 18-49 and 18-50). There may be mild mixed inflammation surrounding vessels in the mid and deep dermis, without leukocytoclastic

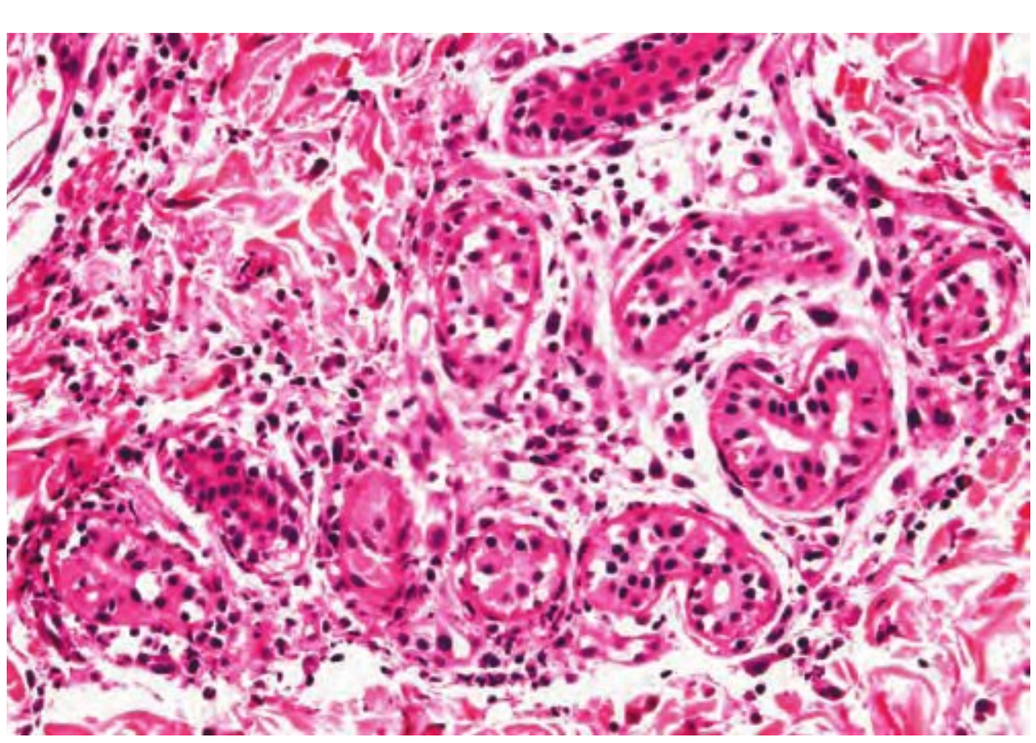

FIGURE 18-50. Palmoplantar hidradenitis. Neutrophils and neutrophilic debris surround an eccrine gland, constituting a pattern of neutrophilic eccrine hidradenitis.

vasculitis. Neutrophilic inflammation may involve the acrosyringium or assume a nodular pattern in the reticular dermis with abscess formation (422,426). Stains for fungi and bacteria are negative, even in those cases in which cultures of lesions are positive for bacteria (404).

In the *Pseudomonas* hot-foot syndrome, biopsies from two of the patients showed superficial and deep perivascular, interstitial, and perieccrine inflammation composed of neutrophils and lymphocytes that extended into subcutaneous fat lobules. One of the cases showed a dermal microabscess with extension into the fat and focal vasculitis with an intravascular thrombus (428). The authors noted that extension into subcutaneous fat lobules was a distinguishing feature from idiopathic NEH in children, a point that others have refuted (430).

INFLAMMATORY DISEASES OF SWEAT GLANDS—APOCRINE

Fox-Fordyce Disease

Fox-Fordyce disease (apocrine miliaria) is a disorder of apocrine sweat glands characterized by firm, itchy, follicular papules in anatomic sites where apocrine glands occur, namely the axillae (Fig. 18-51), areolae, and genitalia (432). It occurs almost exclusively in women after adolescence.

Histopathology. Step sections of a vertically oriented biopsy specimen are usually needed adequately to show the characteristic changes. There is hyperkeratosis of the follicular infundibulum and excretory duct of the apocrine sweat gland at the point where the latter inserts into the hair follicle. The apocrine duct behind the obstructing keratin plug becomes dilated (433). A spongiotic vesicle occurs in the follicular infundibulum, possibly representing an apocrine sweat-retention vesicle, with potential to rupture. Lymphocyte exocytosis is seen in the area of spongiosis. There may also be infundibular acanthosis and mild perivascular and periadnexal lymphocytic inflammation in the adjacent upper dermis (434,435). A comprehensive review of the histopathology noted other possible microscopic findings, including vacuolar alteration at the dermoepithelial junction of infundibula, dyskeratotic cells in infundibula, cornoid lamella–like parakeratosis within an orthokeratotic plug filling a dilated infundibulum, and foamy macrophages surrounding follicular infundibula and apocrine ducts (436). Transverse histologic sections facilitated identification of the diagnostic histologic features in one case, and this technique was touted as the most effective way to diagnose Fox-Fordyce disease on biopsy (437).

FIGURE 18-51. Fox-Fordyce disease. The uniform spacing of these discrete papules in the axilla is a clue to their adnexal origin.

A third type of sweat gland has been identified in the axillae; it is intermediate in size between the larger apocrine gland and smaller eccrine gland (438). Called the apoeccrine gland, it has a secretory coil like an apocrine gland but opens directly to the epidermal surface like an eccrine gland. A recent article details a case of Fox-Fordyce disease characterized by nonfollicular papules that histologically showed blockage of the intraepidermal portion of the apoeccrine sweat duct by cells that were released from the secretory portion via a holocrine mechanism (439).

Pathogenesis. The pathogenesis appears to be related to blockage of the apocrine sweat duct. Apocrine anhidrosis results, as demonstrated by the lack of apocrine secretion following intradermal injections of an epinephrine solution into the affected area (432). There are, however, reports suggesting that mechanical obstruction alone may not explain Fox-Fordyce disease (434).

INFLAMMATORY DISEASES OF CARTILAGE

Chondrodermatitis Nodularis Helicis

Chondrodermatitis nodularis helicis (CNH) usually presents as a single, small, exquisitely tender, erythematous nodule on the superior rim of the helix of the ear (Fig. 18-52) and less frequently on the antihelix or posterior ear (440). The lesion develops a crust and ulceration in the center, producing elevated margins that may mimic basal cell carcinoma. CNH occurs mostly in white men older than 40 years of age (441). The lesion tends to persist indefinitely without treatment.

Histopathology. Epidermal ulceration or a wedge-shaped epidermal defect is usually present. The intact adjacent epidermis is hyperplastic and may contain some dyskeratotic keratinocytes. A crust of exudate, parakeratosis, and dermal debris covers the surface of the epidermal defect (442). The dermis directly below shows fibrinoid collagen degeneration that stains more deeply eosinophilic than reticular dermal collagen, is homogeneous, and is acellular; it may reach the perichondrial tissue beneath (Fig. 18-53). The stroma adjacent to the zone of degeneration shows vascular proliferation with lymphohistiocytic inflammatory cells. There may also be some fibroplasia and occasional plasma cells and neutrophils. Glomus cell aggregates have been described in these vascularized granulation tissue–like areas (443). Peripheral solar elastosis is

FIGURE 18-52. Chondrodermatitis nodularis helicis. Papule on the helical rim with a central crust. Lesions can less commonly involve the antihelix.

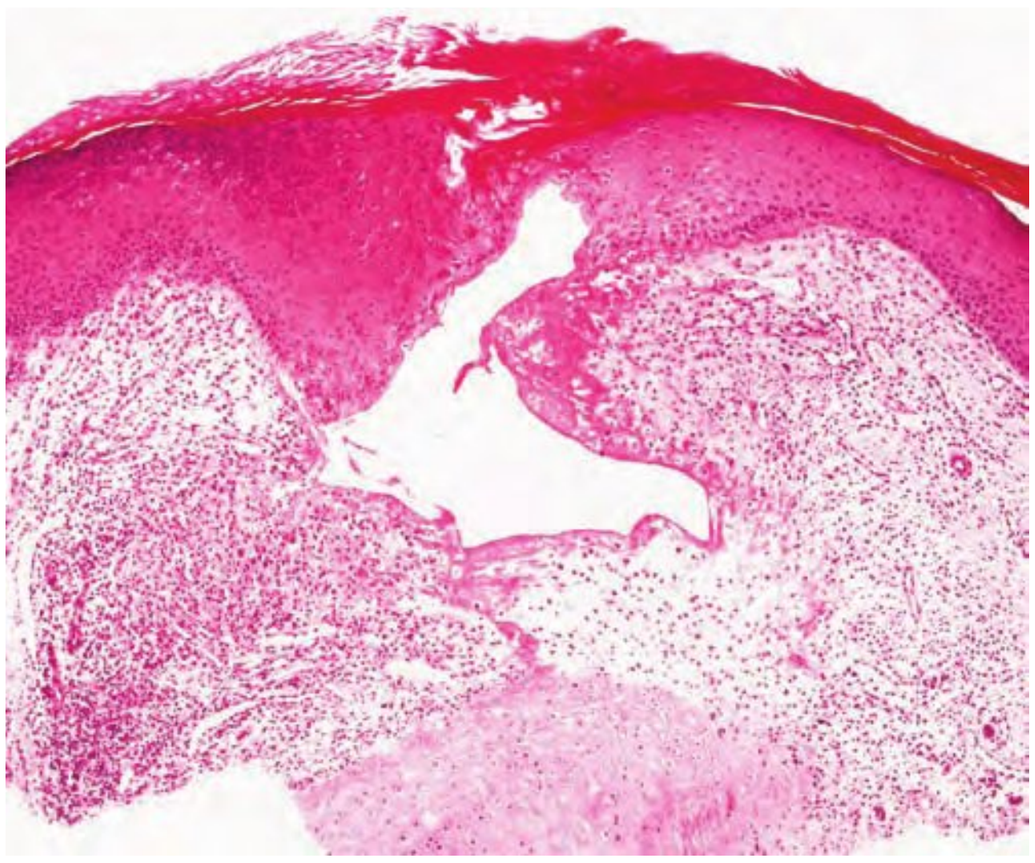

FIGURE 18-53. Chondrodermatitis nodularis helicis. There is a channel through the epidermis with adjacent epidermal hyperplasia. The dermis beneath shows fibrinoid degeneration of collagen that stains brightly eosinophilic and extends to the underlying perichondrium. The surrounding dermis shows a proliferation of small vessels, some mononuclear inflammation, and prominent solar elastosis.

common (442). The underlying perichondrial tissue may be thickened and appear to migrate to the base of the fibrinoid dermal necrosis. Degeneration of underlying cartilage with loss of cell nuclei can occur, although it is usually minimal. If cartilaginous degeneration is severe, there may be focal calcification and ossification. Nerve hyperplasia was found in 35 of 37 cases examined, potentially explaining the tenderness of lesions (444).

Pathogenesis. As the name implies, it was originally believed that this condition begins with cartilaginous degeneration. It is now generally considered to be an attempt at transepidermal elimination of damaged dermal collagen, a type of perforating disorder (442,445), although one report classified it as a necrobiotic process of collagen akin to granuloma annulare (446). The dermal collagen degeneration most likely results from vascular compromise, whether induced by trauma, pressure [during sleep or cell phone use (447)], cold, or complications of dermatoheliosis. The limited vasculature at this anatomic site and lack of subcutaneous fat insulation may contribute to the situation. In one case of CNH, serum autoantibodies to denatured type II collagen were detected (445).

Relapsing Polychondritis

Relapsing polychondritis (RP) is a rare systemic chondromalacia that affects cartilage in multiple sites, including the ear, nose, larynx, trachea, bronchi, and joints (448,449). It also affects proteoglycan-rich tissues, such as the eyes, aorta, heart, kidneys, and skin (449). It usually starts with auricular chondritis and runs an episodic, progressively destructive course. A mortality of about 25% has been reported, most commonly from damage to the respiratory tract or heart valves (450), although one study estimated the survival rate to be 94% at 8 years, a result of improvements in management (449). Disorders commonly associated with RP include rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome, and myelodysplastic syndromes (452). It may also be a paraneoplastic condition, reportedly occurring with non-Hodgkin's lymphoma (453) and chronic lymphocytic leukemia (454).

Primary involvement of the ears and nose, consisting of intermittent attacks of painful erythema and swelling, may lead to a dermatology consult. Rarely, only one ear is involved. Ultimately, the ears become soft and flabby as a result of cartilage destruction, and the nose assumes a saddle nose deformity.

Nonspecific dermatologic findings associated with RP are common, varied, and found most frequently in RP patients with myelodysplasia (455). They sometimes resemble the skin findings seen in Behçet's disease or inflammatory bowel disease: aphthosis, sterile pustules, limb ulcerations, or distal necrosis (455). It has been associated with Behçet's disease (456), described by the acronym MAGIC syndrome for "mouth and genital ulcers with inflamed cartilage" (457). Leukocytoclastic vasculitis is not uncommon (458,459), and, indeed, it has been suggested that the cartilaginous damage may be secondary to a primary vasculitis (460). Other associated

cutaneous lesions include purpuric or erythema nodosum–like lesions (458,459), chronic dermatitis, superficial phlebitis, livedo reticularis (455), septal and lobular panniculitis with vasculitis (461), erythema elevatum diutinum (462), epidermolysis bullosa acquisita (463), and pseudocyst of the auricle (464).

Histopathology. In early cartilaginous lesions, only the marginal chondrocytes appear degenerate, showing vacuolization, nuclear pyknosis, and loss of basophilia, which has been shown to result from the release of chondroitin sulfate from the cartilage matrix (465). A dense inflammatory infiltrate develops in the perichondrium, which comprises neutrophils, lymphocytes, eosinophils, plasma cells, and macrophages. Frequently there is edema or gelatinous cystic degeneration, and with progression, degenerated cartilage blends imperceptibly with the surrounding inflammatory cells, leading to the formation of granulation-type tissue (451). There may be fragmentation of the cartilage with necrosis and lysis of the cartilaginous plates (451). Elastic tissue stain shows clumping and destruction of cartilaginous elastic fibers (466). With successive episodes, fibrosis ensues.

Pathogenesis. Circulating antibodies to type II collagen, found exclusively in cartilage, are detected in patients with RP (467) and are generally found only in patients with active disease (468). The antibodies are directed against native and undenatured type II collagen, suggesting a primary role for these antibodies in the pathogenesis (rather than a secondary response to injured cartilage) (469). Immunoglobulin and complement components have also been identified in the inflamed cartilage (464,465). RP is strongly associated with HLA-DR4 (470).

Pseudocyst of the Auricle

In pseudocyst of the auricle, an asymptomatic, fluctuant swelling measuring about 1 cm in diameter is observed on the upper portion of the anterior aspect of the ear, usually in young men (mean age 38.9 years) (471). It is a form of chondromalacia that arises spontaneously or sometimes after minor trauma or infection, relapses frequently, and only rarely involves both ears. Pseudocyst is due to cavitation within the auricular cartilage, which, when punctured, releases only a few microliters of a clear, deep yellow, viscous fluid. In the differential of cystic swellings of the external ear, this feature aids in the diagnosis, so that if a relatively large amount of liquid is obtained, the cavity must be located outside of the cartilage (472).

Histopathology. A small intracartilaginous cavity without an epithelial lining is found on histologic examination. The wall of the pseudocyst consists of auricular cartilage, which is partially degenerated, appearing as faintly eosinophilic amorphous material (Fig. 18-54). The overlying epidermis, reticular dermis, and perichondrium are all normal (472). Until recently, inflammation was not considered a feature of this condition, but a study of 16 specimens consistently showed a perivascular lymphocytic infiltrate in the connective tissue just superficial to the cartilage (473); the authors believed that this was critical to the development of the condition.

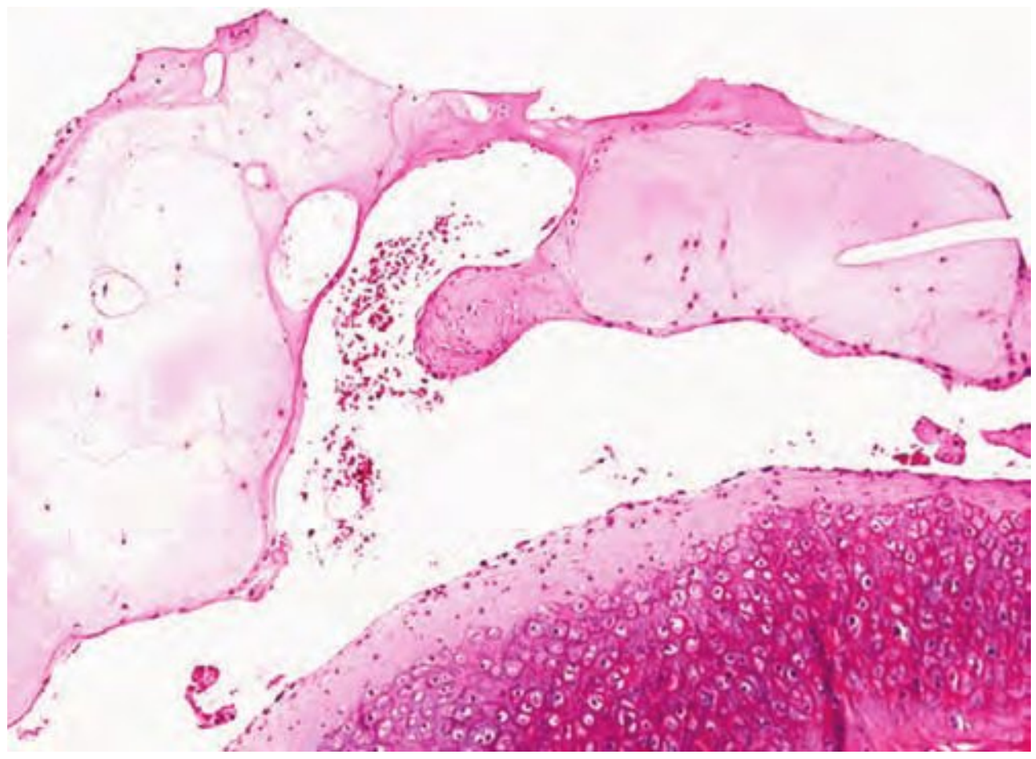

FIGURE 18-54. Pseudocyst of the auricle. There is an intracartilaginous cavity without an epithelial lining. The auricular cartilage is partially degenerated, appearing faintly eosinophilic and smudgy, with loss of nuclei.

Pathogenesis. It has been suggested that the intracartilaginous cavity forms after the release of lysosomal enzymes (474) or overproduction of glycosaminoglycans after repeated trauma or mechanical stimulation. Compared to normal serum, aspirated fluid has been found to contain elevated levels of lactate dehydrogenase (LDH), especially the LDH-4 and LDH-5 isozymes (475,476), as well as the cytokines IL-6 and IL-1((477); investigators hypothesized that these substances were released from the damaged cartilage. Pseudocyst of the auricle has been described in association with relapsing polychondritis (464).

CHAPTER 19

Thomas D. Griffin

Inflammatory Diseases of the Nail

An understanding of the normal anatomy and histology of the nail unit precedes understanding the pathology that may occur there (see Chapter 3). Inflammatory pathologic processes in the nail unit affect mainly the matrix, nail bed, hyponychium, and nail folds. Changes in the nail plate occur secondarily. A basic understanding of where pathologic processes affect the nail unit will guide the practitioner in choosing a site of biopsy. As in other clinical situations, understanding the location and type of pathology leads to more effective diagnosis and treatment of the disease process.

Because of the unique anatomy of the nail unit, there is a limited number of possible reaction patterns to inflammatory processes. These reaction patterns may have different features from those seen in the skin. Because the nail unit produces a product, the nail plate, some inflammatory processes of the nail matrix may lead to irreversible damage resulting in an abnormal or absent plate, much akin to processes affecting the hair unit that lead to scarring alopecia. On the other hand, processes affecting the nail bed and hyponychium that do not affect the formation of the plate may affect its shape or adhesiveness. The nail bed responds to injury by becoming metaplastic, that is, by switching from onycholemmal keratinization (without keratohyalin granules) to epidermoid keratinization. It becomes hyperplastic, showing hyperkeratosis, parakeratosis, hypergranulosis, marked spongiosis, and exudative scale crust formation. The products of this reaction build up between the nail bed and plate. This process leads to the altered shape and shedding patterns of the nail plate that are common to several diseases affecting the nail bed, such as psoriasis and onychomycosis.

Inflammatory diseases may also affect the nail folds. When the ventral surface of the proximal nail fold is affected, inflammation of the cuticle and alterations of the dorsal surface of the nail plate may be seen. Eczema and contact dermatitis of the fingers may affect both the proximal and lateral nail folds.

Inflammatory processes affecting the nail may have many overlapping features. Although a specific diagnosis may be made in many cases, such as in lichen planus affecting the matrix, often it may be difficult to distinguish between, for example, psoriasis and eczema affecting the nail bed.

BIOPSY OF THE NAIL UNIT

Biopsy of the nail unit is recommended in many cases when the diagnosis is in doubt or when definitive histopathologic diagnosis is needed before beginning therapy.

Nail matrix biopsy is best performed after reflecting back the proximal nail fold (1). The nail plate may remain intact or may be avulsed before the biopsy. It is of utmost importance to avoid bisecting the matrix. A 2- to 3-mm punch biopsy from the center of the matrix should be obtained so that the excision is entirely within and surrounded by matrix. It is also important to avoid both the curvilinear portion of the lunula, which represents the distal nail matrix, and the most proximal portion of the matrix, since interruption of these areas may lead to defects in the nail plate.

The nail bed may be sampled by using a punch biopsy through the nail plate down to the periosteum (2). Longitudinal incisional biopsies may also be done. In this procedure, en bloc removal of the lateral nail fold, matrix, bed, and hyponychium is done. This procedure is excellent for defining disease processes of the nail unit. It is probably too extensive for routine nail biopsies and is not necessary for making a histopathologic diagnosis in most cases.

The proximal nail fold region may be sampled by a punch biopsy or a transverse excisional biopsy (2). The distal free margin of the proximal nail fold must be avoided to prevent notching.

Care must be taken to avoid biopsying so deep in the proximal nail area as to transect the tendon of the extensor digitorum communis, which inserts into the proximal dorsal portion of the terminal phalanx. Transection of this tendon will result in a drop deformity of the distal phalanx.

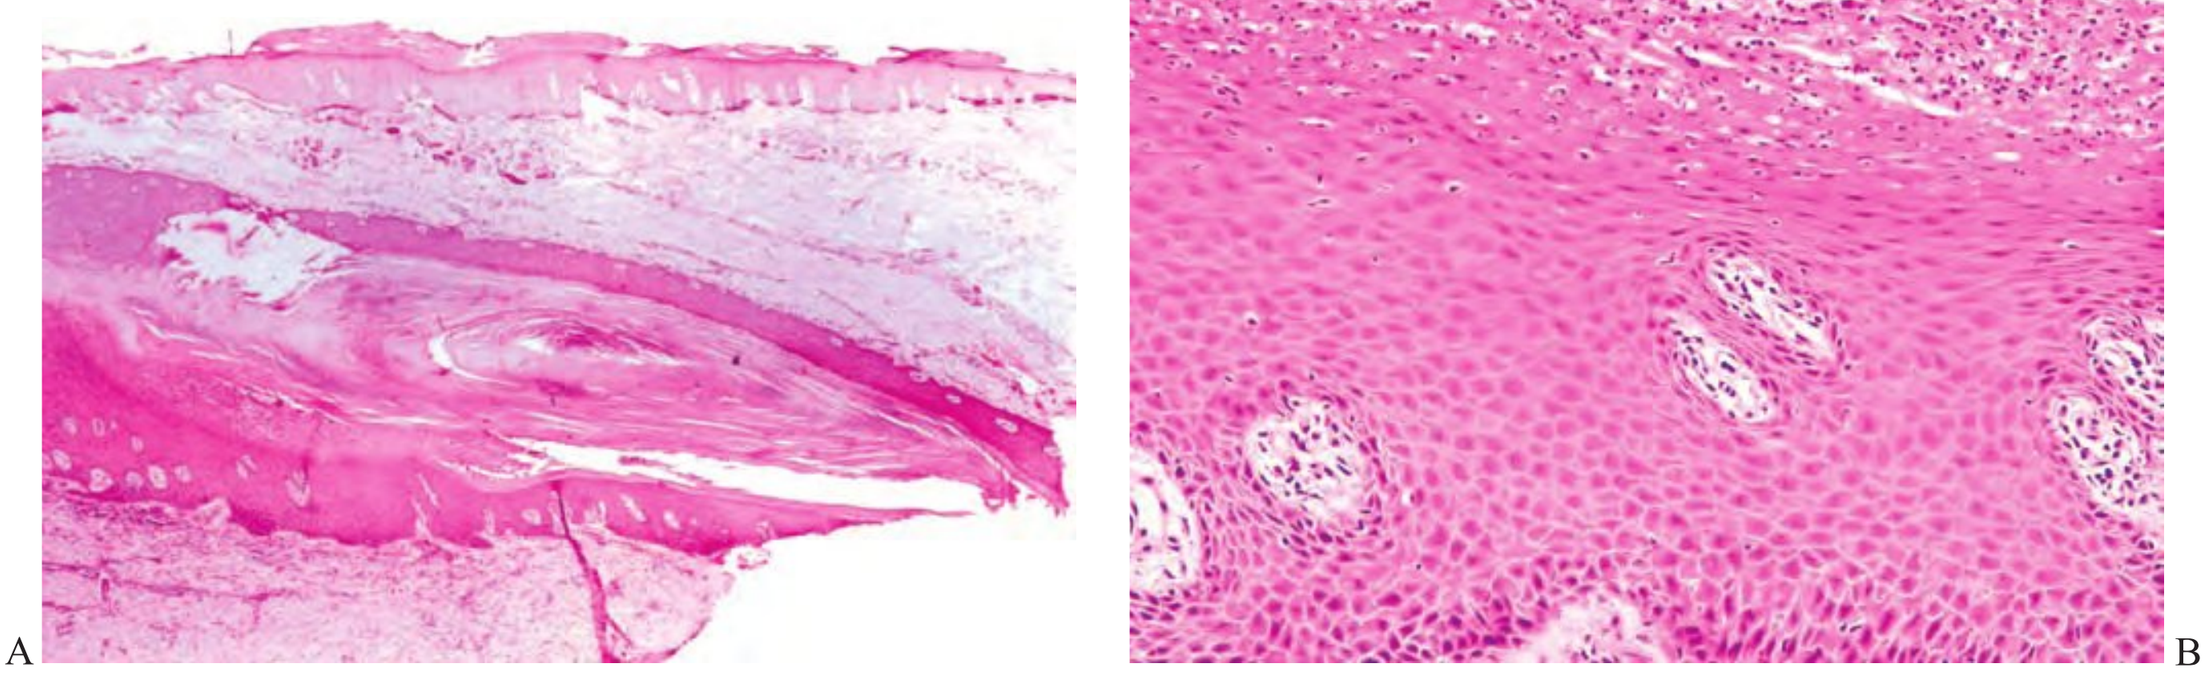
ECZEMATOUS DERMATITIS

Most forms of eczematous dermatitis affect the nail unit, with atopic dermatitis being most common. Contact dermatitis due to nail cosmetics or occupational exposure may affect all areas of the nail unit. Nail plate changes usually result from matrix or proximal nail fold involvement. Onycholysis may be due to nail bed involvement that begins distally at the hyponychium and spreads inward to involve the nail bed. Secondary chronic

paronychial infection may occur. The biopsy should be focused on the site of involvement, usually the nail bed or nail matrix. The histologic changes include spongiosis and exocytosis of mononuclear cells and an acanthotic epidermis. Stains for fungal organisms should be performed to rule out onychomycosis.

PSORIASIS

Nail involvement in psoriasis may occur in up to 50% of patients. Nail changes may occur in up to 80% of patients with psoriatic arthritis. In 10% of patients with psoriasis, nail involvement may be the only manifestation.



Psoriasis may involve any part of the nail unit, including the matrix, nail bed, hyponychium, and nail folds. Biopsy through the nail plate and nail bed is preferred for diagnosis of psoriasis involving the nail. Sections should be stained with hematoxylin and eosin and also with periodic acid-Schiff (PAS) stain or silver methenamine stain to rule out fungal infection. Because psoriasis and onychomycosis share many clinical and histologic features, a positive fungal stain is the only reliable way of distinguishing histologically between psoriasis and onychomycosis (3).

Psoriatic involvement of the proximal nail matrix causes clinical pitting and roughening of the surface of the nail plate. Histologically, foci of parakeratosis on the surface of the plate are seen, which when shed leave pits in the plate. Involvement of the mid- and distal matrix leads to clinical leukonychia. Once again, the histology is that of foci of parakeratosis in the nail plate; however, in leukonychia, the parakeratotic cells are located in the deeper portions of the plate.

FIGURE 19-1. Psoriasis of the nail. Onycholysis (oil drop sign) is seen in the distal nail plate.

The "oil drop sign" of psoriatic nails (Fig. 19-1) is a reddish-brown discoloration of the nail bed and hyponychium (4). It represents an early, acute focus of psoriasis involving the nail bed or nail matrix. Hyperkeratosis and parakeratosis with collections of neutrophils in the stratum corneum representing a Munro microabscess and spongiform pustules in the granular layer are seen (Fig. 19-2). The nail epithelium may show hypergranulosis with focal hypogranulosis. There is elongation of the dermal papillae with dilatation and proliferation of capillaries surrounded by lymphocytes, histiocytes, and occasional neutrophils. Distal nail onycholysis shows a similar histology and therefore has a similar histogenesis. The split in psoriatic onycholysis occurs between where neutrophils and parakeratotic

A B

FIGURE 19-2. Psoriasis of the nail matrix. A: There is absence of the granular layer, acanthosis of the epidermis, and vascular proliferation in the underlying papillary dermis. B: A spongiotic pustule is seen in the epidermis.

foci are located within the plate and the underlying hyponychium (5). The yellow leading edge of onycholytic nail correlates with the presence of neutrophils in the nail plate keratin.

Ultimately, well-developed psoriasis of the nail bed leads to subungual hyperkeratosis and exudate, which lift the nail plate off the bed. The nail bed epithelium shows psoriasiform acanthosis with elongated rete ridges and capillary proliferation. Neutrophils may be present in the superficial epidermis and within the keratin. Late or chronically traumatized psoriatic nails may develop features of lichen simplex chronicus (6), including marked compact orthokeratosis, hypergranulosis, and fibrosis of the papillary dermis, characterized by vertical streaks of coarse collagen fibers.

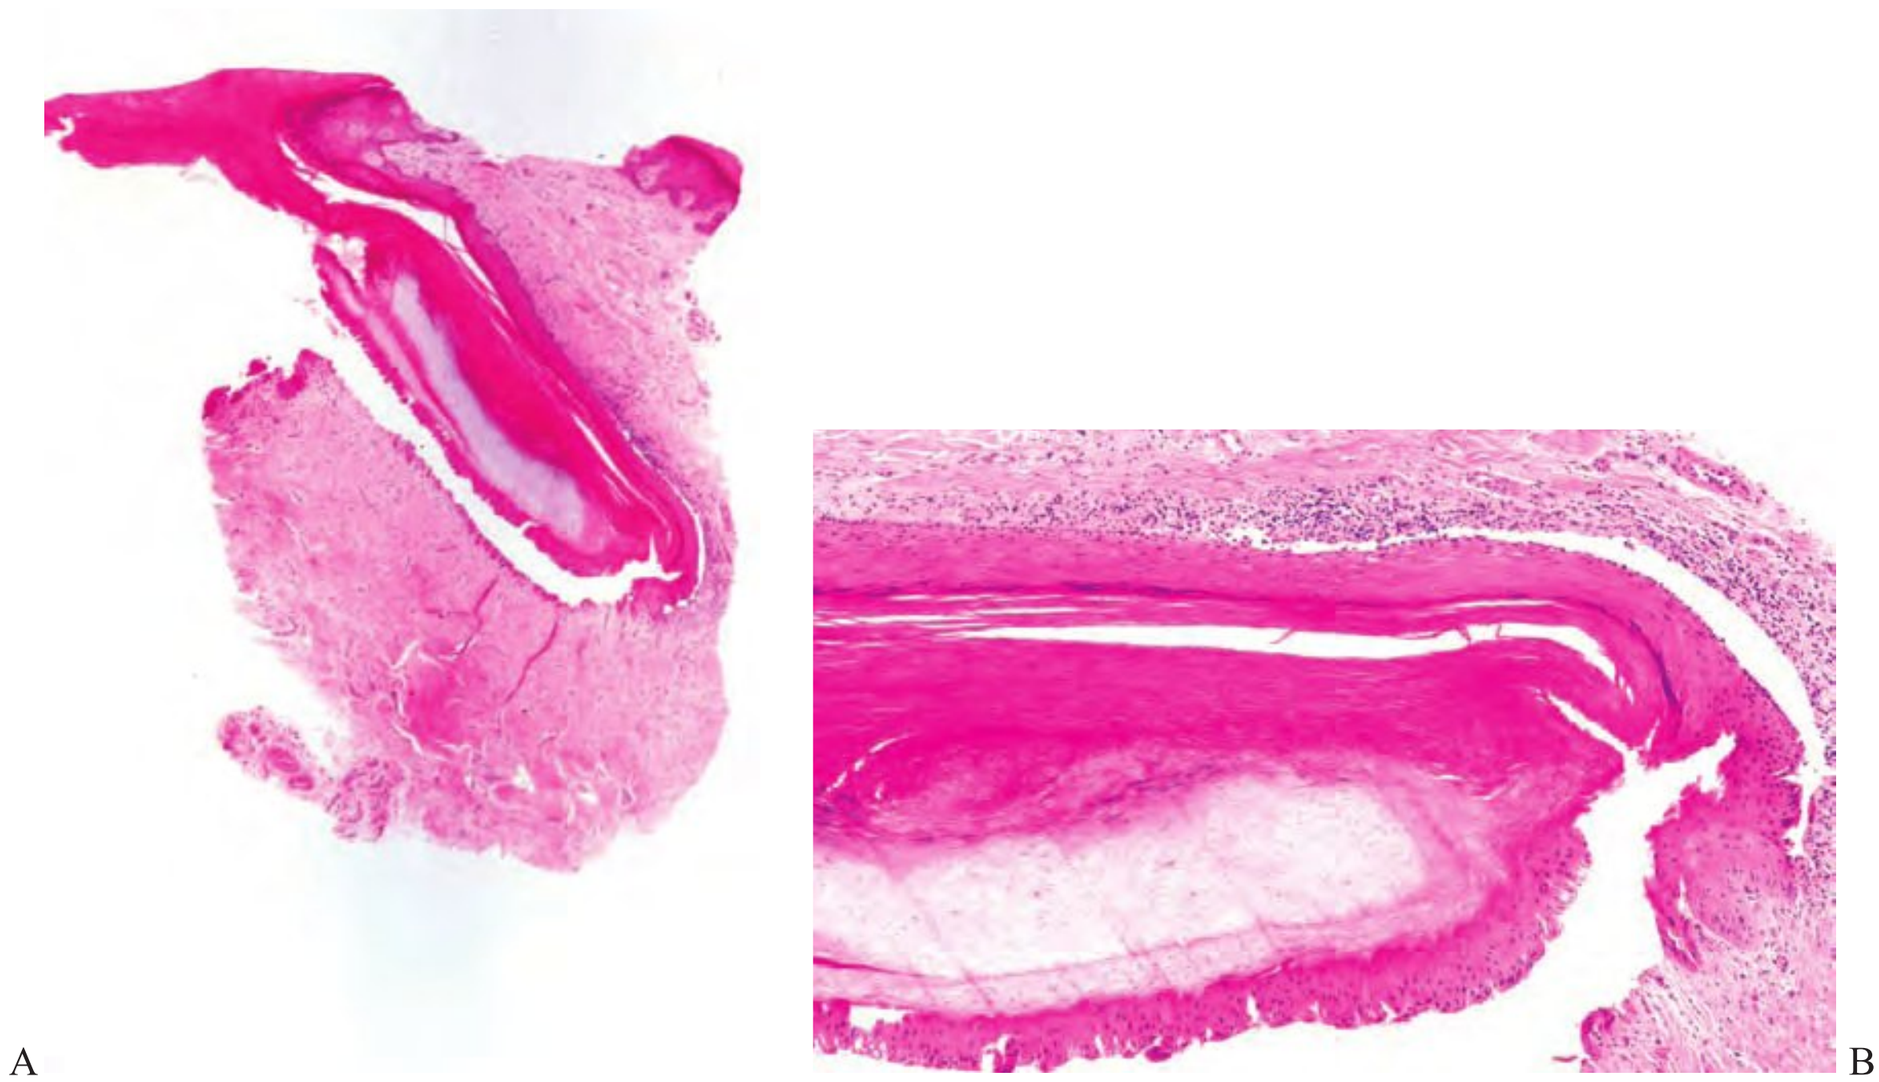


FIGURE 19-3. Lichen planus of the nail. Longitudinal grooves, atrophy, and splitting are seen in the nail plate.

LICHEN PLANUS

The incidence of nail involvement occurring in association with disseminated lichen planus ranges from 1% to 10% (7). Lichen planus may develop in the absence of cutaneous involvement and is most common in the fifth and sixth decades of life. Fingernails are more commonly affected than toenails (8). Lichen planus may involve the nail matrix, nail bed, and hyponychium. Examination and understanding of the pathogenesis of clinical changes will aid the clinician in determining where to sample the nail unit.

Involvement of the proximal nail matrix leads to longitudinal grooves and ridges (onychorrhexis) of the nail plate (Fig. 19-3). As in lichen planus of the skin, hyperkeratosis, hypergranulosis, vacuolar degeneration, necrotic keratinocytes, Civatte bodies, and a bandlike infiltrate of lymphocytes and histiocytes at the dermal–epidermal junction accompanied by melanophages can be seen (Fig. 19-4). Hyperpigmentation of the nail (melanonychia) may result. If lichen planus of the proximal nail matrix is treated early in its course, onychorrhexis may be reversible. As with other skin appendages, such as hair, if the process progresses, fibrosis and scarring may result, leading to permanent deformity.

A B

FIGURE 19-4. Lichen planus of the dorsal nail matrix epidermis. A: Hyperkeratosis and a superficial lymphocytic infiltrate are apparent at scanning magnification. B: At higher magnification, there is a bandlike superficial lymphocytic infiltrate along with vacuolar degeneration at the dermal–epidermal junction.

If the nail matrix is involved diffusely, onychoschizia (lamellar changes with fragility and brittleness) results. Once again, if treated before scarring occurs, the changes are reversible. When the lichenoid inflammation is severe and unchecked, the matrix is replaced by scar connecting the proximal nail fold to the nail bed. As a result, the two epithelia adhere and grow distally together, constituting a pterygium.

Occasionally, lichen planus of the nail bed alone may occur. Proximal onycholysis, to be differentiated from distal onycholysis in psoriasis, occurs because of involvement of the proximal nail bed. The nail plate is otherwise normal. Papular lesions of lichen planus may occur in various locations of the nail bed and lead to focal atrophy. As a result, the overlying nail plate will be focally dimpled or spooned (koilonychia). In some cases, complete shedding of the nail plate due to diffuse nail bed involvement may occur.

BULLOUS DISEASES

Several vesiculobullous diseases may affect the nail unit. In Darier-White disease, nail changes usually occur in association with other clinical findings. Rarely, involvement may be limited to the nail alone. Nail changes may occur in the proximal nail fold, matrix, nail bed, and hyponychium.

The proximal nail fold may show keratotic papules that are histologically similar to those of acrokeratosis verruciformis of Hopf. However, in addition to papillary epidermal hyperplasia, focal areas of suprabasilar acantholysis may be seen (9).

Involvement of the nail matrix in Darier-White disease is usually located in the distal lunula and manifests clinically as a white longitudinal streak. Histologically, this leukonychia is due to foci of persistent parakeratosis in the lower nail plate related to the histology of Darier-White disease of the distal matrix. The features seen are suprabasilar acantholysis, with formation of corps ronds and grains.

The nail bed and hyponychium are commonly involved in Darier-White disease. Involvement may be mild, leading to red and white longitudinal streaks. More severe involvement leads to wedge-shaped, distal, subungual keratosis, accompanied by nail fragility. In time, the nail plate may become markedly thickened. The nail bed epithelium becomes hyperplastic with parakeratosis between the nail bed and nail plate. Suprabasilar clefts are absent in the nail bed (9). An interesting finding is the presence of atypical keratinocytes in the nail bed epidermis, many of which may be multinucleated (9).

Nail involvement in pemphigus vulgaris is uncommon but may affect the proximal and lateral nail folds, leading to chronic paronychia and superficial nail plate changes (10). Biopsy of the involved nail fold reveals suprabasilar acantholysis and positive direct immunofluorescence with immunoglobulin G (IgG) and C3 in the intercellular spaces of the epidermis. Involvement of the matrix causes onychomadesis (proximal separation of the nail plate) (11). Pemphigus foliaceus may also affect the nail unit.

Bullous and cicatricial pemphigoid have been reported to involve the nail unit, with clinical effects implicating involvement of both matrix and nail bed, including longitudinal splits and pterygium formation (12).

Erythema multiforme and toxic epidermolysis may affect the nail matrix, resulting in either sloughing of the nail or, in some cases, scarring, leading to anonychia or pterygium formation (13). Epidermolysis bullosa in many of its manifestations affects the nail unit. Epidermolysis bullosa simplex may cause onycholysis or onychogryphosis. In epidermolysis bullosa simplex–herpetiformis, nail dystrophy or anonychia may result from subungual blister formation. Junctional epidermolysis bullosa may lead to dystrophy and anonychia in all of its forms. Nail changes have been described for the Cockayne-Touraine, albopapuloid, and Hallopeau-Siemens varieties of dystrophic epidermolysis bullosa (14).

CONNECTIVE TISSUE DISEASE

The nail unit is affected by most types of connective tissue disease, primarily in the microvasculature of the proximal nail fold (15). *In vivo* capillary microscopy reveals dilated capillary loops with adjacent hemorrhage and avascularity. This pattern is present in 80% to 95% of patients with progressive systemic sclerosis. However, an identical clinical pattern may be seen in patients with dermatomyositis, other connective tissue disease, and idiopathic Raynaud phenomenon. A crescent-shaped biopsy of the proximal nail fold reveals deposits of eosinophilic PAS-positive material in the keratin of the cuticle (15). These deposits tend to be more extensive in patients with connective tissue disease and in patients with more severe *in vivo* capillary microscopy abnormalities. Direct immunofluorescence can also be performed on a proximal nail fold biopsy revealing vascular deposits in connective tissue disease. More data are needed to determine if a proximal nail fold biopsy to evaluate for the presence and degree of PAS-positive deposits is of value in predicting the development of connective tissue disease in patients with idiopathic Raynaud phenomenon.

INFECTION

Fungal infection of the nails may be the most common nail disorder, accounting for up to 50% of nail disorders (16–19). Onychomycosis is present in 2% to 8% of the general population, rising to 14% to 28% in adults >60 years of age. There are four main types: distal subungual onychomycosis, proximal subungual onychomycosis, white superficial onychomycosis, and candidal onychomycosis. Dermatophytes, mainly *Trichophyton rubrum* and *Trichophyton mentagrophytes* are the most common fungi to cause onychomycosis, accounting for 60% of fungal infections. Nondermatophytes, mainly *Acremonium* sp., *Fusarium*, and *Scopulariopsis*,

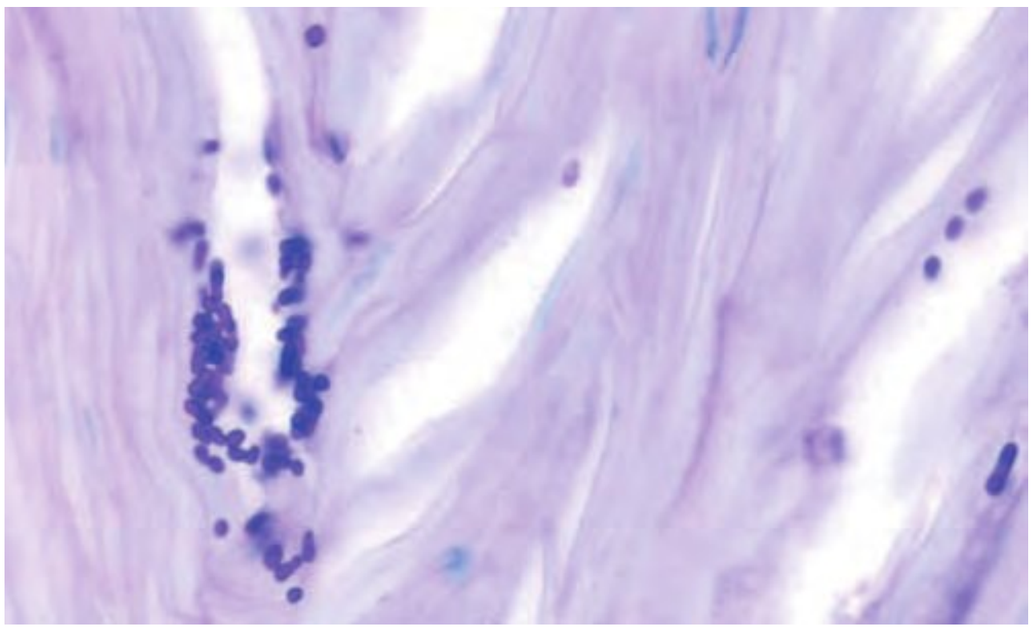

FIGURE 19-5. Candidiasis of the nail plate. Nail clippings showing budding yeasts culture proven to be C. parapsilopsis.

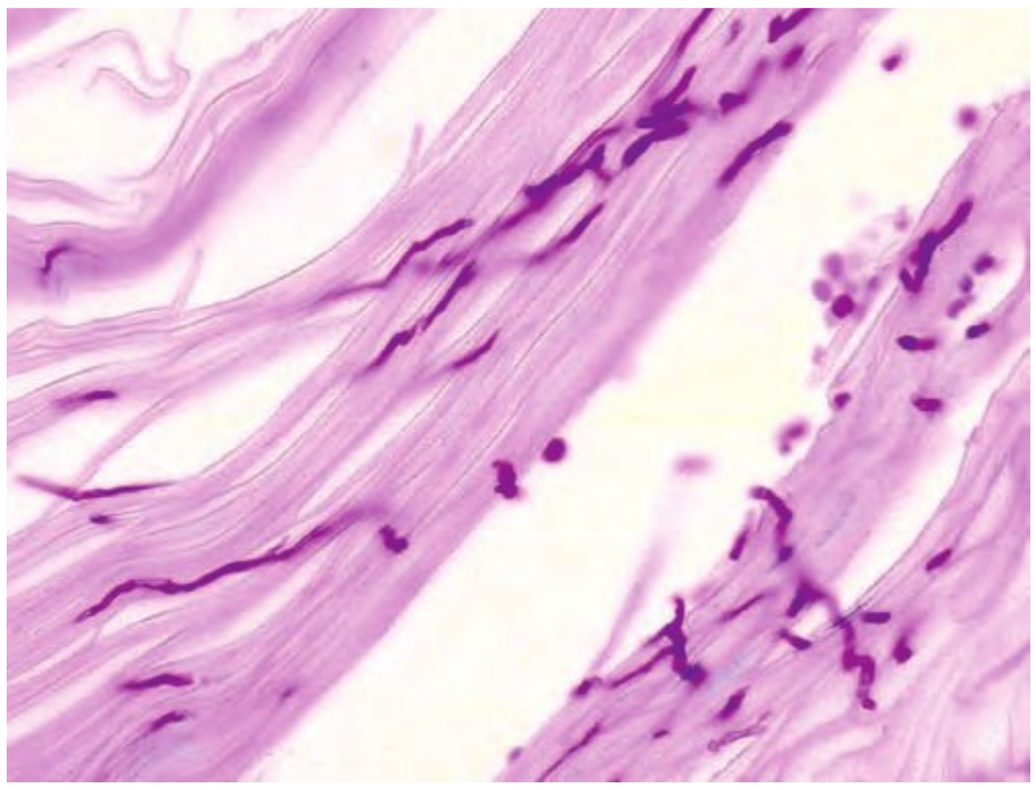

FIGURE 19-6. Onychomycosis of the nail plate. Nail clippings stained by using PAS with diastase showing septate hyphal elements culture proven to be Trichophyton sp. within the nail plate keratin.

and yeasts, mainly *Candida* sp., mostly *Candida parapsilosis* (Fig. 19-5), each account for 20% of infections (20). Ninety percent of toenail infections are caused by dermatophytes of *Trichophyton*, *Microsporum*, and *Epidermophyton* sp.. On the other hand, up to one third of fingernail infections may be caused by yeast forms. Biopsy accompanied by PAS staining has been shown to be the most sensitive test (99%) for diagnosing onychomycosis. PAS stain also has the highest negative predictive value (19). Potassium hydroxide (KOH) with chlorazole black E done on scrapings has been shown to be the most cost-effective test, with a sensitivity of 94%, while culture is the least sensitive test. A PAS with diastase stain should be performed to rule out fungal infection on all nail biopsies because of the overlapping features seen in inflammatory dermatoses involving the nail. This stain reveals fungal organisms that are usually located in the lower stratum corneum near the nail bed epidermis. A PAS with diastase stain performed on a nail biopsy, clippings of infected nail plate, or scrapings of subungual debris will yield a diagnosis of onychomycosis more quickly than fungal culture but will not identify the organism (Fig. 19-6). Distal subungual onychomycosis (Fig. 19-7) is the most common form of onychomycosis and is usually caused by *T. rubrum*. The fungus initially invades the hyponychium and lateral nail folds, causing yellowing, onycholysis, and eventual subungual hyperkeratosis. The nail bed epidermis shows acanthosis, spongiosis, and exocytosis of lymphocytes and histiocytes. In proximal subungual onychomycosis, infection initially involves the area of the proximal nail fold. Proximal white subungual onychomycosis is rare in the general population but common in patients affected with HIV (17). In these patients, proximal white subungual onychomycosis is caused by *T. rubrum*. On the other hand, superficial white onychomycosis is caused by *T. mentagrophytes*, located on the superficial nail plate only (16). In HIV-infected persons, superficial white onychomycosis is usually caused by *T. rubrum* (17). *Candida* sp. are a common cause of chronic paronychia. *Candida* may involve the nail plate and nail bed in patients with chronic mucocutaneous candidiasis and in HIV-infected patients. *Candida albicans* is the major fungus affecting the nail in pediatric patients with AIDS and may cause hypertrophic nail bed infection (17).

Bacterial infections caused by *Staphylococcus aureus* and *Pseudomonas aeruginosa* occur mainly in the nail folds and lead to acute paronychia. Bacteria may also be involved along with *Candida* in chronic paronychia. *Pseudomonas* may colonize onycholytic nail plates, leading to green discoloration (16).

FIGURE 19-7. Onychomycosis of the nail. Distal subungual onychomycosis is seen in the thumb nail.

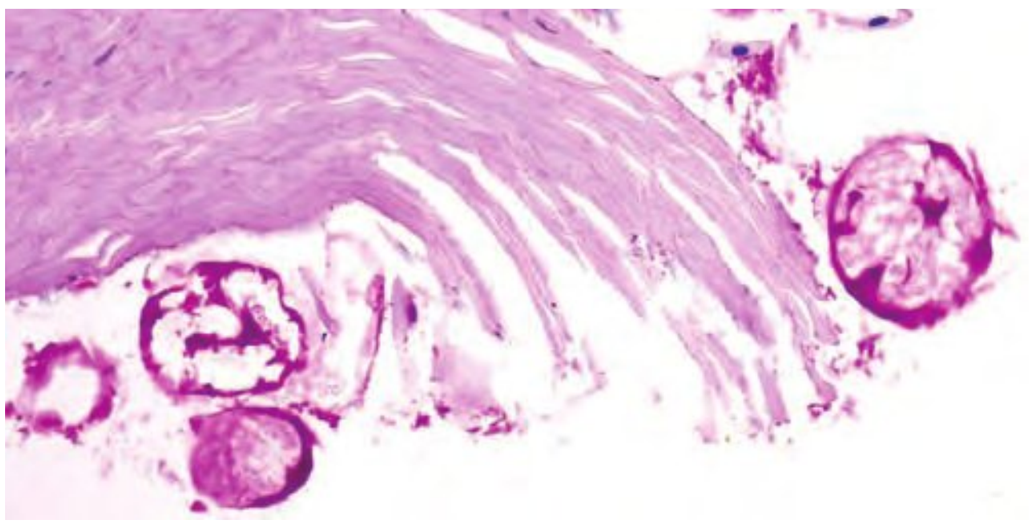

FIGURE 19-8. Scabies of the distal nail. Scrapings of the distal hyponychium stained by using PAS with diastase, which highlights the organism S. scabei.

Sarcoptes scabiei may involve the nail unit. Organisms are often present in distal subungual hyperkeratotic debris found in the hyponychium (Fig. 19-8) and may be a cause of persistent epidemics of scabies because they are seldom identified and treated. Norwegian scabies may cause severe involvement of the nail folds (18).

Herpes simplex type I or II may cause herpetic whitlow or herpetic paronychia involving the nail folds.

Inflammatory Diseases of the Subcutaneous Fat

CLASSIFICATION OF PANNICULITIS

A histopathologic classification of panniculitis is based on the microscopic and macroscopic changes in the subcutaneous fat. The diseases presented in this chapter are divided into groups based on their patterns of involvement of the anatomic structures in the subcutis (1–3) (Table 20-1). However, for definite diagnoses, it is important to consider whether or not there are associated changes, such as in the overlying dermis and epidermis, as well as what types of inflammatory cells are involved (4). Clinical history and distribution of lesions often are important. The subcutaneous fat can be divided into the following anatomic regions: the septa between fat lobules, the fat lobules themselves, the blood vessels, and the nerves. When the septa are involved by inflammation, the histologic changes include septal widening due to edema, hemorrhage, and fibrosis or inflammatory infiltration by neutrophils, eosinophils, and macrophages, with or without granuloma formation. Involvement of the fat lobules includes necrosis, cellular infiltration, and fibrosis. Necrosis of fat is common, and the different types of necrosis have been classified by etiology as ischemic, traumatic, enzymatic, metabolic, inflammatory, and infectious. The cellular infiltrate associated with necrosis can be composed predominantly of polymorphonuclear leukocytes (neutrophils and eosinophils), lymphocytes (occasionally with germinal centers), and macrophages (with or without granulomas). Fibrosis of the fat lobules is a late event, which is the end result of multiple causes of lobular panniculitis ranging from that due to simple trauma to that due to complex connective tissue diseases. By analysis of the patterns of involvement of these regions, it is possible to make a specific diagnosis in a patient with panniculitis even when the interactions between inflammatory cells and target cells in panniculitis show considerable overlap in their basic mechanisms at the cellular and molecular levels.

Although the classification of panniculitis stresses the differences between the lobules of fat and the interlobular septa, there is an intimate relationship between the two. The septa contain the major blood vessels and nerves that supply the delicate plexus of vessels within the fat lobules and also contain the major vessels that pass on to the overlying dermis. When blood vessels are the target of inflammation, the different sizes of the blood vessels and their wall structures can cause certain diseases to be localized in the fat. Inflammation of the walls of large vessels often involves only the fat lobules immediately adjacent to the vessels. The medium-sized vessels are in the septa, and inflammation of their walls leads to septal panniculitis and in some cases also leads to secondary ischemic destruction of the fat lobules. Inflammation of the small vessels can affect the septa, lobules, or both. The relatively sluggish blood flow through the small vessels in the fat facilitates the exudation of substances and the emigration of inflammatory cells into the panniculus. For example, immune complexes or medications can be deposited in the walls of these vessels. Moreover, the subcutaneous fat cells, or adipocytes, form a closely regulated metabolic reserve, on which certain chemical compounds interact preferentially; for example, pancreatic lipases that have been released into the circulating blood or fat-soluble chemicals and medications can localize in the fat and cause metabolic or inflammatory changes. Hereditary and gender differences exist in fat metabolism, and these can be expressed in metabolic differences in different anatomic sites in the same individual. For example, *in vivo* and *in vitro*, abdominal subcutaneous adipose tissue is more responsive metabolically to beta-adrenergic stimulation than is the subcutaneous fat of the thigh. The thickness and orientation of the septa differ in normal males versus females and hypoandrogenized males, which suggests that this is under hormonal control (5). The septa are thicker in areas of the skin that are subjected to greater weight bearing, suggesting that genetic programming and mechanical forces both influence the thickness of the normal septa.

In the upper portion of the panniculus are the secretory coils of eccrine and apocrine glands and the lower portion of hair follicles. Consequently, diseases of the skin appendages can involve the panniculus secondarily. The subcutis also has a lower border on the fascia and inflammatory diseases that affect the fascia can penetrate upward into the septa and lobules.

Unfortunately, a significant problem is that the clinical appearance of the lesions of panniculitis is not very specific, since most patients have deep erythematous nodules. A consideration of the clinical distribution, number of lesions, and whether or not they are ulcerated help in the formulation of a clinical differential diagnosis. Some early clinical studies led to the description of clinical "entities," such as Weber-Christian

TABLE 20-1 Classification of Panniculitis

I. With prominent vasculitis (septal or lobular)
  A. Neutrophilic
    1. Leukocytoclastic immune complex vasculitis

    3. Thrombophlebitis
    4. Type 2 leprosy reaction (erythema nodosum leprosum; Lucio's phenomenon)
    5. Behçet's syndrome
  B. Lymphocytic
    1. Nodular vasculitis
    2. Perniosis
    3. Angiocentric lymphomas
    4. Lupus erythematosus
  C. Granulomatous
    1. Nodular vasculitis/Erythema induratum of Bazin
    2. Type 2 leprosy reaction
    3. Wegener's granulomatosis
    4. Churg-Strauss allergic granulomatosis
II. Without prominent vasculitis
  A. Septal inflammation
    1. Lymphocytic and mixed
      a. Erythema nodosum
      b. Variants of erythema nodosum
    2. Granulomatous
      a. Palisaded granulomatous diseases
      b. Sarcoidosis
      c. Subcutaneous infection
        i. Tuberculosis
        ii. Syphilis
      d. Necrobiosis lipoidica
      e. Necrobiotic xanthogranuloma
    3. Sclerotic
      a. Scleroderma/Morphea
      b. Eosinophilic fasciitis
      c. Ischemic liposclerosis
      d. Toxins, particularly injected ones
      e. Postirradiation panniculitis
  B. Lobular inflammation
    1. Neutrophilic
      a. Infection
      b. Ruptured folliculitis and cysts
      c. Pancreatic fat necrosis
      d. Alpha-1 antitrypsin deficiency
    2. Lymphocytic
      a. Lupus panniculitis (lupus profundus)
      b. Poststeroid panniculitis
      c. Ischemic lipomembranous panniculitis
      d. Localized lipedema (minimal infiltration)
      e. Lymphoma/Leukemia
    3. Macrophagic
      a. Rosai-Dorfman disease
      b. Histiocytic cytophagic panniculitis
      c. Ischemic lipomembranous panniculitis
      d. Insulin-resistant diabetes with CD68+ infiltrate
    4. Granulomatous
      a. Erythema induratum/Nodular vasculitis
      b. Palisaded granulomatous diseases
      c. Sarcoidosis
      d. Crohn's disease
      e. Ruptured follicular cyst
    5. Mixed inflammation, with many foam cells
      a. Alpha-1 antitrypsin deficiency
      b. Weber-Christian disease
      c. Traumatic fat necrosis
      d. Factitial panniculitis (foreign body panniculitis)
    6. Eosinophilic
      a. Eosinophilic panniculitis
      b. Arthropod bite reaction
      c. Hypersensitivity reaction to internal parasites or medications
    7. Enzymatic fat necrosis
      a. Pancreatic enzyme panniculitis
      b. Alpha-1 antitrypsin deficiency panniculitis
    8. Crystal deposits
      a. Sclerema neonatorum
      b. Subcutaneous fat necrosis of the newborn
      c. Gout
      d. Oxalosis
      e. Calcific panniculitis/Calciphylaxis
      f. Cold panniculitis
      g. Poststeroid panniculitis
    9. Altered fat pattern
      a. Lipoatrophy
      b. Lipodystrophy
      c. Lipedema
    10. Sclerotic
      a. Ischemic lipodermatosclerosis
      b. Membranous panniculitis (lipomembranous panniculitis)
      c. Postirradiation panniculitis
      d. Eosinophilic fasciitis, late stage
      e. Morphea and scleroderma
III. Mixed patterns: In the natural progression of lesions of vasculopathic panniculitis, as well as in septal or lobular panniculitis, a complex mixture of patterns can result depending on the stage of evolution of the disease. For example, factitial panniculitis can exhibit a mixed pattern with microscopic features (hematoma, foreign bodies, dermal lesions, and fibrosis) that fit into more than one category. Subcutaneous panniculitic T-cell lymphoma may present with patterns of leukemic infiltration, lupus erythematosus–like lesions, granulomatous lesions, and angiodestructive vasculitic lesions.

disease or panniculitis of Rothmann and Makai, which unfortunately exhibit nonspecific histopathologic changes that occur in a variety of actual diseases that cause panniculitis.

Another major problem in the classification of panniculitis is that often the size of the biopsy is inadequate. The individual lobules of fat may be more than 1 mm in diameter, and several lobules and septa are needed to discern accurately a pattern of involvement. Consequently an adequate biopsy should be an elliptical, excisional, or incisional one that gives at least a specimen of fat 6 mm in greatest dimension and should include deep subcutis as well as the overlying skin. Only a few diagnoses can be made on a specimen of aspirated fat or a needle or punch biopsy of a nodule in the subcutis; the use of these biopsy modalities is to be discouraged for purposes of histologic classification of panniculitis.

A third problem is that most of the lesions have a time course in which there occurs an early form of inflammation with varying degrees of vascular changes, followed by a stage of phagocytosis of fat and a more or less pronounced granulomatous reaction, and by a final stage of fibrosis. Such a time course is evident in the overall lesion and may be different in various areas of the lesion. With small biopsies or with a nonspecific pattern of inflammation, a simple categorical diagnosis of "panniculitis" may be necessary until further studies and clinical follow-up information allows the placement of the disease into a more exact category (6–8).

Table 20-1 presents a summary of the classification of panniculitis. Not all of the disease entities are presented in detail in this chapter, and some can be found elsewhere in this text: leukocytoclastic vasculitis (Chapter 8), systemic polyarteritis nodosa (Chapter 8), sarcoidosis (Chapter 14), granuloma annulare (Chapter 14), rheumatoid nodule (Chapter 14), necrobiosis lipoidica (Chapter 14), scleroderma (Chapter 10), necrobiotic xanthogranuloma (Chapter 26), and gummatous tertiary syphilis (Chapter 22).

ERYTHEMA NODOSUM

Clinical Presentation. An acute form and a chronic form of erythema nodosum exist, which differ in their clinical manifestations but do not have uniformly recognized differences in their histologic characteristics (1,2,7,9).

In the *acute form* of erythema nodosum, there is a sudden appearance of tender, bright red or dusky red-purple nodules to plaques that only slightly elevate the level of the skin surface (Fig. 20-1). The lesions vary from 1 to 5 cm in diameter and have a strong predilection for the anterior surfaces of the lower legs, although they may occur elsewhere, especially on the calves, thighs, and, in severe cases, on the forearms, hands, and even the face. They occur mostly on the dependent regions of the body and tend to be distributed symmetrically. The lesions do not ulcerate and generally involute within a few weeks without leaving a depressed scar. As a result of the intermittent appearance of new lesions, the disease may persist for several months. The acute disease often is accompanied by fever, malaise, leukocytosis, and arthropathy (10). The lesions are tender and warm. Lesions near a joint can mimic an arthritis. Focal hemorrhages are common and can cause the lesions to resemble bruises (erythema contusiforme), even to changing in color from red to purple and on to green and blue, as they age and resolve. Bilateral hilar adenopathy can be present in patients with acute erythema nodosum without sarcoidosis since a number of pulmonary infections can produce both hilar adenopathy and erythema nodosum. Erythema nodosum occurs in 10% to 20% of patients with sarcoidosis and is thought to portend a good prognosis (10).

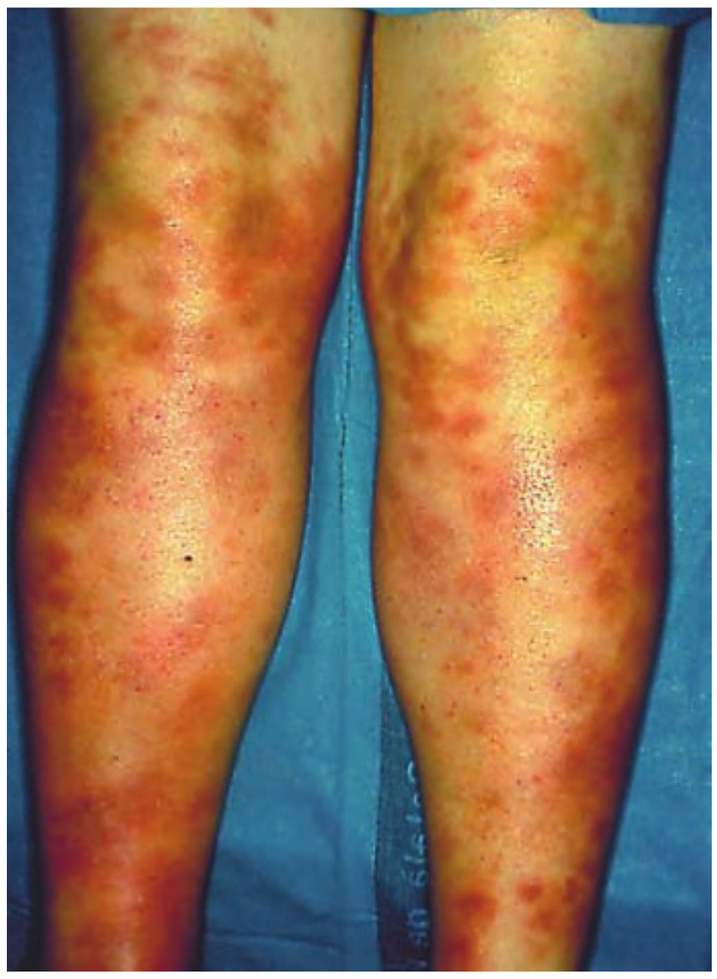

FIGURE 20-1. Erythema nodosum. Erythematous nodules are abundant on the anterior shins bilaterally.

The *chronic form* of erythema nodosum is also known as *erythema nodosum migrans* (11) or *subacute nodular migratory panniculitis of Vilanova and Pinol* (12). There are one or several red, subcutaneous nodules that are found, usually unilaterally, on the lower leg. Vilanova observed that almost all of the patients were women (16 to 65 years of age) with a solitary lesion and a recent history of sore throat and arthralgia. Tenderness is slight or absent. The nodules enlarge by peripheral extension into plaques, often with central clearing. The duration may be from a few months to a few years.

Histopathology. The histologic changes are present mainly in and near the septa of the subcutaneous tissue (Fig. 20-2). The overlying dermis often has only a minimal to moderate, superficial and deep perivascular lymphocytic infiltrate.

In the *early lesions of acute erythema nodosum*, there is edema of the septa with a lymphohistiocytic infiltrate, having a slight admixture of neutrophils and eosinophils (13) (Fig. 20-3A1, B, C). Focal fibrin deposition and extravasation of erythrocytes occur frequently (6) and can be revealed by spectral microscopy (Fig. 20-3A2). Often, the inflammation is most intense at the periphery of the edematous septa and extends

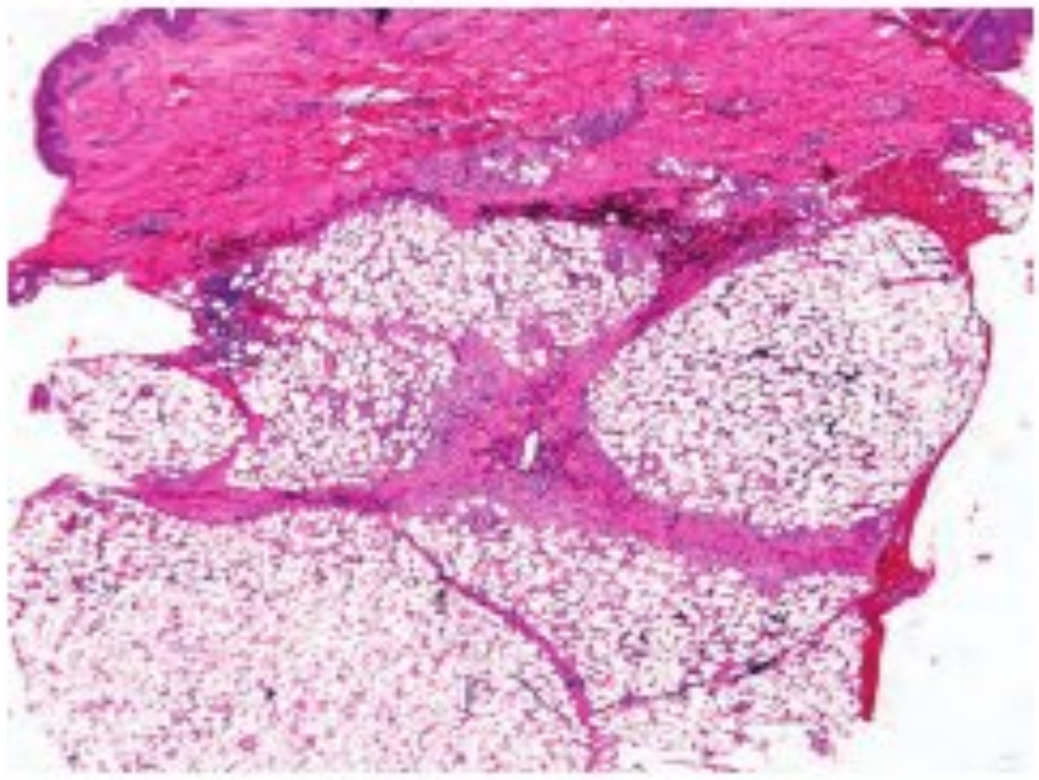

FIGURE 20-2 Acute erythema nodosum. Most of the inflammation is in the subcutis, in and near the septa. The septa at the bottom of the figure are almost normal in thickness, whereas the upper portion of the subcutis has thickened septa.

into the periphery of the fat lobules between the individual fat cells in a lacelike fashion. Necrosis of the fat is not prominent. Rarely, clusters of neutrophils are present or the infiltrate is predominantly neutrophilic (14) (Fig. 20-4). Clusters of macrophages around small blood vessels, or a slitlike space, occur in early lesions and are known as *Miescher's radial nodules* (15,16) (Fig. 20-5). Some authors have failed to find central vessels (2) and have considered Miescher's nodules to be characteristic of erythema nodosum, stating that they can be found in all stages of erythema nodosum (16). The degree of vascular involvement is variable (6,17) (Fig. 20-6). Usually, there is edema of the walls of veins with separation of the muscular layers (Fig. 20-6B). Infiltration by lymphocytes is common, but neutrophils and eosinophils can be present as well. Necrosis of the vessel walls is very rare but has been observed in a few patients with lesions clinically indistinguishable from erythema nodosum (9,18). For example, focal vasculitis has been found in a few patients with acute erythema nodosum secondary to infections (19) and in a few cases of recurrent

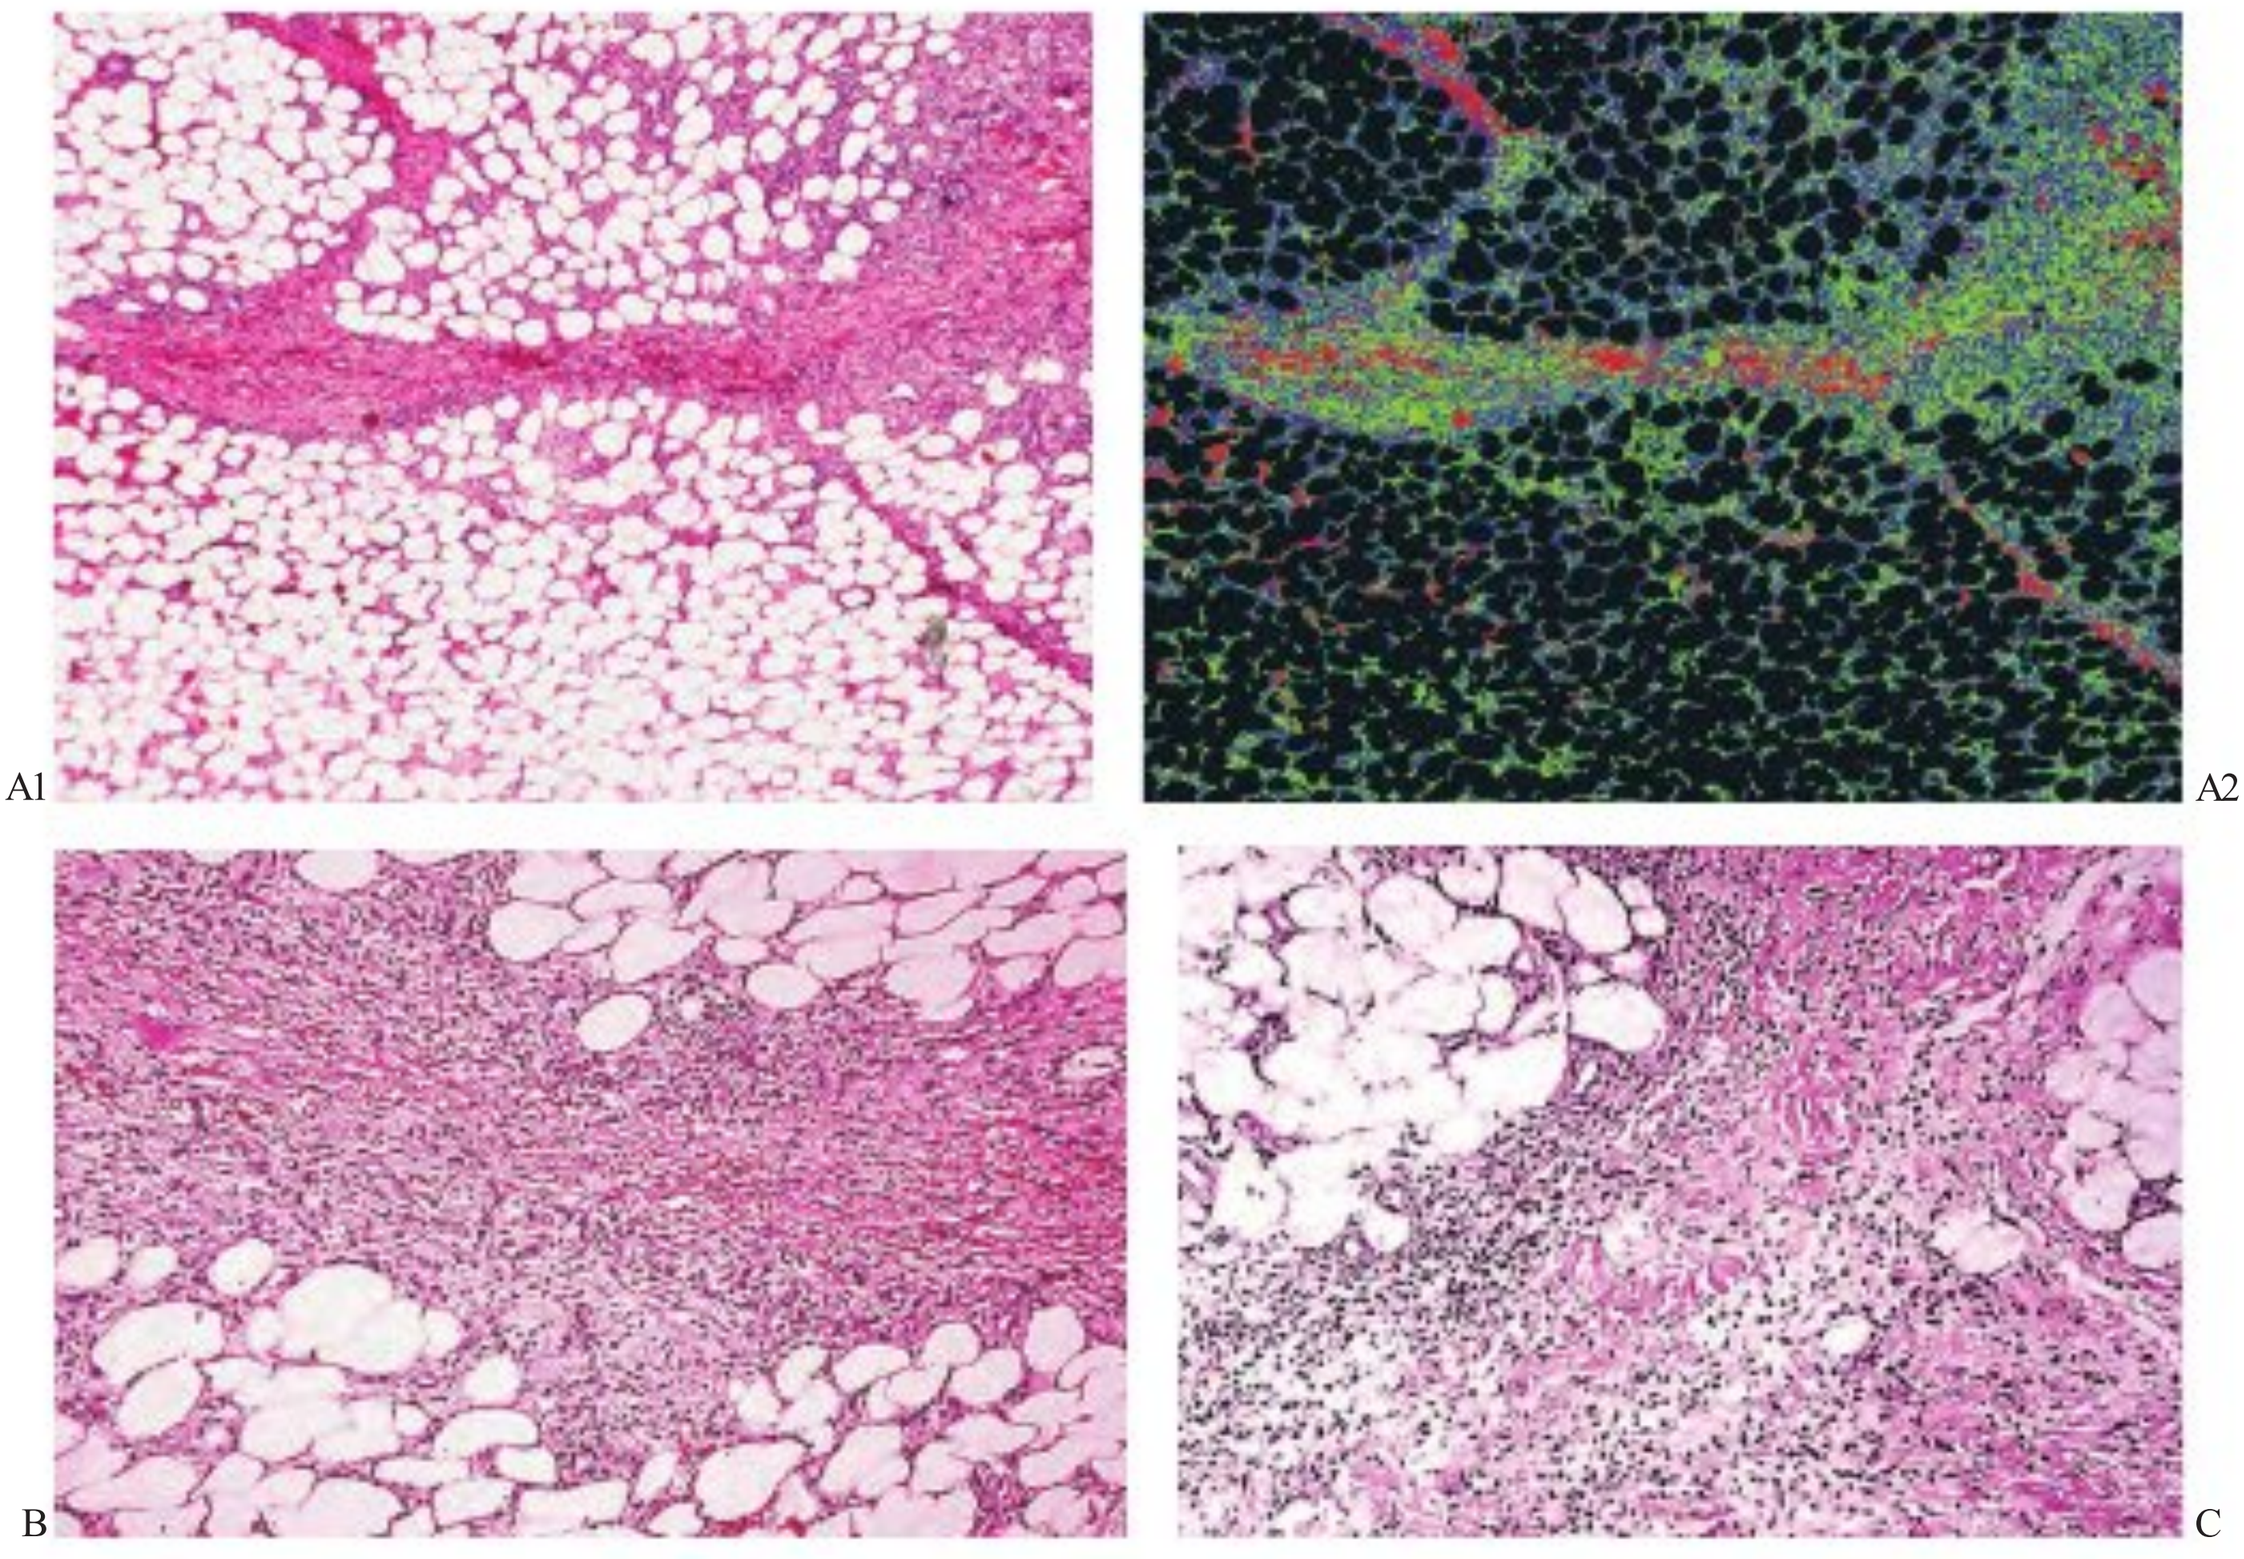

FIGURE 20-3 Acute erythema nodosum. A1: Acute erythema nodosum with inflammation at the junction of the septa and lobules with some hemorrhages. A2: A matching spectral image showing the spectral domains of red blood cells in the hemorrhages in red, as distinguished from the spectral domain of the eosin-stained collagen here shown in green. Hematoxylin in nuclei is shown in blue. B, C: Higher magnification of a septal region showing the paraseptal inflammation (B) and early fibrosis of the edematous septa in acute erythema nodosum (C).

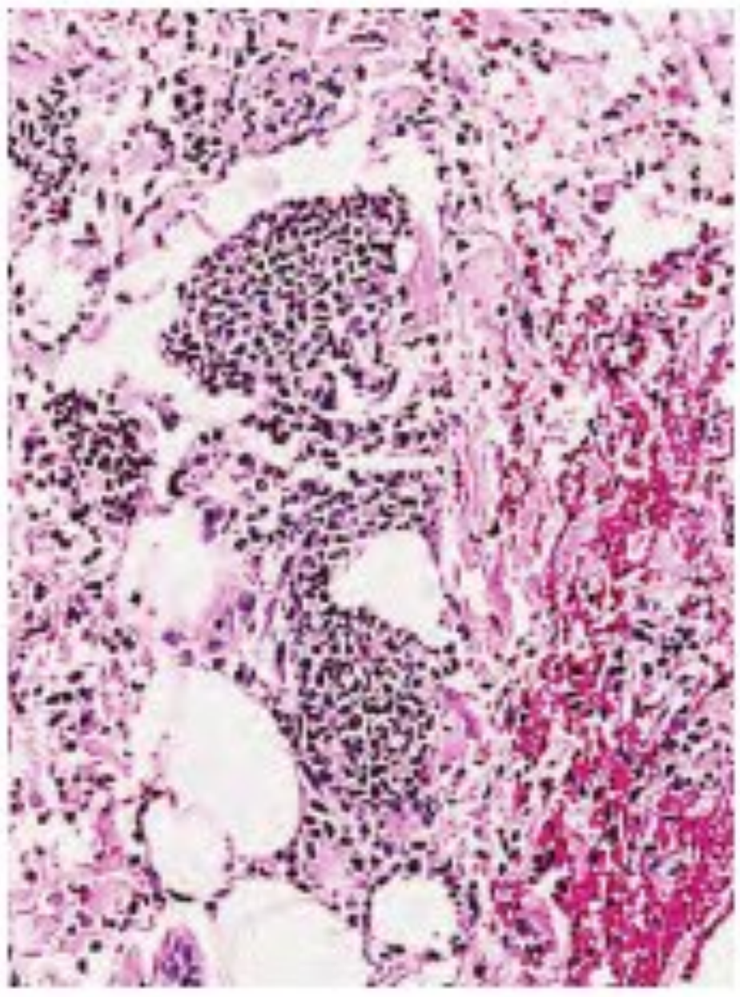

FIGURE 20-4 Acute erythema nodosum. Clusters of neutrophils can be found in the paraseptal region, without evidence of intact bacteria.

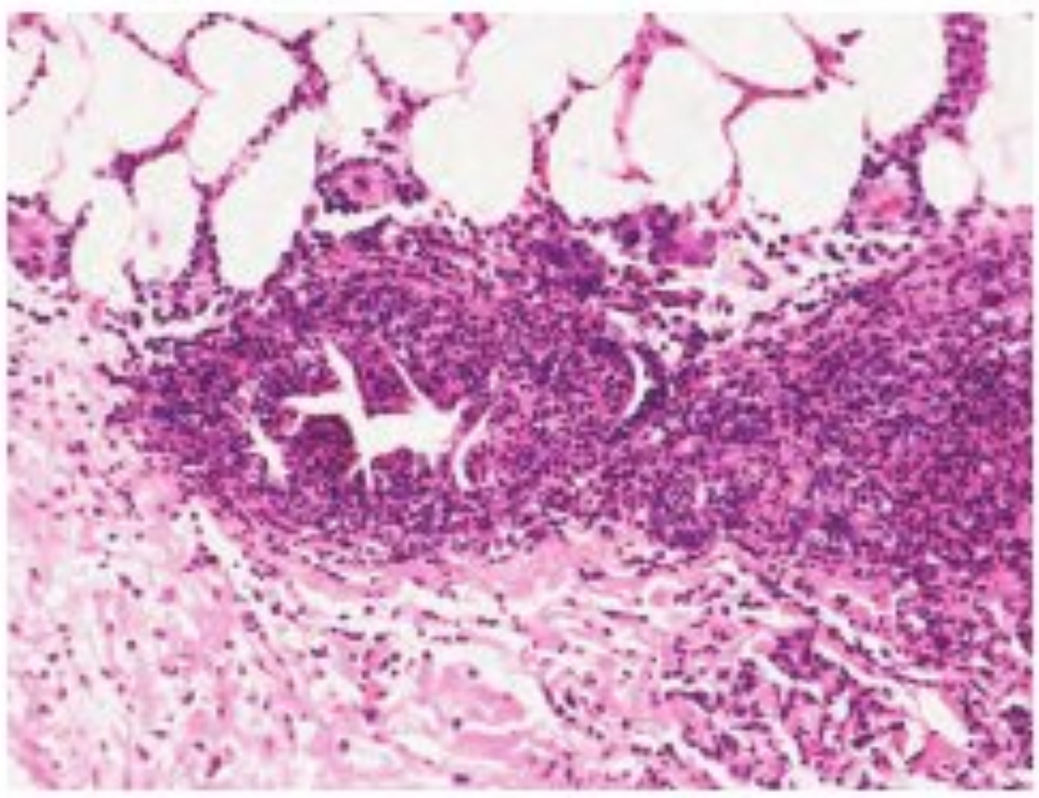
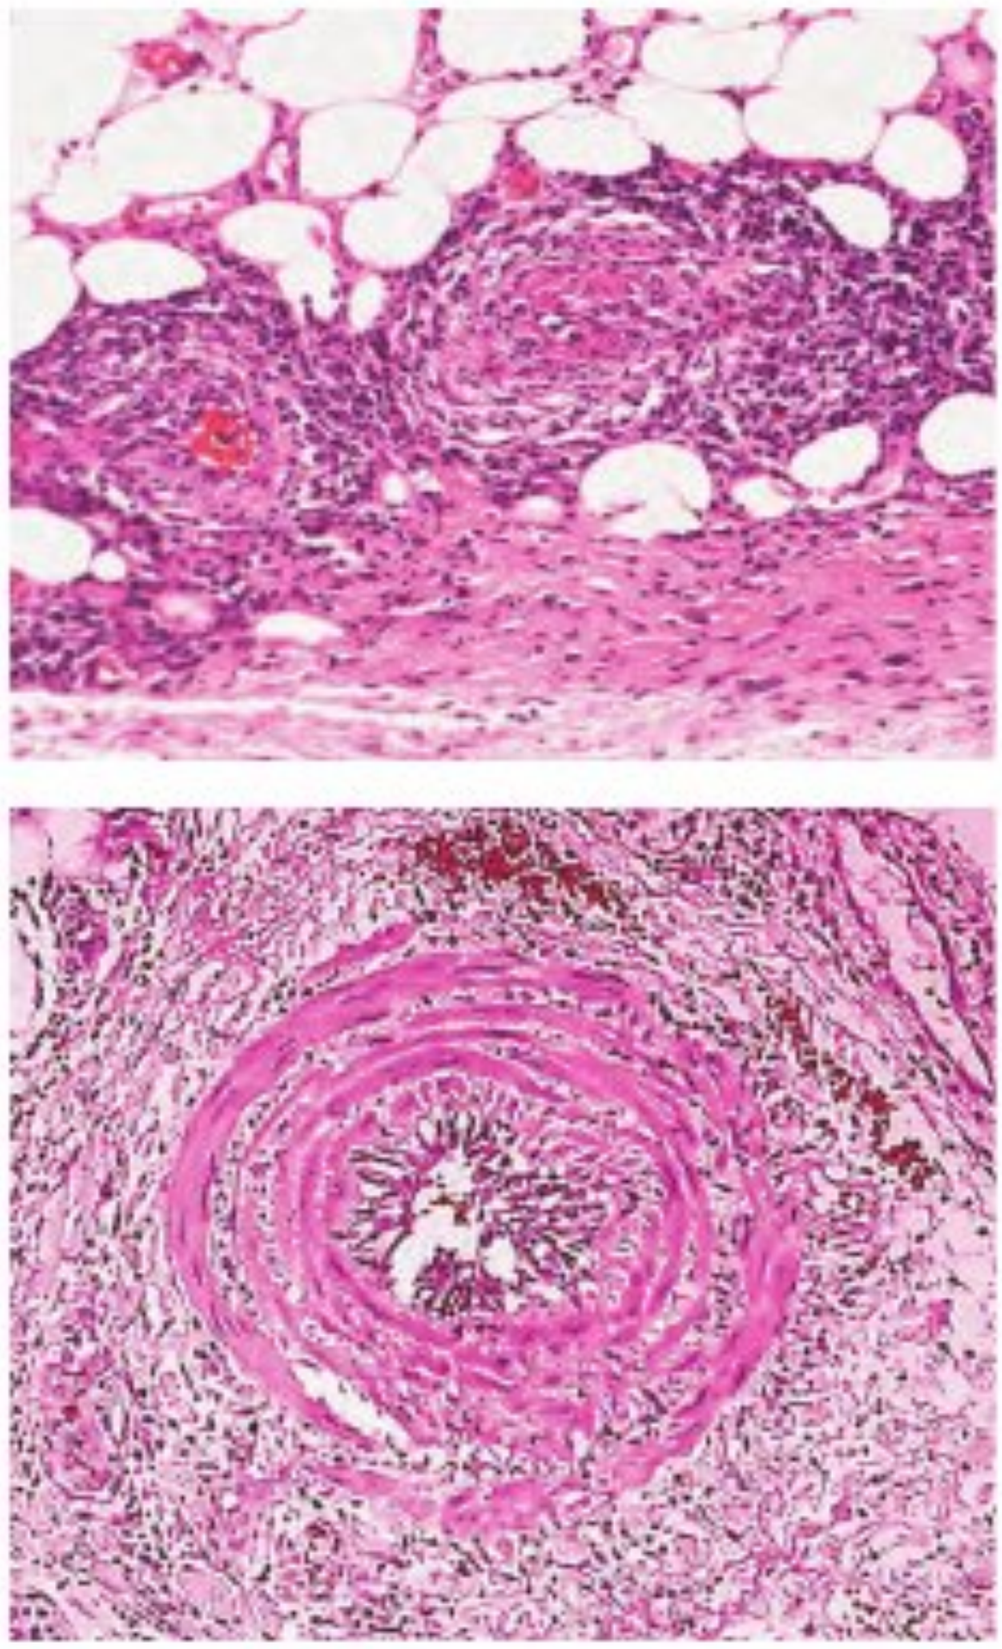
erythema nodosum that is secondary to medications or estrogenic oral contraceptives (Fig. 20-6C).

Later lesions of acute erythema nodosum show widening of the septa, often with fibrosis and with inflammation at the edges of the septa and involving the periphery of the fat lobules (Fig. 20-7). Neutrophils usually are absent, and the vascular changes are less prominent than in early lesions. There are more macrophages in the infiltrate. Macrophages at the edges of the fat lobules show phagocytosis of lipid from damaged adipocytes, and the small droplets of lipid in their cytoplasm give them a "foam cell" appearance. Granulomas formed by macrophages, without lipid deposition, are more frequent





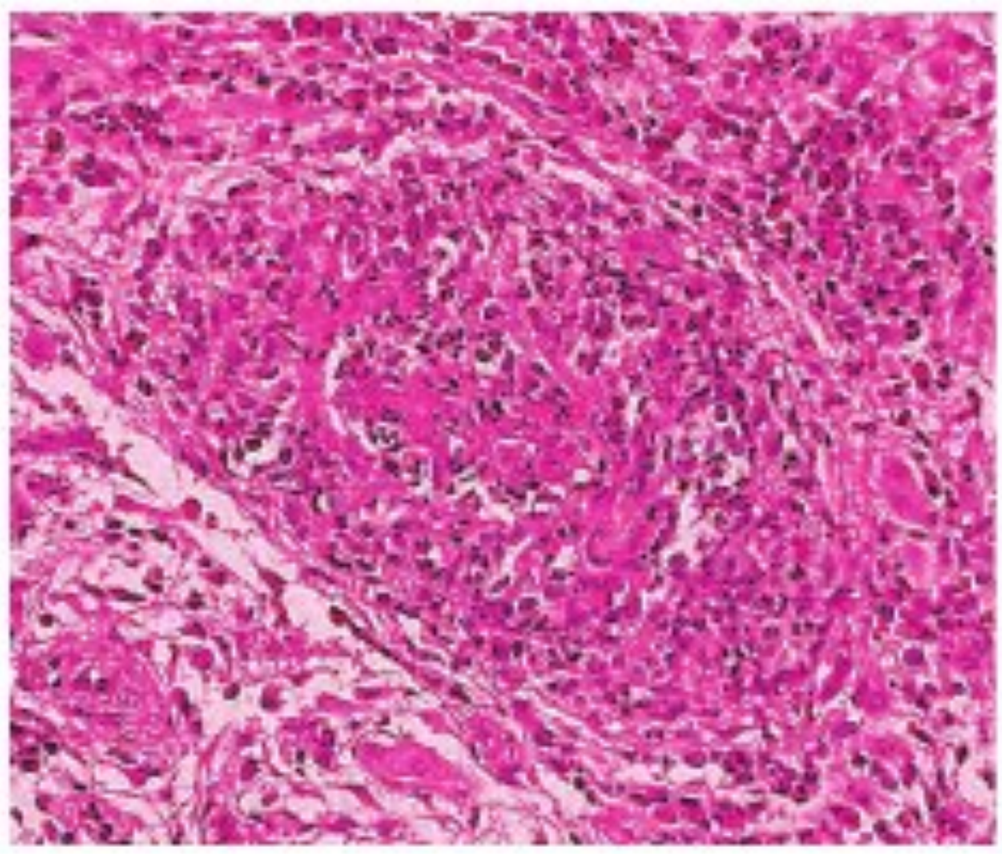


FIGURE 20-5 Acute erythema nodosum. Miescher's radial granulomas are characteristic findings and are formed by macrophages and neutrophils.

A: Vascular damage with a mixed neutrophil and macrophage infiltrate and thrombosis. B: Edema and inflammation in the wall of a small vein in the septa. C: More advanced inflammation of the wall of a vein in erythema nodosum.

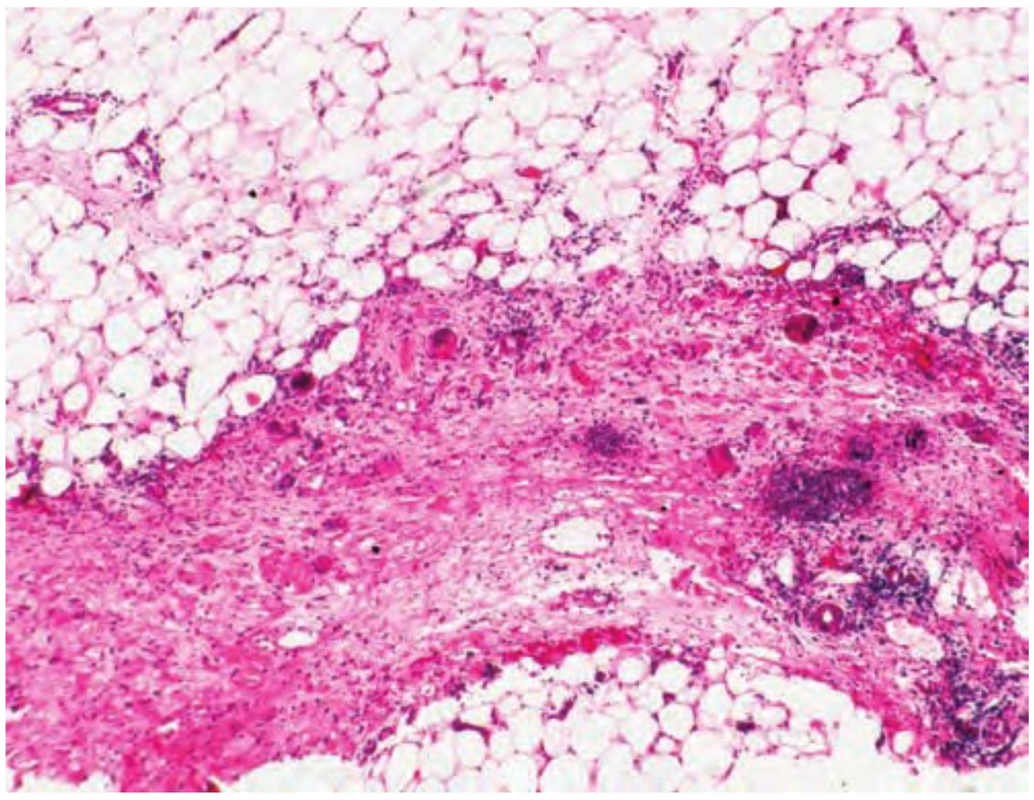

FIGURE 20-7 Late erythema nodosum. Fibrosis of the thickened septa is advanced and accompanied mainly by a lymphocytic infiltrate, often with a few eosinophils.

when late lesions are compared with early ones (Fig. 20-8). The granulomas often are loosely formed with macrophages predominating in a focus with multinucleated giant cells. Occasionally, well-formed, discrete sarcoidal granulomas occur in small numbers in the septa. The multinucleated cells usually have an irregular distribution of the nuclei in the cytoplasm. The oldest lesions have septal widening and fibrosis with a decrease in all of the inflammatory cells.

In *chronic erythema nodosum*, the histologic findings are generally similar to those of the late stages of acute erythema nodosum. However, granulomas and lipogranulomas often are more pronounced in chronic erythema nodosum. There is vascular proliferation and thickening of the endothelium with extravasation of erythrocytes (20). In some instances,

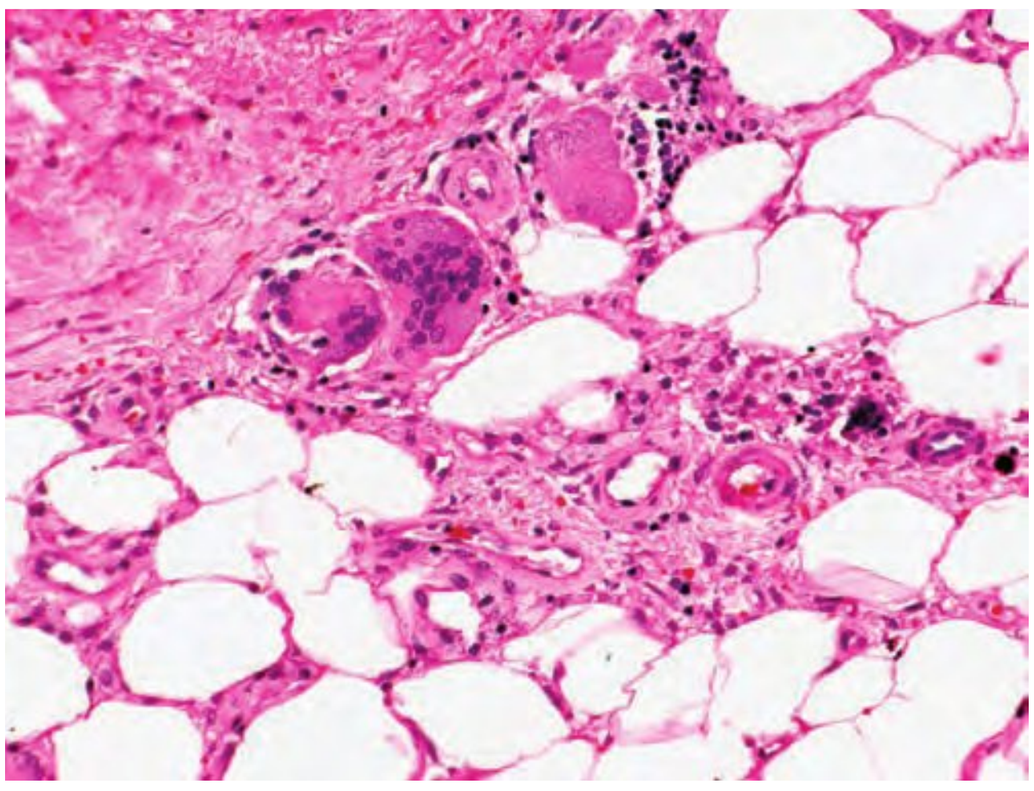

FIGURE 20-8 Late erythema nodosum. Multinucleated giant cells are common in the septa of late lesions. Tuberculoid granulomas can also be found.

numerous well-formed granulomas can be found and consist of epithelioid macrophages and giant cells without caseous necrosis (6). Although significant degrees of vasculitis have been observed by some authors (12,21), others have found vascular changes to be slight or absent (22,23). The presence of thickened fibrotic septa with marked capillary proliferation and massive granulomatous reaction have led several authors to consider *erythema nodosum migrans* as an entity separate from the late lesions of acute erythema nodosum (24). Other authors consider all of these histologic patterns to be included within the spectrum of chronic erythema nodosum (2,9).

Pathogenesis. Although the cause of erythema nodosum cannot always be determined in an individual patient, streptococcal infection is the most common among the known causes, especially in children, as evidenced by elevation of antistreptolysin O titers. The diseases that can be associated with erythema nodosum are numerous and have been reviewed recently (2,25). In short, they may be divided into the following: infections with bacteria, fungi, or protozoa; viral diseases; malignancies; medications; and miscellaneous conditions. The most frequent bacterial infections are streptococcal infection, tuberculosis, *Yersinia enterocolitica* infection (26), brucellosis, leptospirosis, tularemia, *Chlamydia* infection, and *Mycoplasma pneumoniae* infection. The most frequently associated fungal infections are coccidioidomycosis, histoplasmosis (27), dermatophytosis, aspergillosis, and blastomycosis, depending on the geographic location and immune status of the patient. Protozoal infections such as toxoplasmosis, amoebiasis, and *Giardia* infection can cause erythema nodosum. Among the associated viral and rickettsial infections are herpes simplex, infectious mononucleosis (due to Epstein-Barr virus infection), lymphogranuloma venereum, ornithosis, and psittacosis. Erythema nodosum occurs with some cases of leukemia, Hodgkin's disease, and non-Hodgkin's lymphomas, as well as with some other cancers, particularly after irradiation or other treatment releases antigens into the circulation by tumor necrosis. Among the miscellaneous associations are several diseases that can cause considerable difficulty in diagnosis, particularly acute sarcoidosis, which can have erythema nodosum as part of a symptom complex along with slight hilar adenopathy, fever, arthralgias, and occasionally acute iritis, uveitis, and parotid swelling (*uveoparotid fever*). The sarcoidal granulomas that can occur in erythema nodosum are less frequent, are septal in location, and are associated with edema, in contrast to the abundant granulomas that occur in subcutaneous sarcoidosis, without much edema and mostly in the lobules of the subcutaneous fat. Likewise, Crohn's disease can be associated with erythema nodosum (10), and the two diseases can be difficult to distinguish from each other histologically in the skin involvement unless there is ulceration, which does not occur in erythema nodosum (28). Other associated conditions are ulcerative colitis, and Behçet's disease (29). The panniculitis in Behçet's disease may resemble erythema nodosum clinically but often is different histologically in having neutrophilic and

lymphocytic vasculitis, which is predominantly lobular in distribution (30). Erythema nodosum and Sweet's syndrome have been reported in the same patient (31). Among the many medications that can cause erythema nodosum, the most common ones are sulfonamides, estrogens, and oral contraceptives (32). There are rare associations with aminopyrine, antimony compounds, arsphenamine, bromides, iodides, phenacetin, salicylates, immunizations, and vaccinations (2). Such a great diversity in inciting agents and circumstances suggests that several mechanisms may be capable of triggering the clinical and histopathologic changes that are classified as erythema nodosum.

Direct immunofluorescence studies have shown deposits of immunoglobulins only very rarely in the blood vessel walls in erythema nodosum (7). Small amounts of complement in the vessel walls and abundant fibrin around the vessels are frequent but nonspecific findings. On electron microscopic examination, nonspecific vascular changes consisting of damage to endothelial cells and lymphocytic infiltration have been described (33).

The occurrence of erythema nodosum as a response to medications and to tuberculin skin testing in patients with a positive reaction suggest that a type IV delayed hypersensitivity reaction may play an important role, especially given the paucity of reports of immunoglobulin deposition and the usual failure to detect circulating immune complexes (34). However, in some patients, a type III immune complex reaction could be responsible. Circulating immune complexes and rheumatoid factors have been detected in some patients with sarcoidosis and erythema nodosum (35). In approximately 50% of cases, there is no cause identified (36). The predilection for the anterior shins and for dependent parts of the body suggests that trauma or sluggish blood flow play a role in the localization of the lesions, but other factors such as the distribution of immunoreactive macrophages and dendritic cells need investigation as well.

Differential Diagnosis. Erythema nodosum needs to be distinguished from *erythema induratum* and *nodular vasculitis*. Vasculitis and zones of fat necrosis are absent in erythema nodosum and frequent in erythema induratum. In patients suspected to have erythema nodosum but with necrotizing vasculitis, the possibility of *cutaneous polyarteritis nodosa* must be considered. In the latter disease, medium-sized arteries rather than veins or small-caliber blood vessels are affected, with necrosis of the walls of affected arteries. In contrast, *nodular vasculitis* has mainly lymphocytic infiltration with fibrous thickening and obliteration of vascular lumens. *Superficial migratory thrombophlebitis*, unlike erythema nodosum, has a large vein containing thrombus in the center of the lumen. *Syphilitic gummas* are ulcerative irregular granulomatous lesions that produce depressed scars. *Subcutaneous tuberculosis* can mimic erythema nodosum in lesions that are extending from underlying organs, soft tissues, or bone. Stains for acid-fast organisms and cultures are needed. Subcutaneous tuberculosis can spare the upper portion of the panniculus, whereas erythema nodosum does not. Erythema nodosum does not have granulomas or sclerosis in the overlying dermis, and in this way can be distinguished from most cases of sarcoidosis, scleroderma, necrobiosis lipoidica diabeticorum, ruptured follicular cysts, and factitial traumatic panniculitis.

EOSINOPHILIC PANNICULITIS AND FASCIITIS

Clinical Features. The diagnosis of eosinophilic panniculitis is based on the histologic appearance of numerous eosinophils in the fat, which can be found as a reaction pattern in the following clinical diseases or conditions: erythema nodosum, vasculitis, arthropod bites, parasitic infection, drug injections, Well's syndrome, eosinophilic fasciitis, hypereosinophilic syndrome, and eosinophilic leukemia (37–41).

Histopathology. Usually, there is a mixed inflammatory infiltrate of lymphocytes, macrophages, and numerous eosinophils, involving both septa and lobules of the subcutis (Fig. 20-9). A pure infiltrate of normal eosinophils indicates the hypereosinophilic syndrome, in contrast to eosinophilic leukemia, in which the eosinophils are cytologically atypical. The overlying dermis should be studied carefully for important findings as well. The eosinophils aggregate often on dermal collagen fibers and degranulate to form masses of eosinophilic granules, which are called *flame figures* in Well's syndrome. The histologic sections should be searched for parasites, but they may be at a site distant from the skin, such as in the gastrointestinal tract or other sites, in which case the panniculitis is a reaction to circulating antigens.

Differential Diagnosis. The differential diagnosis includes reactions to foreign bodies (need to test for polarizable material in the sections), reactions to parasites, deep arthropod bite reactions, or drug injections. Peripheral blood studies will rule

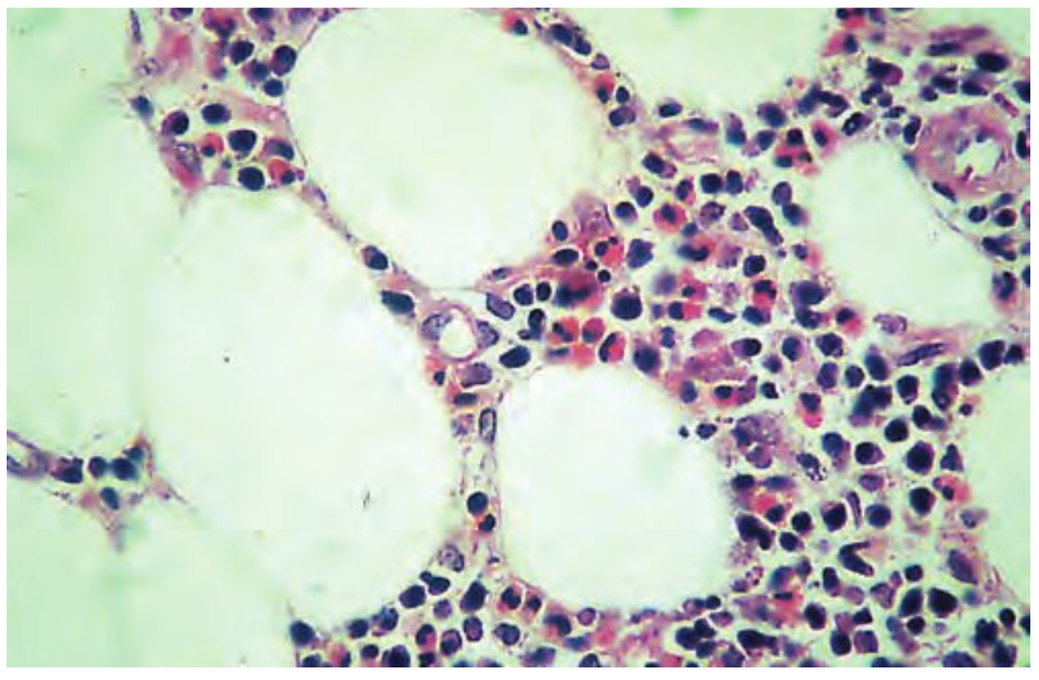

FIGURE 20-9 Eosinophilic panniculitis. Eosinophils in abundance in the fat lobules is not a specific finding, which can be seen in a variety of disorders, most commonly in arthropod bite reactions.

in or out eosinophilic leukemia, which also has eosinophilic precursor cells in the infiltrate in the subcutis. Macrophages can ingest eosinophil granules from degranulated eosinophils in a variety of hypersensitivity reactions and should be distinguished from true eosinophilic myelocytes and metamyelocytes. Several patients have been reported to have a hypereosinophilic syndrome with lymphoid abnormalities that are clonal T-cell proliferations (42,43). In eosinophilic fasciitis, the involvement of the overlying subcutis can produce dense hyalinized sclerosis resembling scleroderma, even with plasma cells. However, if the biopsy includes the fascia itself, the fascia contains eosinophils, which is the finding that separates eosinophilic fasciitis from morphea and scleroderma. Eosinophilic fasciitis may present as Shulman's syndrome, characterized by the sudden onset of thickened, bound-down skin, which follows in some cases a clear episode of intense exercise. Eosinophilic fasciitis also can be a presentation of a reaction to a drug, such as L-tryptophan, toxic oil, or infection (2,44,45).

PANNICULITIS ASSOCIATED WITH SEVERE ALPHA-1 ANTITRYPSIN DEFICIENCY

Clinical Features. Patients born with a severe deficiency of alpha-1 antitrypsin (AAT) have exaggerated damage due to inflammation in the skin—for example, after trauma to the subcutis. AAT deficiency is estimated to be present in 1 in 3,500 live births in the white population (46). This enzyme is the major component of the alpha-1 peak on serum electrophoresis and is an inhibitor of the serine proteases trypsin, chymotrypsin, plasmin, thrombin, and neutrophil-produced elastase. The antitrypsin proenzyme is produced in the liver but is not secreted in most of the affected individuals. Liver disease is often the presenting problem, including hepatomegaly, neonatal cholestatic jaundice, and cirrhosis in children (47,48). Large period acid-Schiff (PAS)-positive, diastase-resistant globules of proenzyme can be seen in hepatocytes, especially near the fibrous septa. Inflammation in the lung leads to unopposed release of neutrophil elastase that produces panacinar emphysema, involving destruction of respiratory bronchioles, alveolar ducts, and alveoli. The pulmonary disease usually becomes evident in young to middle-aged adults. Skin lesions present after trauma as recurrent nodules that can drain a yellow fluid derived from the enzymatic breakdown of the fibrous tissue and fat (49–51) (Fig. 20-10).

FIGURE 20-10 Alpha-1 antitrypsin deficiency panniculitis. The inflammatory lesions in the subcutis are often accompanied by dermal inflammation and can perforate through the epidermis.

Histopathology. Biopsies of well-developed lesions show a mixed pattern of septal and lobular inflammation characterized by many neutrophils and destruction of the fat and the fibrous septa (Fig. 20-11). Sterile abscesses surround and isolate fat lobules (52) (Fig. 20-12). Late lesions have an infiltrate of macrophages and lymphocytes with many foam cells and fibrosis (53). The macrophages can exhibit cytophagic activity and particularly can ingest neutrophil fragments and extravasated erythrocytes. Biopsies of early lesions have not been studied in a series of cases, but in some patients, the early manifestations are neutrophilic infiltrates between collagen bundles in the dermis, with scattered solitary neutrophils and small collections of neutrophils in the septa and lobules of the subcutaneous fat (54). Depending on the size of the lesion, the subcutaneous involvement can be patchy with necrotic foci contrasting with the normal fat lobules in the vicinity (51,53).

Differential Diagnosis. The histopathologic changes are not specific for AAT deficiency but rather are shared by a number of diseases than can be responsible for *necrotizing panniculitis.* A biopsy of a subcutaneous nodule occasionally shows a nonspecific pattern of necrotizing acute inflammation characterized by fat necrosis and a massive neutrophilic infiltrate, often accompanied by karyorrhexis, fibrin deposition, focal vasculitis, and histiocytic reparative reaction. These changes also can be produced

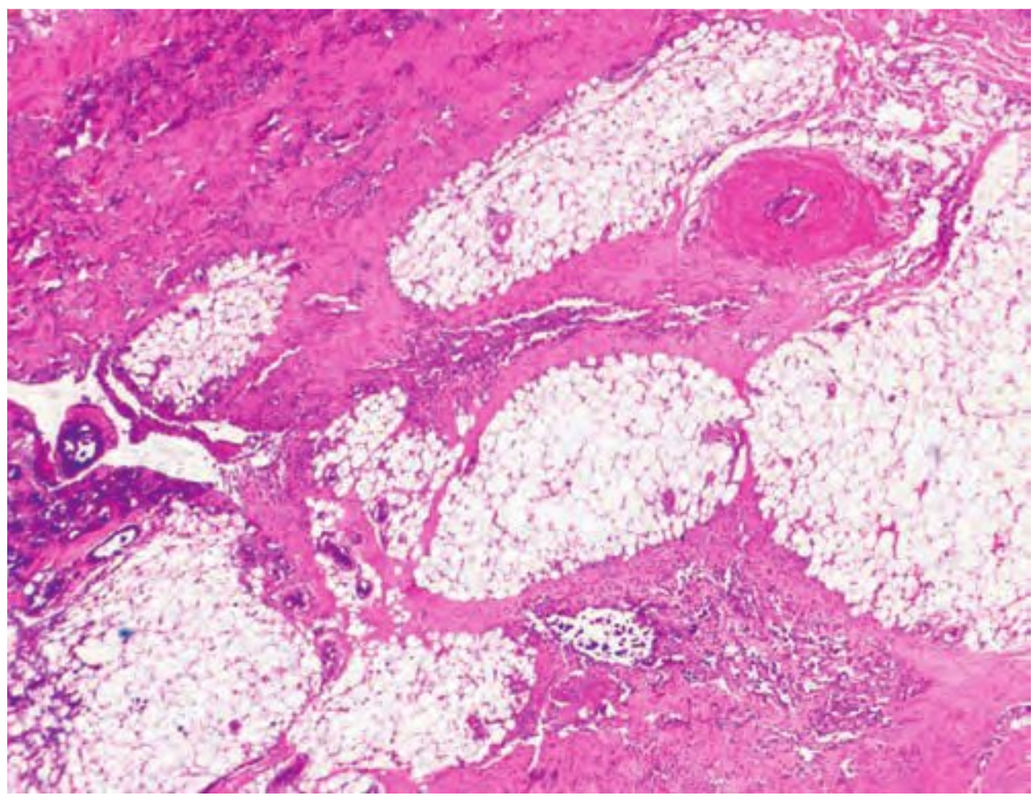

FIGURE 20-11 Alpha-1 antitrypsin deficiency panniculitis. Abscesses dissect between the fat lobules and involve the lower dermis.

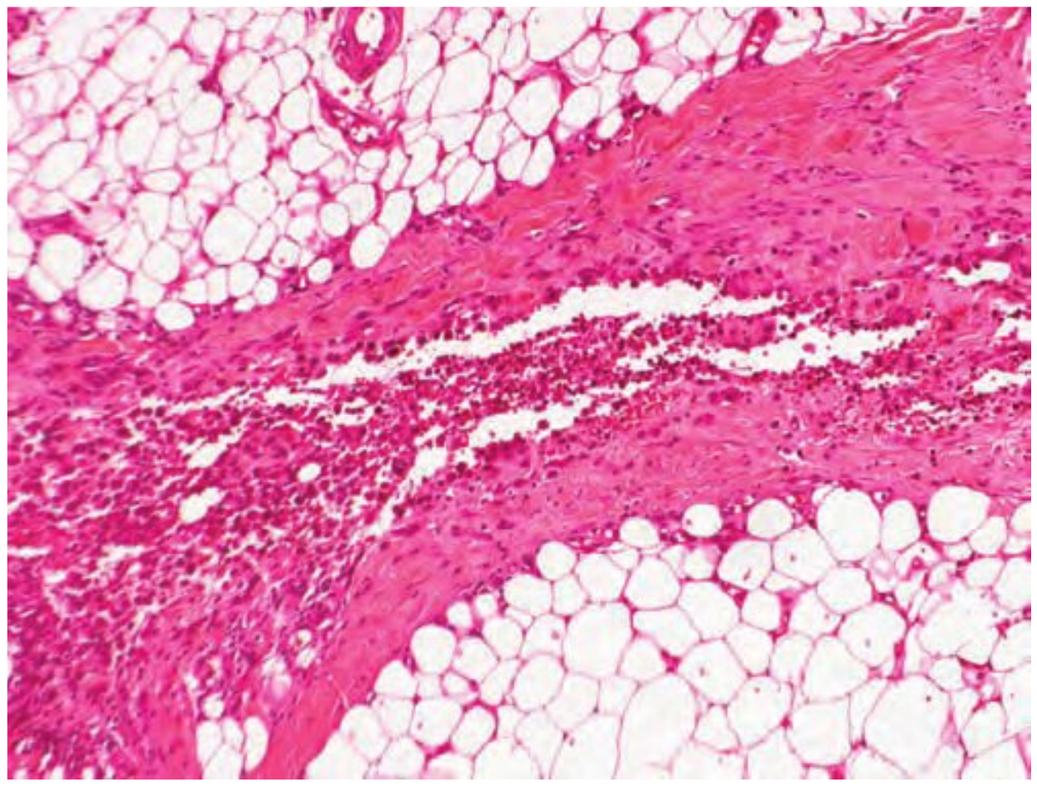

FIGURE 20-12 Alpha-1 antitrypsin deficiency panniculitis. High magnification of an abscess showing the neutrophils in the septa.

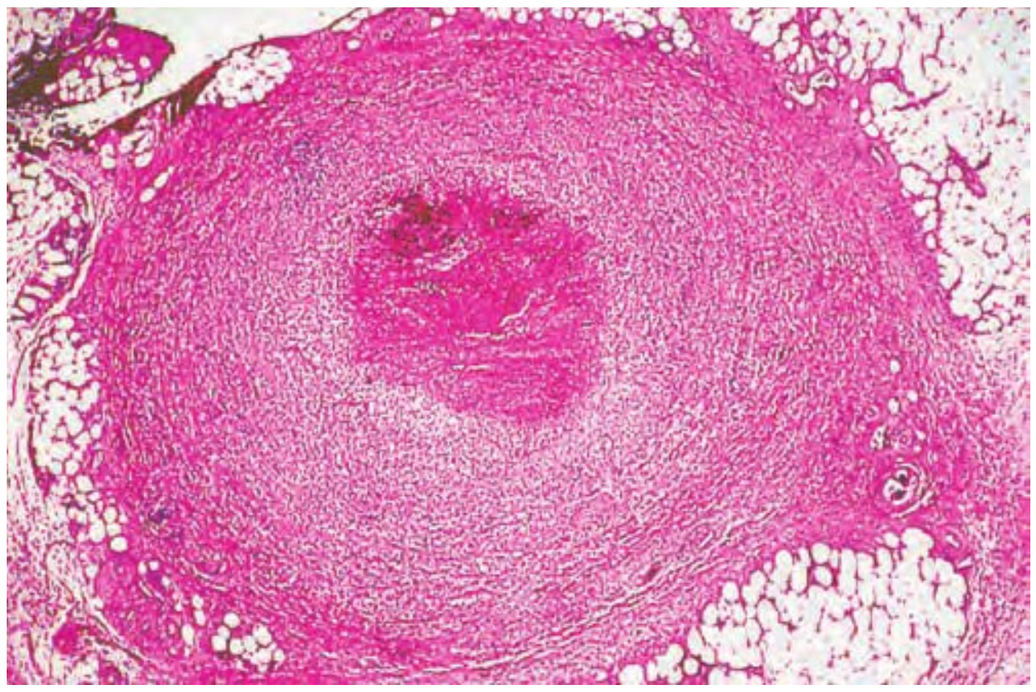

FIGURE 20-13 Superficial migratory thrombophlebitis. A vein is filled with thrombus, and the inflammation involves the adjacent septa and lobules.

by very acute necrosis (liquefaction necrosis) in cases of *nodular vasculitis*, pyoderma gangrenosum, and inflammatory reaction near ulcers from a variety of causes and can represent changes due to infection by pyogenic bacteria, including mycobacteria (55). If a meticulous study, including cultures and enzymatic studies, fails to reveal a satisfactory final diagnosis, then the term *necrotizing panniculitis* can be a suitable histologic diagnosis until other methods or information become available.

The clinical features of AAT deficiency overlap with those of Weber-Christian disease to the extent that a determination of serum levels of the enzyme should be performed on all cases clinically suspected of having Weber-Christian disease or any patient with ulcerating and necrotizing panniculitis. Weber-Christian disease is more restricted to the fat lobules than AAT deficiency panniculitis, which involves septa, lobules, and overlying dermis (54). Histiocytic cytophagic panniculitis (often a form of subcutaneous T-cell lymphoma with reactive histiocytosis) is in the differential diagnosis due to the fact that macrophage cytophagic activity also can occur in AAT deficiency. The prominence of neutrophils in AAT deficiency is in contrast to the lymphocytes in histiocytic cytophagic panniculitis. In the early lesions, infection needs to be ruled out since erysipelas and even some mycobacterial infections can have a similar histology (55). Serum electrophoresis is important in detecting carriers and affected individuals with AAT deficiency.

SUPERFICIAL MIGRATORY THROMBOPHLEBITIS

Clinical Presentation. Multiple tender, erythematous nodules are found usually on the lower legs but occasionally on the arms and trunk (56,57). After several days, a cordlike induration a few centimeters long can be felt along the course of the inflamed vein (58). As the old lesions resolve, usually within a few weeks, new nodules may erupt. Recurrent migratory thrombophlebitis can occur as a manifestation of Behçet's syndrome. It is also part of Trousseau's syndrome, in which there is an associated visceral carcinoma. Hypercoagulability and stasis are precipitating factors (56,57).

Histopathology. The lesion is centered around a large vein in the subcutis, usually in a septal location and occasionally in the deep vascular plexus, at the junction of deep dermis and subcutis (Fig. 20-13). The affected vein has a thick wall with the smooth muscle distributed in fascicles in the wall. The lumen often is completely occluded by thrombus. An inflammatory infiltrate extends between the muscle bundles and only a short distance into the tissue surrounding the vein (2,59). In early lesions, the infiltrate is composed of many neutrophils, but later it consists mainly of lymphocytes, macrophages, and a few giant cells (56,57). If recanalization of the lumen of the vein takes place, granulomas with giant cells can be found even in the lumen of the affected vessel. These granulomas participate in the reabsorption of the thrombus (58).

Differential Diagnosis. Owing to the elevated hydrostatic pressure in the veins of the lower legs in ambulatory patients, the walls of the veins have an increased amount of elastic fibers and smooth muscle in their walls. They can be distinguished from arteries when there is minimal inflammation and when elastic tissue stains show an absence of an internal elastic lamina. Thrombus usually occludes the lumen of veins in superficial migratory thrombophlebitis. Polyarteritis nodosa affects arteries and is recognized if the affected vessels can be identified as arteries based on lumen diameter, wall thickness, internal elastic lamina, and location.

SUBCUTANEOUS POLYARTERITIS NODOSA

Clinical Presentation. Systemic polyarteritis nodosa can affect the skin by several types of presentations. The affected arteries are deeply located, in the deep dermal vascular plexus at the

junction of dermis and subcutis or in the deep subcutis itself. A common clinical manifestation is a region of netlike erythema (*livedo reticularis*), with some tenderness to palpation. This livedo is fixed and not transient or altered by the temperature of the environment. To obtain a biopsy of the affected deep artery, it has been shown that the exact site and depth are important. The affected artery may lie deep beneath the center of the pale area, which is surrounded by a rim of redness due to vasodilation at the periphery of the ischemic region. Biopsies into those red netlike lines visible at the skin surface often miss or show very little of the affected artery. Systemic manifestations can be reflected in hypertension, proteinuria, elevated circulating immune complexes, decreased complement levels, deep muscle tenderness and pain, and cerebral infarcts. In *Sneddon's syndrome*, the combination of livedo reticularis and cerebral infarcts can be due to polyarteritis nodosa, hypercoagulable states, or lupus erythematosus. Cutaneous manifestations of polyarteritis nodosa are common in hepatitis C infection. Superficial biopsies may show only telangiectasia and extravasation of erythrocytes, or occasionally a mild leukocytoclastic vasculitis, probably depending on the sizes of the circulating immune complexes, and the degree of permeability of the endothelium. Some patients with histologically demonstrated polyarteritis nodosa on skin biopsy have a form of polyarteritis that tends to remain limited to the skin for prolonged time periods. Some cases have not shown involvement other than in the skin and subcutaneous tissue for as many as 15 years, which has given dermatologists the impression that there is a distinct entity of skin-limited polyarteritis nodosa, often named *cutaneous polyarteritis nodosa*. Follow-up studies of such patients have shown that despite being initially limited to the skin histologically and clinically, cutaneous polyarteritis nodosa may show signs of systemic disease at variable time periods after initial diagnosis in a considerable proportion of the patients. Hypertension, hematuria, testicular and muscle biopsies showing polyarteritis, and serum tests indicative of hepatitis B or C infection all point to systemic rather than localized cutaneous polyarteritis (60). Perhaps the exact nature and sizes of the circulating immune complexes could explain the overlapping features and why the disease manifestations are limited to the skin for a long time in some patients. Polyarteritis nodosa can lead to deep ulceration of the skin into the subcutis. Some authors have analyzed the same information and have presented the entity of cutaneous polyarteritis as a special distinct condition by discounting the overlap with systemic disease and the importance of following the patients over time (2).

Histopathology. The inflammatory infiltration into the walls of arteries and arterioles tends to be focal. Segments along the length of the artery are involved differently and may have only a portion of its cross-sectioned profile involved by the destructive inflammation (Fig. 20-14). The focal areas have fibrin deposition in the vessel wall with necrosis of the intimal and medial portions of the vessel. Early lesions have mostly neutrophilic infiltration, with

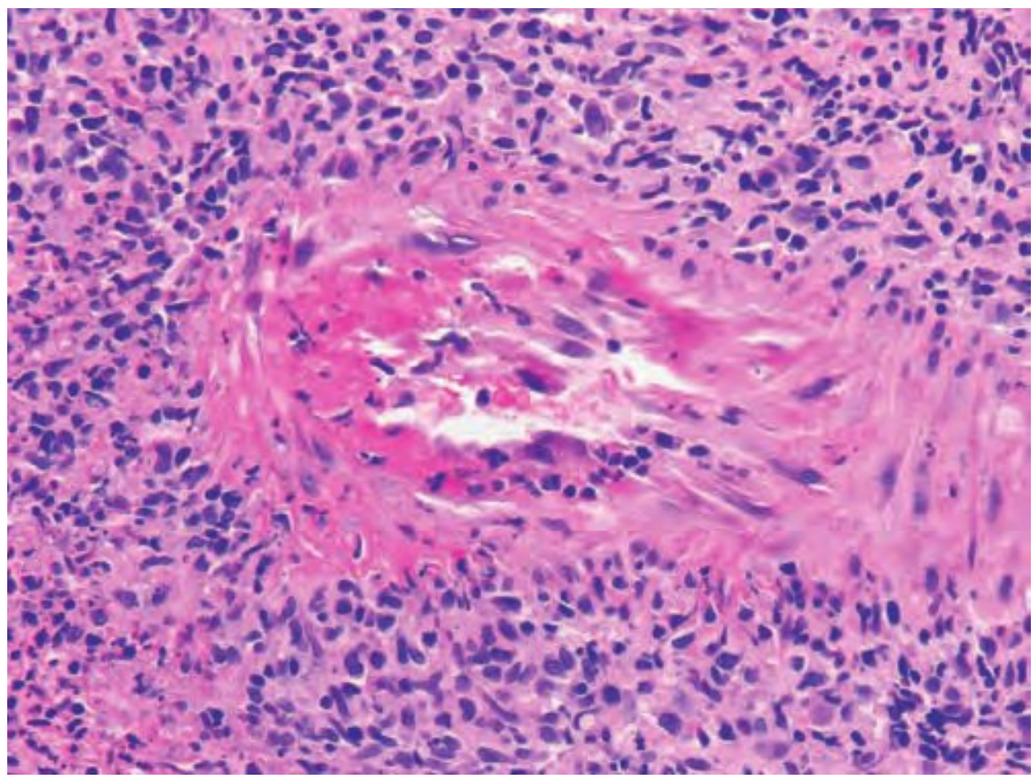

FIGURE 20-14 Subcutaneous polyarteritis nodosa. The small arteries in the septa have focal inflammation of their walls, with neutrophils and fibrin deposition.

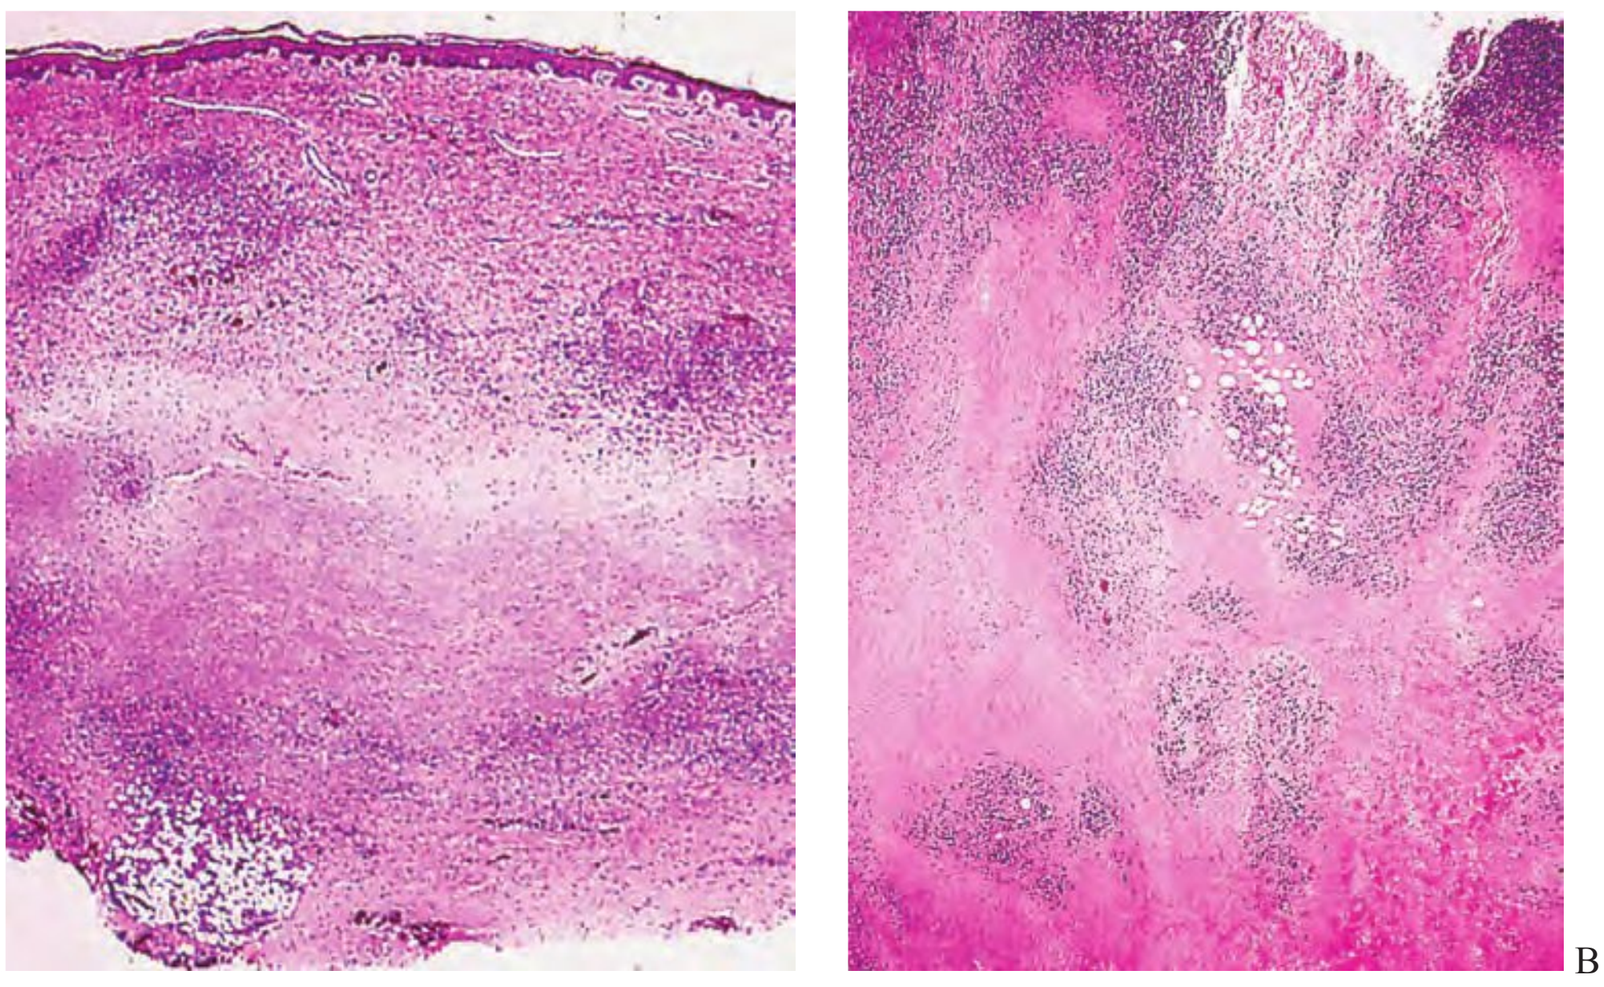
destruction of them to produce fragmented segments of the nuclei, *nuclear dust*. Later lesions have more lymphocytic infiltrate into the vessel as well as around it. Macrophage infiltration is also part of the process of resolution of the lesion. Immunofluorescence has shown immune complexes in the vessel walls (immunoglobulins G and M [IgG; IgM] and C3). The vascular destruction often does not completely occlude the lumen, which is in part a consequence of the tendency of dermatologists to biopsy early lesions rather than ulcerated ones. Some authors have stressed a difference in the localization of the lesions to the bifurcations of arteries in systemic polyarteritis and not in cutaneous polyarteritis (2). Such differences, if they are present, may be related to hydrostatic shear stress forces being greater at bifurcations and greater in patients with hypertension. Since the arteries tend to be in the deep dermal plexus and in the septa, the inflammatory process in the subcutis is classified as a septal panniculitis with vasculitis.

Differential Diagnosis. The distinction between polyarteritis and thrombophlebitis has been discussed previously in the section on thrombophlebitis (previous page). The distinction between systemic versus localized cutaneous polyarteritis depends heavily on the degree of investigation of the systemic factors, including the presence of proteinuria or hematuria (the glomeruli filter out circulating immune complexes). Elevations in muscle enzymes and muscle tenderness could lead to muscle biopsy as part of the investigation. Hypertension may also be a related systemic phenomenon. Investigation into the possible circulating viral antigens, such as hepatitis B or C, could also be revealing of systemic disease. It is most unlikely that arteritis will remain localized only to the skin when it is due to circulating immune complexes. Hypercoagulable states and lupus erythematosus need to be excluded.

ERYTHEMA INDURATUM (NODULAR VASCULITIS)



Clinical Presentation. The lesions of *erythema induratum*, also sometimes referred to as *nodular vasculitis*, consist of painless to tender, deep-seated, circumscribed nodules to plaques, usually on the lower legs with a predilection for the posterior calves. Gradually, the lesions extend toward the surface, forming blue-red plaques that can ulcerate before healing with atrophy and scarring (Fig. 20-15). Recurrences are common and often are precipitated by the onset of cold weather. Women are more commonly affected than men. *Erythema induratum of Bazin* refers to erythema induratum associated with tuberculosis. *Nodular vasculitis* was the name proposed by Montgomery for those cases with erythema induratum-like lesions that were not associated with tuberculosis (20,59).

Histopathology. In contrast to erythema nodosum that is mainly a septal panniculitis, erythema induratum (nodular vasculitis) initially is mainly a lobular panniculitis due to vasculitis that produces ischemic necrosis of the fat lobules with relatively less involvement of the structures of the septa. The fat necrosis can be extensive, caseous as well as coagulative, and elicits granulomatous inflammation (Fig. 20-16). Epithelioid cells and giant cells form broad zones of inflammation surrounding the necrosis but also can form well-delimited granulomas of the tuberculoid type (Fig. 20-17). Ziehl-Neelsen stains do not reveal intact mycobacteria (61). In approximately one third of cases, granulomas are sparse or absent and lymphocytes and plasma cells predominate (61). Both the tuberculoid granulomas and lymphoid infiltrate extend between the fat cells, largely replacing them.

FIGURE 20-15 Nodular vasculitis/erythema induratum. Advanced disease presents as hemorrhagic ulcers and depressed lesions with a predilection for the posterior calf region.

Vascular changes are extensive and severe. Arteries and veins of small and medium size show infiltration of their walls by a dense lymphoid or granulomatous inflammatory infiltrate (Fig. 20-18A) associated with endothelial swelling and edema of the vessel walls and fibrous thickening of the intima (59).

A B

FIGURE 20-16 Erythema induratum. A: Large areas of caseous necrosis replacing the subcutaneous fat, septa, and portions of the overlying dermis. B: A region of perforation of the inflammation through the skin surface.

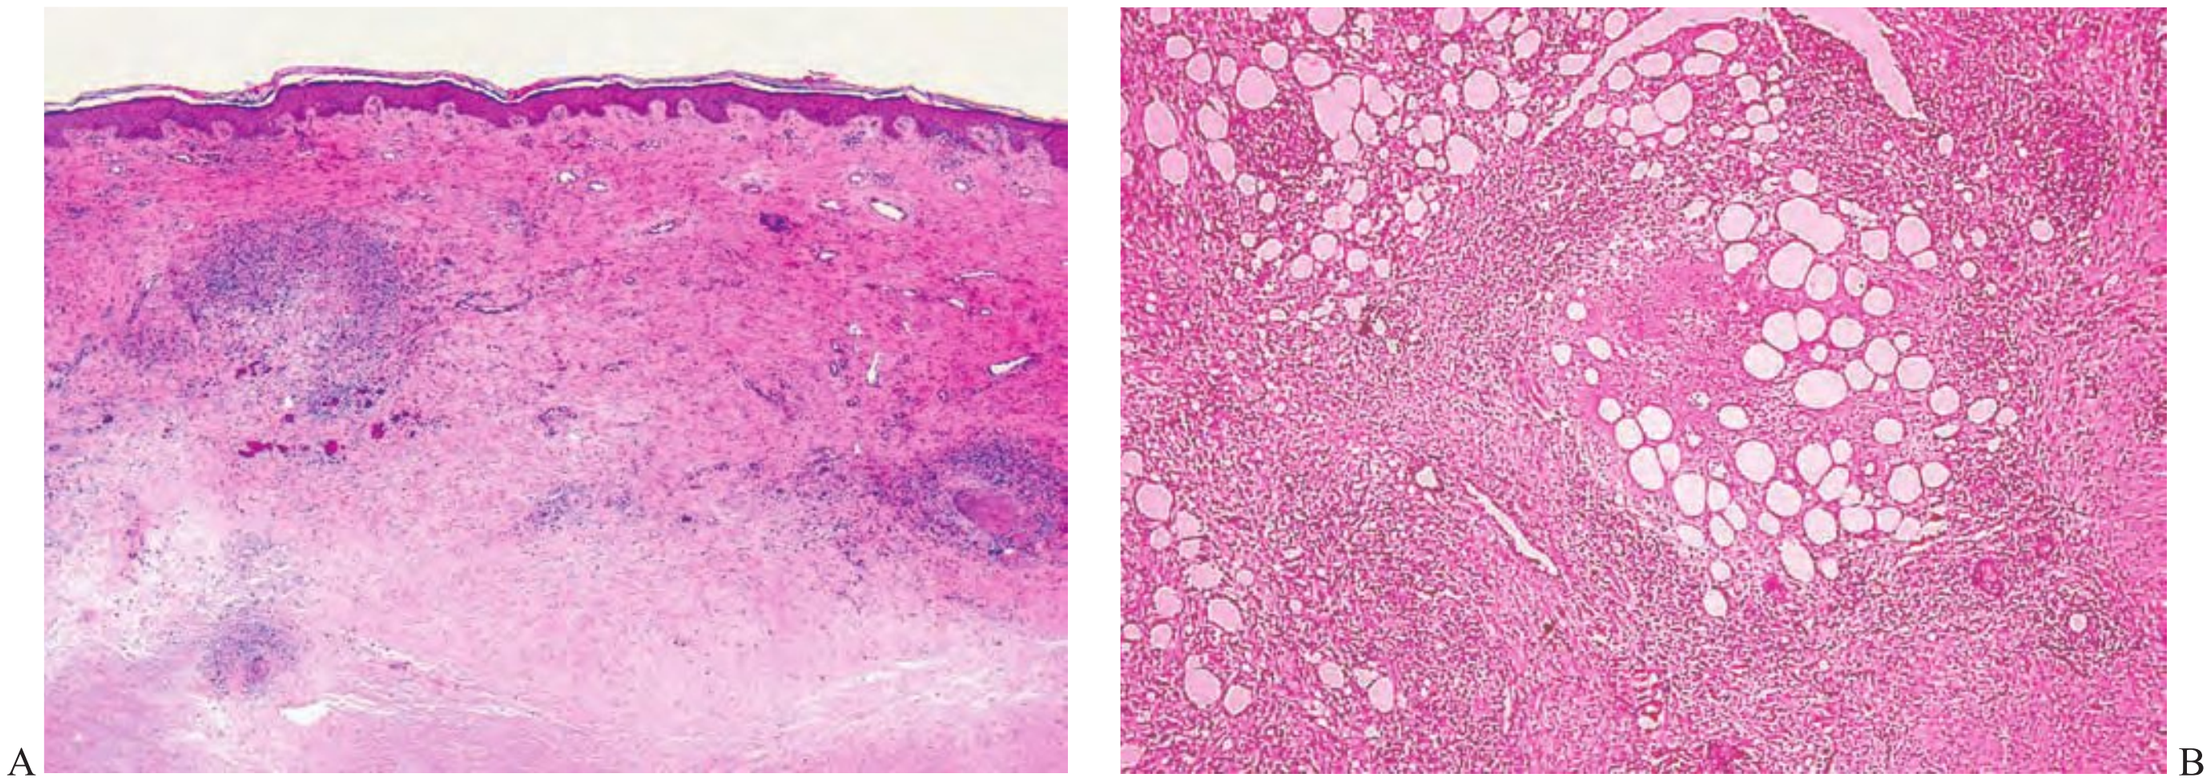


FIGURE 20-17 Erythema induratum. A: A region of caseous necrosis at lower magnification, with mainly lymphocytic infiltrates around remaining subcutaneous and dermal blood vessels. B: A smaller region of lobular fat necrosis with surrounding lymphocytes, macrophages, and multinucleated cells.

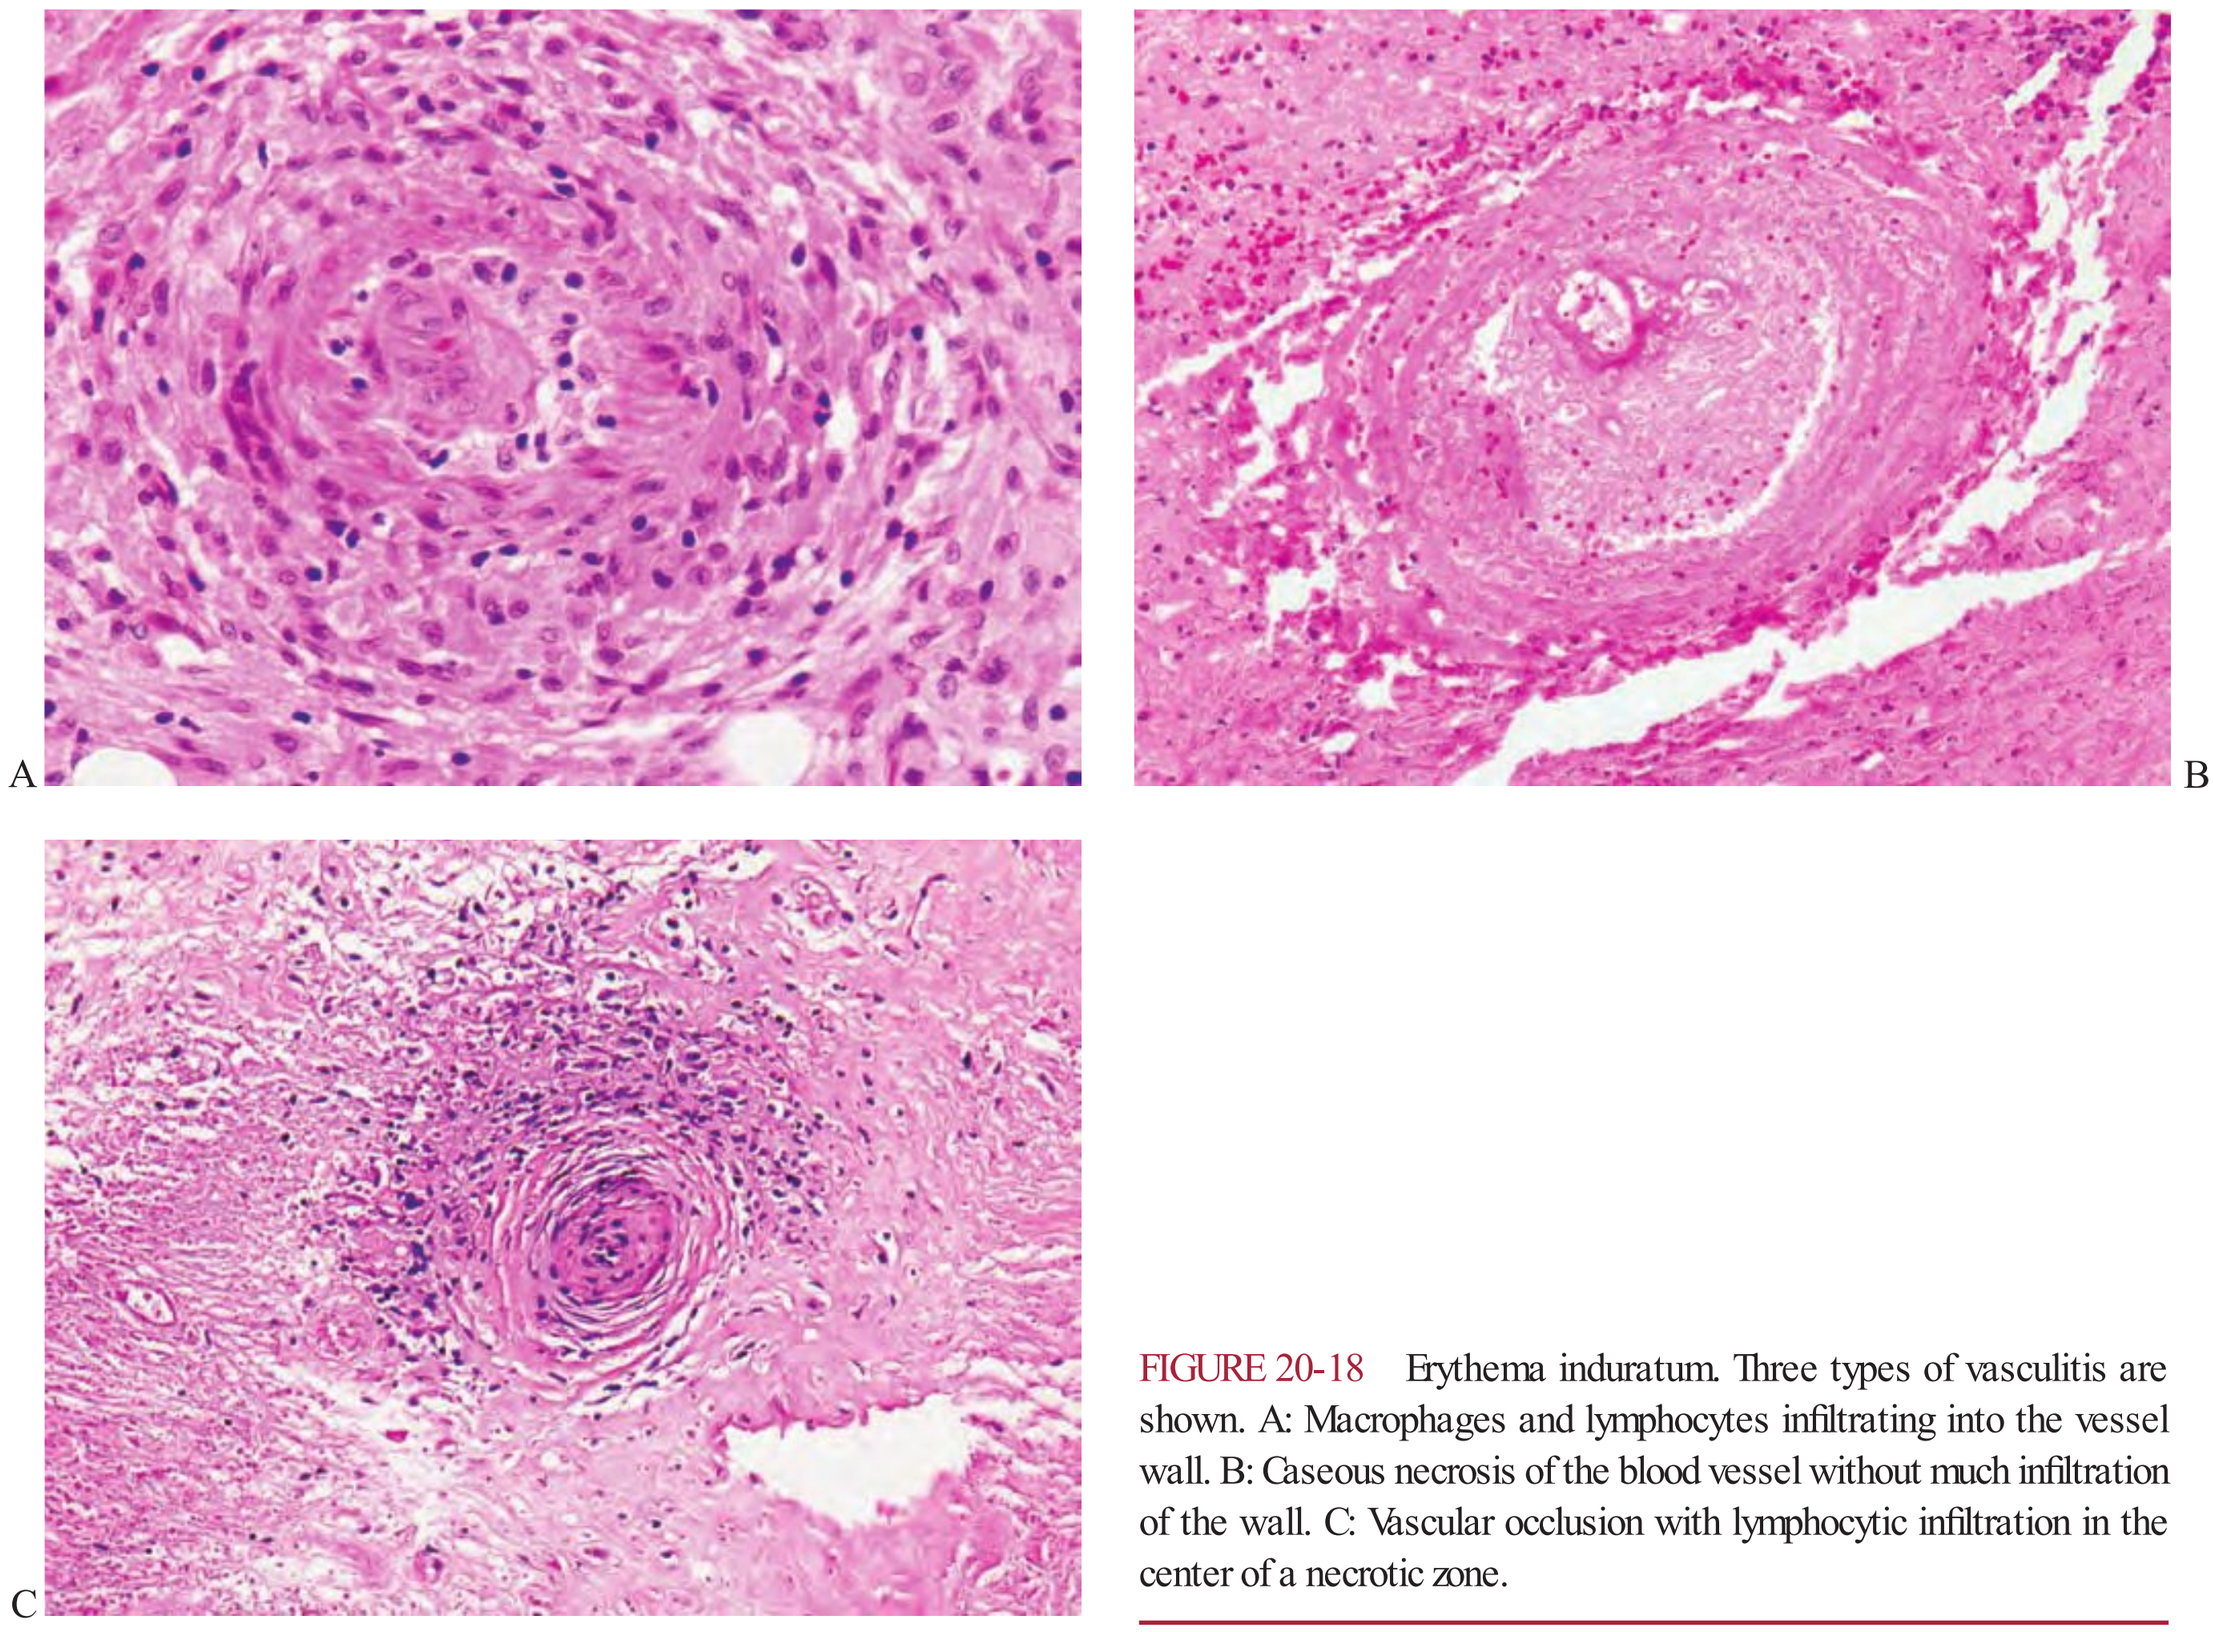

FIGURE 20-18 Erythema induratum. Three types of vasculitis are shown. A: Macrophages and lymphocytes infiltrating into the vessel wall. B: Caseous necrosis of the blood vessel without much infiltration of the wall. C: Vascular occlusion with lymphocytic infiltration in the center of a necrotic zone.

Thrombosis and occlusion, or just compromise, of the lumen can produce extensive ischemic and caseous necrosis of the fat in about half of the cases (Fig. 20-18B, C). Extensive necrosis leads to involvement of the overlying dermis and subsequent ulceration. The necrotic fat contains large fat globules, with surrounding amorphous, finely granular, eosinophilic material with some pyknotic nuclei. Later lesions contain many foamy histiocytes surrounding areas of fat necrosis.

Pathogenesis. The primary event in erythema induratum is a vasculitis of the subcutaneous arteries and veins. If fat necrosis develops, it is the result of ischemia following vascular damage. Erythema induratum in the past usually has been caused by a hypersensitivity reaction to tuberculosis, which is a "tuberculid" reaction (62–64). However, neither inoculation of lesional tissue into guinea pigs nor cultures of such tissue have yielded isolates of tubercle bacilli. Also, erythema induratum responds to treatment with corticosteroids (65). In contrast, evidence against erythema induratum being a tuberculid consists of the finding that active tuberculosis is no more frequent in patients with erythema induratum than in the general population. Also, patients with tuberculosis can develop erythema nodosum (66). A delayed hypersensitivity reaction seems likely to be the basis of nodular vasculitis in nontuberculous patients since S100-positive, dendritic cells are increased in number within granulomas near the vessels in nodular vasculitis and not in polyarteritis nodosa (67). These dendritic cells could present antigens to T cells and trigger an intense inflammatory reaction.

Differential Diagnosis. Erythema induratum can be distinguished from erythema nodosum by the prominent lymphohistiocytic vasculitis in erythema induratum, which can be found only very rarely in erythema nodosum. When caseation necrosis is present, it clearly separates erythema induratum from erythema nodosum. Direct cutaneous mycobacterial infection lacks the vasculitis of erythema induratum. Mycobacteria can be difficult to find in subcutaneous lesions of tuberculosis and are absent from erythema induratum with the Ziehl-Neelsen method for acid-fast staining. Detection of DNA from *Mycobacterium tuberculosis* in lesions of erythema induratum by polymerase chain reaction (68) but with negative cultures suggests a hypersensitivity reaction to fragments of tubercule bacilli (63).

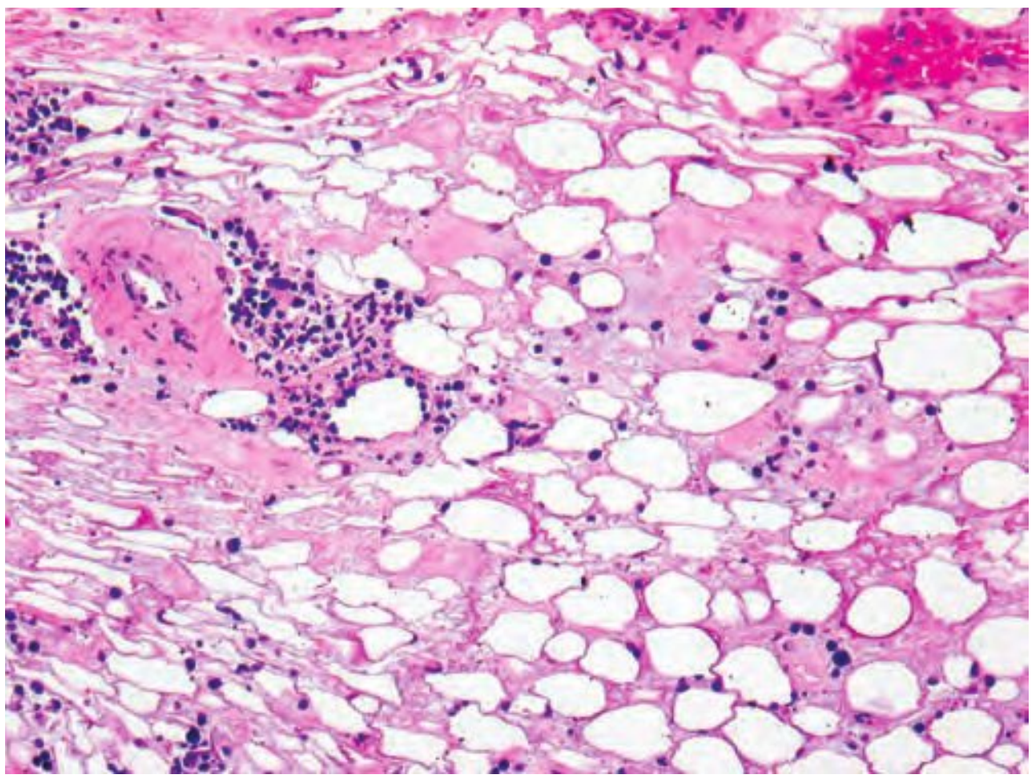
The difficult distinctions are between *erythema induratum*, *thrombophlebitis*, and *subcutaneous polyarteritis nodosa*, all of which can produce the clinical picture of nodules on the legs with vasculitis. Polyarteritis nodosa has neutrophilic infiltrates and fibrinoid necrosis of arterial vessel walls, whereas erythema induratum and nodular vasculitis have lymphohistiocytic infiltrates of the vessel walls with intimal proliferation and thrombosis. Elastic tissue stains are helpful in some lesions for distinguishing small arteries affected by polyarteritis from small veins affected by thrombophlebitis. However, the anatomic distinction between arteries and veins can be difficult when the inflammation destroys the elastic fibers or when the elastic tissue is increased in the walls of veins due to venous hypertension that is commonly present in patients with stasis in the lower legs. Deep biopsies and step sections in the tissue blocks may be necessary to demonstrate the focal necrotizing vasculitis in polyarteritis nodosa, since thrombosis and reactive changes near these foci can closely resemble nodular vasculitis in routine sections. At times, only a general diagnosis of "panniculitis with vasculitis" can be given until other biopsies or additional clinical information clarify the nature of the disorder.

LUPUS ERYTHEMATOSUS PANNICULITIS

Clinical Features. In patients with chronic cutaneous lupus erythematosus, the lesions can be deep and can involve the dermis and subcutis or just the panniculus alone (69–71). The patients can have either chronic discoid lupus erythematosus or systemic lupus erythematosus. In about two thirds to one half of patients with these uncommon lesions, there are firm, indurated subcutaneous nodules with no specific clinical changes in the overlying skin. Histology is more sensitive and detects changes of discoid lupus erythematosus in 67% of these patients (72).

The lesions are deep nodules and plaques that tend to involve the skin of the trunk and proximal extremities, particularly the lateral aspects of the upper arms, thighs, and buttocks. Symmetrical lesions on the anterior chest or upper arms can suggest a traumatic or factitial etiology, and indeed trauma may play a role in the localization of the lupus inflammation to these sites. Approximately 70% of these patients also have other lesions that are typical of discoid lupus erythematosus, and 50% have evidence of mild systemic lupus erythematosus (71). The lesions are painful and have a tendency to ulcerate and to heal leaving depressed scars. When the overlying skin is involved, there is loss of hair, erythema, poikiloderma, and epidermal atrophy. Some patients present with localized depressions without erythema, clinically resembling lipoatrophy (73). The term *lupus profundus* has been used both for lupus panniculitis and also for discoid lupus erythematosus lesions that involve the dermis and extend deeply into the subcutis. Over time, lesions that begin as pure panniculitis can develop dermal sclerosis and leave deep depressions in the skin surface.

Histopathology. The histologic sections reveal a deep lymphocytic infiltration in the fat lobules and in the septa (69). Lymphoid aggregates, nodules, and germinal centers, also known as *follicular centers*, are common (69,74). The dermis can have just a superficial and deep perivascular lymphocytic infiltrate with plasma cells or can have all of the changes of lesions of discoid lupus erythematosus. A distinctive feature is the so-called "hyaline necrosis" of the fat, in which portions of the fat lobule have lost nuclear staining of the fat cells and have an accumulation of fibrin and other proteins in a homogeneous eosinophilic matrix between the residual fat cells and extracellular fat globules (69) (Fig. 20-19). Blood vessels are infiltrated by lymphoid cells and can have restriction of their lumen



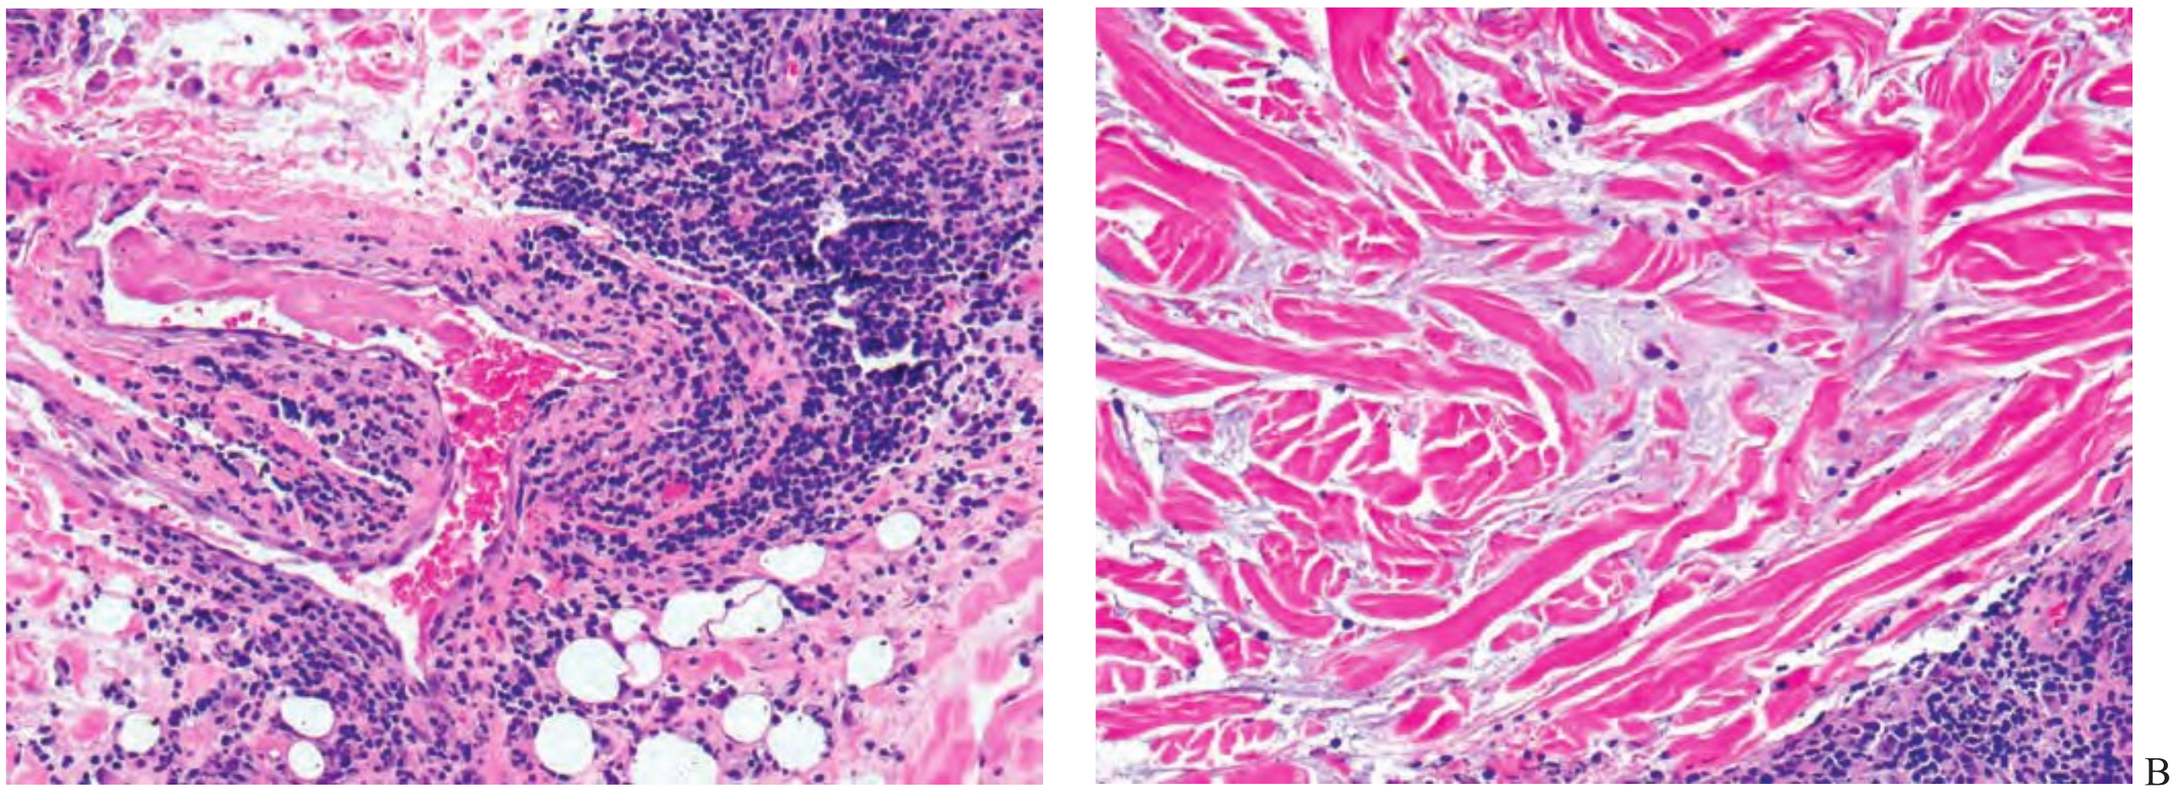


FIGURE 20-19 Lupus erythematosus panniculitis. Fat necrosis is accompanied in the lobules by the deposition of hyaline material and a lymphocytic infiltrate.

diameter (Fig. 20-20A). Usually, there is mucinous edema of the septa and the overlying dermis (Fig. 20-20B). Calcification may be present in older lesions.

Pathogenesis. Approximately 50% of patients with lupus profundus have positive immunofluorescence findings at the dermal–epidermal junction and at hair follicle basement membranes. Usually there is granular deposition of IgM and C3 with linear deposition of fibrin. Granular deposits of IgG and immunoglobulin A (IgA) may be present also in active lupus cases. Many patients have similar deposits in deep dermal and subcutaneous blood vessel walls. Fibrin is distributed diffusely in the panniculus, both in the lobules and in the septa in areas with hyaline necrosis. It seems likely that trauma is involved in the localization of lesions, perhaps through increased vascular permeability and leakage of circulating antinuclear antibodies or immune complexes into the fat lobules. A few patients with lupus panniculitis have a partial genetic deficiency of C2 and C4 (75). A lupus-like syndrome has been reported in approximately one third of patients with C2 deficiency (76,77). In patients with complement at the dermal–epidermal junction, deposition of the so-called membrane-attack complex, composed of C5b-9, can be demonstrated as well.

Differential Diagnosis. Patients with lupus panniculitis have been given a clinical diagnosis of *Weber-Christian disease* in the past. The overlap in appearances may prevent any distinction between these two diseases by routine histology. However, Weber-Christian disease can be sharply localized just to the fat lobules; in contrast, lupus panniculitis causes mucinous edema (detectable with Alcian blue stains) and inflammation around the blood vessels of the dermis and subcutis. Immunofluorescence and serologic studies allow a positive diagnosis of lupus erythematosus in many instances.

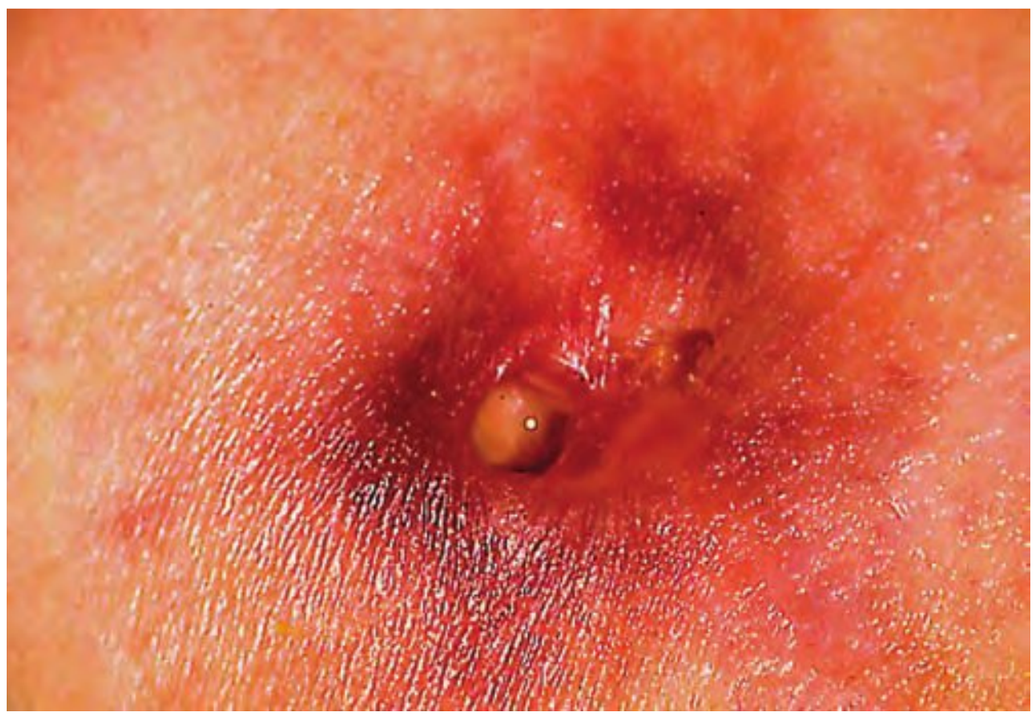
A particularly troublesome differential diagnosis is between lupus panniculitis and *subcutaneous T-cell lymphoma* (78). Although each of these two entities may have dense lymphoid infiltrates in the fat, usually the lymphoma has cytologically atypical lymphocytes. However, some cases of subcutaneous T-cell lymphoma are composed of small cells that lack obvious cytologic atypia in routine sections. A mixed population of $CD4^+$ and CD8-positive T cells may be found, making T-cell receptor gene rearrangement studies necessary for showing a significantly high level of clonality in the lymphoid infiltrate. After these studies, there remain a few indeterminate cases on a spectrum from lupus panniculitis to subcutaneous T-cell lymphoma because they have been classified as lupus panniculitis, responsive to chloroquine and/or prednisone therapy, but have some slightly atypical cells, with CD5 and CD7 diminution, and DNA analysis that is suggestive of the presence of some clonal

A B

FIGURE 20-20 Lupus erythematosus panniculitis. A: Distinctive lymphocytic infiltration through blood vessel walls that can be concentric and induce fibrosis. B: Frequently abundant blue-gray mucinous change between collagen bundles in the dermis and septa of the panniculus.

lymphocytes in the population (78). Subcutaneous panniculitic T-cell lymphoma of the alpha/beta subtype, without evidence of a hemophagocytic syndrome, has an excellent prognosis (i.e., an 82% 5-year survival), even with some patients having conservative treatment. In contrast, subcutaneous T-cell lymphoma of the gamma/delta subtype has a much worse prognosis (i.e., an 11% 5-year survival), even with intensive chemotherapy. Also, the gamma/delta subtype often involves overlying skin, with ulceration, and multiple other organ systems. The gamma/delta subtype should instead be classified as "gamma/delta T-cell lymphoma," with specification of the degree of involvement of the skin, subcutis, and internal sites. A natural killer (NK)/T-cell lymphoma ($CD2^+$ $CD3^-$ $CD56^+$ EBV^+) can also be in the differential diagnosis (79).

Erythema induratum, like lupus panniculitis, also shows hyaline necrosis and vasculitis but has more granulomatous inflammation than in most cases of lupus panniculitis. Erythema induratum lacks the mucinous edema of the dermis.



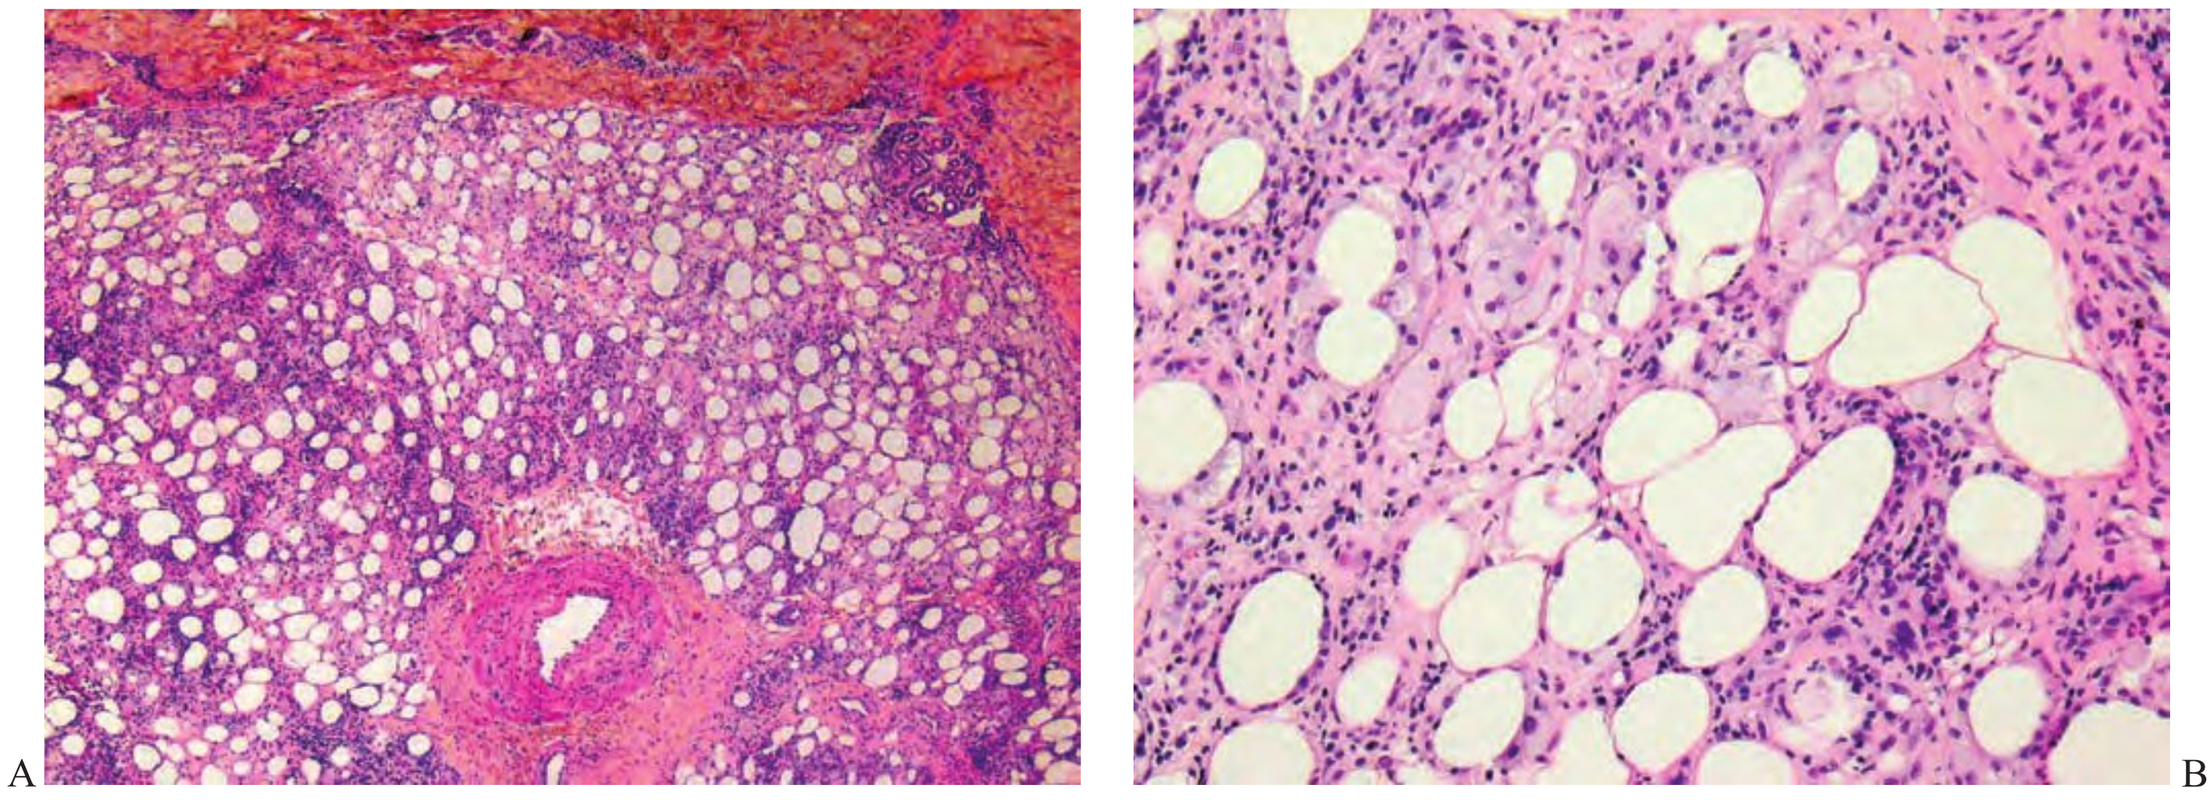


FIGURE 20-21 Weber-Christian disease. An indurated nodule on the leg has developed a perforation and drains a turbid, sterile, oily fluid with some necrotic tissue.

RELAPSING FEBRILE NODULAR NONSUPPURATIVE PANNICULITIS (WEBER-CHRISTIAN DISEASE)

Clinical Presentation. Weber-Christian disease now is a nonspecific clinical impression but is a pathologic diagnosis of exclusion. The diagnosis is made much less frequently now than it was in the period from 1950 to 1970, probably due to the greater power of current laboratory testing to reveal lupus erythematosus panniculitis, AAT panniculitis, or histiocytic cytophagic panniculitis in cases that might have been classified as Weber-Christian disease in the past. The classical clinical description is a disease characterized by the appearance of crops of tender nodules and plaques in the subcutaneous fat, usually associated with mild fever. The lower extremities are favored sites, but lesions may occur elsewhere and may ulcerate (Fig. 20-21). The disease occurs mostly in middle-aged women but has been described in all ages and in both sexes. In general, the disease has a good prognosis. However, if internal organ fat necrosis also is present, it may be fatal (80–82).

Histopathology. The histopathologic appearance itself is not sufficiently specific to exclude other diseases (Fig. 20-22). The classical description of the disease is that it evolves through three stages. In the first phase, there is only erythema and induration clinically. Histologically, acute inflammation is found in the fat lobules with degeneration of fat cells and an infiltrate of neutrophils, lymphocytes, and macrophages. The second phase has an infiltrate discretely localized to the fat lobules, consisting mainly of macrophages, foam cells, and extracellular lipid droplets. In some cases, the lesions perforate the skin surface and discharge a sterile, oily liquid. The third phase

A B

FIGURE 20-22 Weber-Christian disease. A: Sharp localization of the inflammation in the fat lobules that is a distinctive but nonspecific finding. B: Higher magnification showing fat-laden macrophages and lymphocytes in the lobules.

has depressed and indurated clinical lesions. Fibroblasts, collagen, and scattered lymphocytes and a few plasma cells replace the fat. Vascular changes are mild (14,80–86).

Systemic lesions occur in some cases of Weber-Christian disease and serve to distinguish this disease from most other types of panniculitis, except for histiocytic cytophagic panniculitis, gamma/delta T-cell lymphoma, and AAT deficiency panniculitis. In autopsy studies, inflammatory changes have been found in perivisceral fat as well as intravisceral fat in the liver, spleen, bone marrow, or near the pleural or peritoneal cavity. A large amount of oily fluid may accumulate in the pleural or peritoneal cavity (82,86–88).

Pathogenesis. If Weber-Christian disease exists as a distinct disease, the cause is unknown, but circulating immune complexes have been found in some cases (14,82,89).

Differential Diagnosis. The histologic appearance of Weber-Christian disease is most distinctive in the second phase, when there is an infiltration by lymphocytes and macrophages between fat cells that is discretely localized to the fat lobules. *Erythema nodosum* with unusual predominance of neutrophils can resemble the early phase of Weber-Christian disease, except for the localization of erythema nodosum primarily in the septa and Weber-Christian mainly in the lobules. Likewise, *AAT deficiency* can resemble early Weber-Christian disease except that the neutrophilic infiltrate in AAT deficiency usually affects the dermis and septa as well as the lobules. *Subcutaneous fat necrosis of pancreatic disease* can produce some of these findings but usually can be recognized by the extensive necrosis and deposition of bluish calcium precipitates with fatty acids. *Histiocytic cytophagic panniculitis* has some of the clinical features but histologically has a lymphoid infiltrate with macrophages that have ingested sufficient lymphocytes, neutrophils, and eosinophils to be called *bean bag cells* (90).

Subcutaneous panniculitic T-cell lymphoma can underly a histiocytic cytophagic panniculitic reaction, so lymphoma needs to be considered. After adequate investigation for all these other diseases, very few unexplained cases remain to be classified as Weber-Christian disease.

PANNICULITIS ROTHMANN-MAKAI

The term *panniculitis Rothmann-Makai* was proposed in 1945 as a designation for a "heterogeneous group of cases of idiopathic panniculitis that do not fit into any of the distinctly defined syndromes, such as Weber-Christian disease, erythema nodosum, or erythema induratum" (91). This diagnosis is based entirely on negative criteria (92) and consequently should be avoided. It seems preferable to refer to such cases as *unclassified panniculitis* until more definitive studies are available.

PALISADED GRANULOMATOUS PANNICULITIS

Clinical Features. Several granulomatous disorders that usually affect the dermis can also produce deep subcutaneous nodules. Some of these disorders can present in the subcutis without granulomas in the overlying dermis. In the subcutis, these diseases may form lesions that differ clinically and histologically in some aspects from their counterpart dermal lesions. *Subcutaneous granuloma annulare*, for example, is more frequent in young children and young adults, whereas the dermal form is more frequent in adults. The subcutaneous nodules may not produce erythema of the overlying skin. The lesions are most frequent on the head, hands, buttocks, and shins but can occur at other sites. Approximately 25% of patients with subcutaneous granuloma annulare also have dermal lesions. *Rheumatoid nodule* most typically is a deep subcutaneous nodule but can also involve the overlying dermis. Rheumatoid nodules tend to be on the elbows, fingers, and knees and are present in approximately 20% of patients with rheumatoid arthritis, almost all with a positive serum rheumatoid factor. Although they usually occur in patients with severe deforming joint disease, rheumatoid nodules can be the initial clinical presentation of rheumatoid arthritis. The subcutaneous lesions of granuloma annulare and rheumatoid nodule rarely perforate through the skin without associated trauma. The occurrence of granuloma annulare–like lesions in association with systemic disease has been reported (93–95). The list of systemic diseases is long, but rheumatoid arthritis is one of the main associated diseases. Other causes include thyroid disease, collagen-vascular diseases, viral infections (such as with parvovirus B19), and medications. One of the clinical clues that these are granuloma annulare–like reactions to systemic disease is that the lesions often occur in anatomic sites that are unusual for true granuloma annulare (94).

Histopathology. Both subcutaneous granuloma annulare and rheumatoid nodules produce necrosis of the fat lobules, and any involved septa, with a palisade of histiocytic cells around the focal areas of necrosis, which can be relatively large when compared with the size of typical dermal lesions (Fig. 20-23).

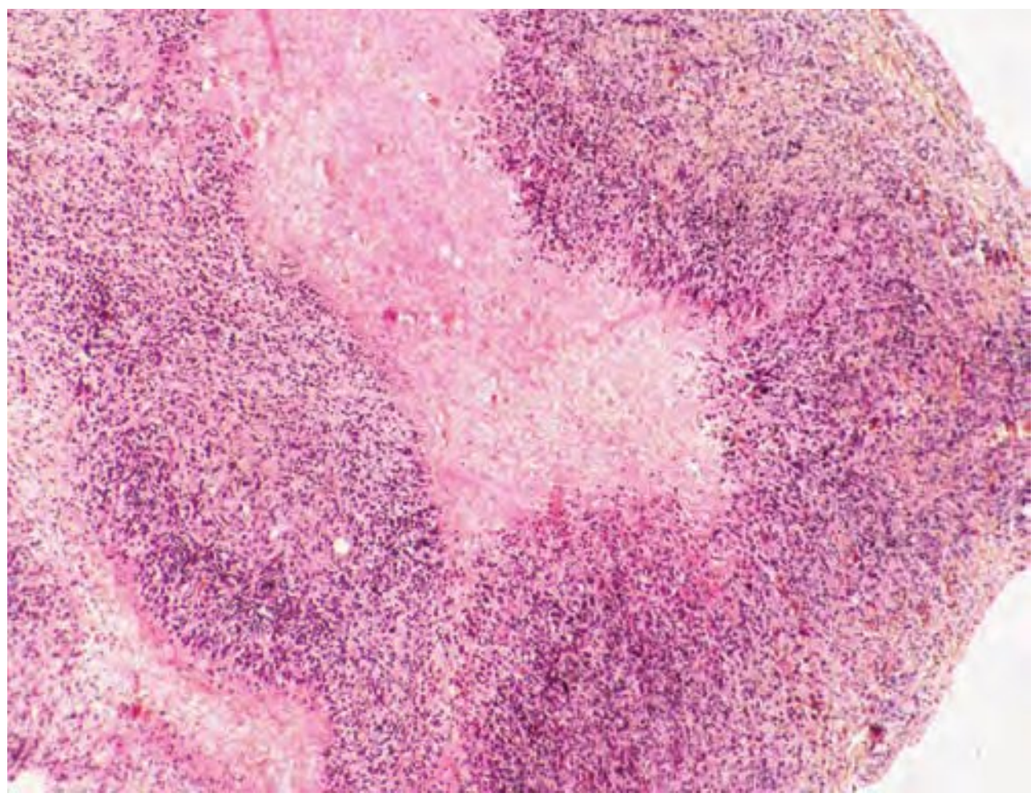

FIGURE 20-23 Subcutaneous granuloma annulare. This is different from the dermal lesions of granuloma annulare in that larger palisaded granulomas with central mucinous deposition and fibrosis are common in the subcutis.

Usually, subcutaneous granuloma annulare has abundant mucin in the necrotic centers of the lesions. The mucin is so abundant as to be visible in routine hematoxylin and eosin–stained sections. The presence of mucin can be confirmed on Alcian blue or colloidal iron stains. However, the detection of small amounts by these sensitive special stains can be less specific for granuloma annulare. In contrast, rheumatoid nodules have more fibrin in the necrotic centers of the lesions in routine sections. Immunofluorescence is so sensitive that it can detect fibrin in the centers of both granuloma annulare and rheumatoid nodules. When both mucin and fibrin are visible in the routine sections of the necrotic centers, a granuloma annulare–like lesion associated with a systemic disease should be suspected. In all of these instances, the macrophages appear similar in that they are enlarged, have abundant eosinophilic cytoplasm, and are aggregated closely together to give them an "epithelioid" appearance. Multinucleated giant cells may be present. Neutrophils may be found in the small vessels in the necrotic centers of the granuloma annulare–like lesions. Neutrophilic infiltrates in the vessels and in the interstitium around collagen bundles are more typical of rheumatoid nodules and papules.

Pathogenesis. The etiology of granuloma annulare is unknown, even in the ordinary dermal form and certainly in the subcutaneous form. With the recognition of the granuloma annulare–like lesions in systemic diseases, multiple etiologies could produce a granuloma annulare–like lesion. If this is true, then granuloma annulare becomes a reaction pattern of the dermis and/or subcutis. Studies of patients with granuloma annulare by routine immunofluorescence showed deposition of immune complexes (IgG, IgM, C3, with fibrin) in the small blood vessel walls in the centers of some lesions. These findings were only present in biopsies of early lesions (96). It is recognized now that the binding of certain types of IgG to the surface of fibroblasts in culture can cause overproduction of mucin by these fibrobasts (97). Therefore, it seems a reasonable hypothesis that the mucin production in granuloma annulare relates to the deposition of IgG on the surface of collagen bundles and fibroblasts. In rheumatoid nodules, the deposition of rheumatoid factor (IgM/IgG complexes) locally in the tissue might stimulate the fibroblasts in some patients to produce sufficient mucin to give the morphology called *granuloma annulare–like lesion in systemic disease*. Further studies are needed on the pathogenesis of these reactions. The presence of anti-Ro and anticardiolipin antibodies in some patients may produce vasculitis and pauciinflammatory vascular thrombosis in association with rheumatoid arthritis lesions (98).

Differential Diagnosis. The distinction between subcutaneous granuloma annulare (mucin depostion) and rheumatoid nodule (fibrin deposition) can be made in many cases in the routine histology. When the lesions exhibit an unusual clinical distribution of lesions for granuloma annulare, and when the lesions have both mucin and fibrin in the necrotic centers, then the diagnosis of granuloma annulare–like lesion in systemic disease can be offered, but it needs further investigation and correlation with the clinical findings in the patient. *Necrobiotic xanthogranuloma* is usually a dermal lesion, but the lesions can be large and involve the subcutis as well. It can have some histologic features in common with the palisaded granulomas, but the necrotic centers contain cholesterol clefts and are surrounded by macrophages with abundant lipid-filled, pale cytoplasm. *Crohn's disease* can produce subcutaneous granulomas with necrosis, but the granulomas usually do not have a palisaded appearance. Most subcutaneous lesions of Crohn's disease are around the perineum or oral sites. They tend to occur near areas of rectal involvement or ileosotomy sites. *Sarcoidosis* may produce granulomas in the septa or in the lobules or both. The lesions tend to remain as discrete granulomas and usually lack necrosis. In large granulomas, the centers may have fibrin deposition but without the granular debris of necrosis. Treatment of sarcoidosis with systemic steroids can produce central necrosis in the granulomas. The lesions lack palisading but may have slight mucin deposition in the stroma around the periphery but not in the centers of the granulomas. Small polarizable crystals have been found in some lesions of sarcoidosis but not in the other disorders in this section (99,100). The presence of other polarizable material raises the question of possible factitial panniculitis.

PANNICULITIS DUE TO PHYSICAL OR CHEMICAL AGENTS

Clinical Features. Trauma may be due to physical injury or to chemical injury, such as that produced by the injection of noxious substances. Physical injury can be produced by blunt pressure or impact, cold or excessive heat, or electrical injury. All of these factors can produce firm nodules in the subcutaneous fat. In many instances, these various inciting agents can be distinguished best by the clinical history and distribution of the lesions. Surreptitious injections of noxious substances can produce bizarre clinical and histologic patterns of lesions but can be suspected clinically by the distribution of lesions only in areas easily reached by the patient (*factitial panniculitis*). Drug injections by nurses usually are located in the deltoid region or on the buttocks. Self-injection of insulin often involves the thigh or lower abdomen and can produce subcutaneous lesions. Meperidine hydrochloride (Demerol) (101) and pentazocine (Talwin) (102) injections are known to produce traumatic panniculitis. The injection of oily substances such as hydrocarbons or silicone was common in the past for certain cosmetic effects, but reactions to these substances or to contaminants in them produce a panniculitis with varying degrees of inflammatory infiltration (103,104). The long-term effects of injection of buttock fat autotransplants to sites, such as the backs of hands, for cosmesis have yet to be studied. Mentally ill persons and drug addicts may purposely or inadvertantly inject themselves with foreign substances, such as feces or milk, sometimes used to dilute or cut narcotics. These various physical and chemical traumas lead to indurated subcutaneous nodules that may undergo liquefaction, ulcerate, and discharge pus

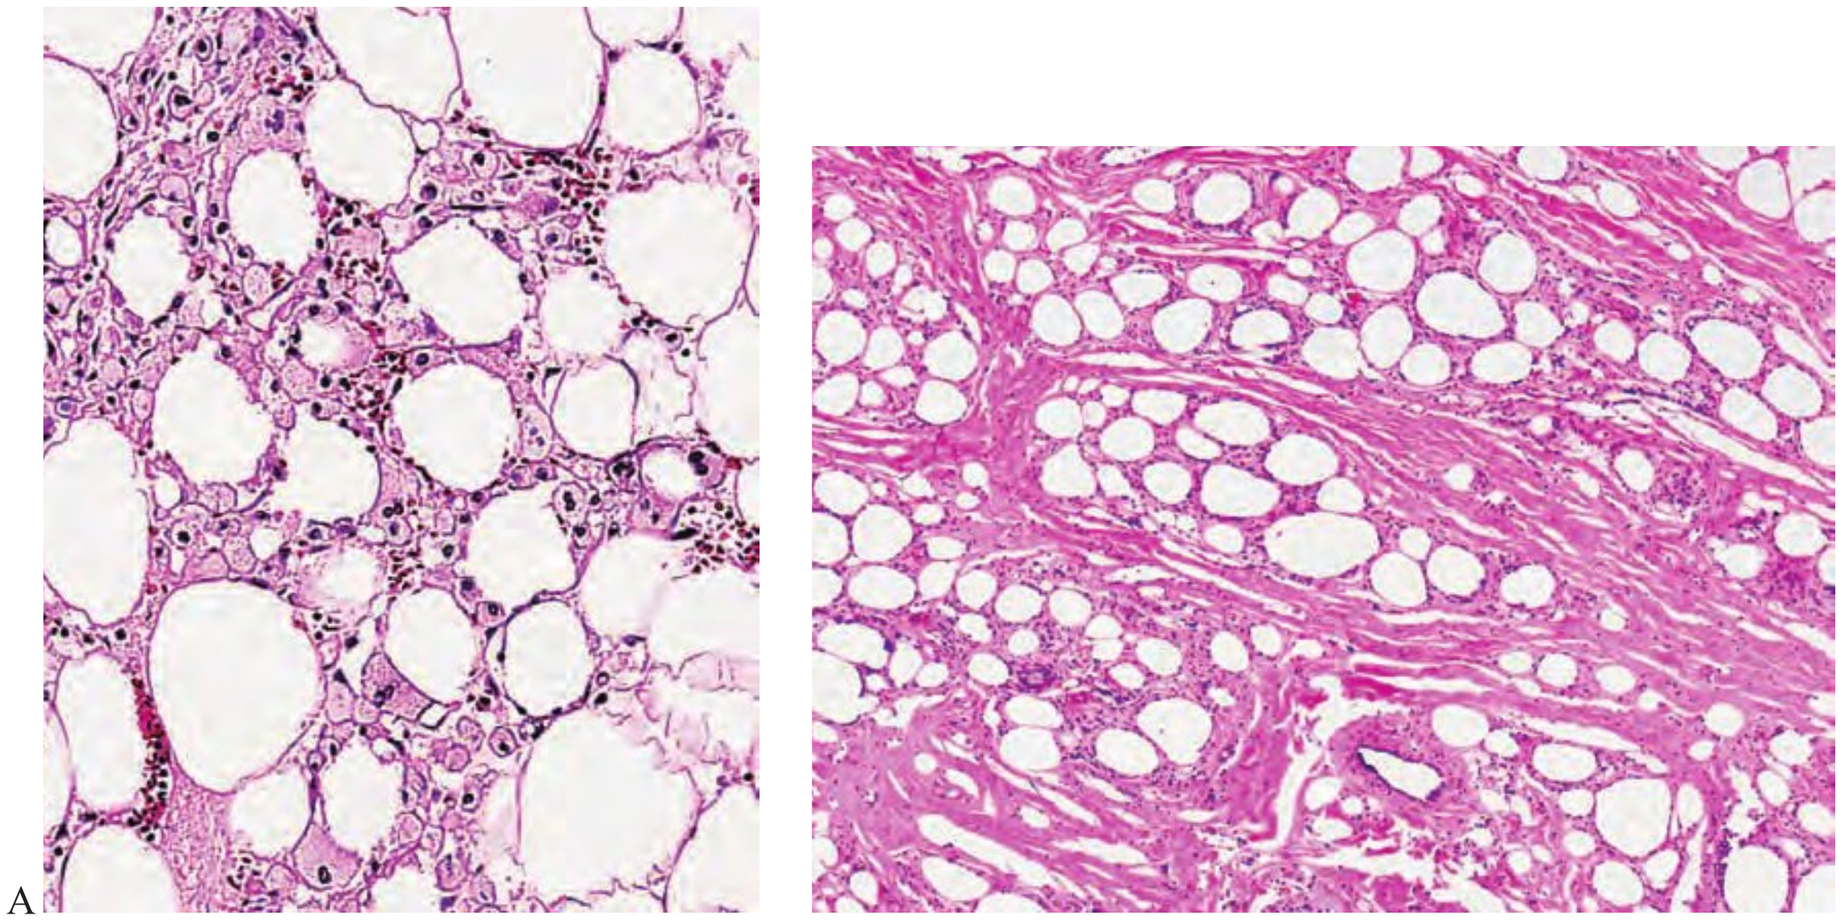

FIGURE 20-24 Traumatic fat necrosis. A: Acute area of fat necrosis with lymphocytes and macrophages in the fat lobules. B: Late lesion in which the fat lobules and septa have been replaced by dense fibrosis.

or a thick oily fluid. Healing leaves depressed scars (105). Lesions produced by extreme cold usually do not ulcerate unless associated with pernio or vasculitis with cryoglobulinemia. Cold injury may occur in children after eating an iced food such as an ice pop (106–108). The cold injury produces nodules or plaques that appear from 1 to 3 days after exposure and that subside spontaneously within 2 weeks. Excessive heat and electrical injury usually are accompanied by ulceration and eschar formation.

Histopathology. The injection of the various toxic agents will produce a variable histologic picture of acute inflammation, with aggregation of neutrophils and focal fat necrosis with hemorrhage (105). Older lesions have infiltrates of lymphocytes and macrophages (Fig. 20-24A) with fibrosis (102) (Fig. 20-24B). Vasculitis usually is absent with injections but can be present with heat-induced injury and with perniosis associated with cold, damp conditions. Polarized light reveals certain types of foreign material in injection sites (101), but polarizable crystals have been found in some lesions of sarcoidosis (99,100). The injection of oily liquids leads to the formation of many pockets of fatty material ("fat cysts"), often with a surrounding fibrous reaction containing foamy macrophages that overall impart a "Swiss-cheese appearance" to the tissue after the fat has been extracted by routine histologic processing (103,104). Fixation of the tissue in osmium tetroxide may be useful since endogenous lipids (but not most exogenous lipids) contain many unsaturated double bonds that react readily with osmium tetroxide to produce a black deposit of reduced osmium oxides (109,110). Injections of granulocyte-monocyte colony-stimulating factor or interleukin (IL)-2 can produce nodules at the sites of injections in the skin and subcutis that mimic leukemic or lymphoma infiltration due to their content of very highly stimulated monocytes or lymphocytes (111). Trauma due to cold injury initially has an infiltrate of lymphocytes and macrophages near the blood vessels of the deep plexus at the junction of dermis and subcutis. Such changes have also been described in perniosis. Biopsies at the third day, at the height of reaction, show rupture of the fat cells with fat pockets in the tissue surrounded by an infiltrate of lymphocytes, macrophages, neutrophils, and occasional eosinophils (107,112).

Pathogenesis. The subcutaneous fat of children is more sensitive to cold injury than that of older children and adults. In all newborn infants and in 40% of infants 6 months of age, the application of an ice cube to the skin produces nodules of cold panniculitis. By 9 months of age, such cold reactivity is rare (108). The greater degree of saturation of the lipids in newborns raises the crystallization temperature of the fat and produces greater susceptibility to cold injury (113,114). This mechanism of injury is involved also in *sclerema neonatorum*.

LOCALIZED LIPOATROPHY AND LIPODYSTROPHY

Clinical Features. Both localized lipoatrophy and lipodystrophy can have lesions with a similar clinical appearance; however, lipoatrophy usually involves one or several circumscribed, round, depressed areas, from 1 cm to several centimeters in diameter. In contrast, lipodystrophy produces the loss of large areas of subcutaneous fat, particularly in *acquired generalized lipodystrophy* (115). Most cases of lipodystrophy are of the cephalothoracic type and involve the face, neck, upper extremities, and upper trunk. Some cases have been noted that extend downward from the iliac crest. Lipodystrophy has been

reported with diabetes (116) and with glomerulonephritis (117). Lipoatrophic panniculitis also occurs in *connective tissue panniculitis* (118). In HIV-positive patients on highly active antiretroviral therapy including protease inhibitors, their prolonged life span has revealed that this therapy can produce a striking lipodystrophy syndrome. Loss of subcutaneous fat on the face and extremities can be severe and is accompanied by redistribution of fat to produce a "buffalo hump" and an increase in visceral fat deposits. This syndrome includes insulin resistance, diabetes mellitus/carbohydrate intolerance, hypertriglyceridemia, reduced high-density lipoprotein cholesterol, elevated low-density lipoprotein cholesterol, and reduced levels of the adipocyte cytokine *adiponectin* and the adipocyte hormone *leptin* (119,120).

Histopathology. Lesions of lipodystrophy are described most dramatically as a total loss of the subcutaneous fat resulting in dermis adjacent to the fascia (116). However, localized lipoatrophy has been described as having two types: inflammatory and noninflammatory or "involutional" types. In *the inflammatory type,* multiple lesions are common and have a lymphocytic infiltrate around the blood vessels and are scattered diffusely in the fat lobules (73,121). Areas of fat necrosis can be present with infiltration by macrophages.

In *the involutional type,* usually there is only a solitary lesion that exhibits a decrease in size of the individual adipocytes. They are separated from each other by abundant eosinophilic, hyaline material or in some instances by mucoid material (121).

Pathogenesis. Adipose tissue in adult mammals is under complex hormonal control. Insulin receptors on the surface of the fat cells inhibit lipolysis and stimulate lipogenesis. This contributes to increased fat deposition, whereas stimulation of beta-adrenergic receptor sites on the plasma membrane of fat cells increases lipolysis. Glucagon can also increase lipolysis. Although the fat cells themselves in the subcutis receive no direct innervation, innervation of the small blood vessels of the fat may produce noradrenergic stimuli for lipolysis. When normal adult adipose tissue is subjected to lipolysis by such stimuli or by fasting for 72 hours, significant changes in the morphology of the fat take place. Unilocular fat cells can become multilocular in senstive fat regions after only 48 hours of fasting. With prolonged fasting, the unilocular engorged fat cells lose their fat droplets and become more spindle-shaped cells that are indistinguishable from fibroblasts or undifferentiated perivascular mesenchymal cells (122,123).

Hormonal influences seem likely to be related to lipoatrophy (e.g., that which is commonly associated with aging). The SIR 2 gene product NAD^+ dependent histone deacetylase is a regulator of aging that has been conserved in evolution from yeast to mammals. In mammals, the SIR T1 gene regulates white adipose tissue, and its overexpression reduces the amount of fat, in the presence of low levels of insulin, and decreases blood glucose. The SIR T4 gene in the nucleus produces a protein in mitochondria that affects energy metabolism. The effects of caloric restriction seem mediated by SIR 2 gene activation. Both SIR 2 activation and direct caloric restriction can produce a slight prolongation of life span in experimental animals (124).

LIPEDEMA

Clinical Features. Lipedema is an entity that is relatively poorly recognized by pathologists but is more prominent in the literature of surgeons and radiologists. In its localized tumefactive form, it presents as localized swelling, sometimes affecting both buttocks, the thighs, or the legs in middle-aged women (125–130). The swelling persists despite elevation of the extremities and is a nonpitting edema. In the tumefactive form, the swelling is not uniform and may have deep depressions in it. More commonly, the swelling is not tumefactive but is more diffuse, painless, bilateral and symmetrical and involves the thighs and lower legs but not the feet (125).

Histopathology. In a localized area, there are increased interspaces between fat cells, without dilation of blood vessels or evident dilation of lymphatic spaces, without increased mucin on Alcian blue or colloidal iron stains, and without much inflammation. In some cases, trauma to these protuberant masses can result in deep depressions in the lesions, which correspond histologically to zones of loose fibrous tissue that lack fat cells and have slight amounts of hemosiderin in macrophages. Mast cells may be slightly increased in the lesions but are probably reactive. There is no collagenous capsule at the periphery of the tumefactive form. There is no atypia of the adipocyte nuclei.

Pathogenesis. The result of the lipedema is great thickening of the subcutaneous tissues without much evidence of classical lymphedema. However, careful studies have shown microaneurysms of the lymphatic vessels localized to the areas of lipedema (131). It is different from *cellulite*, which produces a diffuse peau d'orange pebbly appearance to the skin of the thighs and buttocks regions of women. The cellular basis of cellulite is extension of adipose tissue from the subcutis up into the reticular dermis and not edema of the fat lobules. The anatomic construction of the border between reticular dermis and subcutis is more densely collagenous in males than in females, predisposing women to the development of cellulite (5). Another possible relationship is to *Durcum's disease* or *adiposis dolorosa*, which differs in being painful clinically and in having inflammation of nerves. Further careful histologic and clinical studies of these cases are needed.

Differential Diagnosis. The tumefactive nature of the swelling in some cases of lipedema leads toward a differential diagnosis that includes lipoma with edema or mucinous change, lymphedema, scleredema, or scleromyxedema. The lack of a delicate capsule makes lipedema different from lipoma. The lack of increased mucin on Alcian blue stains separates lipedema from scleredema, scleromyxedema, or myxoid lipoma.

SUBCUTANEOUS NODULAR FAT NECROSIS IN PANCREATIC DISEASE

Clinical Features. In patients with pancreatitis or pancreatic neoplasms, the release of lipase enzymes into the blood can lead to nodules of fat necrosis in the subcutis. The pretibial region is the most common site of the nodules, but they may occur on the thighs, buttocks, and elsewhere (Fig. 20-25). The nodules usually are tender and red and may be fluctuant (132), but they only rarely discharge oily fluid through fistulas (133).

Histopathology. The histologic appearance of the subcutaneous nodules in pancreatic disease is characteristic in most instances (134). In the foci of fat necrosis, there are ghostlike fat cells having thick, faintly stained cell peripheries and no nuclear staining (Fig. 20-26). Calcification forms basophilic granules in the cytoplasm of the necrotic fat cells and sometimes forms lamellar deposits around individual fat cells or patchy basophilic deposits at the periphery of the fat necrosis (132) (Fig. 20-27). A polymorphous infiltrate surrounds the foci of fat necrosis and consists of neutrophils, lymphoid cells, macrophages, foam cells, and foreign body giant cells (135). There can be extensive hemorrhage into the lesions. Old lesions have macrophages, foam cells, lymphocytes, and fibroblasts, with fibrosis and hemosiderin deposition (132). In some cases of pancreatic enzyme panniculitis, possibly with early lesions, biopsies of subcutaneous nodules show only a nonspecific pattern of necrotizing panniculitis with a neutrophilic inflammatory response. Multiple biopsies and deep biopsies or biopsies of lesions of different ages may allow a definitive diagnosis.

Systemic Lesions. Fat necrosis also occurs in internal organs. The symptoms of arthralgia can be due to periarticular fat necrosis (135). Fat necrosis is common also in the pancreas and surrounding fat tissue and in the fat of the omentum, mesentery, pericardial, and perirenal regions as well as in the mediastinum and bone marrow (132). Calcium precipitation with the released fatty acids can be extensive enough to produce life-threatening hypocalcemia.

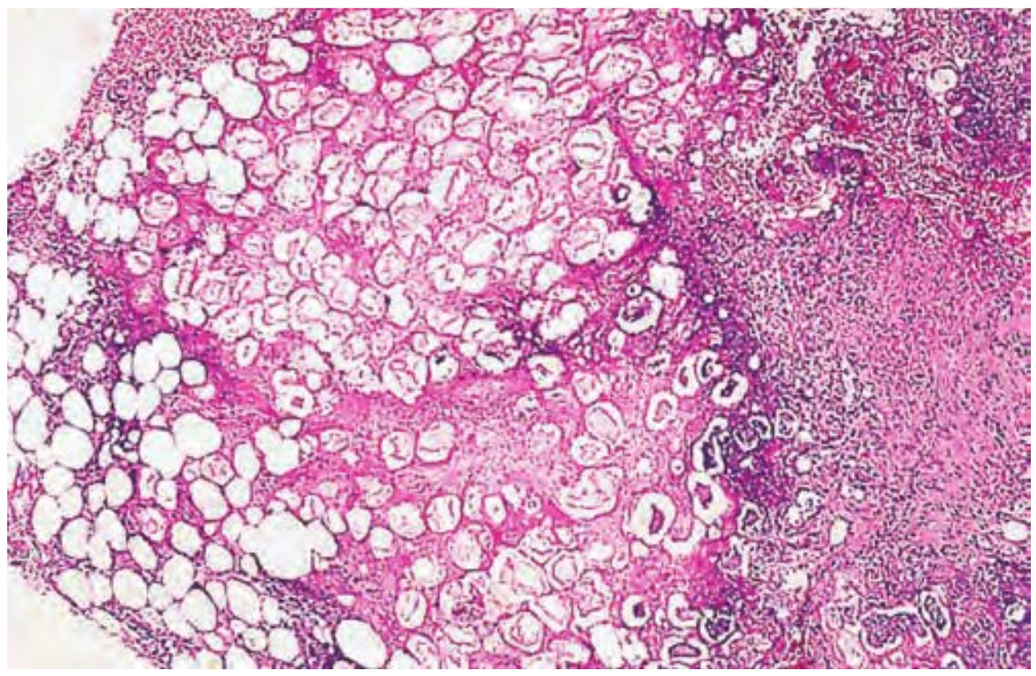

FIGURE 20-26 Pancreatic enzyme panniculitis. Necrotic fat cells contain eosinophilic deposits of partially hydrolyzed fat. Calcification forms granular basophilic material. Focal hemorrhage is frequent.

Pathogenesis. The damaged or tumorous pancreatic acinar cells release lipase, phospholipase, trypsin, and amylase into the surrounding tissues and blood. The serum values for amylase and lipase usually are elevated transiently and may not be detected in all cases. Amylase levels often peak 2 to 3 days after the appearance of the subcutaneous nodules (134). Lipase can be detected in the regions of fat necrosis and in ascitic fluid (136). It is not clear how the pancreatic proenzymes become activated in the tissues to produce fat necrosis. Local changes in vascular permeability due to trauma or other circulating enzymes, such as trypsin or phospholipase A2, may allow the pancreatic lipase to enter the interstitial compartment of the fat lobules and produce fat necrosis. Free fatty acids released by the lipolysis combine with calcium to form the soapy basophilic deposits in the tissue (137). Enzymatic damage to the integrity of the vascular wall can produce extensive hemorrhage.

FIGURE 20-25 Pancreatic enzyme panniculitis. Erythematous nodules appear most commonly on the lower legs.

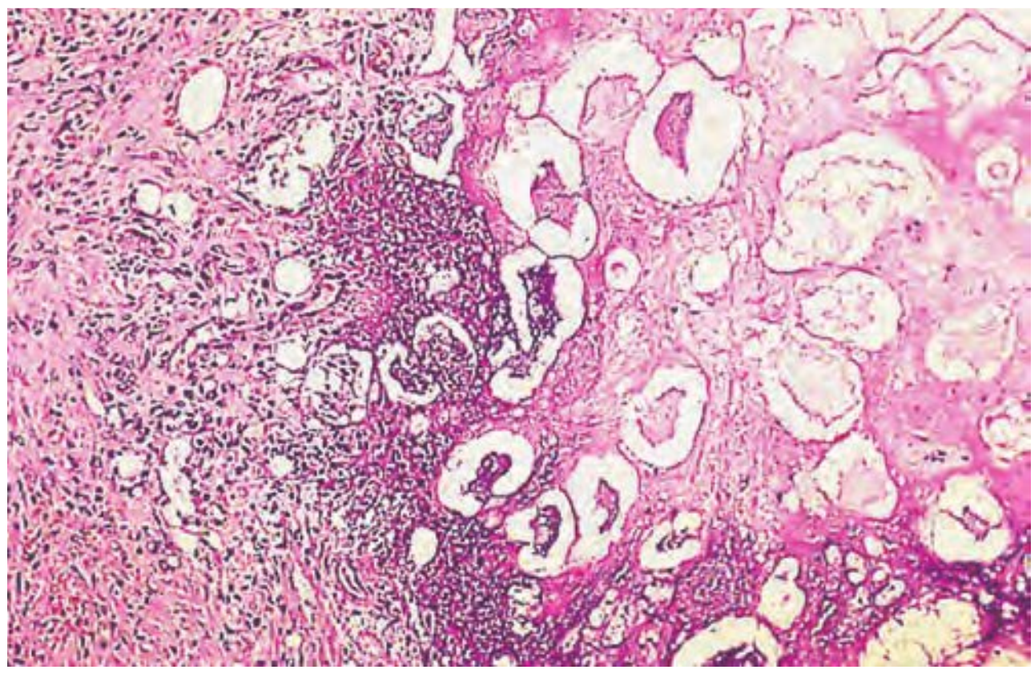

FIGURE 20-27 Pancreatic enzyme panniculitis. Many neutrophils are present in the margin of the zone of calcification and of fat necrosis.

Differential Diagnosis. The usual diagnostic distinction histologically is whether the fat necrosis is due to pancreatic disease or to physical trauma. Clinically, other considerations may include also erythema nodosum, erythema induratum, nodular vasculitis, AAT deficiency, disseminated infection, or Weber-Christian disease. Only pancreatic enzyme fat necrosis produces the basophilic deposits of calcium precipitated with abundant free fatty acids. All of the entities can have neutrophils in the fat. Basophilic DNA debris from neutrophil nuclei must be distinguished from calcium deposits. Von Kossa stains for calcium phosphate are positive on the calcium deposits in pancreatic enzyme fat necrosis and negative on necrotic nuclei. Septic foci of bacterial or fungal infection can require special stains to detect these organisms, especially in the presence of calcific and DNA debris. Despite vascular damage and hemorrhage, neutrophilic vasculitis usually is absent in fat necrosis due to pancreatic disease. Old lesions that have reabsorbed the calcium soaps cannot be distinguished easily from the other entities.

SCLEREMA NEONATORUM

Clinical Features. Sclerema neonatorum is a very rare disorder, usually in premature infants, that is characterized by a diffuse, rapidly spreading, nonpitting hardening of the subcutaneous fat of neonates in the first few days of life. The skin seems waxlike, tight, cold, and indurated. If untreated, death usually supervenes in a few weeks. On autopsy, the subcutis is greatly thickened, hardened, and lardlike. Most infants with sclerema neonatorum are cyanotic at birth, have difficulty maintaining their body temperature, and have a major debilitating illness (114).

Histopathology. The subcutaneous tissue owes its thickening to the increase in the size of the fat cells and to the presence of wide, intersecting fibrous bands (113,114). The lipid crystals inside the fat cells produce rosettes of fine needle-like clefts after lipid extraction in routine processing. In frozen sections, the crystals are not extracted and are visible in polarized light (138). In most instances, there is very little evidence of any inflammatory reaction to the fat necrosis, but very rarely, an inflammatory reaction containing giant cells can be found (138,139). Characteristically, the changes develop rapidly, are extensive, and elicit less inflammatory reaction than those of subcutaneous fat necrosis of the newborn or of localized cold panniculitis in young children.

Systemic Lesions. In most cases of sclerema neonatorum, the changes are limited to the subcutaneous fat (114). However, in two cases, autopsy revealed lesions in the visceral fat that were identical to those in the subcutis. In one case, the lesions were widespread (138), while in the other, the systemic lesions were limited to the perirenal and retroperitoneal fat (139).

Pathogenesis. Compared with the fat of the adult, the subcutaneous fat of the newborn has a greater ratio of saturated to unsaturated fatty acids, which raises the solidification point of the fat closer to room temperature. In sclerema neonatorum, these changes are exaggerated so that the neutral fat (triglyceride) crystallizes at room temperature. The increased ratio of saturated (palmitic or stearic acid) to unsaturated fatty acids (such as oleic acid) may be produced by defective enzyme pathways that lead to an excess of saturated fatty acids (114). X-ray diffraction studies have shown that the crystals in the fat cells are due to triglycerides (140). It is likely that the use of thermally controlled incubators for premature infants has caused this disease to be extremely rare. This same mechanism of injury is operative in localized cold panniculitis in infants.

Differential Diagnosis. Generalized edema due to an immature renal system can mimic some aspects of sclerema neonatorum clinically. However, in renal failure, the generalized edema is pitting while in sclerema it is not. Lymphedema (Milroy's disease) can produce nonpitting edema, particularly of the legs, in an otherwise healthy infant. Biopsies are not advised but show dilation of lymphatics. Erysipelas is more demarcated, warm, and tender than sclerema.

SUBCUTANEOUS FAT NECROSIS OF THE NEWBORN

Clinical Features. Subcutaneous fat necrosis of the newborn usually occurs in premature or full-term infants, often after a complicated delivery by forceps or by cesarean section (141). Indurated, erythematous to violaceous nodules and plaques appear in the subcutis a few days to a week after birth. Rarely, in cases with numerous nodules, the lesions may discharge a caseous material (142). The patient's health generally is good, and the nodules resolve spontaneously after a few weeks or months. Rarely, some infants are severely ill and die (142). In 16 reported cases, the subcutaneous fat necrosis was associated with hypercalcemia, and 3 patients died (143). Thrombocytopenia, hypertriglyceridemia, and hypoglycemia have also been reported (144). The development of extensive fat necrosis has been reported in infants following induced hypothermia used in cardiac surgery (145) or after surface hypothermic treatment of birth asphyxia, producing hypercalcemia 7 weeks later. An underlying defect in composition and metabolism of fat has been assumed to exist in such cases. The cases need to be followed for the development of hypercalcemia, which may occur in approximately one third of cases (141). Subcutaneous fat necrosis has been reported also in a number of rare associations (3), including with maternal cocaine use and intrapartum administration of calcium channel blockers.

Histopathology. Focal areas of fat necrosis are present in the fat lobules and are infiltrated by macrophages and foreign body–type giant cells (Fig. 20-28). Fat deposits in the macrophages and giant cells contain crystalline fat, which after lipid extraction appears as needle-shaped clefts in a radial arrangement (146) (Fig. 20-29). In frozen sections, the radial clefts contain doubly refractile crystals. Calcium deposits usually are small and scattered in the necrotic fat. If the necrosis is

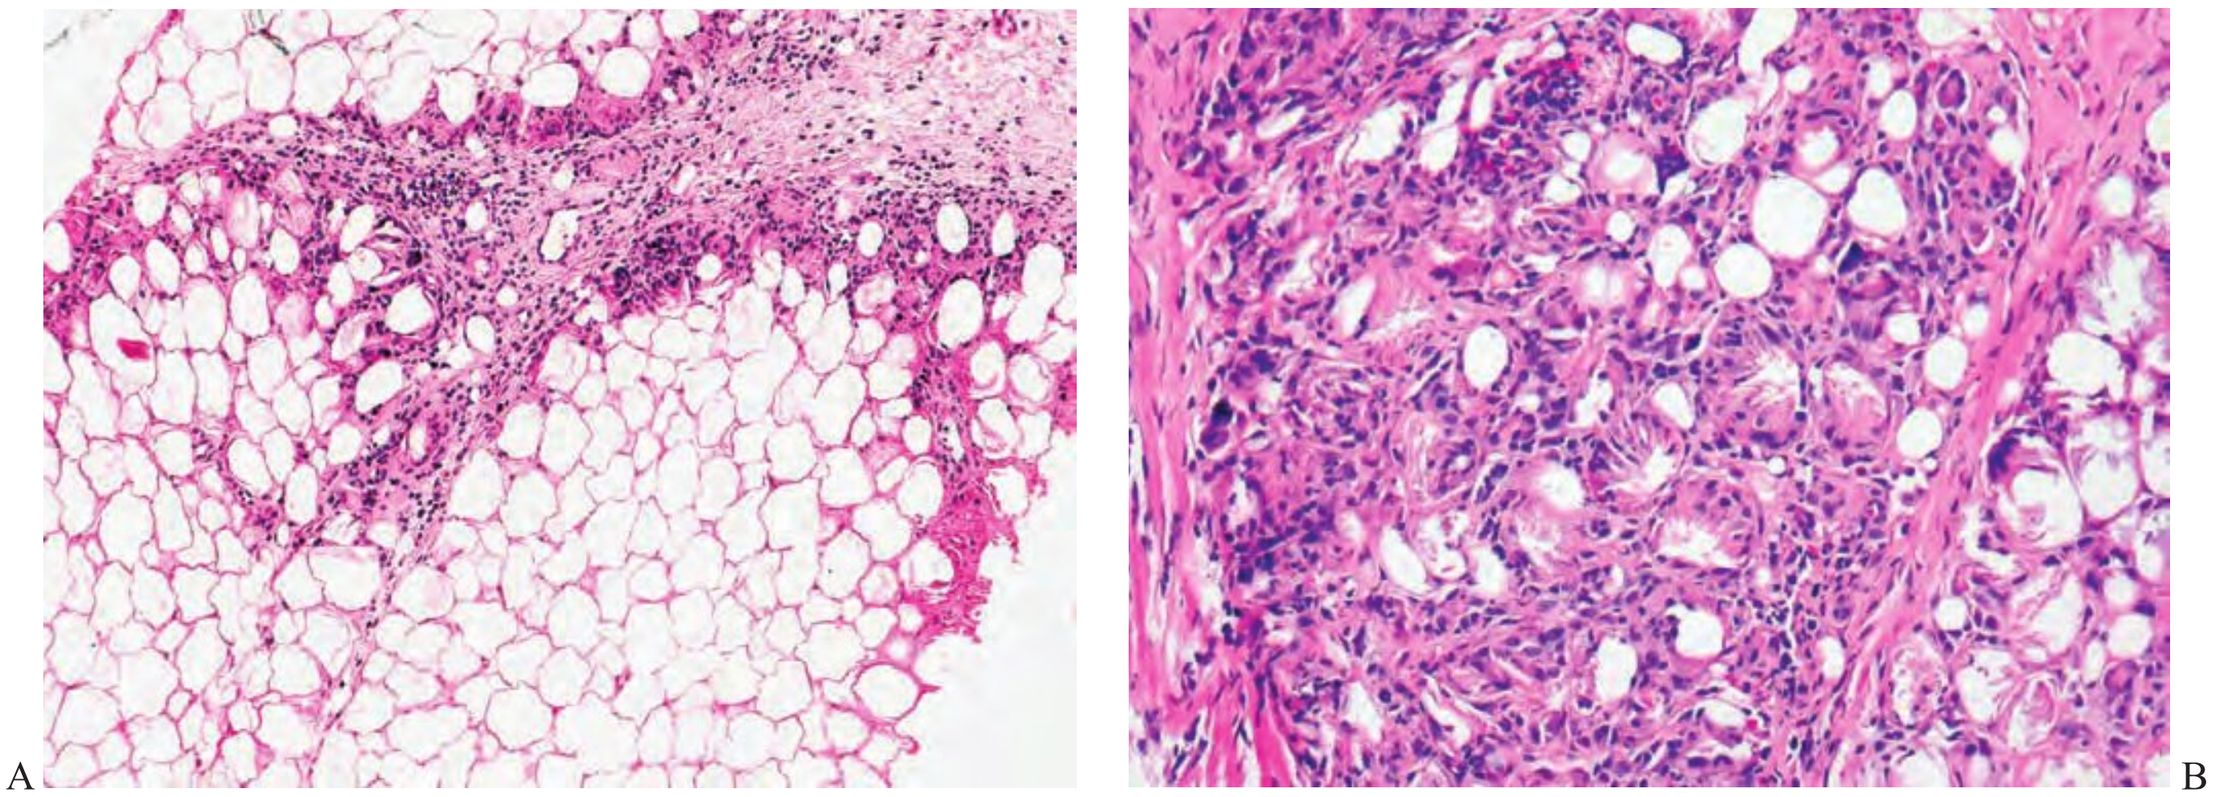

FIGURE 20-28 Subcutaneous fat necrosis of the newborn. A: Early lesion with many macrophages and multinucleated cells at the periphery of the damaged fat lobule. B: Later lesion with replacement of the fat lobules by macrophages and multinucleated cells.

extensive, calcium deposits may be large and require several years to be reabsorbed.

Pathogenesis. Electron microscopic examination shows that the phagocytosis of fat crystals starts with the invasion of fat cells by cytoplasmic projections of macrophages. Subsequently, fat crystals are seen within the cytoplasm of macrophages and of foreign body–type giant cells, which result from fusion of the macrophages (146).

The cause of subcutaneous fat necrosis of the newborn is not known. There is debate about the role of trauma, as many of the patients have been premature infants who were born by forceps delivery or who otherwise endured a difficult delivery. However, lesions have been reported in children delivered by cesarean section (3,141).

Differential Diagnosis. Both subcutaneous fat necrosis of the newborn and sclerema neonatorum have crystalline arrays of needle-like clefts in the fat. Sclerema is a catastrophic diffuse illness that gives little time for extensive inflammation; thus, in sclerema, there is an absence of focal areas of fat necrosis with macrophages and giant cells. In sclerema, there is also an absence of calcifications and the presence of wide bands of fibrous tissue in the subcutis (114). Treatment of children with high doses of steroids—for example, as was done for rheumatic fever—can produce poststeroid panniculitis with subcutaneous lesions very similar histologically to those of subcutaneous fat necrosis of the newborn (147). The deep nodules usually occur within 1 to 30 days after the cessation of high-dose steroid treatment. Traumatic fat necrosis has focal areas of necrosis and inflammation but lacks the crystals in the fat. Localized infection can be difficult to exclude clinically, but the infants with subcutaneous fat necrosis are generally rather healthy and are not septic.

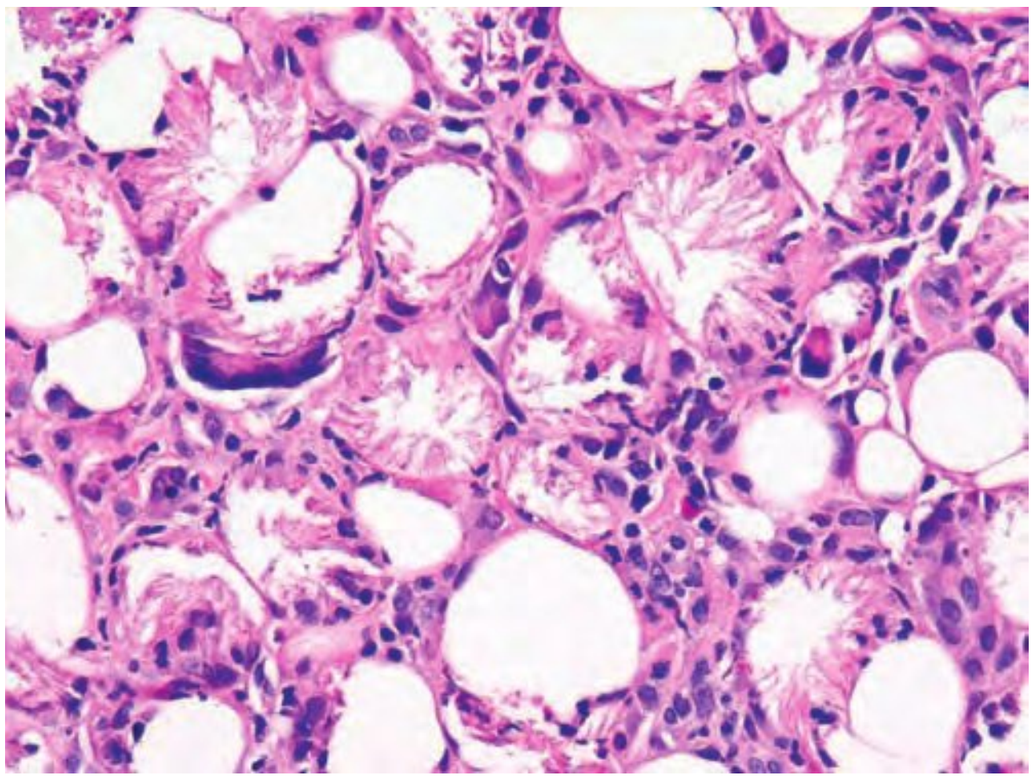

FIGURE 20-29 Subcutaneous fat necrosis of the newborn. A higher magnification shows that the radial arrays of crystalline fat leave clefts in the cytoplasm of the macrophages and damaged adipocytes.

CALCIFYING PANNICULITIS

Clinical Features. Patients with end-stage renal disease or hyperparathyroidism may develop indurated, erythematous, cold, subcutaneous and dermal nodules and plaques (Fig. 20-30). The lesions can progress to extensive dry gangrenous necrosis of the skin and subcutis. The lesions can be related to the prior administration of medications containing calcium or phosphates so that the balance of calcium to phosphate is so disturbed as to favor precipitation of calcium phosphate salts in the tissue. Plaques

FIGURE 20-30 Calcifying panniculitis. This patient with hyperparathyroidism developed erythematous, hemorrhagic, indurated plaques that were cold to the touch.

often are localized at usual sites of subcutaneous injection such as the thighs and abdomen.

Histopathology. The early or minimal lesions of patients with this disorder often have calcification of the media of the medium-sized blood vessels and of the walls of small capillaries in the subcutis (Fig. 20-31). In *calciphylaxis* associated with chronic renal failure, calcification and fibrointimal hyperplasia occlude the lumen of small arteries (148). In severe cases, calcium phosphate crystals form in the small vessels and interspaces between fat cells in the lobules of subcutaneous fat. The affected vessels can undergo thrombosis producing ischemic necrosis of the subcutaneous fat and even the overlying dermis and epidermis.

Pathogenesis. Calciphylaxis is a condition in which the balance of calcium and phosphate favors precipitation of calcium phosphate at the sites of trauma, cold injury, injection of medications containing calcium or phosphate compounds, or in vessel walls. The patients usually have end-stage renal disease and less commonly primary hyperparathyroidism. Case reports indicate that the phenomenon of calcium precipitation can be induced locally by injections of an anticoagulant drug such as calcium heparinate (149), by infusions containing excess phosphate, or for unknown reasons during hemodialysis (150). In young children, extensive subcutaneous calcifications can result from subcutaneous fat necrosis of the newborn. In adults, the differential diagnosis also includes a prior episode of pancreatic fat necrosis or traumatic fat necrosis. Radiologic findings in traumatic fat necrosis are generally a central lucent fat cyst with surrounding curvilinear calcifications, or coarse calcifications, or microcalcifications (151). The extensive calcification of the media of small arterioles is distinctive for calciphylaxis. The concept of calciphylaxis, as introduced by Seyle, has been presented as involving challenge by agents in a setting of hypersensitivity to calcium that led to local calcification. The metastatic calcification in renal disease is due to elevated calcium and phosphate levels and is only vaguely related to the Seyle's presentation of calciphylaxis (152).

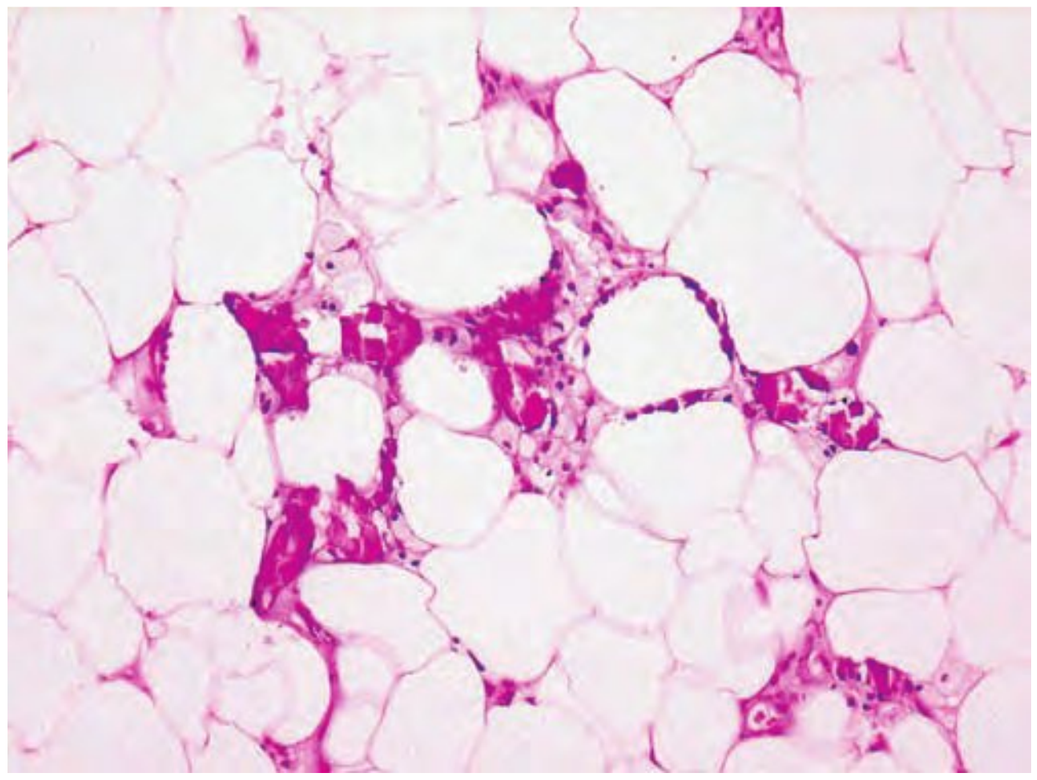

FIGURE 20-31 Calcifying panniculitis. Precipitation of calcium phosphate salts in the blood vessel walls produces a purple-stained deposit. These deposits lead to thrombosis and ischemic necrosis of the adjacent fat and overlying skin.

LIPOMEMBRANOUS CHANGE OR LIPOMEMBRANOUS PANNICULITIS

Clinical Features. Patients with severe stasis, diabetes, and other causes of arterial vascular insufficiency to the lower legs can develop indurated plaques in the subcutis. They are depressed and painful but rarely ulcerate (153–156). The lesions are named *lipomembranous panniculitis* based on the microscopic finding of lipomembranes around fat deposits or "cysts," more properly termed *pseudocysts*. Lipomembranous change has been found also in a number of primary disorders including lupus erythematosus panniculitis, morphea, erythema nodosum, erysipelas, necrobiosis lipoidica, and traumatic panniculitis (157,158). Ischemia and/or stasis can lead to extensive, depressed, hard areas of skin, often on the lower legs and accompanied by hemosiderosis, with epidermal and dermal atrophy, which is a condition named *lipodermatosclerosis* (25).

Histopathology. Biopsies deep into the fat show a lobular panniculitis with focal macrophage infiltration and fibrosis around shrunken lobules. Within the lobules, there are fat pseudocysts that are lined by a thin eosinophilic layer, called a *lipomembrane*, which has fine, feathery projections into the fat cavity (Fig. 20-32A). Spectral imaging shows that the lipomembranes are spectrally distinct from the periphery of surrounding fat cells (Fig. 20-32B). The lipomembrane is positive on PAS stain (Fig. 20-33) and, in late lesions, with elastic tissue stains (158). The lipomembranes are positive for CD68 and lysozyme, suggesting a contribution of these enzymes from the macrophages in the production of lipomembranes. Late or older lesions are only weakly positive or become negative for CD68 and lysozyme (158). Early lesions also have focal areas of fat necrosis, such as those produced by partial ischemia. Lipomembranes

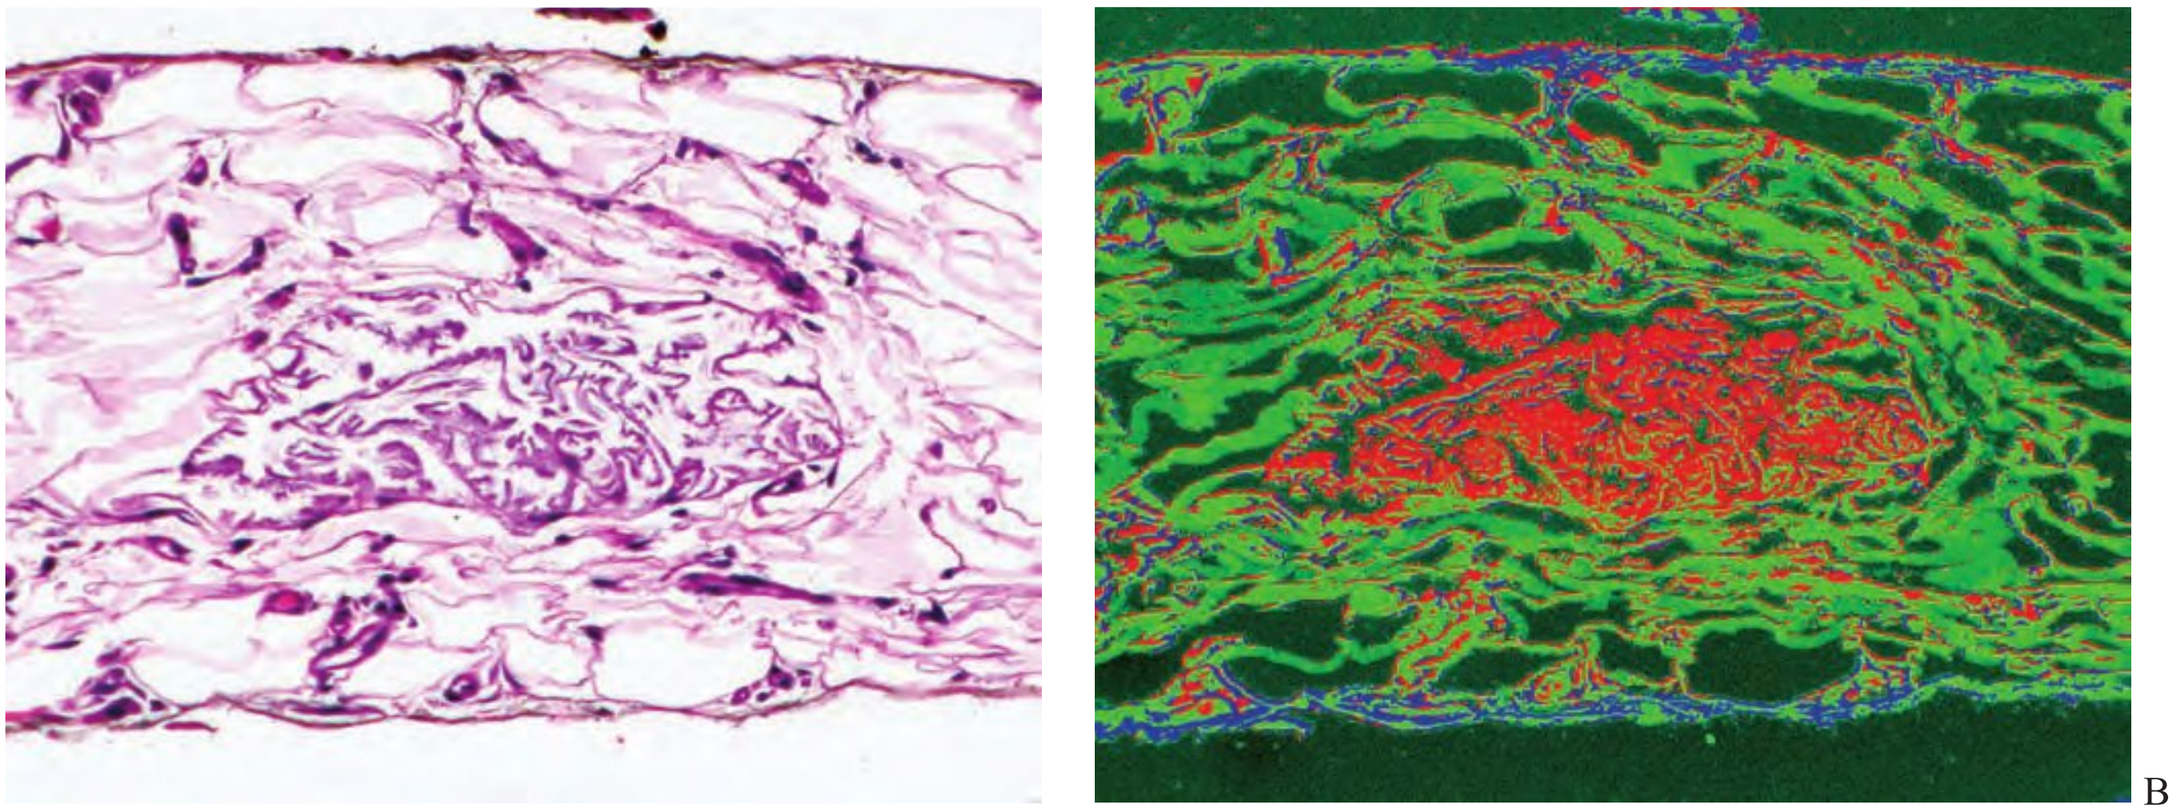

FIGURE 20-32 Lipomembranous panniculitis. A: Necrosis of the fat has produced a layer of pale amphoteric to eosinophilic material, a "lipomembrane" around the periphery of the fat globules. B: Spectral image demonstrating in red that the distinctive spectrum of the lipomembranes is similar to hematoxylin staining of nuclear material. The cytoplasm of adjacent damaged fat cells is shown in green, and the collagen of the septa is in blue.

often can be found in the remaining small fat lobules in late stages of *lipodermatosclerosis*, in which there also is dermal fibrosis with loss of epidermal appendages and fibrous tissue replacement of much of the subcutaneous fat (25).

Differential Diagnosis. This is not a very specific entity and probably reflects the tendency of necrotic fat to accumulate fibrin and lysosomal enzyme containing material from macrophages at the surface of the exposed fat. Although extensive lipomembranous change is rare in uncomplicated traumatic fat necrosis when compared with ischemic panniculitis, a few cases of extensive lipomembranous change have followed minor surgical trauma, possibly related to medications the patient received.

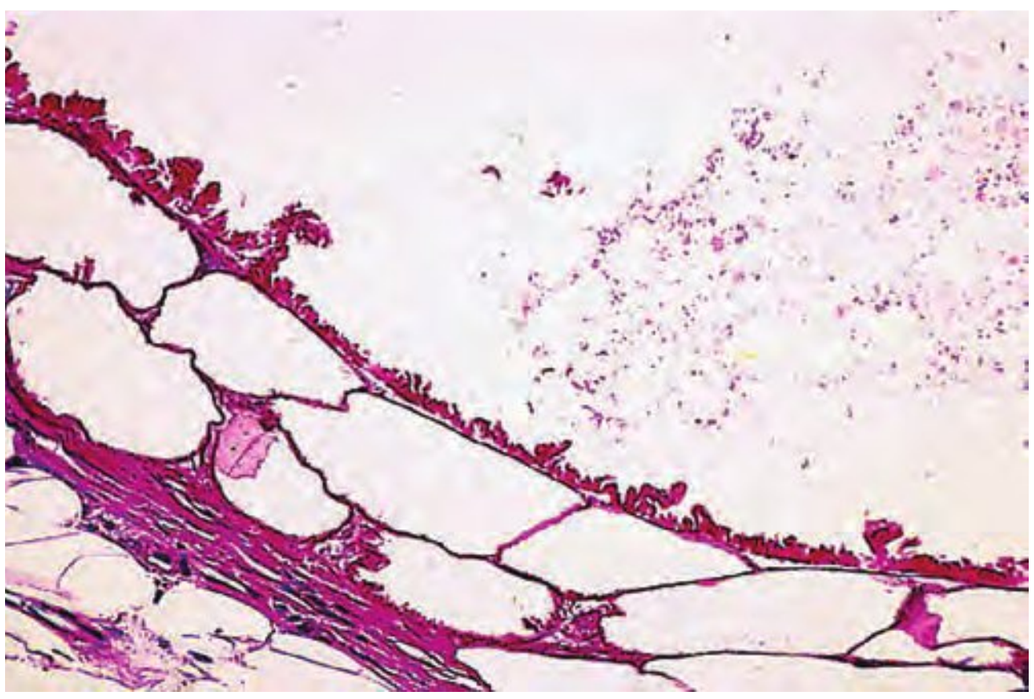

FIGURE 20-33 Lipomembranous panniculitis. Lipomembranes have feathery projections into the fat globules and are PAS positive (PAS stain).

HISTIOCYTIC CYTOPHAGIC PANNICULITIS (SUBCUTANEOUS T-CELL LYMPHOMA WITH HEMOPHAGOCYTIC SYNDROME)

Clinical Features. Histiocytic cytophagic panniculitis is frequently a fatal systemic disease that is characterized by recurrent, widely distributed, painful subcutaneous nodules associated with malaise and fever (90,159–161). The nodules can be hemorrhagic (Fig. 20-34). Ulcers may be present (162).

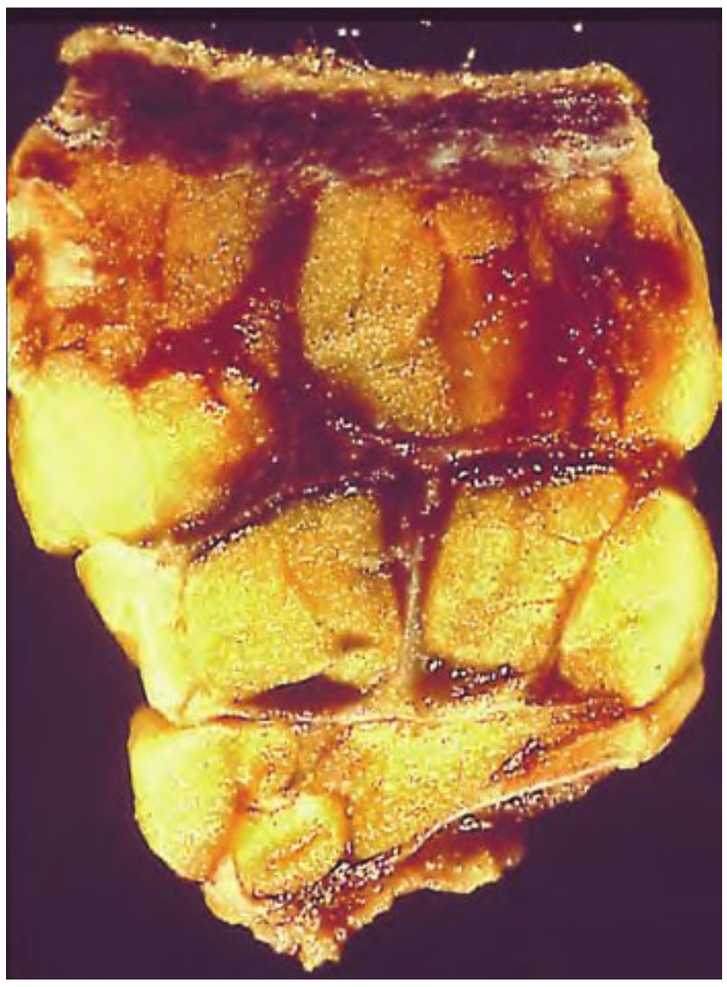

FIGURE 20-34 Histiocytic cytophagic panniculitis. This cross-sectioned skin nodule shows both septal and lobular infiltration and hemorrhage. Note also the dermal hemorrhage.

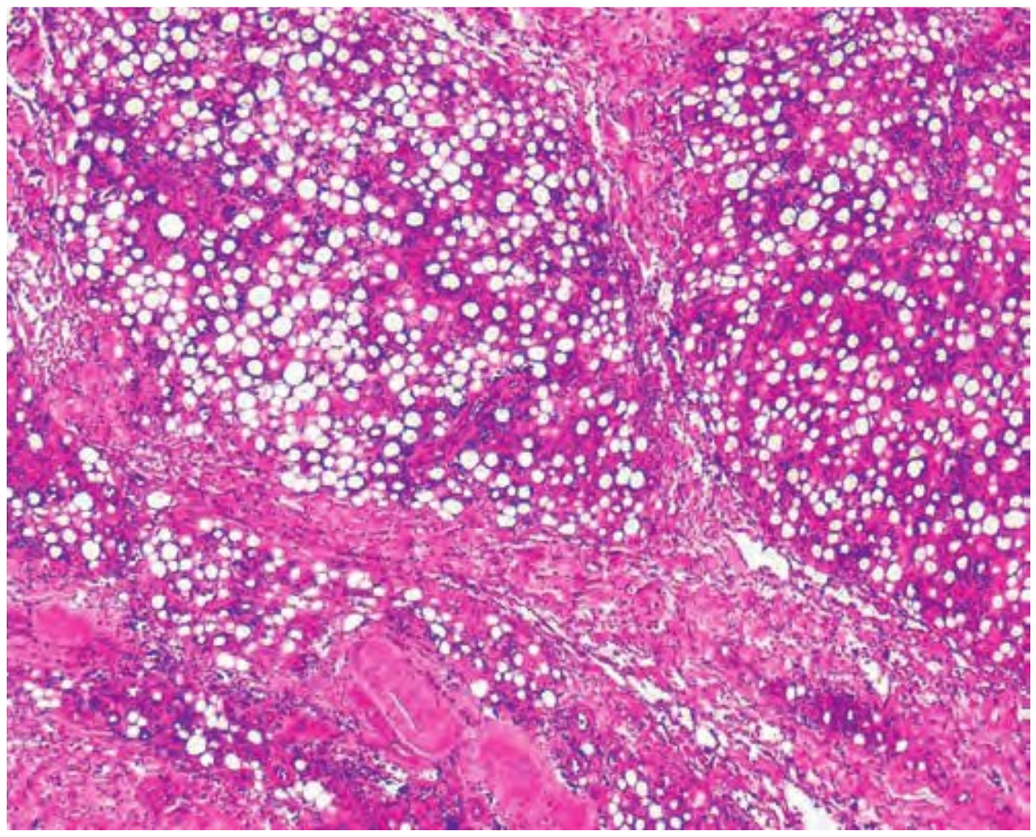
Hepatosplenomegaly, pancytopenia, and progressive liver dysfunction develop in most cases (163). The patients may follow a long chronic course, or the disease can be fulminant. The patients usually die a hemorrhagic death due to depletion of blood coagulation factors. Aggressive chemotherapeutic intervention, analogous to that used for malignant histiocytosis, has resulted in remission in one patient (164). In some patients, the disease seems limited to the skin and subcutaneous tissue and follows a more benign course (159).

Histopathology. In the subcutis, the inflammation is both septal and lobular (Fig. 20-34). A deep biopsy usually shows both subcutaneous and dermal nodules composed of macrophages and a mixed inflammatory infiltrate. Often, there is necrosis and hemorrhage (Fig. 20-35). The nuclei of the macrophages are within the range of sizes and shapes seen in benign inflammatory disorders. In some cases, lymphocytes infiltrate medium-sized blood vessel walls (Fig. 20-36A). In some areas, the macrophages become so engorged by phagocytosis of erythrocytes, lymphocytes, and cell fragments that they have been called *bean bag cells* (90) (Fig. 20-36B). In



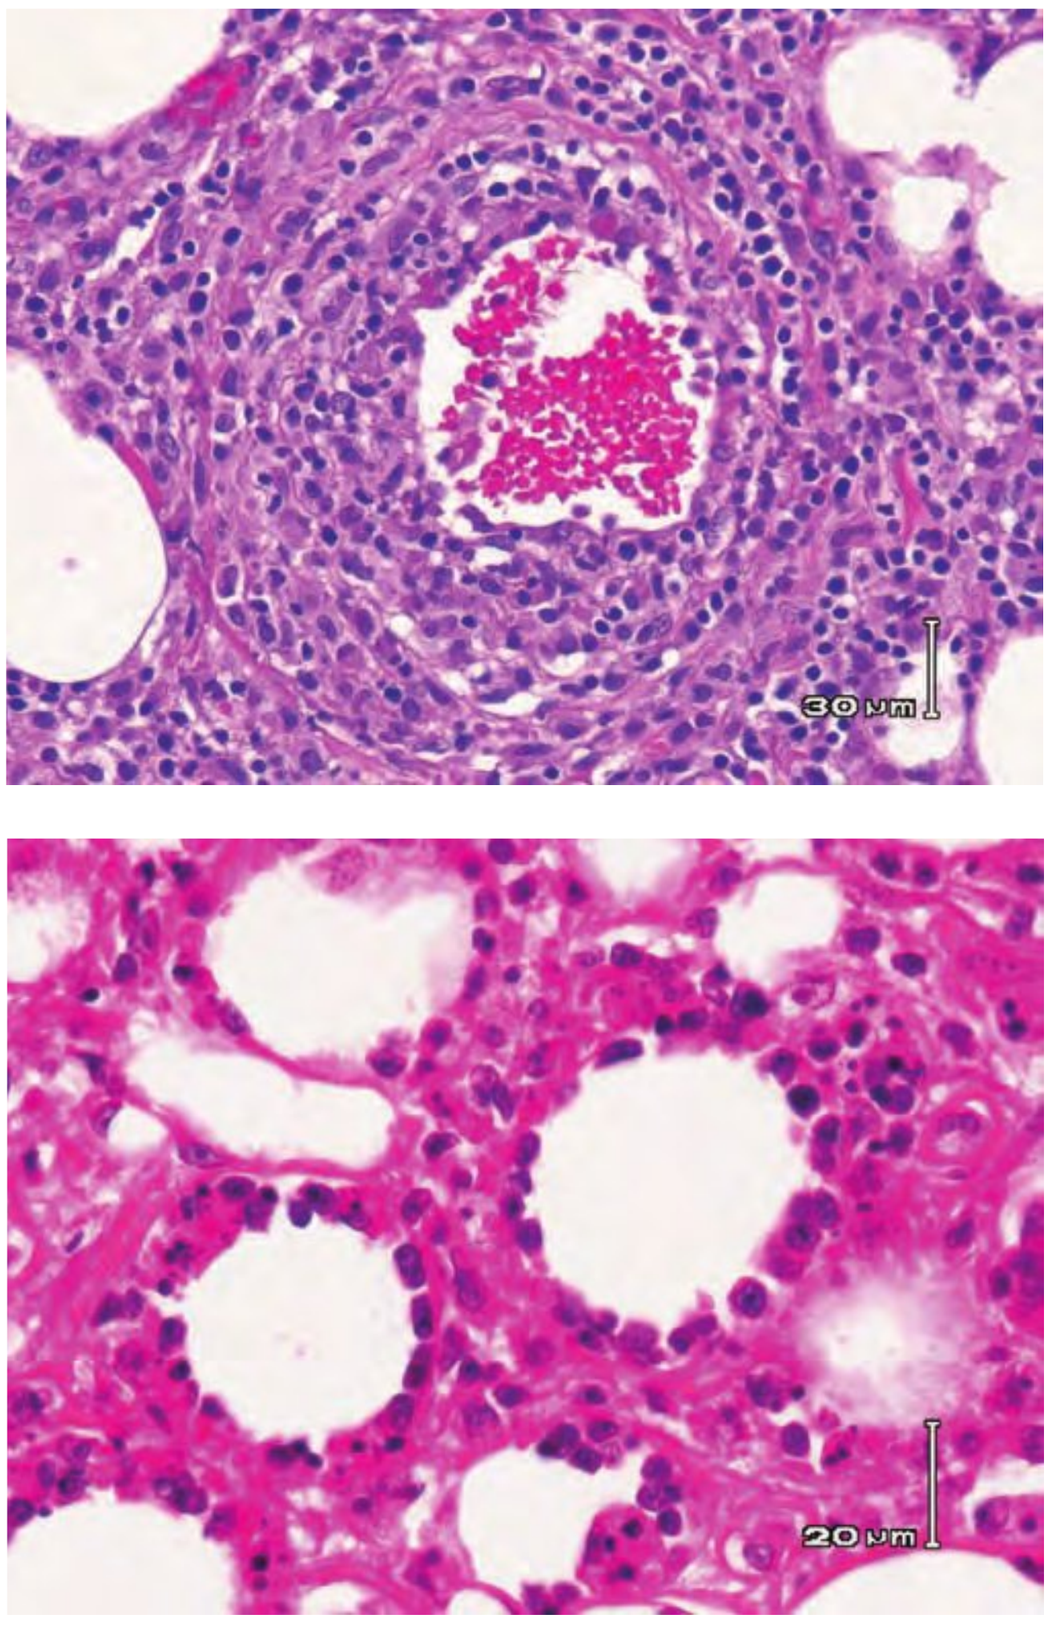


FIGURE 20-35 Histiocytic cytophagic panniculitis. There is hemorrhagic necrosis of the fat with an infiltrate of lymphocytes and macrophages.

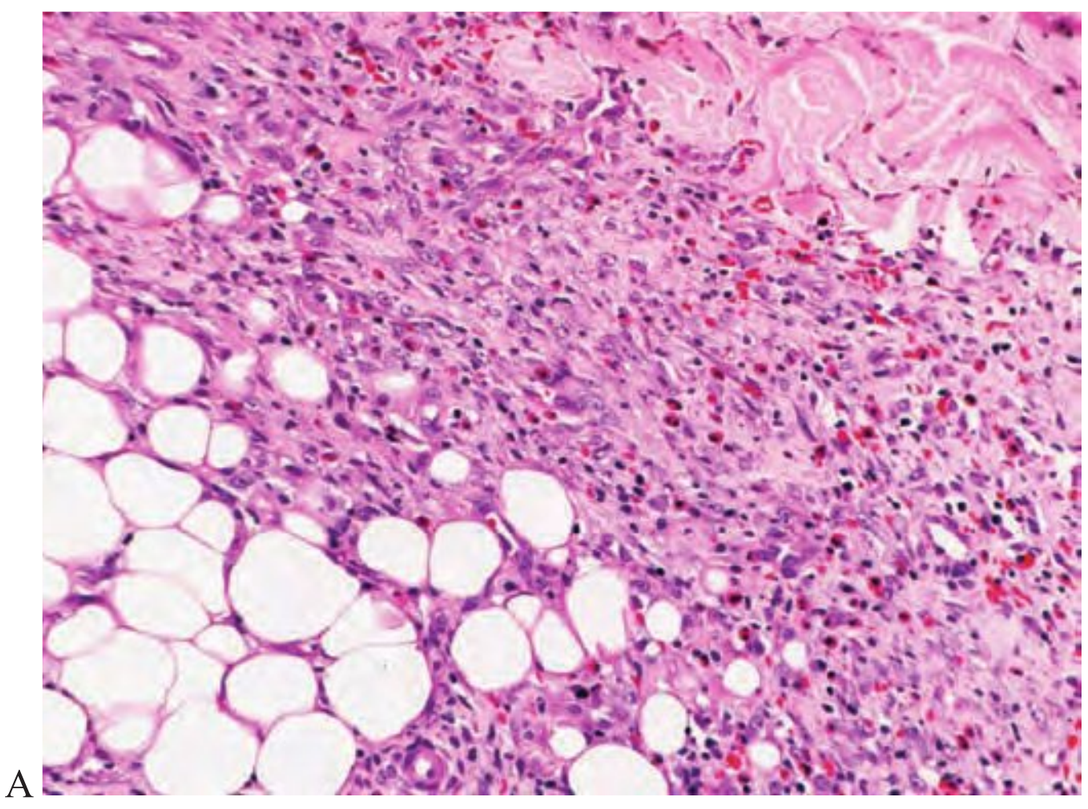
A B C

FIGURE 20-36 Histiocytic cytophagic panniculitis. A: Extensive infiltration of blood vessel walls by lymphocytes. B: Characteristic cytophagic histiocytes that have engulfed lymphocytes and erythrocytes to form so-called "bean bag cells." C: Distinctive rings of atypical lymphocytes around fat cells in subcutaneous T-cell lymphoma, which is often a trigger for the cytophagic histiocytic activity.

some patients, early lesions contain a rather dense infiltrate of small lymphocytes and only a few focal areas with cytophagic histiocytes. In some of the cases due to subcutaneous T-cell lymphoma, atypical lymphocytes can be found in rosettes around fat cells (Fig. 20-36C).

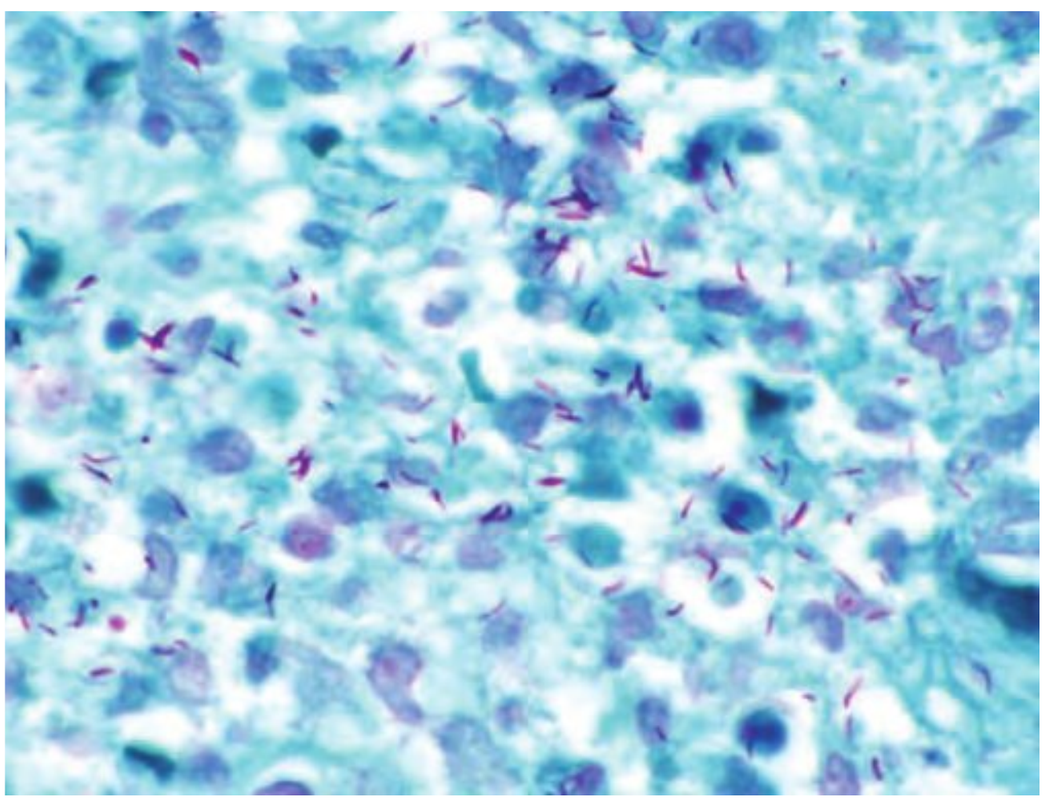
The involvement of other organs by similar cytophagic macrophages leads to diffuse infiltration of the liver, bone marrow, spleen, lymph nodes, myocardium, lungs, and gastrointestinal tract (165). The cytophagic macrophages can deplete almost all of the bone marrow elements.

Pathogenesis. When originally described, the disease was differentiated from malignant histiocytosis by the fact that the nuclei of the macrophages in the cytophagic panniculitis were not cytologically atypical. Due to the fulminant course in some patients, the disease initially was considered by some authors to be a variant form of malignant histiocytosis that can remain confined to the skin and subcutis for a protracted period (166). However, more recently, the similarity to terminal hemophagocytic syndromes associated with lymphomas (167,168) has led to consideration that most cases of cytophagic panniculitis result from an abnormal lymphocyte population that has stimulated benign macrophages to engage in fulminant hemophagocytosis (169–173). The patients may have the hemophagocytosis secondary to a T-cell lymphoma of the gamma/delta subtype (which has an associated hemophagocytic syndrome more frequently than the alpha/beta subtype) or an NK/T-cell lymphoma ($CD2^+$ $CD3^-$ $CD8^+$ $CD56^+$) that has also been associated with a hemophagocytic syndrome (79,174). Viral infections that are associated with hemophagocytic syndromes, without lymphoma, usually do not have panniculitis. Benign cytophagic histiocytes can be found in some cases of AAT deficiency panniculitis, ruptured cysts, and infections and can be mimicked by emperipolesis in Rosai-Dorfman disease (4).



MISCELLANEOUS PANNICULITIS

The administration of bromide and iodide compounds can produce a panniculitis, usually in association with changes in the overlying epidermis and dermis. Due to the decrease in therapeutic use of bromide and iodide compounds, the number of patients with this disorder has decreased dramatically. In reactions to bromides and iodides, there is epidermal hyperplasia that can develop pseudoepitheliomatous features with intraepidermal abscesses of neutrophils and eosinophils. Allergy to potassium bromide has been demonstrated in some patients by a lymphocyte-transformation test (175).



Painful lipomatous masses can develop in severely obese patients with histologic evidence of inflammation of nerves and endocrine abnormalities. This disease, called *adiposis dolorosa* or *Durcum's disease*, is rare, occurs in middle age, and affects females more than males (176,177).

Mycobacterial infection of the fat can produce a *mycobacterial panniculitis* that can mimic erythema nodosum (Fig. 20-37A) as well as erythema induratum (178). Special stains for acid-fast bacteria and cultures are important for the identification of the responsible mycobacteria (Fig. 20-37B). Often, nontuberculous mycobacteria are involved in countries with a low incidence of tuberculosis.

Morphea or scleroderma can produce a panniculitis that has dense infiltrates of lymphocytes and plasma cells at the

A

B

FIGURE 20-37 Mycobacterial panniculitis. Direct M. tuberculosis infection of the panniculus in an HIV-positive patient, which has produced primarily a paraseptal panniculitis with many eosinophils and macrophages adjacent to the septa. A: Erythema nodosum can be mimicked. B: Staining for mycobacteria shows that numerous red, acid-fast bacilli (arrow) are present in this example (AFB stain).

periphery of the fat lobules, particularly at the junction of deep reticular dermis and the subcutis. Characteristically, the septa are widened and have hyalinized sclerotic collagen. Similar changes in the collagen are noted in the overlying dermis in most cases. Some of the changes are similar to those of lupus panniculitis; therefore, immunofluorescence and serologic tests are needed to distinguish them (179–181). Discoid lupus erythematosus with panniculitis has more fibrinoid necrosis of the dermis, which stains more brightly eosinophilic than the staining of the pale sclerotic collagen bundles of morphea or scleroderma panniculitis.

Pyoderma gangrenosum can produce ulcers that are difficult to distinguish from those of an ulcerating primary panniculitis (31,182). However, the gross appearance of pyoderma gangrenosum is characteristic in the irregularity of the ulcers, the usual shallowness, and the undermined violaceous borders. Biopsies taken at the edges of the ulceration may show pustules and lymphocytic inflammation in the dermis with extension of the lymphoid cells into the septa and lobules of the panniculus. The lesions do not have the extensive granulomatous necrosis of the fat that is present in erythema induratum. Acute bullous lupus erythematosus, with its superficial neutrophilic infiltrates, can ulcerate and require immunofluorescence studies to distinguish it from pyoderma gangrenosum. The sterile abscesses of AAT deficiency panniculitis resemble those of pyoderma gangrenosum but extend deeper than pyoderma gangrenosum, which also lacks perilobular subcutaneous abscesses.

SYSTEMIC INTERACTIONS WITH SUBCUTANEOUS FAT

Subcutaneous fat has evolved as an important energy storage system, whose metabolism is set to store energy when food is abundant and to release energy when food is scarce. It also serves for cushioning and maintenance of body temperature. Consequently, pathologic changes in the adipose tissue can have effects on the general metabolic state of the patient. For example, recent studies have revealed a complex interaction between the adipocytes and certain receptors in the hypothalamus that control appetite (183). The protein *leptin* is produced in a constant fashion by adipocytes, with a level that correlates with the size and number of fat cells. When the fat is abundant, leptin levels are increased and normally inhibit the hypothalamus at centers that increase hunger and feeding activity. Children born with a genetic block in the hypothalamus that prevents a response to high blood leptin levels have excessive eating activity that leads to massive obesity. Massive obesity can lead to lymphedema, fat necrosis, and fibrosis, as examples of morphologic impact on the subcutis (184). There are also important systemic complications, including hypertension, and accelerated atherosclerosis. Insulin levels are increased in the blood of such infants, and muscular movement activity levels are low. In obese mice with a defect in leptin production, the administration of synthetic leptin will lead to weight loss. In contrast, in common obesity in adult humans, leptin levels are high in the blood, and the lack of reaction in the hypothalamus prevents a response to synthetic leptin administration. Leptin interaction with the normal hypothalamus can also influence the level of thyroid hormone, decrease reproductive activity, and interfere with inflammatory activity and immune function (185). Leptin-deficient mice (Ob/Ob) with a defective Ob gene are protected in experimental models of inflammation, including autoimmune encephalomyelitis, arthritis, and delayed hypersensitivity reactions. While the hormone production by adipose tissue may be related to increased metabolic energy demand during inflammation, its consequences are at an early level of study. Leptin derived from adipocytes and preadipocytes has been shown to have regulatory activity on Toll-like receptors of the innate immune system. Studies of whole adipose tissue have shown that on stimulation, inflammatory mediators are produced, including tumor necrosis factor (TNF)-alpha, IL-6, and IL-10. TNF-alpha regulates fat mass by decreased lipogenesis, increased lipolysis, and induction of insulin resistance and can initiate apoptosis in adipocytes and preadipocytes. IL-6 increases lipolysis. The balance between preadipocyte differentiation and apoptosis of adipocytes influences the number of adipocytes, even in adults. Apoptosis of adipocytes is likely to play an important role in the lipoatrophy/lipodystrophy syndrome of patients with HIV infection and treatment with protease inhibitors. Adipocytes also secrete the agouti peptide (an antagonist to the melanocortin receptor, with additional multiple paracrine functions). This peptide also functions in the control of peripheral lipid metabolism. Loss of function mutations in the melanocortin receptor gene are a cause of monogenic human obesity (186).

Recent studies have also indicated that cells isolated from adipose tissue, and classified as adipocytes or preadipocytes, express Toll-like receptors, which are the products of evolution based on a need for a very rapid response to certain lethal organisms, for which adaptive immunity may be too slow to save the patient. Approximately 10 Toll-like receptors have been identified, and they recognize different repetitive sequences on the surfaces of bacteria, including mycobacteria, and viruses. Activation of Toll-like receptors can stimulate the production of proinflammatory cytokines and chemokines and the expression of costimulatory molecules necessary for initiating a response of the adaptive immune system. The activation can include the chemoattraction of neutrophils and macrophages to the area. For example, activation of Toll-like receptor TLR-4 leads to activation of the nuclear transcription factor NFkB, which then activates genes that encode for proteins that are involved in the defense against infection. The need for a rapid response system in adipose tissue is most easily understood in the mesenteric fat, which is penetrated by bacterial antigens that filter in from small leaks in the intestinal permeability barrier. Perhaps such reactivity in adipose tissue in other regions, such as the lower legs, has evolved from breaks in the cutaneous permeability barrier (e.g., in the feet and toes). Also low-grade inflammation in the adipose tissue

appears to be important in its correlation with the syndrome of insulin resistance in obese diabetic patients (187). Future research in this area also seems likely to be productive in explaining some of the patterns of inflammation in subcutaneous fat that have been presented in this chapter.

In Memoriam. In July 2007, during the initial phases of this revision of this chapter, Dr. Abelardo Moreno succumbed to a brief illness in Barcelona. His loss is great to us and especially to the young dermatopathologists in training in Spain. His teaching efforts had a worldwide scope, and he pushed us all to do our best work. He remains a coauthor on this chapter in honor of his major contributions to it since the start of our work together.

CHAPTER 21

Sebastian Lucas

Bacterial Diseases

A wide range of bacteria, including mycobacteria and rickettsia, affect the skin and subcutis. In the ensuing descriptions of the histopathology of most of the cutaneous bacterial infections that may be encountered by the diagnostic pathologists, reference is also made to some epidemiology, clinical features and pathophysiology. The pathogenesis of the skin lesions is multifactorial, including the following:

- Toxin production
- Pyogenic and granulation tissue chemoattractants
- Immunopathology (complement activation and cell-mediated immunity)
- Vasculitis

IMPETIGO

Two types of impetigo occur: impetigo contagiosa, or nonbullous impetigo, usually caused by group A streptococci; and bullous impetigo, including the staphylococcal scalded-skin syndrome, which is caused by *Staphylococcus aureus* (1).

Impetigo Contagiosa

Impetigo contagiosa is primarily an endemic disease of preschool-age children that may occur in epidemics. Very early lesions consist of vesicopustules that rupture quickly and are followed by heavy, yellow crusts. Most of the lesions are located in exposed areas. An occasional sequela is acute glomerulonephritis.

Histopathology. The vesicopustule arises in the upper layers of the epidermis above, within, or below the granular layer. It contains numerous neutrophils (Fig. 21-1). Not infrequently, a few acantholytic cells can be observed at the floor of the vesicopustule. Occasionally, gram-positive cocci can also be found within the vesicopustule, both within neutrophils and extracellularly (2).

The stratum malpighii underlying the bulla is spongiotic, and neutrophils often can be seen migrating through it. The upper dermis contains a moderately severe inflammatory infiltrate of neutrophils and lymphoid cells.

At a later stage, when the bulla has ruptured, the horny layer is absent, and a crust composed of serous exudate and the nuclear debris of neutrophils may be seen covering the stratum malpighii.

Pathogenesis. In the United States, group A streptococci used to be the most frequently recovered organisms in patients with impetigo contagiosa, either alone or in association with *S. aureus.* However, the predominant pathogen responsible for impetigo has changed, and *S. aureus* is the most common organism in the United States and United Kingdom (3).

Differential Diagnosis. Histologic differentiation of impetigo contagiosa from subcorneal pustular dermatosis and from pemphigus foliaceus can be difficult. However, only impetigo shows gram-positive cocci in the bulla cavity. In addition, pemphigus foliaceus usually shows fewer neutrophils, more acantholytic cells, and occasionally some dyskeratotic granular cells.

Bullous Impetigo and Staphylococcal Scalded-Skin Syndrome

Phage group II staphylococci may produce bullous impetigo and the staphylococcal scalded-skin syndrome.

Bullous impetigo occurs mainly in newborns, infants, and young children. Occasionally, it is observed in adults, particularly in those with deficiencies in cell-mediated immunity (4,5). It is characterized by vesicles that rapidly progress to flaccid bullae with little or no surrounding erythema. The contents of the bullae are clear at first; later on, they may be turbid. Bullous impetigo may spread and become generalized, so clinical distinction from staphylococcal scalded-skin syndrome may be impossible (6). An important difference, however, is that cultures from intact bullae of bullous impetigo, unlike those of the staphylococcal scalded-skin syndrome, grow phage group II *S. aureus.*

Staphylococcal scalded-skin syndrome, first described more than 100 years ago and also known as Ritter's disease, occurs largely in the newborn and in children younger than 5 years of age. It rarely occurs in adults or in older children (7–9) except in the presence of a severe underlying disease (10).

The disease begins abruptly with diffuse erythema and fever. Large, flaccid bullae filled with clear fluid form and

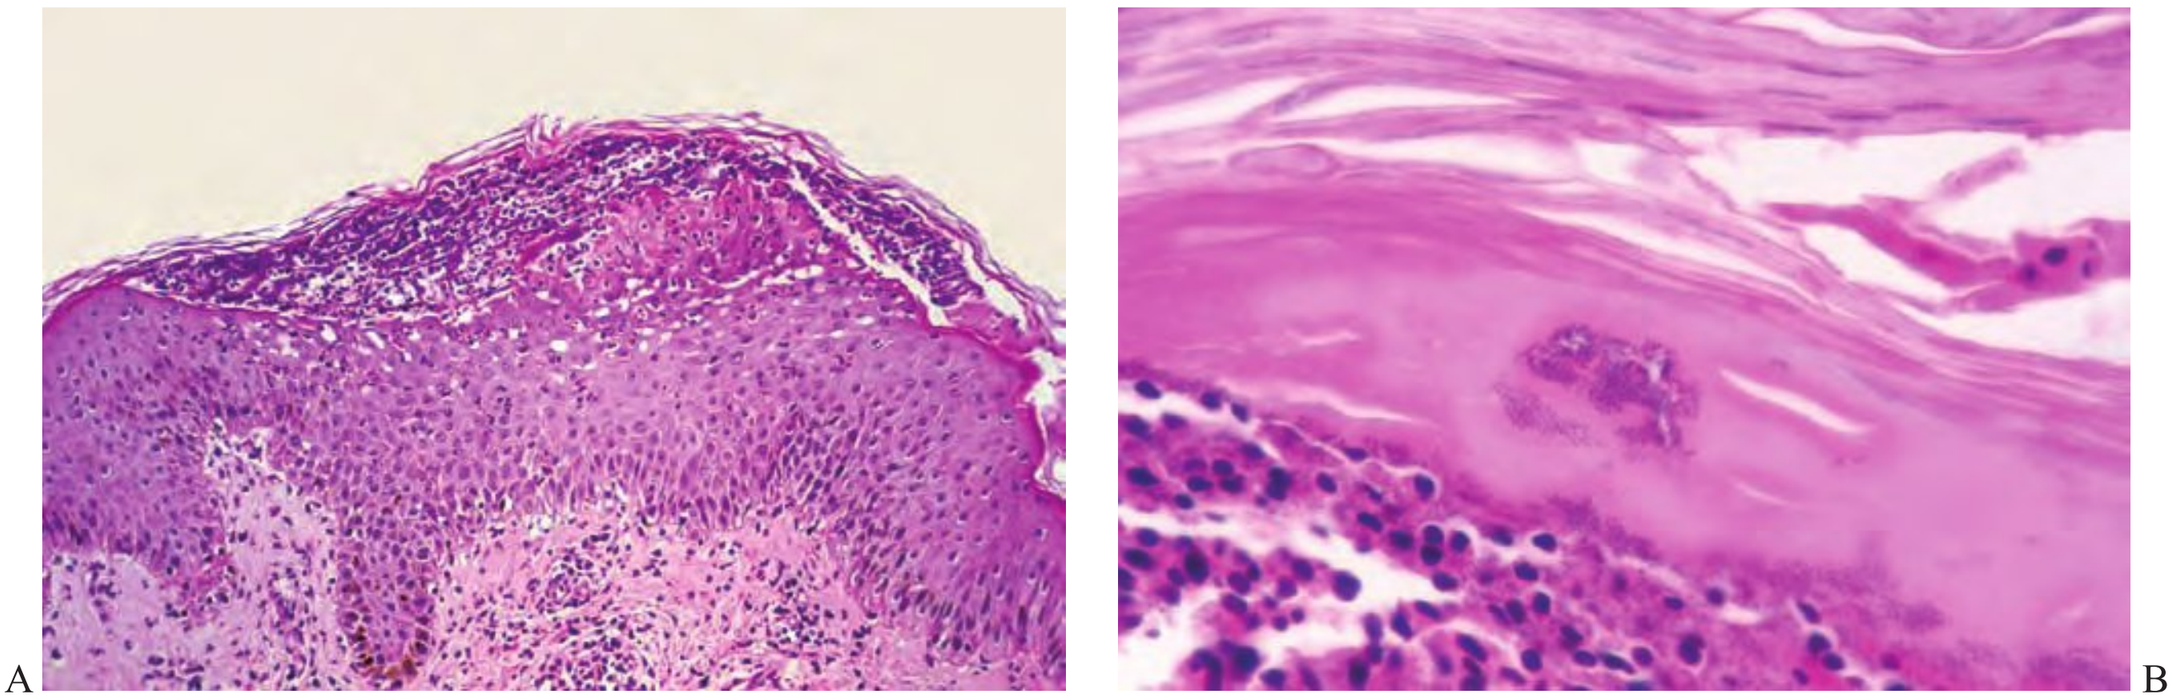

FIGURE 21-1. Impetigo contagiosa. A: In this relatively early lesion, neutrophils are seen in the upper epidermis, forming a subclone pustule. There is a superficial mixed infiltrate within the dermis. B: On closer inspection, neutrophils and bacterial colonies are seen within the stratum corneum. C: Yellow crusted vesiculopustules on the back of the hand of a child. (Part C image courtesy of C. Kovarik.)

rupture almost immediately. Large sheets of superficial epidermis separate and exfoliate. The disease runs an acute course and is fatal in <4% of all cases in children (11). Most fatalities occur in neonates with generalized lesions. In contrast, in the rare cases of staphylococcal scalded-skin syndrome occurring in adults, the prognosis is much worse, with a mortality rate exceeding 50%. Death is usually related to the coexistent disease or to immunosuppressive therapy given for it. Both bullous impetigo and staphylococcal scalded-skin syndrome are transmissible and can cause epidemics in nurseries, where they may occur together (12).

An important difference between the two diseases is that no phage group II staphylococci can be grown from the bullae of the staphylococcal scalded-skin syndrome, in contrast to the bullae of bullous impetigo. The absence of phage group II staphylococci from the bullae of staphylococcal scalded-skin syndrome results from the fact that these staphylococci are present at a distant focus. Usually, the distant focus is extracutaneous and consists of a purulent conjunctivitis, rhinitis, or pharyngitis. Rarely, the distant focus consists of a cutaneous infection or a septicemia.

Histopathology. In both bullous impetigo and staphylococcal scalded-skin syndrome, the cleavage plane of the bulla, like that in impetigo contagiosa, lies in the uppermost epidermis either below or, less commonly, within the granular layer. A few acantholytic cells are often seen adjoining the cleavage plane. However, in contrast to impetigo contagiosa, there are few or no inflammatory cells within the bulla cavity. In bullous impetigo, the upper dermis may show a polymorphous infiltrate, whereas in the staphylococcal scalded-skin syndrome, the dermis is usually free of inflammation.

Pathogenesis. The causative epidermolysins are the exfoliative toxins (ETs) produced by *S. aureus*. There are many strains of these serine protease enzymes. Their target is desmoglein-1, a desmosomal glycoprotein, which has a role in cell-to-cell adhesion in the superficial epidermis (13).

Electron microscopy shows that the cleavage plane of lesions in humans as well as in mice is at the interface between the spinous and granular layers, with some upward extension into the lower granular layer. Splitting occurs without damage to adjacent acantholytic keratinocytes. ET appears to act primarily on the intercellular substance, because in studies carried out on newborn mice, the intercellular spaces widen and microvilli form before the desmosomes separate within their interdesmosomal contact zone (14).

Differential Diagnosis. Both staphylococcal scalded-skin syndrome and severe erythema multiforme of the toxic epidermal necrolysis or Lyell type show clinically extensive detachment of the epidermis and thus may clinically resemble one another. This has resulted in confusion in the past; thus, at one time, both diseases were referred to as *Lyell's disease* or *toxic epidermal necrolysis*. However, the two diseases can be easily differentiated histologically; in severe erythema multiforme, the entire, or nearly the entire, epidermis detaches itself, with considerable necrosis of the epidermal cells, whereas in staphylococcal scalded-skin syndrome, only the uppermost portion of the epidermis becomes detached, with relatively slight damage to the underlying epidermal cells.

ECTHYMA

Ecthyma is essentially ulcerated impetigo contagiosa. It occurs chiefly below the knees as multiple crusted ulcers. It is clearly streptococcal in origin, because skin cultures are nearly always positive for group A streptococci. In addition, coagulase-positive staphylococci as secondary invaders can frequently be cultured from lesions (15).

Histopathology. A nonspecific ulcer is observed with numerous neutrophils both in the dermis and in the serous exudate at the floor of the ulcer.

ERYSIPELAS

Erysipelas is an acute superficial cellulitis of the skin caused by group A streptococci. It is characterized by the presence of a well-demarcated, slightly indurated, dusky red area with an advancing, palpable border. In some patients, erysipelas has a tendency to recur periodically in the same areas. In the early antibiotic era, the incidence of erysipelas appeared to be on the decline, and most cases occurred on the face. More recently, however, there appears to have been an increase in the incidence, and facial sites are now less common whereas erysipelas of the legs is predominant. Potential complications in patients with poor resistance or after inadequate therapy may include abscess formation, spreading necrosis of the soft tissue, infrequently necrotizing fasciitis, and septicemia (16). Nephritic and cardiac complications are rare, because erysipelas is usually produced by nonnephritogenic and nonrheumatogenic strains of streptococci.

Histopathology. The dermis shows marked edema and dilatation of the lymphatics and capillaries. There is a diffuse infiltrate, composed chiefly of neutrophils, that extends throughout the dermis and occasionally into the subcutaneous fat. It shows a loose arrangement around dilated blood and lymph vessels. If sections are stained with the Giemsa or Gram stain, streptococci are found in the tissue and within lymphatics.

In cases of recurring erysipelas, the lymph vessels of the dermis and subcutaneous tissue show fibrotic thickening of their walls with partial or complete occlusion of the lumen.

NECROTIZING FASCIITIS

Necrotizing fasciitis, like erysipelas, is usually caused by group A beta-hemolytic streptococci, and it shows rapidly spreading erythema. However, the erythema is ill-defined and progresses to painless ulceration and necrosis along fascial planes. Whereas erysipelas involves the more superficial layers of the skin, cellulitis extends more deeply into the subcutaneous tissues (17). Although virtually all cases of erysipelas are caused by beta-hemolytic streptococci, primarily group A, the differential diagnosis of cellulitis is much more extensive. In addition to group A streptococci, possible etiologic agents include *S. aureus* and, less frequently, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and (rarely) a laundry list of other organisms including vibrios, gram-negative bacteria such as pseudomonas, areromonas, clostridia, and other anaerobes, legionella, *Erysipelothrix rhusiopathiae,* and *Helicobacter cinaedi*. Minor trauma is frequently a predisposing factor, and there is a significant association with chicken pox in children (18). In these and other patients with necrotizing fasciitis due to group A streptococci, there may be onset of shock and organ failure, which are manifestations of the streptococcal toxic shock syndrome (TSS). Unless treated by wide surgical debridement, necrotizing fasciitis is often fatal (19). Probing of the subcutaneous tissue discloses extensive undermining and a serosanguineous exudate (20).

Histopathology. The histologic picture is characterized by necrosis and variable acute and chronic inflammation (Figs. 21-2 and 21-3). Sometimes, there is minimal inflammation, with only

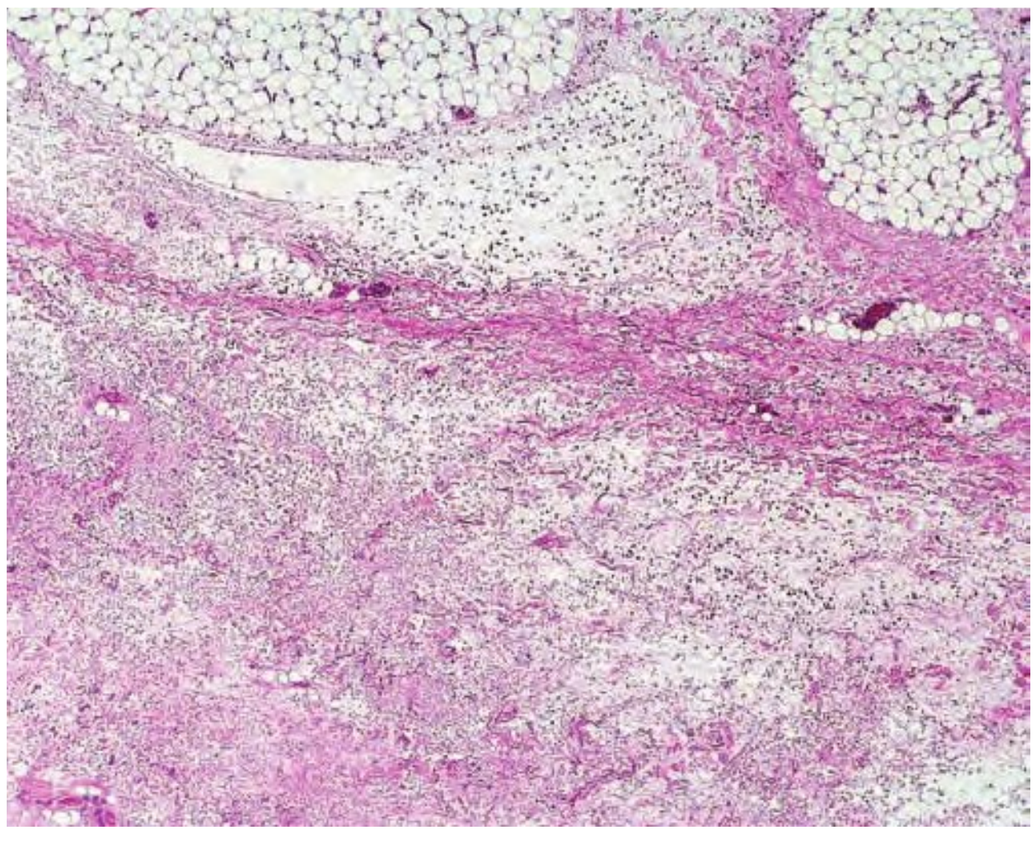

FIGURE 21-2. Necrotizing fasciitis. Subcutis fat with lower zone necrosis and mild inflammatory cells in upper zone (H&E stain).

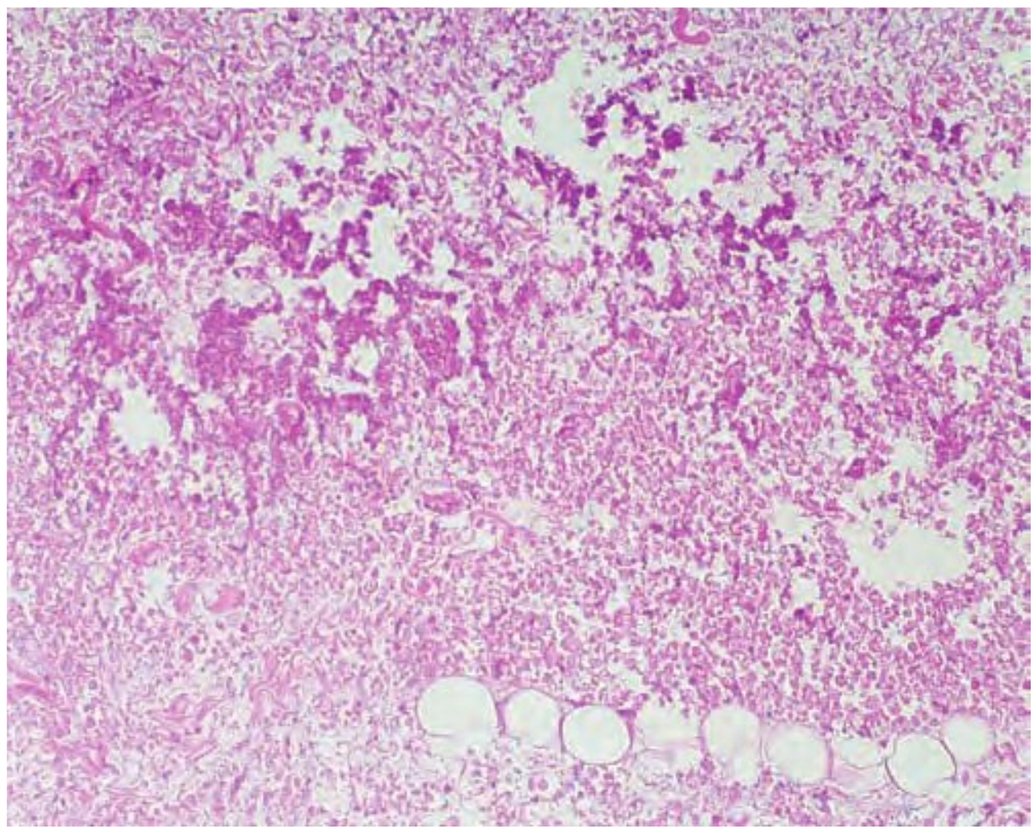

FIGURE 21-3. Necrotizing fasciitis. Higher power view of necrotic subcutis (H&E stain).

necrosis and clusters of bacteria (21). Clumps of gram-positive bacteria are usually present (Fig. 21-4). Often, there is thrombosis of blood vessels as the result of damage to vessel walls from the inflammatory process. The key feature in distinguishing necrotizing fasciitis from a less threatening superficial cellulitis is the location of the inflammation. In the former, the inflammation involves the subcutaneous fat, fascia, and muscle in addition to the dermis. A biopsy may be submitted at the time of surgical debridement for frozen section examination. In an appropriate setting, the presence of edema and neutrophils in these deep locations supports the diagnosis; frank necrosis may not be demonstrable, and bacteria are frequently not evident in an initial biopsy (22).

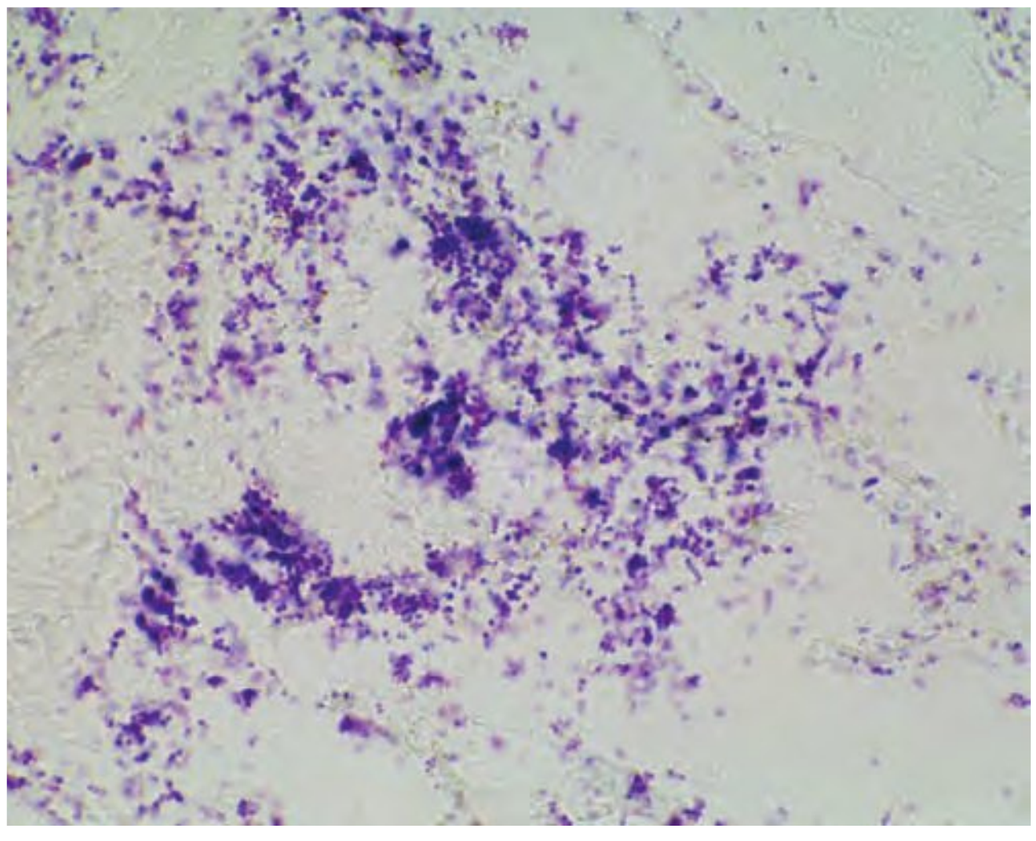

FIGURE 21-4. Necrotizing fasciitis. Clusters of gram-positive streptococci. Note the chains of cocci (Gram stain).

METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS SKIN INFECTIONS

Methicillin-resistant *S. aureus* skin infections have been recently reviewed by Cohen (23). Infection caused by community-acquired methicillin-resistant *S. aureus* (CAMRSA) is considered to represent a worldwide epidemic, often presenting as an infectious skin lesion. Athletes, certain ethnic populations, children, homeless persons, homosexual men, household members of infected people, HIV-infected patients, intravenous drug abusers, military personnel, newborns, pregnant and postpartum women, tattoo recipients, and urban dwellers of lower socioeconomic status in crowded living conditions are said to be at increased risk of developing CAMRSA infection. Colonization by *S. aureus* in patients whose skin barrier is disrupted represents a potential reservoir for CAMRSA. In addition, infection-associated risk factors are absent in many individuals who develop cutaneous CAMRSA infection. The most common presentations of CAMRSA infection are abscess, cellulitis, or both, not uncommonly misinterpreted by the patient as spider insect bites. Other manifestations of cutaneous CAMRSA infection are impetigo, folliculitis, and paronychia. Incision and drainage of abscesses, systemic antibacterial therapy, and adjunctive topical antibacterial treatment are the essential components of management of CAMRSA skin infections. The spread of cutaneous CAMRSA infection can potentially be prevented by a combination of personal, environmental, and health care measures directed at eliminating the causes of acquisition and transmission of the bacteria (23).

ACUTE SUPERFICIAL FOLLICULITIS

Folliculitis may involve the superficial, middle, or deep portion of the hair follicle and may be caused by a variety of etiologies, not all infectious. The common staphylococcal superficial folliculitis is the prototype (Figs. 21-5 and 21-6).

Impetigo of Bockhart

Impetigo of Bockhart, caused by staphylococci, is characterized by an eruption of small pustules, many of which are pierced by hairs.

Histopathology. Impetigo of Bockhart presents a subcorneal pustule situated in the opening of a hair follicle. The upper portion of the hair follicle is surrounded by a considerable inflammatory infiltrate composed predominantly of neutrophils.

Pseudomonas Folliculitis

In recent years, patients have exhibited outbreaks of pruritic macules, papules, and follicular pustules after using heated swimming pools, whirlpools, or hot tubs. The eruption

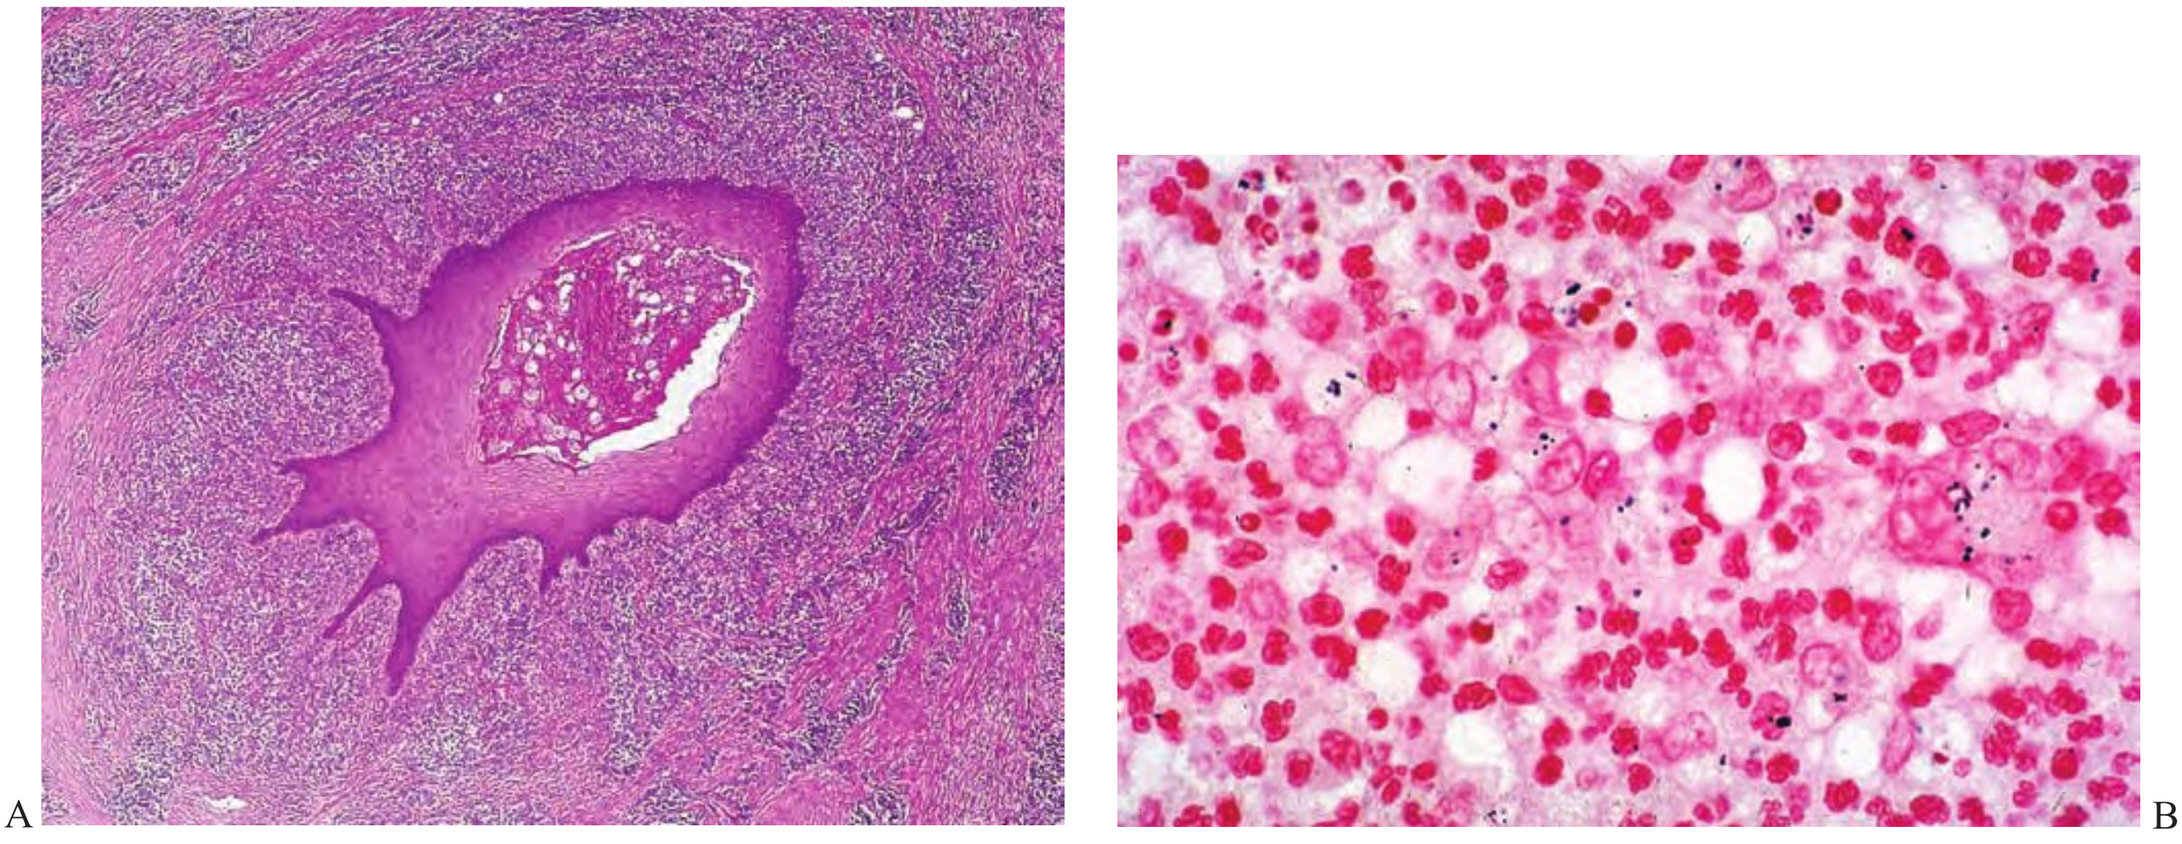
FIGURE 21-5. Acute folliculitis. Multiple follicular pustules on the scalp. Gram-positive cocci were demonstrated in the exudate. (Image courtesy of C. Kovarik.)

usually starts 8 to 48 hours after exposure in a contaminated facility and usually resolves spontaneously within 7 to 10 days (24).

Histopathology. There is distension and disruption of a hair follicle, the pilar canal, of which is filled with a dense infiltrate of neutrophils. There also is a perifolliculitis, and the epithelium of the hair follicle may be disrupted (25).

Pathogenesis. The causative organism is *Pseudomonas aeruginosa*, which is ubiquitous in nature and may be found in soil, in fresh water, and on human skin. Proper chlorination and maintenance of pools decrease the population of *Pseudomonas*.

ACUTE DEEP FOLLICULITIS (FURUNCLE)



A furuncle is caused by staphylococci and consists of a tender, red, perifollicular swelling terminating in the discharge of pus and of a necrotic plug (Fig. 21-7).

Histopathology. A furuncle shows an area of perifollicular necrosis containing fibrinoid material and many neutrophils. At the deep end of the necrotic plug, in the subcutaneous tissue, is a large abscess. A Gram stain shows small clusters of staphylococci in the center of the abscess (26).

CHRONIC SUPERFICIAL FOLLICULITIS

Acne varioliformis, or acne necrotica, is characterized by recurrent, small, indolent, follicular papules on the forehead and scalp. The lesions undergo central necrosis and usually heal with small, pitted scars (27).

Histopathology. Early lesions show a marked perifollicular lymphocytic infiltrate with exocytosis of lymphocytes into the external root sheath. This is followed by necrosis of the hair follicle and of the perifollicular epidermis. Late lesions have central cores of necrotic tissue.

CHRONIC DEEP FOLLICULITIS

Folliculitis barbae is a deep-seated infection of the bearded region in men. There are follicular papules and pustules followed by erythema, crusting, and boggy infiltration of the skin. Abscesses may or may not be present. Scarring and permanent hair loss usually ensue.

Folliculitis decalvans occurs predominantly in men. Scattered through the scalp are bald, atrophic areas showing follicular pustules at their peripheries. In some instances, other hairy areas, such as the bearded and pubic regions and the axillae and the eyebrows and eyelashes, are also involved. Through peripheral spreading, the atrophic areas gradually increase in size (28).

Folliculitis keloidalis nuchae represents a chronic folliculitis on the nape of the neck in men that causes hypertrophic scarring. In early cases, there are follicular papules, pustules, and occasionally abscesses. The lesions are replaced gradually by indurated fibrous nodules.

Histopathology. In early lesions of all three forms of chronic deep folliculitis, a perifollicular infiltrate composed largely of neutrophils but also containing lymphoid cells, histiocytes, and plasma cells is observed. The infiltrate develops into a perifollicular abscess leading to destruction of the hair and hair follicles. Older lesions show chronic granulation tissue containing numerous plasma cells as well as lymphoid cells and fibroblasts. Often, foreign body giant cells are present around remnants of hair follicles, and particles of keratin may be located near the giant cells. As healing takes place, fibrosis is observed. If there is hypertrophic scar formation, as in folliculitis keloidalis nuchae, numerous thick bundles of sclerotic collagen are present.

PSEUDOFOLLICULITIS OF THE BEARD

Pseudofolliculitis of the beard represents a foreign body inflammatory reaction surrounding an ingrown beard hair. It occurs in men with curly hair, especially blacks, who shave closely. Clinically, follicular papules and pustules resembling those of a bacterial folliculitis are observed.

Histopathology. As a result of its curvature, the advancing sharp free end of the hair, as it approaches the skin, causes an invagination of the epidermis accompanied by inflammation and, often, an intraepidermal microabscess. As the hair enters the dermis, a more severe inflammatory reaction develops with downgrowth of the epidermis in an attempt to ensheath the hair. This is accompanied by abscess formation within the pseudofollicle and a foreign body giant cell reaction at the tip of the invading hair (29).

FOLLICULAR OCCLUSION TRIAD (HIDRADENITIS SUPPURATIVA, ACNE CONGLOBATA, AND PERIFOLLICULITIS CAPITIS ABSCEDENS ET SUFFODIENS)

Hidradenitis suppurativa, acne conglobata, and perifolliculitis capitis abscedens et suffodiens, the three diseases included in the follicular occlusion triad, have similar pathogeneses and similar histopathologic findings. Quite frequently, two of the three diseases, and occasionally all three diseases, are encountered in the same patient (30). All three diseases represent a chronic, recurrent, deep-seated folliculitis resulting in abscesses and followed by the formation of sinus tracts and scarring. Although the primary etiology of these conditions is not bacterial, they are discussed in this chapter because the differential diagnosis includes the deep bacterial folliculitides.

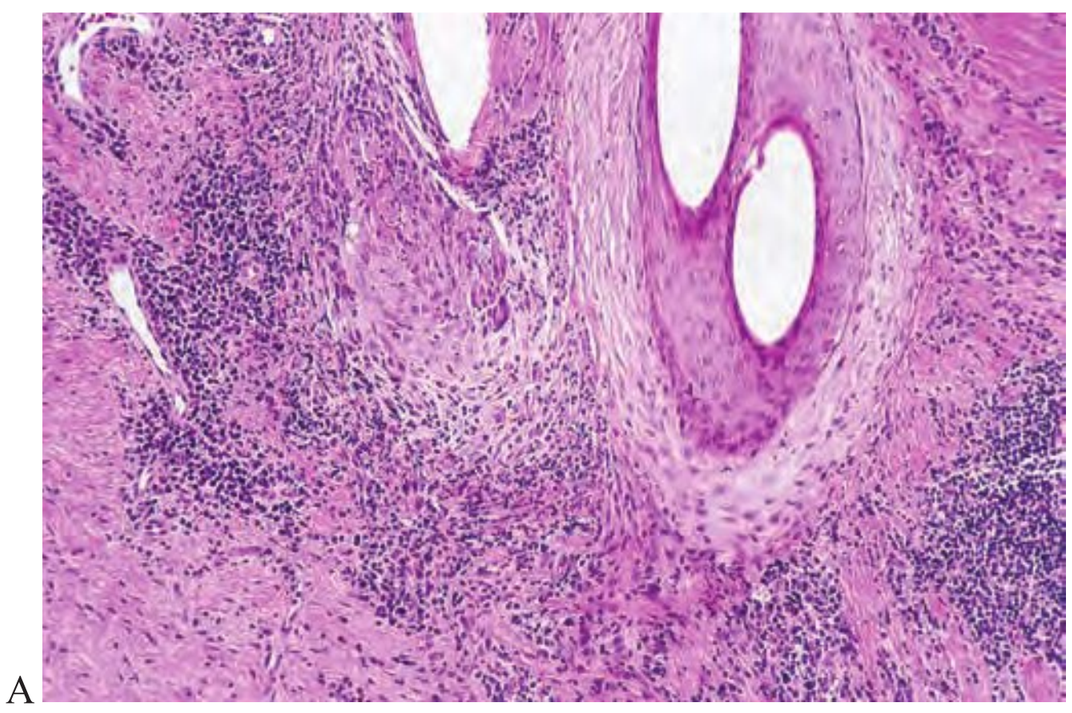
In *hidradenitis suppurativa*, the axillary and anogenital regions are affected. Acute and chronic forms can be distinguished (31). The acute form exhibits red, tender nodules that become fluctuant and heal after discharging pus. In the chronic form, deep-seated abscesses lead to the discharge of pus through sinus tracts. Severe scarring results (32).

Acne conglobata, an entity different from acne vulgaris, occurs mainly on the back, buttocks, and chest and only rarely on the face or the extremities. In addition to comedones, fluctuant nodules discharging pus or a mucoid material occur as well as deep-seated abscesses that discharge through interconnecting sinus tracts.

In *perifolliculitis capitis abscedens et suffodiens,* nodules and abscesses as described for acne conglobata occur in the scalp.

Pilonidal sinus is often considered to be a part of this group of disorders ("follicular occlusion tetrad"). Its pathogenesis appears to be similar, and it is often present in patients with one or more of the other members of the group.

Histopathology. Early lesions in all three diseases of the follicular occlusion triad show follicular hyperkeratosis with plugging and dilatation of the follicle. The follicular epithelium may proliferate or be destroyed (Figs. 21-8 and 21-9). At first there is little inflammation, but eventually a perifolliculitis develops with an extensive infiltrate composed of neutrophils, lymphocytes, and histiocytes. Abscess formation results and leads to the destruction first of the pilosebaceous structures and later also of the other cutaneous appendages. Apocrine glands in hidradenitis suppurativa of the axillae or groin regions may be secondarily involved by the inflammatory process. In response to this destruction, granulation tissue containing lymphoid and plasma cells, and foreign body giant cells related to fragments of keratin and to embedded hairs, infiltrates the area near the remnants of hair follicles. As the abscesses extend deeper into the subcutaneous tissue, draining sinus tracts develop that are lined with epidermis. In areas of healing, extensive fibrosis may be observed (30).



Pathogenesis. The common initiating event in the three diseases of the follicular occlusion triad appears to be follicular hyperkeratosis leading to retention of follicular products. Thus, the designation *hidradenitis suppurativa* is a misnomer, because involvement of apocrine as well as of eccrine glands represents a secondary phenomenon and is the result of extension of the inflammatory process into deep structures.

It appears doubtful that the diseases comprising the follicular occlusion triad are caused primarily by bacterial infection, because cultures from unopened abscesses often are negative (33).

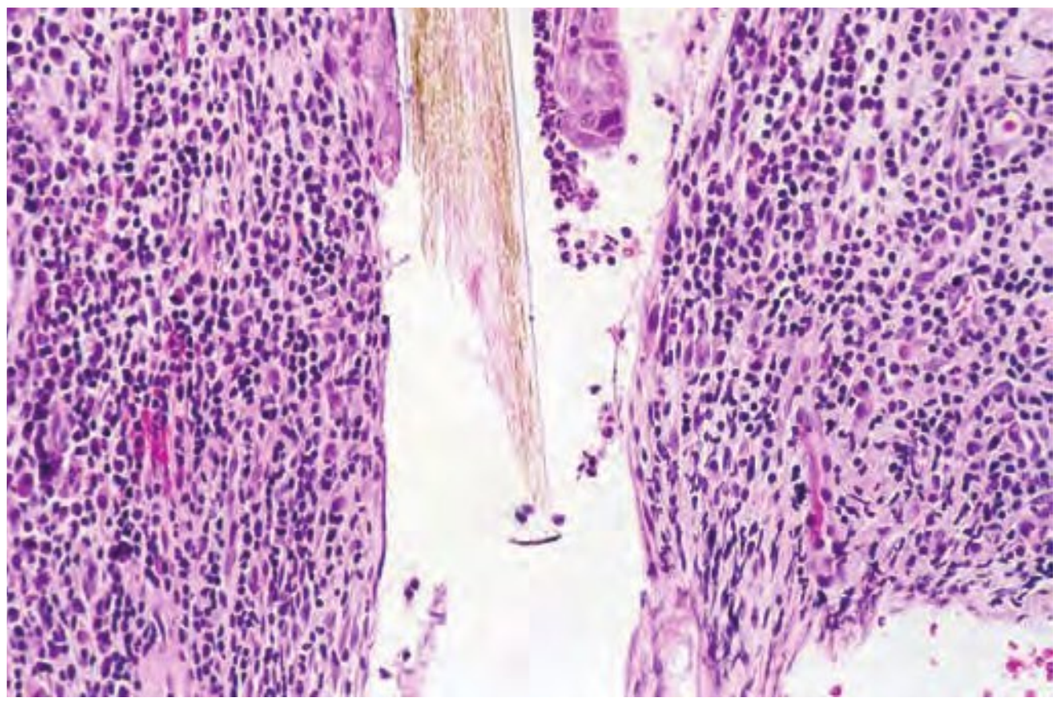


FIGURE 28-8. Follicular occlusion disorder. Dissecting cellulitis of the scalp, low power. Early lesions may show follicular plugging with acute perifollicular inflammation. Eventually, the follicle is destroyed and replaced by dense mixed inflammation. The appearances are indistinguishable from hidradenitis suppurativa.

The beneficial effect of the internal administration of corticosteroid suggests that the three diseases represent antigen-antibody reactions resulting in tissue breakdown. Defects in cell-mediated immunity exist in some patients with hidradenitis suppurativa.

Perifollicular fibrosis ensues and is accompanied by granulomatous inflammation in reaction to follicular contents. Advanced lesions may show sinus tract formation. B. Dissecting cellulitis of the scalp, high power. The follicular epithelium is almost completely destroyed, leaving a hair shaft exposed to the dermis and a mixed infiltrate of neutrophils, lymphocytes, histiocytes, and plasma cells.

BLASTOMYCOSIS-LIKE PYODERMA (PYODERMA VEGETANS)

Two entirely different diseases have been described under the term *pyoderma vegetans* or *pyodermite végétante of Hallopeau*. One disease, now referred to as *pemphigus vegetans of Hallopeau*, shows the typical intercellular immunofluorescence of the pemphigus group on direct immunofluorescence testing. The other disease represents a vegetating tissue reaction, possibly secondary to bacterial infection (34). In order to emphasize the difference between it and pemphigus vegetans of Hallopeau, it is preferable to refer to this disease as *blastomycosis-like pyoderma* rather than *pyoderma vegetans* (35).

Blastomycosis-like pyoderma shows one or multiple large, verrucous, vegetating plaques with scattered pustules and elevated borders. The plaques show considerable resemblance to those observed in fungal blastomycosis. The location of the plaques varies considerably from case to case. In some instances, the face and legs are affected; in others it is the intertriginous areas. Some authors have observed an association with ulcerative colitis (36).

Histopathology. The two major features of blastomycosis-like pyoderma are pseudocarcinomatous hyperplasia and multiple abscesses in the dermis as well as in the hyperplastic epidermis. The abscesses are composed of neutrophils in some cases and of eosinophils in others.

Pathogenesis. Bacteria, most commonly *S. aureus*, can be found regularly in blastomycosis-like pyoderma; however, the presence of several different strains and the variable response of patients to antibiotic therapy suggest that the bacteria are secondary invaders, although they may be responsible for the vegetating tissue reaction. A deficiency in cellular immunity (37) and a decrease in the chemotactic activity of the neutrophils have also been observed.

Differential Diagnosis. In cases with largely eosinophils in the abscesses, pemphigus vegetans must be excluded by direct immunofluorescence. If there is marked pseudocarcinomatous hyperplasia, multiple biopsies may be necessary for differentiation from true squamous cell carcinoma.

TOXIC SHOCK SYNDROME

TSS is an acute febrile illness usually caused by certain toxin-producing strains of *S. aureus*. Occasionally, however, group A beta-hemolytic *Streptococcus* can cause this illness (38). In the initial report in 1978, the disease was described in a series of seven children (39). Although many cases have been associated in recent years with the use of superabsorbent vaginal tampons by menstruating women, additional reported settings for TSS have included surgical wound infections of the skin (40), empyema, fasciitis, osteomyelitis, peritonsillar abscesses, and other infections (41). Fever, hypotension or shock, an extensive rash resembling scarlet fever or sunburn, and involvement of three or more organ systems are the initial defining manifestations, whereas desquamation occurs 1 to 2 weeks after the onset. In rare instances, bullae are also present (42). In addition, there may be a conjunctivitis and an oropharyngitis. Internal organs may be affected by a toxic encephalopathy, thrombocytopenia, renal failure, or hepatic damage. Mortality has been estimated at 5% to 10% (43).

Histopathology. Although in some cases the findings in the skin are not specific, in most instances the histologic findings are quite characteristic, consisting of a superficial perivascular and interstitial mixed-cell infiltrate containing neutrophils and sometimes eosinophils, foci of spongiosis containing neutrophils, and scattered necrotic keratinocytes that sometimes are arranged in clusters within the epidermis (44). If bullae are present, they are subepidermal in location.

Pathogenesis. Even though in rare cases *S. aureus* bacteremia occurs, the cause of TSS is a toxin that is produced locally at the site of a toxigenic staphylococcal infection. Several toxins have been implicated in TSS, including toxic shock syndrome toxin-1 (TSST-1) and the staphylococcal enterotoxins B, C, and F (45). Susceptibility to disease correlates with absence of protective antibodies to the toxin, and cytokine activation may be involved in some aspects of its pathogenesis. Streptococcal TSS has been associated with bacteriemia and extensive necrotizing fasciitis, unlike the staphyloccocal syndrome usually associated with occult or minor focal infections. Streptococcal TSS appears to be caused also by toxins produced by the bacteria, including pyrogenic exotoxin A, that shares some homologies with TSST-1 (46).

ACUTE SEPTICEMIA

Three types of acute fulminating septicemia have cutaneous manifestations that are diagnostically significant. They are those caused by *Neisseria meningitidis*, *Pseudomonas*, and *Vibrio vulnificus*.

Acute Meningococcemia

Fulminating septicemic infections with *N. meningitidis* exhibit extensive purpura consisting of both petechiae and ecchymoses. The centers of the petechiae may show small pustules. In addition, shock, cyanosis, and severe consumption coagulopathy occur (47). Without treatment, death may result within 12 to 24 hours. On autopsy, extensive hemorrhaging is found in many internal organs, especially the lungs, kidneys, and adrenals.

On rare occasions, acute septicemia with purpura can be produced by other organisms, such as *Diplococcus pneumoniae*, *Streptococcus*, or *S. aureus* (48).

Histopathology. The cutaneous petechiae and ecchymoses show, in many dermal vessels, thrombi composed of neutrophils, platelets, and fibrin. In addition, there is an acute vasculitis with considerable damage to the vascular walls resulting in large and small areas of hemorrhaging into the tissue. Neutrophils and nuclear dust are present within and around the damaged vessels. In most instances, many meningococci can be demonstrated in the luminal thrombi, within vessel walls, and around vessels as gram-negative diplococci. They are

present in the cytoplasm of endothelial cells and neutrophils and also extracellularly. Intraepidermal and subepidermal pustules filled with neutrophils may also be observed (49).

Pathogenesis. In the past, vascular collapse and death were attributed to massive bilateral hemorrhaging into the adrenal glands and were known as the *Waterhouse-Friderichsen syndrome*. However, it was then learned that death can occur without significant damage to the adrenals. Therefore, it was assumed that the generalized hemorrhagic diathesis was caused by the consumptive depletion of plasma clotting factors and the resulting disseminated intravascular coagulation (50). It seems likely, however, that there are two distinct pathogenic mechanisms operating in acute meningococcemia (47). First, a shocklike terminal phase is associated with the development of widespread thrombosis of the pulmonary microcirculation. These thrombi, which are caused by meningococcal toxins, are composed of leukocytes and fibrin and often also contain meningococci. They produce severe cor pulmonale, which cannot be prevented by treatment with heparin. Similar microthrombi are found also in the skin, spleen, heart, and liver. Second, a meningococcal endotoxin produces disseminated intravascular coagulation resulting in thrombi composed of fibrin only. These thrombi are found in the capillaries of the adrenal cortex and the kidneys and may cause hemorrhagic infarction of the adrenal glands and renal cortical necrosis. This secondary phase of the disease can be modified with heparin therapy, but its control does not improve survival, because the adrenal and renal lesions are not immediately life threatening, in contrast to the pulmonary lesions, which result in shock and death.

Pseudomonas Septicemia

The classic and diagnostic cutaneous lesions of *P. aeruginosa* or *Pseudomonas cepacia* septicemia are referred to as *ecthyma gangrenosum*. *Pseudomonas* septicemia usually occurs in debilitated, leukemic, or severely burned patients, particularly after they have received treatment with several antibiotics. The cutaneous lesions may be single but usually are multiple. They consist of punched-out ulcers about 1 cm in diameter that have hemorrhagic borders. They usually are preceded by hemorrhagic bullae (51). In Tzanck smears prepared from the bases of the lesions, gram-negative rods can be identified, confirming the diagnosis. In rare instances of *Pseudomonas* septicemia, multiple large, indurated, subcutaneous nodules are observed in addition to the cutaneous ulcers (52,53).

Occasionally, lesions of ecthyma gangrenosum have been observed in immunocompromised patients without bacteremia; these cases have better prognoses (54).

Histopathology. At their bases, the ulcers show a necrotizing vasculitis with only scant neutrophilic infiltration and little nuclear dust. There is, however, extensive bacillary infiltration of the perivascular region and of the adventitia and media of blood vessels. Nevertheless, the intima and the lumen usually are spared (55). *Pseudomonas* bacilli first invade the walls of the deep subcutaneous vessels and then spread along the surfaces of the vessels to the dermis (56). By causing perivascular and vascular necrosis, the bacilli cause extravasation of erythrocytes and the formation of ulcers (Fig. 21-10).

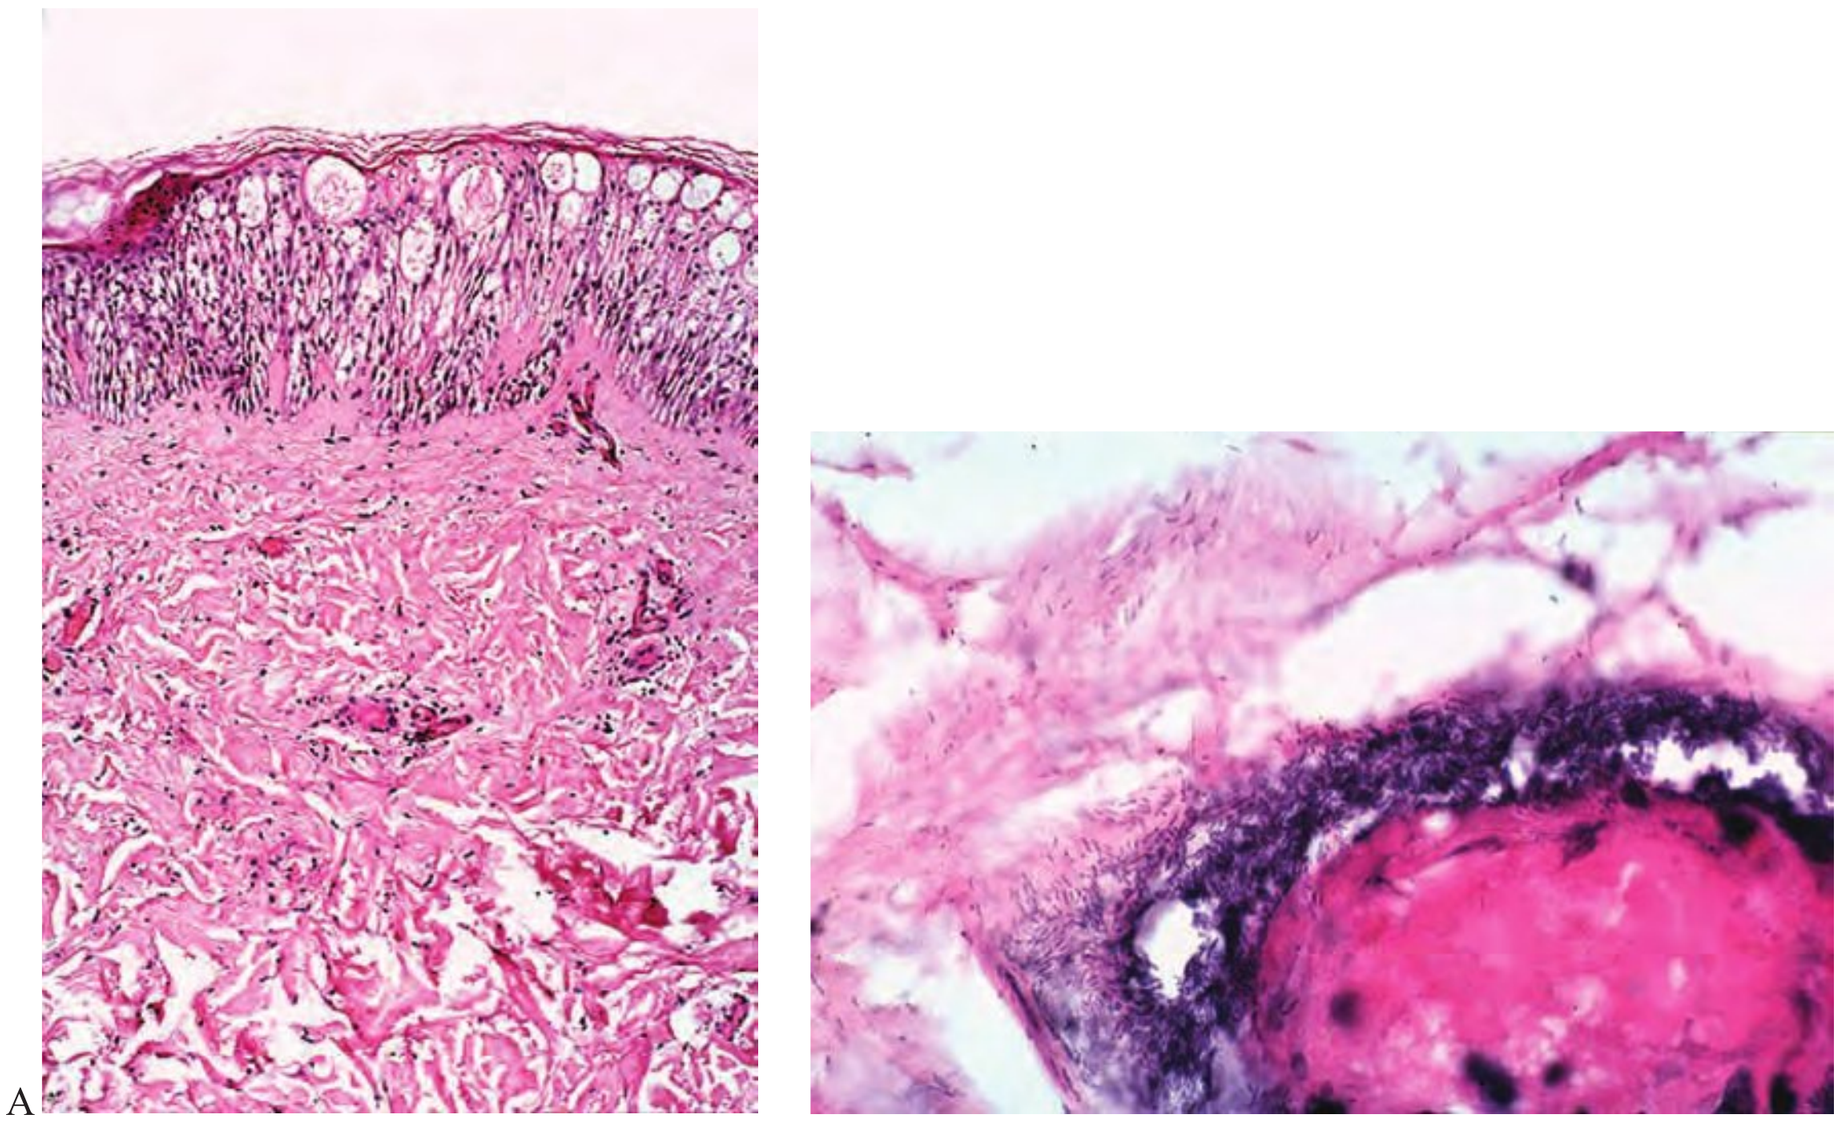

FIGURE 21-10. Pseudomonas septicemia. A: Skin showing infarction of epidermis, with abnormal middermal vessels (H&E stain). In later lesions, a "punched-out" ulcer typically develops. B: Bacilli infiltrating the deep vessel wall and into the surrounding dermis. The lumen is thrombosed. There is no inflammation (H&E stain).

The subcutaneous nodules are the result of cellulitis caused by the presence of large numbers of *Pseudomonas* bacilli (52).

Vibrio Vulnificus Septicemia

V. vulnificus infections occur in coastal regions of the United States. Raw seafood consumption, particularly raw oysters, or wounds acquired in marine environments can cause the infection. *V. vulnificus* is a virulent pathogen, producing significant morbidity and, unless treated, mortality, especially in patients with cirrhosis of the liver.

Striking skin lesions are an early sign of septicemic infection. Indurated plaques show blue discoloration, vesicles, and bullae. Large ulcers may develop (57).

Histopathology. Noninflammatory bullae form as the result of dermal necrosis, which is caused by the extracellular toxin produced by the bacterium. Clusters of bacteria may be seen in dermal vessels without associated dermal infiltrate (58).

Pathogenesis. *V. vulnificus* is a gram-negative rod that is motile by means of a single polar flagellum. It can be isolated from the blood and bullae of patients with this infection.

CHRONIC SEPTICEMIA

Meningococcemia and gonococcemia can occur in association with a chronic intermittent, benign eruption.

Chronic Meningococcemia

In patients with partial immunity to *N. meningitidis*, an infection with this organism produces chronic meningococcemia. This disease is characterized by recurrent attacks of fever, each lasting about 12 hours, associated with migratory joint pains and a papular and petechial eruption. Positive blood cultures are obtained during the febrile attacks.

Histopathology. The cutaneous lesions of chronic meningococcemia, in contrast to those of acute meningococcemia, show no bacteria and no vascular thrombosis or necrosis. Instead, a perivascular infiltrate composed largely of lymphoid cells and only a few neutrophils is observed in popular lesions (59,60). In petechial lesions, in addition to a limited area of perivascular hemorrhage, a fairly high percentage of neutrophils and fibrinoid material in the walls of the vessels may be found; thus, the histologic picture resembles that of a leukocytoclastic vasculitis (Fig. 21-11). The presence of meningococci may be difficult to demonstrate.

Chronic Gonococcemia

Patients with chronic gonococcemia, also referred to as *disseminated gonococcal infection* (61), like those with chronic meningococcemia, have intermittent attacks of fever and polyarthralgia. The cutaneous lesions of the two diseases are also similar, except that those of chronic gonococcemia are few in number and have a predominantly acral distribution. In contrast to chronic meningococcemia, there are often, in addition to papules and petechiae, vesicopustules with hemorrhagic halos and, rarely, hemorrhagic bullae. Blood cultures often are positive for *Neisseria gonorrhoeae*, but only during attacks of fever. A search for gonococci should also be made in possible sites of primary infection.

Histopathology. The capillaries in the upper dermis and middermis are surrounded by an infiltrate of neutrophils and a variable admixture of mononuclear cells and red cells. There often is nuclear dust, as in leukocytoclastic vasculitis. Fibrinoid material may be present in the walls of some vessels, and fibrin thrombi in some lumina (62). Pustular lesions are usually

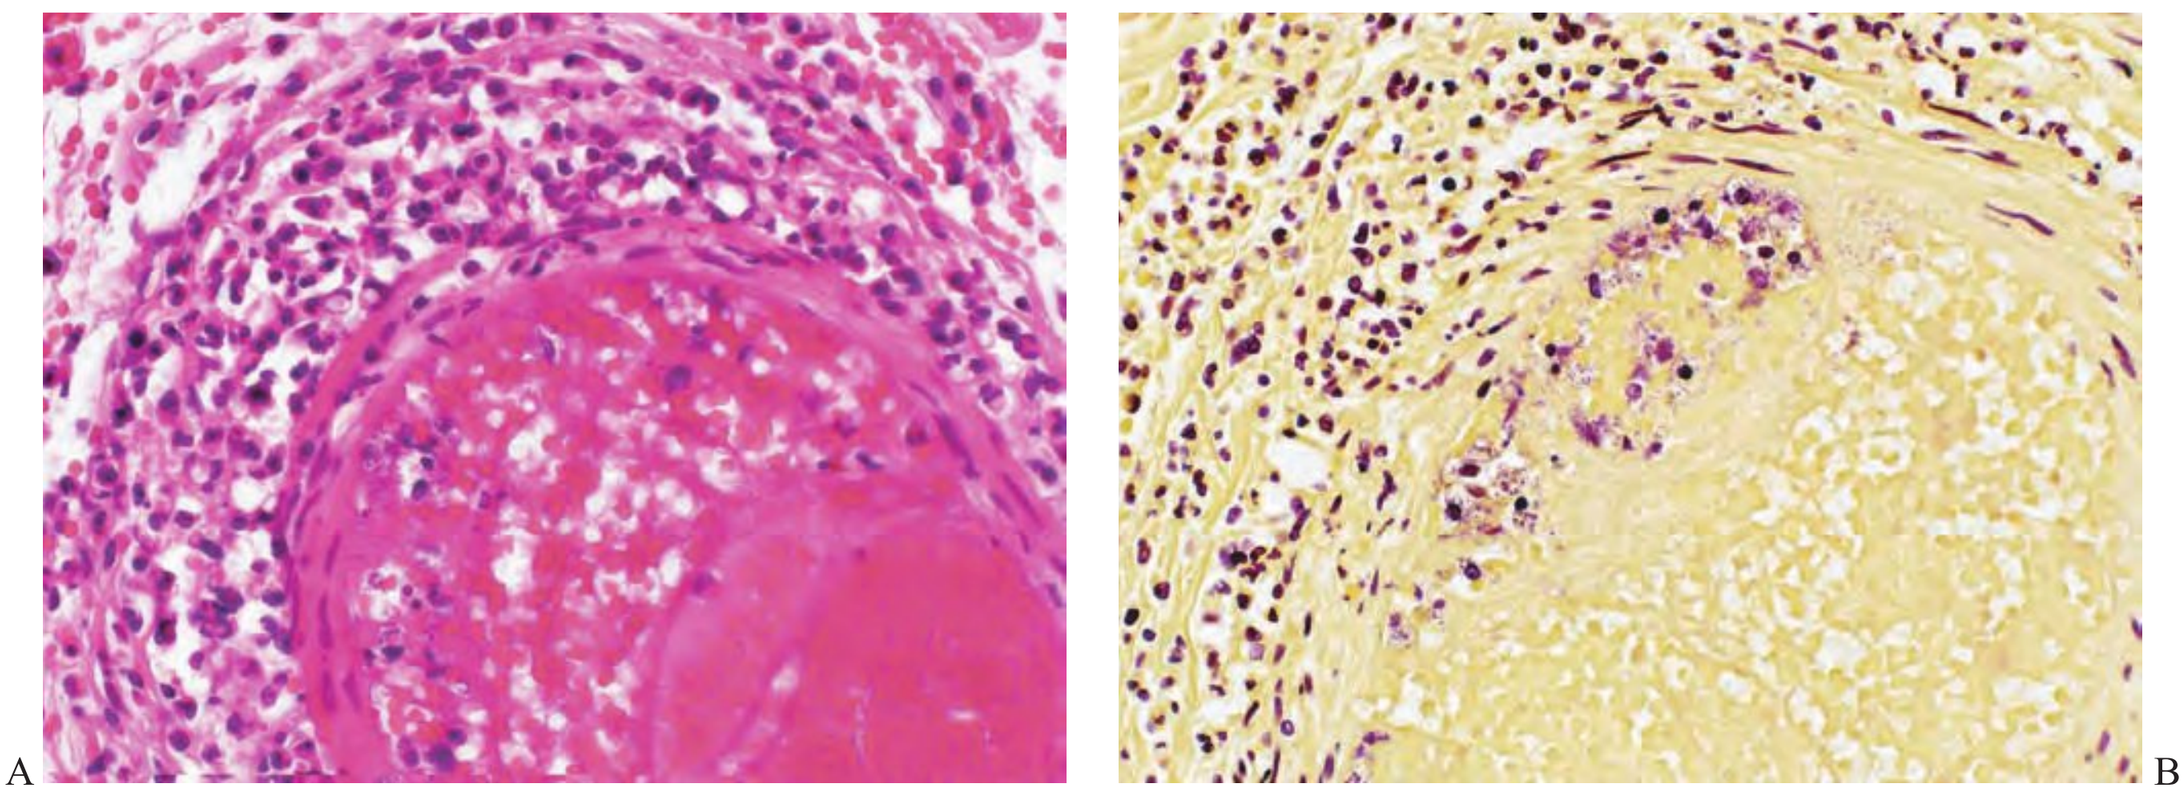

FIGURE 21-11. Meningococcal sepsis. A: Skin vasculitis. Inflamed dermal vessel. B: Skin vasculitis. Brown-Hopps Gram stain showing gram-negative cocci in the monocytes and within the vessel wall.

observed in intraepidermal locations with neutrophils both within them and in the underlying dermis (63). Bullae are subepidermal in location (64).

Gram-negative diplococci are observed in tissue sections only on rare occasions in the walls of blood vessels (65). They are found more readily in direct smears of pus from freshly opened pustules. It is of interest that direct smears reveal gonococci more commonly than cultures (66). However, *N. gonorrhoeae* can frequently be identified in tissue sections by use of fluorescent-antibody techniques (67). For this purpose, fluorescein-labeled antigonococcus globulin is used. Diplococci, as well as single cocci and disintegrated antigenic material, are then observed, largely in perivascular locations. The reason that direct smears are more apt to show diplococci than cultures and that the fluorescent-antibody technique is particularly effective in demonstrating gonococci is that smears and the fluorescent-antibody technique are not dependent on living organisms, as are cultures.

Pathogenesis. Whereas most strains of gonococci are susceptible to the bactericidal action of normal serum, those causing disseminated gonococcal infection are resistant (61).

MALAKOPLAKIA

Malakoplakia may affect various organs, most commonly the urinary tract and the gastrointestinal tract (68). In rare instances, it involves the skin (69,70). The lesions are the result of an inability of macrophages to phagocytose bacteria adequately. The most common organism grown in cultures of tissue material is *Escherichia coli* (71), but in some instances, other bacteria such as *S. aureus*, *Rhodococcus equi*, and nontuberculosis mycobacteria (72) are cultured. Some patients with lesions of malakoplakia have altered immune responsiveness as a result of carcinoma, autoimmune systemic diseases such as systemic lupus erythematosus, or immunosuppressive therapy for lymphoma or for renal transplantation (73).

Cutaneous malakoplakia lesions are chronic and may be associated with internal lesions. The appearance of the cutaneous lesions is nonspecific and variable. Most commonly, a fluctuant area, a draining abscess, draining sinuses, or an ulcer is observed; however, in some patients, a solitary, tender nodule or a cluster of tender papules is observed. The cutaneous disease is benign and self-limited.

Histopathology. There are sheets of large histiocytes containing fine, eosinophilic granules in their cytoplasm. In addition to the granules, many of them contain ovoid or round basophilic inclusions, referred to as *Michaelis-Gutmann bodies*, that vary in size from 5 to 15 μm (70) (Fig. 21-12). These bodies either are homogeneous or have a "target" appearance by showing concentric laminations. The infiltrate may also contain lymphocytes, plasma cells, and polymorphs.

The Michaelis-Gutmann inclusion bodies and the cytoplasmic granules are periodic acid-Schiff (PAS)-positive, diastase resistant, and Alcian blue positive. In addition, the

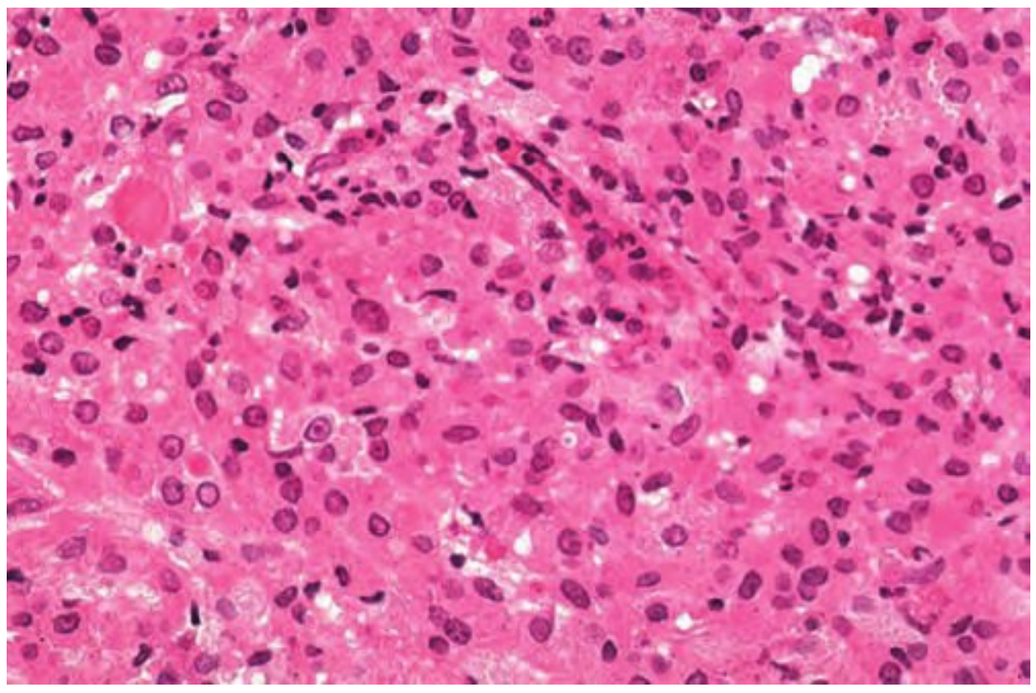

FIGURE 21-12. Malakoplakia. Sheets of macrophages with eosinophilic cytoplasm; several in the center contain Michaelis-Gutmann inclusion bodies (H&E stain).

Michaelis-Gutmann bodies stain with the von Kossa stain for calcium and contain small amounts of iron that may be demonstrated by Perls' stain. With the Gram stain, gram-negative bacteria may be seen in some of the histiocytes, and in the rare case caused by mycobacteria, Ziehl-Neelsen stain reveals the organisms. The bodies may be observed in skin scrapings of lesions (74).

Pathogenesis. Electron microscopic examination reveals that the cytoplasm of the granular cells contains numerous phagolysosomes corresponding to the PAS-positive granules. Some phagolysosomes contain lamellae in a concentric arrangement (70). The Michaelis-Gutmann bodies develop within phagolysosomes by the progressive deposition of electron-dense calcific material on the whorled or concentric lamellae until they are ultimately completely calcified. Bacteria may be observed in the cytoplasm of the granular cells and in various stages of digestion within phagolysosomes (72).

Malakoplakia represents an acquired defect in the lysosomal killing and digestion of phagocytized bacteria. Deficiencies of β-glucuronidase and of 3′,5′ guanosine monophosphate dehydrongenase have been documented (71,75).

MYCOBACTERIAL INFECTIONS

Taxonomically, the mycobacteria are divided into two major groups: the rapid growers and the slow growers in culture. *Mycobacterium leprae* lies outside this scheme because it cannot be cultured *in vitro*. Within each group, the species are organized in subgroups according to certain culture (growth requirement) and biochemical characteristics. Among the infections to be considered in this chapter, the important slow growers are the *Mycobacterium tuberculosis* complex, including bacille Calmette-Guérin (BCG); the *Mycobacterium avium* complex, including *M. avium* and *M. avium-intracellulare*; the

Mycobacterium kansasii complex; the complex that includes *Mycobacterium marinum* and *Mycobacterium ulcerans*; and mycobacteria with special growth requirements, such as *Mycobacterium haemophilum*. Rapid growers that affect the skin include the *Mycobacterium fortuitum* complex, which also includes *Mycobacterium chelonei* (76). Many other mycobacteria can occasionally cause skin lesions (77–79). In a recent series of 25 cases from Israel, there were 16 cases with *M. marinum*, 3 of atypical *Mycobacterium* without species identification, and 1 each with *M. chelonae*, *Mycobacterium xenopi*, *Mycobacterium abscessus*, *Mycobacterium gordonae*, and *M. fortuitum*, and it was emphasized that absence of a pathognomonic clinical picture and variable histologic findings often delay diagnosis of these nontuberculous mycobacteria (NTM)-induced cutaneous infections. The diagnosis of NTM should be confirmed by histology and bacteriology studies of tissue cultures. However, strong clinical suggestion of *M. marinum* infection may warrant initial empirical treatment to prevent progression to deep infection (80).

Tuberculosis and leprosy bacilli are intracellular parasites that are found in the tissues of humans and occasionally animals. Transmission requires exposure to infected people. The other mycobacteria are abundant in nature in both soil and water, and exposure to infection occurs throughout life, although usually without significant clinical disease.

Mycobacteria are bacilli that are weakly gram positive and are classically identified in histologic sections by stains that exploit their resistance to decoloration by acid—that is, acid-fast bacilli (81). All mycobacteria apart from the leprosy bacillus (see section Leprosy beginning on page 558) are well stained by the standard Ziehl-Neelsen technique.

TUBERCULOSIS

Until recently tuberculosis was considered to be a diminishing clinical problem in industrialized nations while remaining a dominant public health problem in resource-poor countries. However, there is a global resurgence of tuberculosis because of a combination of factors, including immigration from endemic countries (particularly in Asia and Africa), increased movement of refugees, the HIV pandemic, and poverty (82). As a result, cutaneous tuberculosis remains a clinical and diagnostic problem (83,84).

Infection of the skin and subcutis by *M. tuberculosis* occurs by three routes: (a) by direct inoculation into the skin (causing a primary chancre, or tuberculosis verrucosa cutis, or tuberculosis cutis orificialis lesions); (b) by hematogenous spread from an internal lesion (causing lupus vulgaris, miliary tuberculosis, and tuberculous gumma lesions); and (c) from an underlying tuberculous lymph node by direct extension (causing scrofuloderma). For descriptive purposes, these different tuberculous dermatitides are delineated (a modified "Beyt classification" is used) (78). But in clinical practice, many cases do not readily fit into these clinical and histologic categories (79,85,86). In a recent study of cutaneous tuberculosis infections in a pediatric population from India, with histopathologic evaluation there was a large spectrum of clinical patterns. The different patterns of cutaneous tuberculosis seen were scrofuloderma (37%), lichen scrofulosorum (33%), lupus vulgaris (21%), tuberculosis verrucosa cutis (4%), papulonecrotic tuberculid (4%), and erythema nodosum (3%). Systemic associations were seen in 53%, namely tuberculosis lymphadenitis (30%), pulmonary tuberculosis (13%), abdominal tuberculosis (6%), and tuberculosis arthritis (6%) (87).

The basic reaction of human tissues to tuberculous bacilli is a sequence, first of acute nonspecific inflammation during which the bacilli multiply and cannot be phagocytosed and killed by neutrophil polymorphs. Macrophages then phagocytose the organisms, but their efficacy in killing them depends crucially on enhanced activation. T-cell mediated allergy to tuberculous antigens induces secretion of cytokines that recruit and activate macrophages, which become epithelioid cells. Some will fuse to form giant cells, the typical form of which in tuberculosis is the Langhans giant cell with the nuclei arranged around the periphery of the cytoplasm. As delayed hypersensitivity increases, there is caseation necrosis within the granuloma, caseation being a homogeneous eosinophilic infarct-like necrotic process whereby the macrophages die. It is probably mediated by cytokines (such as tumor necrosis factor) and the macrophage proteases. This necrotic process inactivates or kills many of the mycobacteria in the lesion, but it does not eliminate them (88,89).

The necrotic granuloma is thus typical of tuberculosis and other mycobacterial infections, but it is not specific, being seen in numerous other infections that involve this type of cell-mediated immunity (e.g., histoplasmosis, syphilis, and leishmaniasis).

The determinants of what happens in tuberculosis infection therefore include the virulence of the organism (tuberculosis is more virulent than most of the nontuberculosis mycobacteria), the size of the inoculum, the route of infection, and the immune status of the patient. It is evident that if cell-mediated immunity is impaired, the T-cell/macrophage system will not operate to contain the infection. The resulting pathology is generally less granulomatous (fewer activated macrophages) and has a higher density of mycobacteria. Such conditions are HIV infection with its sequel of AIDS, steroid therapy, and cytotoxic drugs.

Primary Tuberculosis

Primary infection with tuberculosis occurs only rarely on the skin. Children or adults may acquire it following minor trauma or contact with infected material—as a result, for instance, of mouth-to-mouth artificial respiration (90), inoculation during an autopsy (91), needle-stick injury (92), or inoculation during tattooing (93). Usually, the cutaneous lesion arises within 2 to 4 weeks after the inoculation. It consists of an asymptomatic crust-covered ulcer referred to as *tuberculous chancre*. The regional lymph nodes become enlarged and tender and may suppurate and produce draining sinuses.

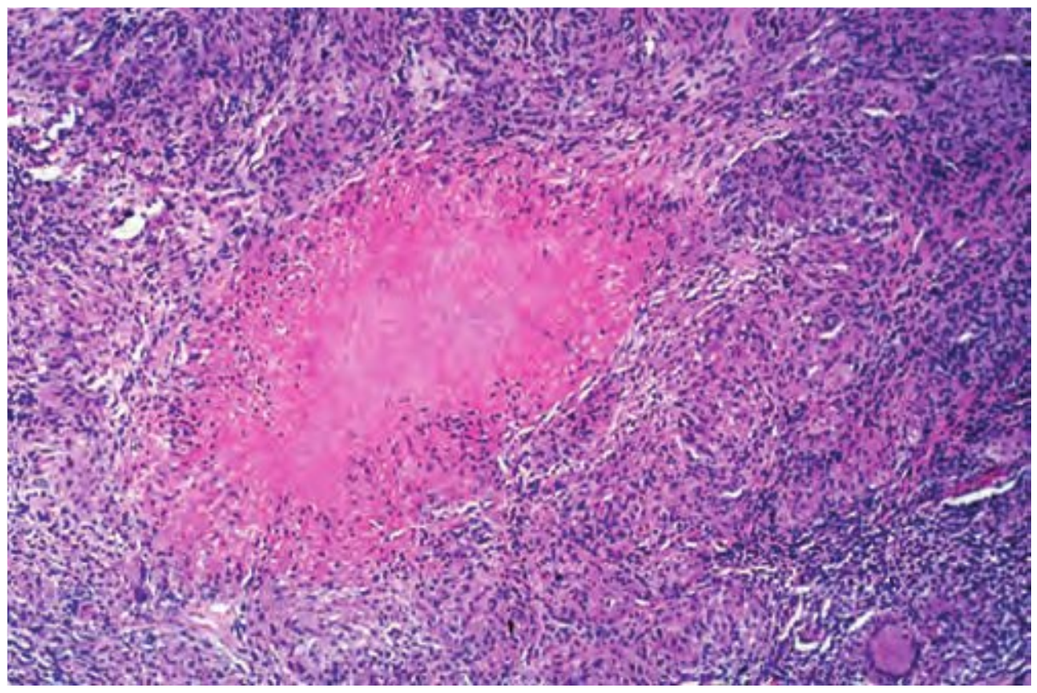

FIGURE 21-13. Tuberculosis. A prosector's wart following inoculation of the finger from a tuberculous cadaver. There is central caseation necrosis with dense macrophage and lymphocyte surround (H&E stain).

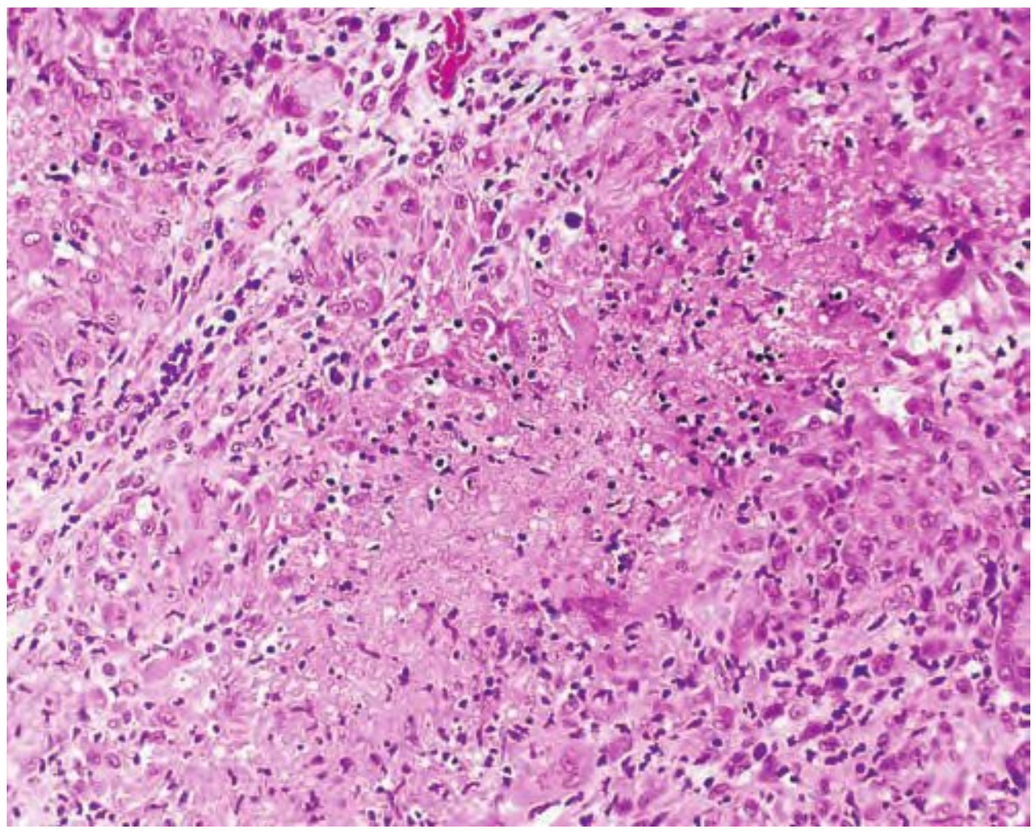

FIGURE 21-14. Tuberculosis. An epithelioid cell granuloma and caseation (H&E stain).

Histopathology. The histologic development of the lesion is very much like that observed in experimental cutaneous inoculation of the guinea pig. In the earliest phase, the histologic picture is that of an acute neutrophilic reaction, with areas of necrosis resulting in ulceration. Numerous tubercle bacilli are present, particularly in the areas of necrosis (91). After 2 weeks, monocytes and macrophages predominate. Three to 6 weeks after onset, epithelioid cells and giant cell granulomas develop, followed by caseation necrosis within the granuloma mass (Fig. 21-13). In time, the necrosis lessens, and the number of tubercle bacilli decreases until it is so greatly reduced that the bacilli may be impossible to demonstrate in histologic sections. Simultaneous with the decrease in the number of tubercle bacilli in the lesion, the tuberculin test with purified protein derivative (PPD), previously negative, becomes positive. The draining lymph nodes receive tubercle bacilli and enlarge through developing caseating granulomas, parallel to a primary infection in the lung.

Tuberculosis Verrucosa Cutis

Tuberculosis verrucosa cutis represents an inoculated exogenous infection of the skin in persons with a degree of immunity—that is, previous exposure to tuberculosis. In tuberculosis verrucosa cutis, a single lesion presenting as a verrucous plaque with an inflammatory border and showing gradual peripheral extension is usually observed. The verrucous surface exhibits fissures from which pus often can be expressed. The most common sites are the hands and, in children, the knees, buttocks, and thighs.

Histopathology. The histologic picture includes hyperkeratosis and acanthosis. Beneath the epidermis, there is an acute inflammatory infiltrate. Abscess formation may be observed in the upper dermis or within downward extensions of the epidermis. In the middermis, tuberculoid granulomas with a moderate amount of necrosis are usually present (Fig. 21-14). Tubercle bacilli are more numerous in this disease than in lupus vulgaris and occasionally can be demonstrated histologically.

Miliary Tuberculosis of the Skin. Involvement of the skin with miliary tuberculosis is rare in the immunocompetent, occurring mostly in infants and only occasionally in adults. Usually, internal involvement is widespread as a result of hematogenous dissemination, and the cutaneous eruption is generalized, consisting of erythematous papules and pustules 2 to 5 mm in diameter (94). The tuberculin test generally is negative. The disease has a high fatality rate.

However, a milder form of hematogenous dissemination of tubercle bacilli exists in neonates born of tuberculous mothers. This form shows limited visceral involvement and only a few scattered erythematous papules with central crusts (95).

Histopathology. In severe cases, the center of the papule shows a microabscess containing neutrophils, cellular debris, and numerous tubercle bacilli. This is surrounded by a zone of macrophages with occasional giant cells. In the milder form, the histologic picture in the skin is similar, except that the Ziehl-Neelsen stain is negative for acid-fast organisms.

Lupus Vulgaris

The lesions of lupus vulgaris are usually found on the head or neck. The skin of and around the nose is frequently involved (96). The lesions consist of one or a few well-demarcated, reddish-brown patches containing deep-seated nodules, each about 1 mm in diameter. If the blood is pressed out of the skin with a glass slide, these nodules stand out clearly as yellow-brown macules, referred to, because of

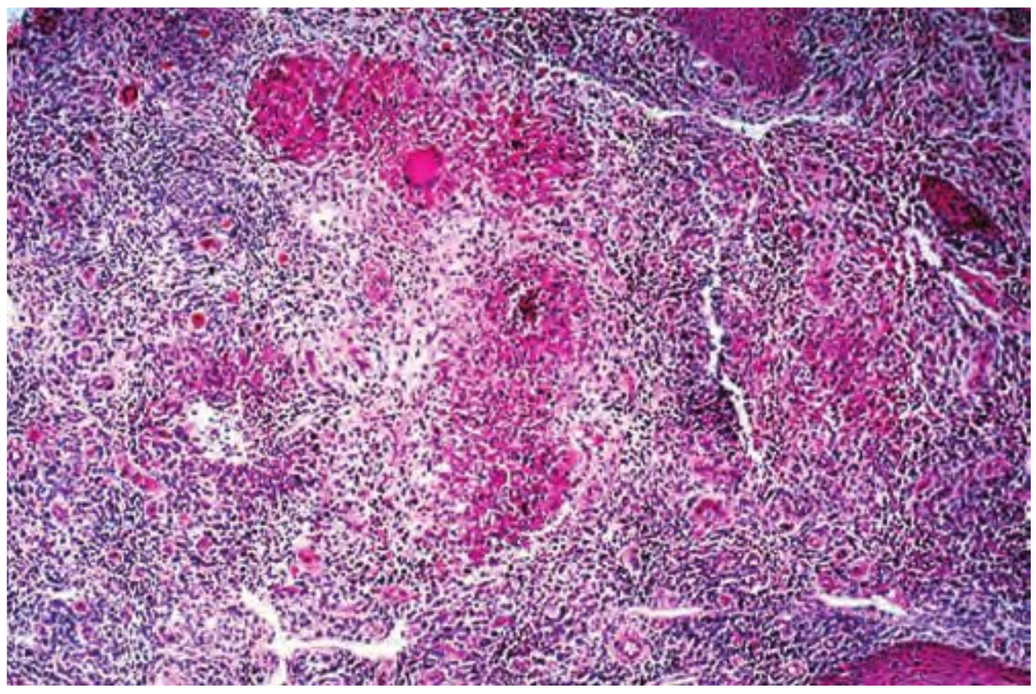

FIGURE 21-15. Tuberculosis. Epithelioid cell granulomas with central acute inflammation ("mixed" granuloma). Scanty acid-fast bacilli were seen in this case (H&E stain).

their color, as *apple-jelly nodules*. The disease is very chronic, with slow, peripheral extension of the lesions. Over time, the affected areas become atrophic, with contraction of the tissue. It is a characteristic feature of lupus vulgaris that new lesions may appear in areas of atrophy. Superficial ulceration or verrucous thickening of the skin occurs occasionally. Squamous cell carcinoma develops at the margins of ulcers in rare instances.

Histopathology. Tuberculoid granulomas composed of epithelioid cells and giant cells are present. Caseation necrosis within the tubercles is slight or absent (97). Although the giant cells usually are of the Langhans type, with peripheral arrangement of the nuclei, some can be of the foreign body type, with irregular arrangement of the nuclei. There is an associated infiltrate of lymphocytes (Figs. 21-15 and 21-16). Sometimes, this may be so prominent that the granulomatous component is obscured. The inflammation is most pronounced in the upper dermis, but in some areas, it may extend into the subcutaneous layer. Tuberculoid granulomas cause destruction of the cutaneous appendages. In areas of healing, extensive fibrosis may be present.

Secondary changes in the epidermis are common. The epidermis may undergo atrophy and subsequent destruction, causing ulceration, or it may become hyperplastic, showing acanthosis, hyperkeratosis, and papillomatosis. At the margins of ulcers, pseudoepitheliomatous hyperplasia often exists. Unless a deep biopsy is done in such cases, only the epithelial hyperplasia and a nonspecific inflammation may be seen, and the diagnosis may be missed. In rare instances, squamous cell carcinoma supervenes (98).

Tubercle bacilli are present in such small numbers that they can very rarely be demonstrated by staining methods. Polymerase chain reaction (PCR) detection of mycobacterial DNA is more often positive (99). In some instances of lupus vulgaris when an old focus of primary infection cannot be detected, a positive tuberculin test and the response to antituberculous therapy must suffice as proof of a tuberculous etiology.

Pathogenesis. Lupus vulgaris is a form of secondary or reactivation tuberculosis developing in previously infected and sensitized persons. Hypersensitivity to PPD tuberculin is high. Although the mode of infection often is not apparent, the disease rarely seems to be the result of an exogenous reinfection of the skin; usually it results from hematogenous spread from an old, reactivated focus in the lung or from lymphatic extension from a tuberculous cervical lymphadenitis (78).

Scrofuloderma

Scrofuloderma represents a direct extension to the skin of an underlying tuberculous infection present most commonly in a lymph node or a bone. The lesion first manifests itself as a blue-red, painless swelling that breaks open and then forms an ulcer with irregular, undermined, blue borders.

Histopathology. The center of the lesion usually exhibits nonspecific changes, such as abscess formation or ulceration. In the deeper portions and at the periphery of the lesion, if the biopsy specimen is adequate, tuberculoid granulomas with a considerable amount of necrosis and a pronounced inflammatory reaction usually are seen. Often, the number of tubercle bacilli is sufficient for them to be found in histologic sections.

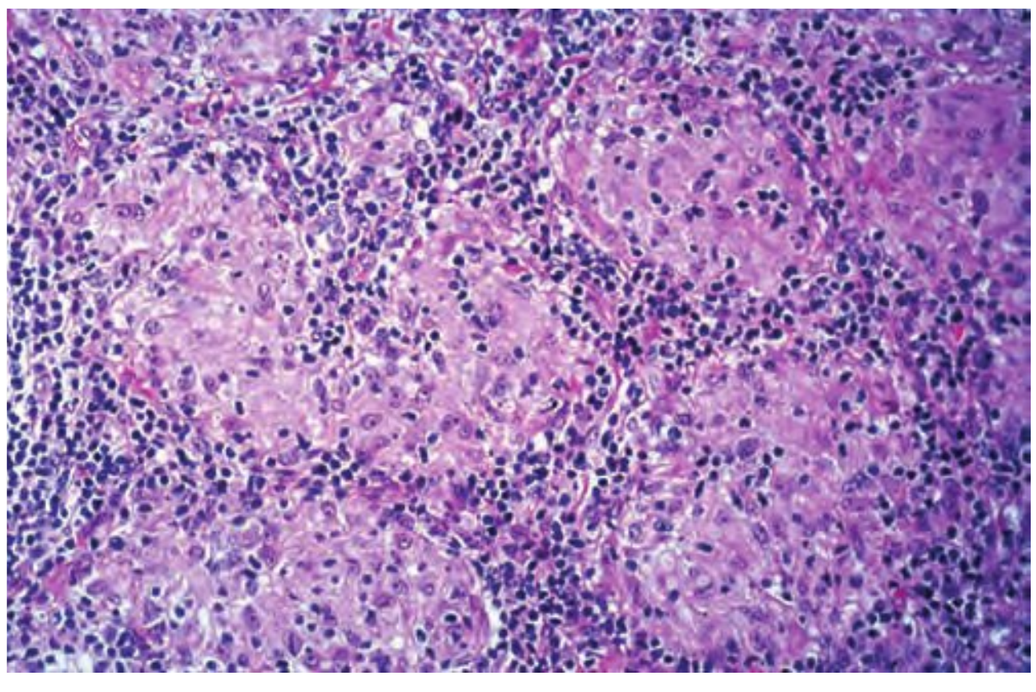

FIGURE 21-16. Lupus vulgaris. Near-confluent nonnecrotizing epithelioid cell granulomas in the dermis (H&E stain).

Tuberculous Gumma

Hematogenous infection of the skin from an internal lesion may result in a large dermal or subcutaneous nodule that is necrotic and ultimately ulcerates the epidermis.

Histopathology. Most of the lesion is caseation necrosis with a rim of epithelioid cells and giant cells (Figs. 21-17 and 21-18). Acid-fast bacilli are scanty.

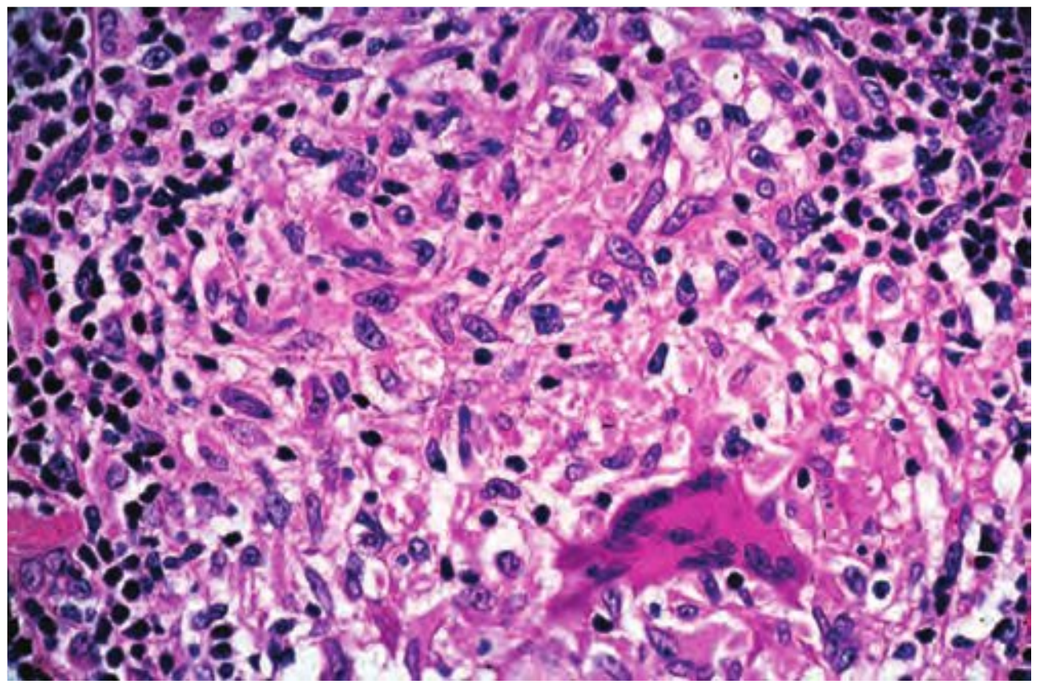

FIGURE 21-17. Lupus vulgaris. Same lesion as in Figure 21-16, showing an epithelioid cell granuloma and Langhans giant cell (H&E stain).

Tuberculosis Cutis Orificialis

The lesions of tuberculosis cutis orificialis are shallow ulcers with a granulating base occurring singly or in small numbers on or near the mucosal orifices of patients with advanced internal tuberculosis. The infection has spread by direct contamination from an internal lesion that is excreting bacilli. Most patients have a low degree of immunity. The ulcers, which are often very tender, may occur inside the mouth, on the lips, around the anus, or on the perineum (100). In the case of genitourinary tuberculosis, ulcers may occur on the vulva.

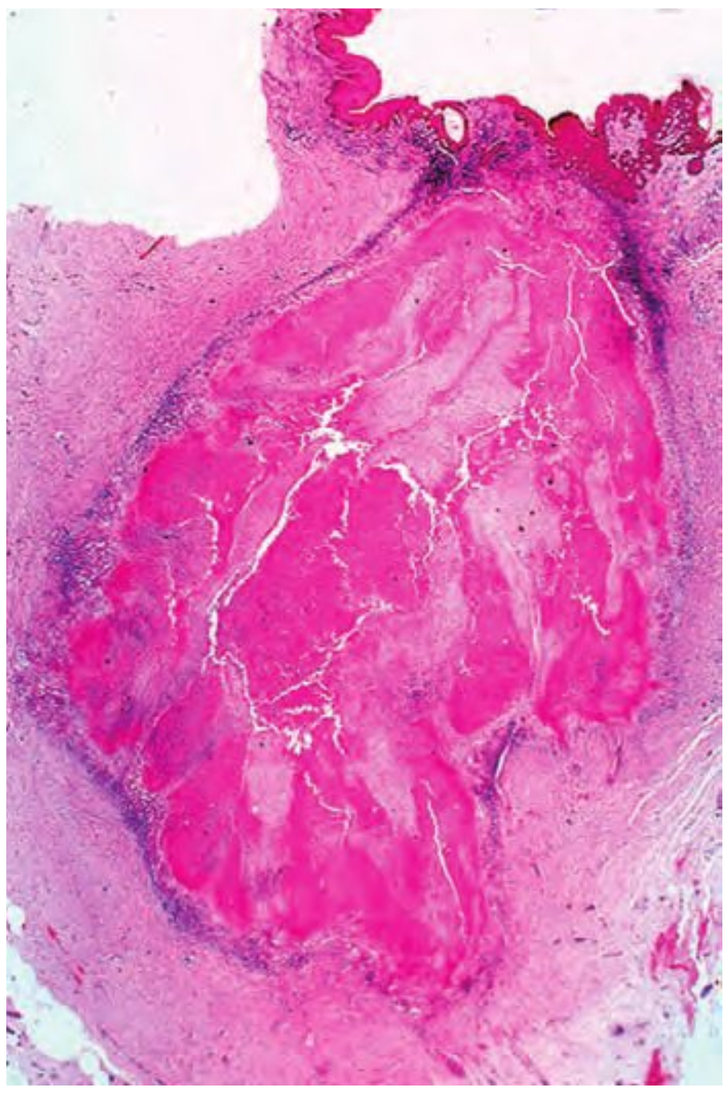

FIGURE 21-18. Tuberculosis. A tuberculoma-like appearance with much caseation necrosis in the dermis (H&E stain).

Histopathology. The histologic picture may show merely an ulcer surrounded by a nonspecific inflammatory infiltrate. In most instances, tuberculoid granulomas with pronounced necrosis are found deep in the dermis. Tubercle bacilli are usually readily demonstrated in the sections, even when the histologic appearance is nonspecific.

Differential Diagnosis of Cutaneous Tuberculosis

Because tuberculosis can produce such a wide variety of inflammatory reactions—nonnecrotic granulomas, necrotic granulomas, nonspecific acute inflammation, and epithelial hyperplasia—it is not surprising that many other lesions have similar histologic appearances. These other lesions include sarcoidosis, mycoses, leishmaniasis, nontuberculosis mycobacterioses and leprosy, syphilis, foreign body implantation reactions, Wegener's granulomatosis, and rosacea.

Sarcoidosis usually has little lymphocytic reaction around the granulomas, unlike most forms of granulomatous tuberculosis. When necrosis occurs in a sarcoid, it is usually fibrinoid in type rather than caseating. A thorough search for acid-fast bacilli, a search for fungal infection with PAS and Grocott stains, and the use of polarizing light to exclude foreign material are obviously important in arriving at a diagnosis. Clinical data and the result of a tuberculin test are also significant. Culture of a lesion should establish the diagnosis in most cases. Recently, the use of PCR technology on paraffin sections to detect specific mycobacterial DNA has proved useful in confirming tuberculosis in the absence of evident organisms in sections (101). In a recent review, the utility of a PCR test versus other laboratory tests was studied in 37 skin biopsies from patients with different variants of cutaneous tuberculosis. The PCR test showed the maximum positivity of 79% followed by histopathology (73%), BACTEC culture (47%), LJ media culture (29%), and smear examination (6%). Using culture as the gold standard, the sensitivity and specificity of PCR testing were 95.2% and 100.0%, respectively. The mean times to a positive result in different tests were $<$24 hours for smear examination, 1 day for the PCR test, and 23 to 38 days for different culture methods, demonstrating that PCR is a rapid and sensitive test for diagnosis of cutaneous tuberculosis using skin biopsy samples (102).

Tuberculids

The *tuberculids*, a term first proposed in 1896 (103), according to some authors comprise two types of dermatoses: papulonecrotic tuberculids and lichen scrofulosorum (104,105). Cases of nodular vasculitis, when associated with tuberculosis, are included within the group of tuberculids and are called *erythema induratum* (Bazin's disease; see Chapters 8 and 20).

Tuberculids are skin lesions in patients with tuberculosis, often occult, elsewhere in the body. The most common sites of infection are lymph nodes (106). By definition, stains for acid-fast bacilli and culture for mycobacteria are negative; delayed hypersensitivity skin tests for tuberculosis are positive, and the lesions

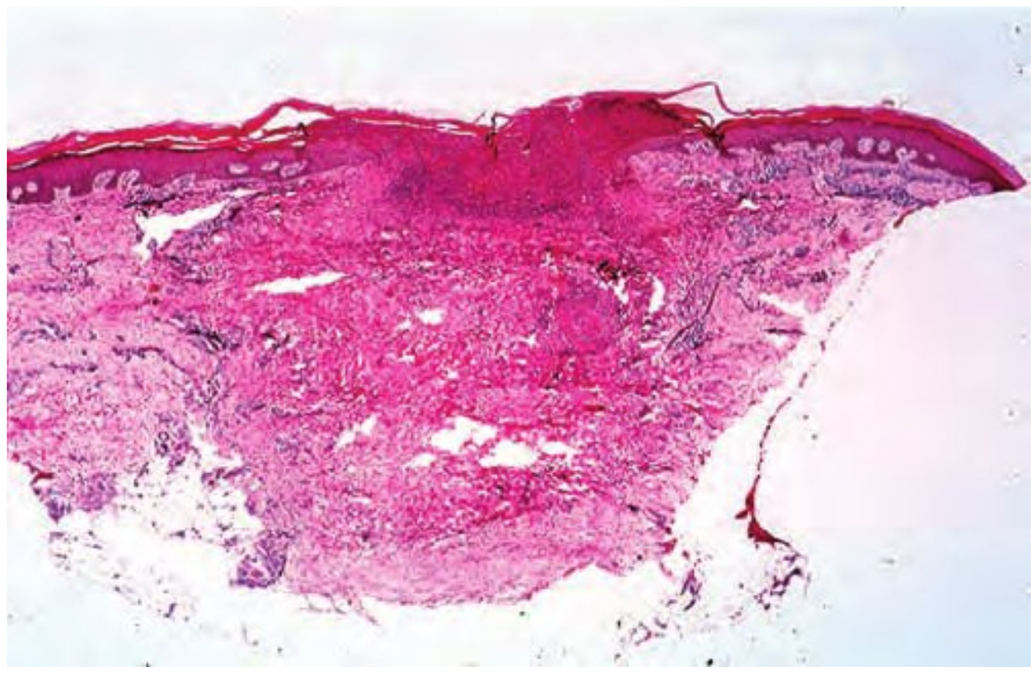

FIGURE 21-19. Papulonecrotic tuberculid. Wedge-shaped infarction of the dermis and epidermis caused by vasculitis (H&E stain).

heal on antituberculous therapy. Recently, using the PCR technique, mycobacterial DNA has been identified in some lesions (107). This supports the concept of tuberculids as immunologic reactions to degenerate dead bacilli or antigenic fragments thereof that have been deposited in the skin and subcutis.

Papulonecrotic Tuberculids

Papulonecrotic lesions are erythematous papules that usually develop on the limbs in a symmetrical distribution (108). They ulcerate and heal, leaving depressed scars. These tuberculids often recur until treated. Occasionally, they may develop into lupus vulgaris.

Histopathology. Vascular involvement is observed in early lesions. It may consist of a leukocytoclastic vasculitis or a lymphocytic vasculitis. In either case, it is associated with fibrinoid necrosis and thrombotic occlusion of individual vessels (109). Subsequently, a wedge-shaped area of necrosis forms, with its broad base toward the epidermis (108) (Figs. 21-19 and 21-20). As this wedge is gradually cast off, epithelioid and giant cells gather around its periphery, although focal granuloma formation is poor. Follicular necrosis or suppuration may occur, although diffuse acute inflammatory cells are infrequent. Ziehl-Neelsen stains are, of course, negative.

Differential Diagnosis. Numerous conditions may be confused clinically or histopathologically with papulonecrotic tuberculids. They include pityriasis lichenoides acuta, syphilides, miliary tuberculosis, perforating granuloma annulare, and suppurative folliculitis (108).

Lichen Scrofulosorum

Lichen scrofulosorum consists of yellow or brown follicular papules, 0.5 to 3.0 mm in diameter, on the trunk. They heal without scarring.

Histopathology. Superficial dermal granulomas are observed, usually in the vicinity of hair follicles or sweat ducts. The granulomas are composed of epithelioid cells, with some Langhans giant cells and a narrow margin of lymphoid cells at the periphery (Fig. 21-21). Generally, caseation necrosis is absent.

Differential Diagnosis. Distinction of lichen scrofulosorum from sarcoidosis may be impossible on histologic grounds alone.

Pathogenesis. The histogenesis of tuberculids is still unclear. Tubercle bacilli are absent in tuberculids, either because they have arrived hematogenously in fragmented form or because they have been destroyed at the sites of the tuberculids by immunologic mechanisms. Mycobacterial DNA is, however, demonstrable in many cases (107,110). The reaction in the papulonecrotic

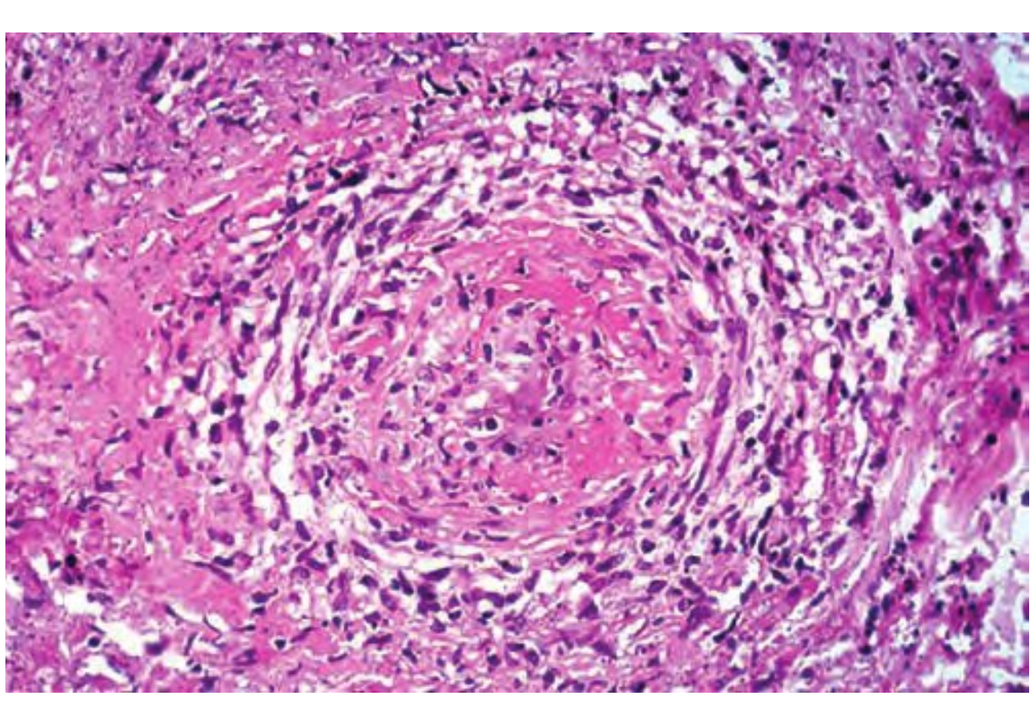

FIGURE 21-20. Papulonecrotic tuberculid. Necrotizing vasculitis of a dermal artery with granulomatous surround (H&E stain).

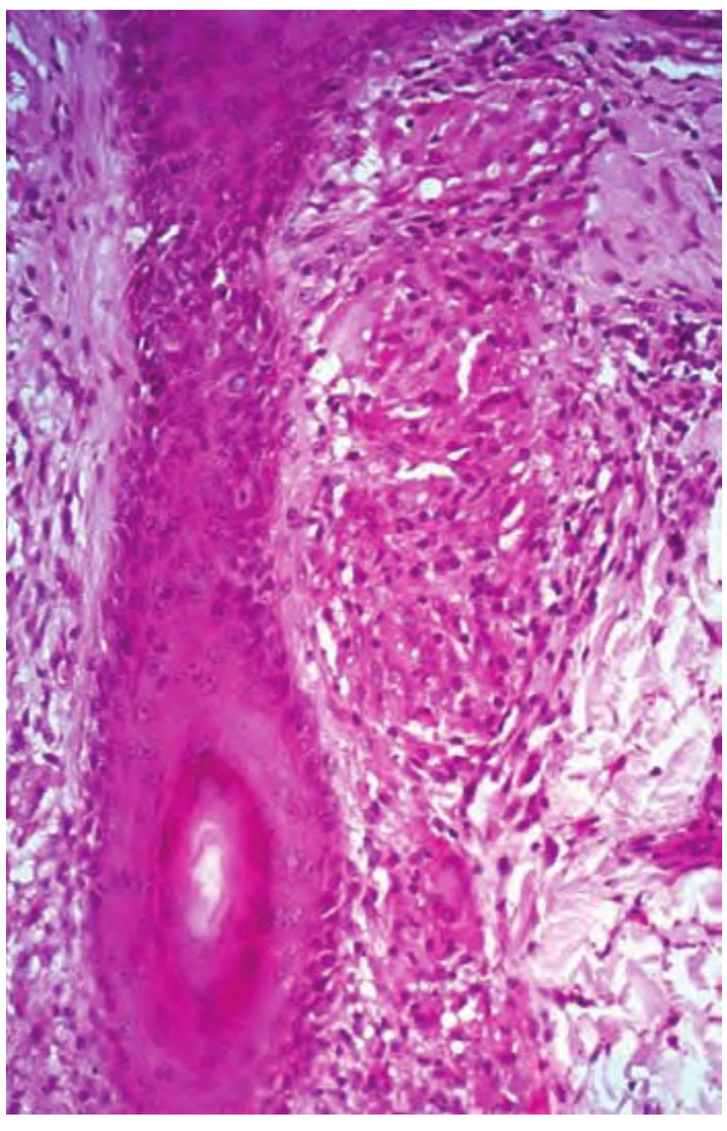

FIGURE 21-21. Lichen scrofulosorum. Nonnecrotizing epithelioid cell granulomas alongside a hair shaft (H&E stain).

tuberculid consists of an Arthus reaction with vasculitis followed by a delayed hypersensitivity response with granuloma formation. In the case of lichen scrofulosorum, there is only a delayed hypersensitivity reaction resulting in granuloma formation (105).

Tuberculid-type reactions are also described with nontuberculosis mycobacteria (*Mycobacterium bovis* and *M. avium*) (111,112).

INFECTIONS WITH NONTUBERCULOSIS MYCOBACTERIA

Among the nontuberculosis, nonleprosy mycobacterial infections of the skin, those caused by *M. marinum* are the most common among nonimmunosuppressed people (113). Unlike *M. tuberculosis*, which is transmitted from person to person, nontuberculosis mycobacteria are abundant in nature, in soil and water, and contact is frequent in most zones of the world (77,114).

These skin infections may be acquired by direct inoculation into the skin or by hematogenous spread from a visceral focus. Increased use of immunosuppression in medicine (e.g., for transplantation and cancer chemotherapy) and the pandemic of HIV/AIDS have resulted in many more mycobacterial skin infections. The cell-mediated immune system is a major defense against such organisms and is affected or destroyed during the course of these immunosuppressive conditions. The clinical and histopathologic patterns are also altered, with organisms being found in greater density than in immunocompetent persons.

The histopathologic picture in nontuberculosis mycobacterioses is just as variable as the clinical picture and may present nonspecific acute and chronic inflammation, suppuration and abscess formation, or tuberculoid granulomas with or without caseation (85,115). In some instances, both tissue reactions occur concurrently. The presence or absence of acid-fast bacilli depends on the tissue reaction. In suppurative lesions, numerous acid-fast bacilli often can be found.

Infection with Mycobacterium Kansasii

M. kansasii is usually a lymph node and pulmonary infection, and skin lesions are unusual. Implantation causes a chronic cutaneous nodule and sometimes ulceration (77). The lesions are often crusted. There may be sporotrichoid lymphatic spread of lesions up the extremity (113). In immunocompromised patients, such as those with HIV infection, there may be multiple visceral lesions (lung and bone) with hematogenous dissemination to skin. The skin lesions are acute abscesses with large numbers of acid-fast bacilli (Fig. 21-22).

Infection with Mycobacterium Avium-intracellulare

M. avium complex infection is a common cause of cervical lymph node mycobacteriosis in normal children and of pulmonary disease in previously damaged lungs (77). Prior to the HIV pandemic, skin infections were rare, with hematogenously borne lesions in skin and subcutis observed in patients usually with immunosuppressing diseases (78).

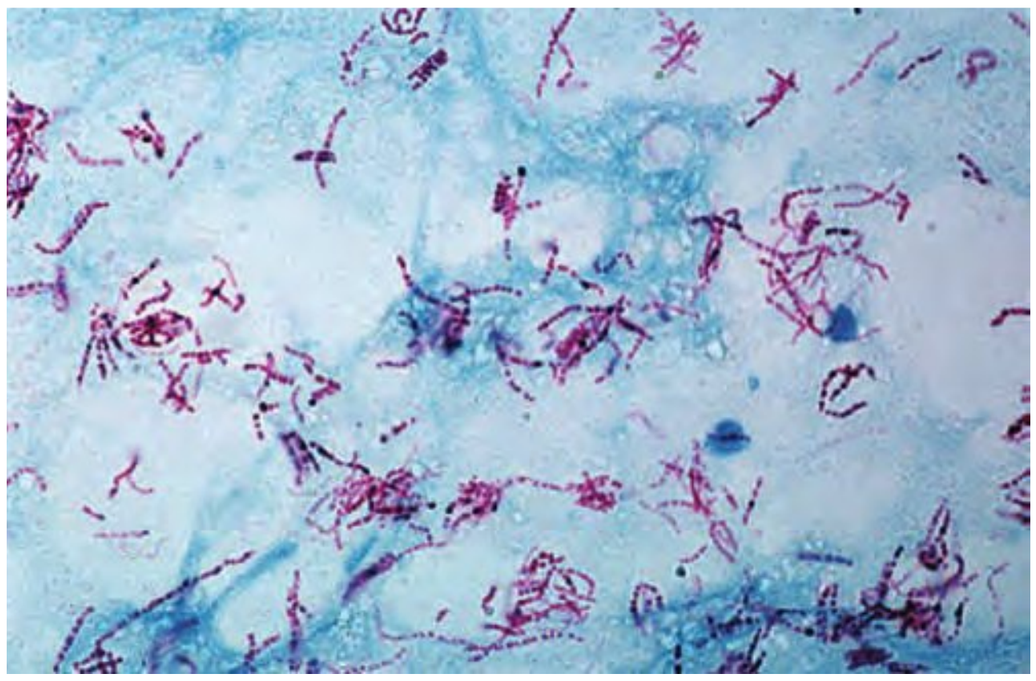

FIGURE 21-22. Mycobacterium kansasii infection. Needle aspirate of a skin lesion on an immunocompromised patient. Abundant elongated and beaded acid-fast bacilli typical of M. kansasii (Ziehl-Neelsen stain).

Severely immunocompromised patients, such as those with HIV infection, have a very high prevalence of *M. avium-intracellulare* bacteremia (116), and many show one or more cutaneous papules and nodules (117,118). Steroid therapy also predisposes to skin lesions. The histology may be granulomatous or mixed acute and chronic inflammatory, as with tuberculosis (77). Sometimes, there is a histology resembling that of lepromatous leprosy (Figs. 21-23 to 21–25). Macrophages contain large numbers of bacilli without necrosis, and a spindle cell transformation of macrophages, forming a histoid-like lesion (as in leprosy), can occur (119,120).

Infection with Mycobacterium Marinum

Infections with *M. marinum* can be contracted through minor abrasions incurred while bathing in swimming pools or in ocean or lake water or while cleaning home aquariums (121). Infected swimming pools have caused epidemics, the largest of

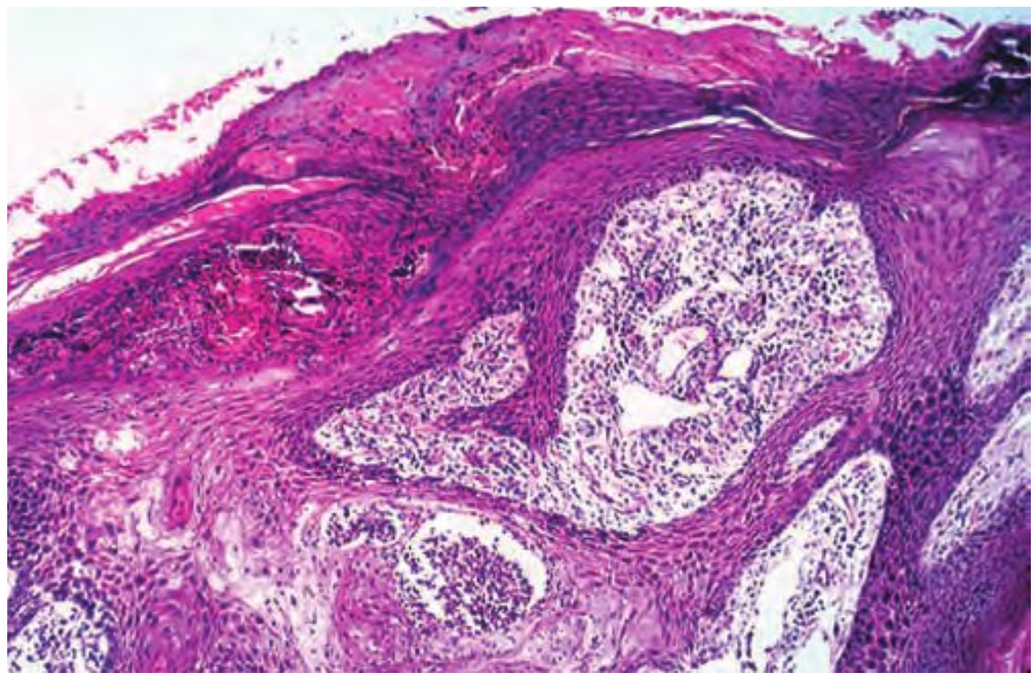

FIGURE 21-26. Mycobacterium marinum infection. A marked pseudoepitheliomatous epidermal hyperplasia, with acute inflammatory foci within the epidermis (H&E stain).

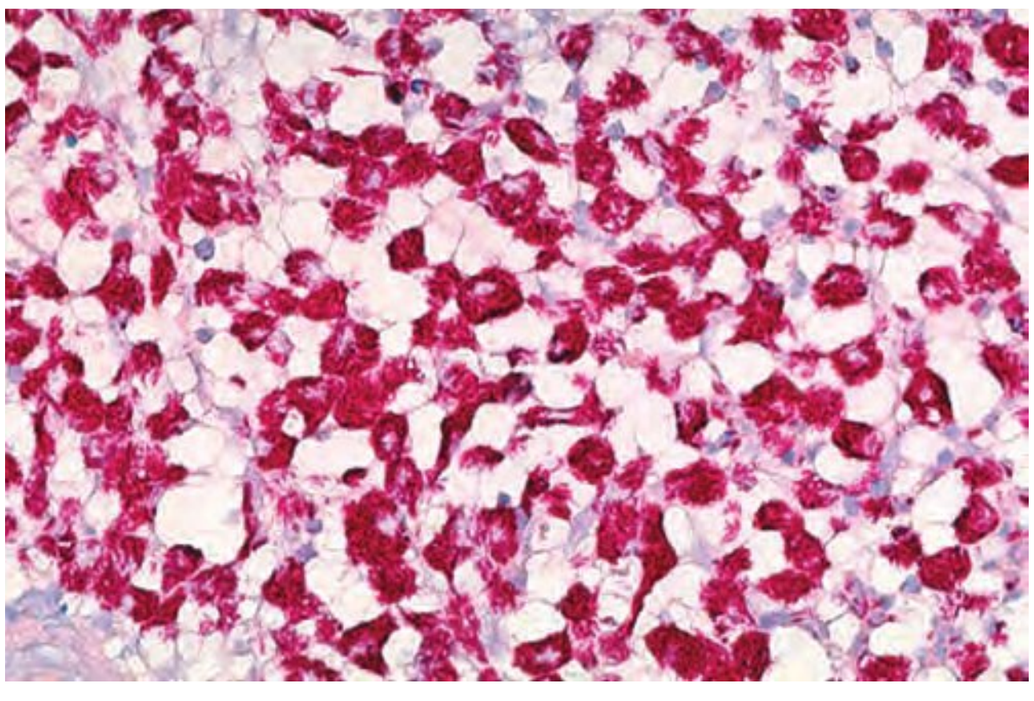
which affected 290 persons (122). The period of incubation usually is about 3 weeks but may be longer (113).

Clinically, most of the lesions caused by *M. marinum* are solitary and consist of indolent, dusky red, hyperkeratotic, papillomatous papules, nodules, or plaques. Superficial ulceration is occasionally observed. The fingers, knees, elbows, and feet are most commonly affected. In some instances, satellite papules arise and ascending sporotrichoid spread occurs (123). Lesions may form at different sites in the case of multiple injuries. Although spontaneous healing usually takes place within a year, the lesions persist in some patients for many years. A few HIV-associated cases have been reported (124). Fatal disseminated *M. marinum* infection is rare (125).

Histopathology. Early lesions no more than 2 or 3 months old show a nonspecific inflammatory infiltrate composed of neutrophils, monocytes, and macrophages. In lesions about 4 months old, a few multinucleated giant cells and a few small epithelioid cell granulomas usually are present, and in lesions 6 months old or older, typical tubercles or tuberculoid structures may be seen (126). Areas of necrosis are only occasionally present in the centers of the granulomas. The epidermis often shows marked hyperkeratosis with an acute inflammatory infiltrate and ulceration (Fig. 21-26).

Acid-fast bacilli usually can be identified in histologic sections of early lesions that show a nonspecific inflammatory infiltrate. In contrast, tuberculoid granulomas generally no longer show acid-fast organisms unless areas of central necrosis are present. Although primary lesions usually require a few months for the formation of tuberculoid granulomas, the sporotrichoid nodules that arise later show tuberculoid granulomas and a lack of acid-fast bacilli even when they have been present for only a few weeks.

Differential Diagnosis. The granulomatous reaction produced by *M. marinum* is similar to that observed in tuberculosis verrucosa cutis or lupus vulgaris. The pattern of pseudoepitheliomatous hyperplasia with granulomas and polymorphonuclear neutrophil infiltrate is also seen in several cutaneous mycoses (e.g., sporotrichosis and chromoblastomycosis), so fungal stains need to be examined alongside Ziehl-Neelsen stains. For definitive identification, culture may be necessary.



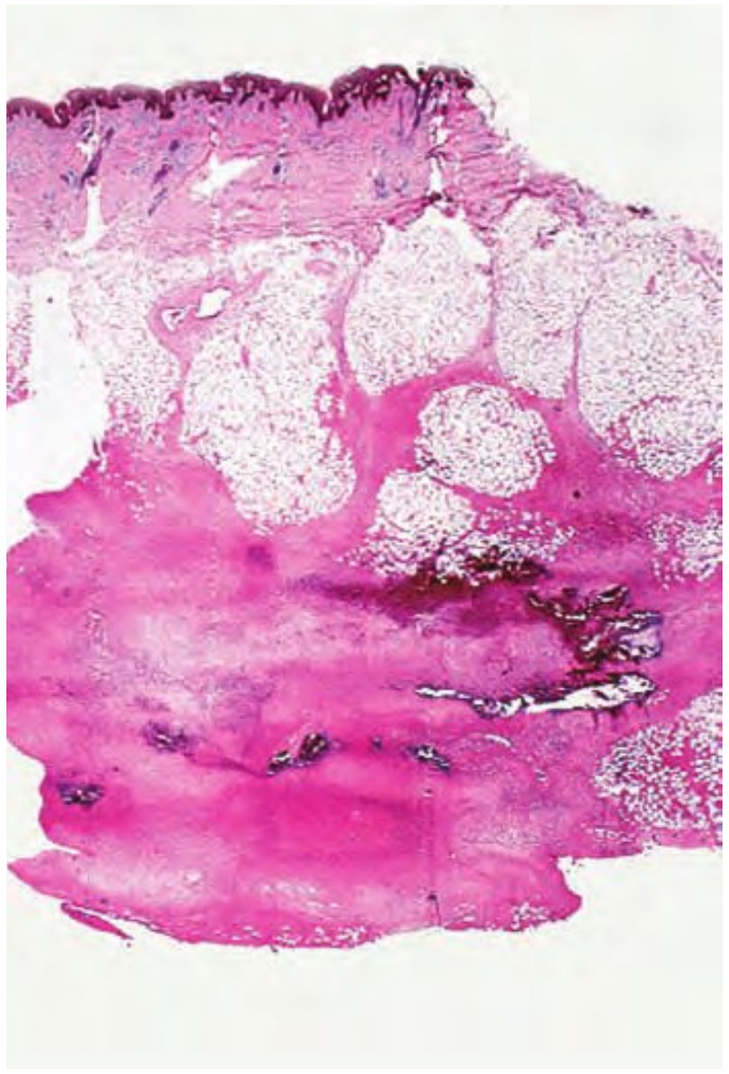


FIGURE 21-25. Mycobacterium avium-intracellulare infection. Same lesion as in Figure 21-23, showing abundant acid-fast bacilli, similar to lepromatous leprosy (Ziehl-Neelsen stain).

Buruli Ulcer (Mycobacterium ulcerans)

Buruli ulceration, an infection caused by a nontuberculosis mycobacterium, *M. ulcerans*, is endemic in West and Central Africa, Central America, and South Australia (127–129). The organism is now identified in nature, near inland water and rivers, and is directly implanted or follows an aquatic insect bite. The infection commences as a palpable cutaneous nodule. In some cases, this may heal but more usually progresses to ulceration of the skin with extensive undermining of the epidermis and extension of the necrosis down to fascia and even bone (130). These painless ulcers are usually located on extremities and buttocks, but trunk and facial ulcers also occur.

A

B

FIGURE 21-27. Buruli ulcer (M. ulcerans infection). A: An evolving ulcer with undermined edge. B: Early, preulcerating lesion, with deep dermal and subcutaneous fat necrosis (H&E stain).

Histopathology. The infection begins as a subcutaneous nodule exhibiting "ghost" ischemic-type dermal collagen and fat necrosis with deposition of fibrin and hematoxyphilic extracellular clumps of mycobacteria. Ulceration proceeds as the epidermis loses its vascular supply. Ziehl-Neelsen stains reveal vast numbers of acid-fast bacilli in the necrotic fat (Figs. 21-27 to 21-29); their distribution is often irregular. A variable degree of neutrophil infiltration and thrombosis of vessels are also observed. In time, a nonspecific granulation tissue or a granulomatous reaction commences from the depth and sides of the ulcer; healing and re-epithelialization take place with considerable scarring. Acid-fast bacilli decline rapidly in number during healing (128,131). The histopathologic case definition for Buruli ulcer, useful for research studies, is (a) the typical pattern of infarctive-like necrosis of deep dermal collagen and fat and (ideally, but not always found in limited samples) (b) nearby clusters of acid-fast bacilli.

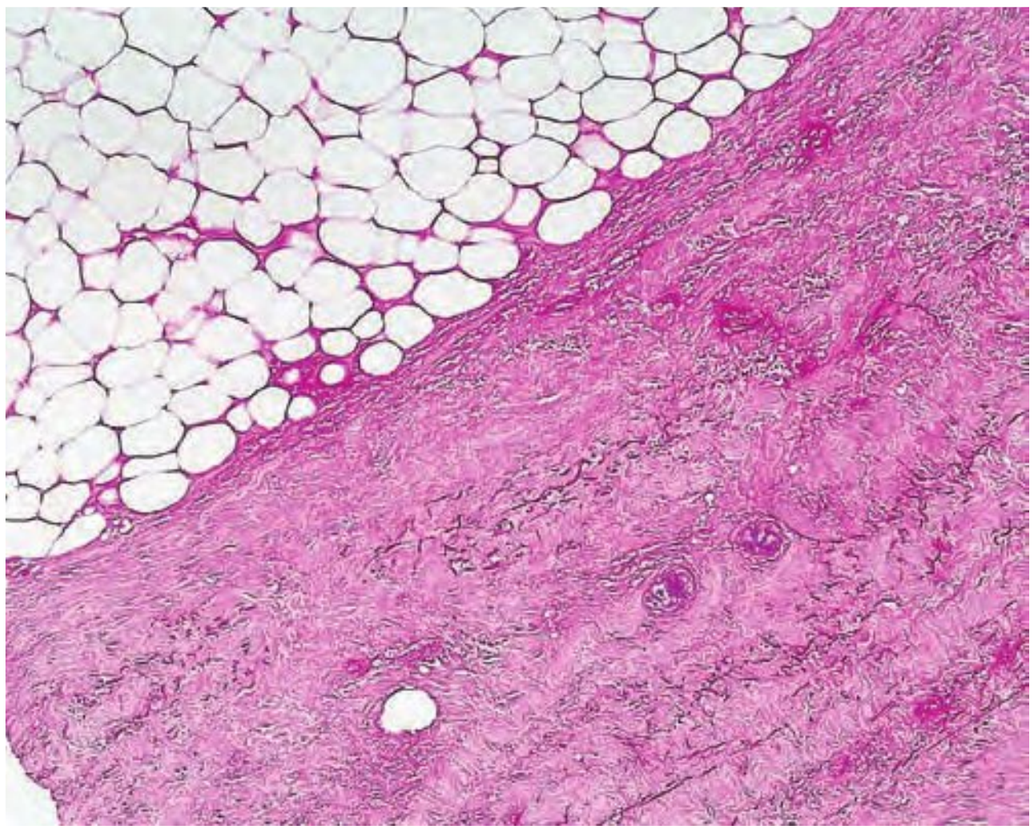

FIGURE 21-28. Buruli ulcer. The ischemic-type fat and collagen necrosis without cellular reaction; the hematoxyphilic clusters are mycobacteria (H&E stain).

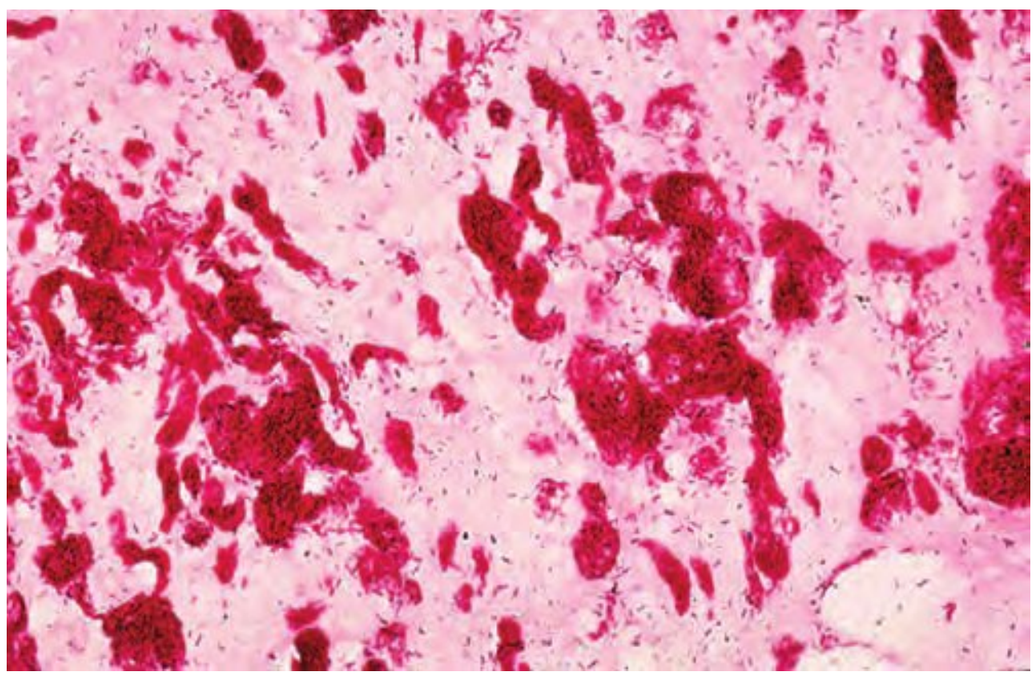

FIGURE 21-29. Buruli ulcer. Clumps of acid-fast bacilli within the fat necrosis (Ziehl-Neelsen stain).

Pathogenesis. The widespread necrosis of subcutaneous tissue is caused by a toxin secreted by *M. ulcerans*, a pathogenesis unique to this species of mycobacteria. It is polyketide mycolactone, and strain and geographical differences in mycolactone virulence are already described (the disease is less severe in Australia than in central Africa, related to different mycolactone strains). This toxin causes necrosis when inoculated into guinea pig skin and into macrophages in tissue culture (127). Like *M. marinum*, *M. ulcerans* shows optimal cultural growth at 30° to 33°C.

PCR technology has been used to track the distribution of *M. ulcerans* in Buruli ulcer lesions and to compare the mycobacterial burden with histopathologic changes (132). While peaks of mycobacterial DNA and histopathologically recognized acid-fast bacilli in the necrotic base of the ulcers marked the position of the primary infection focus, mycobacterial DNA (and sometime microcolonies) was also present in samples from the periphery of the ulcers and occasionally from macroscopically and histologically healthy-looking excised tissue margins and in sites where satellite lesions were developing. Even when granulomas provided evidence for the development of cell-mediated immunity, development of satellite lesions by contiguous spreading was not completely prevented.

Healing of Buruli ulcer coincides with development of delayed hypersensitivity to the mycobacterium, possibly contingent on the cessation of mycolactone production. In a recent study, expression of cytokines was correlated with the inflammatory response evaluated by histopathology (133). All of the cases showed extensive necrosis and chronic inflammation. The most important feature correlating with chronicity was considered to be the presence or absence of granulomas coexisting with a mixed proinflammatory/antiinflammatory cytokine balance. Granulomas were absent from relatively early ulcerative lesions, which contained more bacilli and little interferon (IFN)-gamma, suggesting that at this stage of the disease strong suppression of the protective cellular immune response facilitates proliferation of bacilli. When granulomas were present, significantly higher expression of IFN-gamma was seen as well as lower bacillary counts.

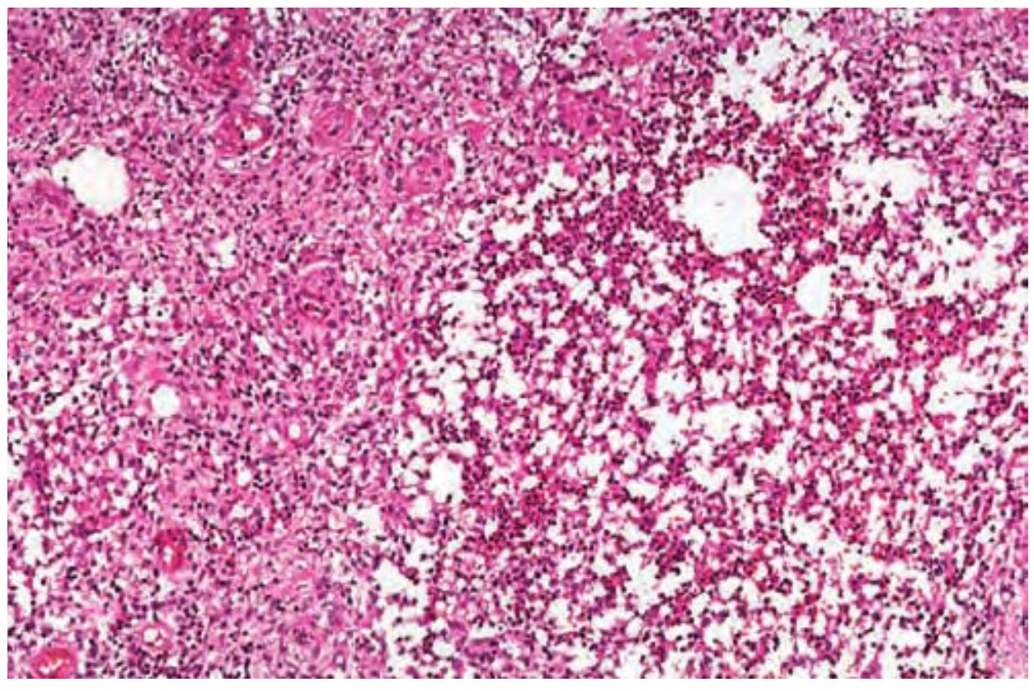

FIGURE 21-30. Mycobacterium fortuitum injection abscess. Dermal mixed granulomatous and acute inflammation (H&E stain).

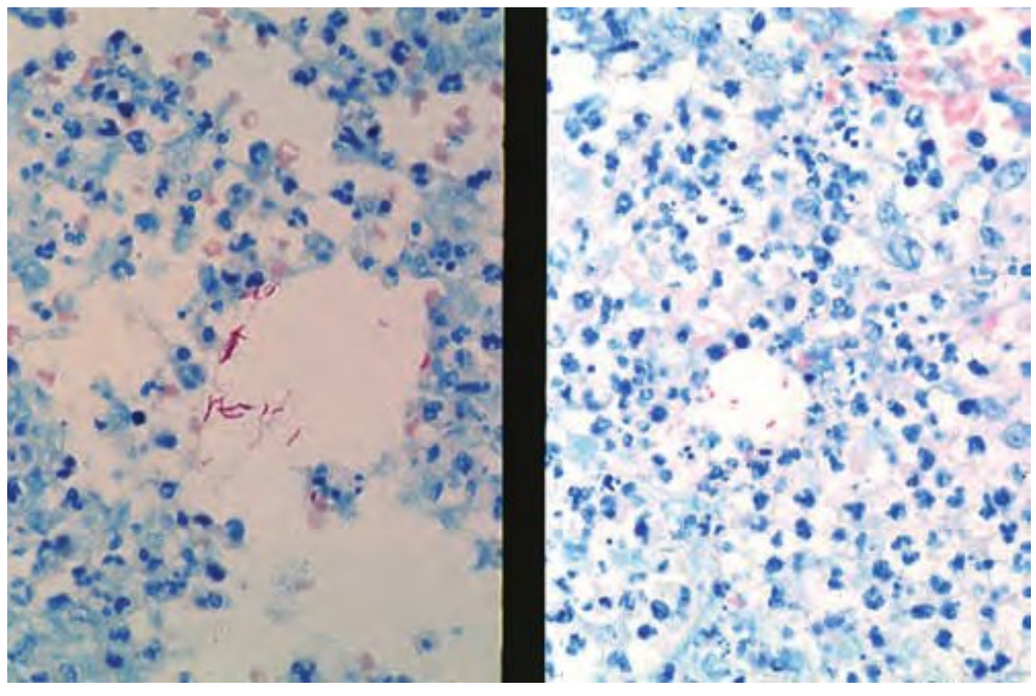

FIGURE 21-31. Mycobacterium fortuitum injection abscess. Clusters of acid-fast bacilli within a fat vacuole (Ziehl-Neelsen stain).

Other Nontuberculosis Mycobacterioses

Infections in the skin and subcutis caused by the rapid growers *M. chelonei*, *M. fortuitum*, and *M. abscessus* are associated with medical injections through unsterile contaminated needles and cannulas (77,134). Sporotrichoid spread can occur with *M. chelonei* (135). The inflammatory reaction is usually a mixed acute (neutrophilic) and chronic (granulomatous) response, with acid-fast bacilli visible on sections (77) (Figs. 21-30 and 21-31). Localized and disseminated *M. haemophilum* infection is reported in patients with HIV and other causes of immunosuppression (136–138).

BCG is the most commonly used vaccine, yet it rarely results in significant cutaneous lesions. Persisting ulcerating lesions may be observed. Histologically, these lesions are caseating granulomas in the dermis, as seen in tuberculosis, but acid-fast bacilli are rarely observed. In immunocompromised patients, there may be generalized cutaneous nodules, and histology shows abundant bacilli, poorly formed bacilli, and variable or no necrosis (139).

LEPROSY

Leprosy is caused by *M. leprae* and predominantly affects the skin and peripheral nerves. The disease is endemic in many tropical and subtropical countries but is declining in prevalence as a result of multidrug therapy. The Indian subcontinent, Southeast Asia, sub-Saharan countries in Africa, and Brazil comprise the areas most affected at present (140,141). The mode of transmission of leprosy is unknown, but it is probably inhalation of bacilli, which may be excreted from the nasal passages of a multibacillary patient or possibly implanted from organisms in the soil. Direct person-to-person infection by means of the skin occurs rarely if at all. After inhalation, it is likely that bacilli pass through the blood to peripheral and cutaneous nerves, where infection and host reaction commence.

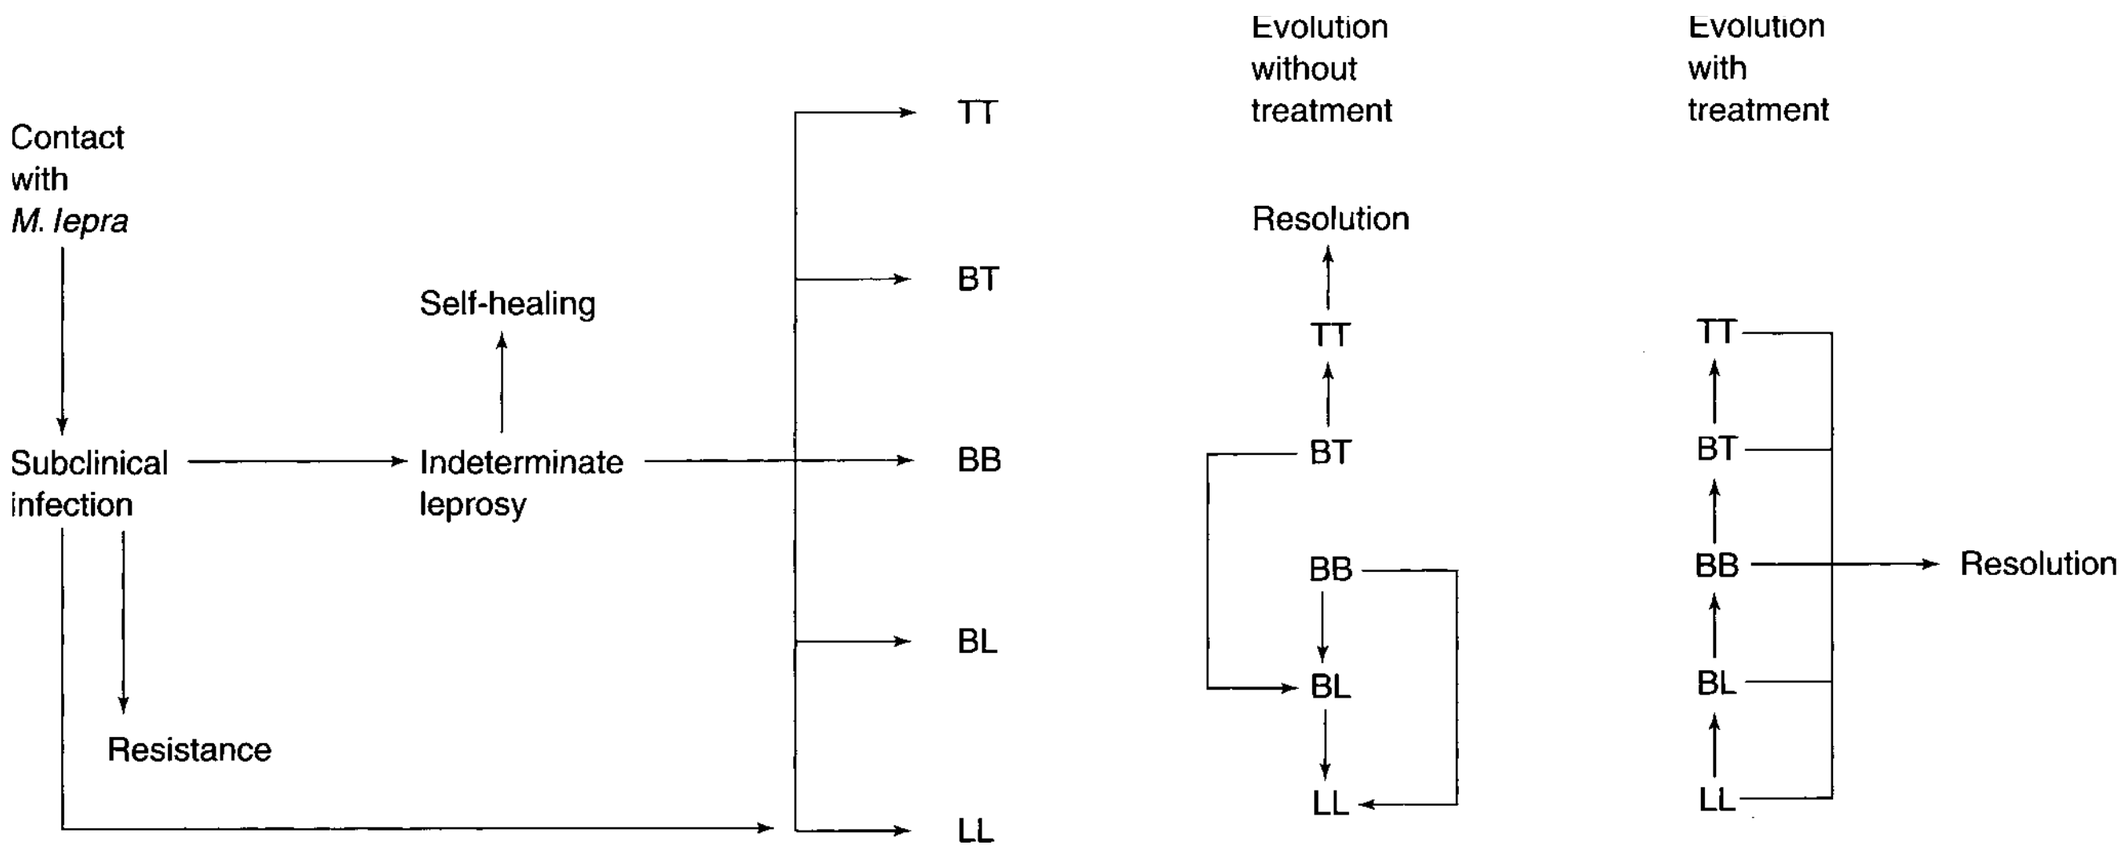

FIGURE 21-32. Leprosy. The sequence of events that may follow infection with M. leprae. (TT, tuberculoid; BT, borderline tuberculoid; BB, midborderline; BL, borderline lepromatous; LL, lepromatous.)

Immunopathologic Spectrum of Leprosy

The sequence of disease pathogenesis is complex, is very chronic, and depends on host-parasite immunologic responses. The leprosy bacillus is nontoxic, and clinicopathologic manifestations are the result of immunopathology and/or the progressive accumulation of infected cells. Leprosy is the best example of a disease showing an immunopathologic spectrum whereby the host immune reaction to the infective agent ranges from apparently none to marked, with a consequent range of clinicopathologic manifestations (142,143). Tuberculoid leprosy indicates a high cellular immune response (i.e., T cells and macrophage activation) and few bacilli in tissues; at the opposite pole, lepromatous leprosy indicates an absent cellular immune response to *M. leprae* antigens, with no macrophage activation and abundant bacilli in tissues. The spectrum of leprosy is a continuum, and patients may move in either direction according to host response and treatment. The standard delineation follows that of Ridley and Jopling, with categories defined along the spectrum by a combination of clinical, microbiologic, histopathologic, and immunologic indices: TT (tuberculoid), BT (borderline tuberculoid), BB (midborderline), BL (borderline lepromatous), and LL (lepromatous). The term *borderline* is used to denote patterns that share some features of both tuberculoid and lepromatous leprosy (141,142).

TT and LL patients are stable, the former often self-healing and the latter remaining heavily infected unless given appropriate chemotherapy. Patients presenting at the BT point will often downgrade toward BL leprosy in the absence of treatment. The central point of the spectrum (BB) is the most unstable, with most patients downgrading to LL if not treated. The term *indeterminate leprosy* is used to describe patients presenting with very early leprosy lesions that cannot be categorized definitely along the immunopathologic spectrum (e.g., cannot be determined as BT or LL).

It is likely that in endemic zones, a high proportion of people are infected by *M. leprae* but either have full immunity and no disease or have developed one or a few lesions that have self-healed without significant morbidity. The progression of infection and disease is summarized in Figure 21-32. Patients with determined leprosy are most numerous at the BT and LL points of the spectrum.

Staining of Mycobacterium leprae Bacilli

The classical method for demonstrating leprosy bacilli in lesions is a modified Ziehl-Neelsen stain, where the degree of acid and alcohol removal of carbol fuchsin is less than in the methods used for identifying other mycobacteria. The Fite methods are the most commonly used (143). Methanamine silver stains are also useful in detecting fragmented acid-fast bacilli. The sensitivity of detection of acid-fast bacilli by histologic means remains poor, because about 1,000 bacilli per cubic centimeter of tissue must be present in order to detect 1 bacillus in a section. For lesions where bacilli are scanty, it is recommended that at least six sections be examined before declaring them negative (144). The standard enumeration of leprosy bacilli in lesions—the bacterial index (BI)—follows Ridley's logarithmic scale (which applies to both skin biopsies and slit skin smears).

- BI = 0: no bacilli observed
- BI = 1: 1 to 10 bacilli in 10 to 100 high-power fields (hpf, oil immersion)
- BI = 2: 1 to 10 bacilli in 1 to 10 hpf
- BI = 3: 1 to 10 bacilli per hpf
- BI = 4: 10 to 100 bacilli per hpf
- BI = 5: 100 to 1,000 bacilli per hpf
- BI = 6: >1,000 bacilli per hpf

Solid-staining bacilli indicate that the organisms are capable of multiplication. Fragmented (beaded) and granular acid-fast

bacilli indicate that they are dead. Patients with no bacilli detectable in lesions are termed *paucibacillary*; those with some or many bacilli are *multibacillary* (this distinction is important in determing the duration of chemotherapy) (145).

Immunocytochemical methods for demonstrating mycobacterial antigens have a limited role. The most frequently used is a polyclonal anti-BCG antibody (146). In untreated lesions, it will not detect small numbers of bacilli if ordinary histochemical methods have proved negative. However, immunocytochemistry does have a role in demonstrating the presence of leprosy antigen after the bacilli have fragmented, been partly digested by macrophage enzymes, and lost their acid-fast staining quality (see page 562).

Clinical Pathology of Leprosy

For general discussions of clinical leprosy and leprosy pathology, the reader is referred to Job (147) and Britton and Lockwood (141).

Early, Indeterminate Leprosy

Many patients present with obvious or advanced skin and peripheral nerve lesions (the latter are primarily nerve enlargement and the consequences of anesthesia). These patients have "determined leprosy." However, the earliest detectable skin lesion comprises one or a few hypopigmented macules with variable loss of sensation. Any part of the body may be affected.

Histopathology. There is mild lymphocytic and macrophage accumulation around neurovascular bundles, the superficial and deep dermal vessels, sweat glands, and erector pili muscle; focal lymphocytic invasion into the lower epidermis and into the dermal nerves may be observed. No formed epithelioid cell granulomas are present (if they were, it would not be indeterminate leprosy but a tuberculoid leprosy). Schwann cell hyperplasia is a feature, but it is highly subjective. Not all of these features are present in every case. The diagnosis hinges on finding one or more acid-fast bacilli in the sites of predilection: in nerve, in erector pili muscle, just under the epidermis, or in a macrophage about a vessel. Without demonstrating bacilli, the diagnosis can only be presumptive (Figs. 21-33 and 21-34).

Lepromatous Leprosy

Lepromatous (LL) leprosy initially has cutaneous and mucosal lesions, with neural changes occurring later. The lesions usually are numerous and symmetrically arranged. There are three clinical types: macular, infiltrative-nodular, and diffuse. In the macular type, numerous ill-defined, confluent, either hypopigmented or erythematous macules are observed. They are frequently slightly infiltrated. The infiltrative-nodular type, the classical and most common variety, may develop from the macular type or arise as such. It is characterized by papules, nodules, and diffuse infiltrates that are often dull red. Involvement of the eyebrows and forehead often results in a leonine facies, with a loss of eyebrows and eyelashes. The lesions themselves are not notably hypoesthetic, although through involvement of the large peripheral nerves, disturbances of sensation and nerve paralyses develop. The nerves that are most commonly involved are the ulnar, radial, and common peroneal nerves.

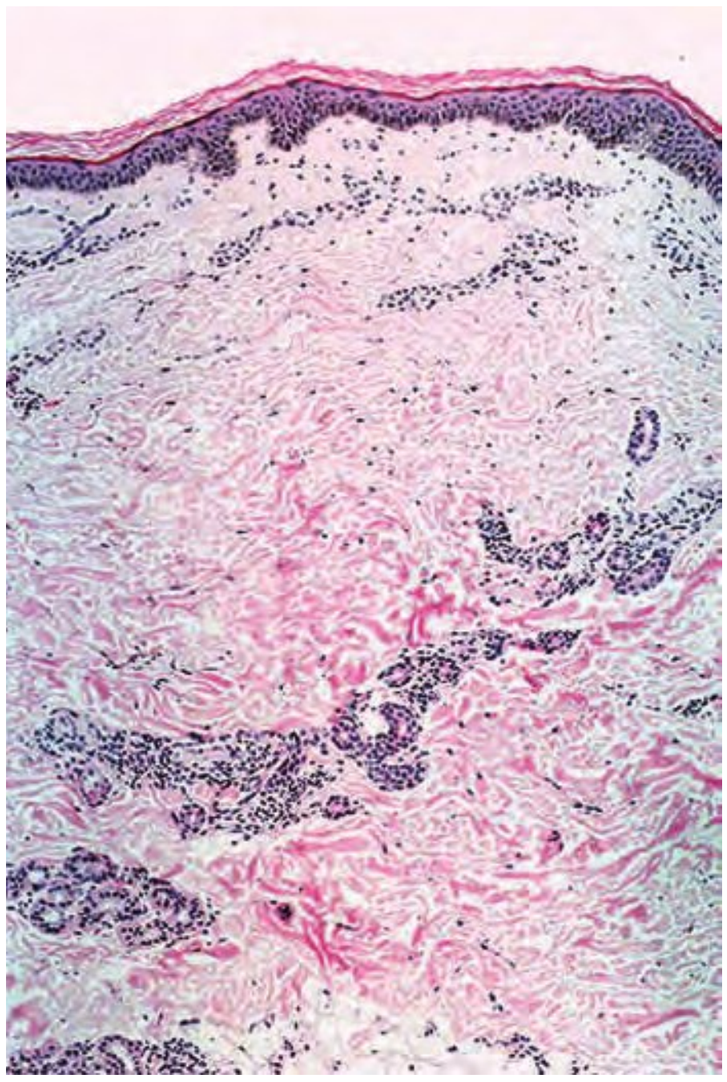

FIGURE 21-33. Indeterminate leprosy. Slight pandermal perineurovascular and periappendageal chronic inflammation (H&E stain).

The diffuse type of leprosy, called *Lucio leprosy*, which is most common in Mexico and Central America, shows diffuse infiltration of the skin without nodules. This infiltration may be quite inconspicuous except for the alopecia of the eyebrows and eyelashes it produces. Acral, symmetric anesthesia is generally present (148).

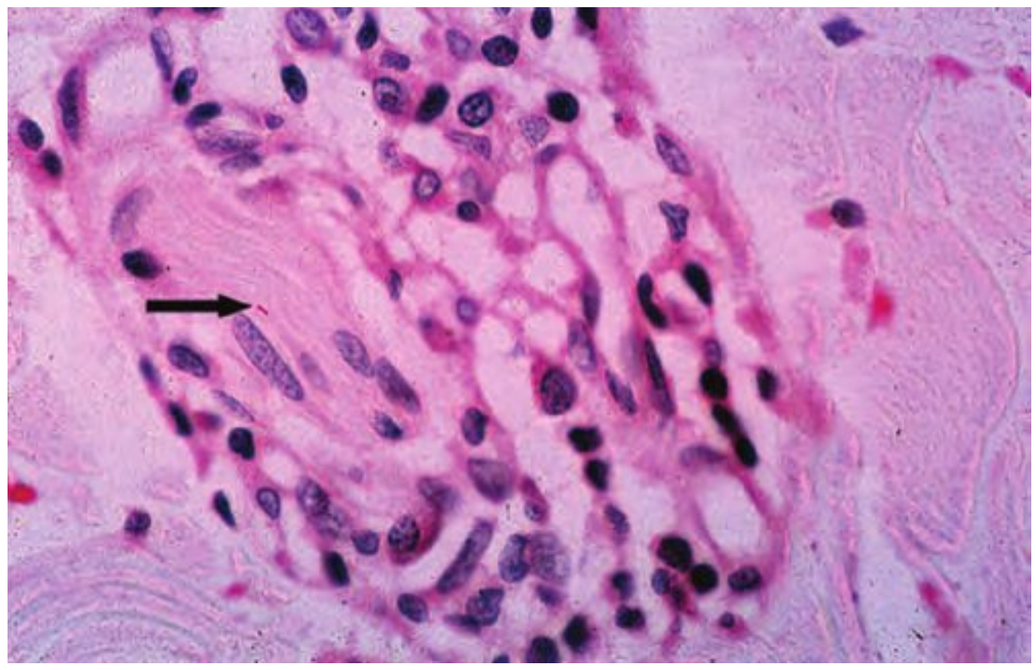

FIGURE 21-34. Indeterminate leprosy. High-power view of a small dermal nerve with surrounding lymphocytes and an intraneural acid-fast bacillus (arrow). There is no granuloma formation (Wade-Fite stain).

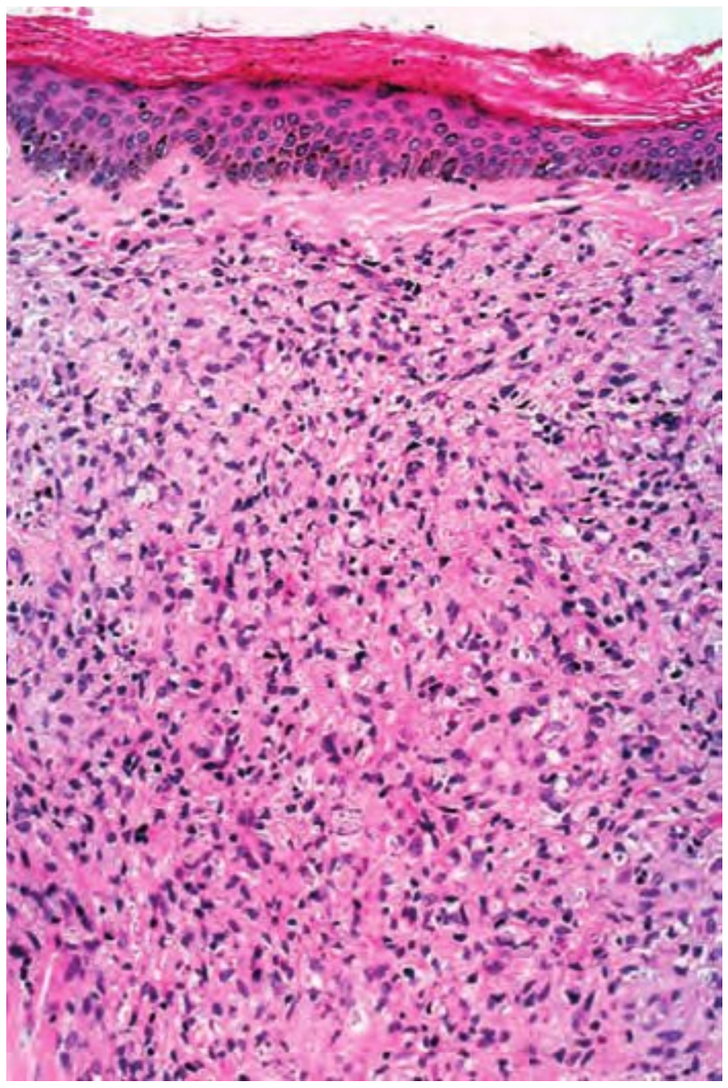

FIGURE 21-35. Lepromatous leprosy. Skin in multibacillary leprosy with a mass of macrophages in the dermis (no granuloma formation), leaving a clear grenz zone under the epidermis (H&E stain).

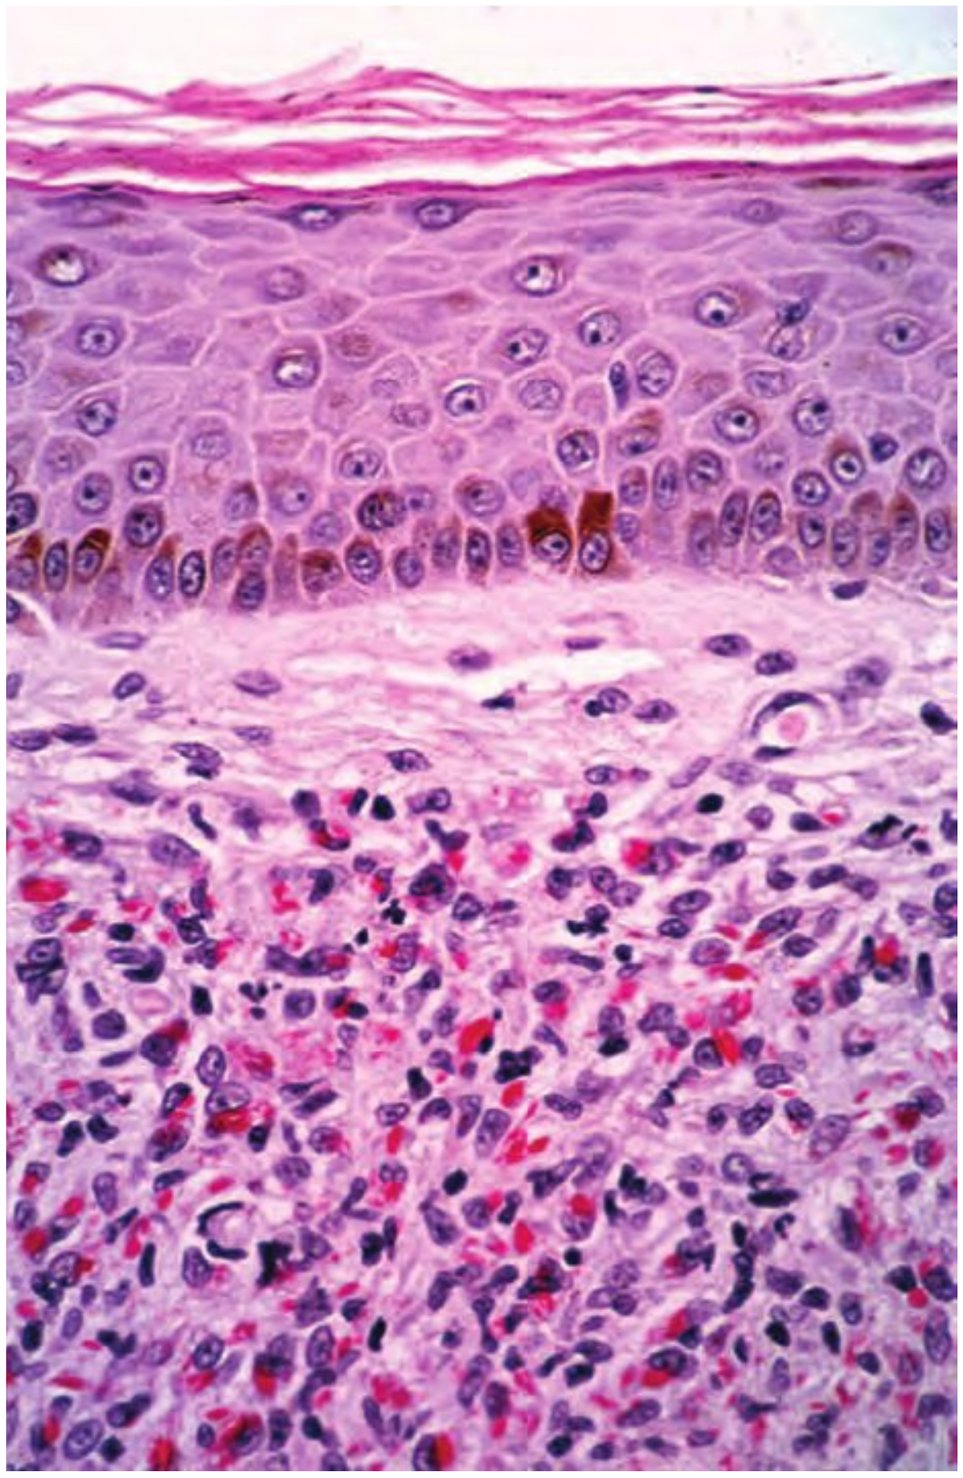

FIGURE 21-36. Lepromatous leprosy. Same case as Figure 21-35. Acid-fast bacilli, mostly solid, in large numbers (Wade-Fite stain).

A distinctive variant of lepromatous leprosy, the histoid type, first described in 1963 (149), is characterized by the occurrence of well-demarcated cutaneous and subcutaneous nodules resembling dermatofibromas. It frequently follows incomplete chemotherapy or acquired drug resistance, leading to bacterial relapse.

Rarely, lepromatous leprosy can present as a single lesion rather than as multiple lesions (150).

Histopathology. Lepromatous leprosy, in the usual macular or infiltrative-nodular lesions, exhibits an extensive cellular infiltrate that is almost invariably separated from the flattened epidermis by a narrow grenz zone of normal collagen (Figs. 21-35 and 21-36). The infiltrate causes the destruction of the cutaneous appendages and extends into the subcutaneous fat. In florid early lesions, the macrophages have abundant eosinophilic cytoplasm and contain a mixed population of solid and fragmented bacilli (BI = 4 or 5) (Figs. 21-33). The bacilli, on Wade-Fite staining, can be seen to measure about 5.0 by 0.5 μm and if solid may be packed like cigars. Bacilli are commonly observed in endothelial cells as well (Fig. 21-37). There is no macrophage activation to form epithelioid cell granulomas. Lymphocyte infiltration is not prominent, but there may be many plasma cells.

In time, and with antimycobacterial chemotherapy, degenerate bacilli accumulate in the macrophages—the so-called lepra cells or Virchow cells—which then have foamy or vacuolated cytoplasm (Fig. 21-38). They resemble xanthoma cells and, on staining with fat stains, are shown to contain lipid—largely neutral fat and phospholipids—rather than cholesterol. The Wade-Fite stain reveals that the bacilli are fragmented or granular and, especially in very chronic lesions, disposed in large basophilic clumps called *globi*. In lepromatous leprosy, in contrast to tuberculoid leprosy, the nerves in the skin may contain considerable numbers of leprosy bacilli but remain well preserved for a long time and slowly become fibrotic.

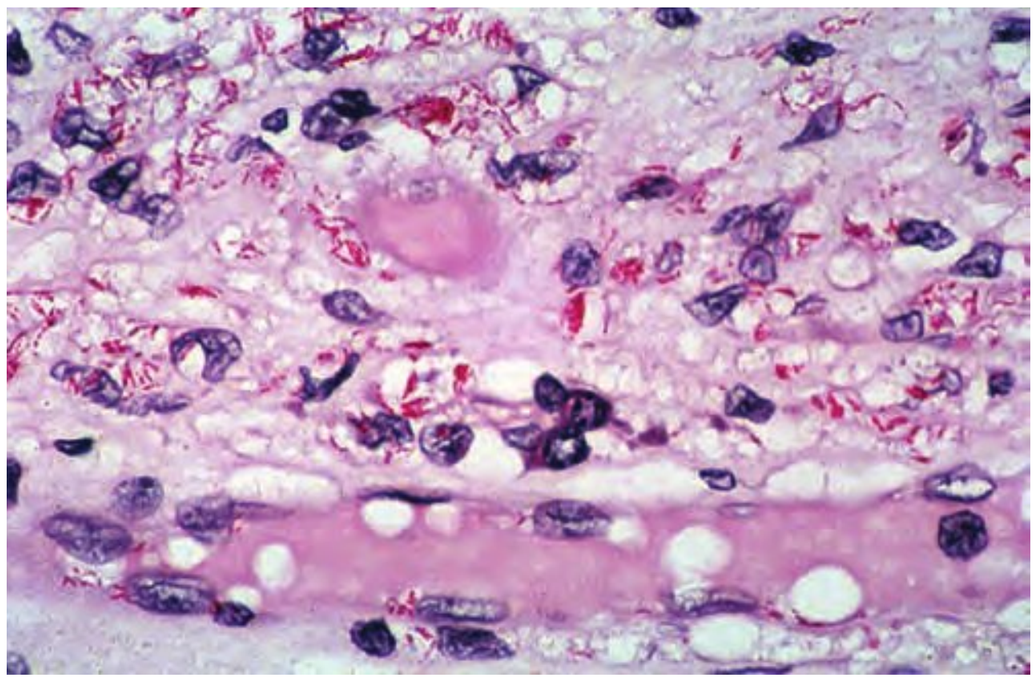

FIGURE 21-37. Lepromatous leprosy. Macrophages and endothelial cells of the capillary contain solid acid-fast bacilli (Wade-Fite stain).

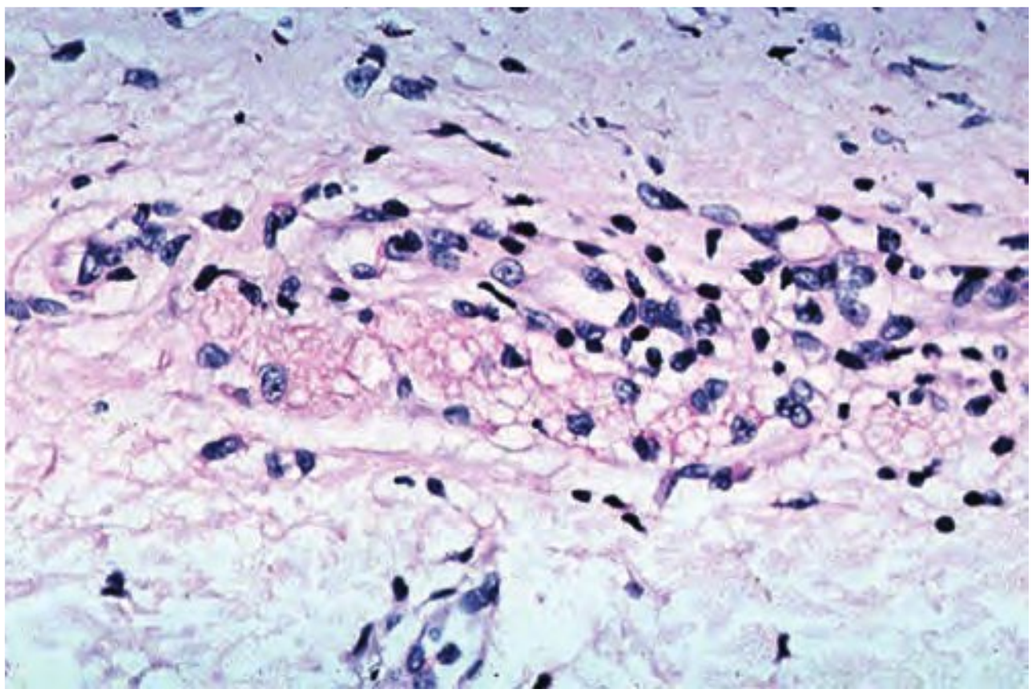

FIGURE 21-38. Lepromatous leprosy. Old, treated lesion, with large foamy macrophages and no identifiable bacilli (Wade-Fite stain).

When lepromatous leprosy is treated, the bacilli die rapidly and become fragmented within weeks or months. However, it can take several years for the bacterial debris to be cleared by host macrophages. The *M. leprae* antigen may persist even longer and can be demonstrated by immunocytochemical stains (Wade-Fite or silver) even when no bacilli are evident (Fig. 21-39).

The histopathology of Lucio (diffuse) leprosy is similar but with a characteristic heavy bacillation of the small blood vessels in the skin (148).

Histoid Leprosy

Histoid leprosy shows the highest loads of bacilli (frequently, the BI is 6), and the majority are solid staining, arranged in clumps like sheaves of wheat. The macrophage reaction is unusual in that the cells frequently become spindle shaped and oriented in a storiform pattern, similar to those of a fibrohistiocytoma (Fig. 21-40). The epidermis may be stretched over such dermal expansile nodules.

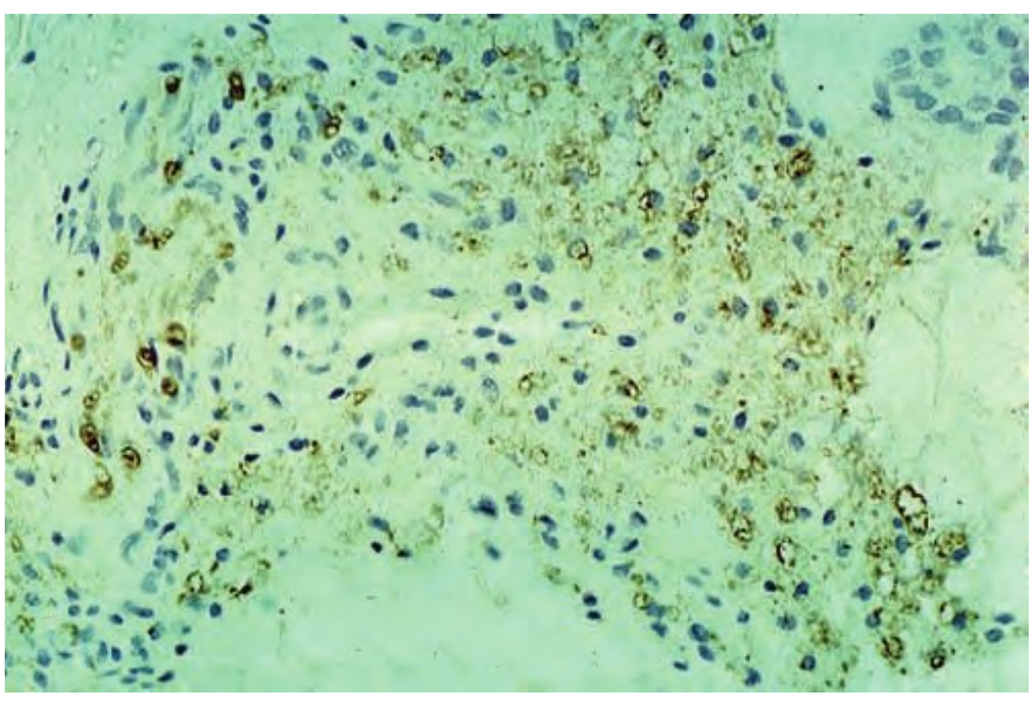

FIGURE 21-39. Lepromatous leprosy. Old, treated lesion; foamy macrophages remain but no acid-fast bacilli visible. However, an antimycobacterial immunocytochemical stain reveals persistent leprosy antigen (anti-BCG stain).

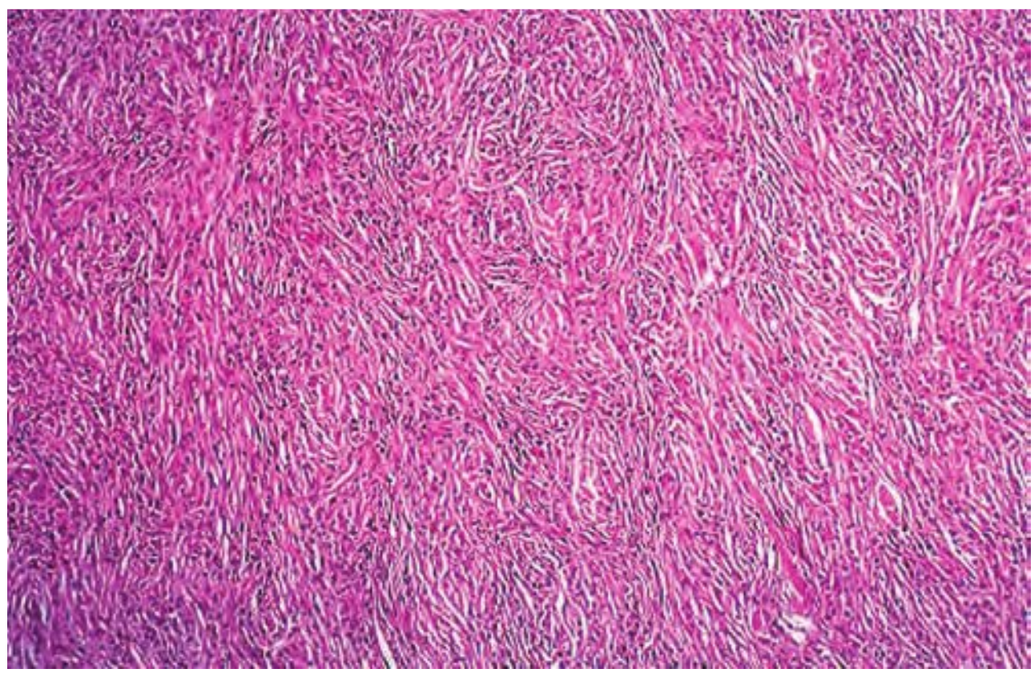

FIGURE 21-40. Lepromatous leprosy. A histoid lesion, with spindle cell proliferation of macrophages, resembling a storiform tumor. The acid-fast bacillus stain showed larger numbers of bacilli (H&E stain).

Borderline Lepromatous Leprosy

The lesions of borderline lepromatous (BL) leprosy are less numerous and less symmetrical than LL lesions and often display some central dimples.

Histopathology: The important difference between LL and BL leprosy histology is that in BL, the lymphocytes are more prominent and there is a tendency for some activation of macrophages to form poorly to moderately defined granulomas. Perineural fibroblast proliferation, forming an "onion skin" in cross-section, is typical. Foamy cells are not prominent, and globi do not usually accumulate; the BI ranges from 4 to 5.

Midborderline Leprosy

In midborderline (BB) leprosy, the skin lesions are irregularly dispersed and shaped erythematous plaques with punched-out centers. There may be small satellite lesions. Edema is prominent in the lesions.

Histopathology: In BB leprosy, the macrophages are uniformly activated to epithelioid cells but are not focalized into distinct granulomas, and lymphocytes are scanty. There are no Langhans giant cells. The BI ranges from 3 to 4. Dermal edema is prominent between the inflammatory cells.

Borderline Tuberculoid Leprosy

In borderline tuberculoid (BT) leprosy, the lesions are asymmetrical and may be scanty. They are dry, hairless plaques with central hypopigmentation. Nerve enlargement is usually found, and the lesions are usually anesthetic.

Histopathology: Granulomas with peripheral lymphocytes follow the neurovascular bundles and infiltrate sweat glands and erector pili muscles. Langhans giant cells are variable in number

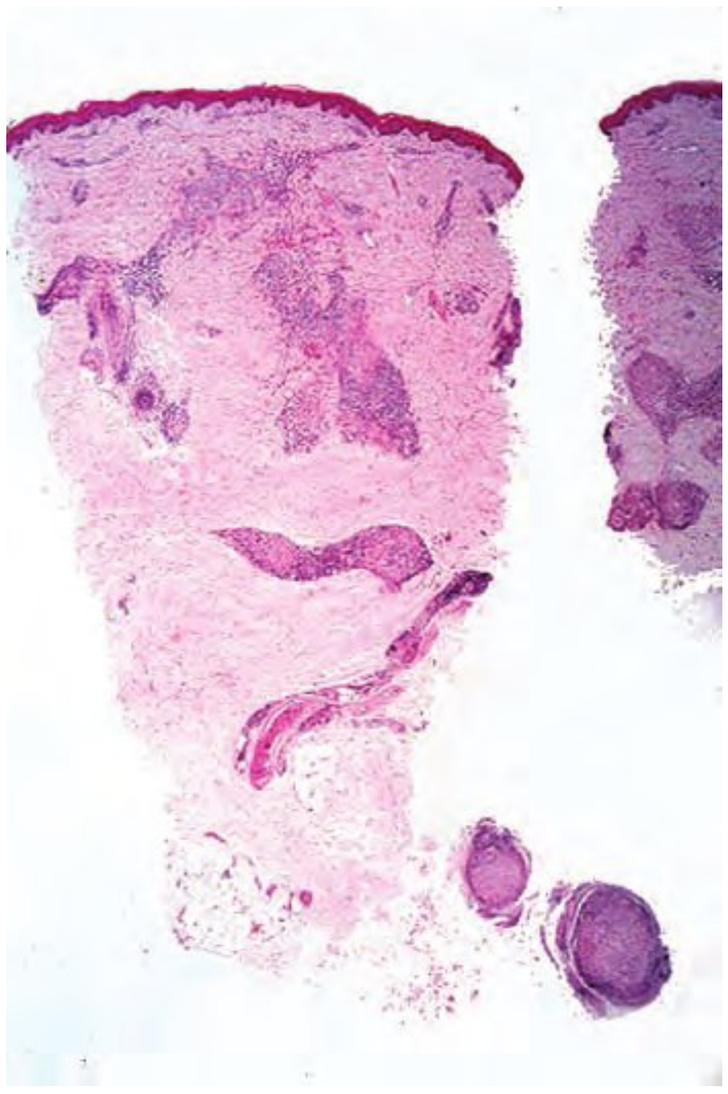

FIGURE 21-41. Tuberculoid leprosy. A typical lesion, showing pandermal perineurovascular granulomas and lymphocytes (H&E stain).

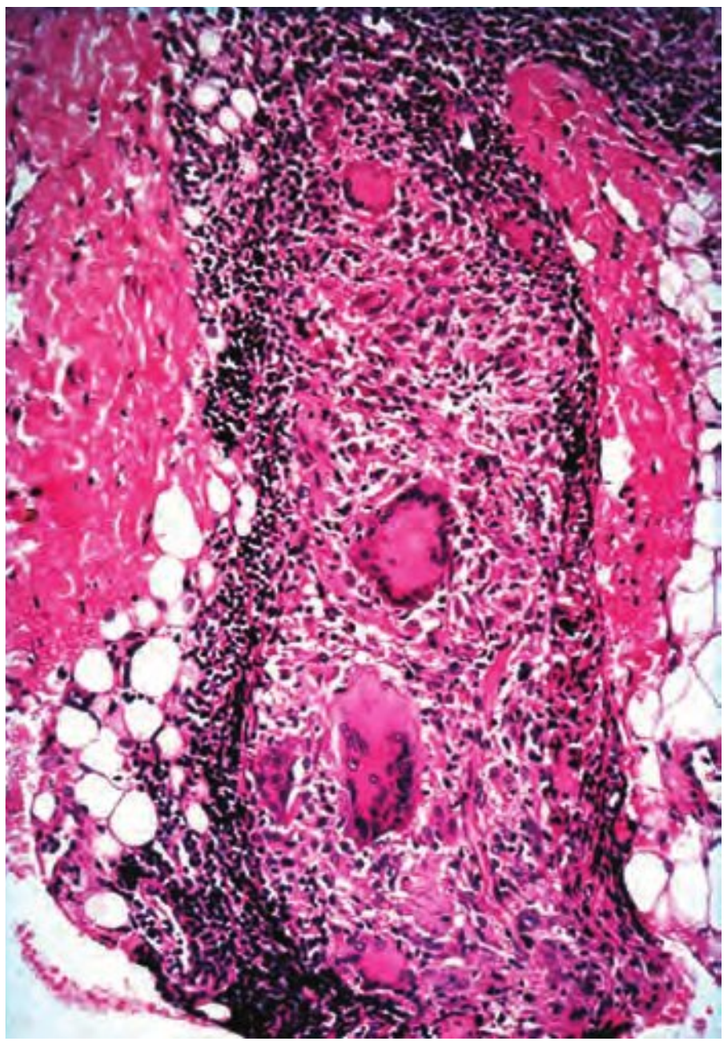

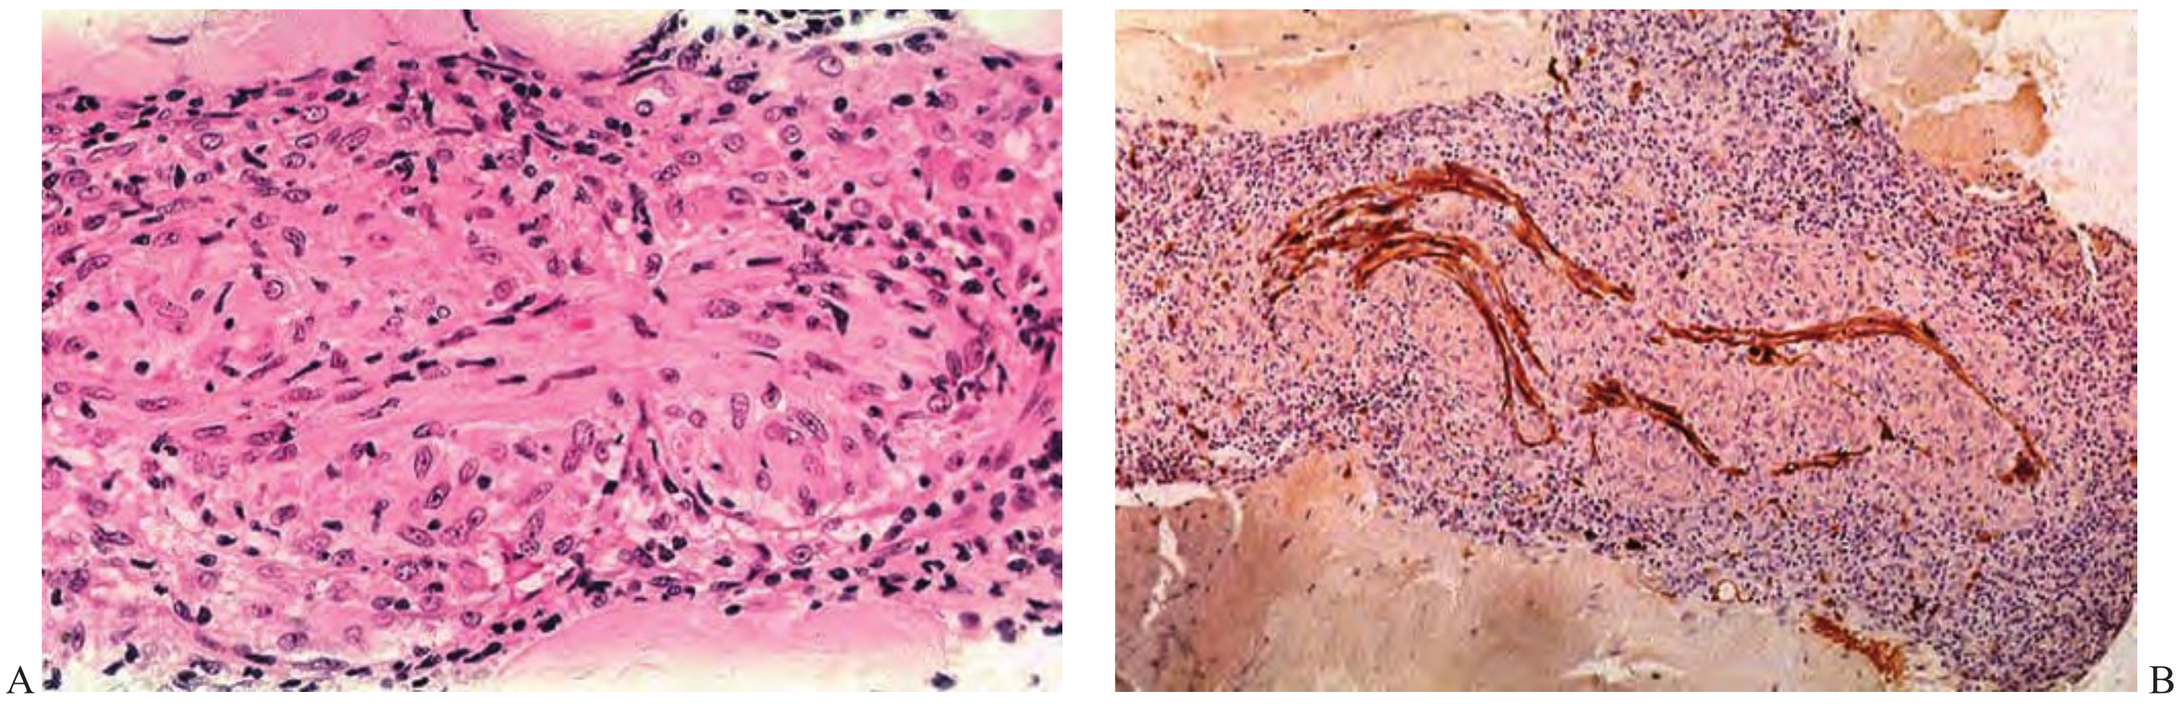

FIGURE 21-42. Tuberculoid leprosy. Granulomatous neuritis; dense lymphocytosis surrounding and eroding into the deep dermal nerve with giant cells (H&E stain).

and are not large in size. Granulomas along the superficial vascular plexus are frequent, but they do not infiltrate up into the epidermis. Nerve erosion and obliteration are typical (Figs. 21-41 to 21-43). Acid-fast bacilli are scanty (BI ranges from 0 to 2) and most readily found in the Schwann cells of nerves. Immunocytochemical staining for S-100 protein often demonstrates the perineural and intraneural granuloma well (Fig. 21-43B).

Tuberculoid Leprosy

The skin lesions of tuberculoid (TT) leprosy are scanty, dry, erythematous, hypopigmented papules or plaques with sharply defined edges. Anaesthesia is prominent (except on the face). The number of lesions ranges from one to five. Thickened local peripheral nerves may be found. The lesions heal rapidly on chemotherapy.

Histopathology. Primary TT leprosy has large epithelioid cells arranged in compact granulomas along with neurovascular bundles, with dense peripheral lymphocyte accumulation. Langhans giant cells are typically absent. Dermal nerves may be absent (obliterated) or surrounded and eroded by dense lymphocyte cuffs. Acid-fast bacilli are rarely found, even in nerves. A second pattern of TT leprosy is found in certain reactional states (see next page).

A B

FIGURE 21-44. Leprosy reversal reaction. A: Pretreatment BL leprosy. B: Three months posttreatment, with enlargement of the skin lesions due to increased inflammation.

Peripheral Nerves

In all of these patterns of leprosy, the major peripheral nerves are often undergoing parallel pathologies. The inflammation is similar, and the same classification system is applied. However, the density of acid-fast bacilli is often a logrithm higher than in the nearby skin (151).

Leprosy Reactions

Leprosy reactions are classified into two main types (1 and 2). A third reaction is specific to Lucio multibacillary leprosy (152).

Type 1 Reactions

Because the immunopathologic spectrum of leprosy is a continuum, patients may move along it in both directions. Should such shifts be rapid, they induce an inflammatory reaction with edema that results in enlargement of lesions with more erythema (Fig. 21-44). Shifts toward the tuberculoid pole are called *upgrading* or *reversal reactions*; shifts toward the lepromatous pole are termed *downgrading reactions*. Both are aspects of delayed hypersensitivity, or type 1, leprosy reactions. TT patients are stable. BT patients may downgrade without treatment. Multibacillary patients, particularly those at the BL point, frequently upgrade on chemotherapy, and about one quarter of them will exhibit significant reactions. BB patients are most unstable and will move either way depending on therapy, often with reactions. The most important aspect of type 1 reactions is not the skin but the condition of the peripheral nerves, in which a similar inflammatory process is going on; reaction induces increased intraneural inflammation and edema, which is damaging. At worst, there is caseous necrosis of large peripheral nerves resulting from upgrading reactions.

Histopathology: The histopathology of type 1 reactions has still not been well evaluated (153). The distinction between upgrading and downgrading reactions is difficult to make and may require serial examinations. Typically, there is edema within and about the granulomas and proliferation of fibrocytes in the dermis. In upgrading reactions, the granuloma becomes more epithelioid and activated, and Langhans giant cells are larger (Fig. 21-45); there may be erosion of granulomas into the lower epidermis, and there may be fibrinoid necrosis within granulomas and even within dermal nerves. In downgrading reactions, necrosis is much less common, and over time the density of bacilli increases. Multibacillary leprosy patients who upgrade on therapy show old foamy macrophages and degenerate bacilli admixed with new epithelioid cell granulomas.

Type 2 Reaction: Erythema Nodosum Leprosum

Erythema nodosum leprosum (ENL) occurs most commonly in LL leprosy and less frequently in BL leprosy. It may be observed not only in patients under treatment but also in untreated patients. Clinically, the reaction has a greater resemblance to erythema multiforme than to erythema nodosum.

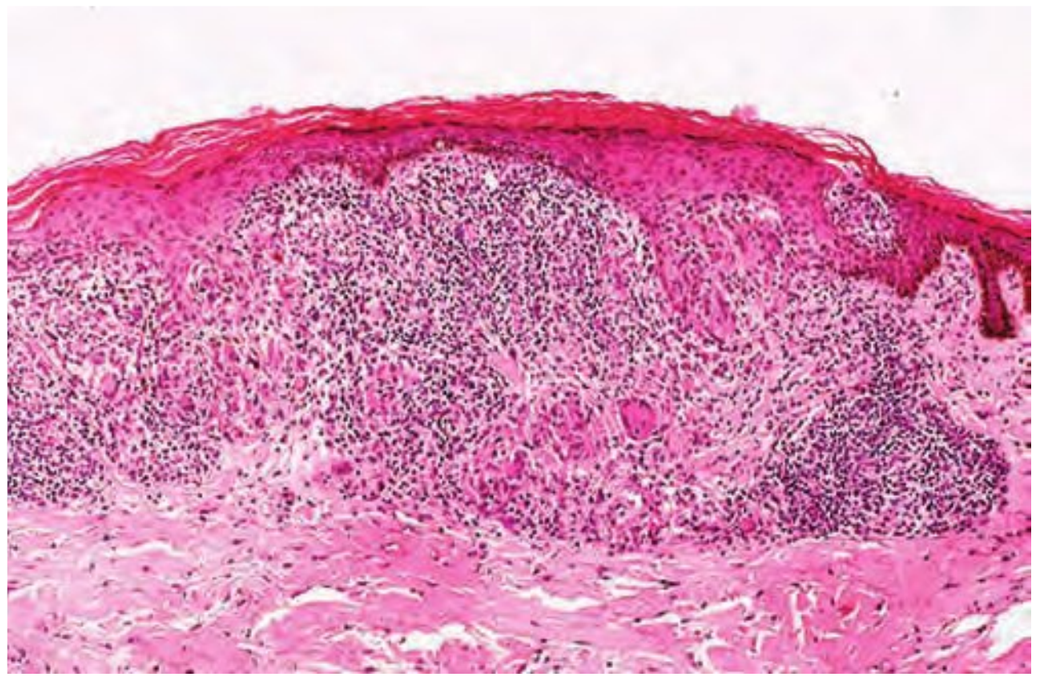

FIGURE 21-45. Leprosy: type 1 reaction (delayed hypersensitivity). Granulomatous erosion of the epidermis; this feature is not usually encountered in nonreacting leprosy (H&E stain).

On the skin, tender, red plaques and nodules together with areas of erythema, and occasionally also purpura and vesicles, are observed. Ulceration, however, is rare. The eruption is widespread and accompanied by fever, malaise, arthralgia, and leukocytosis. New lesions appear for only a few days in some cases but for weeks and even years in others. This is the only type of reactional leprosy that responds to treatment with thalidomide.

Histopathology. In ENL, the lesions are foci of acute inflammation superimposed on chronic multibacillary leprosy (Fig. 21-46). Polymorph neutrophils may be scanty or so abundant as to form a dermal abscess with ulceration (154). Whereas foamy macrophages containing fragmented bacilli are usual, in some patients no bacilli remain and macrophages have a granular pink hue on Wade-Fite staining, indicating mycobacterial debris. An antimycobacterial immunocytochemical stain (e.g., anti-BCG) will indicate abundant antigen. A necrotizing vasculitis affecting arterioles, venules, and capillaries occurs in some cases of ENL; these patients may have superficial ulceration.

Lucio Reaction

The Lucio reaction occurs exclusively in diffuse lepromatous leprosy, in which it is a fairly common complication. It usually occurs in patients who have received either no treatment or inadequate treatment. In contrast to ENL, fever, tenderness, and leukocytosis are absent. The lesions consist of barely palpable, hemorrhagic, sharply marginated, irregular plaques. They develop into crusted lesions and, particularly on the legs, into ulcers. There may be repeated attacks or continuous appearance of new lesions for years.

Histopathology. In the Lucio reaction, vascular changes are critical (143). Endothelial proliferation leading to luminal obliteration is observed in association with thrombosis in the medium-sized vessels of the dermis and subcutis. There is a sparse, largely mononuclear infiltrate. Dense aggregates of acid-fast bacilli are found in the walls and the endothelium of normal-appearing vessels as well as in vessels with proliferative changes (Fig. 21-47). Ischemic necrosis, brought on by the vascular occlusion, leads to hemorrhagic infarcts and results in crusted erosions or frank ulcers.

Electron Microscopy of Leprosy

Under electron microscopy, *M. leprae* can be seen to consist of an electron-dense cytoplasm lined by a trilaminal plasma membrane. Outside of this membrane lies the bacterial cell wall surrounded by a radiolucent area, the waxy coating typical of mycobacteria (81). Lepra bacilli are found in the skin, predominantly in macrophages and in Schwann cells.

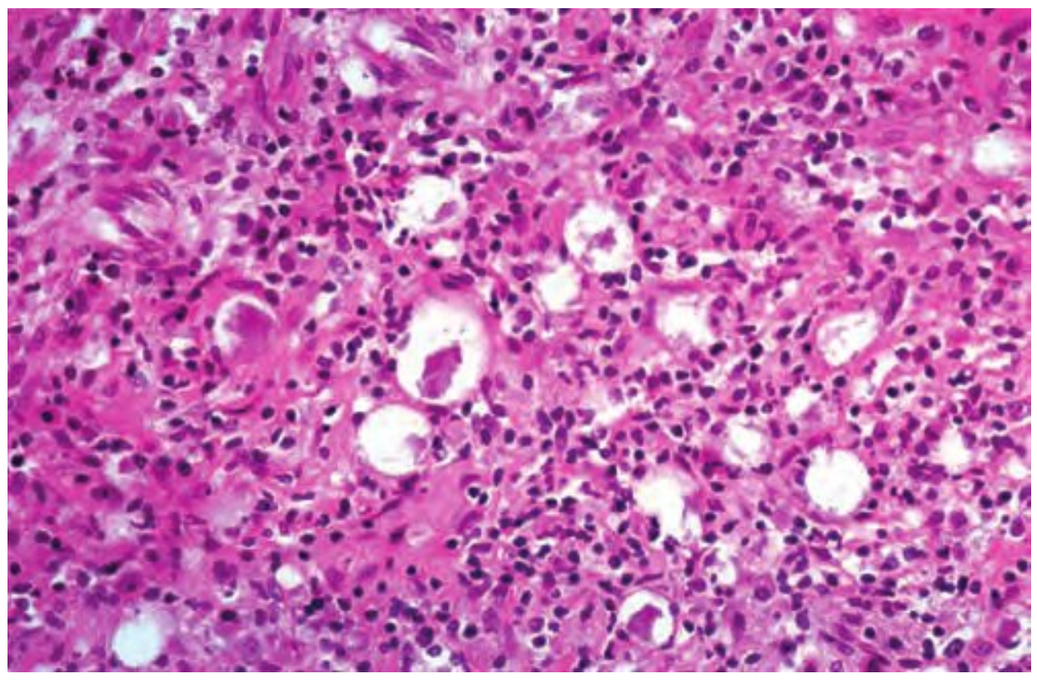

FIGURE 21-46. Leprosy: erythema nodosum leprosum (type 2 reaction). Macrophages with vacuoles and globi and a polymorphonuclear cell infiltrate (H&E stain).

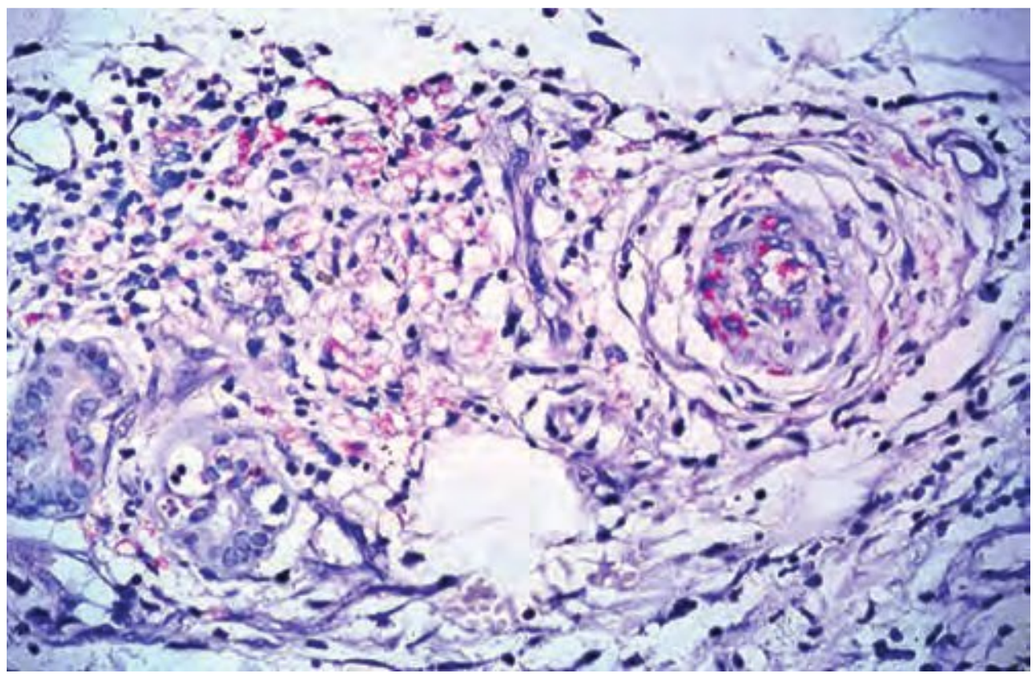

FIGURE 21-47. Leprosy, Lucio reaction. Dermal vessels showing endarteritis obliterans and abundant bacilli within endothelial cells (Wade-Fite stain).

Pathogenesis of Leprosy

With respect to immunologic reactivity, patients with lepromatous leprosy have a defect in cell-mediated immune responses to the lepra bacilli, which therefore cannot be eradicated from the body spontaneously (141,155,156). The primary defect lies in the T lymphocytes, which can be stimulated only slightly or not at all to react against the lepra bacilli and thus do not adequately activate macrophages to destroy phagocytosed bacilli. This defect is specific for *M. leprae*, because patients with lepromatous leprosy show normal immunologic responses to antigens other than lepromin in both *in vivo* and *in vitro* testing.

The specific inability of T lymphocytes obtained from patients with lepromatous leprosy to react against lepromin is shown by the fact that when these lymphocytes are incubated with lepromin, they show little or no production of macrophage migration-inhibiting factor (MIF). In contrast, the lymphocytes of patients with tuberculoid leprosy produce significant amounts of MIF on exposure to lepromin. One modern view is that in tuberculoid patients, exposure to leprosy antigens results in a predominant T helper 1 (Th-1) cytokine secretion profile, which results in macrophage activation. Conversely, in lepromatous patients, the cytokine profile (Th-2) inhibits cell-mediated immunity and promotes humoral immunity, which does not contribute to host defense (155,157). In reversal reactions, there is an increase in the lymphocyte response to lepromin during the reaction and a decrease during the postreaction phase.

Analysis of T-cell subsets in lesions has shown that in tuberculoid leprosy, with its high degree of resistance to the leprosy bacilli, the T helper lymphocytes are distributed evenly throughout the epithelioid cell aggregates, and the suppressor T lymphocytes are restricted to the peripheries of the granulomas. In lepromatous leprosy, both helper and suppressor T lymphocytes are distributed diffusely throughout the lesions (158). It is noteworthy that the distribution of helper and suppressor T cells in tuberculoid leprosy is similar to that observed in sarcoidosis.

In patients with either ENL or the Lucio reaction, deposits of IgG and the third component of complement (C3), as well as circulating immune complexes, have been found in the vessel walls of the dermal lesions. This suggests that both reactions are mediated by immune complexes (Gell and Coombes type III reaction) (146).

The lepromin skin test, or Mitsuda test, consists of the intradermal injection of a preparation of *M. leprae* derived from autoclaved infected human tissue. A positive reaction consists of the formation of a nodule measuring $\geq$5 mm in diameter after 2 to 4 weeks. On histologic examination, the nodule shows an epithelioid cell granuloma. The reaction is positive only in the high-resistance (tuberculoid and borderline tuberculoid) forms of the disease. In indeterminate leprosy, it may be positive or negative. The test reveals the inability of patients at the lepromatous end of the spectrum to react to the injection of *M. leprae* with an epithelioid cell granuloma, and its main value is therefore as a marker of specific cell-mediated immunity to this organism, which varies continuously along the immunopathologic spectrum.

HIV Infection and Leprosy

Because HIV induces a generalized immunosuppressive state, and because a wide range of intracellular infectious agents normally controlled by the T-cell/macrophage system may proliferate to cause significant disease, it was expected that leprosy might also be affected. Specifically, the disease might become more prevalent in HIV and leprosy coendemic areas, and individual patients might downgrade toward lepromatous disease as their HIV disease progresses. However, epidemiologic studies have shown no effect of HIV infection on the incidence of leprosy in properly controlled studies (159,160) nor has a change in the proportions of tuberculoid versus lepromatous patients been noted (161). At present, the only clinicopathologic difference between HIV-infected and noninfected leprosy patients that is suggested is an increased likelihood of HIV-positive patients undergoing type 1 upgrading reactions (161,162). This rather paradoxical phenomenon awaits further evaluation.

Histopathologic Differential Diagnosis

The leprosy bacillus cannot yet be grown *in vitro*. Tuberculoid (granulomatous) leprosy needs to be distinguished from the many other granulomatous dermatitides. The presence of acid-fast bacilli in nerves is conclusive proof of leprosy, as is the demonstration of an intraneural granuloma. The S-100 stain may highlight this phenomenon (163), although in practice, if the diagnosis is in doubt after investigation with ordinary stains, this immunocytochemical method is not usually diagnostic either. In leprosy, naked granulomas are found only in BB leprosy, and acid-fast bacilli will be found in the lesions. Sarcoidosis may rarely cause granulomas to form within peripheral nerves (164) but does not appear to do so in dermal nerves. The general vertical perineurovascular distribution of granulomatous inflammation and involvement of sweat glands in tuberculoid leprosy are helpful. The presence or absence of plasma cells or of intraepidermal lymphocytes is not helpful. Unlike other mycobacterial skin infections such as tuberculosis, and unlike granulomatous leishmaniasis, the epidermis in tuberculoid leprosy is usually flat and nonhyperplastic. Late secondary and tertiary cutaneous syphilis is characterized by epithelioid and giant cell granulomas in the dermis, not directly involving nerves, and the epithelium is usually hyperplastic. Intragranuloma necrosis (fibrinoid or caseating) occurs in leprosy in type 1 reactions, sometimes spontaneously; this can be confused with necrobiotic lesions such as granuloma annulare. Necrosis within a nerve that is granulomatous is diagnostic of leprosy.

Early, indeterminate leprosy overlaps with many specific and nonspecific dermatitides manifesting perineurovascular lymphocytic infiltrates. Finding bacilli in critical sites (in nerve, under the epidermis, in erector pili muscle, or in macrophages) is critical. In the absence of bacilli and the presence of a pandermal infiltrate, leprosy can only be suspected. Problems may arise from contaminant mycobacteria in staining solutions and in the water baths used for floating out sections. Such organisms are usually above the plane of the section, overlap the cell nuclei, and usually stain darker than *M. leprae*. The use of PCR for identifying paucibacillary leprosy in skin sections and tissues has not been as successful as it once was thought to be (165).

Ultimately, there is a proportion of suspect paucibacillary leprosy lesions for which the histopathologist cannot make a firm diagnosis either way, and intra- and interobserver variation may be considerable (166). Clinical diagnosis of single-lesion leprosy is also imperfect (150).

Lepromatous leprosy infiltrates can resemble xanthoma, although the cytoplasmic granularity is coarser in the latter disease. The presence of acid-fast bacilli is obviously important, and in long-treated lesions that may cause confusion, antimycobacterial immunocytochemistry is helpful. ENL may be overlooked because it is a combined chronic and acute inflammatory infiltrate, but once thought of, the presence of bacilli or antigen is diagnostic. Certain other mycobacterioses in immunosuppressed patients, such as *M. avium-intracellulare*, may produce histoid-like multibacillary lesions (119) (see Figs. 21-23 and 21-40); however, nerves are not involved in this infection.

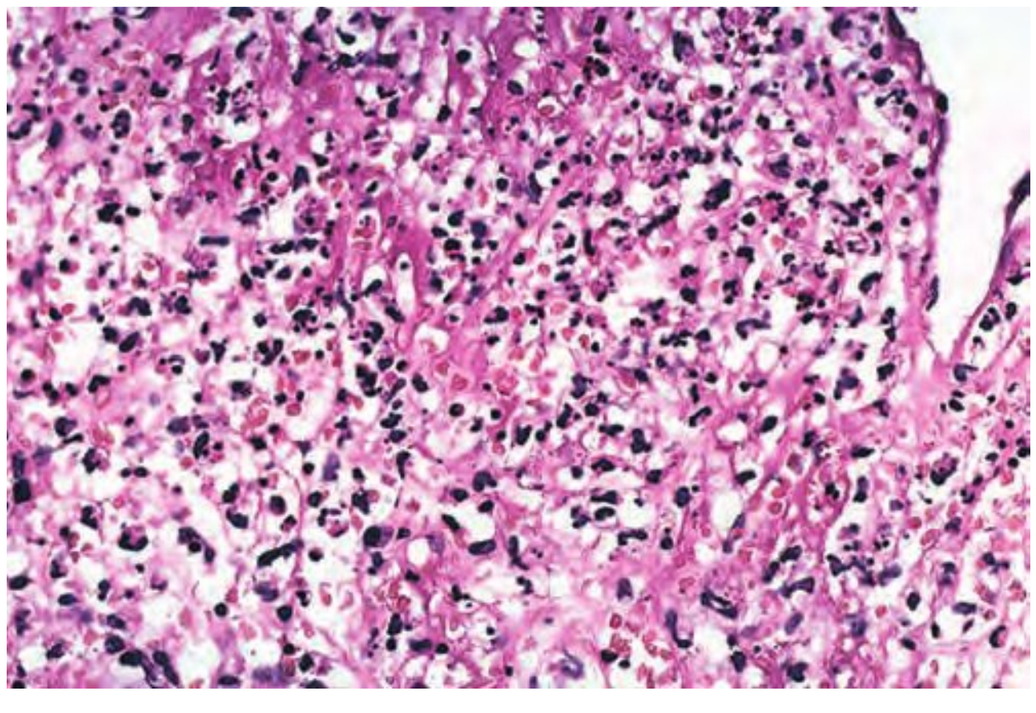

FIGURE 21-49. Anthrax. Acute inflammation and dermal edema (H&E stain).

ANTHRAX

Anthrax, caused by *Bacillus anthracis,* is enzootic in many countries (167). It occurs occasionally among workers in tanneries and wool-scouring mills through the handling of infected hides, wool, or hair imported from Asia. The lesion starts as a papule. The papule enlarges, and a hemorrhagic pustule forms (168). After the pustule has ruptured, a thick, black eschar covers the area. Marked erythema and edema surround the lesion. Characteristically, pain is slight or absent.

Histopathology. At the site of the eschar, the epidermis is destroyed and the ulcerated surface is covered with necrotic tissue. There is marked edema of the dermis. Vasculitis, hemorrhage, and variable acute and chronic inflammatory infiltrate are observed (Figs. 21-48 and 21-49).

Anthrax bacilli are present in large numbers and can be recognized in sections stained with the Gram stain. The bacillus is large, rod shaped, encapsulated, gram positive, 6 to 10 μm long, and 1 to 2 μm thick. Anthrax bacilli are found particularly in the necrotic tissue toward the surface of the ulcer but also in the dermis (Fig. 21-50). Phagocytosis of the bacilli by either neutrophils or histiocytes is absent.

INJECTION ABSCESSES

The pandemic of injection drug abuse has resulted in numerous patients presenting with dermal and subcutaneous abscesses from the use of contaminated syringes and needles. Similar abscesses have also been frequently noted in health care settings, where injection solutions may also be contaminated (169). Numerous bacterial and mycobacterial species may be found on culture, including staphylococci and streptococci. A recent epidemic in the United Kingdon involved *Clostridium perfringens* and *Clostridium novyi* infections (170). These infections may progress to necrotizing fasciitis, myosites, bacteraemia, and septic shock with fatalities.

A standard panel of Gram, silver stain (e.g., Grocott), and Ziehl-Neelsen is useful in identifying the organisms, although culture is required for specific diagnosis (Fig. 21-51). The histopathology is not usually specific. Acute inflammation, edema, and tissue necrosis are usual. In chronic lesions, much

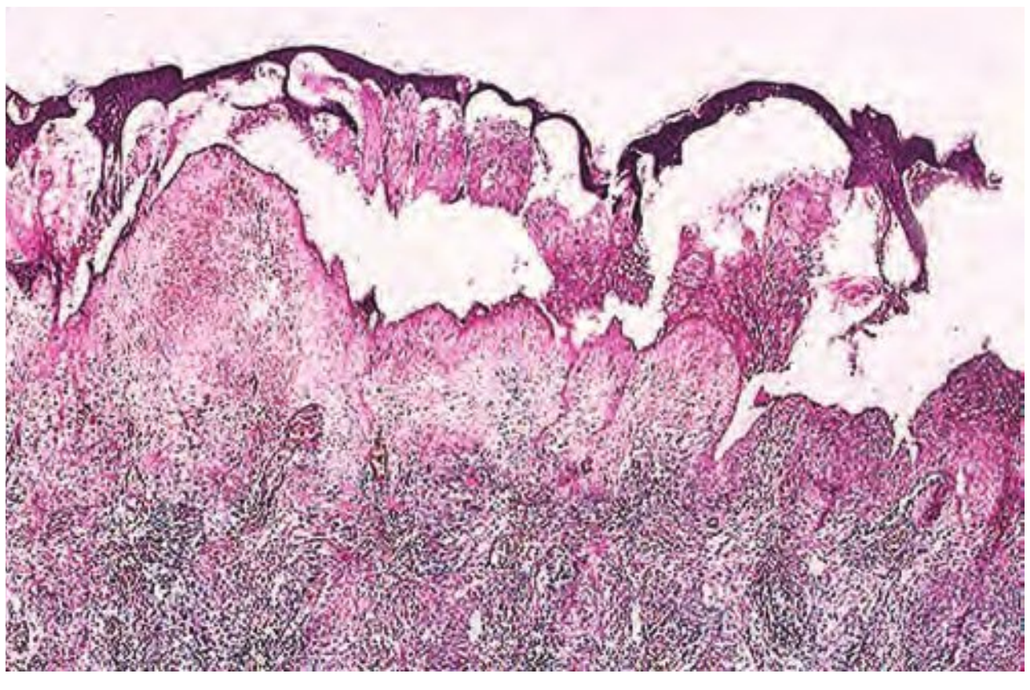

FIGURE 21-48. Anthrax. Acute lesion with epidermal necrosis and pandermal inflammation (H&E stain).

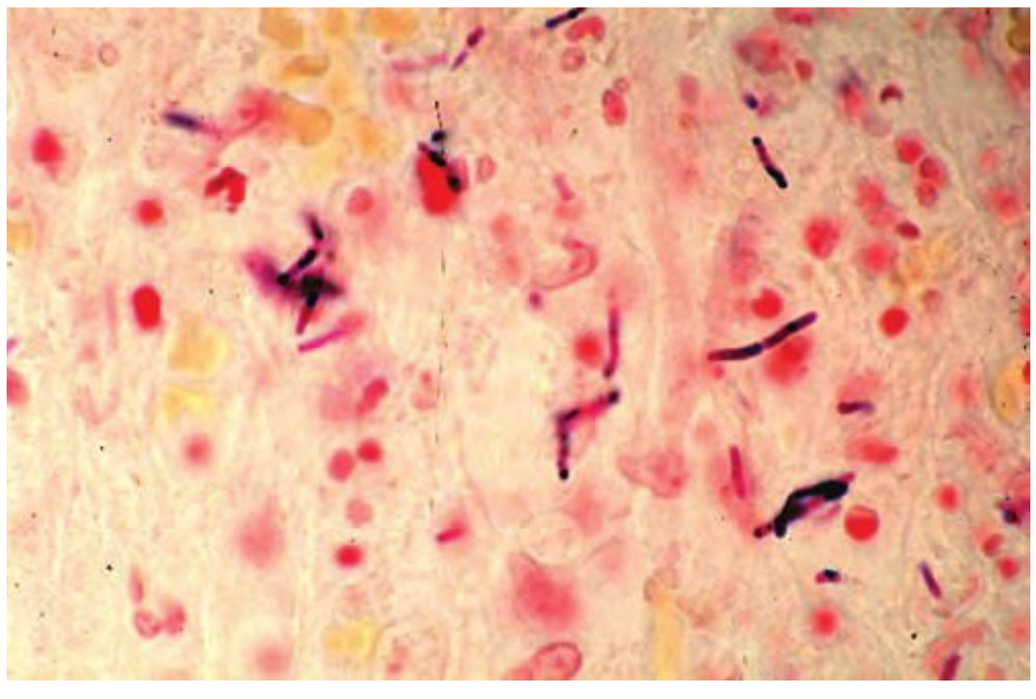

FIGURE 21-50. Anthrax. Numerous gram-positive thick bacilli within the acute inflammation (Gram stain).

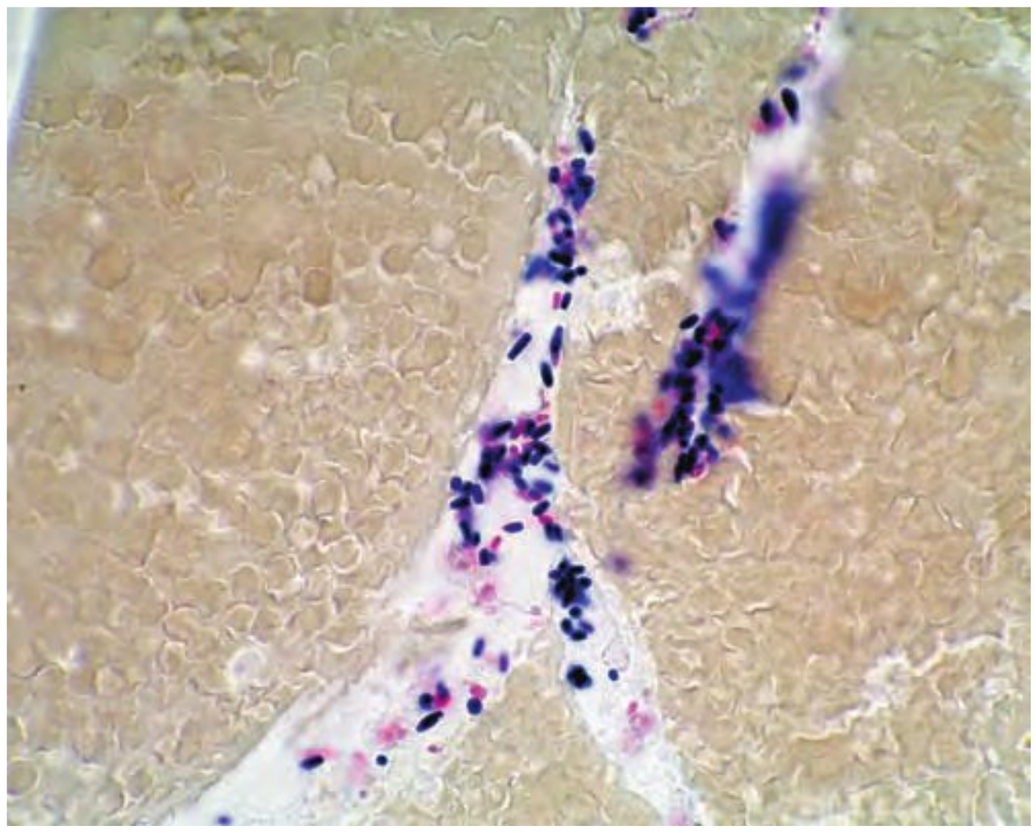

FIGURE 21-51. Clostridium perfringens injection abscess. Cluster of wide gram-positive rods, typical of Clostridium sp. (Gram stain).

granulation tissue, fibrosis, and sinuses develop. In mycobacterial injection lesions, there may also be granulomas.

TULAREMIA

Tularemia is caused by *Francisella tularensis*, a small, gram-negative, pleomorphic coccobacillus. It is usually acquired by humans through direct contact with rodents, but it may be transmitted from rodents to humans by insects, such as mosquitoes, ticks, or deer flies (171). The disease often occurs in small epidemics. There are two types: ulceroglandular (the more common type) and typhoidal. These types reflect differences in host response. In ulceroglandular tularemia, there is a vigorous inflammatory reaction, pneumonia is less common, and the patient's prognosis is good. In the typhoidal form, there are few localizing signs, pneumonia is more common, and the mortality without therapy is much higher.

In the ulceroglandular type, one or several painful ulcers occur as primary lesions at the site of infection, usually on the hands. Tender subcutaneous nodes may form along the lymph vessels that drain the primary lesion or lesions. There is considerable swelling of the regional lymph nodes, and the infection is associated with marked constitutional symptoms. Healing of the lesions takes place in 2 to 5 weeks (172,173).

Histopathology. At its base, the primary ulcer shows a nonspecific inflammatory infiltrate associated with a granulomatous reaction. In some cases, only a moderate number of epithelioid cells and a few giant cells are observed (169). In others, however, large, well-developed tuberculoid granulomas are apparent. These granulomas may show central necrosis with the presence of nuclear dust. Late lesions may show epithelioid cell tubercles that have no central necrosis and are surrounded by only a slightly inflammatory reaction, and they may thus have an appearance resembling that of sarcoidosis (174).

The tender nodes that may be found along lymph vessels show multiple granulomas deep in the dermis and extending into the subcutaneous tissue. The central zones of necrosis in the granulomas may attain a much greater size than in the primary ulcer. Similarly, the regional lymph nodes show multiple granulomas with centrally located abscess necrosis or caseous necrosis (172,175).

RICKETTSIAL INFECTIONS

Rickettsial infections are acquired by tick bites, the natural reservoir being infected animals. Rocky Mountain spotted fever is caused by *Rickettsia rickettsii*, a small, pleomorphic coccobacillus that is an obligate intracellular parasite. Contrary to its name, the disease is encountered most commonly in the southeastern United States and has been acquired even within New York City (176,177). Boutonneuse fever (Mediterranean spotted fever) is caused by *Rickettsia conorii* and is widespread in Africa as well.

In *R. rickettsii* infection, after an incubation period of 1 to 2 weeks, chills and fever develop, and a few days later, a rash appears that begins on the extremities and spreads to the trunk. The lesions at first are macular to papular but become purpuric within 2 to 3 days. There may be only petechiae, but in fatal cases widespread ecchymoses are common. Gangrene may result from small vessel occlusion (178). Because the diagnosis may not be made in the beginning and the course may be rapid, mortality exceeds 10%, despite the effectiveness of antibiotics such as tetracycline and chloramphenicol if given in time. Whenever a diagnosis of Rocky Mountain spotted fever is suspected, a search should be made for an eschar indicating the site of a tick bite. A hemorrhagic crust 8 to 10 mm in diameter surrounded by an erythematous ring may be found. In some severe systemic cases, there are no obvious skin lesions (179,180).

In boutonneuse fever, characteristic "tache noire" eschars develop. The histopathology is similar in both infections (181).

Histopathology. In the advanced lesion, there is dermal and epidermal necrosis. The small vessels of the dermis and of the subcutaneous fat exhibit a necrotizing vasculitis with a perivascular infiltrate consisting mostly of lymphocytes and macrophages (Figs. 21-52

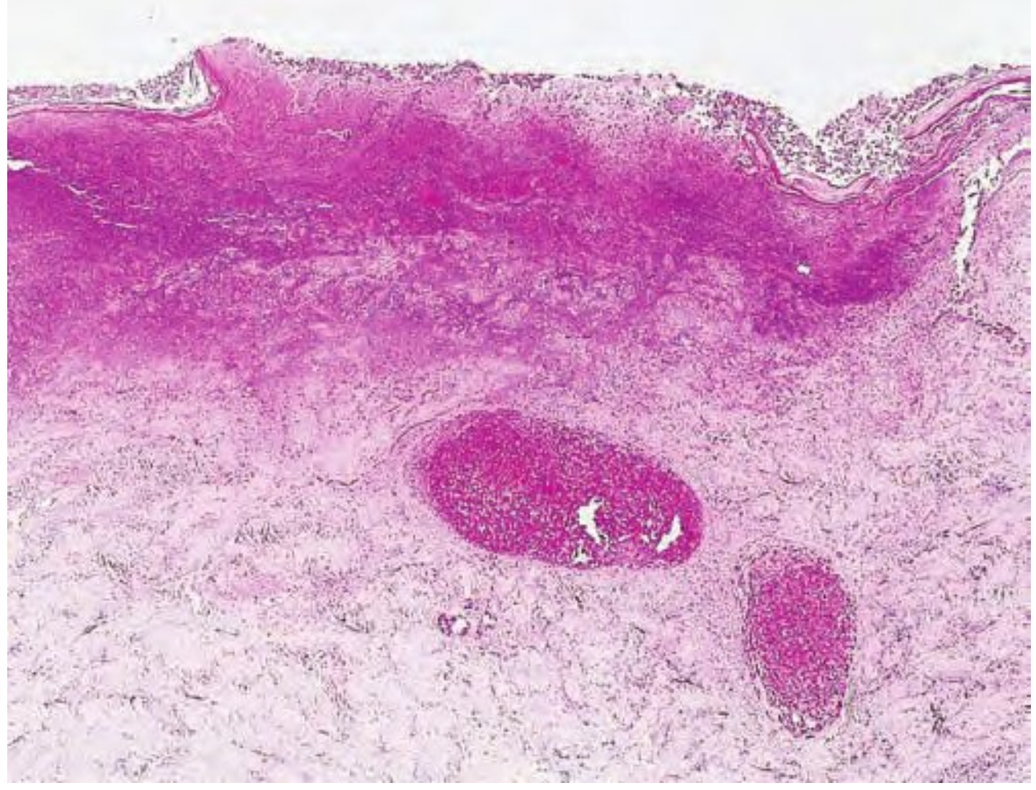

FIGURE 21-52. Rickettsia conorii infection. Typical eschar necrosis of superficial dermis and epithelium (H&E stain).

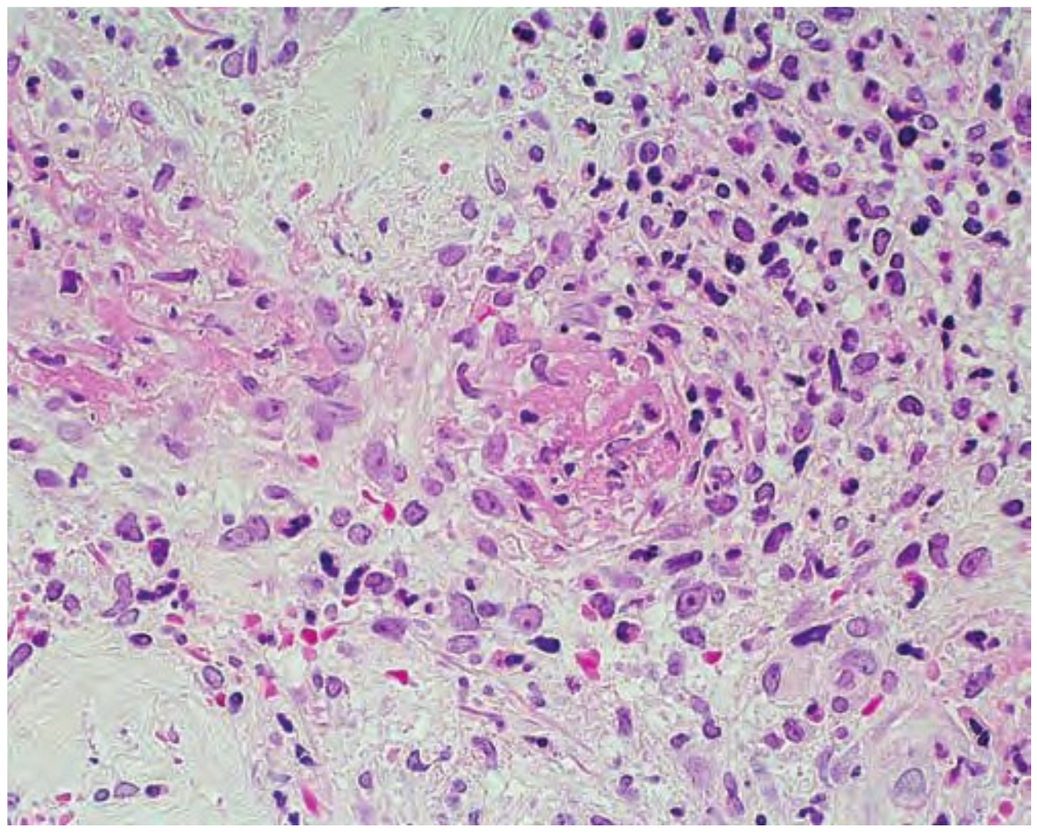

FIGURE 21-53. Rickettsia conorii infection. Dermal arteriole with arteritis and fibrin thrombosis (H&E stain).

and 21-53). There is extravasation of erythrocytes. As a result of injury to the endothelial cells, luminal thrombosis and microinfarcts occur. The causative organism, which measures 0.3 by 1.0 μm, is too small to be visible by light microscopy using ordinary stains. However, rickettsial antigen can be identified in sections of skin lesions by immunocytochemistry (180), and PCR on skin samples is specific. Coccal and bacillary forms are observed in endothelial cells in association with perivascular lymphocytic infiltration. Electron microscopic examination of the tick bite site demonstrates rickettsial organisms within the cytoplasm and the nuclei of endothelial cells. These organisms appear as electron-dense, round or oval structures surrounded by an electron-lucent halo. The entire organism is bounded by a limiting cell wall. The organisms range in size from 0.3 to 0.5 μm in greatest diameter.

CHANCROID

Chancroid, caused by *Haemophilus ducreyi*, is a sexually transmitted disease leading to one or several ulcers, chiefly in the genital region (182,183). The ulcers exhibit little if any induration and often have undermined borders. They are usually tender. Inguinal lymphadenitis, either unilateral or bilateral, is common and unless treated often results in an inguinal abscess.

Histopathology. The histologic changes observed beneath the ulcer are sufficiently distinct to permit a presumptive diagnosis of chancroid in many instances. The lesion consists of three zones overlying each other and shows characteristic vascular changes (182,183) (Fig. 21-54). The surface zone at the floor of the ulcer is rather narrow and consists of neutrophils, fibrin, erythrocytes, and necrotic tissue. The next zone is fairly wide and contains many newly formed blood vessels showing marked proliferation of their endothelial cells. As a result of the endothelial proliferation, the lumina of the vessels are often

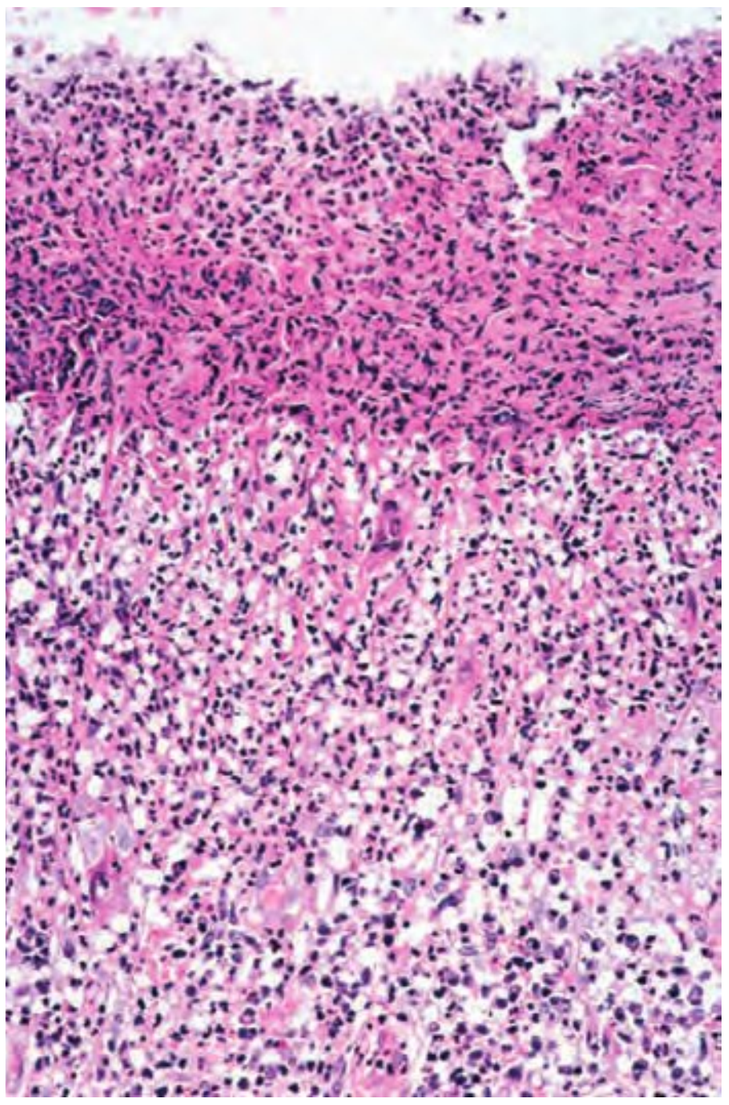

FIGURE 21-54. Chancroid. Three-zone pattern of ulcer and inflammation: superficial necrotic zone, underlying granulation tissue, and deeper fibrosis with plasma cells (H&E stain).

occluded, leading to thrombosis. In addition, there are degenerative changes in the walls of the vessels. The deep zone is composed of a dense infiltrate of plasma cells and lymphoid cells.

Demonstration of bacilli in tissue sections stained with Giemsa stain or Gram stain is occasionally possible (Fig. 21-55). The bacilli are most apt to be found between the cells of the surface zone (184). However, in smears of serous exudate obtained from the undermined edge of the ulcer, the bacilli usually can be seen on staining with the Giemsa or Gram stain. *H. ducreyi* is a fine, short, gram-negative coccobacillus, measuring about 1.5 by 0.2 μm, often arranged in parallel chains. *In situ* hybridization may also specify chancroid organisms (185). Electron

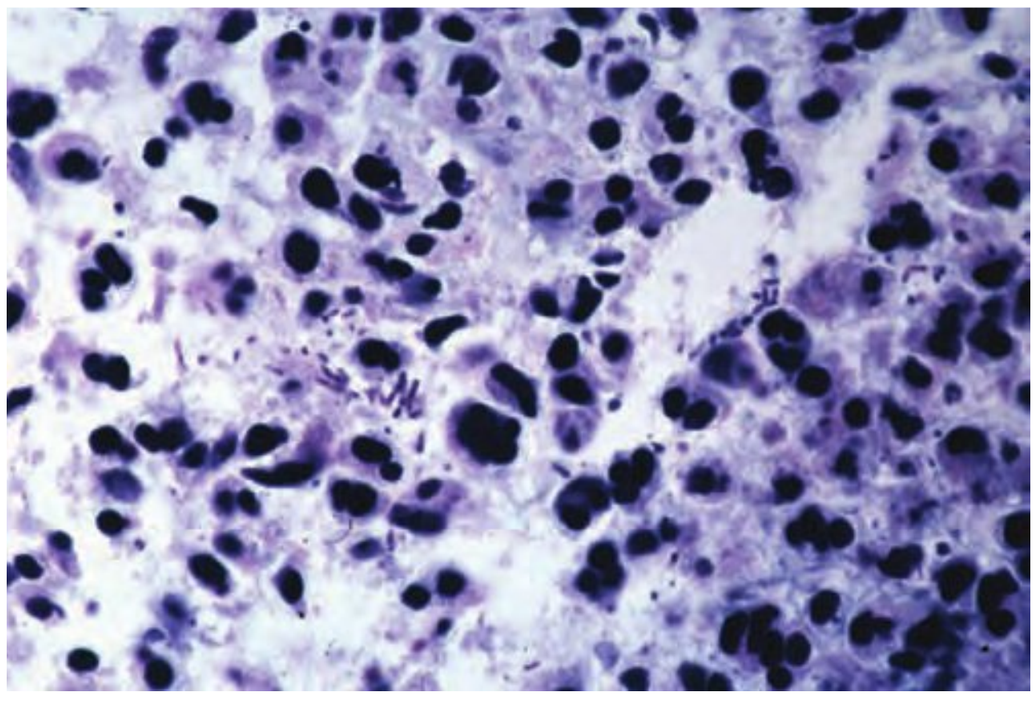

FIGURE 21-55. Chancroid. Bacilli (in the superficial zone) lying in parallel chains (Giemsa stain).

microscopy reveals that the bacilli are extracellular and thus rarely visible in phagosomes of macrophages (186).

The diagnosis of chancroid is confirmed by culture on selective blood-enriched agar (187). Chancroid may clinically resemble donovanosis by showing nontender or only slightly tender, indurated ulcers without undermined margins (188). On the other hand, particularly in the presence of several lesions, herpes simplex has to be excluded, although in herpes simplex the ulcerations usually are not as deep as those in chancroid.

GRANULOMA INGUINALE (DONOVANOSIS)

Granuloma inguinale, also called *donovanosis*, is a sexually transmitted disease caused by *Calymmatobacterium granulomatis* (189). The organism is a gram-negative short bacillus, about 2 to 3 μm long, with bipolar staining. The disease is endemic, but relatively uncommon, in the tropics (190).

Granuloma inguinale occurs in the genital or perianal region either as a single lesion or as several lesions (191). The lesions consist of ulcers filled with exuberant granulation tissue that bleeds easily (the characteristic beefy appearance). The borders of the ulcers are elevated and often have serpiginous outlines. Because the lesions spread by peripheral extension, they may attain a large size. In some instances, ulceration leads to mutilation resulting from destruction of tissue (192). In others, excessive granulation tissue causes vegetating lesions. Occasionally, squamous cell carcinoma supervenes (193). Local lymphadenopathy occurs through secondary infection of ulcerated skin.

Histopathology. At the edge of the ulcer, the epidermis exhibits acanthosis that may reach the proportions of pseudocarcinomatous hyperplasia. Present in the dermis is a dense infiltrate that is composed predominantly of histiocytes and plasma cells (Fig. 21-56). Scattered throughout this infiltrate are small abscesses composed of neutrophils. The number of lymphoid cells is conspicuously small (194).

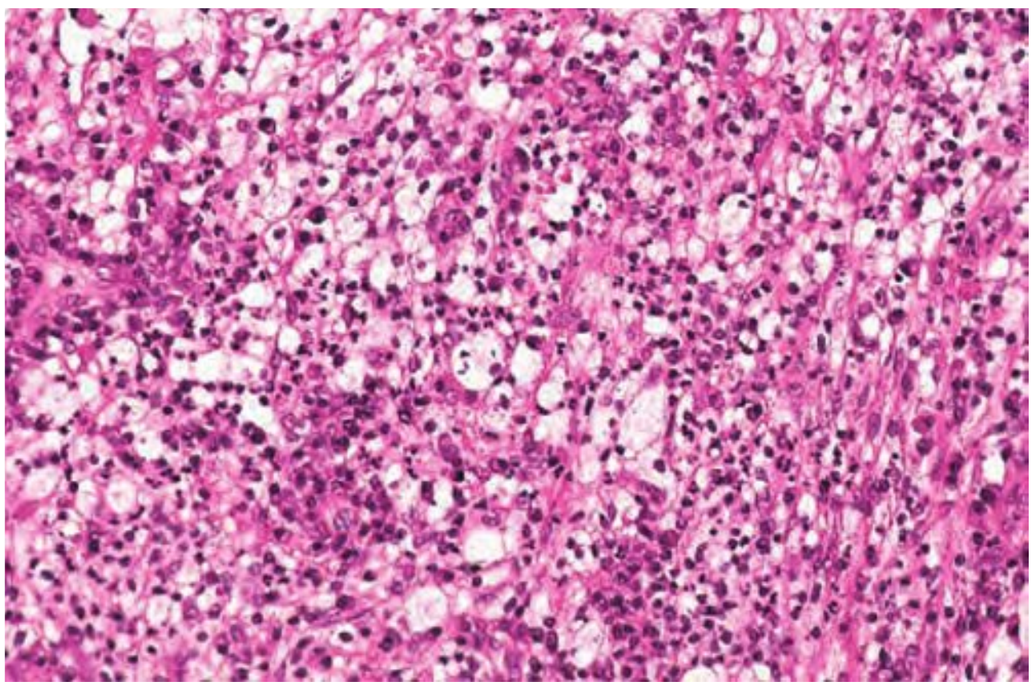

FIGURE 21-56. Donovanosis. Acute inflammation intermixed with foamy macrophages (H&E stain).

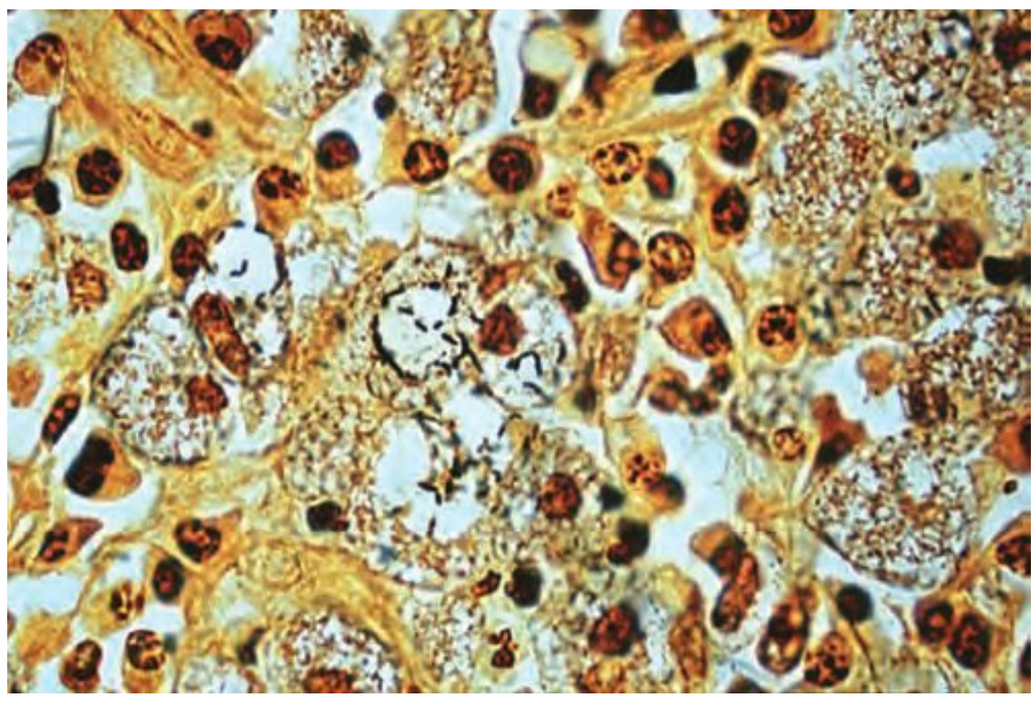

FIGURE 21-57. Donovanosis. Silver-positive bacilli within macrophages (Warthin-Starry stain).

The macrophages, which may be large, have a typical vacuolated appearance; these vacuoles contain bacilli and comprise the so-called "Donovan bodies." *C. granulomatis* does not stain with hematoxylin and eosin (H&E) stains but is well delineated by the Warthin-Starry method as short bacilli, either singly or in clumps (184,195) (Fig. 21-57). Giemsa stain shows bipolar condensations of stain. Electron microscopy reveals that the bacteria reside in phagosomes (196).

Differential Diagnosis. Overdiagnosis of carcinoma is possible because of the epithelial hyperplasia. The inflammatory pattern is similar to that observed in rhinoscleroma.

RHINOSCLEROMA

Rhinoscleroma is a chronic, infectious but only mildly contagious disease caused by *Klebsiella rhinoscleromatis*, a gram-negative bacillus. The nose, pharynx, larynx, trachea, and occasionally also the skin of the upper lip are distorted and infiltrated with hard, granulomatous masses. The disorder always begins in the nose. Although formerly endemic in Central Europe, it is now encountered mainly in Central America and Africa (197–199).

Histopathology. The cellular infiltrate is a chronic granulation tissue with abundant plasma cells and Mikulicz cells. Polymorphs may be present (but they cannot kill the bacteria). Russell bodies (plasma cells with retained globules of immunoglobulins) are frequently observed. The characteristic cell is the Mikulicz cell, a large histiocyte measuring from 10 to 100 μm in diameter (Fig. 21-58). It has a pale, vacuolated cytoplasm. Within the cytoplasm of the Mikulicz cells, one finds many bacilli (Fig. 21-59). They can be seen faintly in sections stained with H&E but are better visualized with the Giemsa stain or a Warthin-Starry silver stain (200). They are also stained red by the PAS technique. They are gram-negative rods that measure 2 to 3 μm in length and appear round or

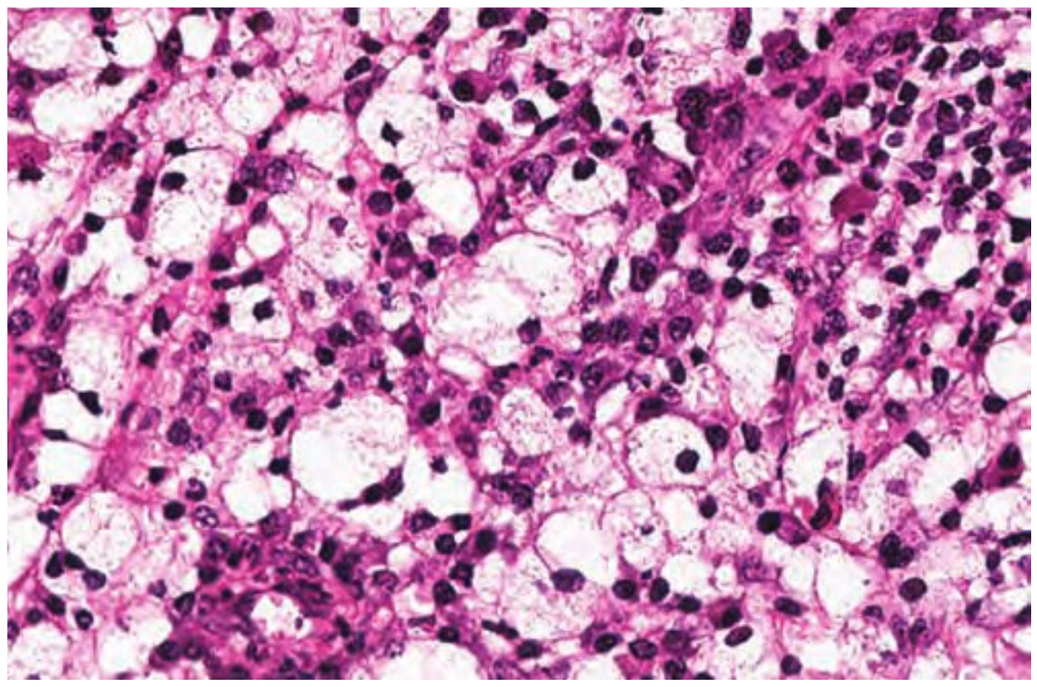

FIGURE 21-58. Rhinoscleroma. Foamy macrophages (Mikulicz cells) and plasma cells; the bacilli are faintly visible within the macrophages (H&E stain).

ovoid in cross-section. Immunocytochemistry can also be used to confirm rhinoscleroma (198,201).

In long-standing lesions, marked fibrosis is present. The mucosal epithelium overlying the cellular infiltrate often exhibits hyperplasia, which may be so pronounced as to give rise to a mistaken diagnosis of squamous cell carcinoma.

Electron microscopy reveals numerous phagosome vacuoles of varying size within the Mikulicz cells. Some vacuoles contain one or a few bacilli up to 4 μm in length. They are surrounded by a characteristic coat of finely granular, filamentous material arranged in a radial fashion. This coating material contains mucopolysaccharides and is responsible for the positive PAS reaction of the bacteria (199).

Differential Diagnosis. The histopathology of rhinoscleroma is essentially similar to that of donovanosis (granuloma inguinale). Foamy, vacuolated macrophages are also observed in many other chronic inflammatory conditions (e.g., leprosy, chronic staphyloccocal abscess, mycoses, and leishmaniasis), but special stains and associated clinicopathologic features usually enable their

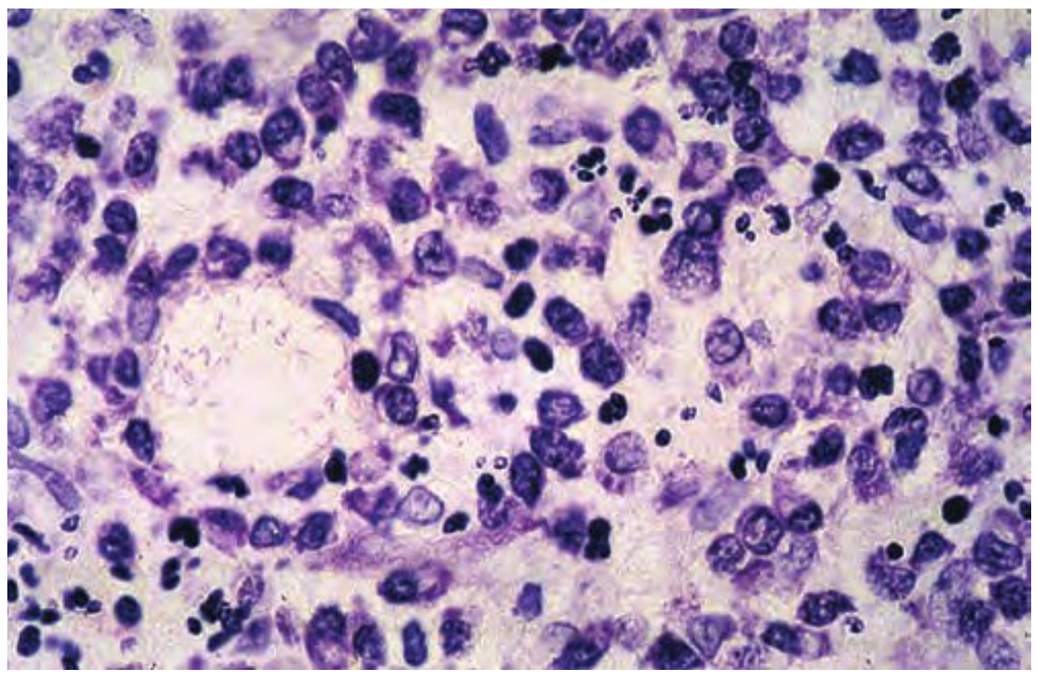

FIGURE 21-59. Rhinoscleroma. Bacilli within the macrophages (Giemsa stain).

distinction. Plasma cells and Russell bodies, similarly, correlate with chronicity in many diverse infections, such as treponematoses, amoebiasis, leishmaniasis, and tuberculosis.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum is a sexually transmitted disease caused by *Chlamydia trachomatis*. Chlamydiae are obligate intracellular parasites with a unique biphasic life cycle (203).

The incubation period of lymphogranuloma venereum varies from 3 to 30 days but averages 7 days. The primary lesion is a small erosion or papule 5 to 8 mm in size. This lesion heals within a few days and may pass unnoticed. Within 1 to 2 weeks after the appearance of the primary lesion, enlargement of the inguinal lymph nodes begins. Inguinal lymphadenopathy occurs in most men infected with this disease but in only some women. The involved inguinal lymph nodes at first are firm but subsequently develop multiple areas of suppuration, resulting in draining sinuses. The lymphadenopathy usually subsides within 2 to 3 months. Rarely, elephantiasis of the penis and scrotum or chronic penile ulcerations arise as a late complication (203).

In women in whom the infection begins in the lower portion of the vagina, drainage is to the iliac and anorectal lymph nodes rather than to the inguinal lymph nodes, which may result in proctitis (192). Rectal stricture and perineal ulcerations are fairly common late complications in these women. Lymph stasis may lead to marked vulvar edema, referred to as *esthiomene*. Proctitis and rectal stricture also occur in homosexual men (204).

Histopathology. The changes in the initial papule are nonspecific. There is ulceration and a nonspecific granulation tissue. In the lymph nodes, stellate abscesses with surrounding epithelioid cells and macrophage giant cells represent the characteristic lesion. A similar pathology is seen in cat-scratch disease nodes. Ordinary histologic stains do not demonstrate the infecting organisms in skin or node. The diagnosis may be confirmed by culture of a skin lesion or lymph node, and serology is useful (205).

Chlamydiae undergo a developmental cycle and, as can be seen by electron microscopy, occur in two forms: elementary body and initial body (202). The elementary body is adapted to an extracellular environment and is infective for other cells. It measures about 0.3 μm in diameter and consists of a round, electron-dense inner body surrounded by an electron-lucid halo and a membrane. After entering a host cell by means of phagocytosis, it develops into a metabolically active initial body 0.5 to 1.0 μm in diameter. Multiplication takes place by division of the nucleus. This division results in two elementary bodies, which on leaving the host cell can infect other cells.

CAT-SCRATCH DISEASE

Bartonella henselae (previously *Rochalimaea henselae*) causes cat-scratch disease, and the organism is carried in the blood and oral cavities of cats (206). The skin lesion develops 2 to 4

days after a scratch or bite from a cat. It may be macular, papular, or a nodule, usually on the arm or hand. Two to 3 weeks later, a large, tender swelling of a group of lymph nodes develops in the drainage area of the scratch. The cat scratch heals in a normal fashion, but the affected lymph nodes become fluctuant as a result of suppuration. The average duration of lymph node enlargement is 2 months (207,208).

Histopathology. The primary papules at the site of the scratch show one or several acellular areas of necrobiosis in the dermis. These areas are of various shapes, including round, triangular, and stellate. Surrounding them are several layers of histiocytic and epithelioid cells, with the innermost layer exhibiting a palisading arrangement. A few giant cells may be present. The periphery of the epithelioid cell reaction is surrounded by a zone of lymphoid cells.

The reaction in the lymph nodes is similar to that observed in the skin, except that the central areas of necrosis in the epithelioid cell granulomas undergo abscess formation through the accumulation of numerous neutrophils. Macrophage giant cells are also present. As the abscesses enlarge, they become confluent.

The delicate, pleomorphic, gram-negative bacilli can be demonstrated with the Warthin-Starry silver impregnation stain peripheral to the necrosis of involved lymph nodes (209) and in the skin at the primary site of inoculation (206). Immunocytochemistry also reveals the bacilli, and serodiagnostic tests are available. For specific identification, PCR techniques and *in vitro* culture may be used (206).

Electron microscopic examination reveals that the bacteria are invariably extracellular and form small clusters. They are 0.8 to 1.5 μm long and 0.3 to 0.5 μm wide, with homogeneous bacterial walls (210).

BACILLARY ANGIOMATOSIS

Bacillary angiomatosis is a new disease, first described in 1983 (211) as a skin or disseminated infection in patients immunosuppressed by HIV infection. It is also rarely encountered in patients with other immunocompromising conditions and even in immunocompetent people (212). The agents are gram-negative bacilli: *Bartonella quintana* and *B. henselae* (213). The pathology is similar to that of the late cutaneous stage of bartonellosis, caused by *Bartonella bacilliformis* (214). As with cat-scratch disease, exposure to cats is a major risk factor for acquiring this infection (215).

The skin lesions are reddish or brown papules on any part of the body, usually in large numbers, that resemble Kaposi's sarcoma. They may also present as subcutaneous lumps without skin involvement (217,218).

Histopathology. The epidermis may be flat or hyperplastic. In the dermis, there are single or multinodular proliferations of capillaries accompanied by an inflammatory infiltrate that includes variable numbers of neutrophil polymorphs and mononuclear cells as well as edema. Leukocytoclasia is frequently observed (218). Characteristic of bacillary angiomatosis are extracellular deposits of palely hematoxyphilic granular material (Fig. 21-60). Warthin-Starry staining reveals these deposits to be dense masses of short bacilli (Fig. 21-61). The Grocott-Gomori methenamine silver method also demonstrates the argyrophilic bacilli. These bacilli may also be delineated by modified Gram stains such as the Brown-Hopps stain.

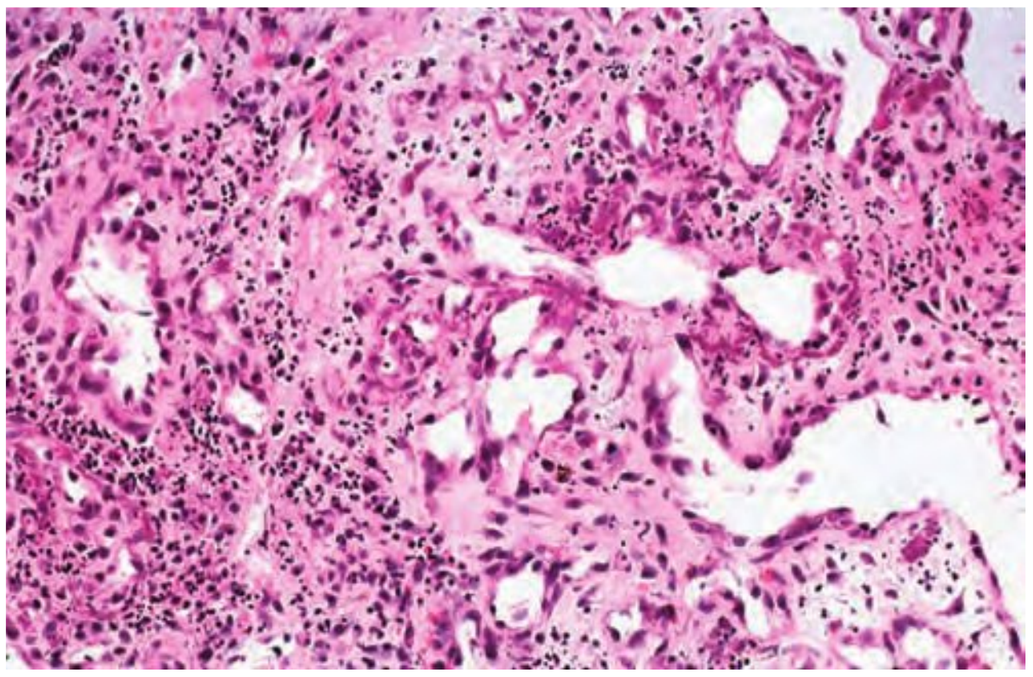

FIGURE 21-60. Bacillary angiomatosis. Dermis shows vascular proliferation, leukocytoclasia, and edema (H&E stain).

Differential Diagnosis. The major differential diagnoses are Kaposi's sarcoma, pyogenic granuloma, and epithelioid hemangioma (218). The presence of clumps of bacilli is obviously important. The capillary proliferation does not have the organized arborizing quality of that in pyogenic granuloma. Spindle cell proliferation and intracellular hyaline globules as seen in Kaposi's sarcoma are not features of bacillary angiomatosis, and Kaposi's sarcoma does not include polymorphs; however, the two conditions may be difficult to distinguish, and many pathologists have learned about bacillary angiomatosis from being informed that the lesions of "Kaposi's

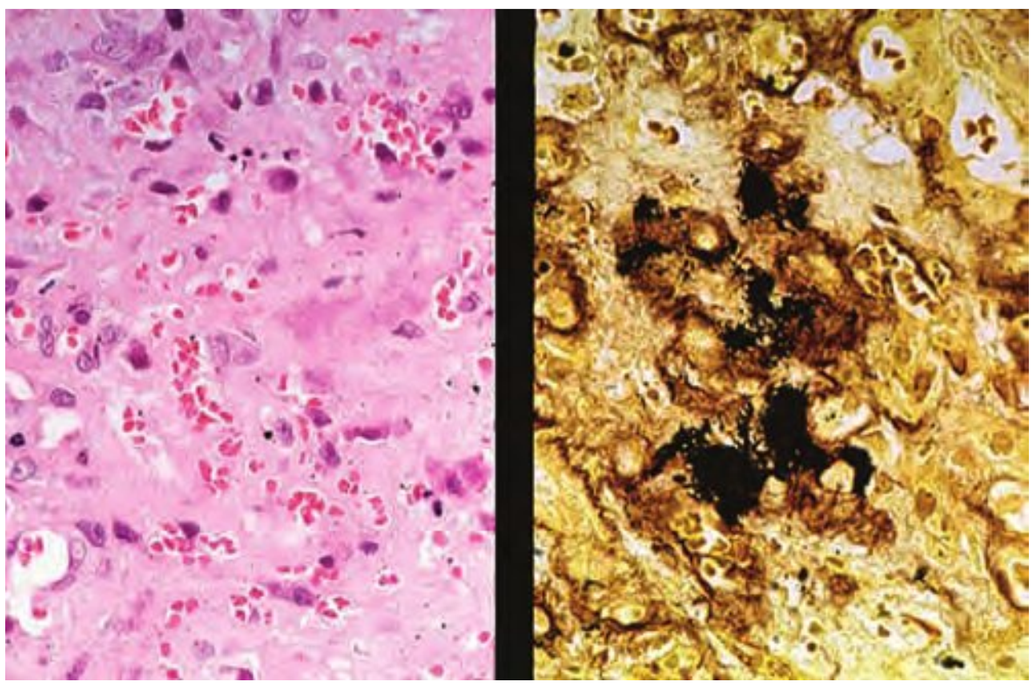

FIGURE 21-61. Bacillary angiomatosis. Left: Clumps and smudges of basophilic extracellular material—the bacteria (H&E stain). Right: Silver-positive bacilli (Warthin-Starry stain).

sarcoma" disappeared on treatment with antibiotics. Epithelioid hemangioma has plumper (histiocytoid) endothelial cell proliferation and no acute inflammation.

BOTRYOMYCOSIS

Botryomycosis, despite its name, is not a fungal infection but a chronic suppurative infection of skin (and other organs such as lungs and meninges) in which pyogenic bacteria form granules similar to those seen in mycetoma (219). Although immunosuppressed patients, including those with HIV infection, may acquire botryomycosis (220), most patients have no known immune defect. Occasionally, the lesion is associated with another dermatosis such as follicular mucinosis (221).

The skin lesions are local nodules, ulcers, or sinuses communicating with deep abscesses. They occur mainly on the extremities.

Histopathology. The dermal inflammation is predominantly that of neutrophil polymorph abscesses with surrounding granulation tissue and fibrosis (Fig. 21-62). Within the abscesses are granules (grains) shaped like a bunch of grapes, hence the name of the disease (Fig. 21-63). The grains may vary from 20 μm to 2 mm in diameter. They are composed of closely aggregated nonfilamentous bacteria with a peripheral, radial deposition of intensely eosinophilic material—a Hoeppli-Splendore (HS) reaction. The bacteria are usually *S. aureus*, but streptococci and certain gram-negative bacilli such as *Proteus*, *Pseudomonas*, and *E. coli* are sometimes found. Gram stains delineate these broad categories of infection, although sometimes the organisms in gram-positive infections are degenerate and lose their gram-positive staining reaction (Fig. 21-64). The HS reaction material comprises antibody and fibrin.

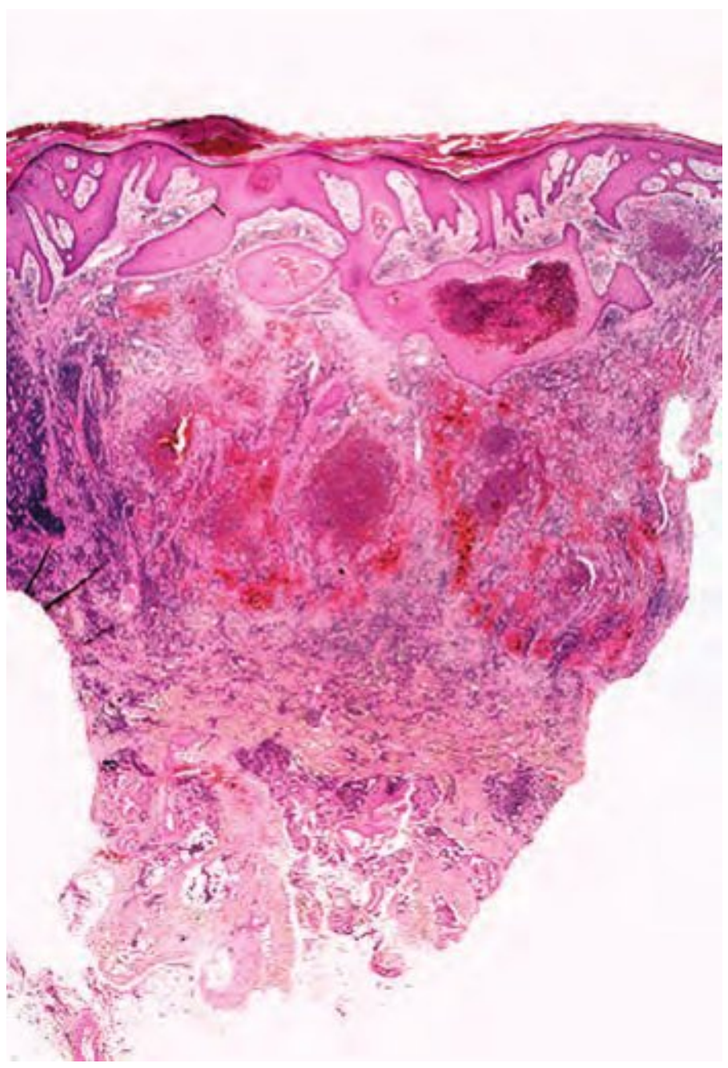

FIGURE 21-62. Botryomycosis. There are pseudoepitheliomatous hyperplasia and small abscesses in the dermis containing clumps of bacteria (H&E stain).

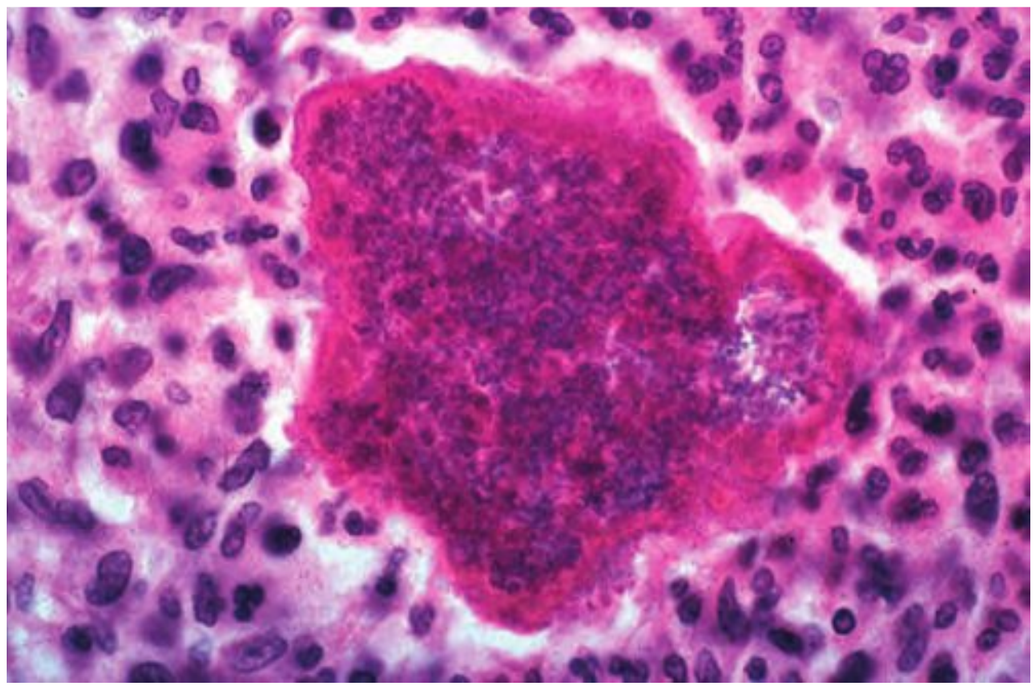

FIGURE 21-63. Botryomycosis. An abscess within which is a basophilic bacterial clump with an eosinophilic surrounding HS reaction (H&E stain, high power).

The overlying epithelium often exhibits pseudoepitheliomatous hyperplasia. Transepithelial elimination of grains may be observed (as with mycetoma) (222).

Pathogenesis. Local implantation of infection may be a factor in some cases, with persistence of a foreign body. Bacteremia is documented in many patients; however, in others, the lesions appear *de novo*. The characteristic formation of the peribacterial HS reaction probably prevents phagocytosis and intracellular killing of the bacteria, leading to chronicity.

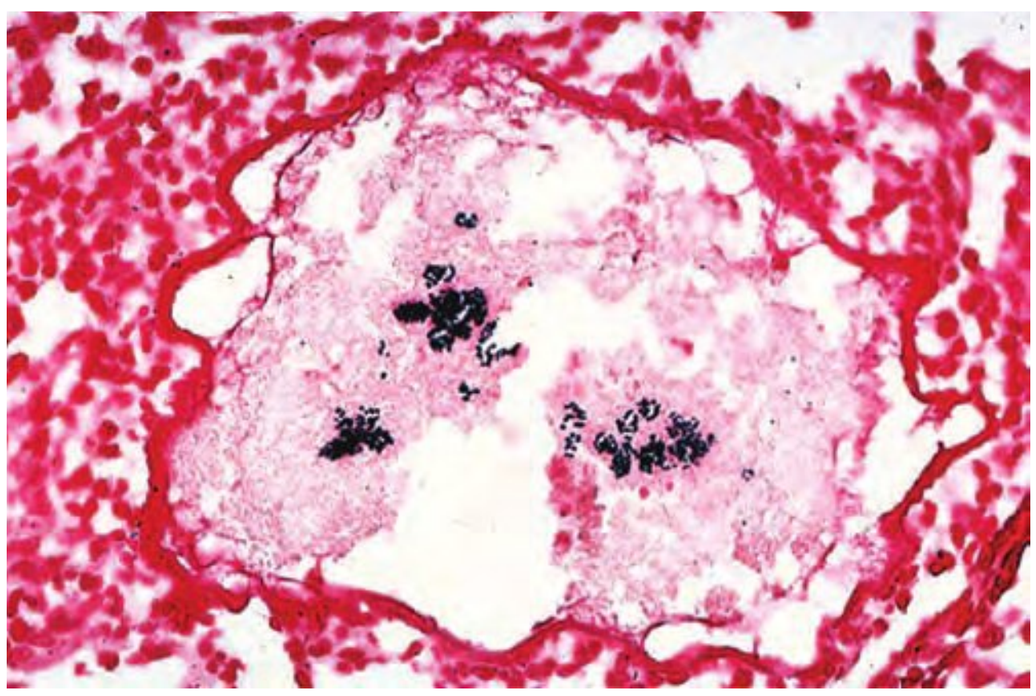

FIGURE 21-64. Botryomycosis. A staphylococcal lesion showing gram-positive cocci (the majority are degenerate and nonstaining) (Gram stain).

NOCARDIOSIS

Nocardia sp. are gram-positive, weakly acid-fast, filamentous, branching bacilli that are ubiquitous in the soil. The main species are *Nocardia asteroides*, which is global in distribution, and *Norcardia brasiliensis*, which is found mainly in the Americas (223,224).

N. asteroides is an opportunist agent, and immunocompromised patients, such as those with HIV infection (225,226) and organ transplant recipients, are liable to nocardiosis. Infection of the skin follows direct implantation from the environment, hematogenous spread from pulmonary infection, or direct spread through the chest wall from a lung lesion. The skin lesions include erythematous nodules, pustular ulcers, and sinuses. They may be single or multiple.

N. brasiliensis affects immunocompetent as well as immunosuppressed people. The primary and secondary skin lesions are similar to those of *N. asteroides*. Sporotrichoid spread up a limb, with lymphatic involvement, may occur (227). Both species may produce a chronic mycetoma-like lesion with much fibrosis and tissue destruction.

Histopathology. The bacteria induce a mixed acute abscess and granulomatous response in the skin, with fibrosis. Occasionally, the bacteria are clumped together with a surrounding HS reaction (see sections on Botryomycosis [page 573] and Mycetoma [chapter 22, chapter 23, page 614]). More often, they are more loosely dispersed and resemble *Actinomycosis* sp. H&E stains demonstrate the bacilli poorly. They are 1 μm in diameter, filamentous, branching, beaded, gram positive, Grocott silver positive, and usually weakly acid fast so that a modified Ziehl-Neelsen stain appropriate for leprosy bacilli stains them (Fig. 21-65). This latter feature assists in the distinction of *Nocardia* from *Actinomyces* and related bacilli; specific antisera with immunocytochemistry are also helpful (225), and culture is definitive. The shape of the organisms distinguishes them from mycobacteria. The Grocott silver method is the most sensitive screening stain for nocardiosis.

ACTINOMYCOSIS

Actinomyces israelii is a gram positive, branching, filamentous bacterium. It resides as a commensal organism in the oral cavity and tonsillar crypts. The main clinicopathologic manifestations are cervicofacial, thoracic, and intestinal actinomycosis (228). In the first of these, skin lesions result from extension of suppuration from the oral mucosa through to the facial skin, with sinus formation and discharge of pus and sulfur granules (see later). Thoracic and intestinal infections may produce discharging sinuses onto the skin from infection tracking outward from lung and gut (229). On rare occasions, purely cutaneous actinomycotic infection occurs, and hematogenous dissemination can produce multiple skin sinuses. An infected pilonidal sinus of the penis has been reported (230).

Histopathology. The inflammatory reaction to actinomycotic infection is typically a chronic abscess with polymorphs, surrounding granulation tissue, and fibrosis (231). The organisms are usually tangled together in a matted colony, forming a granule or grain (like botryomycosis and mycetoma). These grains, commonly termed *sulfur granules*, may be 20 μm to 4 mm in diameter. The bacilli within are 1-μm-diameter filaments that are hematoxyphilic and gram positive (Figs. 21-66 and 21-67). They stain with the Grocott silver method. Often, only the peripheral filaments stain with the Gram method, because of degeneration of the inner bacteria. The peripheral filaments often terminate in a club. A HS reaction may be found peripheral to the bacteria in the grain. The histologic differentiation from nocardiosis was discussed in the previous section.

Further detailed descriptions of these bacterial infections of the skin may be found in Connor and Chandler (232).

CHAPTER 22

A. Neil Crowson
Cynthia Magro
Martin Mihm, Jr.

Treponemal Diseases

The venereal and nonvenereal treponemal diseases are caused by motile bacteria of the family Spirochetacea, which also includes the genera *Borrelia* and *Leptospira*. Accurate recognition of spirochetal infection requires correlation of a given patient's travel and medical history with a detailed knowledge of the clinical and histologic expression of each pathogen. The pathogenic treponemes resemble each other in dark-field and biopsy preparations, being coiled, silver-staining organisms 6 to 20 μm by 0.10 to 0.18 μm, and have a high degree of DNA sequence homology (1,2). A single genetic difference in the 5′ and 3′ flanking regions of the 15-kD lipoprotein gene *tpp15* was described for venereal and nonvenereal treponematoses in one study (3), evidence that suggests that these organisms evolved from a common ancestor to cause different diseases (4). Size and sequence heterogeneity is demonstrated by other treponeme genes, such as those controlling expression of the TprK antigen, a target of opsonizing antibodies that is important to host immune protection, variance in which may play a role in evasion of the host response (5). The nonvenereal treponematoses include yaws, pinta, and endemic syphilis. Recently, the role of oral treponemes in the causation of periodontitis has been explored (6–8).

VENEREAL SYPHILIS

Acquired syphilis, caused by *Treponema pallidum*, has afflicted humanity since at least the fifteenth century (9). Although it was a major cause of morbidity and mortality in the early twentieth century, public health programs and the advent of penicillin so reduced its incidence in First World countries by midcentury that many physicians became unfamiliar with its signs and symptoms (1). The incidence of acquired syphilis has since increased; in 1990, the incidence was 20 per 100,000 in the United States and 360 per 100,000 in areas of Africa, in part reflecting the epidemic of human immunodeficiency virus infection, with which acquired syphilis is linked epidemiologically and with which coinfection is common (10,11). New diagnoses of syphilis increased eightfold in the United Kingdom between 1997 and 2002 (12). In 2003, greater than 60% of all reported cases of syphilis occurred in men who had sex with men (13).

T. pallidum, of which there are three antigenically similar subspecies (14), is generally spread through contact between infectious lesions and disrupted epithelium at sites of minor trauma incurred during sexual intercourse. The transmission rate is between 10% and 60%. Early lesions reflect a delayed-hypersensitivity response to the organism, although some bacteria escape, in part due to integral outer membrane proteins that may render the treponeme invisible to the immune system (15). The result in the untreated host is persistent infectivity over the course of decades.

Primary syphilis is defined by a skin lesion, or chancre, in which organisms are identified; it typically arises 21 days after exposure at the inoculation site and is classically a painless, brown-red, indurated, round papule, nodule, or plaque 1 to 2 cm in diameter. Lesions may be multiple or ulcerative, and the regional lymph nodes may be enlarged.

Secondary syphilis results from the hematogenous dissemination of organisms, yielding widespread clinical signs accompanied by constitutional symptoms inclusive of fever, malaise, and generalized lymphadenopathy. A generalized eruption comprises brown-red macules and papules, papulosquamous lesions resembling guttate psoriasis, and, rarely, pustules (16). Lesions may be follicular based, annular, or serpiginous, particularly in recurrent attacks of secondary syphilis. Other skin signs include alopecia and condylomata lata, the latter comprising broad, raised, gray, confluent papular lesions arising in anogenital areas, pitted hyperkeratotic palmoplantar papules termed "syphilis cornee," and, in rare severe cases, ulcerating lesions that define "lues maligna." Some patients develop shallow, painless ulcers in the mucosae.

Meningovascular syphilis is usually seen in tertiary syphilis after 7 to 12 years of disease (17) but can occur in the secondary stage and be symptomatic; usually, it manifests as basilar meningitis and can be associated with cranial nerve palsies (18). Acute transverse myelitis (19), glomerulonephritis, and self-limited hepatitis are other uncommon manifestations.

Primary- and secondary-stage lesions may resolve without therapy or go unnoticed by the patient, who then passes into a latent phase. This may be subdivided into early and late stages, an arbitrary distinction that may help to guide the therapeutic approach. The Centers for Disease Control base the distinction of the early (infectious) latent stage from the late (noninfectious) latent stage on whether the duration of the infection is less or more than 1 year, respectively. The World Health Organization uses a 2-year period to make this

distinction. After a variable latent period, the patient enters the *tertiary stage*.

Tertiary syphilis comprises gummatous skin and mucosal lesions ("benign tertiary syphilis"), cardiovascular manifestations, and neurologic manifestations. The skin lesions may be solitary or multiple and can be divided into superficial nodular and deep gummatous types. The nodular type has a smooth, atrophic center with a raised, serpiginous border. The gummatous lesions present as subcutaneous swellings that ulcerate (20).

Congenital syphilis, on the rise since the mid-1980s (21), is a diagnosis rendered when organisms are identified in dark-field, immunofluorescent, or conventionally stained tissues or smears of lesional skin, placenta, or umbilical cord (22). A presumptive case is an infant born to a mother with inadequately treated syphilis at the time of delivery, or when an infant or child with a reactive treponemal test for syphilis exhibits evidence of congenital syphilis by virtue of physical or long-bone radiologic examination, a reactive cerebrospinal fluid (CSF) Venereal Disease Research Laboratory test, an elevated CSF protein or white blood cell count of unknown cause, or quantitative treponemal titers four times higher than the mother's at the time of birth (22). Clinical signs include rhinitis, chancres, or a maculopapular desquamative rash (21). Transplacental infection occurs in more than 50% of infants born to mothers with primary or secondary syphilis, roughly 40% of those born to mothers in the early latent stage, and only 10% of those born to mothers with late latent infections (22).

Histopathology of Syphilis. The two fundamental pathologic changes in syphilis are (a) swelling and proliferation of endothelial cells and (b) a perivascular infiltrate of lymphoid cells and often of plasma cells. In late secondary and tertiary syphilis, there are also granulomatous infiltrates comprising epithelioid histiocytes and giant cells. Newborns with congenital syphilis have shown at autopsy multiorgan involvement by an angioinvasive $CD68^+$ mononuclear cell infiltrate that imparts an "onion-skin" morphology to involved vessels with numerous demonstrable spirochetes (23).

Primary Syphilis

The epidermis at the periphery of the syphilitic chancre reveals changes comparable to those observed in lesions of secondary syphilis, namely, acanthosis, spongiosis, and exocytosis of lymphocytes and neutrophils. Toward the center, the epidermis becomes thinned, edematous, and permeated by inflammatory cells. In the center, the epidermis may be absent. The papillary dermis is edematous. A dense perivascular and interstitial lymphohistiocytic and plasmacellular infiltrate spans the entire thickness of the dermis (Fig. 22-1); the lymphocytes are principally of T-helper phenotype. Neutrophils are often admixed. Endarteritis obliterans characterized by endothelial swelling and mural edema is observed (Fig. 22-2).

By silver staining with the Levaditi stain or the Warthin-Starry stain and by immunofluorescent techniques, spirochetes are usually identified along the dermal–epidermal junction

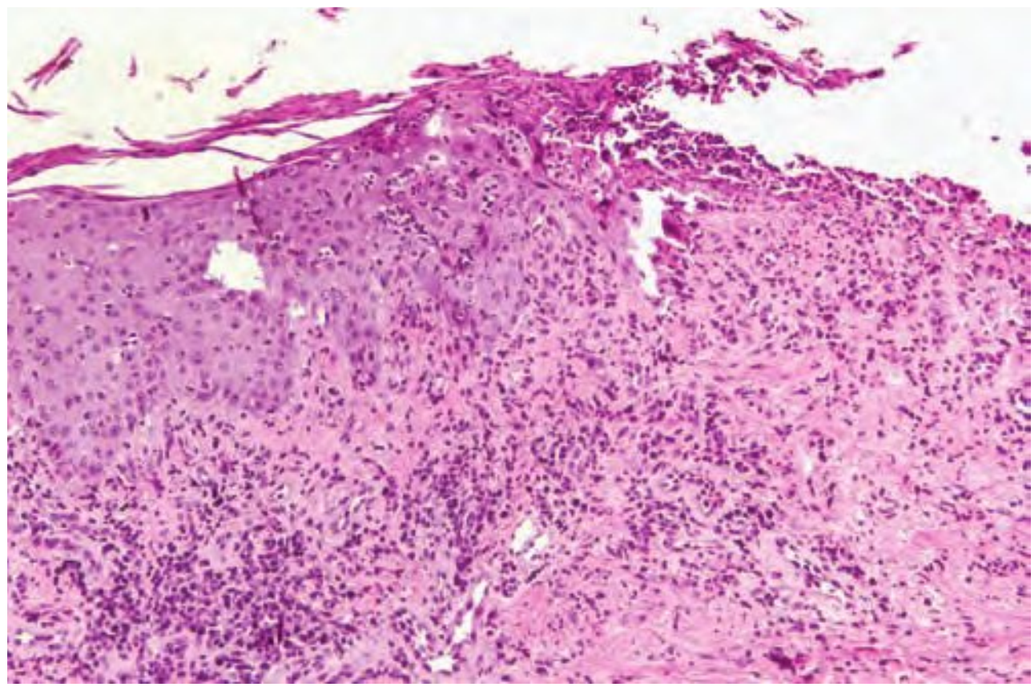

FIGURE 22-1. Primary syphilitic chancre. The epithelium is eroded, and the corium contains a dense, plasma-cell-rich infiltrate. There is neovascularization, with secondary necrotizing vasculitic changes manifested by mural fibrin deposition.

and within and around blood vessels. If seen in their full length, which is rare, spirochetes generally show 8 to 12 spiral convolutions, each measuring from 1 to 1.2 μm in length (Fig. 22-3). It should be remembered that silver also stains melanin and reticulum fibers. Differentiation may cause some difficulties but should be possible based on the fact that the melanin in the dendritic processes of melanocytes has a granular appearance, the granules being thicker and more heavily stained than *T. pallidum* (24). Reticulin fibers, although wavy, do not exhibit a spiral appearance. Correlation with serology is always prudent.

Histologic examination of enlarged regional lymph nodes in primary syphilis most commonly reveals a chronic inflammatory infiltrate containing many plasma cells with endothelial

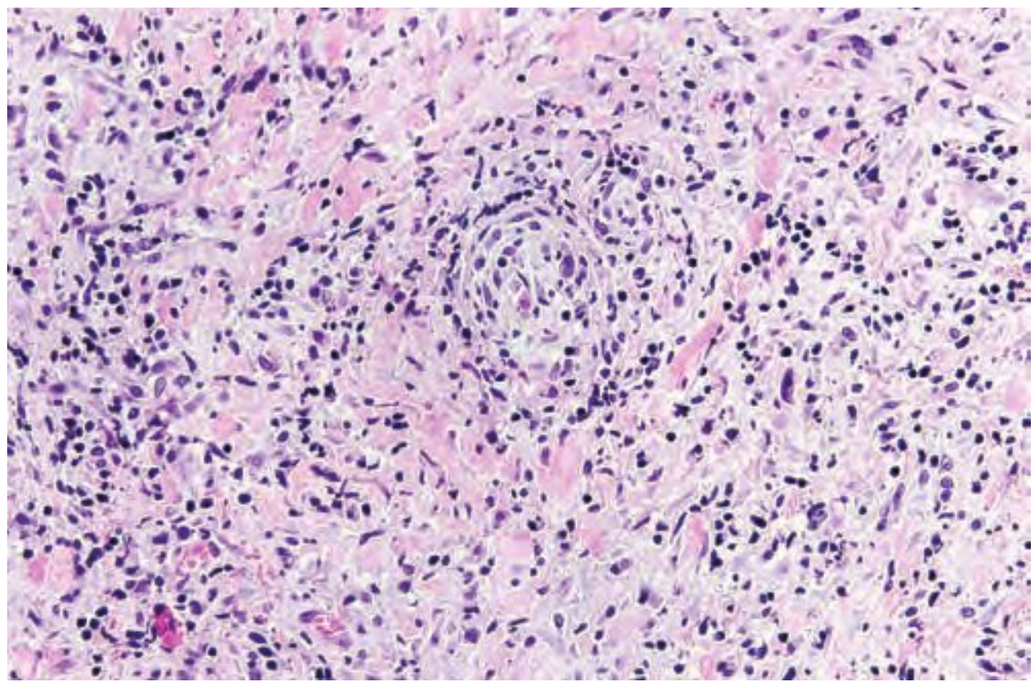

FIGURE 22-2. Primary syphilitic chancre. There is endarteritis obliterans manifested by endothelial cell swelling, endothelial hyperplasia, and expansion of vessel walls by edema and a lymphohistiocytic infiltrate with resultant lumenal attenuation. A diffuse extravascular plasma-cell-rich infiltrate is present.

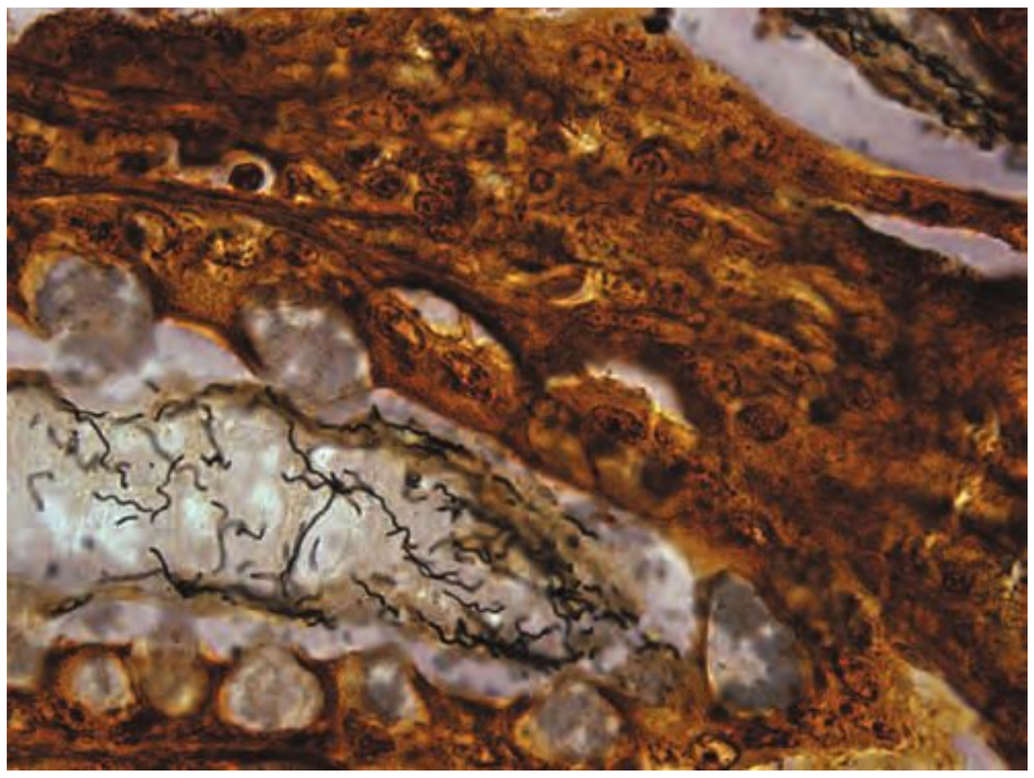

FIGURE 22-3. Treponeme morphology. A silver stain reveals numerous elongate, coiled spirochetes ranging in length from 8 to 12 μm.

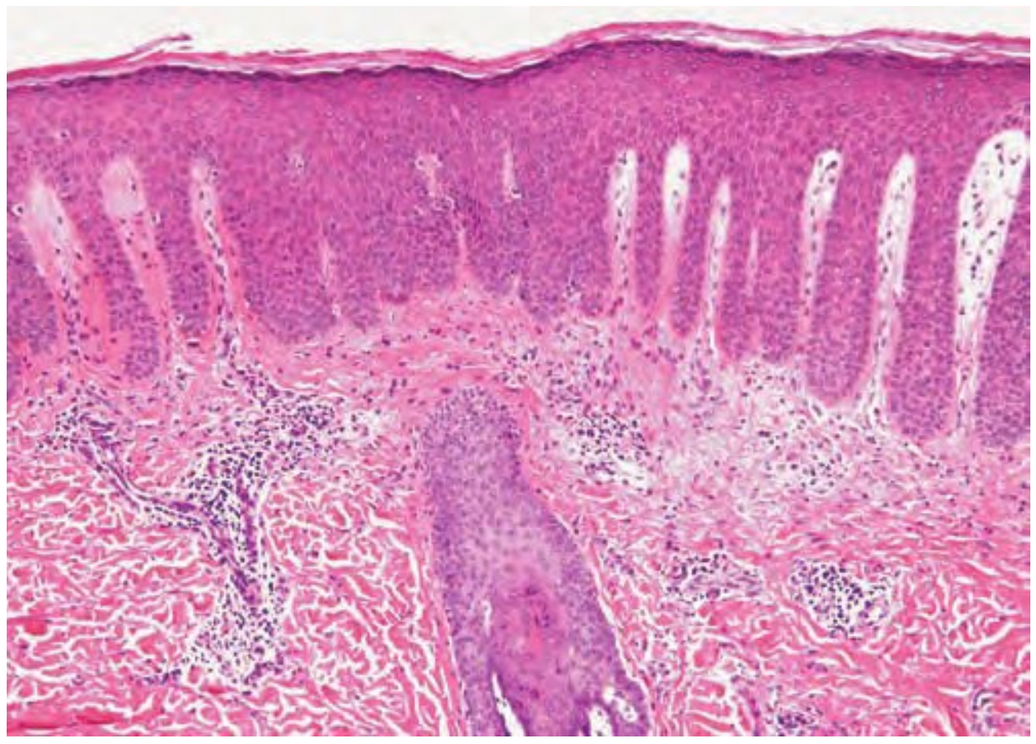

FIGURE 22-4. Secondary syphilis. There is striking psoriasiform hyperplasia of an epidermis surmounted by an orthohyperkeratotic and parakeratotic scale. There is prominent papillary dermal edema.

hyperplasia and follicular hyperplasia. Spirochetes are numerous and can nearly always be identified with the Warthin-Starry stain. In some cases, nonnecrotizing granulomas resembling those of sarcoidosis are found in the lymph nodes (25).

Histogenesis. T. pallidum can be demonstrated by histochemistry or by immunohistochemistry. The latter comprises immunofluorescent methods in frozen (26) or fresh specimens and immunoperoxidase methods employable in fixed tissues (27). By electron microscopy, the organism can be seen in both intra- and extracellular dispositions in the epidermis and dermis (28) and within keratinocyte nuclei (29), fibroblasts (29,30), nerve fibers (31), blood vessel endothelia, and the lumina of lymphatic channels (29). Phagocytic vacuoles of macrophages and neutrophils may contain organisms (32), as may the cytoplasm of plasma cells. Ultrastructurally, the organism is 8 to 16 μm in length with regular spirals, a wavelength of 0.9 μm with an amplitude of 0.2 μm, and a cytoplasmic body 0.13 μm in diameter with tapering ends, all enveloped by a 7-nm trilaminar cytoplasmic membrane (33). The organisms attach to host cells by means of acorn-shaped nosepieces. The contractile motility of the spirochete is mediated by three or four axial filaments that course the length of the cytoplasmic body (34). A paraplastic membrane surrounds these axial filaments in young organisms but is replaced by an electron-dense amorphous substance produced by the host cell as an immunologic response in older spirochetes (31).

Differential Diagnosis. Lesions of chancroid are the most difficult to differentiate clinically from a syphilitic chancre. The characteristic histopathology of chancroid is one of dense lymphohistiocytic infiltrates with a paucity of plasma cells and a granulomatous vasculitis. An epidermal reaction pattern similar to the syphilitic chancre is observed, namely, psoriasiform epidermal hyperplasia and spongiform pustulation. A Giemsa or Alcian blue stain reveals coccobacillary forms between keratinocytes and along the dermal–epidermal junction. The infiltrate is composed mainly of T-helper lymphocytes and histiocytes including Langerhans cells (35).

Secondary Syphilis

There is considerable histologic overlap among the various clinical forms of secondary syphilis, such as the macular, papular, and papulosquamous types (36,37). Nevertheless, epidermal changes are least pronounced in the macular type and most pronounced in papulosquamous lesions.

Biopsies generally reveal psoriasiform hyperplasia, often with spongiosis and basilar vacuolar alteration, often with edema of the papillary dermis (Fig. 22-4). Exocytosis of lymphocytes, spongiform pustulation, and parakeratosis also may be observed (24,36). The parakeratosis may be patchy or broad, with or without intracorneal neutrophilic abscesses. Although lesions may mimic psoriasis, attenuation of the suprapapillary plate is uncommon. Scattered necrotic keratinocytes may be observed. Ulceration is not a feature of macular, papular, or papulosquamous lesions of secondary syphilis. The dermal changes include marked papillary dermal edema and a perivascular and/or periadnexal infiltrate that may be lymphocyte predominant, lymphohistiocytic, histiocytic predominant, or frankly granulomatous and is of greatest intensity in the papillary dermis and extends as loose perivascular aggregates into the reticular dermis. Obscuration of the superficial vasculature and lichenoid morphology is observed in some cases, and a cell-poor infiltrate is seen in others. In a few cases, when the infiltrate is heavy, atypical nuclei may be present and may then suggest the possibility of mycosis fungoides (38) or non-Hodgkin's lymphoma. Neutrophils may permeate the eccrine coil to produce a neutrophilic eccrine hidradenitis or manifest as a neutrophil-imbued scale crust (Fig. 22-5) (24). Granulomatous inflammation is almost invariable in lesions of greater than 4 months' duration (37) and may be present in some cases of early syphilis (39). A plasma cell component is

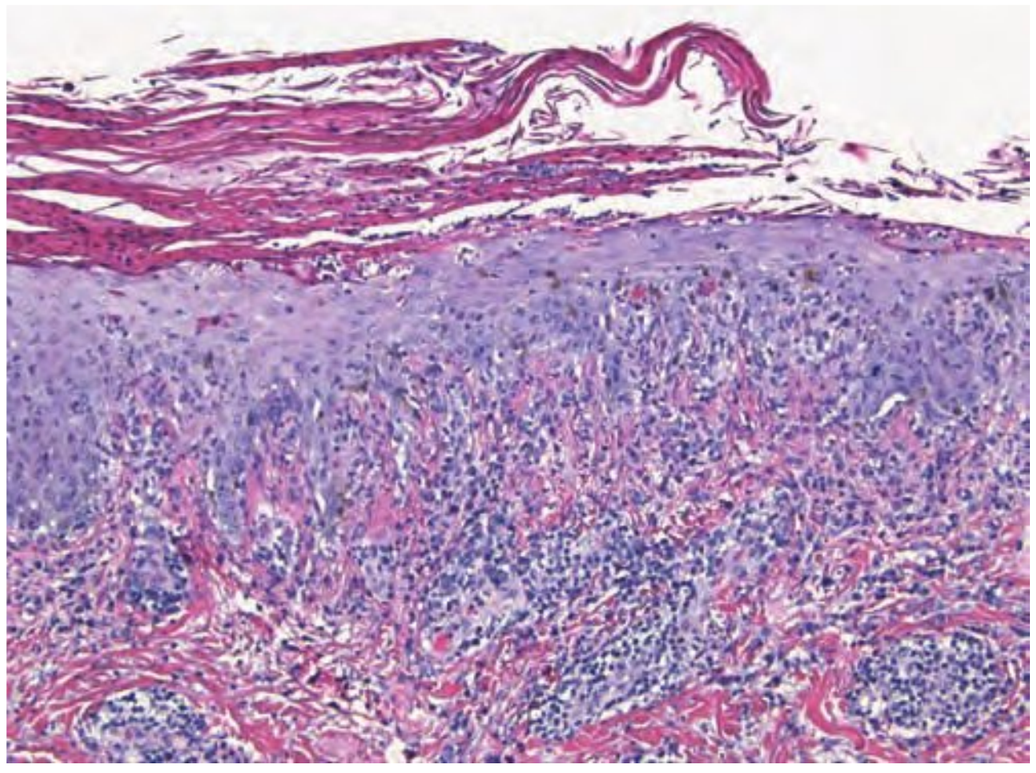

FIGURE 22-5. Secondary syphilis. There is psoriasiform epidermal hyperplasia with basilar vacuolopathy and lymphocytic interface dermatitis. The epidermis is surmounted by a parakeratotic scale rich in neutrophils. Plasma cells may be inconspicuous, as in this example.

inconspicuous or absent in 25% of the cases (Fig. 22-6) (36). Eosinophils are not usually observed. Vascular changes such as endothelial swelling and mural edema accompany the angiocentric infiltrates in half of the cases (36). Necrotizing vascular injury is distinctly unusual. A silver stain is recommended in all cases that are suspected of being secondary syphilis; it shows spirochetes in about one third of the cases of secondary syphilis, mainly within the epidermis and less commonly around the blood vessels of the superficial plexus. In some instances, the silver stain is positive even when dark-field examination of the patient's lesions is negative (24). By the immunofluorescent technique, all cases are positive. Phenotypic analysis of the infiltrate reveals a lymphoid populace composed mainly of T cells, with an equal proportion of cytotoxic and T-helper cells.

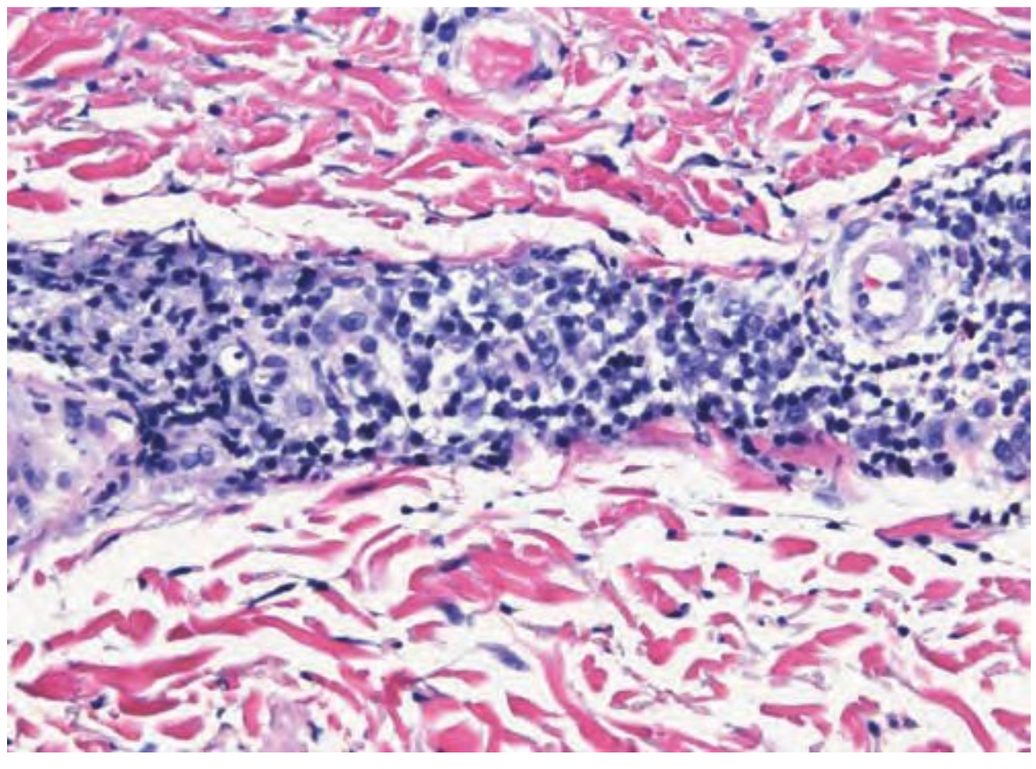

FIGURE 22-6. Secondary syphilis. A dense, lymphocytic, and often plasma-cell-rich infiltrate surrounds the cutaneous vessels of the dermis.

There are several histologic variants of secondary syphilis—namely, condylomata lata, syphilitic alopecia, pustular lesions (Fig. 22-5), syphilis cornee, and lues maligna. Lesions of condylomata lata show all of the aforementioned changes observed in macular, papular, and papulosquamous lesions, but more florid epithelial hyperplasia and intraepithelial microabscess formation are observed (24,40). A Warthin-Starry stain shows numerous treponemes (31).

Biopsies of syphilitic alopecia may demonstrate a superficial and deep perivascular and perifollicular lymphocytic and plasmacellular infiltrate that permeates the outer root sheath epithelium with a concomitant perifollicular fibrosing reaction (24). An involutional tendency characterized by increased numbers of telogen hairs is observed. A concomitant necrotizing pustular follicular reaction may also be seen (16).

An unusual variant of secondary syphilis is lues maligna (41,42), an ulcerative form characterized by severe thrombotic endarteritis obliterans involving vessels at the dermal–subcutaneous junction with resultant ischemic necrosis. A concomitant dense plasmacellular infiltrate with a variable admixture of histiocytes may be observed. Defective cell-mediated immunity may play an integral role in the pathogenesis of lues maligna, particularly in cases in which vascular alterations are minimal (43,44). Several cases of lues maligna arising in the setting of HIV disease have been described, with involvement of the oral cavity as the principal manifestation. A case of secondary syphilis resembling bullous pemphigoid by both light microscopy and immunofluorescent studies has been described (45).

Syphilis cornee/keratoderma punctatum associated with secondary syphilis manifests an epidermal invagination containing a horny plug composed of laminated layers of parakeratotic cells with loss of the granular cell layer and thinning of the stratum spinosum (46). A moderately dense perivascular plasmacellular infiltrate with concomitant capillary wall thickening involves the cutaneous vasculature.

In the rare pustular lesions of secondary syphilis, a necrotizing pustular follicular reaction accompanied by noncaseating granulomata and a perivascular lymphoplasmacellular infiltrate typically characterizes the histopathology (16). A pustular psoriasiform process with an absent granular cell layer and a strikingly thickened cornified layer laced with neutrophils may be seen (Fig. 22-5); if the clinical correlate is rugose or elephantine skin thickening, the designation *rupial syphilis* may be applied (16).

In addition to small, sarcoidal granulomata in papular lesions of early secondary syphilis, late secondary syphilis may show extensive lymphoplasmacellular and histiocytic infiltrates resembling nodular tertiary syphilis (47). Conversely, lesions of early tertiary syphilis may lack granulomata (48).

Although often nonspecific, the hepatitis of secondary syphilis may produce a granulomatous or cholestatic morphology on liver biopsy; hepatic necrosis and spirochetes may also be

observed (49). The nephrosis or glomerulonephritis of secondary syphilis shows proliferative changes in the glomeruli (50).

Histogenesis. The renal changes in secondary syphilis relate to immune complexes containing treponemal antigen. Not only has direct immunofluorescence shown granular deposits of immunoglobulin and complement along the glomerular basement membrane (50,51), but indirect immunofluorescence antibody studies using rabbit treponemal antibody and sheep antirabbit globulin conjugate have demonstrated treponemal antigen in the glomerular deposits (50).

Differential Diagnosis. The differential diagnosis of lesions of secondary syphilis includes other causes of lichenoid dermatitis, including lichen planus, a lichenoid hypersensitivity reaction, pityriasis lichenoides and connective tissue disease, sarcoidosis, psoriasis, and psoriasiform drug eruptions (24). Prominent spongiosis, suprabasilar dyskeratosis, a mid and deep perivascular component, and the presence of plasma cells are not histologic features of lichen planus or psoriasis. Although a middermal perivascular infiltrate, keratinocyte necrosis, and prominent lymphocytic exocytosis are present in pityriasis lichenoides, the infiltrate is purely mononuclear in nature, and neither spongiform pustulation nor plasmacellular infiltration is observed (52). Although lichenoid hypersensitivity reactions and psoriasiform drug reactions may also demonstrate a perivascular infiltrate of plasma cells, tissue eosinophilia is typically observed as well.

Tertiary Syphilis

Tertiary syphilis is categorized into nodular tertiary syphilis confined to the skin; benign gummatous syphilis principally affecting skin, bone, and liver; cardiovascular syphilis; syphilitic hepatic cirrhosis; and neurosyphilis. In the first variant, the granulomas are small and may be absent in rare cases (48). The granulomatous process is limited to the dermis, with scattered islands of epithelioid cells admixed with a few multinucleated giant cells, lymphocytes, and plasma cells. As a rule, necrosis is not conspicuous. The vessels may show endothelial swelling (44).

In benign gummatous syphilis, the main pathology, irrespective of the organ involved, is one of granulomatous inflammation with central zones of acellular necrosis. In cutaneous lesions, the blood vessels throughout the dermis and subcutaneous fat exhibit endarteritis obliterans along with angiocentric plasmacellular infiltrates of variable density. The skin lesions involve the subcutaneous fat and the dermis (53).

In cardiovascular syphilis, elastic tissue fragmentation and reduplication with neovascularization and fibrosis of main arteries occurs. Neurosyphilis includes an asymptomatic form—meningovascular syphilis—and parenchymatous syphilis, which is divided into generalized paresis of the insane and tabes dorsalis (54). In meningovascular syphilis, an inflammatory endarteritis involves the leptomeningeal vessels. In generalized paresis of the insane, gliosis with ventricular dilation is observed; spirochetes are identified in the cortex in 50% of the cases. In tabes dorsalis there is demyelinization of the posterior columns of the spinal cord, atrophy of the posterior spinal roots, and lymphoplasmacellular leptomeningitis (17,54).

NONVENEREAL TREPONEMATOSES

Yaws (Frambesia Tropica)

Yaws is caused by *T. pallidum*, subspecies *pertenue,* which is indistinguishable microscopically from *T. pallidum* subspecies *pallidum* but has been shown to be distinctive by virtue of the substitution of a single nucleotide coding for a 19-kD polypeptide demonstrable by Southern blot analysis (55). Other molecular methodologies confirm distinctive DNA sequences (2,4). Yaws is spread by casual contact between primary or secondary lesions and abraded skin and is most prevalent in warm, moist, tropical climates; 95% of the studied population in one province of Ecuador proved seropositive in one series (56). It is estimated that 2.5 million people globally are affected by this disease (57). Children are particularly afflicted (58). Sites of involvement include buttocks, legs, and feet. Unlike syphilis, yaws does not manifest transplacental spread to neonates (4).

Primary Yaws

The initial primary stage lesion, or "mother yaw," begins as an erythematous papule roughly 21 days postinoculation, which enlarges peripherally to form a 1- to 5-cm nodule surrounded by satellite pustules covered by an amber crust. A red, crusted appearance prompted German physicians to give the appellation "frambesia" to the disease. Lesions may heal as pitted, hypopigmented scars. Fever, arthralgia, and lymphadenopathy may coexist.

Secondary Yaws

Similar constitutional symptoms weeks to months later may herald progression to the secondary stage, characterized by involvement of any or all of skin, bones, joints, and cerebrospinal fluid. *Skin lesions* resemble the "mother yaw" but tend to be smaller and more numerous, hence the designation "daughter yaws." Periorificial lesions may mimic venereal syphilis. A circinate appearance ("tinea yaws") may be observed, as may a morbilliform eruption and/or condylomatous vegetations involving the axillae and groins. Macular, hyperkeratotic, and papillomatous lesions may be present on palmoplantar surfaces and may cause the patient to walk with a painful, crablike gait ("crab yaws"). Papillomatous nail-fold lesions may give rise to "pianic onychia." Relapsing cutaneous disease occurs up to 5 years later, tending to involve periorificial and periaxillary sites. A lifelong noninfectious latent state may then eventuate. *Bone lesions* consist of painful, sometimes palpable periosteal thickening of arms and legs, occasionally accompanied by soft tissue swellings around the involved small bones of the hands and feet.

Tertiary Yaws

Roughly 10% of cases progress to *tertiary yaws*, the skin manifestations of which comprise subcutaneous abscesses, ulcers that may coalesce to form serpiginous tracts, keloids, keratoderma, and palmoplantar hyperkeratosis. The bone and joint lesions of this stage include osteomyelitis, hypertrophic or gummatous periostitis, and chronic tibial osteitis, which may lead to "saber shin" deformities. Bilateral hypertrophy of the nasal processes of the maxilla produces the rare but characteristic "goundou," which obstructs the nasal passages and, if not treated with early antibiotic therapy, may require surgery. Another otorhinolaryngologic complication is "gangosa," characterized by nasal septal or palatal perforation. Although neurologic and ophthalmologic involvement is not a universally accepted phenomenon, reports of macular atrophy and culture-positive aqueous humor suggest that yaws may exhibit neuroophthalmologic manifestations similar to those of venereal syphilis. A less virulent form of the disease, observed in lower-prevalence areas, is termed "attenuated yaws," the cutaneous manifestations of which comprise greasy gray lesions in the skin folds.

Histopathology. *Primary lesions* show acanthosis, papillomatosis, spongiosis, and neutrophilic exocytosis with intraepidermal microabscess formation. A heavy, diffuse, dermal infiltrate of plasma cells, lymphocytes, histiocytes, and granulocytes is observed; unlike the case in syphilis, blood vessels manifest little or no endothelial proliferation (Figs. 22.7and 22.8) (59,60). *Secondary lesions* show the same histologic appearance, resembling condylomata lata in their epidermal changes but differing by virtue of the dermal infiltrate being in a diffuse, as opposed to a perivascular, disposition. The ulcerative lesions of *tertiary yaws* greatly resemble those observed in late syphilis in histologic appearance (60). The spirochetes can be demonstrated in primary and secondary lesions by dark-field examination. Silver stains demonstrate numerous organisms between keratinocytes. Unlike *T. pallidum*, which is found in both epidermis and dermis, *T. pertenue* is almost entirely epidermotropic (60).

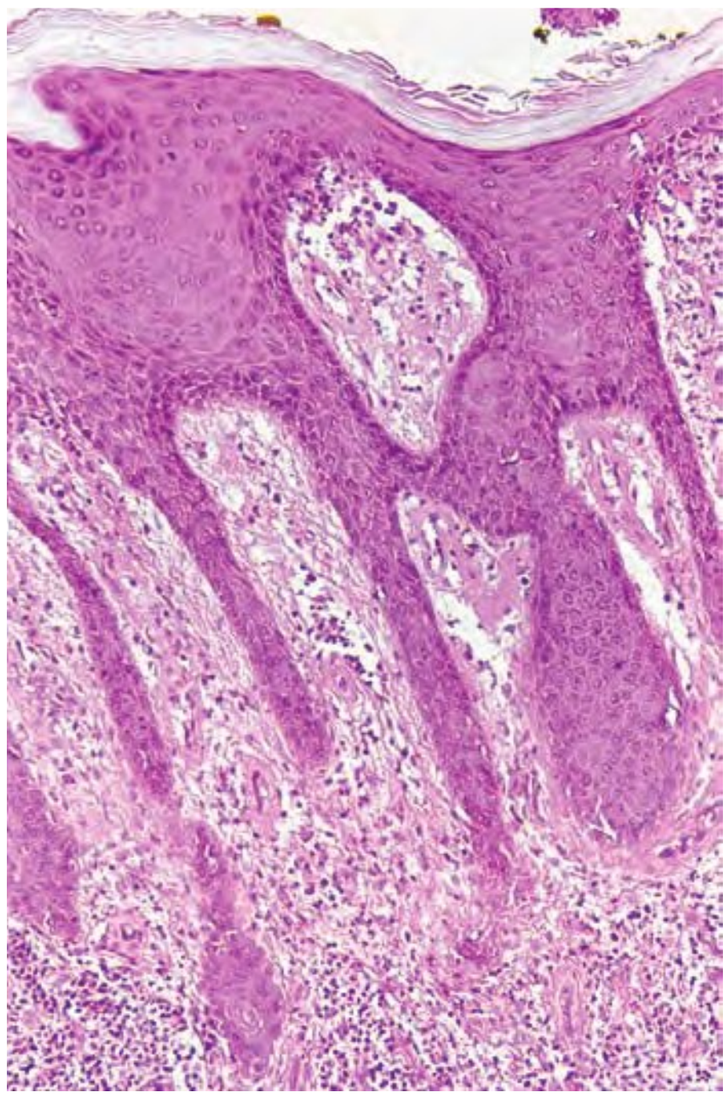

FIGURE 22-7. Yaws, the primary lesion. The biopsy shows a psoriasiform hyperplasia of the epidermis, accompanied by slight spongiosis and an intense lymphohistiocytic and plasmacellular infiltrate in the subjacent corium.

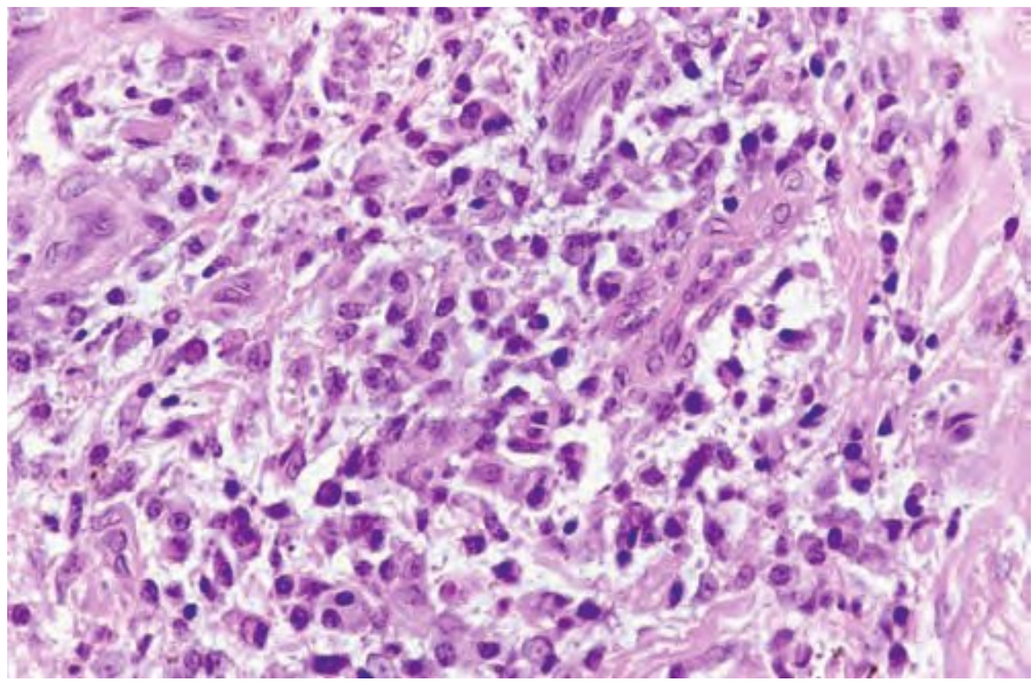

FIGURE 22-8. Yaws, the primary lesion. The biopsy shows an intense angiocentric lymphohistiocytic and plasmacellular infiltrate without the characteristic endarteritis obliterans vascular alterations observed in syphilis.

Differential Diagnosis. The distinction between yaws and syphilis is based on clinical features; although the location of the organism in a skin biopsy may be helpful, no histologic feature or laboratory test absolutely distinguishes the two diseases (61).

Pinta

Unique among the treponematoses, pinta, caused by *T. carateum*, demonstrates only skin manifestations (62). The disorder is endemic to Central America and restricted to the Western hemisphere. It affects no age group preferentially and is the mildest of the treponematoses, with hypopigmentation being the only significant sequela. The incidence of pinta is declining precipitously for unknown reasons. Transmission appears to be from lesion to skin, classically between family members; the ritualistic whipping of diseased adults and unaffected youths is the putative mode of transmission in one aboriginal tribe in the Amazon basin (62).

The *primary lesion* is characterized by an erythematous papule surrounded by a halo and occurs 1 to 8 weeks postinoculation. By direct extension or through fusion of satellite lesions, the primary site may grow to a diameter of 12 cm,

forming an ill-defined erythematous plaque on the legs or other exposed sites. In infants, the primary lesion classically occurs at the sites where the baby was held most closely to the affected mother. The *secondary lesions*, or "pintids," manifest months after inoculation as small, erythematous, scaly papules that coalesce to form psoriasiform plaques. Both primary and secondary lesions are highly infectious. In the tertiary stage, hypopigmented macules are present over bony prominences such as wrists, ankles, and elbows. Symmetric areas of achromia alternating with areas of normal or hyperpigmented skin may result in a mottled appearance. Atrophy and/or hyperkeratosis may be present. An attenuated variant is not described.

Histopathology. *Primary* and *secondary* lesions show a similar morphology—namely, acanthosis with spongiosis and a sparse dermal infiltrate of lymphocytes, plasma cells, and neutrophils disposed about dilated blood vessels (63). Endothelial swelling in the dermal vasculature is inconspicuous (64). Lichenoid inflammation may be present, accompanied by hyperkeratosis, hypergranulosis, basal layer vacuolopathy, and pigmentary incontinence. Increased numbers of Langerhans cells are present in the epidermis (65). Lesions of the *tertiary stage* are hyperpigmented, characterized by a large number of melanophages within the dermis, or depigmented, manifesting complete absence of epidermal melanin. Both lesions show epidermal atrophy and perivascular lymphocytic infiltrates. Organisms are present in all but late, longstanding lesions.

Histogenesis. Electron microscopy reveals absent melanocytes in depigmented lesions of tertiary or late pinta (65).

Endemic Syphilis (Bejel)

Unlike yaws, endemic syphilis, caused by *T. pallidum* subspecies *endemicum*, is largely confined to the arid climates of the Arabian peninsula and the southern border of the Sahara desert (62), whose seminomadic populations term the disease "bejel." Children 2 to 15 years of age constitute the principal reservoir. Infection occurs by skin-to-skin contact or by means of fomites such as communal pipes or drinking vessels.

Primary stage skin lesions are rare and are characterized by erythematous papules or ulcers of the oropharyngeal mucosa or the skin of the nipple of an uninfected mother nursing an infected infant.

More commonly, the initial manifestation is the presence of *secondary-stage* lesions, characteristically multiple, shallow, rather painless ulcers involving lips, buccal mucosa, tongue, fauces, or tonsils. Such lesions may be accompanied by hoarseness due to treponemal laryngitis and/or regional lymphadenopathy. Condylomata lata involving the axillae and anogenital regions are also observed. Rarely, the secondary stage manifests as erythematous, crusted papules, macules, or an annular papulosquamous eruption, which may be accompanied by generalized lymphadenopathy or periostitis.

The *tertiary stage* comprises gummatous lesions of nasopharynx, larynx, skin, and bone, which may progress to ulcers that heal as depigmented, sometimes geographic scars with peripheral hyperpigmentation. Bone and joint involvement may manifest as tibial periostitis, which mimics that of yaws, or as mutilating lesions involving the nasal septum and palate. Ophthalmologic involvement comprises uveitis, chorioretinitis, choroiditis, and optic atrophy; *T. pallidum* has been cultured from intraocular fluid.

Histopathology. Although the pathology of early lesions of endemic syphilis is not well characterized, late lesions are said to show parakeratosis, acanthosis, spongiosis, pigmentary incontinence, and a dermal lymphohistiocytic and plasma cell infiltrate.

Lyme Disease

Background

First described in patients from Lyme, Connecticut, in 1975 (66), Lyme disease is a systemic spirochetosis caused by *Borrelia burgdorferi* and transmitted by the soft ticks of the species *Ornithodorus* (67). Although the disease in the index cases manifested as inflammatory arthritis and central nervous system and cardiac symptoms (68) preceded by cutaneous erythema, manifestations may be protean and perplexing to the clinician. Lyme disease is the most common vector-borne disease in the United States, with roughly 20,000 new cases in 2005 (69). Males are predominantly affected, with a bimodal age peak: children aged 5 to 14 years and adults aged 60 to 65 years; most cases occur between June and August (69). Recurrences after appropriate antimicrobial therapy have been reported, and it appears that most represent second tick bite inoculations as opposed to relapses (70).

Although the tick *Ixodes dammini* is the prototypic vector (67,71), other species of ticks from the genus *Ixodes* can also be infected—namely, *I. ricinus* (72), *I. pacificus,* and *I. scapularis* (73–75). Lyme disease has been reported in 43 states, Europe, elsewhere in North America, Africa, and Asia (73). Infection by multiple different bacterial species transmitted by the same infected tick may occur. Coinfection of ticks and of humans by *Ehrlichia chaffeensis*, the etiologic agent of human granulocytic ehrlichosis, and by *B. burgdorferi* is demonstrable in areas where the two diseases are endemic (76–80). Babesiosis is anther tick-borne infection that can be coexpressed with Lyme disease (78,81). Although it seems counterintuitive, one model suggests that certain animals, such as the lizard *Eumeces fasciatus* (the five-lined skink), can act as a dilutional host, whereby reservoir incompetence can act to reduce vector infection prevalence and the associated risk of human infection (82).

There are three phases of Lyme disease. In stage I disease, hematogenous dissemination from lesions of erythema chronicum migrans to other organs may occur, the effects of which are usually self- limited (83) and include orchitis, splenomegaly, lymphadenopathy, and mild pneumonitis. The two main systems involved in stage II are neural and cardiac (83). The triad of meningitis, cranial neuritis, and radiculoneuritis is characteristic for neural involvement (84); Lyme cerebritis may also occur, and alteration of mental status may be the only initial clinical manifestation (85). Cardiac involvement manifests

mainly as tachycardia and heart blocks, the basis of which is epi- and transmyocarditis. A biopsy of myocardium may show interstitial lymphoplasmacellular infiltrates, with a bandlike endocardial disposition said to be characteristic. A nonneutrophilic myocardial vasculitis has been described. Chronic disease at organ sites where spirochetes persist, most commonly the skin and nervous system in Europe and the musculoskeletal system in North America, constitutes stage III. Lyme arthritis and synovitis are characterized by a migratory oligoarthritis usually involving the knee joint, with the shoulder, wrist, temporomandibular, and ankle joints involved in some cases. Rarely reported is involvement of other sites such as metatarsal heads with edema and soft tissue swelling (86).

Erythema Chronicum Migrans

First described by Arvid Afzelius in 1909 (73), erythema chronicum migrans is the distinctive, albeit not pathognomonic, cutaneous manifestation of stage I Lyme disease in both Europe and the United States and represents the site of primary tick inoculation. Erythema chronicum migrans appears to occur in only roughly half of cases of Lyme disease (69); in the absence of a rash, the diagnosis depends on the demonstration of an antibody response to *B. burgdorferi* in an appropriate clinical setting (87). Unfortunately, patients who are immunosuppressed, such as those with underlying lymphoproliferative diseases, may never mount a detectable antibody response (88). Patients are often unaware of the often painless tick bite (89). The lesion starts as an area of scaly erythema or a distinct red papule within 3 to 30 days after the tick bite, before spreading centrifugally with central clearing after a few weeks, occasionally reaching a diameter of 25 cm (90). The clinical presentation may be atypical by virtue of purpuric, vesicular, or linear lesions. Average lesional duration is 10 weeks in the European variant and 4 weeks in the American variant; in some cases, lesions persist for as long as 12 months. Females are affected more frequently in the European variant than in the American variant. The lesions may be solitary or multiple, the latter reflecting hematogenous dissemination of the spirochete, which may be accompanied by fever, fatigue, headaches, cough, and arthralgias (67).

Histopathology. An intense superficial and deep angiocentric, neurotropic, and eccrinotropic infiltrate predominated by lymphocytes with a variable admixture of plasma cells and eosinophils is the principal histopathology (Fig. 22-9). Plasma cells have been identified most frequently in the peripheries of lesions of erythema chronicum migrans, whereas eosinophils are identified in the centers of the lesions (91). Not infrequently, these florid dermal alterations are accompanied by eczematous epithelial alterations, and some cases exhibit edema of blood vessels with transmural migration of lymphocytes, histiocytes and plasma cells (Fig. 22-9), granulomatous neuritis or vasculitis with luminal thrombosis (personal observation), and interstitial infiltration of the reticular dermis with a concomitant incipient sclerosing reaction. A Warthin-Starry stain may be positive; one study demonstrated spirochetes by this technique in 41% of the cases, with approximately one to two spirochetes, measuring 10 to 25 μm by 0.2 to 0.3 μm, per section (91). Spirochetes have been identified primarily from the advancing border of the lesion. Most patients have elevated immunoglobulin M antibody titers (89).

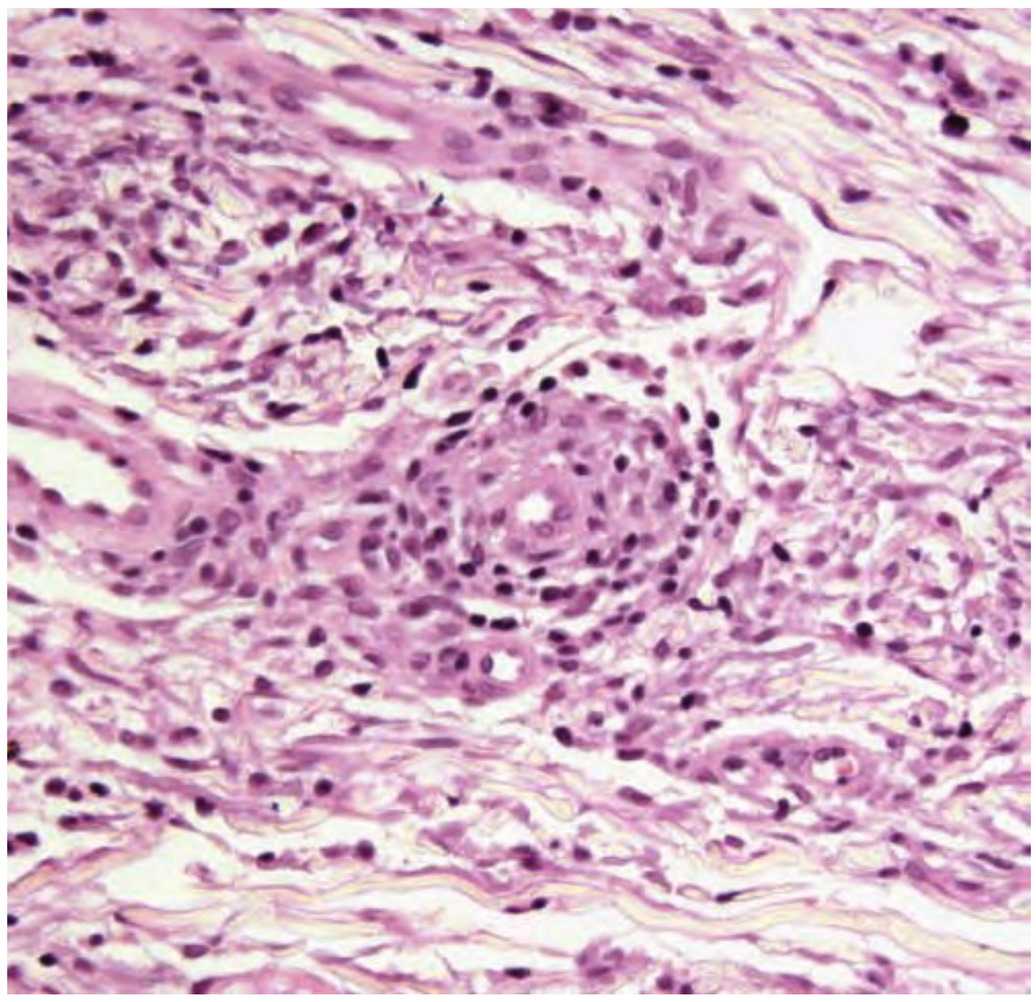

FIGURE 22-9. Erythema chronicum migrans. The central nidus at the inoculation site demonstrates a necrotizing granulomatous vasculitis, whereas the periphery is predominated by an angiocentric lymphohistiocytic vasculopathy, shown here.

Differential Diagnosis. The differential diagnosis includes other causes of delayed hypersensitivity in which potential antigenic stimuli include other forms of arthropod assaults, drugs, and contactants. A similar distribution of the dermal infiltrate is observed in connective tissue disease; however, the presence of tissue eosinophilia along with concomitant eczematous changes is not a feature of the latter. Differentiation from erythema annulare centrifugum may be impossible.

Dermal Atrophying and Sclerosing Lesions as Manifestations of Lyme Disease: Acrodermatitis Chronica Atrophicans

First described in 1883 in Germany and subsequently named by Herxheimer in 1902 (92), acrodermatitis chronica atrophicans usually begins as a diffuse or localized erythema on one extremity with the underlying dermis having a doughy consistency. After several months, the lesions become atrophic. The skin is frequently so thin that vessels and subcutaneous tissue can be easily visualized (93). Appendageal structures disappear, resulting in hair loss and decreased sweat and sebum production. The lesions are located mainly on the upper and lower extremities, frequently around joints, and spare the palms, soles, face, and trunk (93). Sclerosis may predominate in late-stage lesions and take several distinct forms: pseudosclerodermatous plaques over

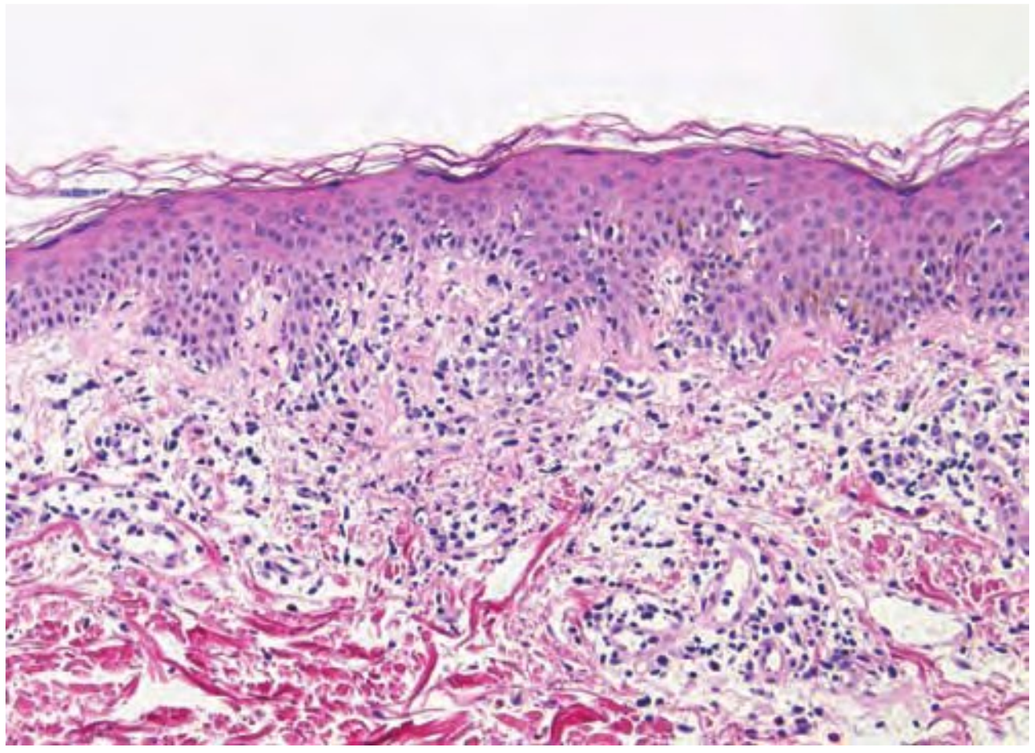

FIGURE 22-10. Acrodermatitis chronica atrophicans. The epidermis shows basket-weave orthokeratosis with a sparse interface dermatitis with lymphocyte tagging along the dermal–epidermal junction. The papillary dermis is edematous, and the reticular dermal collagen fibers exhibit an orientation parallel to the epidermis. A concomitant interstitial lymphohistiocytic infiltrate is found in intimate apposition to the attenuated collagen fibers. This is an incipient or evolving lesion; atrophy follows with loss of the retiform pattern.

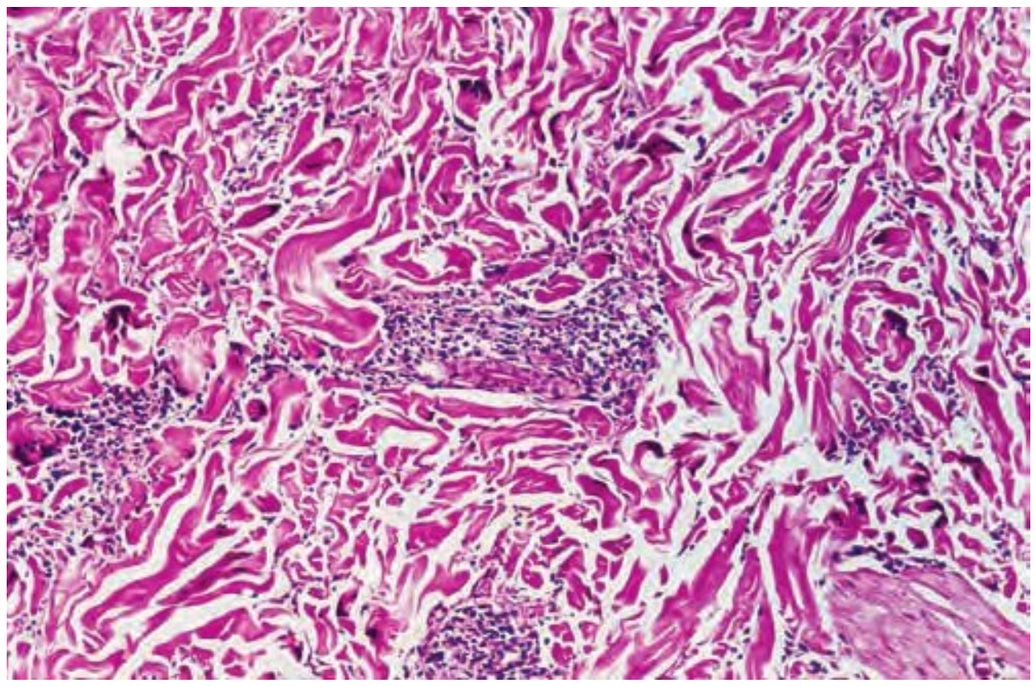

FIGURE 22-11. Borrelia burgdorferi–associated morphea. The dermis exhibits a sclerodermoid tissue reaction characterized by widened hypereosinophilic collagen fibers with loss of the normal fibrillar architecture and an interstitial lymphohistiocytic infiltrate in close apposition to the altered collagen fibers. Special stains reveal spirochetal forms amid the inflammatory infiltrate.

the dorsa of the feet; dense, fibrotic linear bands over ulnar and tibial areas; or localized fibromas overlying joint surfaces (92). Antibodies against *B. burgdorferi* are present in 100% of cases. Patients frequently have an elevated erythrocyte sedimentation rate and hypergammaglobulinemia. Either at the peripheries of lesions or distant from them, anetoderma, lymphocytoma, and morphea have also been described (93).

Histopathology. Within a few months to a year, the epidermis appears atrophic with loss of the rete ridges. There is granular layer diminution, and the epidermis is surmounted by a hyperkeratotic scale. In one study, a sparse interface dermatitis characterized by lymphocyte tagging along the dermal–epidermal junction, as well as basal layer cytolysis, was seen in 41% of cases (Fig. 22-10) (94), resulting in variable postinflammatory pigmentary alterations ranging from leukoderma to hyperpigmentation (92). The papillary dermis appears edematous, with a grenz zone of collagen fibers oriented parallel to the epidermis (95) ranging from a few strands to a wide zone (96), with subsequent eosinophilic homogenization (95). A bandlike lymphocytic infiltrate is found in the mid and upper dermis and in some cases may produce a lichenoid morphology, obscuring the dermal–epidermal junction. Occasionally it extends throughout the cutis and subcutis (94,95). The infiltrate is predominantly in an angiocentric, eccrinotropic, and folliculotropic disposition and comprises mainly lymphocytes and histiocytes (95). Eosinophils, neutrophils, and plasma cells form a minor cell populace (95). The vessels amid the superficial infiltrate appear destroyed (94). Within the infiltrate, there is piecemeal fragmentation of collagen, and elastic tissue is lacking. Beneath the infiltrate, disorganization and destruction of the collagen, along with hyperplasia, fragmentation, and basophilia of the elastic fibers (95), are observed. An end-stage lesion exhibits a characteristic constellation of epidermal atrophy, large dilated dermal vessels, and an attenuated dermis composed of damaged and degenerated collagen and elastic fibers with lipoid phanerosis (95). The collagen may appear homogenized and hypereosinophilic (Fig. 22-11) (95). There is ultimately marked atrophy of adnexae with periadnexal fibrosis.

Histogenesis. Acrodermatitis chronica atrophicans is mainly a stage III (late) cutaneous manifestation of the European variant of Lyme disease; the major vector is *I. racinus* (92), and hence the distribution of the lesion is worldwide, with middle Europe being the epicenter (92). Most North American cases occur in European immigrants; *I. ricinus* is not an inhabitant of North America (92). Immunophenotyping reveals that most of the lymphocytes are of T cell phenotype and that the elastic fibers express HLA-DR (94), suggesting a role for cell-mediated immunity in lesional development.

Other Atrophying and Sclerosing Disorders Associated with Lyme Disease

Atrophoderma of Pasini and Pierini, facial hemiatrophy of Perry-Romberg, lichen sclerosus et atrophicus, eosinophilic fasciitis, and morphea (Fig. 22-11) are among the atrophying and sclerosing disorders of connective tissue that have been associated with *B. burgdorferi* infection based on the positive serology for *B. burgdorferi* in patients with these conditions, the isolation of spirochetal organisms in cultures of the respective skin lesions, and/or their identification in histologic sections (73,74,96,97). In addition, acrodermatitis chronica atrophicans and morphea may coexist in the same patient.

A possible etiologic basis of the sclerosis in all five entities—either as the inciting event (in morphea and eosinophilic fasciitis) or as an end-stage phenomenon (in atrophoderma, facial hemiatrophy, and lichen sclerosus)—may relate to increased production of interleukin-1 mediated by the *B. burgdorferi* spirochete, resulting in enhanced fibroblast production (95). Only progressive facial hemiatrophy will be considered further; all of the conditions are covered elsewhere in this book (see Chapter 10).

Facial hemiatrophy is an apposite term for an atrophying condition of the skin, subcutaneous fat, muscle, and bone involving either one division of the trigeminal nerve or half of the face. Occasionally the entire ipsilateral side of the body may be affected, or the atrophy may first manifest on the trunk or extremities.

Histopathology. A sclerodermoid tissue reaction mimicking morphea is observed, including the presence of adnexal atrophy and subcutaneous fibrosis. The muscles are atrophic, with loss of striations, edema, and vacuolation. Ocular and neurologic complications including iritis, keratitis, optic nerve atrophy, trigeminal neuralgia, and facial palsy may occur (73).

Borrelial Lymphocytoma Cutis

Lymphocytoma cutis is a benign cutaneous lymphoid hyperplasia first described by Spiegler before the end of the nineteenth century and subsequently named lymphocytoma cutis in 1921 by Kaufmann-Wolff. Various triggering factors have been isolated, such as drugs, contactants, and infections, suggesting that an excessive immune response to antigen may be its etiologic basis. The *B. burgdorferi* spirochete transmitted by *I. ricinus* has been implicated among the infectious agents. Evidence supportive of a spirochetal etiology of some cases of lymphocytoma cutis includes the identification of spirochete-like structures in mercury- and silver-stained sections of skin biopsies from patients with lymphocytoma cutis in whom increased serum titers of antibodies against *Borrelia* spirochetes are observed (98). The term *borrelioma* has been coined to describe such lesions. Lymphocytoma cutis in association with *B. burgdorferi* infection has the same clinical appearance as lesions arising in other settings—namely, as isolated or multiple violaceous, firm nodules and infiltrative plaques (73). Sites of predilection for the solitary lesions are the earlobes, nipples, and areolae mammae. Lesions of lymphocytoma cutis may occur at sites of erythema chronicum migrans or in patients with stage II Lyme disease. Jessner's lymphocytic infiltrate of skin is considered by some authors to be a form of lymphocytoma cutis and was reported in one patient whose biopsy showed spirochetes (73).

Histopathology. Skin biopsies show superficial and deep angiocentric, neurotropic, and eccrinotropic lymphocytic infiltrates, often accompanied by plasma cells and eosinophils, the former at the periphery and the latter in the center of lesions (91). The dermal alterations may be accompanied by epidermal spongiosis, and some cases show edema of blood vessels, transmural migration of lymphocytes and plasma cells, granulomatous vasculitis with luminal thrombosis, lymphohistiocytic neuritis, and interstitial reticular dermal infiltrates with a sclerosing reaction. Germinal centers may be observed. A florid inflammatory cell infiltrate with granulomatous vasculitis and neuritis is seen at the tick bite punctum, whereas a biopsy taken within 1 cm of the edge shows a pauci-inflammatory process with only sparse mononuclear cells, no eosinophils or plasma cells, and a vasculopathy comprising endothelial swelling and hyperplasia and mural edema accompanied by mucinosis (99). Biopsies taken between the center and edge show superficial and deep perivascular lymphocytic, plasmacellular, and eosinophilic infiltrates with variable eczematous alterations. Although spirochetes have been identified in the lesional border in only 40% of cases (91), most patients manifest elevated immunoglobulin M antibody titers (74), and we therefore rely heavily on serology to make the diagnosis. Others hold that the diagnosis at this stage is largely a clinical one due to the incidence of false-positive and false-negative results (100); the sensitivity and specificity of confirmatory molecular tests are not optimal, and culture is insensitive (101). The background high seropositivity rates in healthy patients in endemic and nonendemic areas have prompted a two-tiered approach through which seropositive patients undergo a subsequent and more specific Western blot analysis (102,103). Meta-analysis of molecular methods shows that assays of skin and synovial fluid have the highest sensitivities and specificities; plasma and cerebrospinal fluid assays are less accurate (101). Quantitative polymerase chain reaction of erythema chronicum migrans lesions shows positivity in up to 80% of cases, with the mean number of spirochetes in a 2-mm biopsy specimen ranging from 10 to 11,000; larger numbers of spirochetes correlate with smaller lesions and shorter duration of skin symptomatology (104). Molecular tests for Lyme disease are reserved as complementary or confirmatory tools for cases in which the index of suspicion is high (101).

Differential Diagnosis. The clinical differential diagnosis encompasses other forms of annular erythema (105). Other causes of lymphocytoma cutis should be considered, such as drug therapy (106) or other infections (e.g., herpetic or mycobacterial). A well-differentiated lymphocytic lymphoma and chronic lymphocytic leukemia should be excluded because both may mimic the diffuse type of lymphocytoma cutis. When eosinophils and plasma cells are present and when there are germinal centers, the distinction from malignant lymphoma (apart from marginal zone lymphoma) is less challenging.

Other arthropod assaults, drug hypersensitivity, contact reactions, and connective tissue diseases such as lupus erythematosus, scleroderma, morphea, Sjögren's syndrome, mixed connective tissue disease, and relapsing polychondritis can mimic Lyme disease. Tissue eosinophilia and epidermal changes help to discriminate Lyme disease from connective tissue disease, but differentiation from erythema annulare centrifugum is more problematic. Tissue necrosis at the primary inoculation site of Lyme disease can mimic a brown recluse spider bite (107).

Histogenesis. Most ticks become infected with *B. burgdorferi* by feeding on small animals, in particular the white-footed

mouse. *B. burgdorferi* is a long, narrow spirochete with flagella (108). It has at least 30 different proteins, including two major outer-surface proteins—Osp A and Osp B, which elicit antibody responses late in the course of the disease (108). It has been suggested that phagocytosis of the spirochete by macrophages leads to two different mechanisms of degradation: a phagolysosomal process, which may lead to major histocompatibility class (MHC) class II–restricted antigen processing, and cytosolic degradation, which leads to MHC class I–restricted antigen presentation. This disparity may in part explain the variable immunologic aspects of Lyme disease (109).

CHAPTER 23

Molly Hinshaw
B. Jack Longley

Fungal Diseases

Fungi are eukaryotic protists that are distinguished from plants by their lack of chlorophyll (1). The Greek word *mycoses* means "fungus" and was first penned by R. Virchow in 1856 to describe infections by this group of organisms. In the past, bacterial infections, lymphoma, and other disorders have also been termed *mycoses* despite a lack of relation to fungi. Actinomycosis, botryomycosis, and erythrasma are examples of bacterial diseases that have historically been discussed with fungal diseases. These entities are covered in Chapter 21. Protothecosis is a cutaneous infection by algae of the genus *Prototheca* and will continue to be included in this chapter because there is no separate chapter for infections by algae.

Defining terminology in fungal diseases aids comprehension and diagnostic consistency (Table 23-1). *Hyphae* are elongated filamentous forms of fungi that usually form an intertwining mass called a *mycelium*. Septate hyphae give rise to arthrospores by asexual reproduction. Frequently, rounded, boxlike, or short cylindrical arthrospores can be identified. *Yeasts* are single-celled, usually rounded fungi that reproduce by budding (blastospore formation). Yeast cells and their progeny may adhere to one another and form chains or *pseudohyphae* that may also form mycelia; thus, they may be difficult to distinguish from true hyphae by light microscopy. *Dematiaceous fungi* are fungi that bear melanin-like pigment in their walls. *Tinea* is a clinical term that describes superficial fungal infections of the skin; it is usually modified with an anatomic or other term to describe the location or color of the infection. The *dermatophytes* are fungi that were originally classified by Sabouraud (2) and redefined by Emmons (3), including the three genera *Microsporum*, *Trichophyton*, and *Epidermophyton*. Therefore, *dermatophytosis* is not an appropriate histologic diagnostic term unless a definite assignment of an organism to one of these three genera of dermatophytes can be made. *Dermatomycosis* refers to any fungal infection of the skin and may be caused by dermatophytes, yeast, or other fungi, including those that do not usually cause cutaneous disease.

The primary cutaneous fungal pathogens can be separated into two groups: those that tend to cause superficial infections and those that cause deep infections. A third group of cutaneous fungal pathogens are those that usually cause systemic disease and only secondarily involve the skin. The basic pattern of cutaneous infection is relatively uniform within each of these three groups. The degree of inflammatory response to these three categories of fungal infection, however, varies based on a number of factors, particularly host immune status. For example, infections with organisms causing superficial dermatomycoses, such as the dermatophytes, *Candida* sp., *Malassezia* (*Pityrosporum*) *furfur*, and *Cladosporium* (*Exophiala* or *Phaeoannellomyces*) *werneckii*, are generally characterized by hyphae or pseudohyphae and sometimes yeast cells in the keratin layer of the epidermis and in follicles. The variable intensity of the tissue reaction in the epidermis and follicular epithelium ranges from almost no response to a very mild focal spongiosis to a more exuberant or chronic spongiotic-psoriasiform pattern. Superficial fungal infections may provoke a superficial lymphocytic or a mixed dermal inflammatory infiltrate. Organisms causing superficial dermatomycosis are not found in the dermis except in the case of follicular rupture.

Deep cutaneous fungal infections typically show a mixed dermal inflammatory cell infiltrate that is often associated with pseudoepitheliomatous hyperplasia and occasionally with dermal fibrosis. Primary cutaneous aspergillosis, chromomycosis, phaeohyphomycosis, eumycetoma, rhinosporidiosis, and lobomycosis are examples of fungi that infect the deeper cutaneous tissues.

Incidental cutaneous infections by fungi that usually primarily involve other organs, such as blastomycosis or coccidioidomycosis, typically show a pattern similar to that seen with the deep primary cutaneous fungi: a mixed dermal infiltrate with multinucleated giant cells associated with pseudoepitheliomatous hyperplasia. However, a few organisms such as *Histoplasma* and *Lobo̧a loboi* are more likely to be associated with epidermal thinning than with hyperplasia. Other systemic fungal infections show characteristic tissue reaction patterns. For example, disseminated candidiasis has prominent microabscess formation, cryptococcosis has a gelatinous or granulomatous reaction pattern, and zygomycosis and aspergillosis have a tendency for vascular invasion and infarction.

Multiple special stains highlight certain fungal elements. These techniques can be helpful especially when the overall histologic pattern is suspicious for a fungal infection but fungi are not apparent on hematoxylin and eosin (H&E)-stained sections. The periodic acid-Schiff (PAS) reaction stains fungi red and can be used with diastase (PAS-D), which clears the tissue of glycogen granules that may be mistaken for fungal spores. Fungi stain positively with PAS-D because their walls contain cellulose

TABLE 23-1 Terminology of Fungi

Term	Definition	Example
Dermatophyte	Imperfect fungi	Trichophyton, Microsporum, Epidermophyton
Dermatomycosis	Any fungal infection of the skin caused by dermatophytes, yeast, or fungi, including those that do not usually cause disease. Dermatomycoses may be superficial or deep.	
Mold	Filamentous structural morphology of fungus	Dermatophytes, chromomycosis
Arthrospores	Asexual fungal spore formed by hyphal segmentation	Dermatophytes
Hyphae	Elongated filamentous forms of fungi	Dermatophytes
Mycelium	Intertwining mass of hyphae	
Yeast	Round to oval fungal forms that reproduce by budding or blastogenesis	Candida, Cryptococcus, Malassezia
Blastoconidia	Daughter cells of parent yeast	
Pseudohyphae	Chains of yeastlike cells that resemble hyphae	Candida sp.
Dematiaceous fungi	Mold or yeast with melanin pigment in their walls	Phaeohyphomycosis, chromomycosis
Sporangia	Spherule containing endospores	Coccidioides imitis
Sporangioblasts	Another term for endospores	Rhinosporidium seeberi
Grains	Dense accumulations (microcolonies) of fungi or bacteria	Eumycetoma
Tinea	Clinical term to describe superficial fungal infections of the skin	Facei, cruris, pedis, manus
Dimorphic	Fungus that grows in more than one form (mold, yeast, sclerotic body, sulfur grains, spherules with endospores, etc.)	Histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidiomycosis

and chitin, both of which are rich in neutral polysaccharides and diastase resistant. Gomori methenamine silver (GMS) nitrate stains fungi black and is also useful. Giemsa, Gram, silver, Fontana-Masson, mucicarmine, Alcian blue, India ink and acid-fast stains also highlight various fungal elements in other primary or secondary cutaneous fungal infections.

DERMATOPHYTOSIS

Dermatophytes are a group of molds that invade and consume keratin by generating proteases (4). They originally came from soil where they lived on keratinaceous debris but ultimately were picked up by animals and humans to become the pathogens known today (5,6).

Three genera of imperfect fungi comprise the dermatophytes: *Epidermophyton*, *Microsporum*, and *Trichophyton*. More than 40 species exist, although many are not pathogenic to humans. Dermatophytes may be grouped according to their natural habitat as anthropophilic, zoophilic, and geophilic, with primary reservoirs of infection in humans, animals, and soil, respectively (5). Fungi in all three categories may cause human infections. In immunocompetent hosts, the dermatophytes cause only superficial infections of the epidermis, hair, and nails. *Epidermophyton* sp., as the name suggests, infect mainly the epidermis, although occasionally the nails are involved. *Microsporum* sp. infect the epidermis and hair, while *Trichophyton* sp. may infect the epidermis, hair, and nails.

Clinically, fungal infections of seven anatomical regions are commonly recognized: tinea capitis (including tinea favosa or favus of the scalp), tinea faciei, tinea barbae, tinea corporis (including tinea imbricata), tinea cruris, tinea of the hands and feet, and tinea unguium (Table 23-2).

Tinea capitis is dermatophytosis of the skin and hair of the scalp. Clinically, scale crust and hairs that are broken off either at the level of the scalp or slightly above it are often seen. In the United States, *Tricophyton tonsurans* is the most common pathogen of this anatomic site where only broken-off hairs (black-dot ringworm) are seen in some patients and a marked inflammatory reaction in others. *Tricophyton schoenleinii* causes *favus*, but favus may also rarely be caused by other *Trichophyton*. *Microsporum audouinii*, *Microsporum canis*, and much less commonly other *Microsporum* sp. may also cause tinea capitis. *M. canis* is zoophilic and therefore tends to cause a more inflammatory

TABLE 23-2 Common Causal Dermatophytes by Anatomic Regions

Clinical diagnosis	Causal organisms
Tinea capitis	T. tonsurans (black dot), T. violaceum (black dot), T. schoenlenii (favus), M. canis
Tinea faciei	T. verrucosum, T. mentagrophytes, T. rubrum
Tinea corporis	T. rubrum, T. mentagrophytes, E. floccosum, T. concentricum
Tinea manus	T. rubrum
Tinea pedis	T. rubrum, T. mentagrophytes, E. floccosum
Tinea unguium	T. rubrum, T. mentagrophytes (vesicobullous), E. floccosum

response than *M. audouinii*, which is anthropophilic; both show a band of bright green fluorescence in the hair under a Wood light. A severe inflammatory boggy plaque, called *kerion Celsi*, may result from infection with zoophilic dermatophytes such as *M. canis*. *Trichophyton* sp. other than *T. schoenleinii*, which shows subtle pale green fluorescence along the length of the hair, do not fluoresce in a Wood light.

Favus is a severe tinea capitis usually caused by *T. schoenleinii*, although a similar clinical picture may occasionally be seen with other fungi. Favus affects mainly the scalp, where it produces inflammation with formation of perifollicular hyperkeratotic crusts called *scutula*. Destruction of the hair occurs relatively late in the infection. The lesions may heal with scarring and permanent alopecia.

Tinea faciei is a fungal infection of the glabrous skin of the face characterized by a persistent eruption of red macules, papules, and patches, the latter of which may show an arcuate border. It is caused usually by *Tricophyton rubrum* and occasionally by *Tricophyton mentagrophytes* or *T. tonsurans* (7).

Tinea barbae is a fungal infection limited to the coarse hair-bearing beard and mustache areas of men. Tinea barbae may be caused by *T. mentagrophytes* but usually is due to *Trichophyton verrucosum* (*faviforme*), an infection also often referred to as *cattle ringworm* because it is usually contracted from cattle. Both *T. mentagrophytes* and *T. verrucosum* are zoophilic and typically cause a kerion-like, boggy, nodular inflammatory infiltration (8).

Tinea corporis is a dermatophytosis of glabrous skin most commonly caused by *T. rubrum* followed by *M. canis* and *T. mentagrophytes*. In cases caused by *T. rubrum*, large erythematous patches with central clearing and an arcuate or polycyclic scaly border are seen. In infections with *M. canis*, tinea corporis is more inflammatory, and annular lesions with raised papulovesicular borders and central clearing are common. *T. mentagrophytes* typically produces a few annular lesions with little or no central clearing. *T. verrucosum* may occasionally cause tinea corporis appearing as grouped follicular pustules referred to as *agminate folliculitis* (8). The term *Majocchi's granuloma* describes a nodular granulomatous perifolliculitis caused by rupture of an infected follicle, typically of the lower extremity. Majocchi's granuloma is often associated with tinea pedis or onychomycosis and therefore is commonly caused by *T. rubrum*.

Tinea cruris, usually caused by *T. rubrum* and occasionally by *T. mentagrophytes* or *Epidermophyton floccosum*, shows sharply demarcated erythematous patches or thin plaques in the groin. The infection may spread to the perineal and/or perianal regions as well as the scrotum.

Tinea of the feet and hands (tinea pedis et manus) is the most common form of dermatophyte infection and is usually caused by *T. rubrum*, *E. floccosum*, or *T. mentagrophytes*. Tinea pedis may present clinically as interdigital maceration, plantar (i.e., "moccasin" scale), or vesiculobullous lesions. *T. rubrum* is anthropophilic and causes relatively noninflammatory scaling on the plantar feet. Infections with *T. mentagrophytes* tend to cause inflammatory, vesicobullous tinea pedis.

Tinea unguium specifically refers to a dermatophyte infection of the nail whereas onychomycosis is a nail infection due to any fungi including dermatophytes, *Candida*, or a nondermatophyte (9). Up to 90% of mycotic toenail infections and 50% of fingernail infections are caused by dermatophytes, but yeasts (especially *Candida albicans*) and nondermatophyte molds are also implicated (10). Criteria for diagnosing nondermatophyte onychomycosis have been offered as (a) the presence of hyphae in the infected subungual debris, (b) the persistent failure to culture recognized dermatophytes, and (c) positive cultures of a nondermatophyte (11).

The four clinical types of onychomycosis include distal and lateral subungual onychomycosis (DLSO), superficial white onychomycosis (SWO), proximal subungual onychomycosis (PSO), and *Candida* infections of the nail. In general, hyperkatosis and onycholysis are common clinical presentations of onychomycosis. DLSO is the most common form found in all patients, including those with HIV, and is caused by dermatophytes, usually *T. rubrum* (12). SWO is caused primarily by *T. mentagrophytes* and is more commonly seen in HIV. PSO is typically caused by *T. rubrum* and is rare in the general population but can be a presenting sign of HIV. PSO in AIDS is often caused by *T. mentagrophytes* (13). *Candida* nail infections present as paronychia, hyperkeratosis, or onycholysis. Nondermatophytes implicated in onychomycosis include *Candida* sp., *Scytalidium* (*Hendersonula*), and *Aspergillus* (most commonly *Aspergillus niger*). Fungi thought to be contaminants in nail cultures in all but the immunosuppressed include *Cladosporium*, *Alternaria*, *Fusarium*, *Acremonium*, and *Scopulariopsis* (14). There is considerable controversy about the clinical significance of nondermatophyte fungi in nail cultures when a dermatophyte is also identified on culture.

Histopathology. In *tinea capitis* and *tinea barbae*, infection of follicles usually starts with colonization of the stratum corneum of the perifollicular epidermis (Fig. 23-1). Hyphae extend down the follicle and invade the hair, penetrating the cuticle first in the subcuticular portion of the cortex, just under the hair surface, and then more deeply in the hair cortex, extending to the upper limit of the zone of keratinization. Rounded and boxlike arthrospores may be found mainly

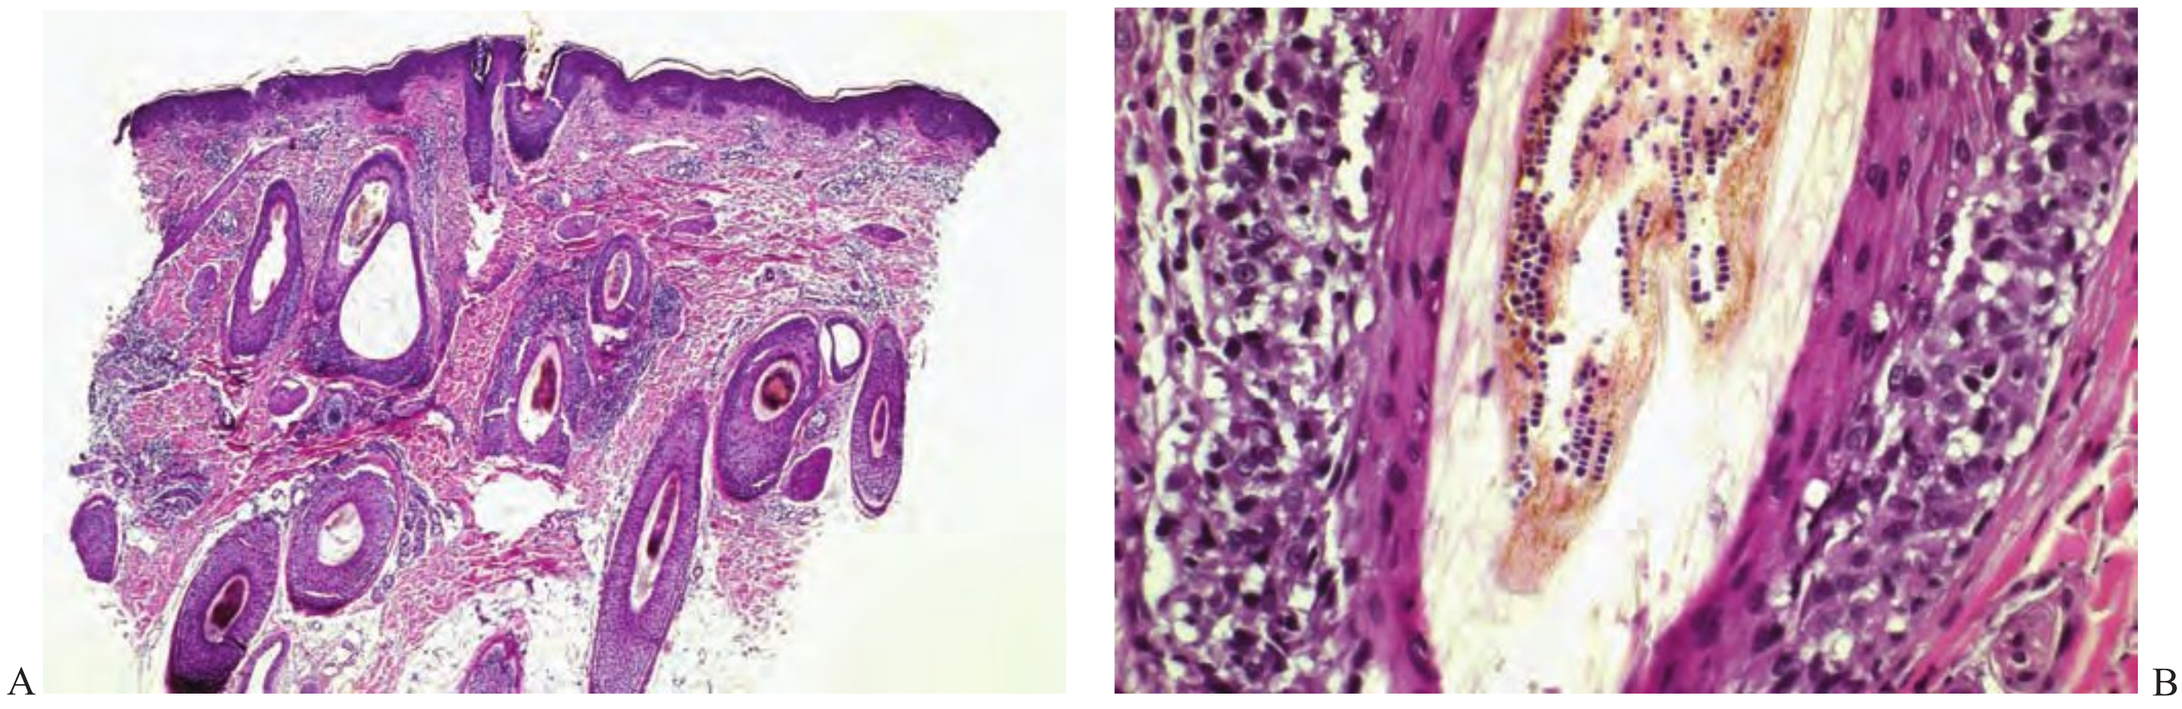

FIGURE 23-1. Tinea capitis. A: H&E stain shows arthrospores and hyphal elements in most follicles. A lymphohistiocytic, perifollicular infiltrate is present. B: H&E stain shows arthrospores in endothrix infection.

within the hair shaft in *endothrix* infections or penetrating the surface of the hair shaft and forming a sheath around it in *ectothrix* infections. *Endothrix* infections are caused by *T. tonsurans* or *Trichophyton violaceum*. Except for *T. schoenleinii*, which causes favus, dermatophytes infecting hair shafts cause *ectothrix* infections. Although hyphae invade the shafts in both types of infections, they may not be evident in a hair plucked from an endothrix infection because the more superficial hyphae rapidly break up into arthrospores and destroy the keratin of the hair shaft. When plucked, the weakened shaft typically breaks at a relatively superficial point so that only the arthrospores are seen. The dermis, which rarely contains fungi, shows a perifollicular mononuclear cell infiltrate of varying intensity. In addition to a chronic inflammatory infiltrate, multinucleated giant cells may be present in the vicinity of disrupted or degenerated hair follicles. In kerion Celsi, there is a pronounced inflammatory tissue reaction to the fungi with follicular pustule formation and interfollicular neutrophilic infiltration as well as a marked chronic inflammatory infiltrate surrounding the hair follicles. In cases with a severe inflammatory reaction, fungi may be difficult to identify either by microscopic examination or by culture but may be demonstrated by using fluorescein-labeled *T. mentagrophytes* antiserum that cross-reacts with antigens of all dermatophyte species.

In *tinea of the glabrous skin*, which includes tinea faciei, tinea corporis, tinea cruris, and tinea of the feet and hands, fungi occur only in the horny layers of the epidermis and do not invade hairs and hair follicles. Two exceptions to this are *T. rubrum* and *T. verrucosum*, both of which may invade hairs and hair follicles, causing a subsequent perifolliculitis.

The number of fungi seen in the horny layer varies greatly but may be so small that they may be challenging to find even when treated with the PAS reaction or stained with GMS. Occasionally, they are present in sufficient numbers that even in sections stained with H&E, they can be recognized as faintly basophilic, refractile structures (Fig. 23-2). Their identification in H&E-stained sections may be aided by lowering the microscope condenser, which enhances the refractility of the

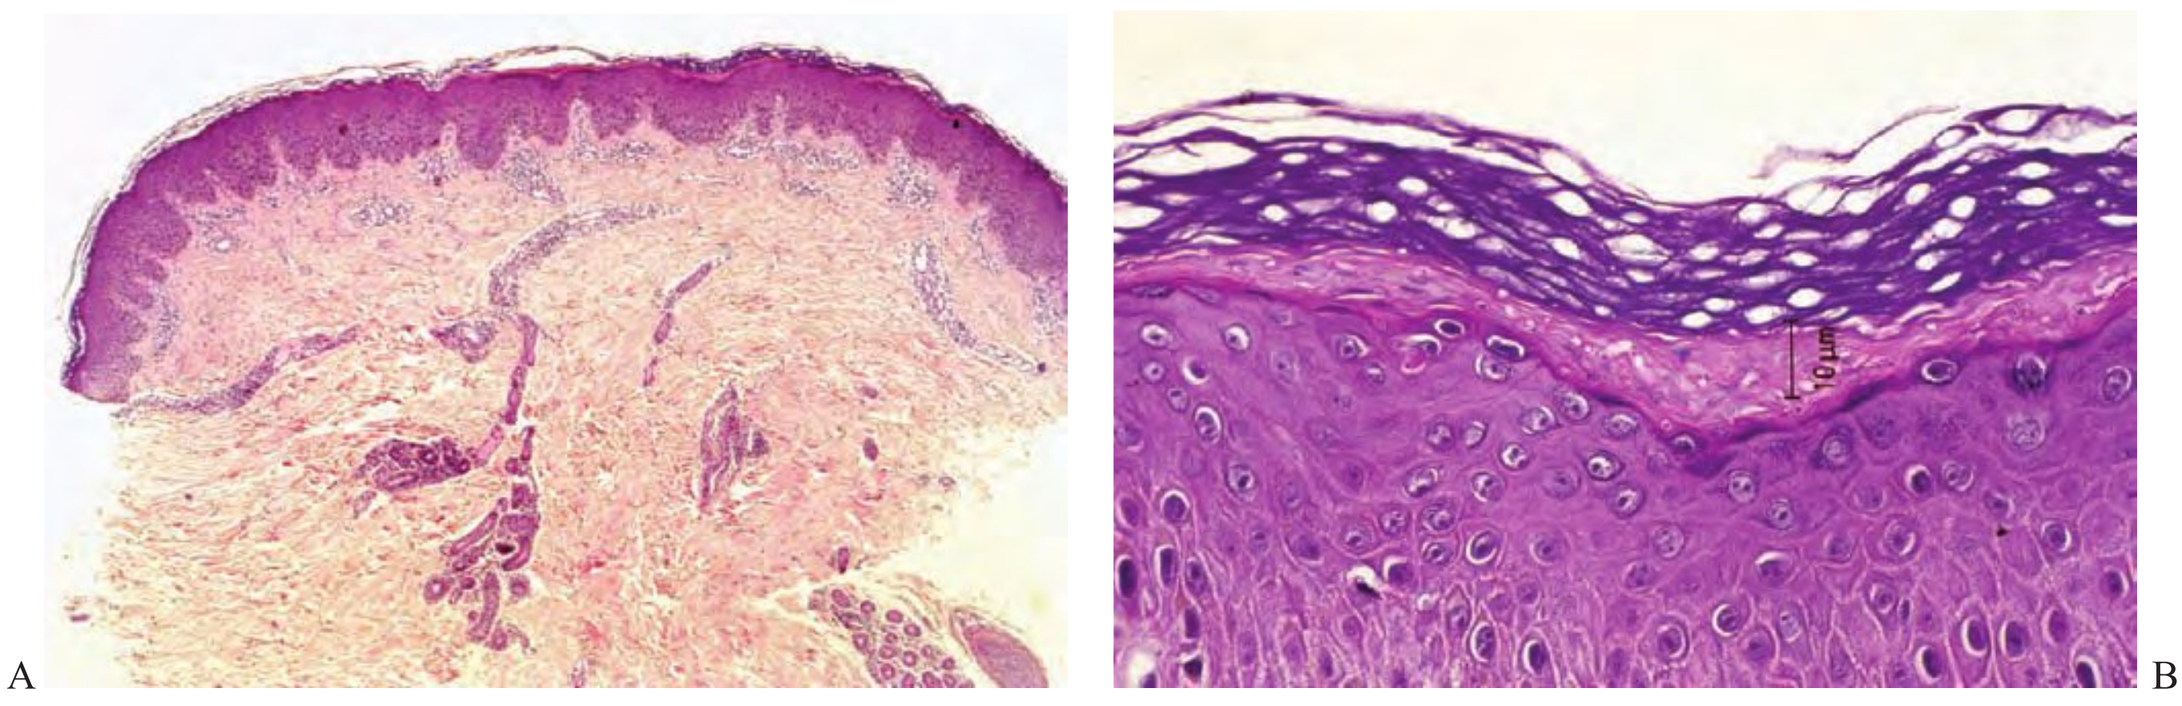

FIGURE 23-2. Tinea corporis. A: H&E stain shows a superficial perivascular, predominantly lymphoid infiltrate with mild psoriasiform epidermal hyperplasia and compact hyperkeratosis. B: Cross-sections of refractile hyphae are visible as clear spaces in parakeratotic stratum corneum (H&E stain).

fungal elements. In infections with *Microsporum* or *Trichophyton*, only hyphae are seen, and in infections with *E. floccosum*, chains of spores are present. If fungi are present in the horny layer, they usually are "sandwiched" between two zones of cornified cells, the upper being orthokeratotic and the lower consisting partially of parakeratotic cells. This "sandwich sign" should prompt the performance of a stain for fungi for verification. The presence of neutrophils in the stratum corneum is another valuable diagnostic clue (15). In the absence of demonstrable fungi, the histologic picture of fungal infections of the glabrous skin is not diagnostic. Depending on the degree of reaction of the skin to the presence of fungi, the histologic features of an acute, subacute, or chronic spongiotic dermatitis can be seen (see Chapter 9).

On staining with the PAS reaction or GMS, nodular perifolliculitis, or Majocchi's granuloma, caused by *T. rubrum* shows numerous hyphae and spores within hairs and hair follicles and in the inflammatory infiltrate of the dermis. Fungal elements may also reach the dermis through a break in the follicular wall. Although the spores present within hairs or hair follicles measure about 2 μm in diameter, those located in the dermis, especially within multinucleated giant cells, may be larger measuring up to 6 μm (16). The dermal process shows an inflammatory infiltrate of lymphoid cells, macrophages, epitheloid cells, and multinucleated giant cells as well as central necrosis and occasionally suppuration.

The agminate folliculitis caused by *T. verrucosum* (*faviforme*) shows hyphae and spores within hairs and hair follicles in PAS-stained sections (10). However, the dermis around the hair follicles contains no fungi. Depending on the severity and stage of the inflammatory reaction, either an acute or a chronic inflammatory infiltrate is predominant around the hair follicles in the dermis. In well-established lesions, the inflammatory infiltrate contains many plasma cells, microabscesses, and small aggregates of foreign body giant cells (8).

In *tinea unguium*, nail plate biopsy is potentially the method of choice for diagnosis. Although microscopic examination of potassium hydroxide mounts or cultures of nail fragments often establish a diagnosis of onychomycosis, false-negative results may occur if the infection is in the nail bed or situated in the lower portion of the nail plate. Nail clippings or nail biopsy taken by punch technique or scalpel under local anesthesia will often reveal the fungi on PAS-D–stained sections (17). By far, *T. rubrum* is the most common causal fungus; occasionally, *T. mentagrophytes* is present.

Three histologic patterns are common in nail plate biopsies of onychomycosis (18). In superficial infections, mycelial elements, best visualized with PAS or GMS, are seen in the outer layer of the nail plate. Routine histologic examination of nail plate with PAS staining is a simple, rapid, and sensitive test for fungal elements (19). The second histologic pattern is seen in clinical onycholysis when PAS stained sections of nail plate reveal slender, uniform mycelial elements invading the undersurface of the nail plate (Fig. 23-3). In this pattern, there may also be an inflammatory infiltrate of lymphocytes and neutrophils as well as serum and keratotic debris on the undersurface of the nail plate. Biopsies of nail bed or nail fold epithelium may reveal psoriasiform hyperplasia, spongiosis, and hyperkeratosis, making the identification of fungal elements critical to the correct diagnosis. The third common histologic pattern is seen in *Candida* infections, where hyphal forms are seen on the undersurface of the nail plate; this will be discussed in a later section (see page 599). Other less typical morphologic patterns of onychomycosis may signal an infection with unusual fungi or partial treatment with antimycotics.

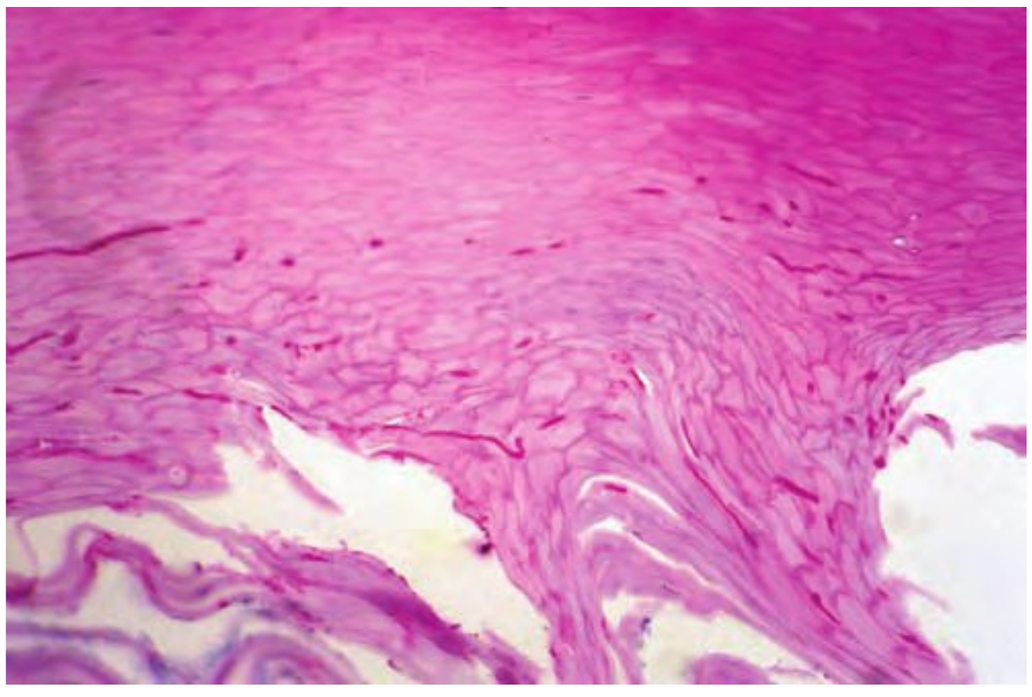

FIGURE 23-3. Tinea unguium. Slender, uniform mycelial elements can be seen within this parakeratotic nail plate (PAS-D stain).

Polymerase chain reaction (PCR) amplification of DNA from nail plate biopsies has been studied for the diagnosis of onychomycosis but is not routinely used (20). PCR is very senstitive and could be used to identify individual species of fungus, but ubiquitous contaminant fungi may cause false-positive results, meaning that fungal cultures or histologic confirmation of true hyphal or yeast forms might still be needed.

Pathogenesis. Debate exists regarding factors that predispose individuals to onychomycosis. Trauma is thought to facilitate the entry of fungus into the nail. Epidemiologic data suggests that the incidence increases with age, but other factors such as humidity, local trauma, and common living/bathing sites have been variably significant predictors (21).

In *favus*, mainly hyphae and only a few spores of *T. schoenleinii* are present in the stratum corneum of the epidermis around and within hairs. The scutula (see page 593) consist of compact keratin as well as parakeratotic cells, exudate, and inflammatory cells intermingled with segmented hyphae and spores that are well preserved at the periphery but appear degenerated and granular in the center of the scutula (22). In active areas, the dermis shows a pronounced inflammatory infiltrate containing multinucleated giant cells and many plasma cells in association with degenerating hair follicles. In old areas, there is fibrosis and an absence of pilosebaceous structures.

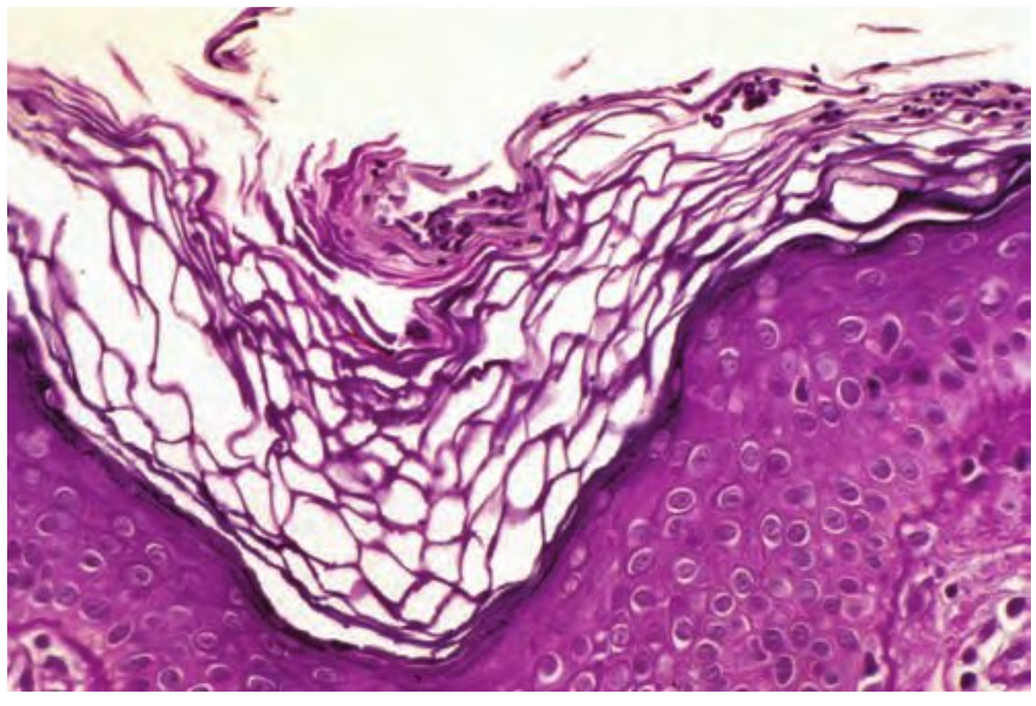
DISEASES CAUSED BY MALASSEZIA FURFUR

Malassezia is a genus of lipophilic yeast that causes two dermatoses: pityriasis versicolor and *Malassezia* (*Pityrosporum*) folliculitis (23). The frequently used term *tinea versicolor* is not accurate, because *Malassezia* are not dermatophytes. In pityriasis versicolor, multiple round to oval pink to light brown patches with fine white scale are seen primarily on the trunk and upper extremities. Gentle scraping of the patches will induce the scale that can be examined for spores and short hyphae. *Malassezia (Pityrosporum)* folliculitis is a pruritic eruption of 2- to 4-mm acneiform follicular papules and pustules on the trunk and arms of otherwise healthy hosts (24). Potassium hydroxide (KOH) examination of the lesions will reveal only yeast forms.

In addition to these two diseases, *Malassezia* has been found in lesions of seborrheic dermatitis, atopic dermatitis, neonatal cephalic pustulosis, and confluent and reticulated papillomatosis of Gougerot and Carteaud (25,26). Seborrheic dermatitis, for example, has been reported to respond to antifungal therapy and has been associated with heavy colonization by *M. furfur.* However, these observations and their interpretation are controversial, and it has not been definitively established that *M. furfur* contributes to the pathogenesis of seborrheic dermatitis (27,28).

Histopathology. In contrast to other fungal infections of the glabrous skin, the horny layer in lesions of *pityriasis* (*tinea*) *versicolor* contains abundant fungi, which can often be visualized in sections stained with H&E as faintly basophilic structures. *Malassezia* (*Pityrosporum*) is present as a combination of both hyphae and spores (Fig. 23-4), the light microscopic appearance of which is often referred to as *spaghetti and meatballs.* The inflammatory response in pityriasis versicolor is usually minimal, although there may occasionally be slight hyperkeratosis (29), slight spongiosis, or a minimal superficial perivascular lymphocytic infiltrate.

Histogenesis. The names *M. furfur, Pityrosporum orbiculare,* and *Pityrosporum ovale* are often used interchangeably probably because these are identical in culture (30). *In vivo, M. furfur* becomes dimorphous by forming numerous true septate hyphae in addition to spores. The organism then becomes pathogenic (23).



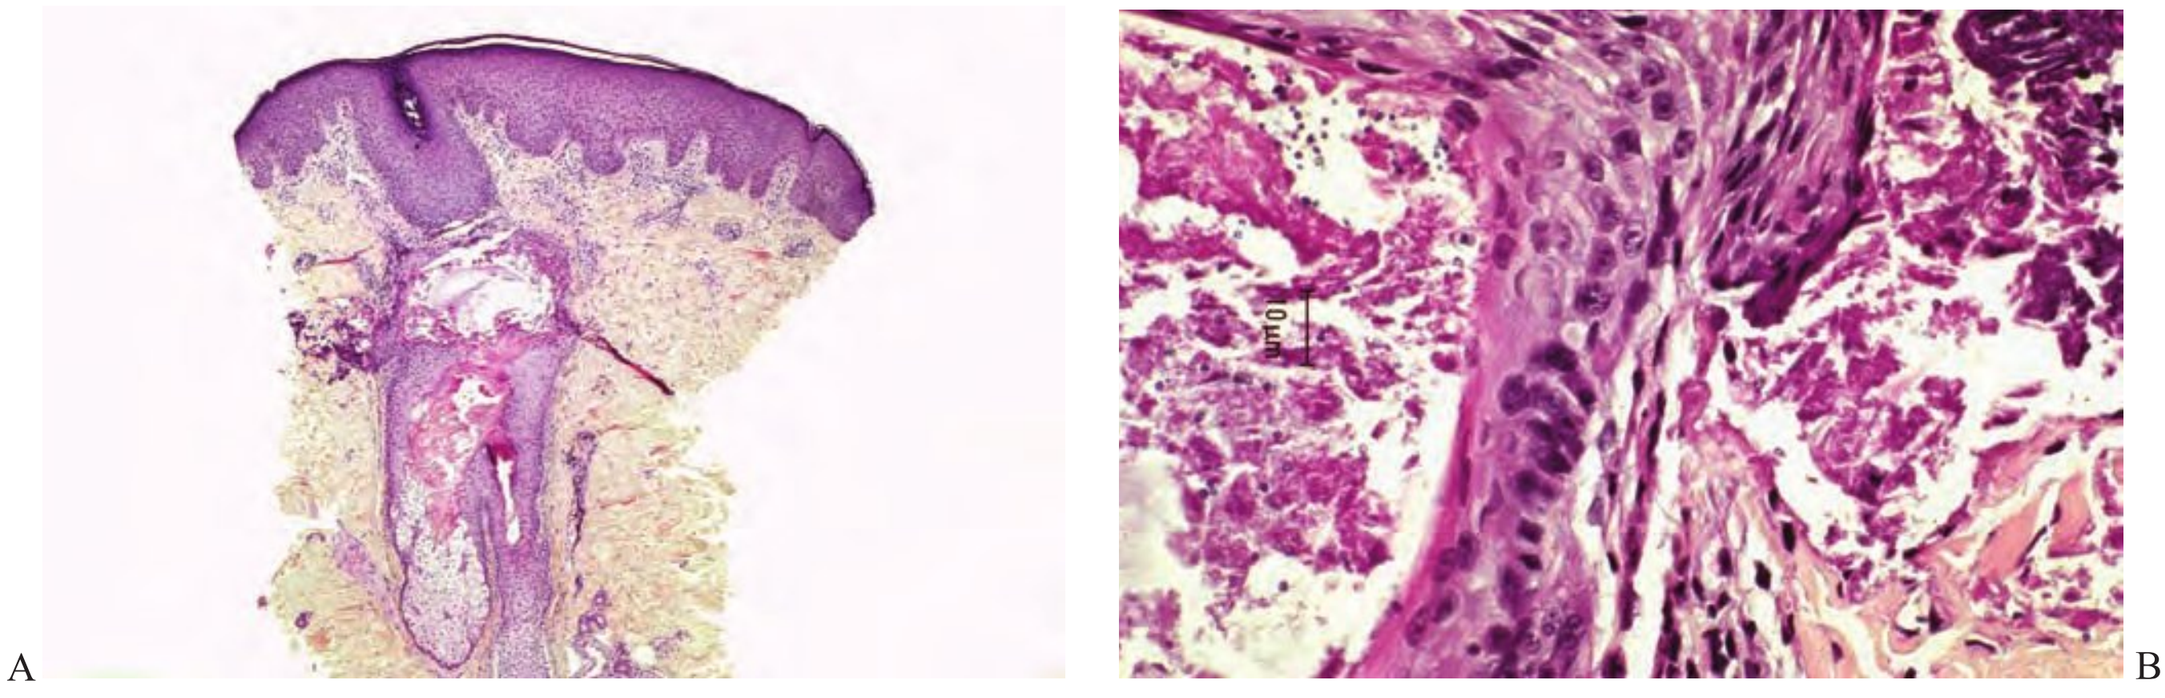


FIGURE 23-4. Pityriasis (tinea) versicolor. A slightly hyperkeratotic stratum corneum contains numerous hyphae and spores (H&E stain).

Several theories exist to explain the characteristic pigmentary alterations in pityriasis versicolor, although none have been convincingly proven. Hypopigmentation may be caused by filtering of ultraviolet light by the organism, a block in melanosome transfer to keratinocytes, or the inhibition of melanin synthesis by azelaic acid or lipoxygenase produced by *Malassezia* (31). Hyperpigmentation is thought by some to be secondary to inflammation, hyperkeratosis, or greater numbers of organisms in the skin.

Malassezia (Pityrosporum) Folliculitis

The involved pilosebaceous follicles show hyperkeratosis with dilatation resulting from plugging of the infundibulum with keratinous material. Inflammatory cells are present both within and around the follicular infundibulum. In some instances, the follicular epithelium is disrupted with development of a peri-infundibular abscess (32) (Fig. 23-5). PAS-stained sections show PAS-positive, diastase-resistant, spheric

A B

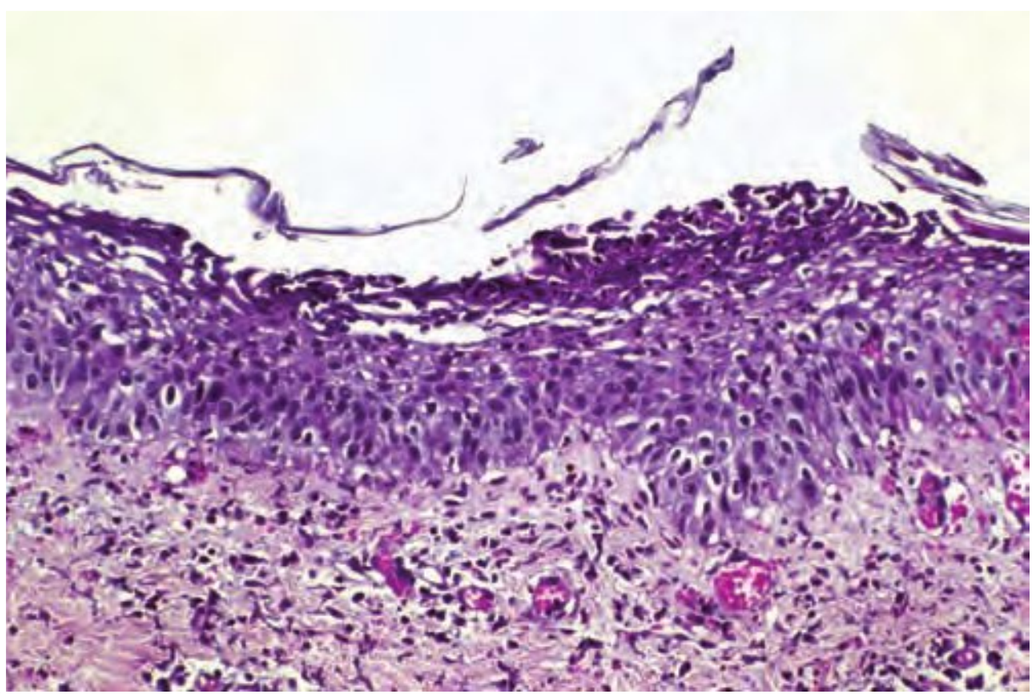
FIGURE 23-5. Malassezia (Pityrosporum) folliculitis. A: A plugged and ruptured follicle contains numerous round yeast forms (H&E stain). B: H&E stain shows round and budding yeast forms in follicle and surrounding dermis.

to oval, singly budding yeast organisms that are 2 to 4 μm in diameter. They are located predominantly within the infundibulum and at the dilated orifice of the follicular lumen but are occasionally observed also in the perifollicular dermis.

Histogenesis. It has been assumed that *Malassezia* organisms cause hyperkeratosis in the follicular ostium, thereby preventing the normal flow of sebum and causing the follicular, acne-like lesions.

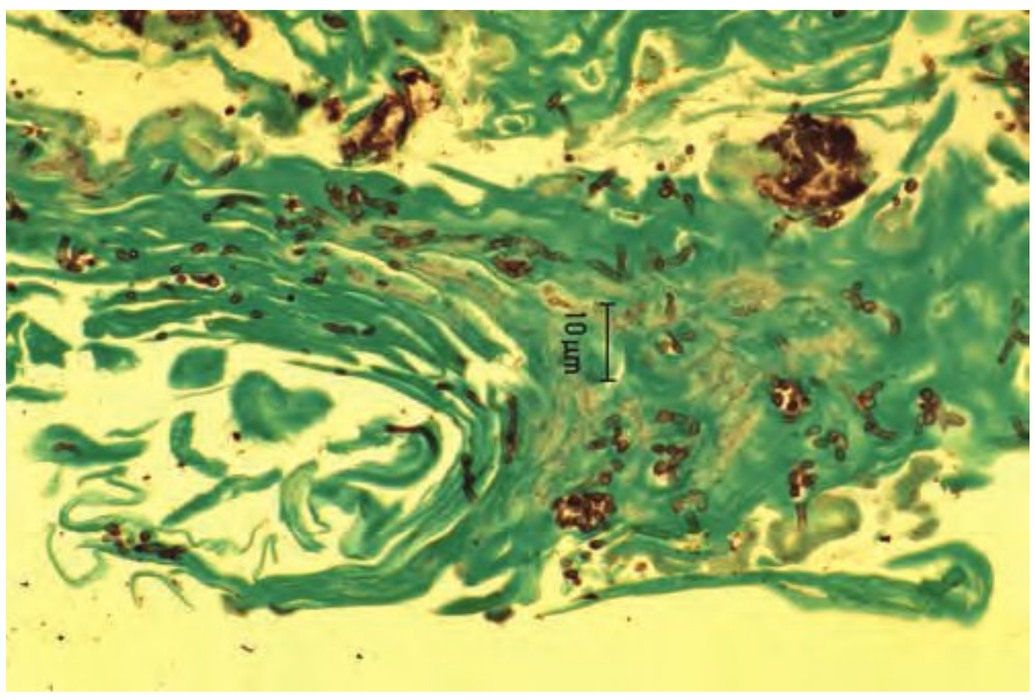
CANDIDIASIS

C. albicans is a dimorphous fungus growing in both yeast and filamentous forms on the skin. It exists in a commensal relationship with man. The spectrum of infection may be divided into four groups: acute mucocutaneous candidiasis, chronic mucocutaneous candidiasis (CMC), disseminated candidiasis, and *Candida* onychomycosis.



Acute Mucocutaneous Candidiasis

Acute mucocutaneous candidiasis is the benign, self-limited form of candidiasis and is caused by environmental changes that are local, as in hot, humid conditions, or that are systemic, as in antibiotic or corticosteroid therapy. Clinical variants of acute mucocutaneous candidiasis include erosio interdigitalis blastomycetica, *Candida* vaginitis, paronychia, *Candida* intertrigo, and thrush. Intertriginous lesions show erythematous, often-eroded patches and thin plaques often with peripheral erythematous macules and papules, the so-called satellite lesions. *Candida* infection of the mucous membranes is noted as erythematous patches or white plaques that reveal a glistening, erythematous undersurface when scraped.



Candida infection is associated with specific host and environmental factors. *Candida* is the most common pathogen in patients who have had a solid organ transplant, and candidiasis tends to occur within the first 6 months after transplant. Age (infancy, old age), antibiotic use, malignancy, chemotherapy, endocrinopathies (diabetes, Cushing's syndrome), and disorders of immunity including HIV/AIDS are risk factors for *Candida* infection (33,34). More effective treatment of AIDS has led to a decline in the incidence of clinically apparent candidiasis in these patients.

Congenital cutaneous candidiasis is a result of ascending intrauterine infection from vaginal candidiasis. There are widely scattered macules, papulovesicles, and pustules at birth or in a few days thereafter. *Neonatal candidiasis*, on the other hand, manifests as oral candidiasis or diaper dermatitis after the first week of life and is acquired during passage through the birth canal (35).

Histopathology. Cutaneous and mucous membrane *Candida* infection show similar features. If the primary lesion is a vesicle or pustule, it is usually subcorneal as in impetigo (Fig. 23-6A, B).

A

C

FIGURE 23-6. Candidiasis. A: H&E stain shows a subcorneal pustule with an underlying mixed dermal infiltrate. B: GMS stain shows pseudohyphae and ovoid yeast in hyperkeratotic stratum corneum. C: Erythematous to violaceous papulonodules of disseminated candidiasis in a patient with leukemia.

TABLE 23-3 Histological Appearance of Tissue and Fungi in Superficial Dermatomycoses

Disease	Histologic appearance	Fungal size and morphology
Dermatophytosis	Minimal to spongiotic-psoriasiform, pustular, or folliculitis pattern with mixed dermal infiltrate	Refractile, 1–2 μm septate hyaline hyphae in stratum corneum, occasional chains of spores.
Pityriasis (tinea) versicolor	Slight hyperkeratosis	2–8 μm round spores, 2–3 μm thick, short sometimes curved hyphae
Mallassezia (Pityrosporum) folliculitis	Plugged, sometimes ruptured follicle with follicular and perifollicular mixed infilterate	2–8 μm round spores within follical, rarely in perfollicular tissue. Usually no hyphae.
Candidiasis	Spongiotic or subcorneal pustular dermatitis with mixed dermal infiltrate. Erosions may be present.	3–6 μm round to oval, sometimes budding spores, 2–4 μm thick pseudohyphae

In some instances, the pustules have a spongiform appearance, similar to the spongiform pustules of Kogoj seen in pustular psoriasis (see Chapter 7).

The fungal organisms are present, usually in small amounts only, in the stratum corneum. They are predominantly pseudohyphae and ovoid spores, with some of the latter in the budding stage. These septate pseudohyphae show branching at a 90-degree angle and measure from 2 to 4 μm in diameter. The pseudohyphae tend to be constricted at their septa and to have septa at their branch points (36). The ovoid spores vary from 3 to 6 μm in size (Table 23-3).

Pathogenesis. By electron microscopy, the majority of the mycelia and spores are situated inside the cells of the stratum corneum, many of which are parakeratotic (37).

Chronic Mucocutaneous Candidiasis

CMC is a heterogeneous group of conditions in which patients have chronic and recurrent candidal infections of the skin, nails, and mucous membranes. CMC may be inherited as an autosomal dominant or recessive condition. It may also be due to endocrinopathies or immunodeficiency. By definition, systemic involvment does not occur in CMC (38). The individual lesions of CMC are similar clinically and histologically to those seen in acute mucocutaneous candidiasis and must be distinguished by their clinical course (38). The exception is seen in CMC beginning in childhood when a rare clinical variant called *Candida granuloma* may develop. Candida granuloma presents clinically as numerous hyperkeratotic, crusted plaques on the face and scalp but occasionally elsewhere (39).

Currently, the most common type of CMC is probably seen in patients with AIDS who often have recurrent candidal infections of the mouth and perianal area. Oral candidiasis may occur as an early sign of immunosuppression, before other symptoms have appeared (40), and if persistent may be an indication of esophageal candidiasis (41). In addition, *Candida* organisms are frequently observed on the surface of lesions of oral hairy leukoplakia, which is a viral leukoplakia caused by Epstein-Barr virus, perhaps in combination with human papillomavirus (see Chapter 25).

Histopathology. The histologic findings are identical with those of acute mucocutaneous candidiasis, except in cases of candidal granuloma. *Candidal granuloma* shows pronounced epidermal papillomatosis and hyperkeratosis and a dense infiltrate in the dermis composed of lymphoid cells, neutrophils, plasma cells, and multinucleated giant cells. The infiltrate may extend into the subcutis. *C. albicans* usually is present only in the stratum corneum (39). In some instances, however, fungal elements are found also within hairs, viable epidermis, and dermis.

Disseminated Candidiasis

Candida is the fourth leading cause of hospital-acquired bloodstream infection in the United States, but cutaneous involvement is only seen in 13% of cases (42). It primarily affects those with impaired host-defense mechanisms, particularly those with hematologic malignancies. *C. albicans* accounts for just over half of the cases of *Candida* fungemia, and *Candida glabrata* ranks number two, with incidence of the latter increasing directly with age (42,43). Cutaneous lesions of disseminated candidiasis are erythematous or violaceous papulonodules with central clearing that measure 0.5 to 1.0 cm in diameter (Fig. 23-6C). They are distributed singly or, more commonly, grouped on the trunk and proximal extremities. The triad of fever, rash, and diffuse muscle tenderness in an immunocomprised host is presumptive for disseminated candidiasis. However, the clinical diagnosis may be delayed, as patients often present with nonspecific symptoms and current methods for diagnosing candidemia rely on blood cultures that require several days. In addition, the speciation of *Candida* by culture is problematic given that all yeast cultures that form germ tubes and chlamydospores are by generalization designated *C. albicans* in many labs (44). Thus, a skin biopsy may be critical to the early diagnosis of disseminated candidiasis. Because the diffuse muscle tenderness is caused by infiltration of muscle tissue by yeast organisms, biopsy of a tender muscle may also aid in establishing the diagnosis of disseminated candidiasis (45).

Histopathology. Histologic examination reveals one or several aggregates of hyphae and spores focally within the dermis, often at sites of vascular damage and generally visible only in sections stained with the PAS reaction or GMS. Some of the spores,

which are 3 to 6 μm in diameter, show budding. The aggregates of hyphae and spores may lie in an area of leukocytoclastic vasculitis (46), within a microabscess (44), or in an area of only mild inflammation. The aggregates of *Candida* often are small, and step sections through the biopsy specimen may be necessary to find them. The epidermis is usually unaffected.

Candida Onychomycosis

Candida onychomycosis is a form of nail infection characterized by separation of the nail plate from the nail bed. Paronychia and loss of the proximal nail fold are not uncommon in *Candida* infections of the nail unit.

Histopathology. *Candida* commonly causes onycholysis but distinguishes itself histologically from the dermatophytes by its lack of nail plate invasion (18). Yeast forms may be seen along the undersurface of the nail plate. *Candida* may mimic the psoriasiform changes and inflammatory response of onychomycosis caused by dermatophytes. *Candida* sp. occur as ovoid yeasts that measure 3 to 6 μm in diameter and as pseudohyphae that measure 2 to 4 μm in diameter. These pseudohyphae may appear thick and bulbous, and have an irregular caliber compared with the smooth, thin, and regular hyphae of dermatophytes.

ASPERGILLOSIS

Aspergillus sp. are ubiquitous in the environment. Humans are constantly exposed to and frequently colonized by these organisms, although they rarely cause disease. Severe, invasive aspergillosis typically involves the lungs and is usually seen only in immunocompromised hosts, particularly those with neutropenia, hematologic malignancy, or a history of chronic corticosteroid or antibiotic therapy (47). *Aspergillus fumigatus* is the most common cause of both colonization and invasive aspergillosis, followed in frequency by *Aspergillus flavus* and *A. niger* (48). Cutaneous aspergillosis may occur as a primary infection or may be secondary to disseminated aspergillosis (Table 23-4). The lesions of primary cutaneous aspergillosis are usually found at an intravenous infusion site: either at the actual access site (49) or where the unit has been secured with a colonized board or tape (50). There may be one or more macules, papules, plaques, or hemorrhagic bullae that may rapidly progress into necrotic ulcers with a heavy black surface eschar (Fig. 23-7A). In immunocompromised patients, dissemination may follow and is often fatal if untreated with amphotericin B, itraconazole, or newer antifungals such as caspofungin (47).

Primary cutaneous infection has been seen in patients with AIDS, but dissemination is not typical in these patients unless they have one or more of the previously mentioned risk factors mentioned in the previous paragraph (51). Umbilicated papules clinically resembling lesions of molluscum contagiosium, and representing "dermatophyte-like" involvement of follicles, have been described in AIDS-related cases (50). In addition, *Aspergillus* may colonize burn or surgical wounds and subsequently invade viable tissue; in these cases, the prognosis is generally good.

Secondary cutaneous aspergillosis, usually associated with invasive lung disease, shows multiple scattered lesions as a result of embolic hematogenous spread and has a poor prognosis (47,52).

Histopathology. Unlike the case with most deep cutaneous fungal infections, pseudoepitheliomatous epidermal hyperplasia is not characteristic of cutaneous aspergillosis. In the more serious primary forms and in the secondary disseminated form, numerous *Aspergillus* hyphae are seen in the dermis (Fig. 23-7B, C). Hyphae may be seen in H&E-stained sections, but PAS or silver methenamine staining may be required. The hyphae, which measure 2 to 4 μm in diameter (47), are often arranged in a radiate fashion, are septate, and show branching at an acute angle. Spores are absent. Hyphae may be seen invading blood vessels (47) and may be seen around areas of ischemic necrosis with very little inflammation in some instances. In other cases, there may be an acute inflammatory reaction with polymorphonuclear leukocytes in addition to lymphocytes and histiocytes.

In patients with primary cutaneous or subcutaneous aspergillosis who are otherwise in good health, the number of hyphae present is relatively small, and there may be a well-developed granulomatous reaction.

ZYGOMYCOSIS (MUCORMYCOSIS, PHYCOMYCOSIS)

Zygomycosis describes infections by ubiquitous molds of two orders: Mucorales and Entomophthorales. The term *mucormycoses* describes infection with *Rhizopus* or *Mucor*, the two medically significant genera of the order Mucorales (53). Infections with these organisms are aggressive and often occur in ketotic diabetics, but infections may also be seen in other settings such as burns, iatrogenic immunosuppression, chronic renal failure, hematopoietic malignancy, and AIDS (54). Entomophthoraceae may cause chronic cutaneous and subcutaneous infections in otherwise healthy hosts.

Cutaneous zygomycosis occurs by implantation of fungi or by hematogenous dissemination. Three main forms exist: rhinocerebral, primary cutaneous, and chronic subcutaneous zygomycosis.

Rhinocerebral zygomycosis is a fulminant infection of the paranasal sinuses that quickly spreads to contiguous structures such as the skin, nose, orbit, and brain (53). Clinical findings include nasal discharge, swelling, mucocutaneous ulceration, and eschar formation.

Primary cutaneous zygomycosis may occur following burns or major trauma or following minor trauma in immunosuppressed patients or those with diabetes (53). It has also been reported after the use of infected tape (55,56). Individual lesions occur early as pustules or blisters that soon ulcerate and form eschars. Depending on the host status, the ulcers either heal or lead to fatal systemic spread. These molds may cause acute, rapidly developing, often lethal infections of immunocompromised

TABLE 23-4 Histologic Appearance of Tissue and Fungi in Deep and Secondary Dermatomycoses

Disease	Histologic appearance	Fungal size and morphology
Aspergillosis	Primary infection: granulomatous infiltrate. Immunocompromised host (primary and secondary infection): angioinvasion, ischemic necrosis, and hemorrhage.	2–4 μm septate hyphae with dichotomous branching at 45-degree angle.
Zygomycosis (mucormycosis, phycomycosis)	Angioinvasion with thrombosis and infarction, necrosis, and variable, mild, neutrophilic infiltrate.	7–30 μm hyphae with branching at irregular angles and intervals. Variably thin, often collapsed or twisted walls.
Subcutaneous phaeohyphomycosis (phaeohyphomycotic cyst)	Deep, coalescing, suppurative granulomatous foci surrounded by fibrous capsule.	Loosely arranged, septate, occasionally branching pigmented hyphae varying from 2 to 25 μm in diameter.
Alternariosis	Pseudocarcinomatous epithelial hyperplasia with intraepidermal microabscesses and suppurative granulomatous dermal infiltrate.	5–7 μm septate hyphae with variable branching and brown pigmentation. 3–10 μm round to oval spores, often with double contours.
North American blastomycosis	Pseudocarcinomatous epithelial hyperplasia with intraepidermal microabscesses. Suppurative granulomatous dermal infiltrate with giant cells.	8–15 μm thick-walled spores with single broad-based buds.
Paracoccidioidomycosis	Like North American blastomycosis.	6–20 μm spores with narrow-necked, single or multiple buds. "Mariner's wheels" up to 60 μm in diameter.
Lobomycosis	Atrophic epidermis with dermal macrophage and giant cell infiltrate. Unstained organisms give sievelike appearance to dermis.	9–10 μm "lemon-shaped" spores with single budding, often in chains.
Chromoblastomycosis	Like North American blastomycosis.	6–12 μm thick-walled, dark brown spores, often in clusters. Some cells possess cross walls.
Coccidioidomycosis	Primary inoculation: mixed dermal infiltrate with granulocytes, lymphocytes, and occasional histiocytic giant cells. Systemic: like North American blastomycosis, but granulomas may be more tuberculoid in nature.	10–80 μm thick-walled spores with granular cytoplasm. The larger spores contain endospores.
Cryptococcosis	"Gelatinous reaction" with many spores; "granulomatous reaction" with fewer spores.	4–12 μm spore with wide capsule in "gelatinous reaction;" 2–4 μm spore in "granulomatous reaction."
Histoplasmosis		
var. capsulatum	Suppurative granulomatous infiltrate in ulcerative skin lesions, neutrophils and eosinophils in oral lesions. Histiocytes contain variable numbers of organisms.	2–4 μm round, narrow-necked budding spores with clear halo (pseudocapsule) in the cytoplasm of large histiocytes.
var. duboisii (African)	Granulomatous dermal infiltrate with focal suppuration.	8–5 μm ovoid spores in macrophages and free in tissue.
Sporotrichosis	Cutaneous lesions: epidermal hyperplasia with intraepidermal abscesses, suppurative granulomatous dermal infiltrate, occasional asteroid bodies. Subcutaneous nodules: central zone of neutrophils surrounded by zones of epithelioid macrophages and round cells.	4–6 μm round to ovel spores.
Eumycetoma	Abscess in granulation tissue, fibrosis, and sinus tracts.	0.5–2.0 mm sulfur granules composed of 4–5 μm thick septate hyphae.
Rhinosporidiosis	Hyperplastic epithelium with papillomatosis, deep invagination with pseudocysts, and "Swiss cheese" corium.	7–12 μm spores, sporangia up to 300 μm.

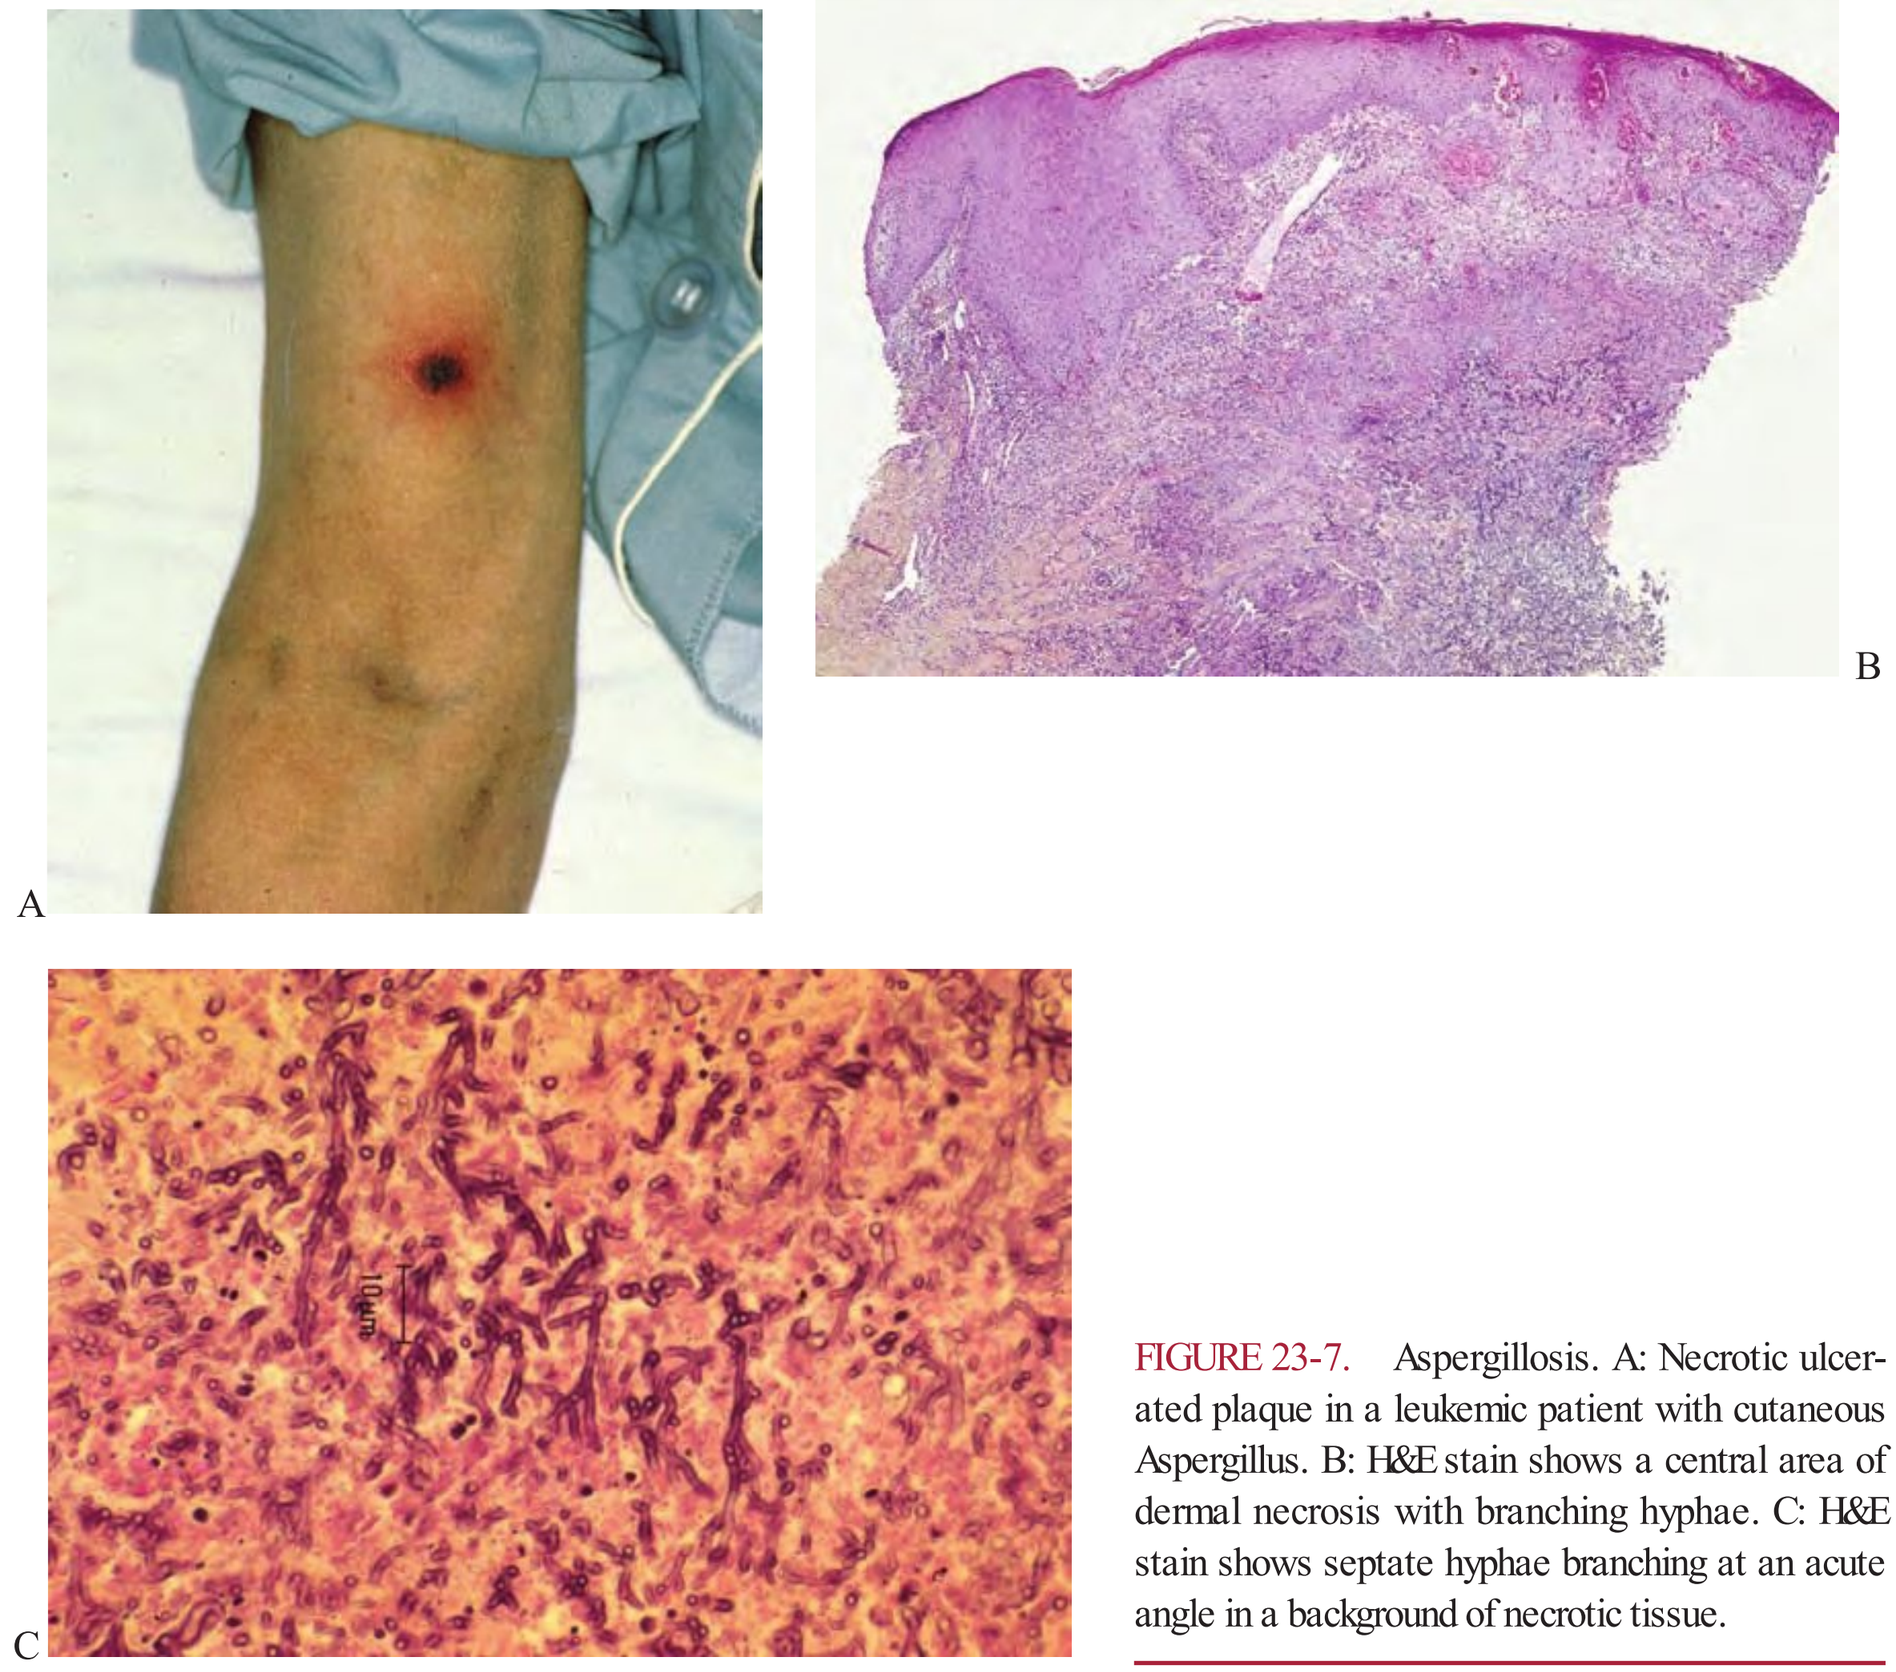

FIGURE 23-7. Aspergillosis. A: Necrotic ulcerated plaque in a leukemic patient with cutaneous Aspergillus. B: H&E stain shows a central area of dermal necrosis with branching hyphae. C: H&E stain shows septate hyphae branching at an acute angle in a background of necrotic tissue.

patients. Cutaneous lesions may also be seen as a result of embolization and infarction in patients with systemic zygomycosis. The lesions may begin as erythematous macules that blister and ulcerate or may occur as an indurated nodule (57).

Chronic subcutaneous zygomycosis occurs in tropical and subtropical areas in otherwise healthy people. Lesions most commonly occur on the face and are slowly enlarging, painless, firm swellings in the dermis (53).

Histopathology. The histologic changes in zygomycosis are primarily dermal. The hallmark of zygomycosis is vascular invasion by very large, long, nonseptate hyphae with thrombosis and infarction (53,57) (Fig. 23-8A). Hyphae branch at 90-degree angles and may also be found in the surrounding tissue (58). The hyphae are thin walled, so they may be twisted or collapsed and often appear ring shaped or oval in cross- or tangential sections (53) (Fig. 23-8B). They are often easily located even in routinely stained sections because of their very large size, up to 30 μm in diameter, although they may be visualized even better in PAS- or GMS-stained sections. Spores are rarely seen.

SUBCUTANEOUS PHAEOHYPHOMYCOSIS

Phaeohyphomycosis is a subcutaneous or systemic infection caused by dematiaceous, mycelia-forming fungi (59). This is a histopathologic definition of a disease process that can be caused by many different organisms and can have multiple different clinical presentations. *Bipolaris*, *Phialophora*, *Alternaria*, and *Exophiala* are fungi responsible for phaeohyphomycosis (60,61). Phaeohyphomycosis has been labeled a "chromic mycosis" in the past but is distinct from chromomycosis, which is characterized by pigmented spores without hyphal forms. Although eumycetoma caused by dematiaceous fungi

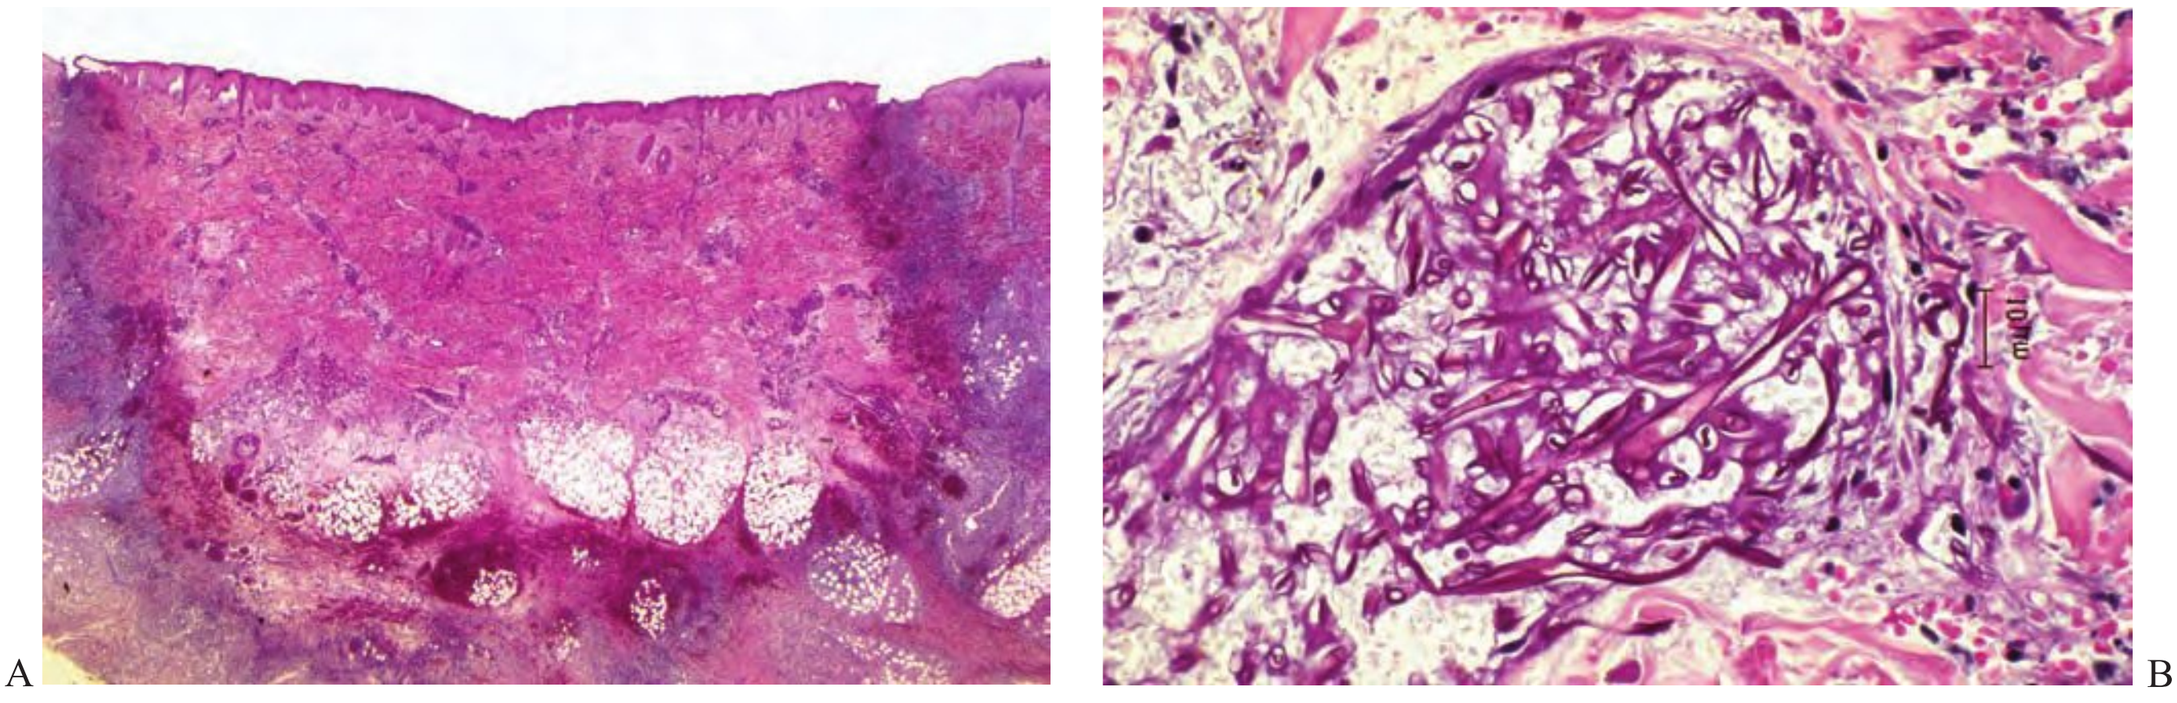

FIGURE 23-8. Zygomycosis (mucormycosis). A: H&E stain shows infarction of dermis, epidermis, and subcutaneous fat with lymphohistiocytic and neutrophilic infiltrate as well as angioinvasion by broad nonseptate hyphae. B: H&E stain shows irregularly branching, twisted, and collapsed hyphae.

could be included under this definition, that has not generally been the case, probably since eumycetoma is such a distinctive clinical entity (62).

Phaeohyphomycetes often infect people who are not overtly immunosuppressed. However, immunosuppression does increase the risk of infection with less commonly pathogenic phaeohyphomycetes such as *Alternaria infectoria* and increases the risk for disseminated disease (63,64).

Subcutaneous phaeohyphomycosis typically presents as a solitary abscess or nodule on the extremity of an adult male. A history of trauma or a splinter can sometimes be elicited. The other major clinical forms of phaeohyphomycosis are infection of the paranasal sinuses and central nervous system.

Histopathology. Lesions of subcutaneous phaeohyphomycosis start as small, often stellate foci of suppurative granulomatous inflammation. The area of inflammation gradually enlarges and usually forms a single large cavity with a surrounding fibrous capsule, the so-called phaeohyphomycotic cyst (65) (Fig. 23-9A). The central space is filled with pus formed of polymorphonuclear leukocytes and fibrin. There is a surrounding granulomatous reaction composed of histiocytes, including epithelioid cells and multinucleated giant cells; lymphocytes; and plasma cells. Diligent search may identify an associated splinter in the tissue or liquid pus. The organisms are found within the cavity and at its edge, often within histiocytes (Fig. 23-9B). The hyphae often have irregularly placed branches and show constrictions around their septae that may

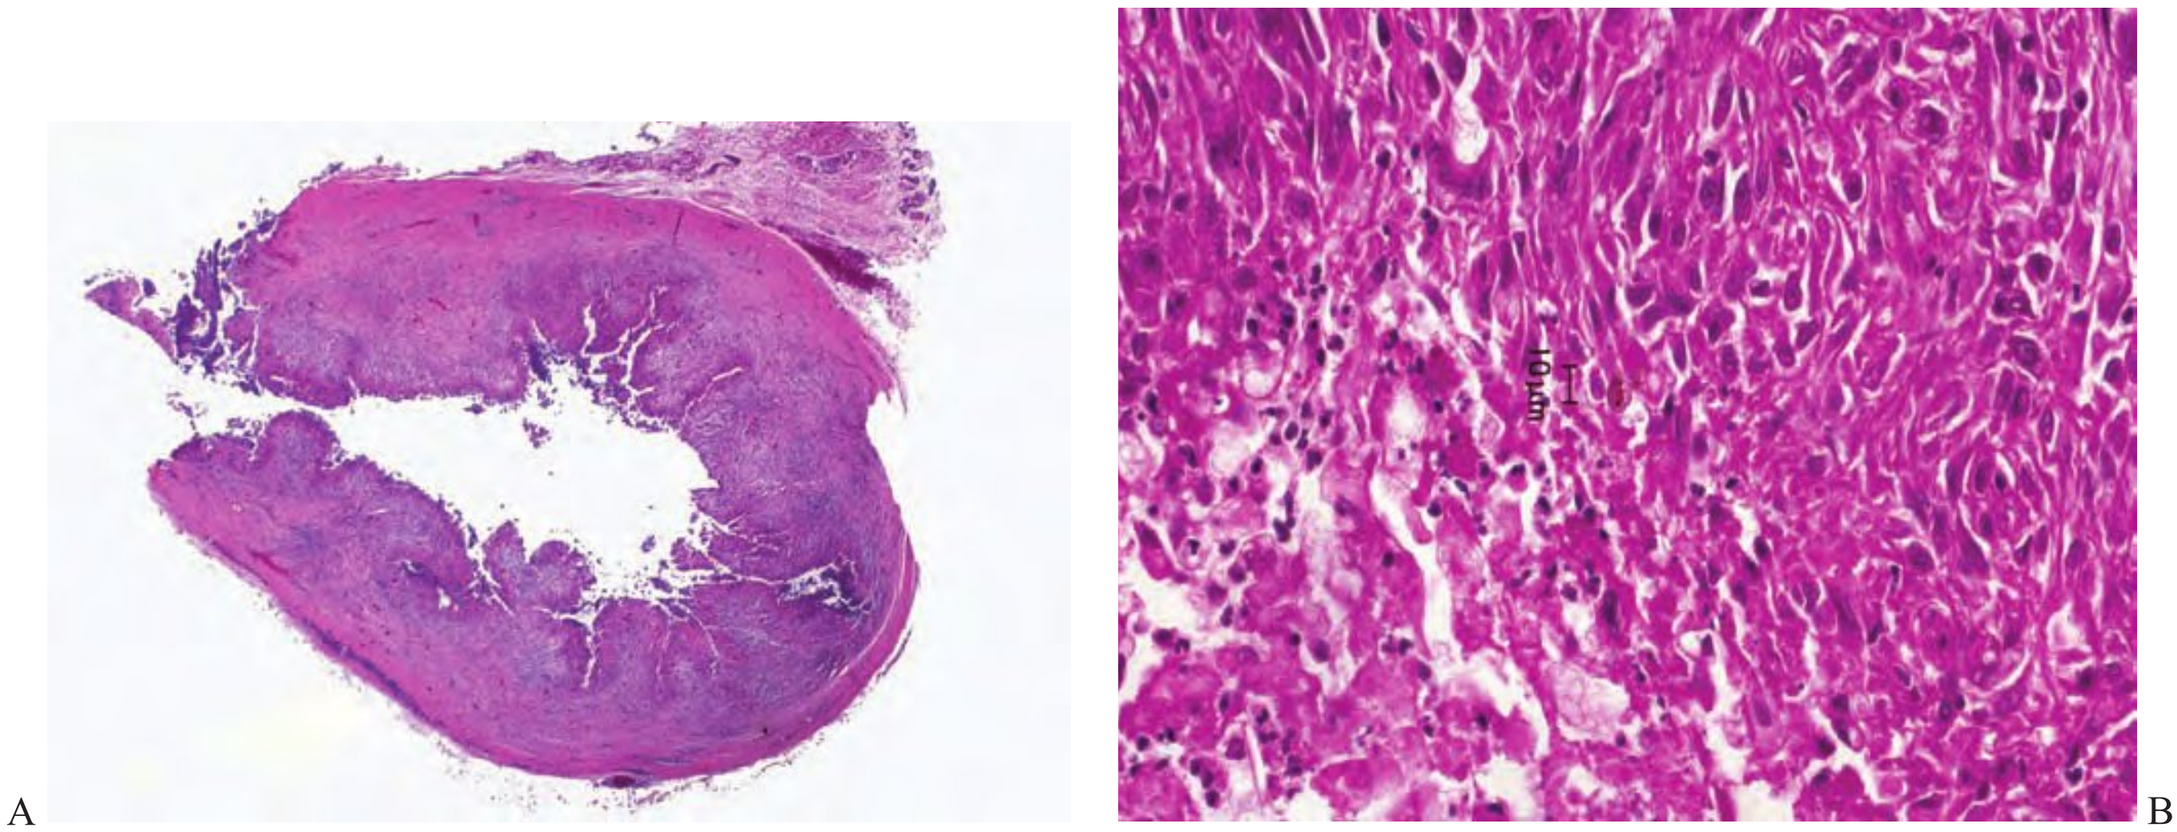

FIGURE 23-9. Phaeohyphomycosis. A: H&E stain shows a pseudocyst with a large central cavity and a fibrous capsule. B: H&E stain shows pigmented hyphal forms at edge of cavity.

cause them to resemble pseudohyphae or yeast forms, but true yeast forms are rare. Mycelia, if present, are more loosely arranged than the compact masses of hyphae seen in eumycetoma. Pigment is not always obvious and may be highlighted using the Fontana-Masson stain (60).

Pathogenesis. The subcutaneous cystic type of phaeohyphomycosis is usually caused by *Phialophora gougerotii* (formerly called *Sporotrichum gougerotii*) *(*66). Less commonly, it is due to *Exophiala (Fonsecaea, Wangiella) dermatitidis* (67). Melanin is directly involved in the virulence of phaeohyphomycetes. Melanin is able to scavenge free radicals used by phagocytic cells to kill fungi, and melanin may also bind the hydrolytic enzymes used by phagocytic cells to lyse fungal cell membranes. Strains of these fungi that lack pigment demonstrate reduced virulence in mouse models (68,69). Nondematiaceous strains have decreased resistance to fungicidal effects of the phagolysosome (70). These factors may also help to explain the virulence of phaeohyphomycetes in immunocompetent patients.

Differential Diagnosis. The organisms of phaeohyphomycosis can be distinguished from *Aspergillus* sp. because the latter have hyphae with relatively uniform diameter and regular dichotomous branching (71). Furthermore, disseminated aspergillosis is associated with vascular invasion, ischemic necrosis, and relatively less inflammation.

CUTANEOUS ALTERNARIOSIS

Because the hyphae of *Alternaria* sp. are pigmented, alternariosis may also be considered a phaeohyphomycosis. *Alternaria* sp. commonly colonize human skin (72) but are generally nonpathogenic for humans. Cutaneous alternariosis may occur following trauma (73); by colonization of a preexisting lesion (74); or rarely by hematologic spread, most commonly from pulmonary infection caused by inhalation of the organism. Patients with cutaneous alternariosis are often debilitated, immunocompromised, or receiving immunosuppressive therapy (71,75). Despite the increasing prevalence of HIV infection, however, the disease is rare in patients with AIDS (76). Morphologically, the lesions of cutaneous alternariosis are so variable as to be nonspecific and include crusted ulcers, verrucous or granulomatous and multilocular lesions (74), and subcutaneous nodules (73).

Histopathology. Although fungi are found mainly in the deeper layers of the dermis and in the subcutaneous region in the hematogenous and the traumatogenic forms, they are localized predominantly in the epidermis in cases in which *Alternaria* colonizes preexisting lesions (74). The dermis shows a suppurative granulomatous reaction associated with variable pseudoepitheliomatous epidermal hyperplasia and ulceration. Organisms may be present both as broad, branching, brown septate hyphae, 5 to 7 μm thick (62) (Fig. 23-10), and as large, round to oval, often doubly contoured spores measuring 3 to 10 μm in diameter (74). The spores may be seen both lying free in the tissue (72) and within macrophages and giant cells (77). There may be intraepidermal microabscesses with hyphae in the stratum corneum and stratum spinosum (72). The hyphae and spores stain deeply with PAS or silver methenamine.

NORTH AMERICAN BLASTOMYCOSIS

North American blastomycosis, caused by *Blastomyces dermatitidis*, occurs in three forms: primary cutaneous inoculation blastomycosis, pulmonary blastomycosis, and systemic blastomycosis (78).

Primary cutaneous inoculation blastomycosis is very rare and occurs almost exclusively as a laboratory or autopsy room infection. It starts at the site of injury on a hand or wrist as an indurated, ulcerated, chancriform solitary lesion. Lymphangitis

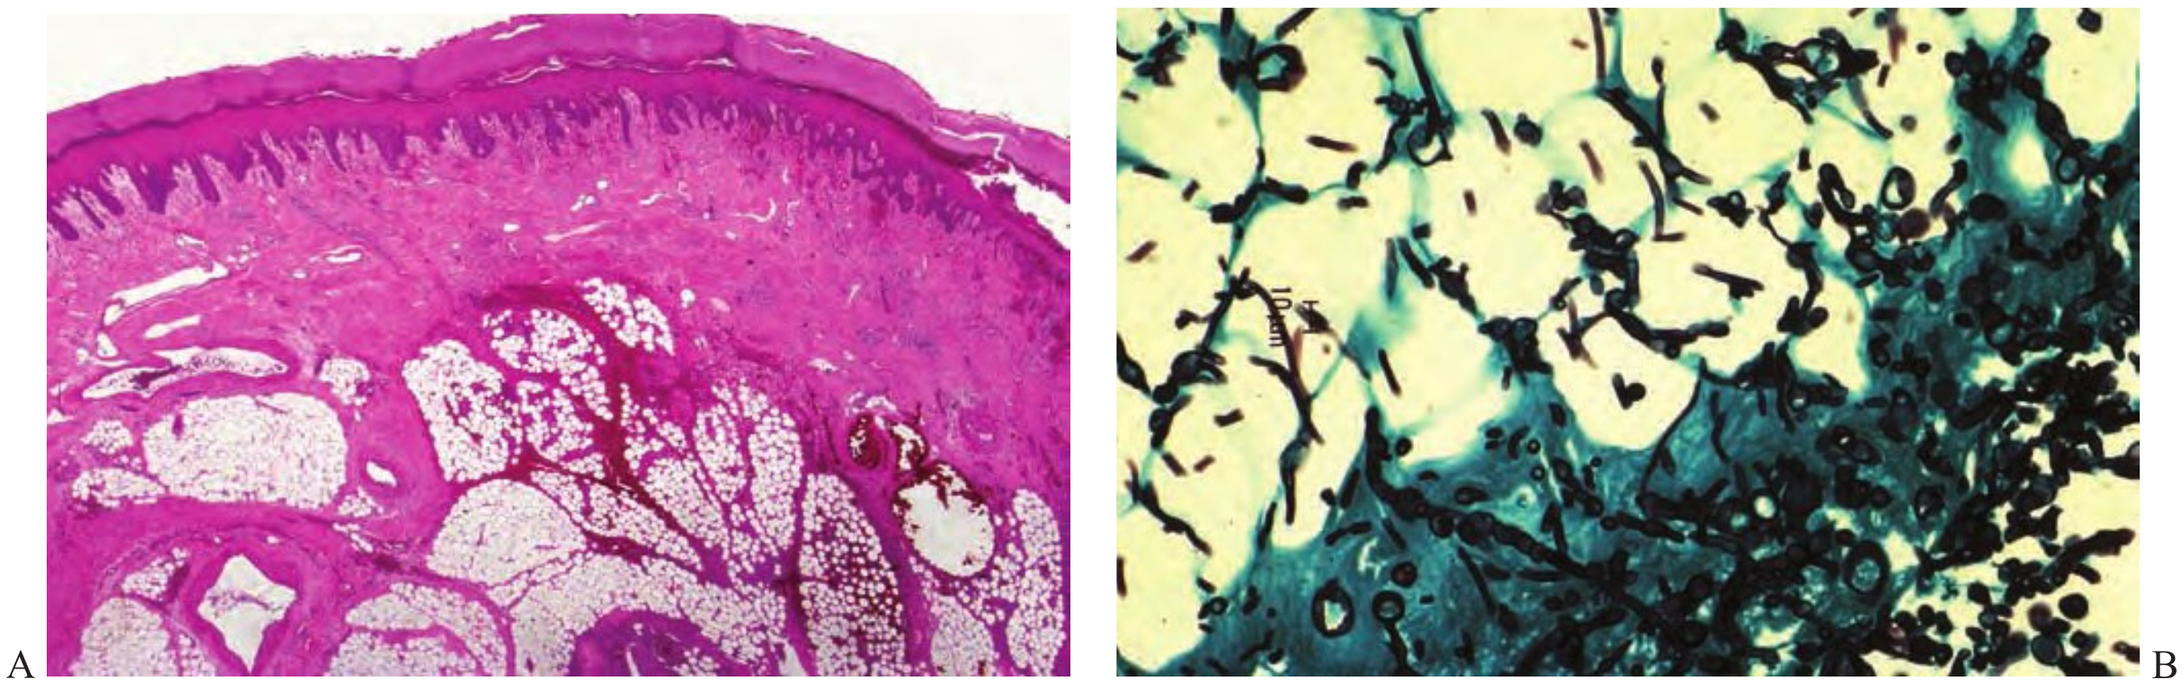

FIGURE 23-10. Alternariosis. A: H&E stain shows a mixed inflammatory infiltrate in the deep dermis and subcutaneous fat. B: GMS stain shows broad, branching hyphae.

and lymphadenitis may develop in the affected arm. Small nodules may be present along the involved lymph vessel. Spontaneous healing takes place within a few weeks or months (79).

Pulmonary blastomycosis, the usual route of acquisition of the infection, may be asymptomatic or may produce mild to moderately severe, acute pulmonary signs, such as fever, chest pain, cough, and hemoptysis. The pulmonary lesions either resolve or progress to chronic pulmonary blastomycosis with cavity formation. In rare instances, acute pulmonary blastomycosis is accompanied by erythema nodosum (80). Occasionally, however, cutaneous lesions are the only clinical manifestation after pulmonary infection. This phenomenon of a benign systemic disease presenting with cutaneous lesions may also be seen rarely after infection with coccidioidomycosis, cryptococcosis, histoplasmosis, and sporotrichosis. In the benign systemic form of blastomycosis with only cutaneous lesions, the lesions usually are on the face and are of the verrucous type (81).

In systemic blastomycosis, the lungs are the primary site of infection. Granulomatous and suppurative lesions may occur in many different organs, but aside from the lungs, they are most commonly found in the skin, followed by the bones, male genital system, oral and nasal mucosa, and central nervous system. Untreated systemic blastomycosis has a mortality rate in excess of 80% (82). Antimycotic therapy can reduce mortality to 10% in otherwise uncomplicated cases, but systemic blastomycosis has a particularly aggressive course in immunosuppressed patients and carries at least a 30% mortality rate even with treatment (83,84).

Cutaneous lesions are very common in systemic blastomycosis, occurring in about 70% of patients. They may be solitary or numerous. They occur in two types, either as verrucous lesions, the more common type, or ulcerative lesions. Verrucous lesions show central healing with scarring and a slowly advancing, raised, verrucous border that is beset by a large number of pustules or small, crusted abscesses. Ulcerative lesions begin as pustules and rapidly develop into ulcers with a granulating base. In addition, subcutaneous abscesses may occur; they usually develop as an extension of bone lesions. Lesions of the oral or nasal mucosa may present either as ulcers or heaped-up masses of friable tissue. In some instances, they are contiguous with cutaneous lesions (82). An unusual early cutaneous manifestation of systemic blastomycosis is a pustular eruption that may be widespread (85) or largely acral in distribution (86) (Fig. 23-11A).

Histopathology. Early lesions of blastomycosis demonstrate a dermal inflammatory infiltrate of polymorphonuclear leukocytes with numerous organisms. After a few weeks, occasional giant cells may be seen. Later, a verrucous histologic pattern with pseudoepitheliomatous hyperplasia is characteristic (Fig. 23-11B). The regional lymph nodes show a granulomatous reaction with numerous giant cells, in which the organisms are predominantly located.

A biopsy from the active border of a verrucous lesion will best demonstrate diagnostic histopathology. There is considerable downward proliferation of the epidermis, often amounting to pseudocarcinomatous hyperplasia. Intraepidermal abscesses often are present. Occasionally, multinucleated giant cells are completely enclosed by the proliferating epidermis. The dermis is permeated by a polymorphous infiltrate. Neutrophils usually are present in large numbers and form small abscesses. Multinucleated giant cells are scattered throughout the dermis. Usually, they lie alone and not within groups of epithelioid cells. Occasionally, there are tuberculoid formations, although without evidence of caseation necrosis. In the ulcerative lesions, the dermal changes are the same as in the verrucous lesions, but the epidermis is absent.

The spores of *B. dermatitidis* are found in histologic sections often only after a diligent search, usually in clusters of neutrophils or within giant cells (Fig. 23-11C). One or several spores may lie within a giant cell, where they are easily spotted even in H&E-stained sections. Unstained, the spores resemble small, round holes punched out of the cytoplasm of the giant cells. On high magnification, the spores are seen to have a thick wall, which gives them a double-contoured appearance. They measure 8 to 15 μm in diameter (average, 10 μm). Occasionally, spores show a single broad-based bud. As in most fungal infections, many more spores are visualized in sections stained with the PAS reaction or with methenamine silver than in routinely stained sections.

Pathogenesis. The diagnosis of *B. dermatitidis* is based on finding physical evidence of the organism, because reliable serologic tests are not available and clinical examinations are nonspecific. Fine needle aspiration or wet prep of wound fluid fixed in 95% alcohol and stained with Papanicolaou and H&E is a rapid means to find diagnostic broad-based budding forms (87,88). Also of great value is the demonstration of the spores of *B. dermatitidis* in tissue sections either by direct immunofluorescence (89) or by immunoperoxidase (90). The required antiserum is prepared in rabbits with pure cultures of fungi and is conjugated either with fluorescein isothiocyanate or with horseradish peroxide. The antiserum can be applied to fresh as well as to formalin-fixed, paraffin-embedded tissue sections. Prior staining with H&E does not interfere with the procedure.

Corresponding antisera are valuable also for the demonstration of the spores of *Sporothrix schenckii, Cryptococcus neoformans (90), C. albicans, Candida tropicalis, Candida krusei, Aspergillus,* and *Histoplasma capsulatum* (91).

Differential Diagnosis. The verrucous lesions of systemic blastomycosis must be differentiated from other deep fungal infections, tuberculosis verrucosa cutis, halogenodermas, and squamous cell carcinoma. Mucicarmine staining, which highlights the capsule of *C. neoformans*, allows its differentiation from the spores of *B. dermatitidis*, and the narrow-necked budding forms of *H. capsulatum* can be distinguished from the broader-based buds of *B. dermatitidis* without special stains. Tuberculosis verrucosa cutis shows no spores in the tissue, the number of neutrophils is smaller, and areas of caseation necrosis usually are present. Halogenodermas may be difficult to differentiate from a deep fungal infection without obvious organisms, but the presence of intraepidermal abscesses, a mixed dermal inflammatory

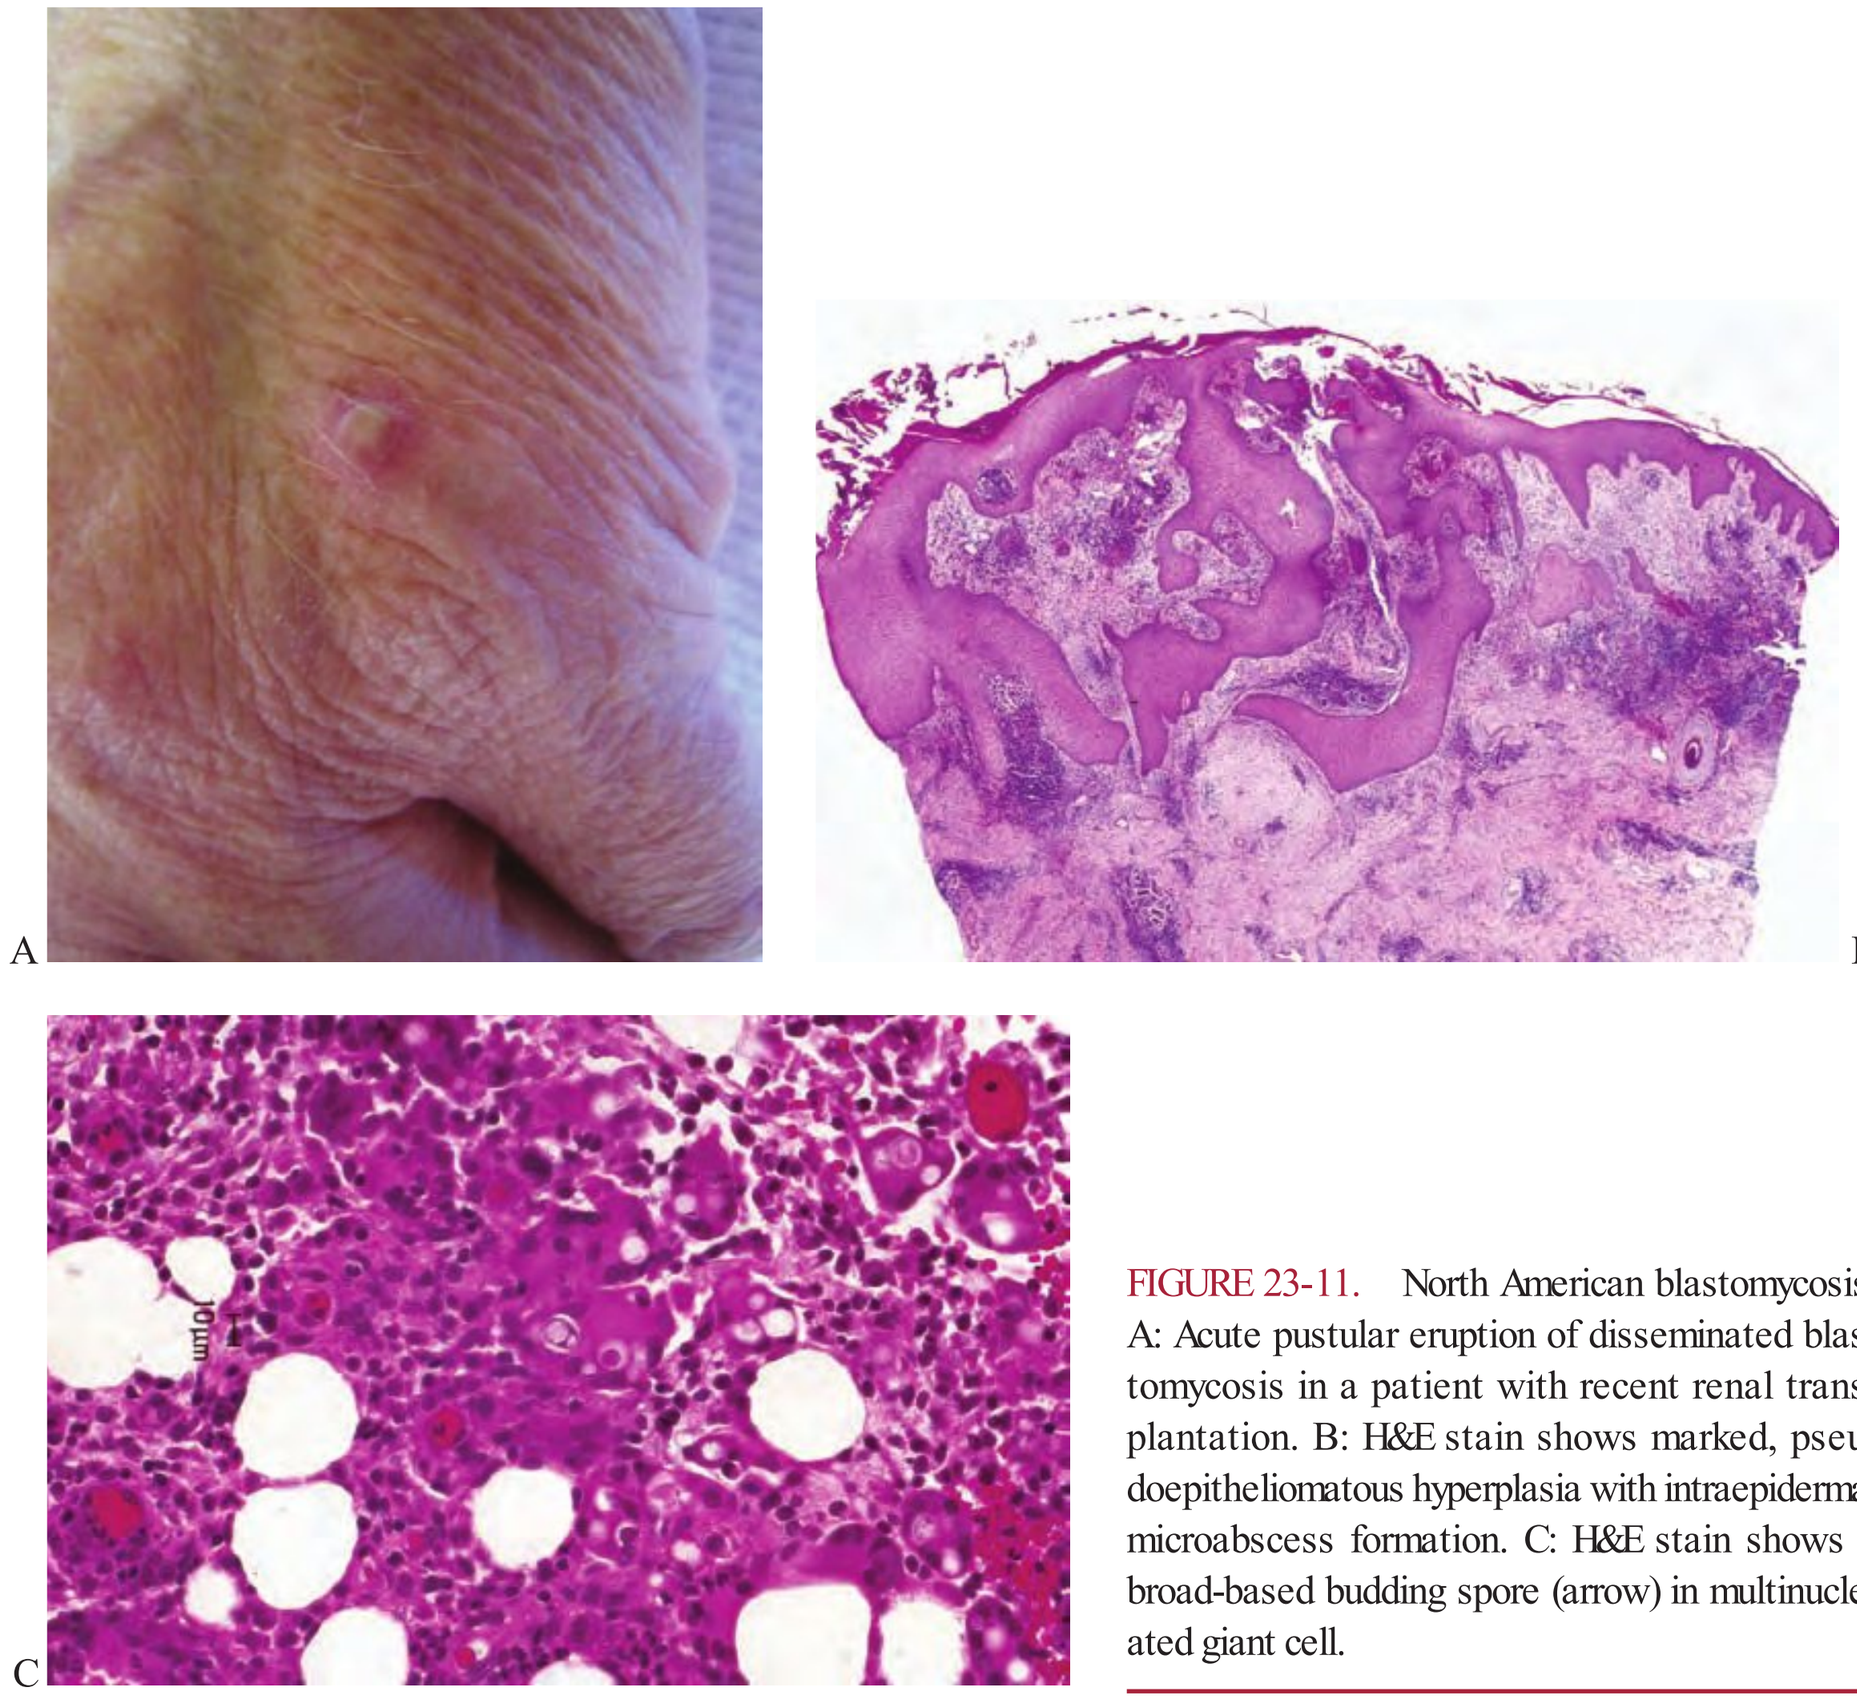

FIGURE 23-11. North American blastomycosis. A: Acute pustular eruption of disseminated blastomycosis in a patient with recent renal transplantation. B: H&E stain shows marked, pseudoepitheliomatous hyperplasia with intraepidermal microabscess formation. C: H&E stain shows a broad-based budding spore (arrow) in multinucleated giant cell.

infiltrate, and multinucleated giant cells is usually sufficient to rule out squamous cell carcinoma. Keratoacanthoma shares morphologic features with blastomycosis, including a verrucous architecture and intraepidermal abscesses. However, keratoacanthoma has a high degree of keratinization, a glassy appearance of the keratinocytes, and an abrupt cut-off between the central crater and adjacent epidermis.

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis, also called *South American blastomycosis* because it occurs almost exclusively in South and Central America, is a chronic granulomatous disease caused by *Paracoccidioides brasiliensis*.

P. brasiliensis almost always gains entrance into the human body through inhalation and infects the lungs, where there is a subclinical infection that can be recognized only through a positive paracoccidioidin skin test (92). The typical patient with clinical disease is an adult male with an indolent, slowly progressive course. The first clinical manifestation is usually lesions in the oropharynx and on the gingivae. The lesions in the mouth begin as papules and nodules that then ulcerate. Subsequently, extensive granulomatous, ulcerated lesions develop in the mouth, nose, larynx, and pharynx. Extensive cervical lymphadenopathy develops, with suppuration of some of the lymph nodes. The oral lesions may extend to the neighboring skin, with formation of similar granulomatous, ulcerated lesions around the mouth and nose (92).

Through both lymphatic and hematogenous spread, the disease may subsequently involve many lymph nodes, both subcutaneous and visceral, and the lower gastrointestinal tract. In cases with wide dissemination, the lungs are clinically involved, presenting a picture greatly resembling chronic pulmonary tuberculosis (93). Adrenal insufficiency due to destruction of the adrenal glands, uncommon in other systemic mycoses except histoplasmosis, is not infrequent (94). Rarely, widely scattered cutaneous lesions resulting from hematogenous spread are observed during the stage of dissemination. The lesions may be papular, pustular, nodular, papillomatous, or ulcerated (95).

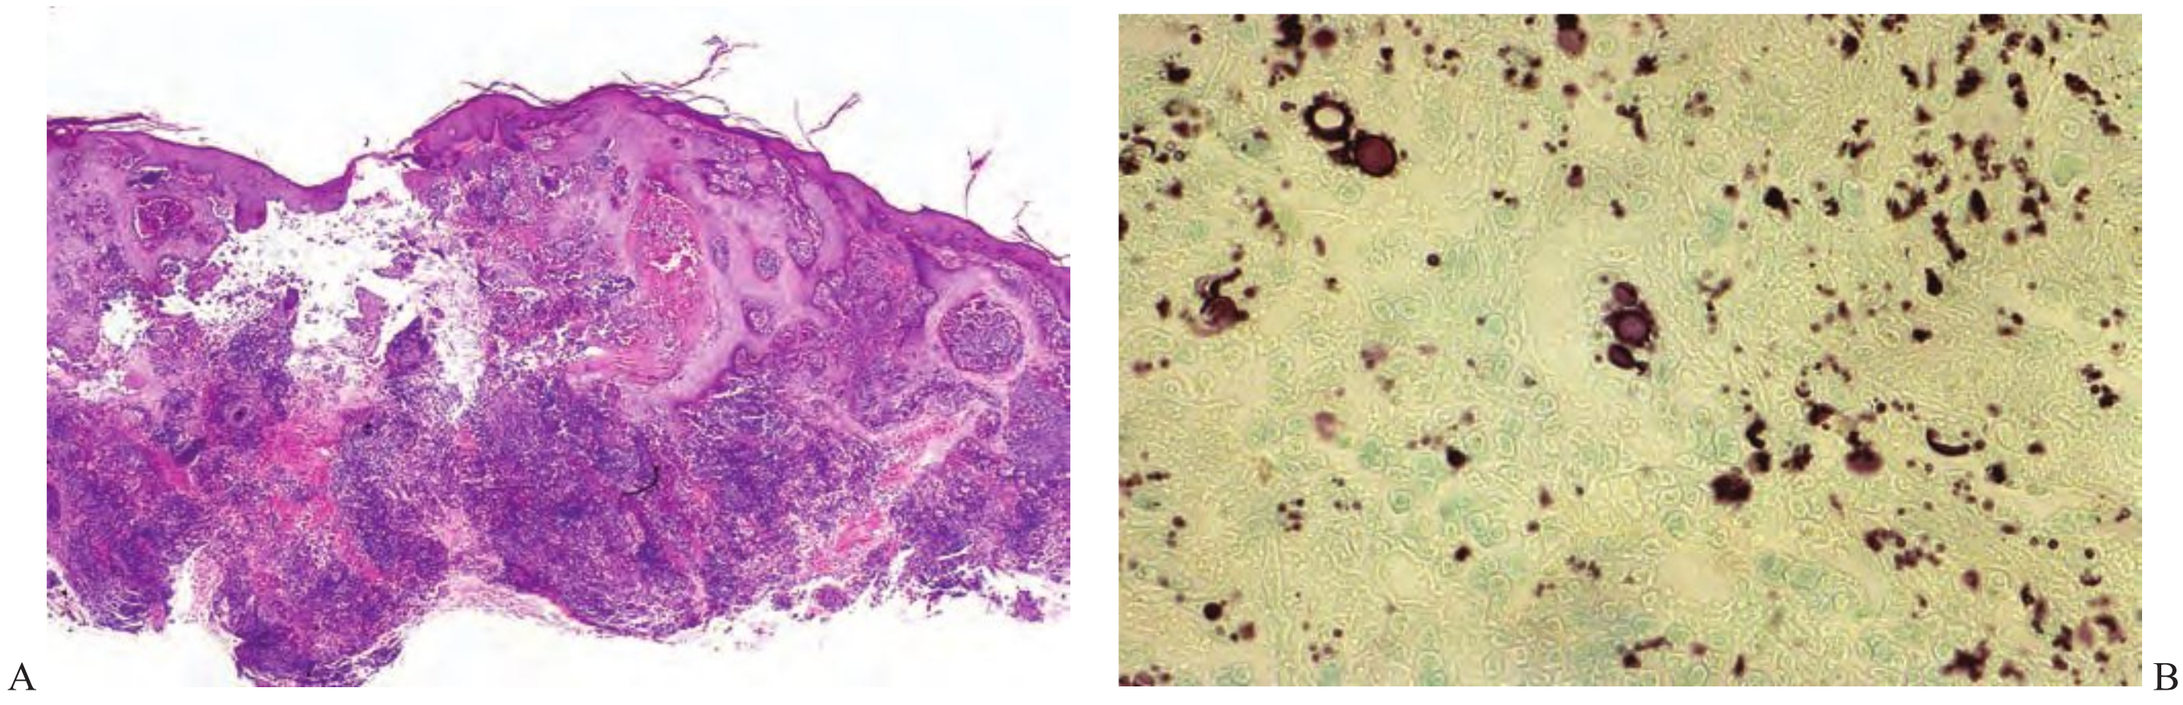

FIGURE 23-12. Paracoccidioidomycosis. A: H&E stain shows marked pseudoepitheliomatous epidermal hyperplasia with microabscess formation and a mixed dermal infiltrate. B: GMS stain shows variably sized yeast, some with multiple buds.

The disease develops and disseminates more rapidly in children and is then termed the *subacute progressive juvenile form* (96). Although experience is limited, it appears that there is little effect on the course of paracoccidioidomycosis in early HIV infection but that HIV patients with severe immunosuppression are at risk for a more fulminant course (97).

Histopathology. Examination of cutaneous or mucosal lesions reveals a granulomatous infiltrate showing epithelioid and giant cells in association with an acute inflammatory infiltrate and abscess formation (98). Spores may lie within giant cells or free in the infiltrate, especially in the abscesses. They are best demonstrated with the PAS reaction or methenamine silver. Pseudoepitheliomatous hyperplasia may be marked (Fig. 23-12A).

Many of the spores present in the tissue show only single, usually narrow-based buds or no buds at all (95). In the rare spores with multiple budding, peripheral buds are distributed over the whole surface of the ball-shaped fungus cell (Fig. 23-12B). Because of protrusion of the peripheral buds, such yeast cells in cross-sections have the appearance of a marine pilot's wheel. Whereas nonbudding or singly budding spores measure from 6 to 20 μm in diameter, spores with multiple budding may measure up to 60 μm in size.

Differential Diagnosis. *B. dermatitidis* and *C. neoformans* may be difficult to distinguish from paracoccidioides when only single budding organisms are seen. North American blastomycosis is distinguished by its thick refractile wall and broad-based blastospores. The capsule of C. *neoformans* stains with mucicarmine and is thus specifically identified.

LOBOMYCOSIS

Lobomycosis is an extremely indolent fungal infection characterized by asymptomatic, usually smooth, nodular lesions that resemble keloids on the ear, face, or extremity. The lesions may coalesce to form plaques but generally are limited to one area. Although the lesions persist, the condition is limited to the skin, except for occasional involvement of a regional lymph node (99). The infection, which is probably caused by a minor local injury, occurs sporadically in the South American tropics and Panama (100). The causative fungus is designated as *L. loboi*.

Histopathology. The dermis shows an extensive infiltrate of macrophages and large giant cells separated from a usually atrophic epidermis by a grenz zone. Scattered lymphocytes and plasma cells are present, but neutrophils are not typically present. Numerous fungus spores lie both within these cells and outside of them, and because the fungus does not stain with H&E, there may be so many unstained areas that the section may have a sievelike appearance (Fig. 23-13).

On staining with the PAS reaction or methenamine silver, the fungus spores average 10 μm in diameter. They possess a

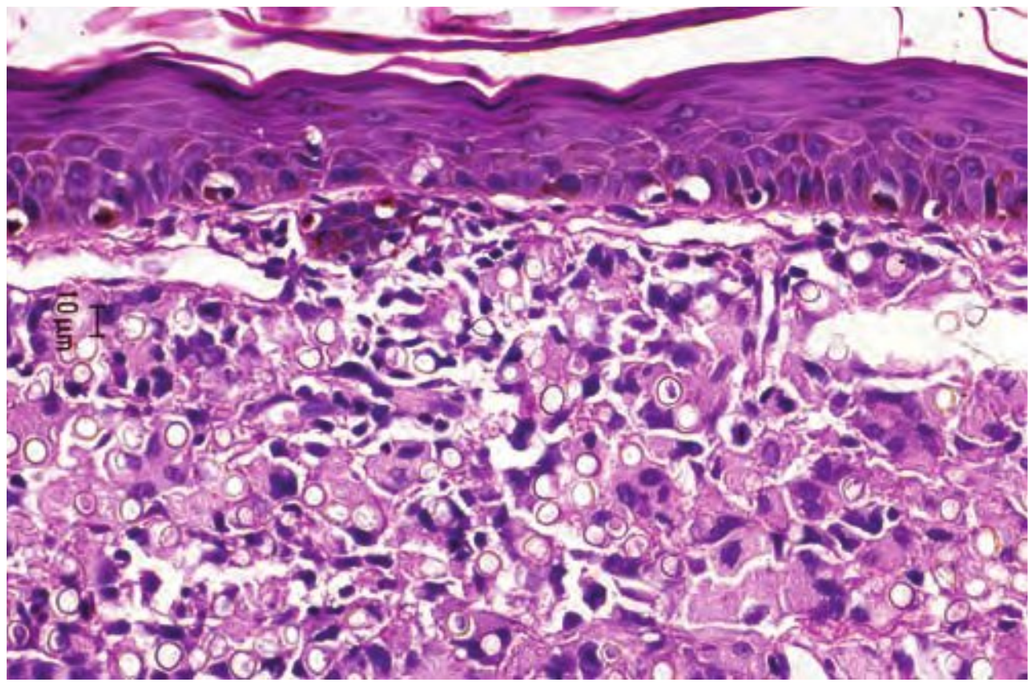

FIGURE 23-13. Lobomycosis. A diffuse dermal infiltrate of multinucleated giant cells containing spores is present beneath a flattened epidermis (H&E stain).

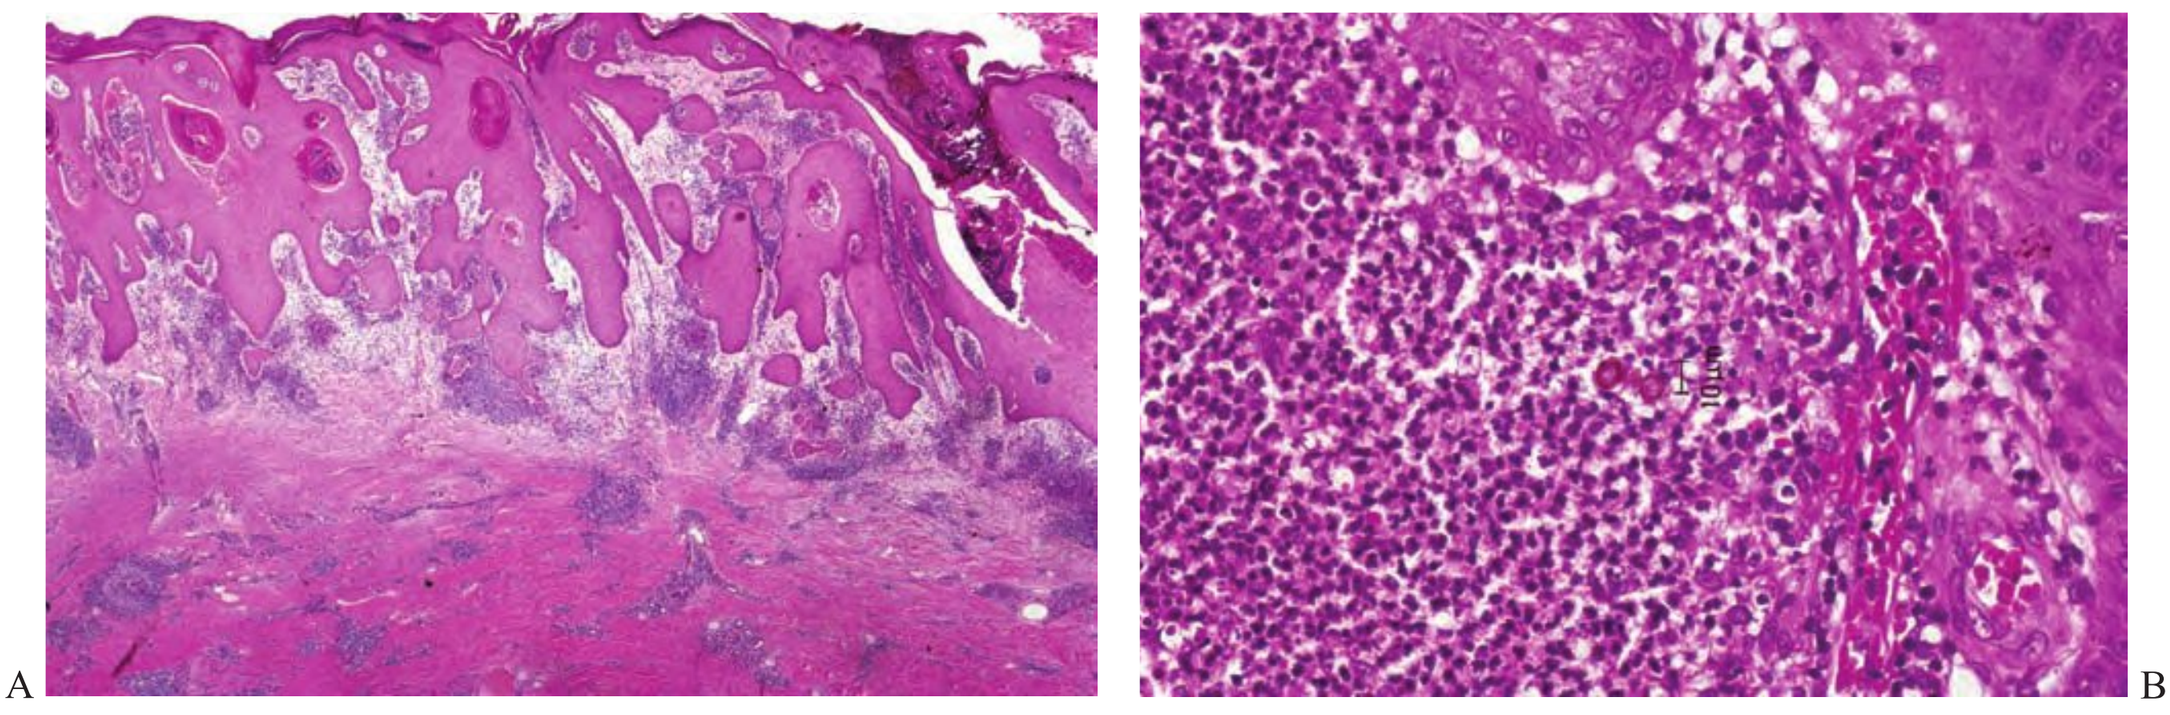
thick capsule, about 1 μm in thickness, with a tip that gives the organisms a distinctive "lemon-like" appearance. The spores occasionally show single budding (100) and often form single chains joined together by small, tubular bridges (101).

Pathogenesis. The macrophages contain abundant PAS-positive granular material that appears to consist of fragments of fungal capsules, indicating that the host macrophages are unable to digest the glycoproteins in the capsules (102).

CHROMOMYCOSIS

Chromomycosis is a slowly progressive cutaneous mycosis caused by pigmented (dematiaceous) fungi that occur as round, nonbudding forms in tissue sections. Inasmuch as budding is absent, the designation chromo*blasto*mycosis is somewhat inappropriate. In the past, the related term *chromomycosis* has also been used for cutaneous infections as well as for subcutaneous and cerebral infections by dematiaceous fungi in which hyphal forms almost always predominate. These two latter types of infections are clinically and histologically distinct and usually are classified as phaeohyphomycoses (103).



Chromomycosis is most often caused by one of five closely related species: *Phialophora verrucosa*, *Fonsecaea pedrosoi*, *Fonsecaea compactum*, *Exophiala* (*Fonsecaea*, *Wangiella*) *jeanselmei*, *Exophiala spinifera*, *Rhinocladiella aquaspersa*, and *Cladosporium carrionii* may each produce chromomycosis (104). These fungi are saprophytes and thus can be found growing in soil, decaying vegetation, or rotten wood in subtropical and tropical countries. The primary lesion is thought to develop as a result of traumatic implantation of the fungus into the skin (105).

The cutaneous lesions generally arise on the lower extremities and are variably pruritic, papular, nodular, verrucous, or plaquelike lesions (104,105). While some of the lesions heal with scarring, new ones may appear in the vicinity as a result of spreading of the fungus along superficial lymphatic vessels or autoinoculation (103). Lymphatic disruption with elephantiasis may occur.

Hematogenous dissemination may cause extensive cutaneous lesions (106), but it is a rare event, even in immunocompromised persons, and the disease is not as aggressive as other systemic fungal infections that secondarily involve the skin (107).

Histopathology. Cutaneous chromomycosis resembles North American blastomycosis in that both demonstrate a lichenoid-granulomatous inflammatory pattern. In chromomycosis, there is pseudoepitheliomatous epidermal hyperplasia and an extensive dermal infiltrate composed of many epithelioid histiocytes (108). Other components of the infiltrate include multinucleated giant cells; small abscesses and clusters of neutrophils; and variable numbers of lymphocytes, plasma cells, and eosinophils. Tuberculoid formations may be present, but caseation necrosis is absent.

Fungi are found within giant cells as well as free in the tissue, especially in the abscesses. They appear as conspicuous, dark brown, thick-walled, ovoid or spheric spores varying in sizes from 6 to 12 μm that are likened to "copper pennies" and that may lie either singly or in chains or clusters (103) (Fig. 23-14). Because of their brown pigmentation, the spores can be seen easily without the use of special stains. Reproduction is by intracellular wall formation and septation, not by budding, and cross walls can be seen in some of the spores. In cases demonstrating marked hyperplasia of the epidermis, fungal spores can be seen within microabscesses or giant cells, as in North American blastomycosis. Transepidermal elimination of fungal spores may be observed, resulting in clinically visible black dots (109,110).

A B

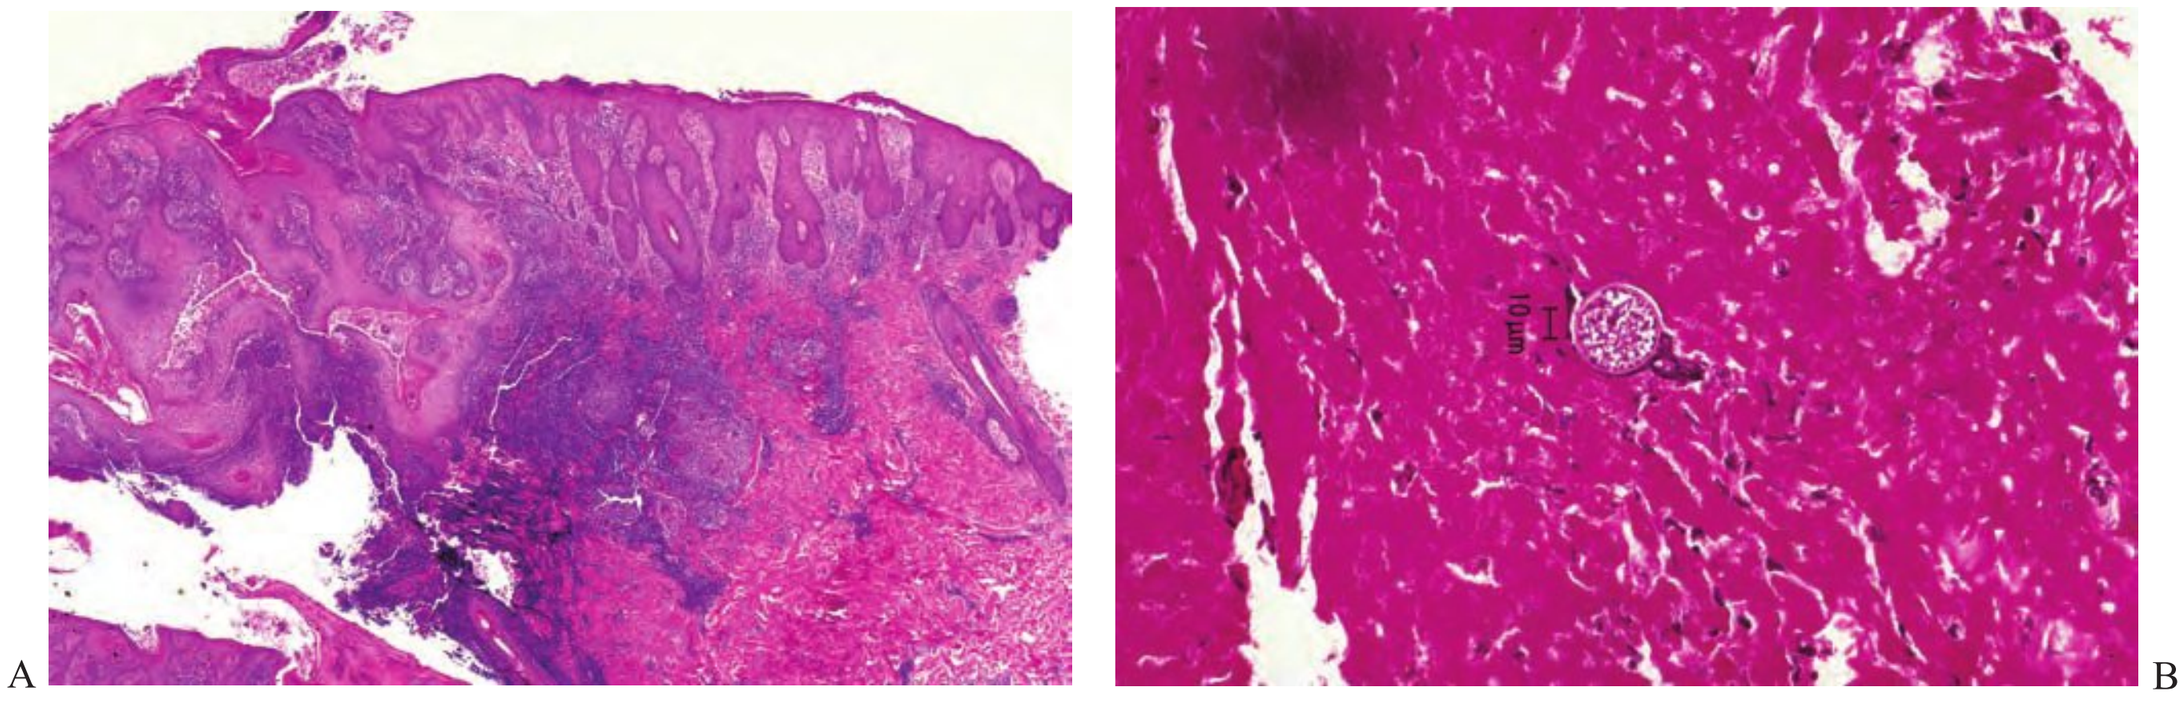
FIGURE 23-14. Chromoblastomycosis. A: H&E stain shows pseudoepitheliomatous epidermal hyperplasia with microabscess formation and a mixed inflammatory infiltrate. B: Pigmented spores (adjacent to scale marker) resembling "copper pennies" are surrounded by a neutrophilic infiltrate (H&E stain).

Pathogenesis. Although percutaneous inoculation of the fungus is widely accepted as the mode of infection, the fact that the cutaneous manifestations show no chancriform syndrome but rather a granulomatous infiltrate resembling that of North American blastomycosis suggests that the cutaneous lesions of chromomycosis may arise by hematogenous dissemination from a silent primary pulmonary focus. Although this view is supported by occasional reports of hematogenous dissemination and by the observation of multiple areas of calcification in the chest x-ray film of a patient with chromomycosis (111), convincing evidence is lacking. In support of the concept that cutaneous inoculation may cause cutaneous chromomycosis, pigmented fungal elements were found on embedded wood splinters associated with a foreign body reaction and in direct contact with the surrounding dermis in two patients (112), and one patient developed classic cutaneous chromomycosis caused by *F. pedrosoi* after trauma with a tree branch containing the same organisms (113).

COCCIDIOIDOMYCOSIS

Coccidioidomycosis, also known as *Valley fever*, is caused by the dimorphic fungus *Coccidioides immitis*. Like blastomycosis, it occurs in three forms: primary cutaneous inoculation coccidioidomycosis, pulmonary coccidioidomycosis, and systemic coccidioidomycosis. This soil-dwelling organism is endemic in the southwestern United States, especially in the San Joaquin and Sacramento valleys, southern Arizona, and Mexico (114). The vast majority of infections with *Coccidioidomycosis* result from inhalation of the aerosolized arthrospores. Approximately 60% of those infected are asymptomatic, and of the symptomatic patients, 90% to 99% experience only mild flulike symptoms (114).

Primary cutaneous inoculation coccidioidomycosis is very rare. In a few instances, as in primary cutaneous inoculation blastomycosis, it has occurred as a laboratory or an autopsy room infection (115,116); but unlike primary cutaneous inoculation blastomycosis, it has also been found as a naturally occurring infection through injuries by contaminated thorns or splinters (117,118). A tender, ulcerated nodule forms within 1 to 3 weeks at the site of inoculation and may enlarge into a granulomatous, ulcerated plaque. This is followed, as in the case of accidental inoculation with *B. dermatitidis*, by regional lymphangitis and lymphadenitis. Healing usually takes place within a few months, but meningitis developed in one reported patient, requiring prolonged intrathecal treatment with amphotericin B (118).



Pulmonary coccidioidomycosis is the most common form of the infection; epidemiologic skin test studies suggest that between 30% and 90% of the population in the southwestern United States have been infected (119–121). The fungus is resident in the soil of these arid or semiarid areas, and arthrospores are inhaled by the host when the soil is disturbed. Most immunocompetent infected individuals are asymptomatic, although about 40% will develop transient symptoms of an acute respiratory infection. The development of erythema nodosum is not uncommon, and most individuals recover without serious sequelae (122). In 2% to 8% of cases, however, the pulmonary lesions progress to chronic disease with cavity formation before finally healing.

Systemic coccidioidomycosis follows the primary pulmonary infection in only about 1 in 10,000 cases in otherwise immunocompetent whites. However, Mexicans are about 5 times, blacks 25 times, and Filipinos 175 times more likely to acquire systemic disease than whites, which has a mortality rate of about 50% when untreated (114). Studies of this difference have focused on human leukocyte antigen (HLA) genes, which produce molecules responsible for antigen presentation to T cells, the portion of the immune system important in elimination of fungi. Some studies have shown HLA subtypes -A9 and -B5 as well as ABO blood group B to be associated with disseminated coccidioidomycosis, and each occurs with greater frequency in blacks and Filipinos than in whites. The risk of dissemination and a fatal outcome is also greater in HIV-infected patients, particularly those with AIDS (123,124). Disseminated coccidioidomycosis may occasionally represent the first manifestation of AIDS (123). Immunosuppressive therapy may cause activation of a latent pulmonary infection of coccidioidomycosis. Dissemination of the infection after iatrogenic immunosuppression is frequently explosive and may be fatal. Therefore, all patients with a history of travel or residence in endemic areas should receive a coccidioidin skin test and have a chest roentgenogram before immunosuppressive therapy is initiated (125). In systemic coccidioidomycosis, many organs, especially the meninges, lungs, bones, and lymph nodes, may be involved (126). Coccidioidal fungemia often occurs in severe, acute forms of systemic coccidioidomycosis and is associated with a high mortality (123,126).

The coccidioidin skin test, which consists of the intradermal injection of 0.1 mL of a 1:100 dilution of coccidioidin, is of value in diagnosing early infection. The test converts from negative to positive within a few weeks of the primary pulmonary infection, even before a blood test would be positive. Patients with erythema multiforme or nodose lesions are exquisitely sensitive to coccidioidin, and even higher dilutions have been recommended for use in such cases (127). The test is helpful when positive; however, those patients with anergy or disseminated disease tend to have a persistently negative skin test (116).

Cutaneous lesions occur in 15% to 20% of cases of systemic coccidioidomycosis. They may consist of verrucous papules, nodules, or plaques, or of subcutaneous abscesses, which may break through the skin to form draining sinuses. One or a few cutaneous nodules or plaques may occasionally be the only clinical manifestation of systemic coccidioidomycosis, heralding a relatively good prognosis (125). A rare manifestation is the sudden widespread appearance of small pustules on an erythematous base (126), just as described in North American blastomycosis.

Histopathology. In primary cutaneous inoculation coccidioidomycosis, a dense dermal inflammatory infiltrate of neutrophils, eosinophils, lymphoid cells, and plasma cells with an occasional giant cell can be observed. Small abscesses may be

A B

FIGURE 23-15. Coccidioidomycosis. A: The low-power pattern is similar to that of North American blastomycosis with pseudoepitheliomatous epidermal hyperplasia and a mixed inflammatory infiltrate (H&E stain). B: A large, round, thick-walled spore with granular cytoplasm is present in a background of necrotic tissue (H&E stain).

seen (115). Spores, and in some cases also hyphae, are present. The regional lymph nodes show a well-developed granulomatous reaction consisting of epithelioid and giant cells. Spores are found within and outside the giant cells.

The verrucous nodules and plaques of the skin in systemic coccidioidomycosis histologically resemble those of North American blastomycosis (Fig. 23-15A). However, they show less of a tendency toward abscess formation, and caseation necrosis may occur. The causative organisms are found as spores, free in the tissue and within multinucleated giant cells, and as a rule, they are present in large numbers.

The subcutaneous abscesses show a central area of necrosis surrounded by a granulomatous infiltrate that is tuberculoid in type and composed of lymphoid cells, plasma cells, epithelioid cells, and some giant cells. Numerous spores are present extracellularly as well as intracellularly in the giant cells. The pustules seen in a few cases show the presence of spores within them (128).

The nodose skin lesions occurring in primary pulmonary coccidioidomycosis have the same histologic appearance as those in idiopathic erythema nodosum (128).

The spores of *C. immitis* vary in size from 10 to 80 µm (Fig. 23-15B), with the average size being about 40 µm. Thus, the fungi of *Coccidioides* are much larger than those of *Blastomyces, Cryptococcus,* or *Phialophora.* The spores are round and thick walled and have a granular cytoplasm. Multiplication takes place by the formation of endospores, which may be seen lying inside the larger spores. The endospores are released into the tissue by rupture of the spore wall. Endospores may measure up to 10 µm in diameter.

CRYPTOCOCCOSIS

Cryptococcosis is an infection caused by the yeast *C. neoformans,* which occurs throughout much of the world. *C. neoformans* is found in the excreta of birds, mainly pigeons and chickens, and in soil contaminated by them. The yeast is spread by aerosol, and transient colonization of the respiratory tract and skin of humans is not rare (129). Primary cutaneous (inoculation) cryptococcosis is extremely rare (130,131). The organism generally enters the body through the respiratory tract, where it can cause symptomatic or asymptomatic infection, either of which may be followed by hematogenous spread (132). Although clinical disease occurs in some apparently normal individuals, it usually develops in immunocompromised hosts, especially those with AIDS (133) (Fig. 23-16A), but also in patients taking corticosteroids (134,135) and in patients with hematopoietic malignancies (136,137) or sarcoidosis (137–139).

Meningitis is the most common clinical manifestation of systemic infection. Symptom onset is insidious. Patients report a dull headache, most commonly with little fever until late in the disease. Other signs of meningeal irritation such as nuchal rigidity are absent (132). In addition, there may be osseous lesions and involvement of the kidneys and prostate. Cutaneous lesions are found in 10% to 15% of the cases of systemic cryptococcosis (140). In rare instances, lesions of the oral mucosa also occur (136). Without adequate treatment, mortality with the systemic form is 70% to 80%; untreated cerebromeningeal cryptococcosis is almost invariably fatal. Cryptococcemia is an extremely grave prognostic sign (132,141).

In some instances of systemic cryptococcosis, central nervous system involvement is not seen, and there are only one or a few lesions in the skin, lymph nodes, bones, or eyes. In cases in which only cutaneous lesions are present, the disease may take a benign course, ending with healing of the lesions, even without treatment (142,143). However, cutaneous lesions may be the presenting sign of systemic cryptococcosis and may be followed by wide dissemination of the disease with a fatal ending (132,141).

Cutaneous lesions are variable and may consist of papules, pustules, herpetiform vesicles, nodules, infiltrated plaques, subcutaneous swellings or abscesses, or ulcers (140). Lesions resembling those of molluscum contagiosum, Kaposi's sarcoma, or acne have been described in patients with AIDS

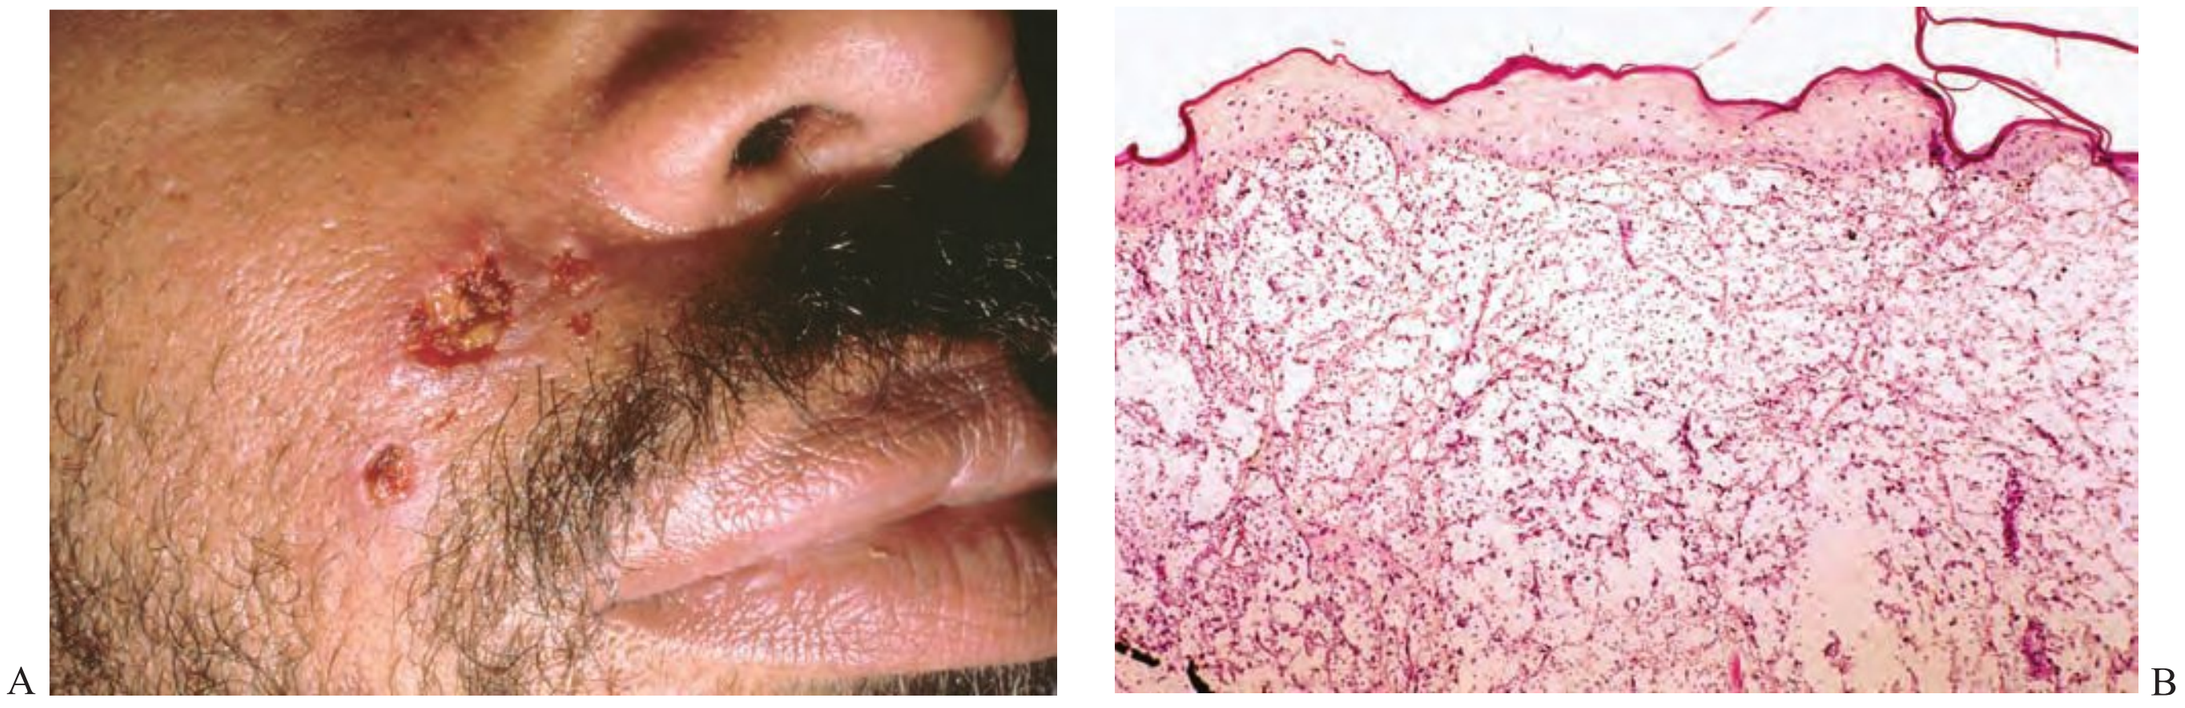


FIGURE 23-16. Cryptococcosis. A: Ulcerated papules and plaques of crytococcal infection in a HIV-positive male. B: H&E stain shows spores surrounded by wide capsules with relatively little inflammatory reaction. C: Spores, but not their capsules, can be visualized in routine stained sections (H&E stain).

(144–146) (Fig. 23-16A). In infections limited to the skin, generally only one or possibly two lesions are present, but in cases with widespread systemic infection, there are often multiple cutaneous lesions (134,140).

Cryptococcal cellulitis is a variant form that may occasionally be limited to the skin. This form has an abrupt onset and spreads rapidly. There may be multiple sites of involvement. It is seen only in markedly immunosuppressed hosts, especially in renal transplant patients (147).

Histopathology. Two types of histologic reaction to infection with *C. neoformans* may occur in the skin as well as elsewhere: gelatinous and granulomatous. Both types may be seen in the same skin lesion (132,135). Gelatinous lesions show numerous organisms in aggregates and only very little tissue reaction (Fig. 23-16B). In contrast, granulomatous lesions show a pronounced tissue reaction consisting of histiocytes, giant cells, lymphoid cells, and fibroblasts. Areas of necrosis may also be seen, and the organisms are present in a much smaller number than in gelatinous lesions, found mainly within giant cells and histiocytes or occasionally free in the tissue (148).

C. neoformans, a round to ovoid spore, measures from 4 to 12 μm in diameter in the gelatinous reaction but often only 2 to 4 μm in the granulomatous reaction (148) (Fig. 23-16C). The spore stains with the PAS reaction or methenamine silver and shows a dark brown or black color with the Fontana-Masson stain, which completely disappears with melanin bleach (149). Like *B. dermatitidis,* it multiplies by budding. In the gelatinous reaction pattern, a broad capsule surrounds the fungus, and there is very little infiltration of inflammatory cells. The capsule does not stain with H&E or the PAS reaction, but because of the presence of acid mucopolysaccharides, it stains metachromatically purple with methylene blue, blue with Alcian blue (150), and red with mucicarmine. When the Alcian blue stain and PAS reaction are combined, the yeast cell stains red and the surrounding capsule blue. However, when the yeast cells do not form a capsule, an intense granulomatous inflammatory reaction of histiocytes, giant cells, lymphocytes, and fibroblasts is elicited (149).

Cryptococcal cellulitis shows nonspecific acute and chronic inflammation in which cryptococcal organisms can be demonstrated with the PAS and mucicarmine stains (147).

Pathogenesis. *C. neoformans* is inhaled as a relatively small, nonencapsulated organism measuring approximately 3 μm in diameter. Under favorable nutrient conditions in the human host, the size of the organism increases up to 12 μm, and a wide gelatinous capsule forms. The lack of a tissue reaction to encapsulated *C. neoformans* is best explained by the fact that the thick capsule prevents contact of the organism with the host tissue and thus inhibits phagocytosis of the organism (148). Failure of the organism to form a capsule probably is the result of a defect in one of its metabolic pathways (149).

On electron microscopy, the mucinous capsule of *C. neoformans* is seen to consist of radially arranged fibrillary material, with the fibrils intertwining and having a beaded appearance (151).

Ever since cases of cryptococcosis with only one or a few cutaneous lesions have been described, some authors have assumed that a purely cutaneous form of cryptococcosis produced by cutaneous inoculation exists (152). However, the fact that purely cutaneous lesions show no chancriform syndrome with regional lymphadenopathy speaks against the theory of primary inoculation of the skin (134). It has been recommended that all cases seeming to be purely cutaneous cryptococcosis should be considered potentially disseminated (153). Cultural studies should include the spinal fluid, sputum, prostatic fluid, and urine to rule out disseminated disease (154). Of note, there are multiple reports of cross-reactivity of *Cryptococcus* with unrelated fungi with the use of agglutination kits (155,156). Confirmation of a positive capsular antigen test with a second test helps to limit false positives.

Differential Diagnosis. In the granulomatous type of reaction, *C. neoformans* may have no capsule, may be small with an average diameter of only 3 μm, and is found largely within macrophages and giant cells. Histologic differentiation from *B. dermatitidis,* which also reproduces by budding; *H. capsulatum*; and other fungi may then be difficult. However, only *C. neoformans* stains black with the Fontana-Masson stain (149).

HISTOPLASMOSIS

Histoplasmosis is found throughout the world, but the largest endemic focus is in the central eastern United States, especially the Ohio and lower Mississippi river valleys, where 85% to 90% of the population have positive skin tests for histoplasmin. It has been estimated that 40 million persons have undergone pulmonary infection with *H. capsulatum* and that there are 200,000 new cases annually in the United States (157,158).

Like blastomycosis and coccidioidomycosis, histoplasmosis may occur in three forms: primary cutaneous inoculation histoplasmosis, primary pulmonary histoplasmosis caused by inhalation, and disseminated histoplasmosis.

Primary cutaneous inoculation histoplasmosis, a very rare event, is benign and self-limited in duration. It generally occurs as a laboratory infection and presents as a chancriform syndrome, with a nodule or ulcer at the site of inoculation and associated lymphangitis and lymphadenitis (159,160).

Primary pulmonary histoplasmosis, the common form of infection, is usually asymptomatic, although acute pulmonary histoplasmosis with symptoms resembling those of influenza may develop in a minority of patients. Chronic pulmonary histoplasmosis usually occurs in patients with preexisting lung disease and may result in the formation of cavities. It develops in about 1 in 2,000 infections, resembles pulmonary tuberculosis in its symptoms, and may end fatally unless treated. Reactivation of pulmonary histoplasmosis following treatment with infliximab (Remicade) has been reported and should be considered when fever and pulmonary symptoms develop in these patients (161).

Before the advent of HIV, disseminated histoplasmosis developed in only 1 in 50,000 infections (162) and was usually found in infants, patients with lymphoma (163), or those receiving immunosuppressive treatment (164). Although not as frequent in the general AIDS population as coccidioidomycosis and cryptococcosis (165), disseminated histoplasmosis can be the most frequent opportunistic infection in AIDS patients living in highly endemic areas (166,167).

Disseminated histoplasmosis presents a variable clinical picture, depending on the degree of parasitization. Cases with severe degrees of parasitization (acute disseminated disease) occur principally in infants and immunosuppressed patients and may be fatal. There is often high, persistent fever and extensive involvement of the reticuloendothelial system with hepatosplenomegaly; anemia, leukocytopenia, and thrombocytopenia may also be seen. Cases with moderate degrees of parasitization (subacute disseminated disease) occur in both adults and infants, who if adequately treated may survive. Fever, hepatosplenomegaly, and bone marrow depression are mild or moderate. Adrenal involvement leading to adrenal insufficiency, as well as gastrointestinal ulceration, meningitis, and endocarditis, are common. Cases with mild degrees of parasitization (chronic disseminated disease) are associated with destructive focal lesions in a number of organs and occur almost exclusively in adults. There may or may not be fever, hepatosplenomegaly, bone marrow depression, adrenal insufficiency, meningitis, or endocarditis. In the chronic disseminated form, the response to treatment generally is good (159). If no cutaneous or oral lesions are present, the most useful diagnostic method is a bone marrow biopsy and occasionally also biopsy of the liver or a palpable lymph node (164).

Cutaneous lesions occur in only 6% of patients with disseminated histoplasmosis but may rarely be the presenting sign (168–170). Cutaneous lesions occur in a wide variety of forms, none of which can be said to be characteristic. Most commonly, they consist of primary ulcers, often with annular, heaped-up borders (169,171). They may also consist of papules, nodules, or large plaquelike lesions (168,172). Papules may umbilicate, causing a resemblance to lesions of molluscum contagiosum (173). Lesions may be purpuric or crusted or may develop pustular caps and ulcerate. There may be tender, red nodules due to panniculitis (174). A rare cutaneous manifestation is a generalized pruritic erythroderma (175,176). In addition, there may be a number of nonspecific cutaneous manifestations associated with histoplasmosis, including erythema nodosum and erythema multiforme.

In contrast to the rarity of cutaneous lesions, lesions of the oral mucosa occur in about half of all cases of disseminated histoplasmosis and are not infrequently the presenting sign of the disease (168). Lesions of the oral mucosa often start as painless papular swellings and usually ulcerate. The contiguous skin may also be involved. Biopsy of a mucosal or cutaneous lesion may be the most rapid method of arriving at a specific

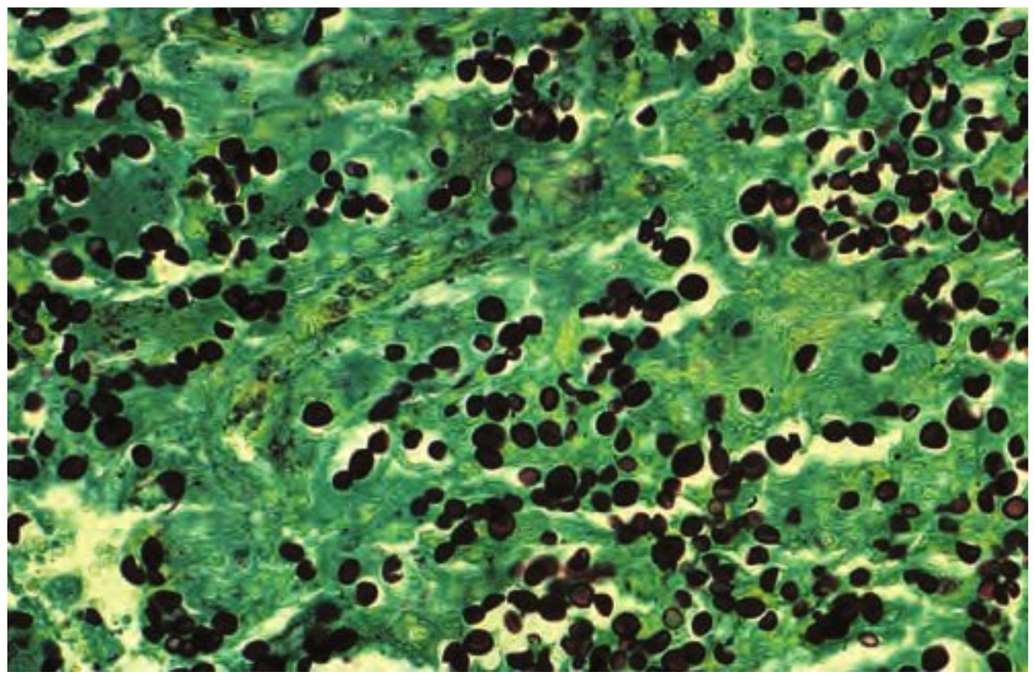

FIGURE 23-17. Histoplasmosis. Large spores of H. capsulatum var. duboisii are seen extracellularly and in giant cells (GMS stain).

diagnosis of disseminated histoplasmosis and may allow for the rapid institution of lifesaving therapy as culture may require up to a 4-week incubation period (177).

Histopathology. The diagnostic feature in all types of cutaneous histoplasmosis is the presence of tiny 2- to 4-μm spores within the cytoplasm of macrophages and variably within giant cells (172,178). The spores of *H. capsulatum* are visualized in sections stained with H&E, Gram, or Giemsa (Fig. 23-17). They appear as round or oval bodies surrounded by a clear space that was originally interpreted as a capsule, giving rise to the name *H. capsulatum*. The spores, not including the clear space surrounding them, measure from 2 to 4 μm in diameter. Silver impregnation stains and electron microscopic studies show that *H. capsulatum* does not possess a capsule and that the inner portion of the clear space represents the cell wall of the fungus and the clear space itself is filled with granular material that separates the cell wall of the fungus from the cytoplasm of the macrophage (178). On electron microscopy, it can be seen that each spore of *H. capsulatum*, including its halo, is located within a phagosome that is lined by a trilaminar membrane (178).

In acute disseminated histoplasmosis, lesions consist mostly of heavily parasitized histiocytes with relatively little surrounding tissue reaction. Cutaneous lesions in the chronic form of the disease tend to be composed of better-differentiated macrophages with fewer organisms (168). A suppurative granulomatous pattern may develop, especially in ulcerated lesions. There may be foci of necrosis, and giant cells may also be present. Although well-developed tubercles are characteristic of pulmonary histoplasmosis, they are unusual in the skin. Oral lesions, especially when ulcerated, may show a more mixed infiltrate with neutrophils and eosinophils.

Pathogenesis. *H. capsulatum* is a dimorphous fungus that grows in culture at temperatures below 35°C and on natural substrates in soil as a mycelial fungus elaborating macroaleuriospores (8 to 16 μm) and microaleuriospores (2 to 5 μm). When inhaled, the latter sprout and transform into small budding yeasts that are 2 to 5 μm in diameter. In cultures at a temperature of 37°C, the organism also grows in the yeastlike form (179).

Differential Diagnosis. The histologic appearance of histoplasmosis, characterized by the presence of parasitized macrophages within a chronic inflammatory infiltrate, is much like that of rhinoscleroma, granuloma inguinale, and cutaneous leishmaniasis. *H. capsulatum* is the only pathogen to parasitize macrophages that stains with the usual fungal stains, such as the PAS reaction and methenamine silver. *Histoplasmosis* does not possess a true capsule and can thus be distinguished from *C. neoformans*, particularly when the latter is noted to stain black with Fontana-Masson stain.

African Histoplasmosis

In addition to classical histoplasmosis caused by *H. capsulatum*, there is a form of histoplasmosis that is caused by *H. capsulatum* var. *duboisii*, and that has been called *African histoplasmosis* because it occurs almost exclusively in Central Africa. The portal of entry is not known. It usually occurs as a relatively indolent form involving the skin as well as the subcutaneous tissue, bones, and lymph nodes (180,181). This organism relatively rarely causes a disseminated form of disease that involves many internal organs and may be fatal, thus resembling more classical disseminated histoplasmosis (182).

The cutaneous lesions may be one, a few, or many. They consist of papules, nodules, and plaques that often ulcerate (183). There may be large, subcutaneous granulomas that develop into fluctuant, nontender abscesses (179). Purulent bone lesions may result in draining sinus tracts extending through the skin (181).

Histopathology. The cutaneous lesions show a dense, mixed cellular infiltrate containing numerous giant cells and scattered histiocytes, lymphocytes, and plasma cells. There are focal aggregates of neutrophils forming small abscesses (183). Numerous yeast cells, 8 to 15 μm in diameter, are present mainly in the giant cells but also in histiocytes and extracellularly (181).

Pathogenesis. Despite the fact that African histoplasmosis differs in its clinical character and in the size of the organism from classic histoplasmosis, it is clear that *H. capsulatum* and *Histoplasma duboisii* are variants of the same species, since after prolonged *in vitro* growth at 37°C, the small yeast cells of *H. capsulatum* can assume the same size as those of *H. duboisii* (181).

SPOROTRICHOSIS

Surveys with the sporotrichin skin test show a positive reaction in up to 10% of the population in certain areas, suggesting that many infections with *S. schenckii* are minor or asymptomatic and not recognized clinically (184,185). Clinical sporotrichosis usually occurs as one of two primary cutaneous forms, either

the fixed cutaneous or the lymphocutaneous form. Both result from direct inoculation at a site of minor trauma. Although the infection may rarely disseminate from either form by autoinoculation to other skin sites or by hematogenous spread (186–188), systemic sporotrichosis more commonly follows pulmonary infection. Development of systemic sporotrichosis, although rare, occurs particularly in persons with a depressed immune response, such as patients with lymphoma or persons receiving long-term systemic corticosteroids. *S. schenckii* is not a common opportunist in HIV-infected individuals, but disseminated sporotrichosis has been seen in a few patients with AIDS (189).

The lymphocutaneous form of sporotrichosis starts with a painless papule that grows into an ulcer, usually on a finger or hand. Subsequently, a chain of asymptomatic nodules appears along the lymph vessel draining the area ("sporotrichoid spread"). These lymphatic nodules may undergo suppuration with subsequent ulceration.

In the fixed cutaneous form, a solitary plaque or occasionally a group of lesions is seen, most commonly on an arm or the face. It may show superficial crusting or a verrucous surface (190–192). There is no tendency toward lymphatic spread.

Systemic sporotrichosis may be unifocal or multifocal and usually develops subsequent to pulmonary infection. Unifocal systemic sporotrichosis may affect the lungs, a single joint or symmetric joints, the genitourinary tract, or rarely the brain (193). Chronic pulmonary sporotrichosis resembles pulmonary tuberculosis (194). Multifocal systemic sporotrichosis nearly always shows widely scattered cutaneous lesions, which start as nodules or as subcutaneous abscesses and undergo ulceration. In addition, involvement of the lungs (188) or of several joints of the extremities is usually observed. The predilection of *S. schenckii* for cooler parts of the body, such as the skin, lungs, and joints of the extremities, has been attributed to the fact that the organism grows best at temperatures less than 37°C.

Histopathology. Early primary cutaneous lesions of sporotrichosis usually show a nonspecific inflammatory infiltrate composed of neutrophils, lymphoid cells, plasma cells, and histiocytes (195). Longer-standing, clinically verrucous lesions show a hyperplastic epidermis with small, intraepidermal, and dermal lymphoplasmacytic infiltrate with small abscesses, eosinophils, giant cells, and small granulomas often associated with asteroid bodies (191,195). Later, through coalescence, a characteristic arrangement of the infiltrate in three zones may develop. These include a central "suppurative" zone composed of neutrophils; surrounding it, a "tuberculoid" zone with epithelioid cells and multinucleated histiocytes; and peripheral to it, a "round cell" zone of lymphoid cells and plasma cells.

The lymphatic nodules of lymphocutaneous sporotrichosis and the cutaneous nodules of multifocal systemic sporotrichosis at first show scattered granulomas within an inflammatory infiltrate predominantly in the deep dermis and subcutaneous fat (191,196). These enlarge and coalesce to form irregularly shaped suppurative granulomata, and eventually a large abscess surrounded by zones of histiocytes and lymphocytes as described for primary lesions (191).

In many instances, it is not possible to recognize the causative organisms of *S. schenckii* in tissue sections, particularly in the two common forms: the lymphocutaneous and fixed cutaneous. This seems to be true especially in cases of sporotrichosis reported from the United States (197) and Europe (196). In these areas, negative findings are common even with diastase digestion of glycogen granules prior to staining of sections with the PAS reaction. Staining with methenamine silver has not increased the frequency of positive findings (196). Even in cases with positive findings, numerous sections often have to be examined before one or a few organisms are visualized. Immunohistochemical staining using primary antibodies directed against *S. schenckii* may increase the percentage of cases in which the organism can be demonstrated to 83%, more than double that achieved with ordinary histochemical methods (198). In addition, there are apparently significant geographic differences, since in a series of cutaneous sporotrichosis reported from Japan, 98% of the cases showed spores in tissue sections on staining with the PAS reaction (199). If present, the spores of *S. schenckii* appear as round to oval bodies 4 to 6 μm in diameter that stain more strongly at the periphery than in the center (196) (Fig. 23-18). Single or occasionally multiple buds are present. In some instances, small, cigar-shaped bodies up to 8 μm long are also present (187,195). In only very few cases can clumps of branching, nonseptate hyphae be demonstrated (197,199).

Asteroid bodies may be seen in sporotrichosis, as well as in a number of other infectious processes, and sarcoidosis. Asteroid bodies are visible in sections stained with H&E, and in sporotrichosis consist of a central spore 5 to 10 μm in diameter surrounded by radiating elongations of a homogeneous eosinophilic material. The phenomenon of radiating eosinophilic material found around infectious agents, described in sporotrichosis by Splendore (200) and in schistosomiasis by Hoeppli (201) and known as the *Splendore-Hoeppli phenomenon,* has been thought to represent deposition of antigen-antibody complexes and debris from host inflammatory cells (202). Measurements of the greatest diameter of asteroid bodies in sporotrichosis vary from 7 to 25 μm, with a mean of 20 μm (191). Asteroid bodies have been observed in only a few cases of sporotrichosis occurring in the United States, and it may be difficult to demonstrate the central spore. However, asteroid bodies are found frequently in cases of sporotrichosis from South Africa, Japan, and Australia, with an incidence varying from 39% to 65% (203).

Pathogenesis. *S. schenckii* occurs throughout the world and is commonly contracted through exposure to vegetal matter, often a splinter or thorn, although transmission by insects and animals has been reported (204). In nearly all cases of sporotrichosis, even in those without demonstrable fungi in the tissue, *S. schenckii* can be grown easily on Sabouraud medium. The fungus is dimorphic: At room temperature, it grows in a mycelial form with conidiophores bearing conidia as a "bouquet" at the

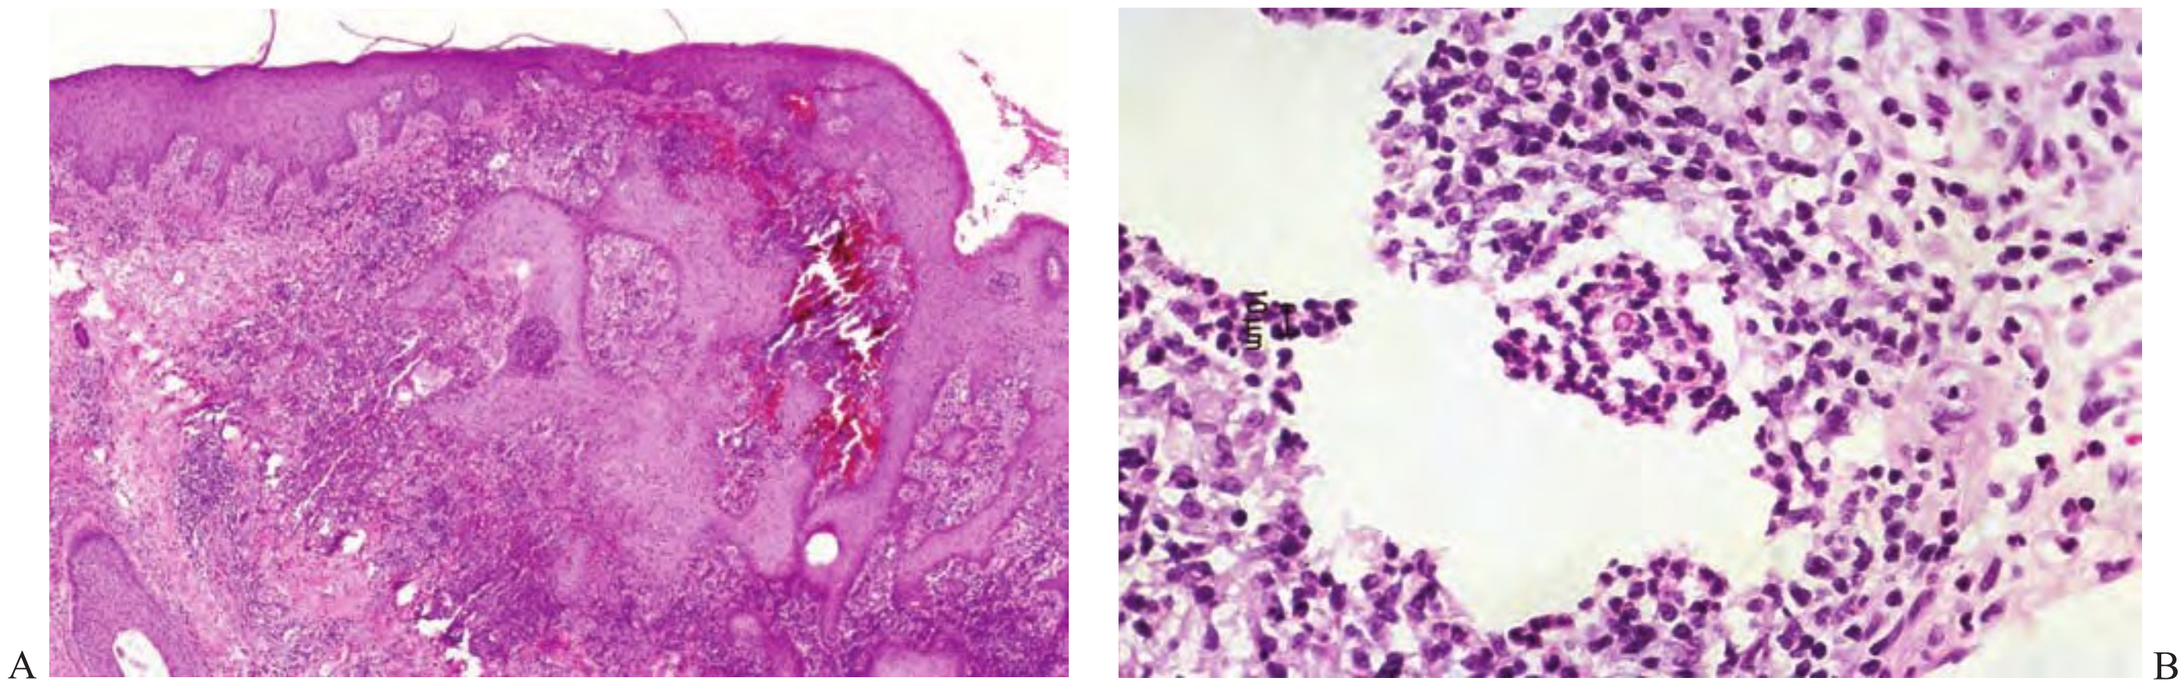

FIGURE 23-18. Sporotrichosis. A: H&E stain shows pseudoepitheliomatous epidermal hyperplasia with microabscess formation. B: H&E stain shows a round spore, staining more darkly at the periphery than centrally, surrounded by a neutrophilic infiltrate.

tip; at 37°C, it grows as a yeast (197). At 39°C, there is no growth, a fact that has led to the use of local thermotherapy (196,199).

Differential Diagnosis. If the fungus is not found in sections, a diagnosis of sporotrichosis can only be suspected; however, it can be excluded in dubious cases by a negative cutaneous sporotrichin test, which is almost always positive except in cases of disseminated disease (196). The subcutaneous abscesses of tularemia and of infections with *Mycobacterium marinum* may have the same histologic appearance as the cutaneous and subcutaneous nodules and abscesses of sporotrichosis and must be excluded.

EUMYCETOMA (FUNGAL MYCETOMA)

A number of fungi and filamentous bacteria may cause an indolent local infection, characterized by induration associated with draining sinuses. These diverse agents may have clinically identical presentations that have been collectively called *mycetoma* (205). The term *actinomycetoma* refers to such infections when filamentous bacteria cause them; they are discussed further in Chapter 21. *Eumycetoma*, however, is caused by a group of true fungi with thick septate hyphae, including *Petriellidium boydii* (*Allescheria boydii*, *Pseudallescheria boydii*), *Madurella grisea*, and *Madurella mycetomatis* (206). Although much more common in tropical regions, eumycetoma is seen occasionally in the United States, where the most common cause is *P. boydii* (207). Differentiation between actinomycetoma and eumycetoma is important, because they respond to different treatments.

Eumycetoma is a persistent, invariably progressive local infection without a tendency for systemic spread. There is no obvious association with immunosuppression. The infection starts as a subcutaneous nodule(s) usually on the foot at a site of trauma; in the past, these infections were not uncommon in the Madras region of India, and thus the term *Madura foot* has been used synonymously with mycetoma (206). The nodules eventuate in abscesses and draining sinuses (Fig. 23-19A). Gradually, the muscles and tendons are damaged and osteomyelitis develops. Grossly visible "sulfur granules" or "grains," which are tightly knit clusters of organisms, are discharged from the draining sinuses. These granules are black in cases of eumycetoma caused by the dematiaceous fungi *M. grisea* and *M. mycetomatis* (208,209), whereas they are colorless in eumycetoma caused by *P. boydii* (210).

Histopathology. Histologic examination of the indurated skin shows extensive granulation tissue containing abscesses that may lead into sinuses. The granulation tissue is nonspecific in appearance. In the early phase of the disease, the tissue surrounding the abscesses is composed of lymphoid cells, plasma cells, histiocytes, and fibroblasts, whereas in the late phase, fibroblasts may predominate. The diagnosis can be established only by finding the "sulfur granules" (Fig. 23-19B). Because they occur almost exclusively in abscesses or sinuses, an area containing purulent material should be chosen as the site for biopsy.

Most granules measure between 0.5 and 2.0 mm in diameter and are thus large enough to be visible macroscopically (208). The granules of both eumycetoma and actinomycetoma stain with the PAS reaction and methenamine silver (Fig. 23-19C). Granules of eumycetoma are composed of septate hyphae 4 to 5 μm thick, whereas the granules of actinomycetoma usually consist of fine, branching filaments or bacillary forms that are only about 1 μm thick (209). A Gram stain aids in differentiating bacterial from fungal causes of mycetoma; the filaments of actinomycetoma are gram positive, whereas the hyphae in grains of eumycetoma are gram negative (211). The study of discharged granules crushed on a slide and stained with lactophenol blue also allows differentiation between the thin filaments of actinomycetoma and the thicker hyphae of eumycetoma (211).

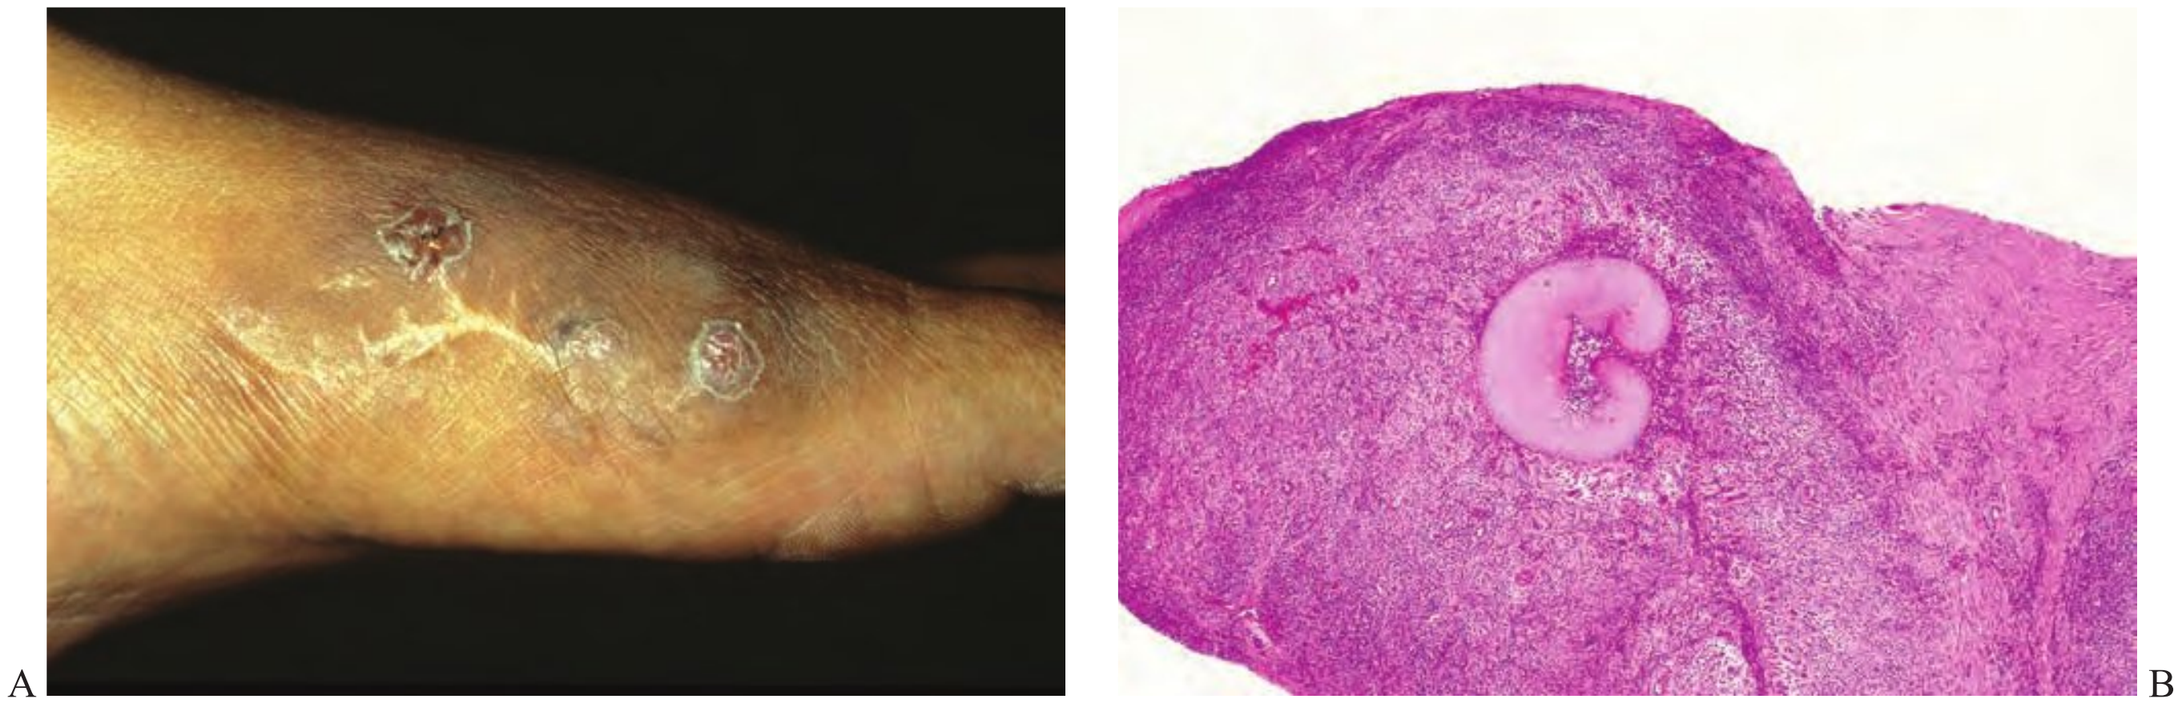

FIGURE 23-19. Eumycetoma. A: Ulcerated, indurated plaque of eumycotic mycetoma on the foot. B: H&E stain shows a "sulfur granule" in a purulent area of granulation tissue. C: The sulfur granule is composed largely of septate hyphae of P. boydii (GMS stain).

RHINOSPORIDIOSIS

Rhinosporidiosis is a chronic infection that is caused by *Rhinosporidium seeberi*. Rhinosporidiosis typically involves mucosal surfaces, most frequently the nasal mucosa, and may involve contiguous skin. This disease is seen primarily in India and Ceylon, but a number of cases have been seen in South America and a few in the United States (212).

The mode of transmission is not known. Lesions start as an often puritic papule, which grows into an erythematous polypoid mass that may cause obstruction of the nose and nasopharynx. Small cysts and pseudocysts develop and may discharge a combination of mucus, pus, and organisms, creating tiny white dots and giving lesions a characteristic strawberry-like appearance. Lesions of the ocular mucosa tend to be flatter, and skin lesions have a warty shape (212). Involvement of the genital mucosa has also been reported (213). Dissemination of the organism is extremely rare (214).

Histopathology. The epithelium is hyperplastic with papillomatosis and deep invaginations, some of which form pseudocysts (Fig. 23-20A). Numerous globular cysts of varying shape, representing sporangia in different stages of development, give the corium a distinctive "Swiss cheese" appearance. There is a surrounding dense, mixed inflammatory infiltrate with lymphocytes and histiocytes, including occasional giant cells, plasma cells, neutrophils, and eosinophils.

R. seeberi is a large, endosporulating organism with a distinctive morphology that can usually be recognized in H&E-stained sections (Fig. 23-20B). Sporangia develop from individual spores about the size of an erythrocyte (215). The spores develop into small uninucleate cysts that enlarge and develop a chitinous, eosinophilic wall. With increasing size, nuclear divisions lead to the development of up to 16,000 spores in a sporangium. These distinctive structures may be 300 μm in diameter. Rupture of the cyst or release of the spores through a pore in the cyst wall results in individual spores into the surrounding tissue. The organisms stain with the PAS reaction at all stages, but GMS and mucicarmine stains are not effective for organisms <100 μm in diameter (216).

Differential Diagnosis. The different clinical presentations of coccidioidomycosis and the smaller size of the spherical coccidioidal sporangia (<60 μm in diameter) allow for an easy distinction of that disease from rhinosporidiosis.

CUTANEOUS PROTOTHECOSIS

Prototheca is a genus of algae that causes cutaneous infections in humans. Discussion of *Prototheca* is included in this chapter because this organism may be isolated on Sabouraud's medium and has traditionally been discussed in mycology texts as well as because this text has no separate chapter for diseases caused by algae. Although there is one report of cutaneous infection in

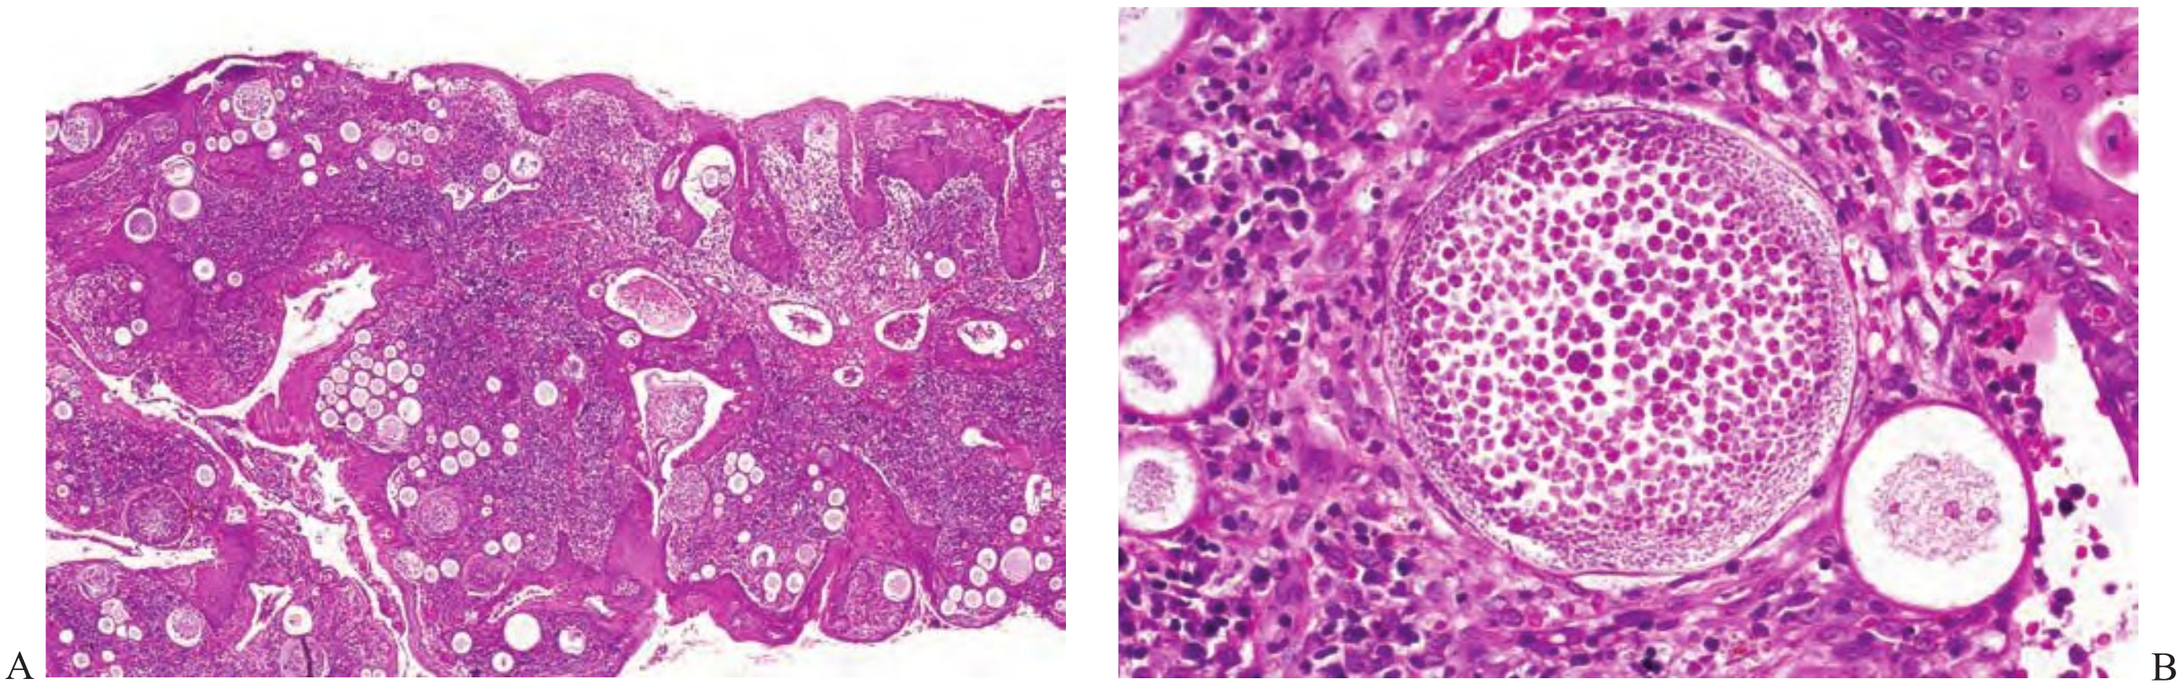

FIGURE 23-20. Rhinosporidiosis. A: H&E stain shows marked papillomatosis and deep invaginations of the nasal mucosa. B: A sporangium contains many individual spores (H&E stain).

a patient also infected with HIV (217), cutaneous protothecosis usually occurs in otherwise healthy persons following trauma and wound contamination with water (218). Lesions develop very slowly and may be single or multiple papules, plaques, or nodules with smooth, verrucous, or ulcerated surfaces (218–222).

Histopathology. The histologic appearance, like the clinical appearance, is not characteristic, so the diagnosis depends on the finding of the organisms. Usually, there is a mixed inflammatory infiltrate with areas of necrosis and fairly numerous giant cells (Fig. 23-21). In sections stained with H&E, the organisms stain faintly or not at all. On staining with PAS or silver methenamine, however, the organisms stain well and are seen both within giant cells and free in the tissue (219).

Individual organisms are spheric and measure 6 to 10 μm in diameter (222). However, as the result of septation, many contain endospores and then are considerably larger. Further subdivision of daughter cells within the parent cell leads to the formation of "sporangia" containing as many as 50 cells lying clustered together as morula-like structures (218). Ultimately, such a sporangium breaks down into individual organisms.

Pathogenesis. *Prototheca* is a genus of saprophytic, achloric (nonpigmented) algae. These organisms reproduce asexually by way of internal septation, producing autospores identical to the parent cell. *Prototheca* forms creamy, yeastlike colonies on Sabouraud's medium between 25°C and 37°C. These colonies become visible within 48 hours (219).

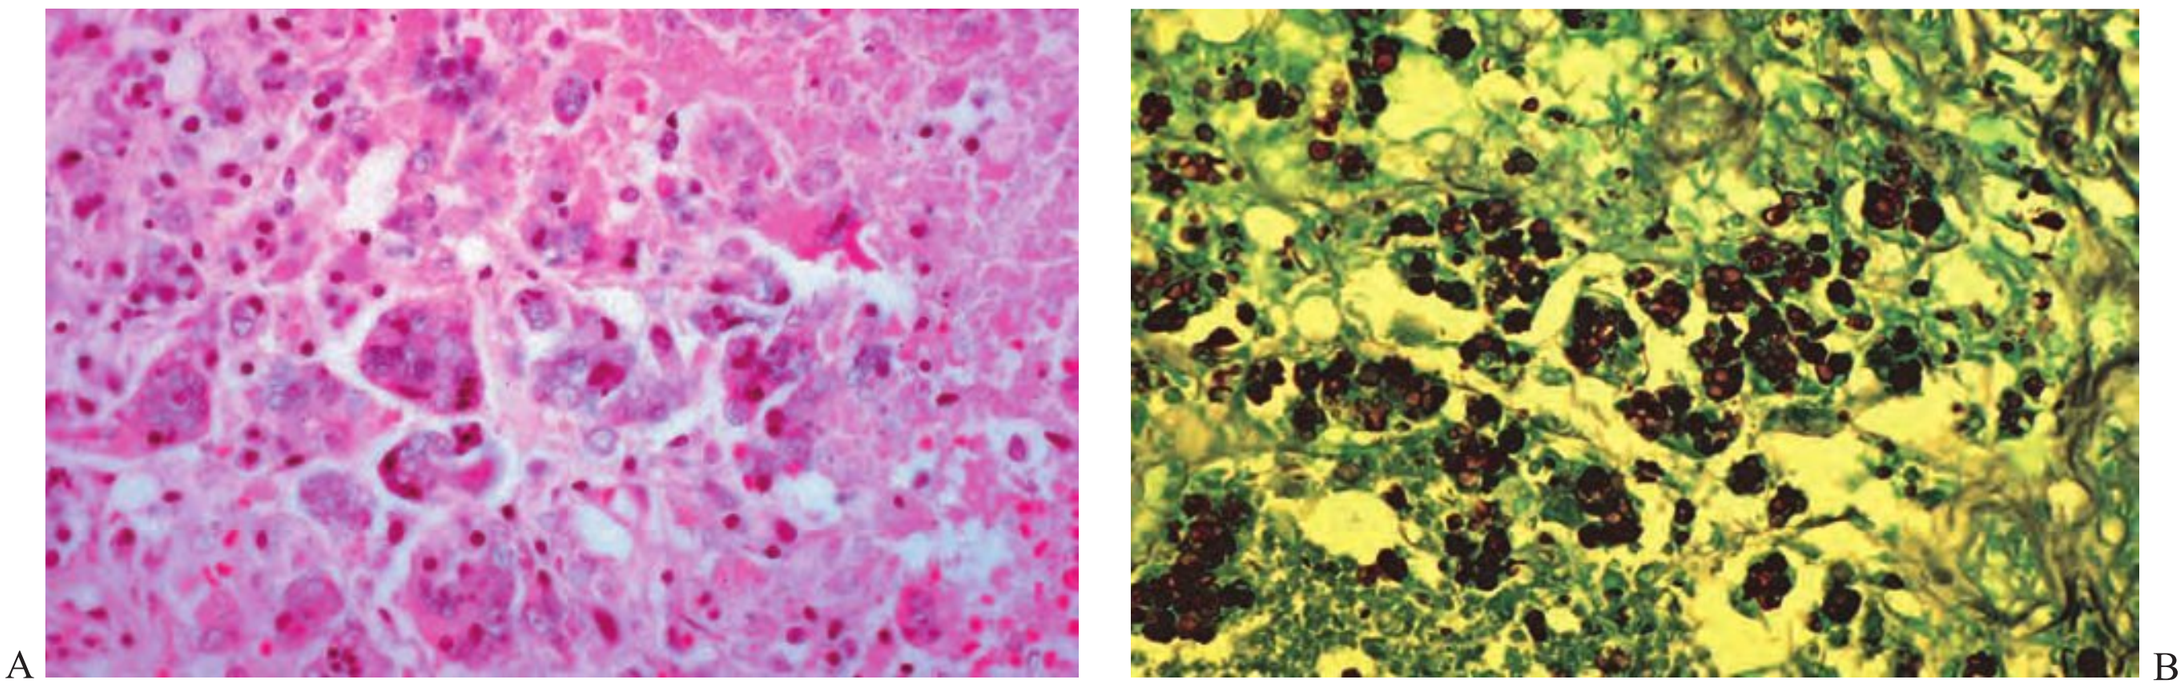

FIGURE 23-21. Protothecosis. A: H&E stain shows individual cells and clusters of organisms within giant cells. B: The morula-like clusters in multinucleated giant cells are highlighted by silver impregnation (GMS stain).

CHAPTER 24

Klaus Sellheyer
Eckart Haneke

Protozoan Diseases and Parasitic Infestations

The increase in international travel from endemic regions has brought diseases to North America and Europe that were once thought of as being confined to tropical countries. Furthermore, HIV infection has become an important cofactor in acquiring diseases that are normally rare in the developed world. In particular, leishmaniasis is considered to be an emerging opportunistic disease particularly in HIV-infected individuals (1). Immigrants from Asia, Africa, and South America represent another contingent of patients afflicted by diseases that are normally not prevalent in the United States and Western Europe.

LEISHMANIASIS

Leishmaniasis is a protozoan disease with a prevalence of 12 million cases and an incidence of almost 2 million new cases worldwide, making it, together with malaria, helminthic infestations of the gastrointestinal tract, and HIV infection, one of the most common infectious diseases worldwide (2). The inciting organism belongs to the order Trypanosomatida, which comprises two genera pathogenic to humans: *Trypanosoma* and *Leishmania* (3).

Leishmania species primarily affect cells of monocyte-macrophage lineage and exist in two forms during their life cycle: a flagellar (promastigote) and an aflagellar (amastigote) stage. The former is found in the intestines of sandflies, which function as the arthropod vector to *Leishmania* species. In the Old World the sand flies belong to the genus *Phlebotomus*, and in the New World to the genera *Lutzomia* and *Psychodopygus* (3). After the promastigotes enter the skin of the human host via the bite of infected sandflies, they transform into amastigotes within histiocytes. If the histiocytic response to *Leishmania* species remains confined to the skin, cutaneous lesions develop; if dissemination of the protozoa occurs, internal organs become involved.

At the center stage of all of the different forms of leishmaniasis is a disruption of macrophage activation with the subsequent avoidance of intracellular killing mechanisms (4). The parasites do so by inhibiting lysosomal phosphatases and protein kinase C. Substrates of protein kinase C are involved in cytoskeletal rearrangements and vacuolar trafficking and are thus important in cellular signaling. *Leishmania* species also inhibit the synthesis of proinflammatory and increase the production of antiinflammatory cytokines, thereby preventing their elimination from the human host.

Classification of Leishmaniasis

The former simplistic classification dividing leishmaniasis into cutaneous, mucocutaneous, and visceral forms has been abandoned in favor of a classification that recognizes the overlap in the clinical spectrum of the different types of leishmaniasis (1,5–8):

- Localized (acute) cutaneous leishmaniasis
- Diffuse (acute) cutaneous leishmaniasis (= disseminated anergic cutaneous leishmaniasis)
- Chronic cutaneous leishmaniasis (including leishmaniasis recidivans or lupoid leishmaniasis)
- Post–kala-azar dermal leishmaniasis
- Mucocutaneous leishmaniasis
- Visceral leishmaniasis
- Viscerotropic leishmaniasis

Each form of leishmaniasis is associated with a different type of *Leishmania* species and has a specific predilection for a geographic location (Table 24-1).

Localized (Acute) Cutaneous Leishmaniasis

Representing the most common form of skin involvement, localized acute cutaneous leishmaniasis affects primarily the exposed parts of the body, such as face, scalp, and arms (9–11). It appears initially as a painless, erythematous papule that enlarges over a period of 4 to 12 weeks to a nodule or a plaque measuring up to 2 cm in diameter (Fig. 24-1A). Ulceration is common. After several months the lesion spontaneously regresses, starting from the center and progressing outward. The end stage is represented by a scar accompanied by hypo- or hyperpigmentation (1,5,8,12). New World leishmaniasis commonly presents with a single lesion and Old World leishmaniasis with multiple ones (1,5).

Histopathology. The characteristic changes are noted throughout the dermis and consist of a dense, diffuse infiltrate of histiocytes admixed with lymphocytes and few plasma cells (Fig. 24-1B) (1,5,7–13). Eosinophils and neutrophils are rare;

TABLE 24-1 Leishmania Species and Geographic Locations Associated with the Different Clinical Forms of Leishmaniasis

Form of disease	New World parasite	Old World parasite	Geographic location
Localized (acute) cutaneous leishmaniasis	L b. braziliensis, L b. guyanensis, L b. panamensis, L m. mexicana, L m. amazonensis, L donovani chagasi	L major, L tropica, L aethiopica, L infantum	North Africa, India, Middle East, China, southern Russia, Pakistan, Mediterranean, Central and South America, Texas, Caribbean region
Diffuse (acute) cutaneous leishmaniasis	L m. amazonensis, L mexicana, L m. pifanoi	L aethiopica	Venezuela, Bolivia, Mexico, Dominican Republic, Brazil, Ethiopia
Leishmaniasis recidivans	L braziliensis	L tropica	Central and South America, Middle East
Post–kala-azar dermal leishmaniasis	L donovani chagasi	L donovani, L tropica L infantum	India, Bangladesh, East Africa, Sudan
Mucocutaneous leishmaniasis	L b. braziliensis		Brazil, Venezuela, Peru, Ecuador, Colombia
Visceral leishmaniasis	L donovani chagasi	L donovani, L infantum, L tropica	China, India, Bangladesh, Asia, Sudan, Africa, eastern Russia, Mediterranean, South America
Viscerotropic leishmaniasis		L tropica	Iraq, Kuwait

Note: New World parasites have a species and subspecies name; Old World parasites have only a species name.
L b. braziliensis, Leishmania braziliensis braziliensis; L m. mexicana, Leishmania mexicana mexicana.
Adapted and slightly modified from Grevelink SA, Lerner EA. Leishmaniasis. J Am Acad Dermatol 1996;34:257.

the latter are more numerous if the lesion is ulcerated (12). The cytoplasm of the histiocytes is filled with numerous dull blue-gray, round to oval bodies measuring 2 to 4 μm in diameter and exhibiting a round basophilic nucleus and a rod-shaped paranuclear kinetoplast, a specialized mitochondrial structure containing extracellular DNA (Fig. 24-1C). These intracellular bodies stain red or dark blue with Giemsa but not with periodic acid-Schiff (PAS) and Grocott's methenamine silver (GMS) because of a lack of a capsule and represent amastigotes, known as Leishman-Donovan bodies. When numerous, they can also be seen extracellularly. The number of leishmania organisms decreases with time and is often inversely related to the amount of plasma cells.

The epidermal changes are nonspecific and consist of hyperkeratosis, parakeratosis, and epidermal atrophy or hyperplasia (1,5,7,9,11,13). Ulceration is also noted. The basal cell layer may show hydropic degeneration and the follicular ostia may display plugging with compact orthokeratotic material (13).

Differential Diagnosis. The organisms of histoplasmosis do not exhibit a kinetoplast and do stain with (PAS) and (GMS) stains. *Klebsiella rhinoscleromatis*, the inciting agent of rhinoscleroma, also resides in macrophages and measures 2 to 3 μm in diameter. In contrast to leishmaniasis, rhinoscleroma reveals a large number of plasma cells with formation of Russell bodies. Granuloma inguinale, caused by *Calymmatobacterium granulomatis*, displays numerous small abscesses throughout the inflammatory infiltrate (see Chapters 21 and 23).

Diffuse (Acute) Cutaneous Leishmaniasis

Diffuse acute cutaneous leishmaniasis, also known as disseminated anergic cutaneous leishmaniasis, is a rare variant of localized cutaneous leishmaniasis and is due to a lack of a *Leishmania*-specific cellular immune response (14). It begins as a single lesion and then spreads diffusely all over the body, characteristically as nonulcerated nodules, often involving upper and lower extremities, buttocks, and face (Fig. 24-2) (1,5,14). In atypical cases ulceration of the nodules is noted (15).

Histopathology. The histopathologic changes of the individual lesions are the same as those seen in localized acute cutaneous leishmaniasis except for a larger number of Leishman-Donovan bodies and a relative lack of accompanying lymphocytes

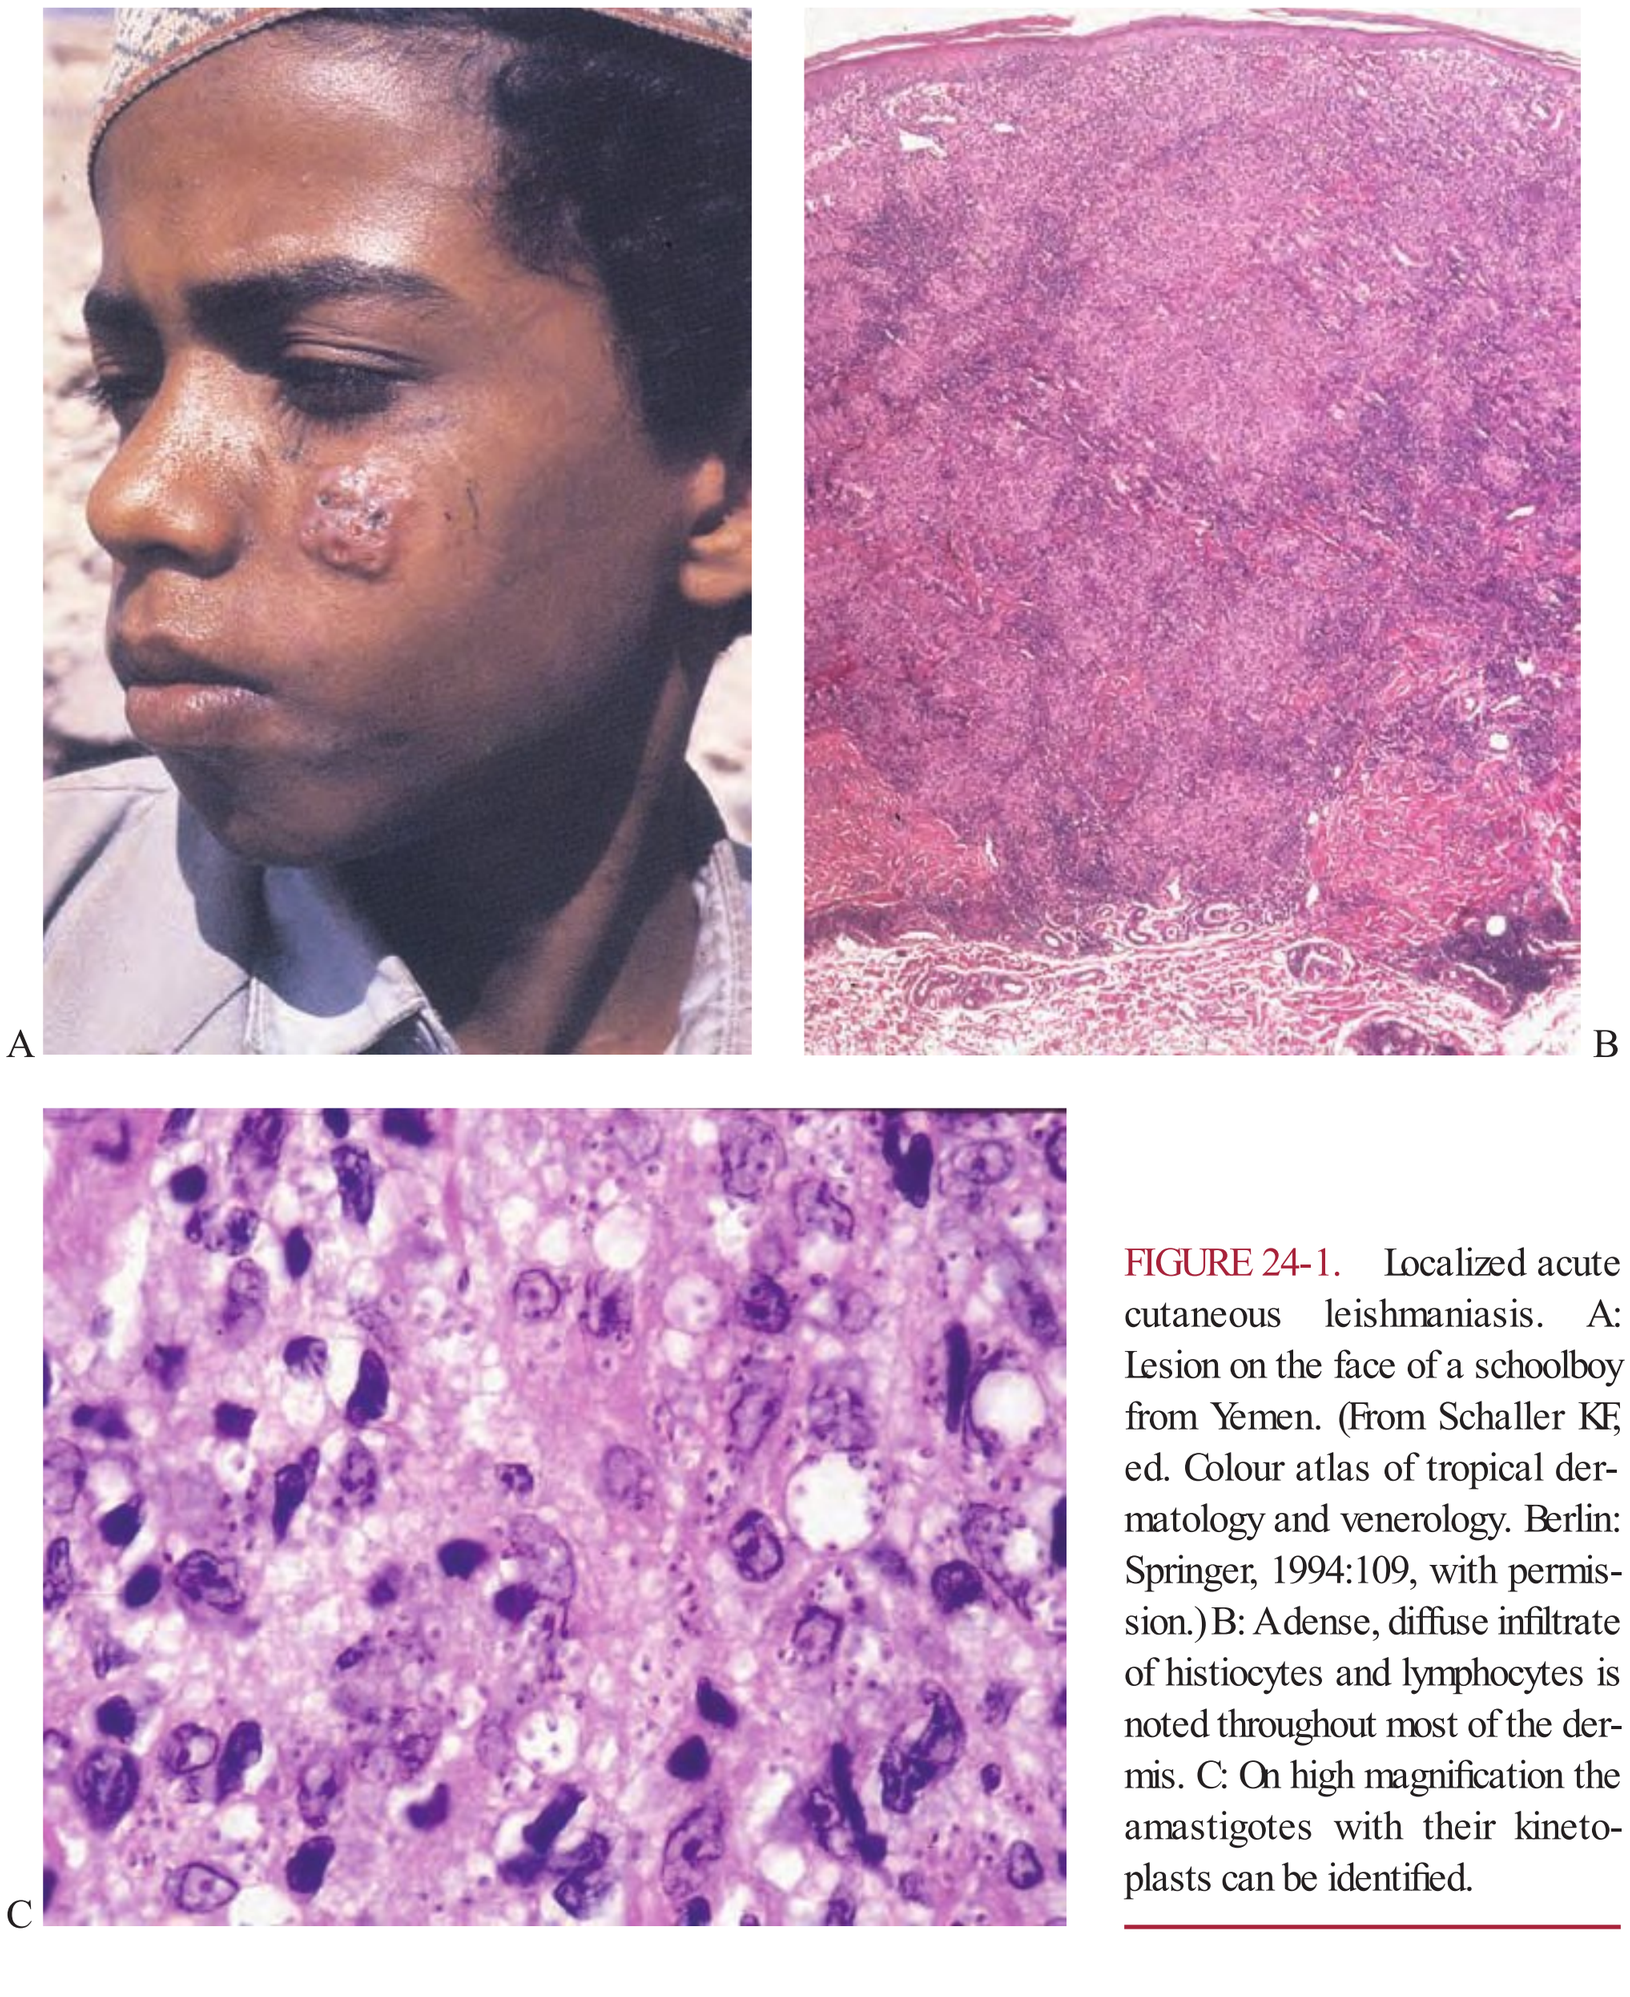

FIGURE 24-1. Localized acute cutaneous leishmaniasis. A: Lesion on the face of a schoolboy from Yemen. (From Schaller KF, ed. Colour atlas of tropical dermatology and venerology. Berlin: Springer, 1994:109, with permission.) B: A dense, diffuse infiltrate of histiocytes and lymphocytes is noted throughout most of the dermis. C: On high magnification the amastigotes with their kinetoplasts can be identified.

(1,5,14,16). In the rare ulcerated lesions of diffuse cutaneous leishmaniasis, eosinophils are predominant within the inflammatory infiltrate and reveal ultrastructural characteristics of parasitocidal activity (15).

In reactivated, previously dormant leishmaniasis in a kidney transplant recipient, a subcutaneous inflammatory infiltrate with numerous intracellular amastigotes was seen; the dermis was not involved (17).

Chronic Cutaneous Leishmaniasis

If the lesions do not resolve within 1 to 2 years, the condition is termed chronic cutaneous leishmaniasis (8,18). Two subtypes are noted: nonhealing chronic cutaneous leishmaniasis and leishmaniasis recidivans (the latter is also called lupoid leishmaniasis, relapsing chronic cutaneous leishmaniasis, or recurrent cutaneous leishmaniasis) (18–20). In the former the original lesion of localized (acute) cutaneous leishmaniasis persists, clinically presenting as an erythematous plaque of several years' duration and no evidence of healing (18). Leishmaniasis recidivans refers to the appearance of new lesions in the center or at the periphery of an atrophic scar derived from a previous lesion of localized (acute) cutaneous leishmaniasis (5,18,19). It carries great clinical resemblance to lupus vulgaris and presents with erythematous papules, often coalescing into crust-covered plaques, in association with a scar. The face is the area of predilection (19,20). It is either due to reactivation of persistent organisms or exogenous reinfection (5).

Histopathology. Both subtypes of chronic cutaneous leishmaniasis reveal essentially the same histopathologic changes, except for the presence of scar tissue in leishmaniasis

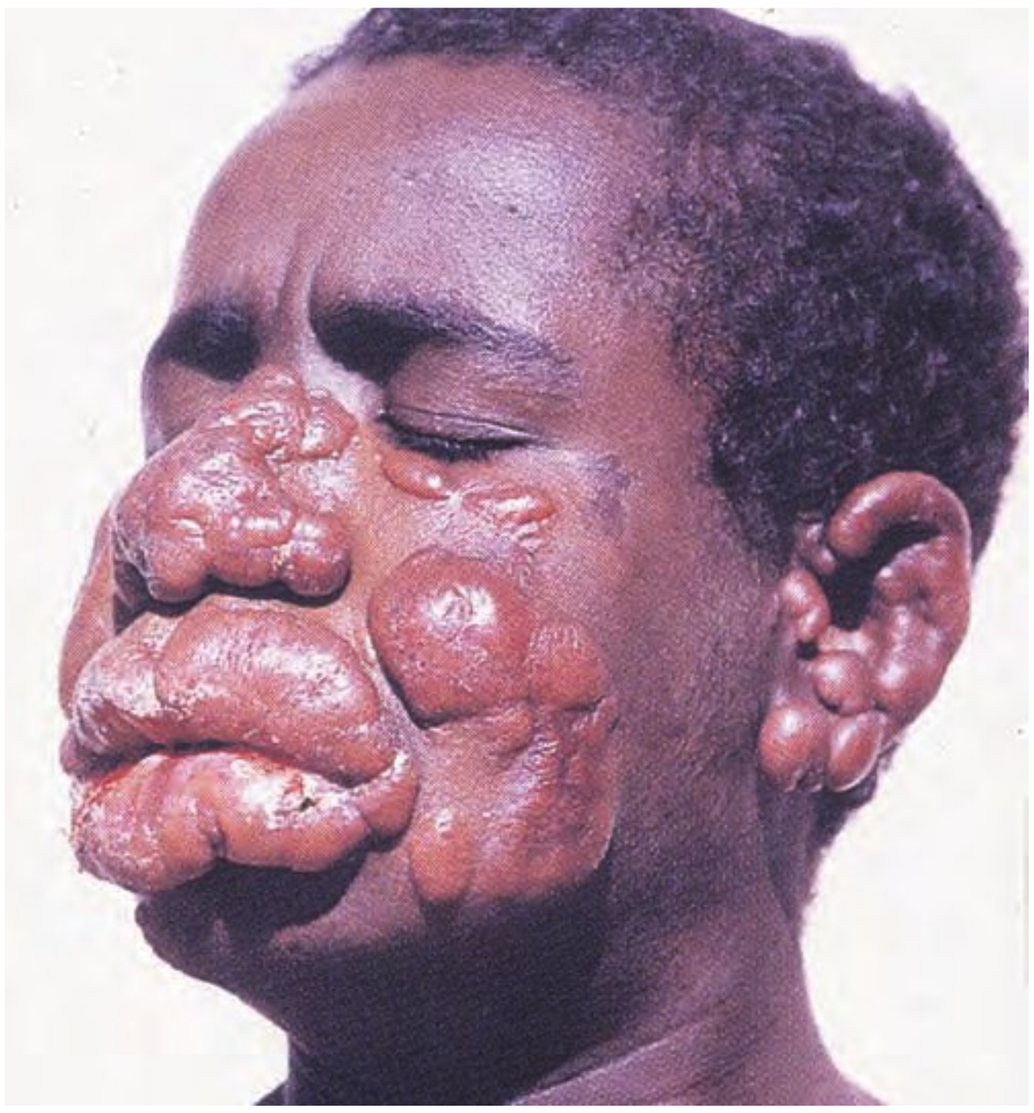

FIGURE 24-2. Diffuse acute cutaneous leishmaniasis. Ethiopian patient with pseudolepromatous appearance. (From Schaller KF, ed. Colour atlas of tropical dermatology and venerology. Berlin: Springer, 1994:113, with permission.)

recidivans in contrast to nonhealing chronic cutaneous leishmaniasis (19).

The histopathologic hallmark of chronic cutaneous leishmaniasis is a dense, diffuse, or nodular infiltrate composed of epithelioid cell granulomas within the superficial and deep dermis (7,13,20–22). The granulomas are tuberculoid in nature, made up of epithelioid histiocytes and Langhans giant cells surrounded by lymphocytes and plasma cells. Necrosis at the center of the granulomas is exceedingly rare (7,13,20,22), although it is occasionally documented (20). Leishman-Donovan bodies are either absent or very small in number. There is an inverse relationship between the number of organisms and the age of the lesion (23). The epidermal changes are nonspecific.

Differential Diagnosis. Other granulomatous dermatitides, especially lupus vulgaris, have to be differentiated from chronic cutaneous leishmaniasis (20,21). This may require the use of ancillary techniques such as immunohistochemistry with *Leishmania*-specific antibodies (24) or the polymerase chain reaction (25).

Post–Kala-azar Dermal Leishmaniasis

Post–kala-azar dermal leishmaniasis occurs 1 to 5 years after successful treatment of visceral leishmaniasis (1,5,8,18). It presents initially as hypopigmented macules over the trunk and extremities. The macules become progressively erythematous and evolve into nonulcerated papules and nodules with marked involvement of the face, clinically resembling lepromatous leprosy (1,5,8,18,26,27). The human host is apparently able to confine *Leishmania* to the skin but cannot eradicate the organisms from the body (26).

Histopathology. Reports on the histopathology of post–kala-azar dermal leishmaniasis are sparse. Hypopigmented macules display a superficial perivascular lymphocytic infiltrate with admixed plasma cells without evidence of granuloma formation (26). The amount of epidermal melanin is decreased (7).

The nonulcerated papules and nodules show a dense, diffuse infiltrate composed of histiocytes, lymphocytes, and plasma cells within the dermis with sharply defined margins and a narrow grenz zone (26,27). Granulomas are not reported, and organisms are sparse. This is in contrast to earlier studies, which described the presence of well-formed epithelioid cell granulomas in nodular lesions of post–kala-azar dermal leishmaniasis (28,29). The overlying epidermis is often atrophic, and the hair follicles show prominent keratotic plugging (27).

Mucocutaneous Leishmaniasis

Mucocutaneous leishmaniasis, most commonly seen in South America, affects the upper respiratory tract and usually develops subsequently to healed localized (acute) cutaneous leishmaniasis (1,5,18,23). The mucosal lesions usually appear within 2 years of the initial skin involvement but may take as long as 30 years to develop (23). They often begin in the nasal septum, which becomes inflamed and later perforates. The lips (especially the upper lip), oral cavity, the pharynx, and even the trachea and bronchi can become involved, imposing a severe life-threatening condition. South American mucocutaneous leishmaniasis probably develops secondary to hematogenous or lymphatic dissemination from primary cutaneous lesions or occasionally from direct extension of nearby skin lesions (5).

Histopathology. The histopathologic changes of mucocutaneous leishmaniasis are subdivided into an edematous, a granulomatous proliferative, and a granulomatous necrotizing stage (30). In the early edematous stage parasites are scanty, a lymphohistiocytic infiltrate with admixed plasma cells in the superficial and deep dermis is noted, and the overlying epidermis is thin. When the patient develops proliferative lesions, parasites become obvious, tuberculoid granulomas can be seen, and pseudocarcinomatous epidermal hyperplasia develops. These changes characterize the granulomatous proliferative phase. In clinically destructive lesions areas of necrosis with numerous neutrophils and abundant Leishman-Donovan bodies constitute the granulomatous necrotizing phase.

Visceral Leishmaniasis

Visceral leishmaniasis is a systemic disease characterized by fever, lymphadenopathy, hepatosplenomegaly, ascites, pancytopenia, and emaciation (1,5,18). The Indian name *kala-azar*

(meaning "black fever") refers to the diffuse darkening of the skin, most pronounced on the face, hands, and feet, which is seen, however, only in a small proportion of patients and peculiarly confined to those from the Indian subcontinent (18). The initial cutaneous lesion of visceral leishmaniasis—the leishmanioma—is rarely seen. Although generally being devoid of cutaneous involvement during the course of the active visceral disease, patients coinfected with HIV can present with skin lesions. The lesions comprise erythematous papules, often confluent to plaques, and, less often, hypo- and hyperpigmented macules with a tendency to localize symmetrically on acral zones (31). These lesions have to be differentiated from those seen in post–kala-azar dermal leishmaniasis, which appear after the patient has been successfully treated for visceral leishmaniasis.

Histopathology. The cutaneous lesions in HIV-infected patients consist of a perivascular infiltrate within the superficial dermis composed of lymphocytes and histiocytes with numerous intracytoplasmic organisms within the latter (31). Leishman-Donovan bodies are also found extracellularly (31,32) and, in one case in eccrine sweat glands, suggesting transepithelial elimination (32). Parasitization of Kaposi's sarcoma by *Leishmania* species (32,33) and a leishmanial cutaneous spindle cell pseudotumor (32,34) have also been reported.

Viscerotropic Leishmaniasis

Originally thought of as causing cutaneous lesions only, *L. tropica* was recently found as the inciting agent of a visceral form of leishmaniasis in veterans of Operation Desert Storm (35). The condition was termed viscerotropic leishmaniasis. No skin involvement is documented.

ACANTHAMOEBIASIS

Among the three free-living genera of amoebae capable of producing cutaneous lesions (*Acanthamoeba* species, *Entamoeba histolytica*, and *Balamuthia mandrillaris*), acanthamoebiasis recently surfaced as the most common one, seen mostly in conjunction with the AIDS epidemic. It also causes keratitis in nonimmunocompromised individuals who wear soft contact lenses. Granulomatous amebic encephalitis, a fatal disease, is another manifestation of *Acanthamoeba* species infection; like cutaneous acanthamoebiasis, it affects primarily immunoincompetent patients (36–38). In disseminated acanthamoebiasis, other organ systems, such as bones (causing osteomyelitis), can be affected (39).

Acanthamoeba species exist in two forms. The amebic cysts, measuring 13 to 19 μm in diameter (36), are resistant to desiccation and excyst to trophozoites only in a favorable environment such as the human host; the second form, between 10 and 20 μm in size (40), reveals slender acanthopodia for slow movement and represents the infectious and invasive form of *Acanthamoeba* species (37).

The cutaneous lesions in acanthamoebiasis are nonspecific and consist of papules, nodules, and chronic, nonhealing ulcers, tender or nontender, ranging from 0.5 to 3 cm in diameter, with the ulcers being sometimes larger (37–43). The skin may serve either as the initial port of entry or may become secondarily involved via hematogenous spread (42,43).

Histopathology. Depending on the number of organisms, a nodular or diffuse inflammatory infiltrate composed mostly of neutrophils and histiocytes admixed with extensive tissue necrosis is noted, sometimes evolving into abscess formation (36,39,42). Cutaneous lesions can also present under the histopathologic picture of a leukocytoclastic vasculitis with fibrin deposits within the vessel wall and leukocytoclasis (36,40–42). Lobular panniculitis with necrotizing vasculitis is another form of presentation (38).

Mixed within the inflammatory infiltrate are the round trophozoites projecting acanthopodia and revealing a vacuolated cytoplasm with a centrally placed nucleus and a single prominent nucleolus (Fig. 24-3). Despite often being numerous, the trophozoite forms are inconspicuous and can be missed easily, closely resembling macrophages (37,39,42). The cyst forms, also being present, display a double wall; the outer wall is wavy and wrinkled in appearance, and the inner wall is shallow and scalloped surrounding the cytoplasm. The cyst walls stain with PAS and GMS (39,42).

Differential Diagnosis. The yeast forms of *Blastomyces dermatitidis* are slightly smaller and have characteristically thick cell walls and broad-based buds; often an overlying epidermal hyperplasia with neutrophilic microabscesses is present (39,42). The cysts of *Entamoeba histolytica* are negative for GMS and do not display an undulating double membrane (42).

SCABIES

Acarid mites produce several skin manifestations in humans, the most common one represented by scabies, which is caused by the eight-legged itch mite *Sarcoptes scabiei* var. *hominis*, also referred to as *S. sarcoptes scabiei*. Animal pathogenic mites also affect the skin, although only transiently because the mites do not survive for an extended period of time (3).

Burrows are the pathognomonic lesions of scabies and are found mostly in the florid, papulovesicular type of sarcoptic acariasis (Fig. 24-4A). They are produced by female mites and occur mainly on the palms and plantae, the palmar and lateral aspects of the fingers and toes, the interdigital spaces, the flexor surfaces of the wrists, the nipples of women, the genitals of men, and, to a lesser extent, on the buttocks and axillae. Characteristically, the head is spared, except in newborns and infants (44). The burrows appear as fine, tortuous, blackish threads a few millimeters long. A vesicle may be visible near the blind end of the burrow. The mite is situated in this vesicle and may be visible as a tiny gray speck by dermatoscopy. Although pathognomonic, the burrow is not the most common lesion seen in scabies. Small, erythematous, often excoriated papules are more frequent (44).

In some patients, itching nodules persist for several months after successful treatment, and therefore are named nodular scabies or persistent scabietic nodules. They are found most commonly on the scrotum and are believed to result from a prolonged response to persistent scabies antigens (45).

In a third, rare variant, the so-called Norwegian scabies or crusted scabies, innumerable mites are present. Patients with this variant show widespread erythema, hyperkeratosis, crusting, nail thickening, and subungual hyperkeratosis but no obvious burrows.

Histopathology: A definitive diagnosis of scabies can be made only by demonstration of the mite or its products. A very superficial epidermal shave biopsy of an early papule or, preferably, of an entire burrow may be carried out with a #15 scalpel blade (46). Local anesthesia is not required. The biopsy specimen is placed on a glass slide, and a drop of immersion oil and then a cover slip are placed on top of it (Fig. 24-4B). This technique yields a higher percentage of positive preparations than the often performed mere scraping of a suspicious lesion with a scalpel blade.

Histologic examination of a specimen containing a burrow reveals that the burrow in almost its entire length is located within the horny layer (47). Only the extreme, blind end of the burrow, where the female mite is situated, extends into the stratum malpighii (48). The mite has a rounded body and measures about 350 to 450 μm in length and 250 to 350 μm in width (Fig. 24-4C) (3).

FIGURE 24-4. Scabies. A: Numerous pustules and papules are noted on the back of the foot and the toes of this infected child. B: Adult female mite found in skin scrapings. C: The female mite is located in the upper portion of the epidermis underneath the stratum corneum.

In the papulovesicular form of scabies, spongiosis is present in the stratum malpighii near the mite to such an extent that formation of a vesicle is often the result. Even if no mite is found in the sections, the presence of eggs containing larvae, of egg shells, or of fecal deposits (scyballa) within the stratum corneum is indicative of scabies (47,49). The dermal infiltrate in sections containing mites shows varying numbers of eosinophils.

In nodular or persistent nodular scabies, there is a dense, chronic inflammatory, often pseudolymphomatous infiltrate in which many eosinophils may be present. Vasculitis is considered by some as being frequent (49) but by others as representing a rather uncommon event (45). These different findings may be related to the duration of the scabietic nodules and the timing of the biopsy (45). The nodules are rich in indeterminate cells, sometimes misleading to the diagnosis of Langerhans cell histiocytosis based on light microscopy and immunophenotyping alone (50). Atypical mononuclear, $CD30^+$ cells may be found (51), and in some instances, the nodules show, as in persistent arthropod bites or stings (see later discussion), a histologic picture resembling that of lymphoma (52). Viable mites are hardly ever found in the nodules. However, mite parts are seen in up to 22% of cases (45).

In Norwegian scabies, the thickened horny layer is riddled with innumerable mites, so that nearly every section shows several parasites (49).

Pathogenesis. Earlier scanning electron microscope studies revealed the keratinocytes around the burrow to be compacted, indicating that the mite physically forces its way in between the keratinocytes rather than chewing a passage (48). More recent studies, however, also using transmission electron microscopy, have found that the secretion of cytolytic substances by the mite as a contributing factor in advancing the parasite body through the skin in addition to mere compression (53). The cellular damage was greatest around the body, especially the mite capitulum.

Both cell-mediated and humoral immune responses are activated in scabies. The acute eczematoid reaction in the epidermis is indicative of cell-mediated hypersensitivity. A role for humoral hypersensitivity is suggested by the presence of immunoglobulin M and the third component of complement in vessel walls (45,54). Besides being reported in mentally deficient and physically debilitated patients, Norwegian scabies is observed generally in patients who are severely compromised in their immune responses, including those with leukemia, lymphoma, and the acquired immunodeficiency syndrome (55).

HOOKWORM-RELATED CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans is caused by skin-penetrating larvae of nematodes, most commonly of the cat and dog hookworm *Ancylostoma braziliense*, *A. caninum, A. tubaeformis, Uncinaria stenocephala*, and *Bunostomum phlebotomum* (3,56–58). Other forms of cutaneous larva migrans are caused by human- and animal-type *Strongyloides* species and are then known as larva currens (see later discussion). *Gnathostomum spinigerum* does not belong to the hookworm family but to the group of spiruriids and can also evoke cutaneous larva migrans (3).

Hookworm-related cutaneous larva is the most common variant. The infestation occurs through contact with soil contaminated with the larvae. The exposed parts of the body, most commonly the feet but also the buttocks in vacationers, for example, who lie nude in the sand, are most commonly involved. Creeping eruption represents the clinical manifestation of cutaneous larva migrans and is manifested by an irregularly linear, thin, raised, serpiginous burrow that is 2 to 3 mm wide (Fig. 24-5A). The larva moves a few millimeters per day. The eruption is self-limited because humans are accidental hosts, leaving the hookworm incapable of sexually maturing.

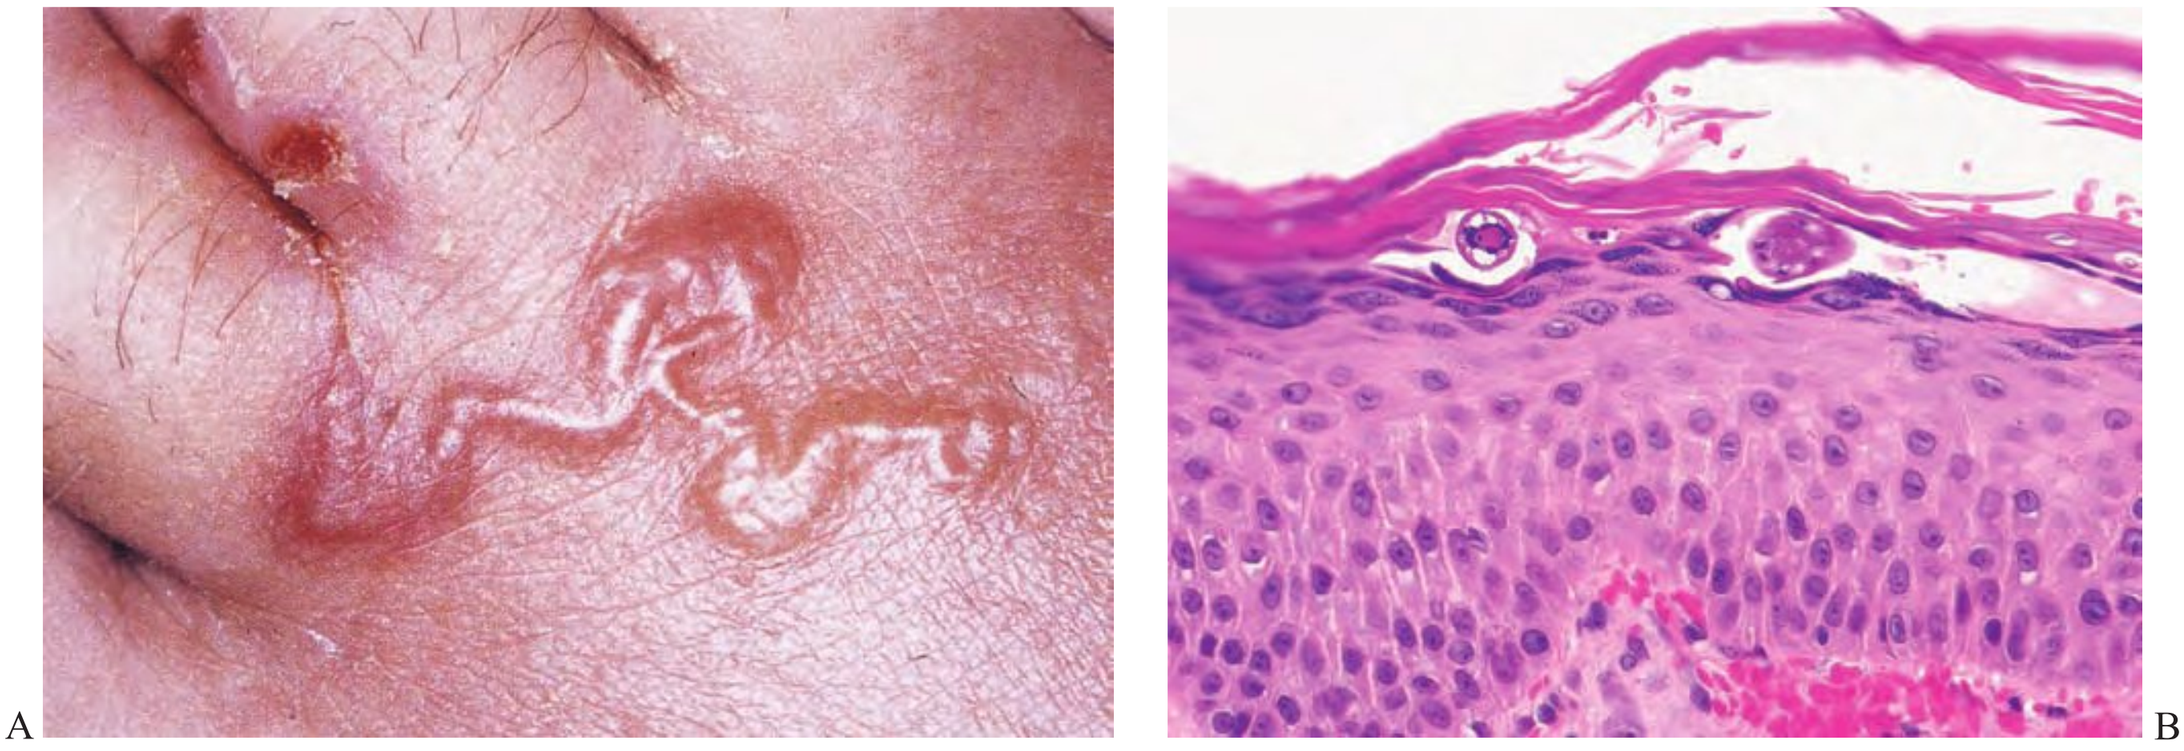

FIGURE 24-5. Cutaneous larva migrans. A: This curvilinear superficial burrow is the prototypical clinical manifestation. B: The organism is found underneath the stratum corneum in the upper portion of the stratum malpighii. (Specimen courtesy of Mandi Sachdeva, MD, and Rajiv Patel, MD, Cleveland Clinic Foundation, Cleveland, Ohio.)

Histopathology. The visible track does not correlate with the exact location of the larva and represents an inflammatory response composed of lymphocytes admixed with many eosinophils in the epidermis and upper dermis (3,57,58). The parasite is found 1 to 2 cm ahead of the visible track within a burrow located in the upper layers of the epidermis (Fig. 24-5B) (59). The lesion, aside from the larva, which is often not observed in the biopsies, shows spongiosis and intraepidermal vesicles in which necrotic keratinocytes can be seen. Numerous eosinophils in the superficial and deep reticular dermis are also commonly observed. A specific subtype of hookworm-related cutaneous larva migrans is known as hookworm folliculitis, in which the organism is associated with the hair follicle (60). It is important to recognize this variant because it is typically more difficult to treat.

Pathogenesis. The tissue penetration and the movements of the hookworm larvae within the epidermis are at least in part due to active production and secretion of proteases by the parasite (61). However, with the exception of hookworm folliculitis, these enzymatic activities are typically not adequate to allow penetration into the dermis, and hence the nematode is located in the upper portion of the epidermis (62).

STRONGYLOIDIASIS

Strongyloides stercoralis is a small intestinal nematode that is mainly endemic in the tropics and subtropics but is also found in the southeastern United States (especially eastern Kentucky, rural Tennessee, southern Virginia, and western North Carolina and South Carolina) (63). It is a geohelminth contracted by humans through cutaneous penetration of filariform larvae. A unique cycle includes traveling of the larvae via the venous system to the lungs, the patient coughing up and subsequently swallowing the larvae, and the parasite finding its final habitat in the small intestine (3). Three forms of strongyloidiasis can be delineated clinically: a not well characterized acute form, a chronic form, and a disseminated form (63). The chronic type presents with gastrointestinal and pulmonary symptoms and the pathognomonic larva currens. The latter represents a linear or serpiginous urticarial tract moving at a rate of 5 to 15 cm/hour caused by rapidly migrating larvae and is a subtype of cutaneous larva migrans (see previous discussion). It is believed to derive from autoinoculation with intestinal larva in the perineal area. The disseminated variant of strongyloidiasis occurs in the setting of severe immunodepression and is commonly fatal. Patients with advanced hyperinfection present with a purpuric skin eruption, often located periumbilically (64,65). Other cutaneous manifestations of strongyloidiasis include chronic urticaria, prurigo nodularis, and lichen simplex chronicus (64–66).

Histopathology. The serpiginous urticarial lesions believed to represent the migrating path of larvae are consistently negative for organisms (64). In contrast to hookworm-associated cutaneous larva migrans, the migratory tracts of larva currens are not located in the epidermis but in the dermis (3). It is only in the disseminated variant of strongyloidiasis that organisms can be found. They occur in the form of filariform larvae, measuring from 9 to 15 μm in diameter, which can be seen at all levels of the dermis, commonly associated with vascular damage producing purpura and petechiae, which are likely due to vascular damage by the filariform larvae migrating through the vessel wall (Fig. 24-6A–C) (64,65,68,69). These changes often do not provoke a dermal inflammatory response, probably because these patients are severely immunocompromised (64,65,70) (Fig. 24-6A). Changes of leukocytoclastic vasculitis are also not noted (68–70). Eosinophil-rich granulomata around *Strongyloides* larvae are, however, occasionally described (63,69).

SUBCUTANEOUS DIROFILARIASIS

Dirofilariasis is a zoonosis most commonly seen on the North American continent in the southeastern United States, with 75% of almost all cases being reported from Florida, which thus represents the epicenter of the infestation (71). The definite hosts of *Dirofilaria* species are dogs, cats, and raccoons, but hosts also include bears and porcupines (the two last ones are seen in the northern United States and Canada, from where dirofilariasis cases have also occasionally been reported).

Subcutaneous infection of humans by *Dirofilaria* species is rare and usually caused in North America by *D. tenuis, D. ursi*, or *D. subdermata* and in Europe, Africa, and Asia by *D. repens* (72,73). Mosquitoes transmit microfilariae from infected animals to humans, who act as a terminal host. In humans, the parasite never reaches the sexually mature adult stage capable of producing microfilariae, thereby rendering human-to-human transmission impossible (74).

Over the course of the infestation, one or, occasionally, several well-defined, firm, slightly red, tender nodules measuring 1 to 2 cm in diameter and clinically often mistaken for lipomas (72) develop in areas not covered by clothes, especially the head. Multiple lesions usually result from migration of a single worm (71).

Histopathology. At the center of the subcutaneous nodule, there is a tightly convoluted worm seen in multiple transverse and diagonal sections. Transverse sections measure from 50 to 300 μm in diameter, with the male worms being smaller than the female ones (71). The parasite possesses a thick, laminated cuticle displaying longitudinal ridges and transversal striae in *D. repens* and *D. tenuis* (Fig. 24-7) and a smooth cuticle in the dog heartworm *D. immitis*, the cause of pulmonary dirofilariasis in humans, allowing for species identification on histologic sections (72). It is imperative to thoroughly section the tissue block so as not to miss the helminth (75). The worm is embedded in eosinophilic material and surrounded by an inflammatory reaction that includes many eosinophils, mononuclear cells, and often foreign-body giant cells. Unlike fungal infections, fat necrosis is conspicuously absent (75). The extent of

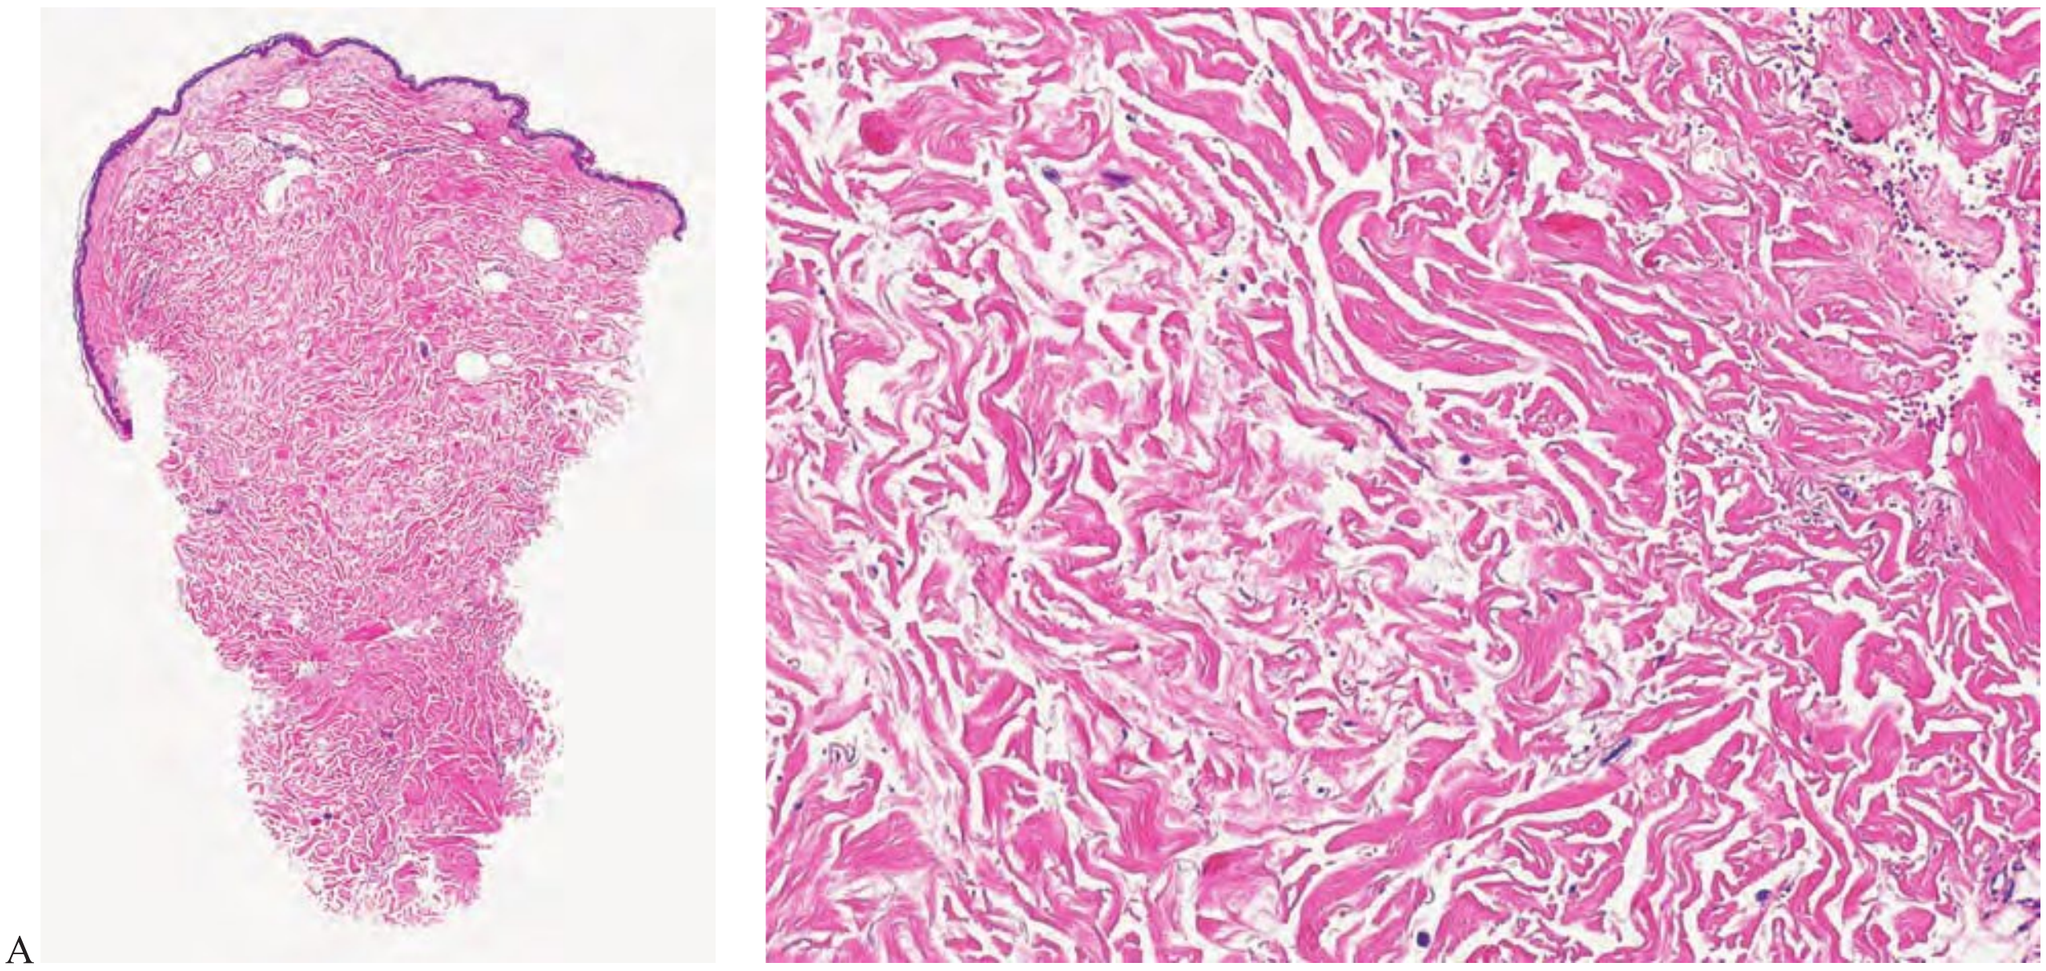

FIGURE 24-6. Strongyloidiasis. A: On scanning magnification, the punch biopsy from the periumbilical purpuric eruption shows no obvious histopathologic changes. The patient died from disseminated strongyloidiasias. B: On medium-power magnification, extravasated erythrocytes are noted (upper right corner) and basophilic linear and round structures become apparent. C: On rare occasions an entire nematode cut at the right angle is seen percolating between the collagen bundles. Note extravasated erythrocytes at the top of the micrograph. fibrosis in the surrounding tissue correlates with the extent to which the parasite is degenerated (71).

Differential Diagnosis. Although having an identical clinical presentation to the infestation with *D. tenuis,* subcutaneous sparganosis, caused by the larval stage of the tapeworm *Spirometra* species, can affect any organ system. The larva in sparganosis has the typical histology of a pseudophyllidian tapeworm, consisting of a tegument, a cellular subtegument, and mesenchymal tissues with numerous large, longitudinal muscle cells and excretory canals (71). However, it still can be histologically mistaken for *Dirofilaria* species (71,75).

ONCHOCERCIASIS

Onchocerciasis is common in certain regions of Central America, Venezuela, and tropical Africa. It is transmitted by black flies of the genus *Simulium*, which breed in fast-flowing rivers;

through their probosces, the infective larvae of *Onchocerca volvulus*, a filarial nematode, enter the human skin. They mature to the adult stage in the subcutaneous tissue. The adult worms live in the deep dermis and subcutis and become clinically apparent as asymptomatic subcutaneous nodules called onchocercomas, of which there are usually only a few, ranging in size from 0.5 to 2.0 cm (Fig. 24-8A). The adult worms do not cause any harm; however, their progeny, consisting of millions of microfilariae, live in the dermis and the aqueous humor of the eyes, where they provoke inflammatory changes after several years. In the eyes, keratitis, iridocyclitis, chorioretinitis, and optic atrophy ultimately result in blindness (76). On slit-lamp examination, the microfilariae in the anterior chamber of the eyes may be seen to be moving actively (76). Clinically, onchocercal dermatitis is characterized by itching, edema, lichenification, and pigment shifting ("leopard skin") (Fig. 24-8B) (77–79). Later, the skin becomes atrophic. A clinical classification and grading system of the cutaneous changes in onchocerciasis has been proposed but is not yet universally accepted (77). *Onchocerca volvulus*, like *Wuchereria bancrofti*, may also be a cause of lymphatic filariasis, in which massive numbers of microfilariae may occlude lymphatics and result in elephantiasis (81). Lymphadenopathy and so-called hanging groins (adenolymphoceles) are other manifestations of the disease (81).

Histopathology. The onchocercomas show a chronic inflammatory infiltrate and fibrosis at their peripheries. Their centers consist of dense, fibrous tissue containing transverse and diagonal sections of adult worms measuring from 125 to 450 μm in

FIGURE 24-8. Onchocerciasis. A: African patient with onchocercoma on the head. B: African patient with onchocercal dermatitis. C: In an onchocercoma, multiple cross sections of the adult organism can be seen surrounded by dense fibrosis. D: On high magnification the microfilariae within the female adult worm become obvious. When released by the female worm, the microfilariae evoke the changes seen in onchocercal dermatitis. (A, B: From Schaller KF, ed. Colour atlas of tropical dermatology and venerology. Berlin: Springer, 1994:127, with permission. C, D: Specimen courtesy of Yezid Gutierrez, MD, PhD, Cleveland Clinic Foundation, Cleveland, Ohio.)

transverse diameter and up to 500 mm in length in females and 42 mm in males (Fig. 24-8C, D) (81). Some of them are alive at the time of biopsy. Dead worms are surrounded by an inflammatory reaction containing foreign-body giant cells. Microfilariae, hatched by female worms, are occasionally observed within lymphatic vessels of the onchocercomas, through which they are disseminated in the skin. They are from 5 to 9 μm in diameter and from 220 to 360 μm in length (81).

In early, untreated onchocercal dermatitis, many undulating microfilariae are present within the dermis, mainly close to the epidermis (78). Their number decreases greatly with time, and thus they may be difficult to find in old lesions (79). In early infections, reactive changes in the dermis are minimal, but in the course of years, chronic inflammatory cells including eosinophils accumulate around the vessels, and, ultimately, fibrosis of the dermis, especially perivascularly, results (78). Hyperorthokeratosis, parakeratosis, epidermal hyperplasia (in the late-stage flattening of the epidermis), tortuosity of dermal vessels, and pigment incontinence are other features of long-standing onchocercal dermatitis (78).

Pathogenesis. The slow development of the cutaneous changes and also of the ocular changes suggests that microfilariae, as they gradually disintegrate, act as a source of foreign protein and that the dermatitis and the various forms of eye involvement are the result of a coordinated response by the cellular and humoral immune system (78,79,81). Indeed, while alive, microfilariae do not evoke a strong inflammatory response. Only when dying or dead, either during the natural course of their life span or therapeutically induced, do microfilariae produce a prominent inflammatory reaction, with eosinophils being essential in the process (78,79,81).

SCHISTOSOMIASIS

Schistosomiasis is caused by trematodes of the genus *Schistosoma* and affects 180 to 200 million people in 71 countries, making it the most important trematode pathogenic to humans worldwide (82). It is acquired through exposure to skin-penetrating cercariae, a stage in the life cycle of the parasite. The cercariae emerge from a freshwater snail, which functions as an obligate intermediate host to the fluke. The cercariae burrow through the skin and migrate to venous plexuses, where they mature.

Three species of *Schistosoma* are pathogenic to humans. *S. mansoni* is common in the Caribbean islands and in northeastern South America; *S. japonicum* is found in Eastern Asia; and *S. haematobium* is common in the Middle East and in Africa. The usual habitats of *S. mansoni* are the portal circulation and mesenteric venules of the large intestines, with discharge of the eggs in the stool. The usual habitat of *S. japonicum* is the small gut, also resulting in discharge of the eggs with the stool. The usual habitats of *S. haematobium* are the pelvic and vesical venules, with passage of the eggs with the urine. *S. mansoni* and *S. japonicum,* through granulomas in the liver, may cause portal hypertension and esophageal varices, and *S. haematobium,* through granulomas in the bladder, may lead to hematuria and hydronephrosis (83). In Africa, mixed infections with both *S. mansoni* and *S. haematobium* are not uncommon (84,85).

The cutaneous manifestations of schistosomiasis can be divided into three types, depending on the life cycle of the trematode (82,86).

Dermatitis schistosomica (swimmer's itch) is caused by the initial penetration of the skin by human or nonhuman cercariae and manifests as a pruritic maculopapular eruption usually lasting several hours, sometimes days, and, rarely, weeks, depending on previous sensitization. Cercariae of nonhuman *Schistosoma* species (usually avian species primarily affecting ducks or other water birds) can penetrate the skin but subsequently die. The dermatitis produced by anthropophilic *Schistosoma* is milder than that caused by nonhuman species (82).

The second cutaneous manifestations of schistosomiasis, also transitory, are the *bilharzides* or *schistosomides.* Several weeks after penetration, the cercariae have matured into worms 15 to 25 mm in length. The female then releases thousands of eggs into the bloodstream. Their release may be accompanied by anaphylactoid reactions manifested by a combination of fever, urticaria, and sometimes purpura known in Japan as Katayama's syndrome and in China as Yangtze fever (82,86).

A specific cutaneous involvement (known as *bilharziasis cutanea tarda*) represents the third cutaneous manifestation of schistosomiasis and is caused by ectopic deposition of eggs within the dermis when ova have become dislodged from their natural habitat in the venous circulation. Most commonly seen in *S. haematobium*, it is a rare event and presents as papular, verrucous, ulcerative, or granulomatous lesions usually of the genital or perianal skin (82,86,87). In rare instances, the thorax, abdomen, and, even less commonly, the face or scalp are involved (84,88–90).

Histopathology. Bilharziasis cutanea tarda represents the main persistent cutaneous lesion of schistosomiasis. Its pathologic hallmark is a palisading, necrotizing granulomatous inflammation within the dermis consisting of histiocytes, lymphocytes, plasma cells, and rare multinucleated giant cells surrounding complete or degenerated schistosomal ova located in the central area of necrosis (Fig. 24-9) (84,87,88). A predominant population of eosinophils as part of the inflammation is also described (87,90). In older lesions the eggs are calcified and surrounded by fibrosis; the inflammatory infiltrate is sparse or absent (82). The overlying epidermis often reveals pseudocarcinomatous hyperplasia (87,88,91,92). Transepithelial elimination of the ova is described (92).

The ova measure up to 1 mm in greatest dimension and possess a chitinous outer shell staining positively with the PAS stain. However, only *S. mansoni* but not *S. haematobium* or *S. japonicum* is acid fast-positive (84,88,90). The presence and position of a spine on the shell of the ova permit their classification within the tissue. *S. haematobium* ova have a spine in

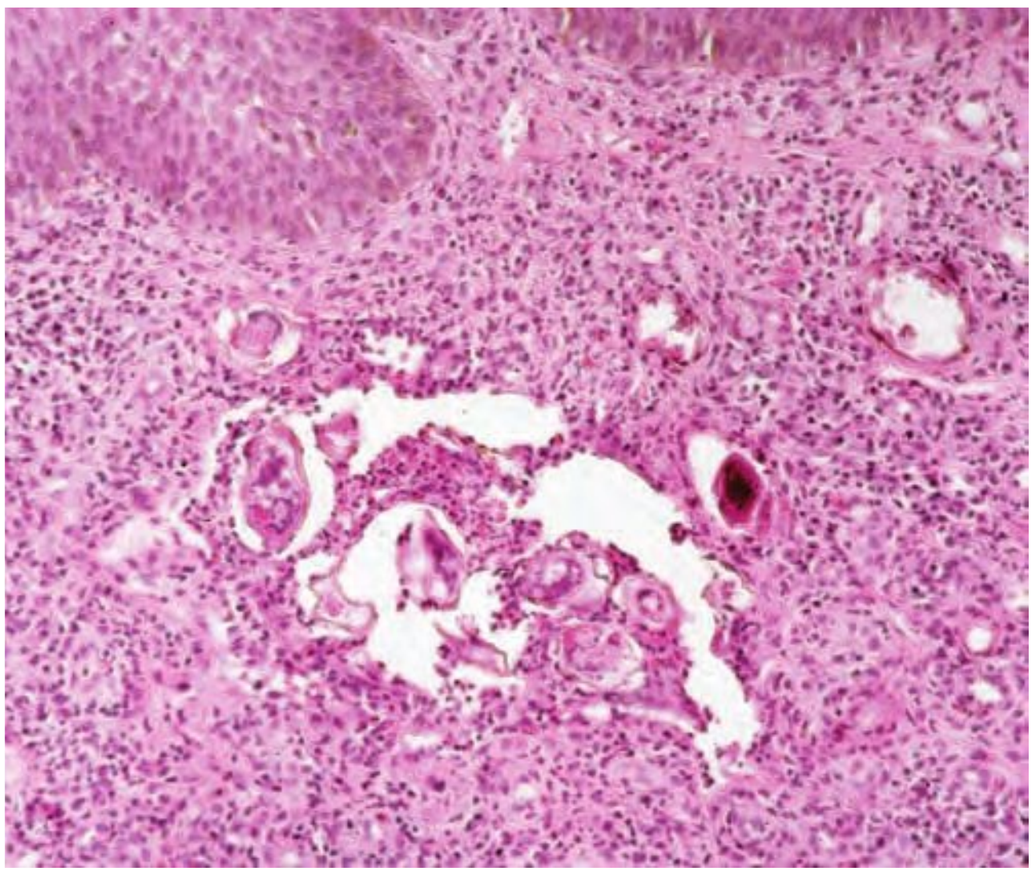

FIGURE 24-9. Schistosomiasis. In bilharziasis cutanea tarda (see text) the schistosomal eggs provoke a granulomatous reaction within the dermis. (Courtesy of Yezid Gutierrez, MD, PhD, Cleveland Clinic Foundation, Cleveland, Ohio.)

the apical position, whereas the spine of *S. mansoni* ova is on the lateral aspect, and *S. japonicum* ova have no spine. In rare instances, one may also see adult worms within distended blood vessels in the dermis (88).

Pathogenesis. The eggs and embryos are said to release soluble substances that act as antigens sensitizing T lymphocytes. These, in turn, release lymphokines, leading to migration of macrophages and eosinophils and to granuloma formation (82).

SUBCUTANEOUS CYSTICERCOSIS

The pork tapeworm *Taenia solium* develops in the human intestinal tract after the ingestion of inadequately cooked pork containing *T. solium* larvae. The tapeworm discharges its eggs in the feces. When eggs with the encysted larvae are ingested by humans, usually through contamination of hands and food by the subject's own feces but also by regurgitation of eggs from the intestinal tract into the stomach by reverse peristalsis (93), they hatch, and larvae entering the bloodstream invade various tissues, where they develop into cysticerci. Whereas the infestation with an egg-producing adult tapeworm confined to the intestines (taeniasis) imposes little harm to the patient, cysticerci can have deleterious effects by evoking cerebral cysticercosis, which is the most common parasitic infestation of the central nervous system worldwide (94). More than 1,000 cases per year are reported in the United States (95).

Subcutaneous cysticercosis is considerably less frequent. Clinically, one, several, or, rarely, numerous firm, asymptomatic nodules are present in the subcutaneous tissue. They usually measure 1 to 2 cm in diameter and can persist for many

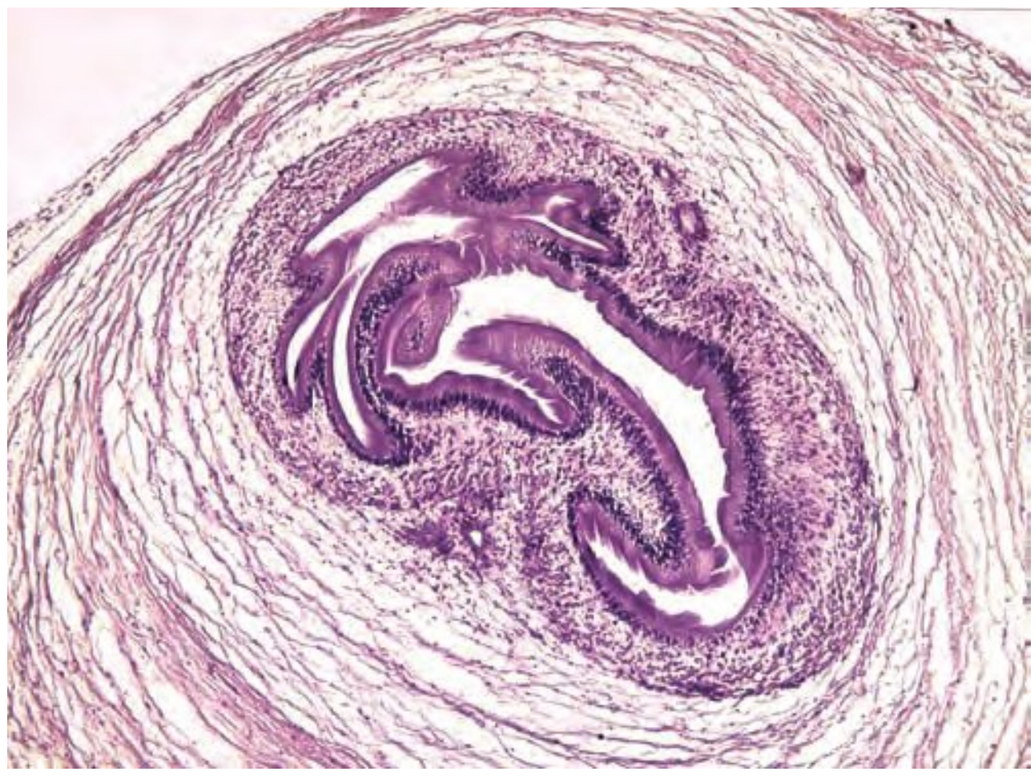

FIGURE 24-10. Subcutaneous cysticercosis. This cysticercus larva was found in a cavity within the subcutis surrounded by granulation tissue and necrotic debris. (Specimen courtesy of Dieter Krahl, MD, Institut für Dermatohistologie, Heidelberg, Germany.)

years (93,96,97). The subcutaneously located cysts of cysticercosis do not carry any risk to the patient's health but are of great value in the diagnosis of cerebral cysticercosis, which causes seizures (94).

Histopathology. A thick, fibrous capsule covered by several layers of epithelioid cells admixed with a few Langhans giant cells but without caseous necrosis surrounds a cystic cavity containing clear fluid and a white, irregularly shaped membranous structure representing a cysticercus larva (98). Eosinophilic infiltration of the capsule is present (89). Step sections reveal the scolex of the larva with suckers and hooks (Fig. 24-10) (93,96).

MYIASIS

The order Diptera (having two wings) includes flies, gnats, and mosquitoes. When fly larvae inhabit the human body, the condition is called myiasis (from the Greek word for fly, *myia*). The distribution of myiasis is worldwide, with greater abundance of cases and of causative species in the tropics.

The cutaneous manifestations of myiasis can be subdivided into three clinically recognized subcategories: wound myiasis, furuncular myiasis, and creeping myiasis (not to be mistaken with the creeping eruption caused by cutaneous larva migrans) (99–101).

In wound myiasis, which may be caused by many different fly species, including the common housefly *Musca domestica*, the fly larvae (maggots) are deposited on necrotic flesh.

Furuncular myiasis occurs mostly in the tropics and is caused in Africa by the tumbu fly *Cordylobia anthropophaga* and in the American tropics by the human botfly *Dermatobia hominis*. The latter has a unique life cycle. The female fl y

captures blood-sucking insects such as mosquitoes or other flies in the air and deposits a number of eggs on their abdomen. When these vectors come in contact with a human host, the *Dermatobia* larvae hatch and enter the skin, where they cause a furuncular lesion known as a "warble." Within 6 to 12 weeks an adult fly develops and leaves the human host through its breathing orifice.

In creeping myiasis, larvae of *Gasterophilus* species or *Hypoderma* species—flies parasitic to horses or cattle—burrow into the skin and cause a migratory pattern. In contrast to the creeping eruption seen in larva migrans, the movements are more restricted and proceed more slowly.

Histopathology. In wound myiasis the larvae generally remain superficial, are usually alive, and can be recognized grossly at the time of biopsy (100). In furuncular myiasis, there is an intense mixed inflammatory infiltrate composed of neutrophils, eosinophils, lymphocytes, plasma cells, and Langerhans giant cells surrounding the cavity, which is occupied by the larva (Fig. 24-11) (99,102,103). In creeping myiasis due to *Hypoderma* species, the inflammatory response is very minimal (100).

Pathogenesis. Both *Dermatobia hominis* and *Cordylobia anthropophaga* secrete a bacteriostatic fluid that prevents secondary bacterial infection of the larval cavity (99,104,105).

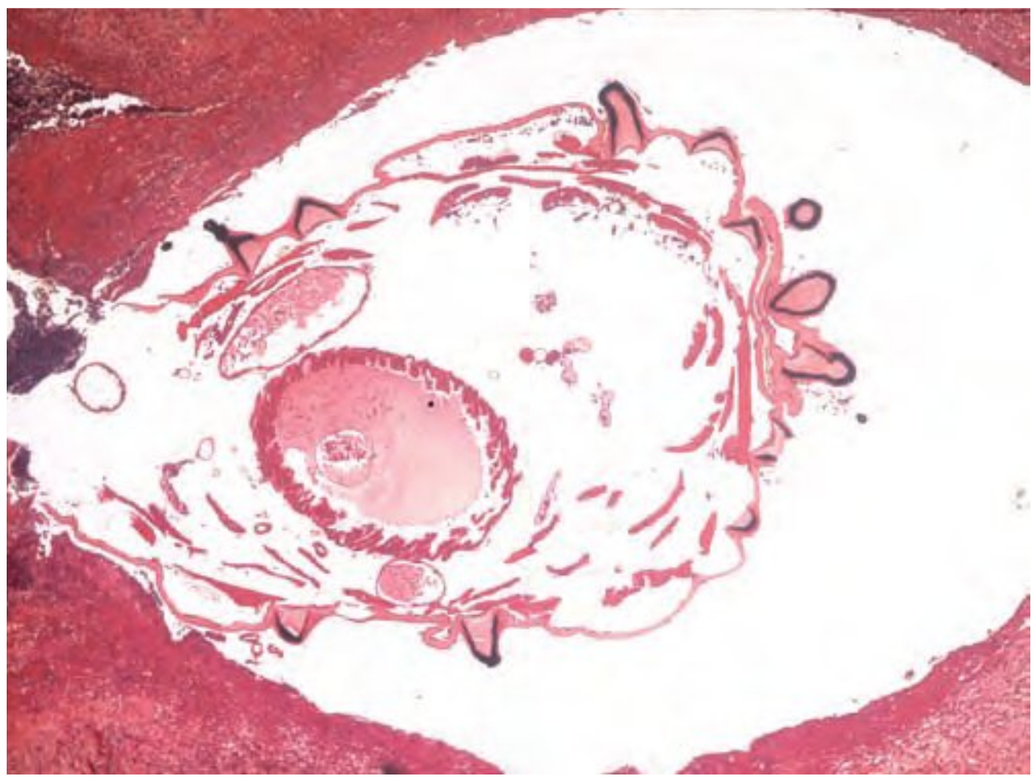

FIGURE 24-11. Myiasis. An intense inflammatory reaction surrounded this larva seen in a case of furuncular myiasis. (Specimen courtesy of Dieter Krahl, M.D., Institut für Dermatohistologie und Oralpathologie, Heidelberg, Germany.)

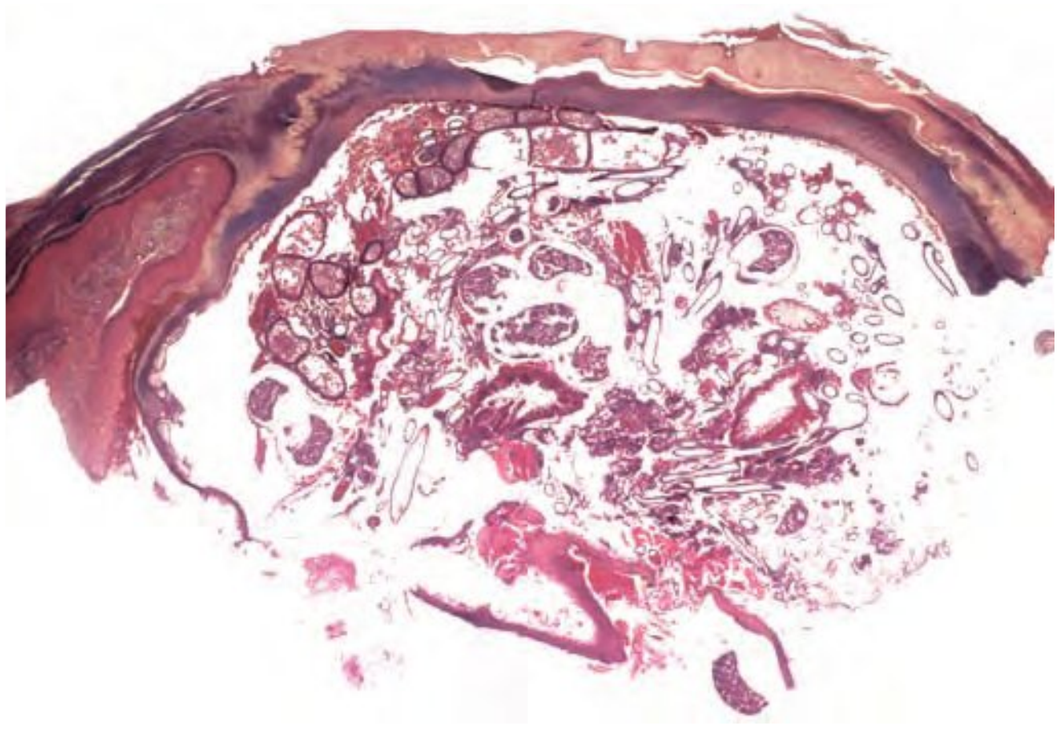
TUNGIASIS

Tungiasis is a cutaneous infestation by the gravid female sand flea *Tunga penetrans*, which is endemic in the Caribbean region, Central and South America, sub-Saharan Africa, and the Indian subcontinent (106,107).



Only the female fleas are capable of penetrating the skin. They burrow a cavity with the head turned toward the dermis, feeding on the host. The gravid female eliminates its eggs through an apical opening of the cavity to the outside and dies soon thereafter, exhibiting a total life span of approximately 1 month (106).

The condition is acquired by walking barefoot. Characteristically, the lesions are located on the toes, the interdigital spaces, and the soles and heels. They are mostly single and consist of a tender nodule 5 to 6 mm in diameter with a black-to-brown central tip representing the posterior end of the parasite.

Histopathology. The flea is located in the epidermis and upper dermis inside a cavity (Fig. 24-12A, B). In its apical

FIGURE 24-12. Tungiasis. A: This scanning electron micrograph shows the swollen abdomen of the female sand flea feeding on human blood. (From Schuller-Petrović S, Mainitz M, Bohler-Sommeregger K. Tungiasis–eine immer häufigere Urlaubsdermatose. Hautarzt 1987;38:162–164, Fig. 3, with permission.) B: On hematoxylin and eosin–stained section, the typical superficial intradermal location of the flea is noted.

portion it is surrounded by a hyperplastic epidermis. In the absence of bacterial superinfection any perilesional inflammatory infiltrate is usually minimal and consists of lymphocytes, neutrophils, and eosinophils (106). Inside the cavity, portions of the exoskeleton, hypodermal layer, trachea, and digestive tract identify the organism as an arthropod. The uniformly present developing eggs are likely the most useful to differentiate *T. penetrans* from other organisms (108).

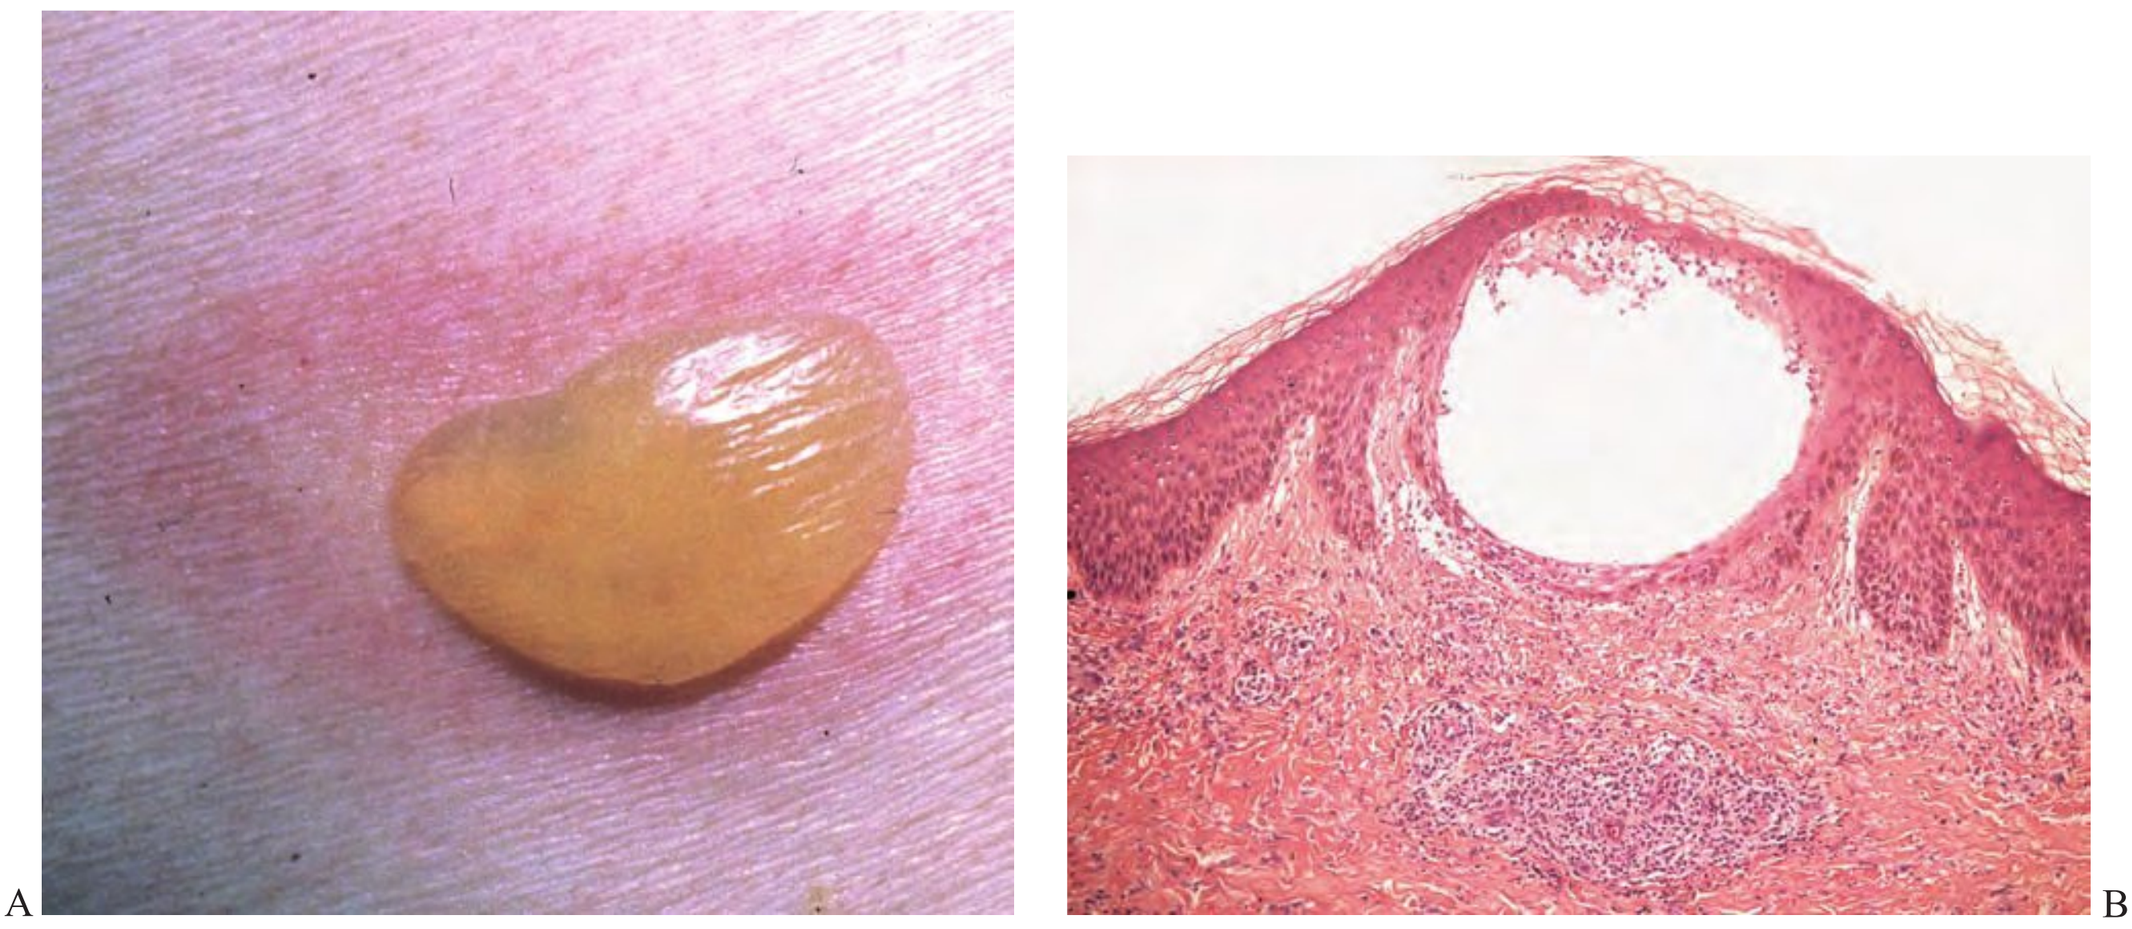
ARTHROPOD ASSAULT REACTIONS

Arthropod bites and stings are common afflictions in humans. They induce a localized or a widespread and often also a systemic reaction, depending on the type of the assaulting species and the capacity of the body to react.

Most stings evoked by mosquitoes, bees, wasps, hornets, or bedbugs are characterized initially by a localized urticarial reaction, often followed by the development of a papule and papulovesicle associated with intense pruritus. Frequently, a central punctum can be recognized. In more intense reactions, most commonly seen on the legs, the lesions are bullous (Fig. 24-13A) (109). Typically they resolve without sequelae within days. In rare cases, however, they may persist for weeks or months and are then referred to as a persistent arthropod assault reaction (110,111).

Bites by the brown recluse spider *Loxosceles reclusa* are common in the south central United States. Often painless initially, they are capable of inducing significant skin necrosis (necrotic arachnidism) (112).

Hypersensitivity to insect bites, especially from fleas, gnats, mosquitoes, or bedbugs, may result in papular urticaria, also known as lichen urticatus or strophulus infantum. It is characterized by grouped urticarial papules and papulovesicles with a tendency to spread. Spontaneous resolution within several days is usual (113). The condition cannot be reliably distinguished from arthropod bites (114).



Histopathology. The classical histopathologic hallmark of an arthropod bite is a wedge-shaped, superficial and deep, perivascular and interstitial inflammatory dermal infiltrate composed of lymphocytes and eosinophils, often in association with an overlying focus of spongiosis, sometimes evolving into a vesicle or even progressing to epidermal necrosis (Fig. 24-13B) (115). These changes are indistinguishable from those of papular urticaria (114).

Mosquito bites initially show mainly neutrophils, mostly vasculocentric, and later a predominantly mononuclear infiltrate of lymphocytes and plasma cells. Eosinophils are few or absent (116,117).

Bites of the brown recluse spider initially show a neutrophilic perivasculitis with hemorrhage. Later, in cases of necrotic ulcers, one finds arterial wall necrosis and an infiltrate containing many eosinophils (118).

Some persistent arthropod assault reactions produce a dense lymphoid infiltrate, often with formation of lymphoid follicles, which has to be differentiated from lymphoma (119). In contrast to lymphomas, the lymphoid follicles in persistent arthropod reactions frequently show germinal centers and do not show evidence of clonality. Large transformed, $CD30^+$ lymphoid cells with hyperchromatic nuclei may also be found but do not represent a sign of malignancy (111).

Occasionally parts of the sting apparatus may be retained within the dermis, inducing a chronic inflammatory response,

A B

FIGURE 24-13. Arthropod assault reaction. A: Sometimes the clinical reaction to an arthropod assault is intense and results in a blister (so-called culicosis bullosa). B: On histologic sections often an intraepidermal vesicle can be seen in the center of the arthropod assault.

often with associated eosinophils, accompanied by pseudocarcinomatous epidermal hyperplasia (120). Retention of the string apparatus is more commonly seen in ticks.

Pathogenesis. The primary toxin in the brown recluse envenomation is sphingomyelinase D, which interacts with the outer plasma membrane of erythrocytes, endothelial cells, and platelets. The severe skin necrosis seen in this spider bite is a consequence of vascular damage (121).

ACKNOWLEDGMENTS

The excellent technical assistance of Lisa Wierzbicki, Philadelphia, is greatly appreciated. Issa Issa, Philadelphia, provided invaluable assistance with the microphotography. We thank Dr. Rajiv Patel, Cleveland, for taking the photographs for Figs. 24-5B and 24-6A, B.

Diseases Caused by Viruses

Many viral infections have prominent skin manifestations. Characteristic skin lesions suggest a specific viral illness, the diagnosis of which can be confirmed by appropriate procedures. Viral infections of the skin are of increased significance in immunocompromised patients. Viruses are complexes of nucleic acids and proteins that have the capacity for replication in animal, plant, and bacterial cells. They are obligatory intracellular organisms that lack organelles, such as ribosomes and mitochondria. To replicate themselves, viruses use the metabolic machinery of the host cells. Virally induced alterations in cell function and antigenicity, cell death, and host responses to the presence of viruses are factors that lead to the manifestations of viral disease (1). Before viruses can enter a cell, they must attach themselves to specific receptors on the cell surface. Thus, virus infection is a receptor-mediated, species and cell type–specific process (2). Viruses enter the cytoplasm of a cell by a process called *endocytosis*, acquiring an outer coat of plasma membrane. Once inside the cell, uncoating is triggered by pH changes in endosomes. As the outer coat and the capsid are being digested, the exposed nucleoids lose their characteristic structure (3). The viruses now are in "eclipse phase" and do not become apparent until replication has taken place and new virions or viruses appear. During the process of replication, the viral proteins that are produced follow the genetic code of the specific virus nucleic acid, and the proteins formed are characteristic of the virus rather than of the host cells. Viral particles are assembled in the infected cells and released either by lysis of the cell or by budding from the cell surface.

The diameters of viruses infecting skin vary from 20 nm for the echoviruses to 300 nm for the poxviruses. Under favorable conditions, poxviruses may be recognizable under a light microscope—for example, variola viruses as Paschen bodies. As a rule, however, viruses can be resolved by light microscopy only when aggregated into inclusion bodies. *Inclusion bodies* are roughly spherical. Their average size is about 7 μm, the size of an erythrocyte. Electron microscopy has shown that inclusion bodies represent sites at which virus replication is occurring or has occurred. They are observed in three groups of viruses: the herpesvirus and papillomavirus groups, where they are found within the nuclei of cells; and in the poxvirus group, where they occur within the cytoplasm. In the nucleus, they are surrounded by a clear halo as a result of margination of the nuclear chromatin. In some viral infections, such as molluscum contagiosum, inclusion bodies contain masses of virions and are basophilic and Feulgen positive; in contrast, in other infections such as herpesvirus infection, the viruses have left the inclusion bodies, except for a few residual nucleoids, and the inclusion bodies are then eosinophilic and Feulgen negative.

There are five families of viruses that commonly affect the skin or adjoining mucous surfaces: (a) the Herpesviridae, DNA viruses that multiply within the nucleus of the host cell, including herpes simplex virus (HSV) types 1 and 2 (HSV-1, HSV-2), varicella-zoster virus (VZV), Cytomegalovirus (CMV), Roseolovirus (human herpesvirus [HHV]-6), Epstein-Barr virus (EBV; Lymphocryptovirus), HHV-7 and HHV-8; (b) the Poxviridae, which are DNA viruses that multiply within the cytoplasm, including smallpox, milkers' nodules, orf, and molluscum contagiosum; (c) the Papovaviridae, which contain DNA and replicate in the nucleus, including the various types of verrucae; (d) the Picornaviridae, which contain RNA in their nucleoids, including coxsackie virus group A, causing hand-foot-and-mouth disease; and (e) the Retroviridae, whose genetic material is RNA, including HIV, the cause of AIDS. In addition to these five families, exanthems can occur following infection with many other virus families, such as Adenoviridae, Togaviridae, Reoviridae, Parvoviridae, Paramyxoviridae, Flaviviridae, and Hepadnaviridae. Lesions from the first three DNA virus family infections contain diagnostic viral inclusions. Infections from the other virus families often produce rather histologically nonspecific changes with superficial perivascular dermatitis and occasional apoptotic cells in the epidermis.

Besides histologic examination, two other laboratory approaches can be used: virologic and serologic approaches. The virologic approach includes isolation of virus in cell culture, detection of viral particle by immunoassays or electron microscopy, and detection of viral nucleic acid by polymerase chain reaction (PCR)-based assays or labeled complementary DNA probes. The serologic approach includes demonstration of a fourfold or greater rise in antiviral immunoglobulin G (IgG) antibody using acute and convalescent sera or demonstration of virus-specific immunoglobulin M (IgM) antibody in a single late acute or early recovery phase serum. A serologic approach is still used today for certain viral infections, such as infectious mononucleosis (IM) and hepatitis. However, the virologic approach is used more frequently than before. The timing,

quality, and handling of the specimen are critical for an accurate diagnosis using the virologic approach. It is important to obtain specimens during the acute phase of a virus infection from the site of the infection. The optimal temperature for storage and transport of specimen for viral culture is 4°C in a refrigerator or on wet ice. Most of the viruses are stable at this temperature for 3 to 5 days. If a specimen needs to be stored longer than 3 to 4 days, a –70°C freezer should be used and the specimen should be transported on dry ice. With the development of molecular biology, PCR-based rapid viral detection assays have been developed and are used in clinical diagnostic laboratories.

HERPESVIRIDAE

The Herpesviridae are double-stranded DNA viruses with three subfamilies. Herpesvirus infections of humans include HSV-1, HSV-2, Varicellovirus, CMV (HHV-6), EBV (Lymphocryptovirus), HHV-7, and HHV-8.

Herpes Simplex

Two immunologically distinct viruses can cause herpes simplex: HSV-1 (orofacial type) and HSV-2 (genital type) (4). HSV is transmitted through the exchange of saliva, semen, cervical fluid, or vesicle fluid from active lesions. Primary infection with HSV-1 is often subclinical in childhood. In about 10% of the cases, acute gingivostomatitis occurs, usually in childhood and only rarely in early adult life. Primary infection may also occur in rare instances as a respiratory infection, Kaposi's varicelliform eruption, keratoconjunctivitis, or a fatal visceral disease of the newborn. Recurrent HSV-1 infections occur most commonly on or near the vermilion border of the lips (herpes labialis—"cold sores") (Fig. 25-1A). Recurrences may be triggered by sunlight, physical or emotional stress, immunosuppression, menses, hot or cold, or febrile illness (5). Besides the lips, any parts of the skin or oral mucosa can be affected by HSV-1. Herpes genitalis is one of the most common sexually transmitted diseases worldwide (6). Seroconversion for HSV-2, the most common cause of genital herpes, rarely occurs before the onset of sexual activity. Occasionally, an infant contracts HSV-2 *in utero* or by direct contact in the birth canal (7). Even though most infections of the genitalia and adjoining skin are caused by HSV-2, some infections in this area are caused by HSV-1. Genital HSV-1 infections are less likely to recur than HSV-2 infections: the rate of recurrence was 14% for HSV-1 infections compared with 60% for HSV-2 infections (8). Only 10% to 25% of individuals who are HSV-2 seropositive report a history of genital herpes (9).

Both primary and recurrent herpes simplex, in their earliest stages, show one or several groups of tiny clear vesicles on an edematous red base. If located on a mucous surface, the vesicles erode quickly, whereas if located on the skin, they may become pustular before crusting. The lesions usually heal without scarring, except in cases where secondary bacterial infection occurs. The following are special forms of cutaneous herpes simplex: eczema herpeticum (Kaposi's varicelliform eruption), herpetic folliculitis, and herpetic whitlow.

Eczema herpeticum is a potentially life-threatening herpetic infection of a preexisting skin disease (10). It occurs most commonly in patients with atopic eczema; however, it may also occur in other skin diseases such as seborrheic dermatitis, pityriasis rubra pilaris, pemphigus foliaceus, Darier's disease, and post perioral dermabrasion (11). An extensive rash with small vesicles filled with yellow pus and high fever is the common presentation of eczema herpeticum (Fig. 25-1B), which has been linked to increased interleukin (IL)-4 and decreased natural killer cells and IL-2 receptor in patients with atopic eczema (12,13). *Herpetic folliculitis* presents as painful, grouped erythematous, perifollicular vesicles that do not respond to antibacterial or antifungal agents, usually occurring in the bearded region and scalp (14). The characteristic

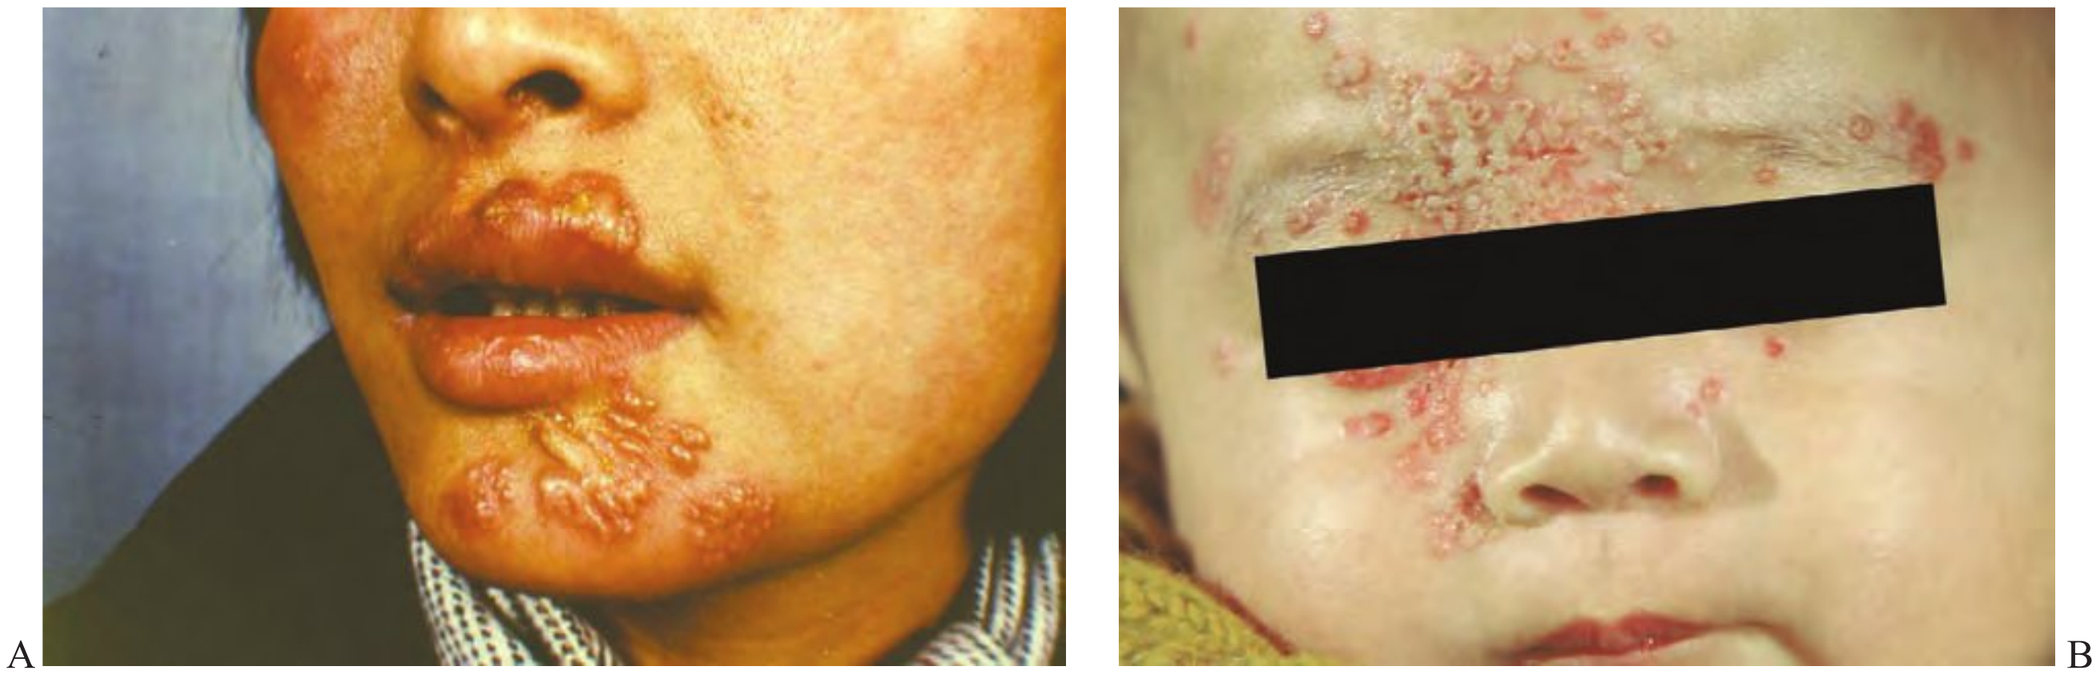

FIGURE 25-1. A: Herpes simplex. Recurrent HSV-1 infection showing grouped vesicles on an erythematous base, occurring most commonly on or near the vermilion border of the lips. B: Eczema herpeticum. This condition often occurs in atopic children.

vesiculofollicular lesions usually heal within a few weeks. *Herpetic whitlow* manifests as painful, deep-seated vesicles limited to the paronychial or volar aspects of the distal phalanx of a finger. Herpetic whitlow occurs largely in medical and dental personnel following minor injuries and may be caused by either HSV-1 or HSV-2 (15). Other forms of HSV infections include HSV keratoconjunctivitis, which is the number one cause of corneal blindness in the United States (16), and a rare necrotizing balanitis (17). Noncutaneous forms of herpes simplex infection include herpetic oropharyngitis, pneumonia, encephalitis, esophagitis, and proctitis.

Recurrent Infection. Recurrent infections of the oral cavity, skin, or genitals can result either from reactivation of a latent infection or from a new infection. Primary infection with either HSV-1 or HSV-2 is often subclinical and is followed by emergence of specific circulating antibodies and latency of the infection. In some persons infected with either HSV-1 or HSV-2, the virus can become activated intermittently and give rise to recurrent lesions. Although recurrences, particularly of HSV-2, can be due to reinfection, they are often caused by reactivation of a latent infection of the regional sensory ganglia, where the virus exists in a latent, nonreplicative state.

Herpes Simplex in Compromised Hosts

Severe primary or secondary herpetic infection with systemic involvement may occur in immunocompromised patients. Coinfection with HSV and HIV frequently occurs, probably because they potentiate each other's transmission. About 70% of HIV-positive patients are seropositive for HSV-2 (18). Three forms of herpes simplex are characteristically found in children or adults with impairment of the cellular immune system. The most common of the three forms is *chronic ulcerative herpes simplex*, and the other two are *generalized acute mucocutaneous herpes simplex* and *systemic herpes simplex*.

Chronic ulcerative herpes simplex exhibits persistent ulcers and erosions, usually starting on the face or in the perineal region (19). Without treatment, gradual widespread extension is the rule. The infection may progress into systemic herpes simplex. *Generalized acute mucocutaneous herpes simplex* follows an initial localized vesicular eruption. Dissemination associated with fever takes place, which is suggestive of smallpox or varicella infection (20). In some instances, death results without the presence of visceral lesions. *Systemic herpes simplex* usually follows oral or genital lesions of herpes simplex. Areas of necrosis, particularly in the liver, adrenals, pancreas, and brain, lead rapidly to death. In some patients, a few cutaneous lesions of herpes simplex also exist.

Congenital Herpes Simplex

Because almost 1% of patients in prenatal clinics have HSV-2 infections by culture of the vagina and one third of these have active lesions, there exists the potential of congenital herpes simplex infection. It is important, however, to distinguish primary HSV-2 infection of the mother from recurrent infection. In recurrent infection, the presence of neutralizing antibody to HSV-2 results in a low rate of attack of the fetus (21). In maternal HSV-2 *primary infection*, the mode of infection of the infant is important. Transplacental infection of the fetus occurring during the first 8 weeks of gestation produces severe congenital malformations. If infection occurs at a later time, malformations are less severe and consist of growth and psychomotor retardation; microcephaly; and a widespread, recurrent vesicular eruption that can mimic a mechanobullous disorder.

Localized herpetic lesions appearing several days after delivery are the initial manifestation if infection is acquired in the birth canal. In vertex deliveries, the scalp is a common site for the development of initial herpetic vesicles. It is rare for transplacental or neonatal infection to remain limited to the skin. It can be followed by systemic herpetic infection, such as encephalitis, hepatoadrenal necrosis, and pneumonia (22).

Herpes Simplex Associated With Erythema Multiforme

HSV is the most common identified etiologic agent in recurrent erythema multiforme (23). Molecular diagnostic methods, primarily PCR, have been used to detect herpetic DNA in the skin lesions of recurrent erythema multiforme in both adults and children (24). The association is further supported by suppression of recurrent lesions in this group by therapy directed at HSV.

Histopathology of Herpes Simplex

The earliest changes of herpes simplex lesions include nuclear swelling of keratinocytes. With hematoxylin and eosin stains, these nuclei appear slate gray and homogeneous with margination of the nuclear chromatin. A few necrotic keratinocytes in the epidermis may also be seen. The changes usually begin along the basal layer keratinocytes and then involve the entire epidermis. Later, skin herpes simplex produces profound degeneration of keratinocytes, resulting in acantholysis and vesicle formation (Fig. 25-2). Degeneration of epidermal

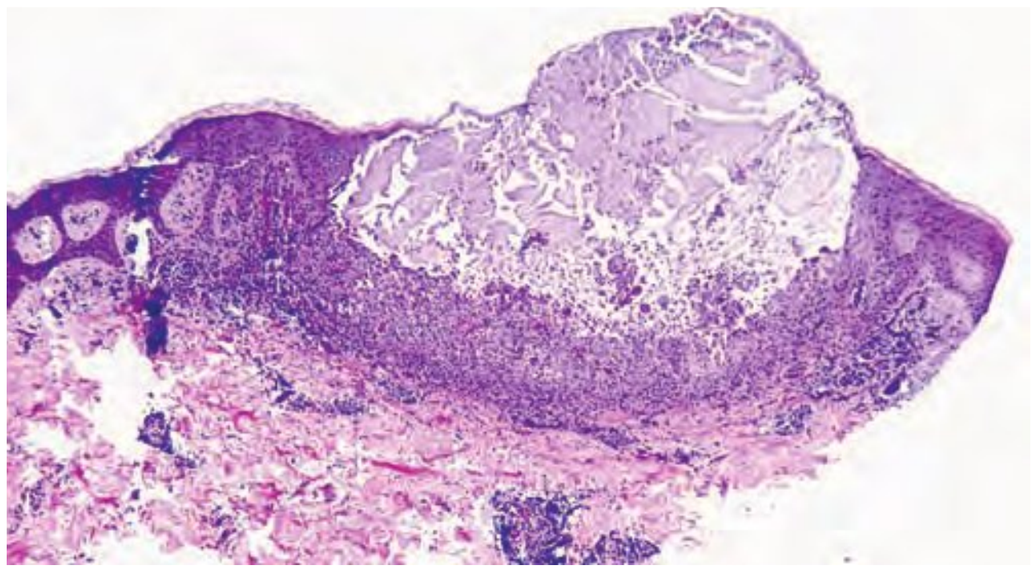

FIGURE 25-2. Herpes simplex. An intraepidermal vesicular lesion with marked acanthosis and ballooning degeneration of the cells at the floor of the vesicle (low magnification).

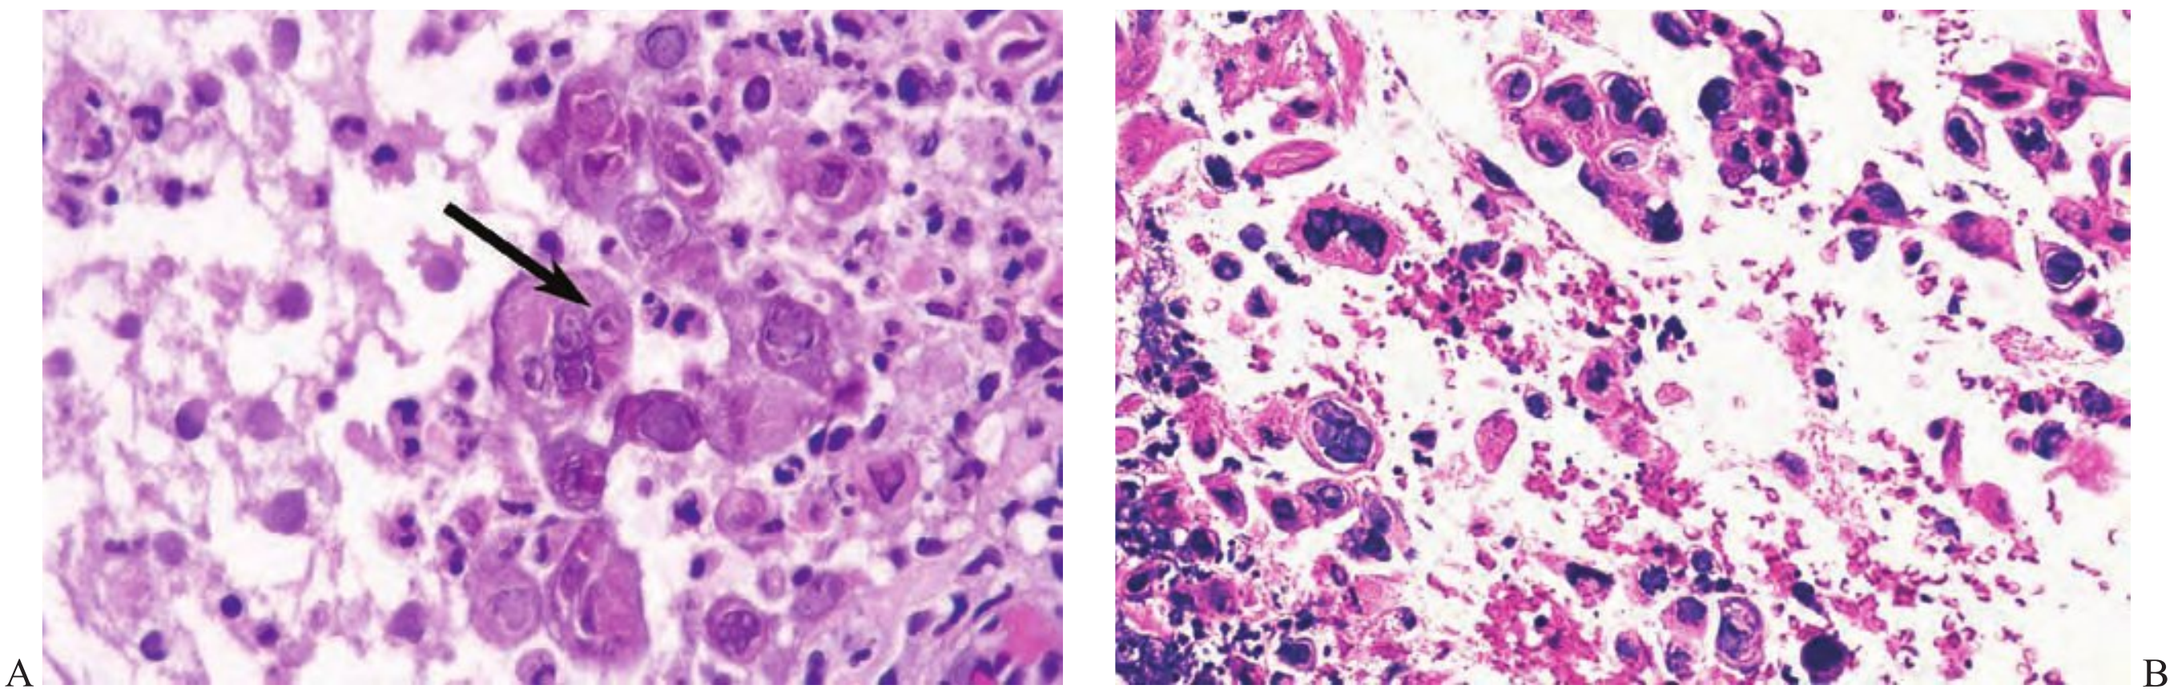

FIGURE 25-3. Herpes simplex. A: Same lesion as in Figure 25-2 but at high magnification. Balloon cells at the floor of a vesicle are shown. In the center, eosinophilic inclusion bodies surrounded by a halo lie in the nuclei of balloon cells (arrow points to the intranuclear inclusion). Other cells exhibit the more characteristic pattern of homogeneous pale chromatin without inclusion bodies. B: At high magnification, balloon cells at the floor of a vesicle are shown. These cells exhibit characteristic homogeneous pale chromatin with nuclei molding.

keratinocytes occurs in two forms: ballooning degeneration and reticular degeneration. Ballooning degeneration is swelling of epidermal keratinocytes. Balloon cells have a homogeneous, eosinophilic cytoplasm (Fig. 25-3). They may be multinucleated (Tzanck cells). Balloon cells lose their intercellular bridges and become separated from one another (secondary acantholysis), and unilocular vesicles result. Ballooning degeneration occurs mainly at the bases of viral vesicles, so the vesicle formed intraepidermally ultimately may be subepidermal. Ballooning degeneration can affect epithelial cells of hair follicles, sebaceous glands, and rarely eccrine duct cells. Reticular degeneration is the result of rupture of ballooning cells due to progressive hydropic swelling of the epidermal cells (Fig. 25-4A). Reticular degeneration occurs in the upper portions and at the peripheries of viral vesicles. Reticular degeneration is not specific for viral vesicles, because it also occurs in the vesicles of contact dermatitis. Through coalescence of cells with reticular degeneration, a multilocular vesicle may result, the septa of which are formed by residual cell membrane. In older vesicles, the cellular walls disappear. The originally multilocular portions of the vesicle may become unilocular.

Inclusion bodies are frequently observed in the centers of enlarged, round nuclei of balloon cells. The inclusion bodies are eosinophilic and surrounded by a clear space or halo (Fig. 25-3A). They measure from 3 to 8 μm in diameter. The majority of the balloon cells at the floor of a vesicle exhibit characteristic homogeneous pale chromatin and nuclei molding without inclusion bodies (Figs. 25-3B and 25-4B). Neutrophils

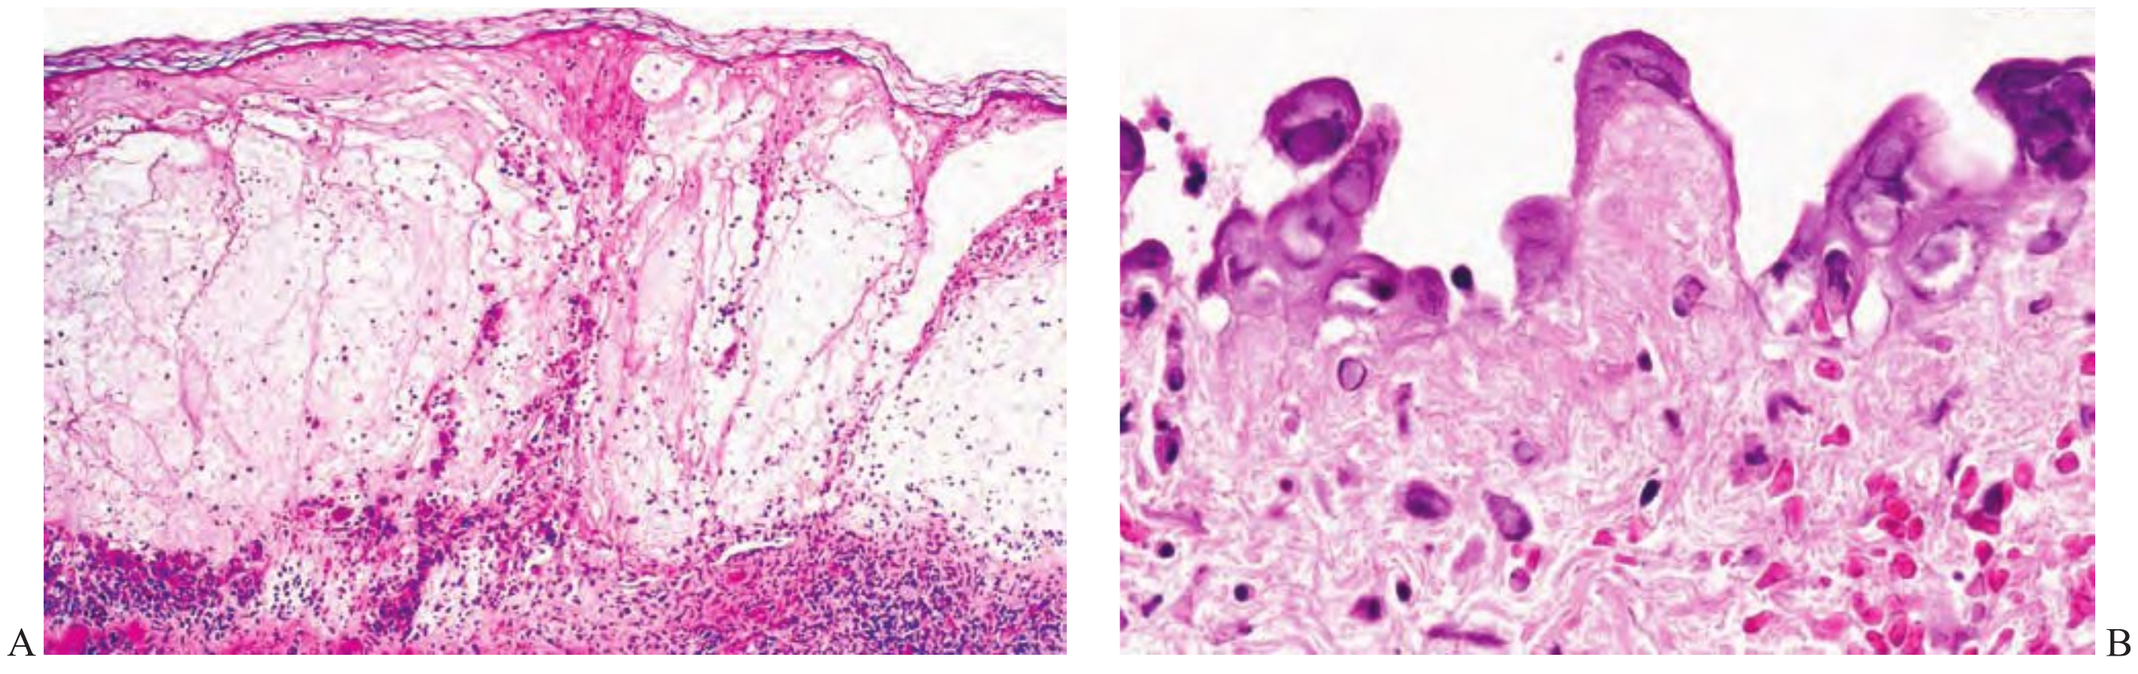

FIGURE 25-4. Varicella and herpes zoster. A: Reticular degeneration is present, especially at the top of the vesicle, resulting in a multilocular vesicle. In addition, ballooning degeneration can be seen at the floor of the vesicle. B: At high magnification, balloon cells exhibit characteristic homogeneous pale chromatin and nuclear molding. Dermal hemorrhage is common.

are often present within established vesicles. Neutrophils may be prominent in the lesions of herpetic whitlow. The upper dermis beneath viral vesicles contains an inflammatory infiltrate of variable density. In some cases of herpes simplex, vascular damage is present, showing necrosis of vessel walls, microthrombi, and hemorrhage subjacent to the vesicle. In addition, eosinophilic inclusions may be found in endothelial cells and fibroblasts. In later lesions, necrosis of epidermis is often present with abundant neutrophils. A dense mixed cell infiltrate in the upper dermis with ghosts of necrotic multinucleated acantholytic cells with slate gray nuclei may still be seen. As in all vesiculobullous diseases, an early lesion should be selected for biopsy; otherwise, secondary changes, especially invasion of inflammatory cells, may obscure the diagnostic features.

Herpetic involvement of hair follicle and pilosebaceous units is not uncommon in recurrent lesions (25). In fact, necrosis of a pilosebaceous unit is a clue to search for multinucleated cells with characteristic slate gray nuclei. In herpetic folliculitis, pilosebaceous involvement is a predominant feature. Rarely, the eccrine ducts and glands are involved by the virus. The histology of eczema herpeticum is similar to vesicles of herpes simplex, but usually with more dense neutrophilic infiltrates.

Chronic ulcerative herpes simplex may be difficult to recognize as being of viral genesis if the epidermis is absent. However, viral cytopathic changes may be observed in keratinocytes at the margin of the ulcer. Viral cultures or typing of HSV-1 and HSV-2 by direct immunofluorescence or immunoperoxidase technique can be used to prove the diagnosis. However, the most rapid and accurate method may be the use of molecular diagnostic methods such as PCR (26).

Tzanck Smear. Cytologic examination of a Giemsa-stained smear taken from the floor of a freshly opened early vesicle is often useful. The presence of many balloon cells results from the fact that the smear is taken from the floor of the blister, where ballooning degeneration is most pronounced. Many acantholytic balloon cells with one or several nuclei may be seen in herpes simplex, varicella, and zoster. The Tzanck smear cannot distinguish among HSV-1, HSV-2, and VZV.

Histogenesis and Viral Identification. HSV can be directly identified by culture, direct immunofluorescence testing, *in situ* hybridization, immunoperoxidase staining, or molecular diagnostic tests. The gold standard for diagnosis is a viral culture. For culture, material from the floor of a blister or other infected material is inoculated onto HeLa cells, human amnion cells, or fibroblasts. The virus has cytopathic effects on the cultured cells. Direct immunofluorescence examination for the presence of the viral antigen in cells infected with HSV is then performed. Herpes simplex DNA can be extracted and amplified by PCR from stained or unstained Tzanck smears, crusts, fresh tissue, and paraffin sections of suspected lesions. With appropriate primers, each herpes-type virus can be specifically identified.

For distinction between the two types of HSV, immunoperoxidase staining may be performed on sections of the lesions by using monoclonal antibodies, one directed against HSV-1 and the other against HSV-2. *In situ* hybridization can also be used for visual demonstration of viral genomic material in tissue (27). For determination of the antibody titer in the patient's serum, a complement fixation reaction is usually used. The serologic test for HSV is useful to confirm HSV infection in persons with a questionable history of herpetic disease and in those who have unrecognized or subclinical infection; thus, they may be aware of their potential to transmit the virus.

On electron microscopy, HSV is spherical. Its DNA-containing core measures approximately 40 nm in diameter. The virion has a diameter of about 100 nm and together with its outer coat measures around 135 nm (28). Ultrastructurally, the virion of herpes simplex is indistinguishable from that of varicella.

Differential Diagnosis. Viral vesicles produced by HSV and by the VZV are identical. Furthermore, an incompletely developed case of herpes zoster can mimic herpes simplex infection, both clinically and histologically. In the context of immunosuppression, chronic cutaneous forms of both viruses exist, and their specific identification may not be possible by clinical morphology or light microscopy. Molecular diagnostic methods are the quickest and most reliable way to separate and identify the specific viruses in these situations.

Kaposi's Varicelliform Eruption

Kaposi's varicelliform eruption (eczema herpeticum) is a distinct cutaneous eruption caused by HSV-1 and HSV-2, vaccinia virus, and coxsackie A16 virus, superimposed on a preexisting dermatosis (29), usually atopic dermatitis (30). Occasionally, seborrheic dermatitis or other dermatosis, such as Darier's disease, benign familial pemphigus, pemphigus foliaceus, mycosis fungoides, Sézary's syndrome, or ichthyosis vulgaris, provide the "soil" in which Kaposi's varicelliform eruption develops (11).

Eczema herpeticum is usually caused by HSV-1 and on rare occasions by HSV-2. Eczema herpeticum can occur as either a primary or a recurrent type of infection. A primary infection with HSV-1 occurs in persons without circulating HSV-1 antibodies. The great majority of patients with the primary type of eczema herpeticum are infants and children. The recurrent type of eczema herpeticum occurs in patients with circulating HSV-1 antibodies. The first attack of eczema herpeticum, whether of the primary or the recurrent type, may be the result of exogenous infection, whereas subsequent attacks may result from either reinfection or reactivation. The primary type of eczema herpeticum can be a serious disease with viremia and potential internal organ involvement resulting in death. In contrast, the recurrent type of eczema herpeticum generally shows no viremia and internal organ involvement except in immunologically compromised patients. Occasionally, secondary bacterial infection with subsequent septicemia may cause death. The mortality of eczema herpeticum is approximately 10%, with most fatalities occurring in infants and children with a primary type of herpetic infection and in adults with inadequate cellular immunity.

Clinically, all forms of eczema herpeticum and eczema vaccinatum (a condition caused by exposure to vaccinia virus, a poxvirus) look alike, but eczema vaccinatum has not been seen in modern practice because vaccinia virus has not been used, until recently, for smallpox prevention (31). Both show a more or less extensive eruption composed of vesicles and pustules that may be umbilicated. These vesicles and pustules occur chiefly in the areas of the preexisting dermatosis but also on normal skin. The face is usually severely affected and may be edematous. There may be fever and prostration.

Histopathology. Both eczema herpeticum and eczema vaccinatum show vesicles and pustules of the viral type. Even though the pustules exhibit only necrotic epidermis in their centers, reticular and ballooning degeneration at their peripheries may still be seen. In eczema herpeticum, but not in eczema vaccinatum, multinucleated epithelial giant cells often are present.

Differential Diagnosis. Because eczema herpeticum and eczema vaccinatum look alike clinically, and the histological similarity is great in the absence of inclusion bodies and of multinucleated epithelial cells, differentiation of the two diseases may have to depend on nonhistologic means, such as a history of possible exposure to the vaccinia virus. The most efficient and rapid means of identifying the viral agent is to use DNA amplification methods and appropriate probes.

Varicella and Herpes Zoster

Varicella (chickenpox) and herpes zoster (shingles) are produced by the same virus—VZV. VZV is endemic in the population but becomes epidemic during late winter and early spring (32). Varicella results from contact of a nonimmune person with this virus, whereas herpes zoster occurs in persons who have had previous varicella, either clinically or subclinically. Herpes zoster is caused by reactivation of a latent infection in either a spinal or a cranial sensory ganglion. On reactivation, the virus spreads from the ganglion along the corresponding sensory nerve or nerves to the skin.

Varicella

In varicella, a generalized eruption develops after an incubation period of about 2 weeks. Varicella is primarily a disease of childhood; 90% of cases occur in children 14 years of age or younger (33). The transmission rate of acute varicella to susceptible household contacts is estimated to be as high as 80% to 90%, making it one of the most infectious viral diseases of humans. VZV is acquired from patients with primary varicella or herpes zoster through either direct contact with infected vesicular fluid or inhalation of aerosolized respiratory secretions. Recent experiments suggest that VZV is lymphotropic, especially to T cells. After the initial viremia and a period of viral replication, a second, higher-titer viremic phase results in widespread dissemination of the virus. The rash develops as VZV-infected mononuclear cells invade vascular endothelial cells, gaining access to cutaneous tissue. After the primary varicella infection resolves, VZV enters a latent phase in the dorsal root ganglia (34). Pruritic rash of chickenpox, the hallmark of the disease, typically begins on the head and spreads to the trunk and finally the extremities; proximal involvement is greater than distal. The skin lesions of varicella begin as erythematous macules to small papules, which develop into vesicles (Fig. 25-5). In mild cases, most vesicles become crusted without changing into pustules. In severe cases, the vesicles may have slightly hemorrhagic bases ("dew drops on rose petals"). New lesions continue to develop for several days, so lesions in different stages, papules, vesicles, pustules, and crusted lesions can be observed. Typically, varicella lesions heal without scarring as new epithelium forms at the base; however, hypopigmentation, skin pitting, and keloid formation may result, especially among darker-skinned individuals. Varicella in adults is generally associated with a greater number of skin lesions, more systemic complaints, and a higher risk of such serious complications as pneumonia, encephalitis, and death. Subclinical varicella, documented by increases in antibody titer after exposure to the virus, has been estimated to occur in as much as 5% of the population (35).

FIGURE 25-5. Varicella (chickenpox). A vesicular eruption in crops with "dew drops on rose petals" appearance.

Three systemic complications can occur in varicella without the existence of immunosuppression: primary varicella pneumonia, Reye's syndrome, and varicella of the fetus and newborn. Primary varicella pneumonia occurs in approximately 14% of adults with varicella and carries a significant mortality. Reye's syndrome is an acute, severe, and usually fatal encephalopathy associated with fatty degeneration of the viscera, particularly of the liver. It follows mainly varicella but also other viral infections. Although usually observed in children, it also may occur in adults (36). Varicella in the first 20 weeks of pregnancy has a 2% risk of producing embryopathy or other congenital malformations (37). Maternal varicella late in pregnancy may be transmitted to the fetus transplacentally or may contaminate the baby during passage through the birth canal, resulting in neonatal varicella.

Varicella in Compromised Hosts

In patients with impairment of the cellular immune system, continued viral replication may lead to a prolonged course and dissemination to various organs. Varicella pneumonia is not uncommon, even in children, and death may result from dissemination. VZV may produce particularly severe problems for patients with AIDS. There may be continuous dissemination of vesicular lesions, formation of chronic vegetative lesions, and large necrotic lesions (38).

Herpes Zoster

It is known that VZV establishes latency in ganglia following the primary infection causing varicella (chickenpox) and that the virus may reactivate after years of dormancy to produce herpes zoster (shingles). It is now widely accepted that the virus is mainly latent in neuronal cells, with only a small proportion of nonneuronal cells infected. The ganglia most often involved are those of the lumbar and thoracic nerves. When the virus is reactivated, newly synthesized viruses are transported along the sensory nerve and released into the skin. Trigger mechanisms include trauma, stress, older age, cancer (especially lymphoma), and other causes of immunosuppression including therapeutic agents. The incidence of herpes zoster increases with age (39). Although herpes zoster occurs largely in adults, particularly in those of advanced age, about 5% of patients with herpes zoster are children younger than 15 years of age. The course in children without immune defects usually is mild. The eruption in herpes zoster consists of grouped vesicles on inflammatory bases and arranged along the course of a sensory nerve (Fig. 25-6). The bases of the lesions frequently are hemorrhagic, and some may become necrotic and ulcerate. Not infrequently, there are a few scattered nondermatomal lesions, and rarely there is a generalized eruption, including mucosal lesions, indistinguishable from that of varicella. The most common places of involvement include the thoracolumbar (T3-L2) and facial (V1) dermatomes. Severe neuritis with acute pain, dysesthesia, and skin hypersensitivity is common and more severe in people older than 50 years of age and in immunocompromised patients. Zoster sine herpete, or "pain without the rash," is a rare presentation of herpes zoster; dermatomal pain is present with failure to develop a rash, likely because of neural inflammation and damage caused by viral reactivation. Herpes zoster during pregnancy is not as serious a problem as primary varicella during pregnancy; it does not result in serious morbidity or intrauterine VZV infection. Transplacental transmission of the virus does not occur with maternal herpes zoster; preexisting normal immunity is thought to protect the fetus.

FIGURE 25-6. Herpes zoster (shingles). Vesicles with a characteristic dermatomal distribution.

Herpes Zoster in Compromised Hosts

Both the incidence and the severity of herpes zoster are greater in patients with impaired cellular immunity. The incidence of herpes zoster is particularly high in patients with advanced Hodgkin's disease who are receiving chemotherapy or radiation and in persons infected with HIV. In the context of HIV infection, herpes zoster may fail to resolve, may disseminate, or may produce atypical vegetative and ulcerative lesions (40). Although patients with disseminated herpes zoster but without associated serious illness have good prognoses, patients with impaired cellular immunity may develop widespread, fatal systemic manifestations, such as pneumonia, gastroenteritis, or encephalitis.

Histopathology. Lesions of varicella and herpes zoster are histologically indistinguishable from those of herpes simplex (Fig. 25-4A, B). Frequently, however, the degree of vessel damage, microthrombi, and hemorrhage are more pronounced in varicella and, particularly, in herpes zoster than in herpes simplex. Herpes zoster vasculitis may mimic giant cell arteritis (41). In severe cases of varicella and in disseminated herpes zoster, eosinophilic inclusion bodies have also been observed in the dermis within the nuclei of capillary endothelial cells and of fibroblasts bordering the affected vessels. In contrast, in localized herpes zoster, in which the virus reaches the epidermis by way of the cutaneous nerves rather than the capillaries, inclusion bodies have been demonstrated within neurilemmal cells of the small nerves in the dermis underlying the vesicles. Immunohistochemical methods using specific monoclonal antibodies may have some utility in separating VZV from HSV. Using an antibody specific for an envelope glycoprotein, Nikkels and colleagues (42) demonstrated VZV reactivity in sebaceous cells, endothelial cells, mononuclear phagocytes, and factor XIIIa-positive dendrocytes.

Tzanck Smear. Cytologic examination of the contents of vesicles is carried out for varicella and herpes zoster in the same way as for herpes simplex. It is a very useful diagnostic test, confirming the diagnosis in 80% to 100% of the cases, whereas viral cultures can confirm in only 60% to 64% (43).

Histogenesis and Viral Identification. Cultures remain the gold standard for virologic confirmation, and the virus can be cultured easily from vesicular fluid within 5 days of the onset

of symptoms or before the crusting of lesions. However, culture is not very sensitive, and in contrast with herpes simplex, VZV does not grow in ordinary tissue cultures—it only grows in human fetal diploid kidney cells or human foreskin fibroblasts. Specific antibodies are available for serologic or immunohistochemical viral identification. Electron microscopic examination of the cutaneous lesions of varicella and herpes zoster reveals virus particles in the capillary endothelium in varicella and sporadically in the axons of dermal nerves in herpes zoster. HSV and VZV are indistinguishable by electron microscopy.

CYTOMEGALOVIRUS

CMV is a herpesvirus that is ubiquitous in human populations. It has been estimated that 1% of newborns are infected transplacentally, and about 5% more acquire the infection at the time of birth. There is a steady increase with age in the number of individuals with antibodies in the serum, and this number takes a significant jump at the time of adolescence, presumably due to transfer of virus through the oral route (44). CMV may also be sexually transmitted. Owing to its ability to remain latent in peripheral leukocytes, CMV can be transmitted via transfusion. Most individuals have a mild flulike episode on initial infection; however, the virus subsequently becomes latent and persists in many tissues in the body. In immunocompromised individuals, reactivation and involvement of almost any organ of the body can take place and produce a widespread, potentially fatal, systemic infection (45).

Skin manifestation of CMV infection is rare in immunocompetent persons. Cutaneous lesions reported in the immunocompromised patients varies greatly, from genital ulceration to ulceration of the chest. A more or less widespread maculopapular rash that may become purpuric, sharply punched-out ulcers, urticaria, vesiculobullous lesions, keratotic lesions, and epidermolysis have been reported (46). In the context of HIV infection, CMV-associated viral cytopathic changes can be observed as epiphenomena in skin biopsies in that they do not appear to be the primary pathogen in the specimen and the cause of the skin eruption.

Neonates with congenital CMV infection may exhibit the clinical picture of the "blueberry muffin baby" at delivery, which is manifested by petechiae and purpuric magenta-colored macules, papules, and plaques as well as blueberry-colored ecchymoses. The hemorrhagic-purpuric looking skin lesions are thought to reflect extramedullary hematopoiesis. Ultrastructural study demonstrates that complexes of red cells in various stages of maturation occur in the skin of these patients, similar to the erythroblastic islands in the bone marrow (47). Transplacental transfer of CMV is one of the causes of *TORCH*, a congenital infection caused by Toxoplasmosis, other infections, Rubella, Cytomegalovirus, and Herpes simplex virus, with extensive damage to the developing brain, chorioretinitis, and pneumonitis (48).

Histopathology. Dilated dermal vessels exhibit, among normal endothelial cells, large, irregularly shaped endothelial cells with large, hyperchromatic, basophilic, intranuclear inclusions that are around 10 μm in size as well as small intracytoplasmic inclusions (around 3 μm in size) (Fig. 25-7). Some of the inclusions are surrounded by clear halos. A mixed inflammatory infiltrate with focal leukocytoclastic changes may also be present. In the context of HIV infection, other pathologic processes may also be present in the same tissue section.

Histogenesis and Viral Identification. CMV culture can be performed by using human fibroblasts. PP65 is a CMV viral protein that is detectable in infected peripheral mononuclear cells, which is a sensitive method to estimate the systemic viral load (49). Immunohistochemical studies using monoclonal or polyclonal antibodies to CMV antigens can be used in paraffin-embedded sections to reveal viral proteins and confirm the presence of the virus. CMV DNA can also be amplified from skin biopsy specimens with PCR by using specific primers for CMV or can be identified by *in situ* hybridization. Electron microscopy shows intranuclear viral particles approximately 110 nm in diameter. The virus greatly resembles that of herpes simplex.

Epstein-Barr Virus

EBV is thought to be responsible for a number of diseases such as infectious mononucleosis (IM), oral hairy leukoplakia, and cutaneous lymphoproliferative disorders as well as Burkett's lymphoma and nasopharyngeal carcinoma (50). Infection with the EBV develops first in the salivary gland. Large amounts of the virus are released in the saliva, enabling it to spread from one person to another. People infected with EBV will retain it for life, and most are asymptomatic. It has been estimated that the virus infects almost everyone in developing countries and >80% of people in developed countries. Most people are infected with the virus during childhood and usually are not noticeably affected. On the other hand, people infected for the first time during or after adolescence (10% to 20% of people living in developed countries) have a 50% chance of developing IM. The main site of viral persistence is within latently infected lymphocytes, although infectious virus is also released into saliva from infected cells in the oropharynx (51).

IM is a self-limited manifestation of acute EBV infection. The transient rash that occurs quite commonly in patients with IM who have received antibiotic therapy is an erythematous, maculopapular eruption, usually located on the trunk and upper extremities. The palms, soles, and oral mucosa also have been reported to be occasionally involved. The pathogenesis of the rash is believed to be secondary to polyclonal B-cell activation that occurs during EBV infection with production of polyclonal antibodies that form immune complexes capable of fixing complement (52). Oral hairy leukoplakia is another manifestation of EBV infection that occurs in immunosuppressed HIV-positive and HIV-negative individuals. In HIV-positive individuals, it serves as an indicator of disease severity and rapid progression to AIDS. The presence of oral hairy leukoplakia in an individual should prompt the clinician to perform a thorough history taking and investigation of

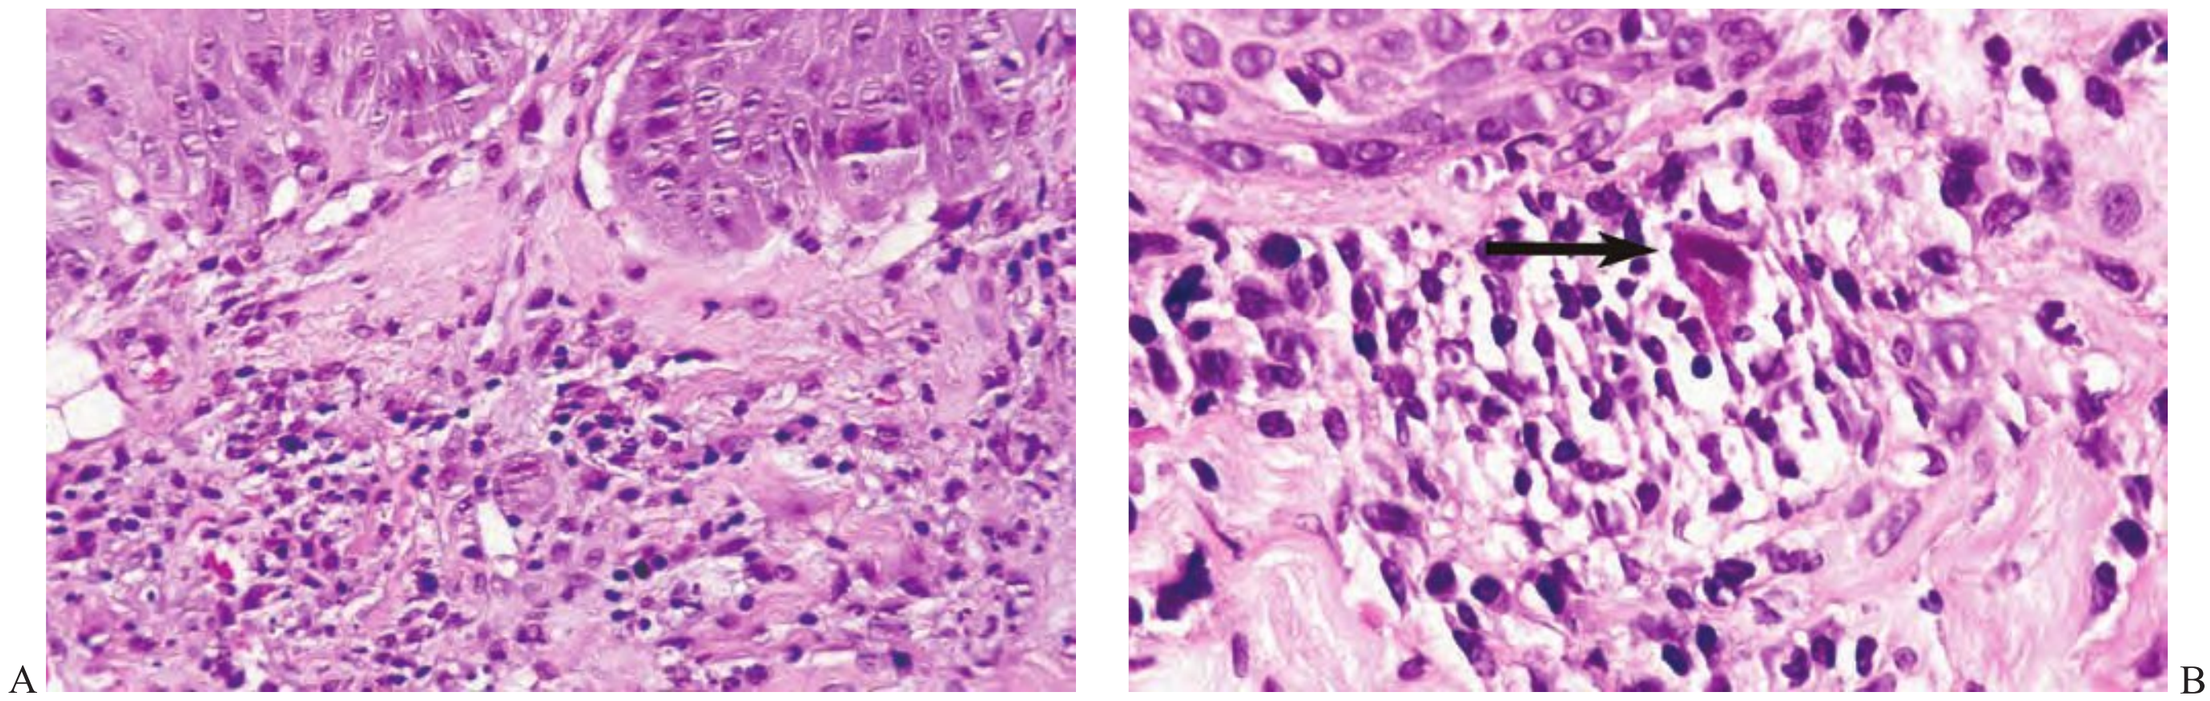

FIGURE 25-7. Cytomegalic inclusion disease. A: Scanning magnification shows superficial perivascular and diffuse inflammation with prominent vessels. Enlarged endothelial cells may be apparent at this magnification. B: At high magnification, one infected dermal cell in the center shows enlarged, hyperchromatic, basophilic, intranuclear inclusions. There is a mixed inflammatory infiltrate in the dermis. C: Dilated dermal vessel with large, irregularly shaped endothelial cells. The enlarged endothelial cells contain hyperchromatic, basophilic, intranuclear inclusions (arrow points to an inclusion). There may be basophilic cytoplasmic inclusions as well.

immune status. These lesions characteristically resemble whitish patches with a verrucous or filiform irregular surface that cannot be scraped off and are located primarily on the lateral surfaces of the tongue unilaterally or bilaterally. The condition is usually asymptomatic; however, in some cases, a burning sensation can occur, which is most likely secondary to coinfection by *Candida* (53). Lymphoproliferative disorders associated with EBV are well documented in the literature. EBV has recently been demonstrated to be associated with cutaneous T-cell lymphoma (54). EBV genome has also been detected in postrenal transplant cutaneous lymphoma, recurrent necrotic papulovesicles of the face (55), and cutaneous angiocentric lymphoma (56).

Histopathology. The histology of the macular lesion associated with IM is nonspecific and usually shows superficial perivascular lymphohistiocytic infiltrates. The histologic features that typify oral hairy leukoplakia include irregular epithelial hyperplasia with associated parakeratosis and acanthosis (Fig. 25-8A). Ballooning of keratinocytes occurs, and there are small, pyknotic nuclei with intranuclear inclusions and a clear perinuclear halo. The cytoplasm may adopt a ground-glass appearance (Fig. 25-8B). There is also a mild inflammatory infiltrate observed in the superficial dermis. Langerhans cells are noted to be absent in the epithelium. Hyphae of *Candida* are observed within the superficial epithelium of a majority of the patients with oral hairy leukoplakia and may play a role in the development of the epithelial hyperplasia observed in oral hairy leukoplakia. A leukocytoclastic vasculitis and neuropathy associated with chronic EBV infection have also been reported. EBV can be detected by *in situ* hybridization (Fig. 25-8C).

Human Herpesvirus-6, -7, and -8

HHV-6, -7, and -8 are relatively newly discovered viruses. These ubiquitous viruses may cause primary or chronic persistent infection or remain in a state of latency for many years, until a decrease in the immunologic state of the host leads to reactivation of infection (57). HHV-6 was first isolated in 1986 from patients with lymphoproliferative disorders and was classified into two variants as HHV-6A and HHV-6B. HHV-6B is the causative agent of exanthem subitum. Children start to be infected with HHV-6 at 6 months of age, and almost all get antibody by 2 years old. The transmission of HHV-6 is essentially by a salivary route (58). HHV-6 infects latently after the primary infection and reactivates especially under an immunosuppressive condition. Skin rash in the first month after allogeneic bone marrow transplant (59), generalized vesiculobullous eruptions after allogeneic bone marrow transplantation (60), papular-purpuric "gloves and socks" syndrome (61), papular acrodermatitis of childhood (Gianotti-Crosti syndrome) (62),

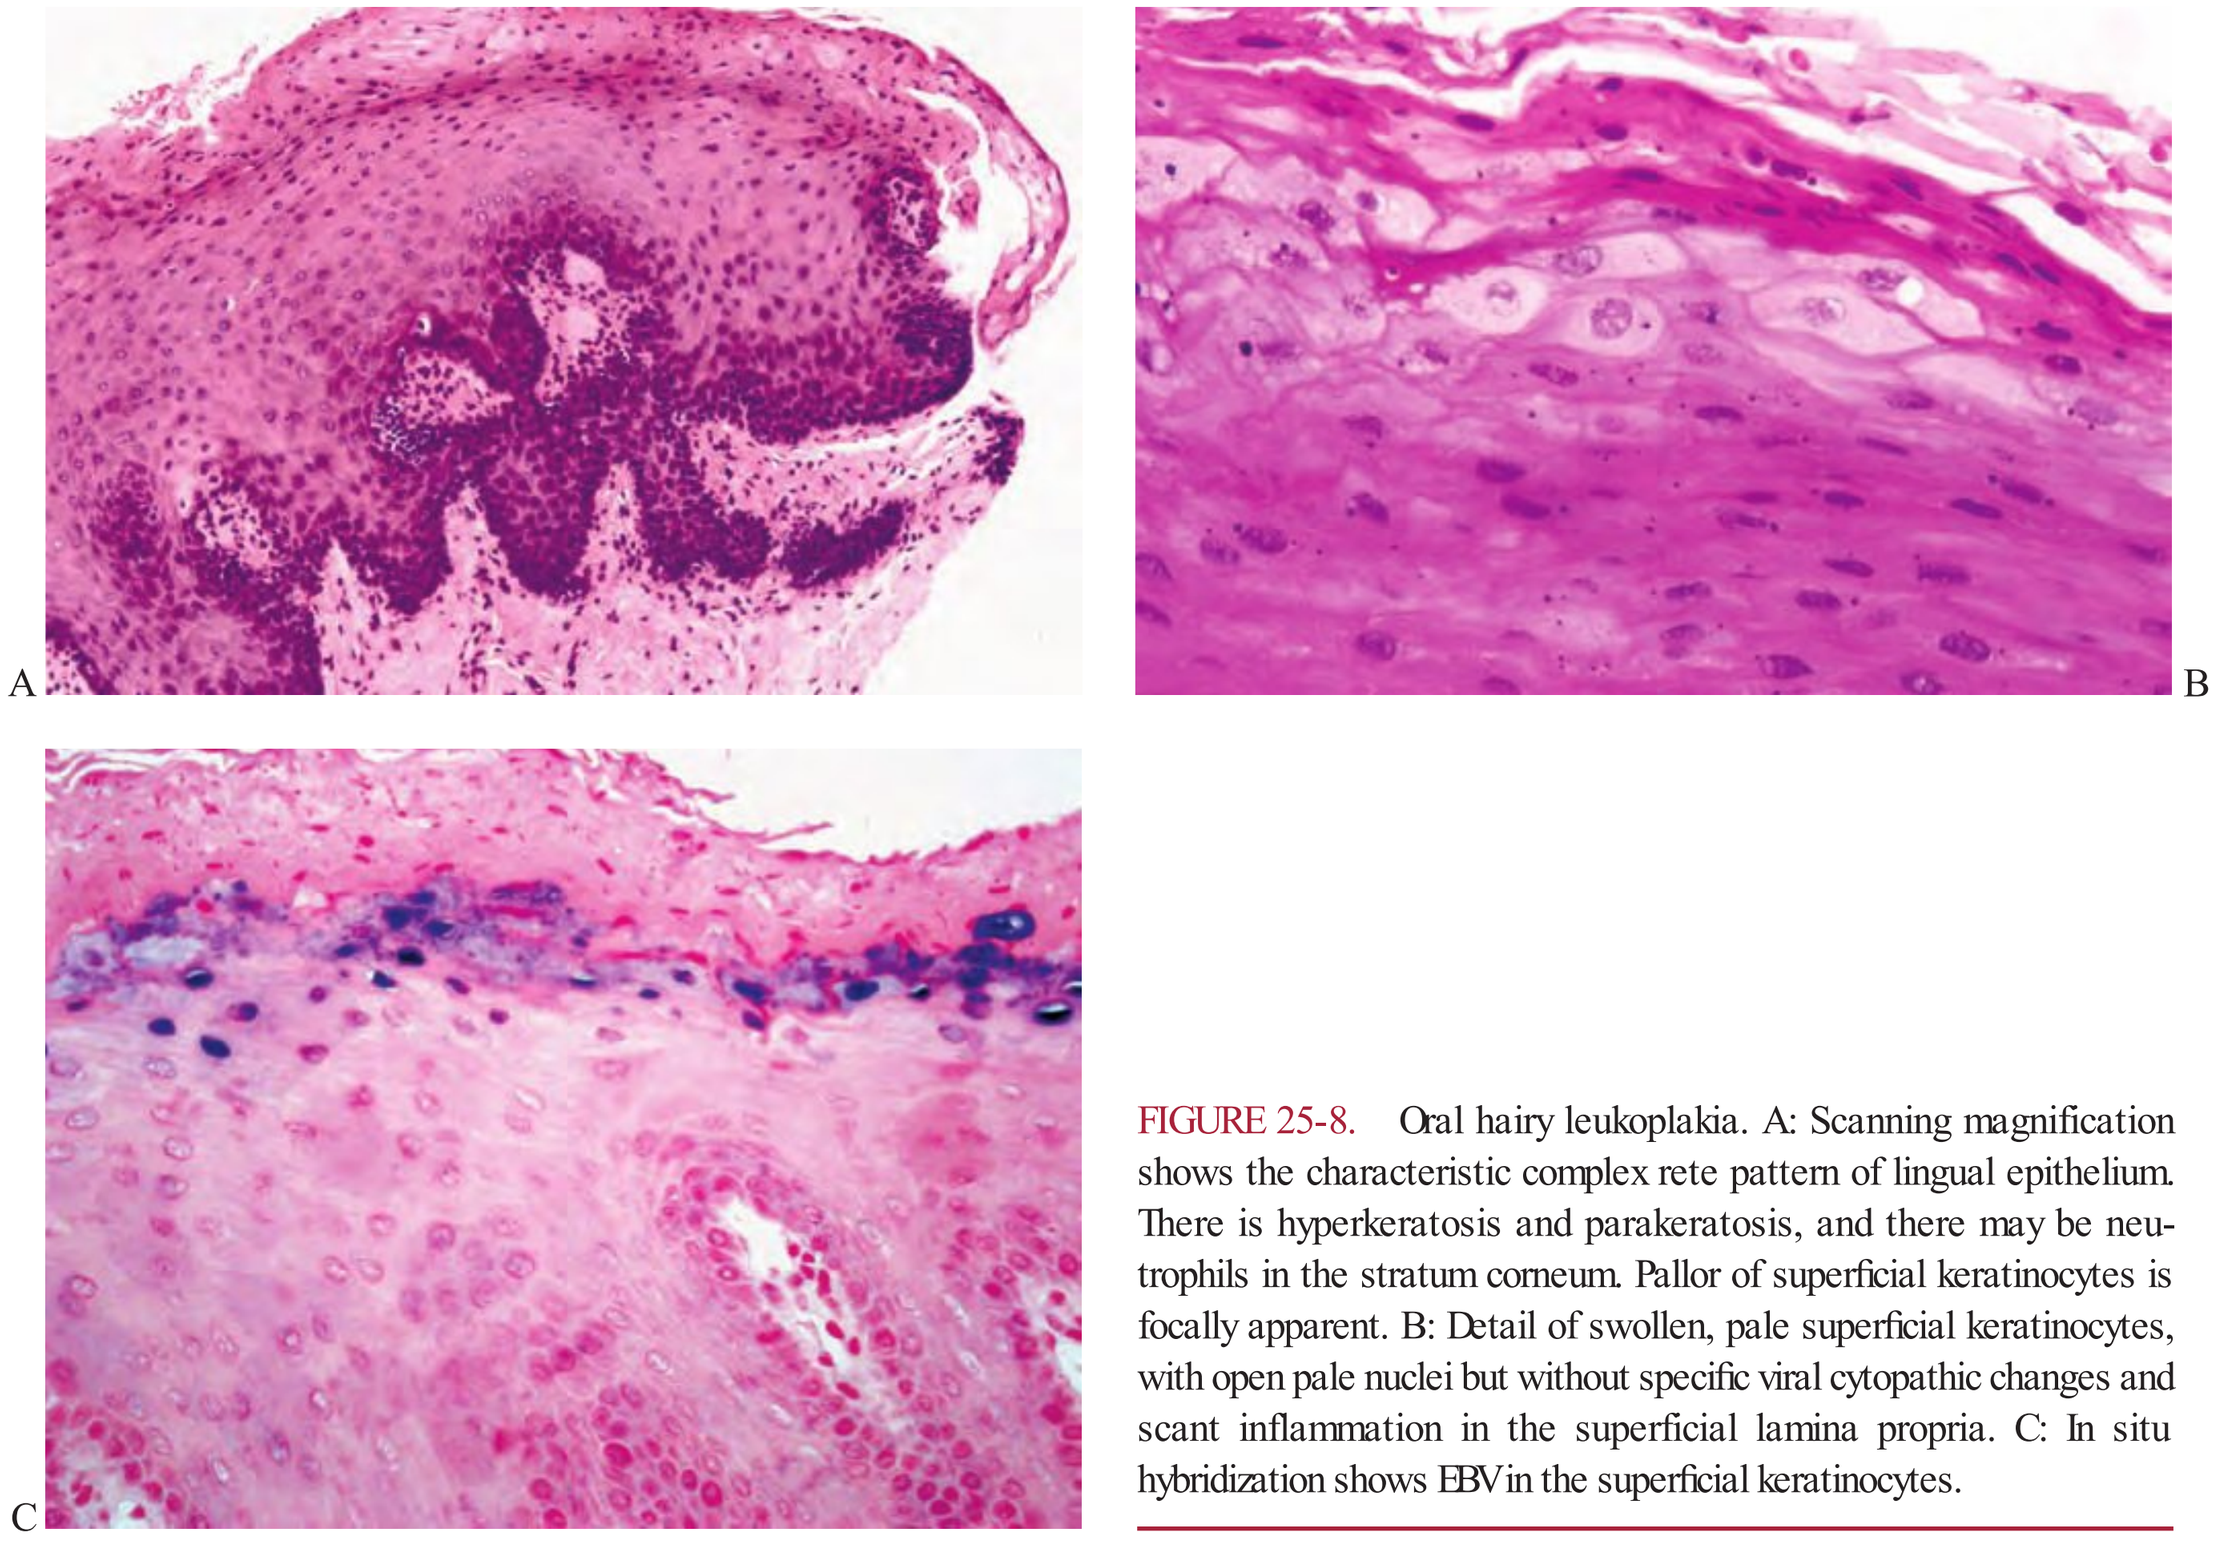

FIGURE 25-8. Oral hairy leukoplakia. A: Scanning magnification shows the characteristic complex rete pattern of lingual epithelium. There is hyperkeratosis and parakeratosis, and there may be neutrophils in the stratum corneum. Pallor of superficial keratinocytes is focally apparent. B: Detail of swollen, pale superficial keratinocytes, with open pale nuclei but without specific viral cytopathic changes and scant inflammation in the superficial lamina propria. C: In situ hybridization shows EBV in the superficial keratinocytes.

and a serious systemic reaction to a limited number of drugs called *hypersensitivity syndrome* have been associated with HHV-6 (63). HHV-6 has also been detected in skin biopsy samples of patients with graft-versus-host disease, pityriasis rosea, and lymphoproliferative malignancies.

HHV-7, isolated from $CD4^+$ T lymphocytes from the peripheral blood of a healthy individual, has been recognized as a new lymphotropic herpesvirus. Healthy adults frequently shed the virus into saliva, and children are infected at a young age but somewhat later than HHV-6B. Latency is established in peripheral blood T cells, and a persistent infection in the salivary glands is believed to be the most likely mode of transmission. The primary infection with HHV-7 is linked to febrile illness with or without rash that resembles exanthema subitum. Pityriasis rosea is thought to be associated with HHV-7; however, the association is still controversial (64).

HHV-8 was first identified in tissue samples of patients with Kaposi's sarcoma (KS) associated with AIDS in 1994. Serologic studies have demonstrated that unlike other human herpesviruses, HHV-8 is not ubiquitous; instead, its infection rates parallel the incidence of KS in the region. HHV-8 spreads through exchange of saliva and other sexual activities. HHV-8 can be found in all types of KS, whether related to HIV or not. HHV-8 seems to resemble EBV virus in its possible transforming properties, and it is clearly associated with KS, multicentric Castleman disease, and primary effusion lymphoma (65). There may be a synergistic relationship between the HIV-1 Tat protein and HHV-8 infection. Tat promotes the growth of the KS spindle cells. Like other herpesviruses, HHV-8 establishes latent and persistent infection. Only a minority of infected cells yields infectious viral particles, and their role in the development of KS and other associated diseases has not been clearly established. Presence of virus can be established in mononuclear cells of peripheral blood, endothelial cells, and spindle cells within skin lesions.

Histopathology. Exanthem subitum is linked to HHV-6 infection. It is a form of superficial perivascular dermatitis with papillary dermal edema. Exocytosis of lymphocytes is often present. Inclusions similar to those in herpes simplex infection are not seen.

POXVIRIDAE

The Poxviridae are double-stranded DNA viruses with two subfamilies and eleven genera. Poxvirus infections of humans include variola (smallpox), cowpox, vaccinia, molluscum

contagiosum, paravaccinia (milkers' nodules), and orf (ecthyma contagiosum).

Variola (Smallpox)

Before it was eradicated in 1977, smallpox was one of the most infectious and deadly diseases in the world, afflicting millions of people each year regardless of age, race, or socioeconomic status (66). There were two forms of smallpox: variola major and variola minor. Variola major had a case fatality rate of approximately 25% among those affected, while variola minor, a less virulent form, had a case fatality rate below 1%. Although the two forms cause disease of different severity, they are indistinguishable from one another. Smallpox was spread through respiratory transmission of virus found in the oropharyngeal secretions of infected individuals. Penetration was usually through the respiratory tract and local lymph nodes and then the virus entered the blood (primary viremia). Internal organs would be infected; later, the virus would reenter the blood (secondary viremia) and spread to the skin. The onset of smallpox was acute, with fever, malaise, headaches, and backaches. The initial toxemia phase lasted 4 to 5 days. On about the third or fourth day, the characteristic rash appeared. First, it appeared on the buccal and pharyngeal mucosa, face, and forearms. Within a day, it spread to the trunk and lower limbs. The lesions of the rash began first as macules, which soon became papules and then developed into pustular vesicles. The lesions usually protruded from the skin, and they were firm to touch. The lesions dried up and often became crusted by day 14. By the end of the third week, most crusts had fallen off, with the exception of those on the palms and the soles (67). This entire process took 3 to 4 weeks, and the areas affected by the rash could be permanently scarred. The rare hemorrhagic type smallpox that appeared in immunocompromised individuals was associated with bleeding from the conjunctiva and mucous membranes, very severe toxemia, and early death, usually before the lesions of the skin had developed. Modified-type smallpox was seen in persons who had been vaccinated, usually many years earlier. In these cases, the skin lesions evolved quickly and were more variable in size.

Histopathology. There is prominent ballooning and reticular degeneration. Under light microscopy, aggregations of variola virus particles, called *Guarnieri bodies*, may be found in the cytoplasm; occasional intranuclear inclusions can also be found. However, similar changes can be seen in vaccinia, monkeypox, or cowpox.

Vaccinia

Vaccinia virus was used for smallpox vaccination via inoculation into the superficial layers of the skin of the upper arm. However, with the eradication of smallpox, routine vaccination with vaccinia virus ceased for many years but may soon become more common because of security concerns. Four to 5 days following vaccination with vaccinia virus, a papule appears at the site of vaccination. Two or 3 days later, the papular lesion becomes vesicular, growing until it reaches its maximum diameter on the ninth or tenth day. The lesion dries from the center outward, and the brown scab falls off after about 3 weeks, leaving a scar—a mark by which previous vaccinees can be recognized (68). Complications of vaccination can occur but are very rare, including the following conditions: progressive vaccinia (vaccinia necrosum), which is a severe, potentially fatal illness characterized by progressive necrosis at the site of vaccination; eczema vaccinatum, which is similar to eczema herpeticum in patients with chronic eczema; generalized vaccinia, which is characterized by a vesicular rash that sometimes has covered the entire body; and postvaccinial encephalitis, the most serious neurologic complication, which has occurred from vaccination with vaccinia virus (69). Other localized lesions such as keloid, dermatofibrosarcoma protuberans, and malignant fibrous histiocytoma have been reported at the site of inoculation. These complications are extremely rare.

Histopathology. The histologic changes are similar to those of herpes simplex and zoster and varicella. However, intracytoplasmic inclusions are seen in vaccinia, unlike in herpes infection.

Human Cowpox Infection

Despite its name, the reservoir hosts of cowpox virus are rodents, from which it can occasionally spread to cats, cows, humans, and zoo animals, including large cats and elephants. Infection in these animals is usually manifested as a single, small, crusted ulcer. Transmission to humans has traditionally occurred via contact with the infected teats of milking cows. However, currently, infection is seen more commonly among domestic cats, from which it can be transmitted to humans. Patients present with painful, hemorrhagic pustules or black eschars, usually on the hand or face, accompanied by edema, erythema, lymphadenopathy, and systemic involvement (70). Crusted lesions resembling anthrax and sporotrichoid infection have been reported.

Histopathology. The pathology of the skin lesions caused by cowpox virus is similar to that of smallpox. However, there is greater epithelial thickening and less rapid cell necrosis. Early lesions of human cowpox infection show prominent reticular degeneration. Eosinophilic, intracytoplasmic inclusion bodies are present, a valuable feature in distinguishing poxvirus from herpesvirus infections. Under electron microscopic examination, it is rectangular and morphologically indistinguishable from the virus of variola.

Parapoxvirus Infections (Milkers' Nodules and Orf)

Milkers' nodules, orf, and bovine papular stomatitis pox are clinically identical in humans and are induced by indistinguishable paravaccinia viruses. *Milkers' nodules* are acquired from udders infected with pseudocowpox or paravaccinia (parapox). This disease is called *bovine papular stomatitis pox* when the source of the infection is calves with oral sores

contracted through sucking infected udders. *Orf* (ecthyma contagiosum) is acquired from infected sheep or goats with crusted lesions on the lips and in the mouth.

The most common presentation of orf is a circumscribed solitary nodule or papule on the fingers or hands (71). Milkers' nodules usually presents with multiple lesions. After an incubation period of 3 to 7 days, parapoxvirus infections produce one to three (rarely more) painful lesions measuring 1 to 2 cm in diameter on the fingers or occasionally elsewhere as a result of autoinoculation. During a period of approximately 6 weeks, they pass through six clinical stages, each lasting about 1 week: (a) the maculopapular stage; (b) the target stage, during which the lesions have red centers, white rings, and red halos; (c) the acute weeping stage; (d) the nodular stage, which shows hard, nontender nodules; (e) the papillomatous stage, in which the nodules have irregular surfaces; and (f) the regressive stage, during which the lesions involute without scarring.

Histopathology. During the maculopapular and target stages, there is vacuolization of cells in the upper third of the stratum malpighii, leading to multilocular vesicles. Eosinophilic inclusion bodies are in the cytoplasm of vacuolated epidermal cells, a distinguishing feature from herpesvirus infections (Fig. 25-9C). Intranuclear eosinophilic inclusion bodies are also present in some cases. During the target stage, vacuolated epidermal cells with inclusion bodies are only in the surrounding white ring. Ballooning degeneration occurs, the affected keratinocytes rupture, and the resulting defects have a tendency to coalesce and produce reticulated vesicles (Fig. 25-9A). The epidermis shows elongation of the rete ridges, and the dermis contains many newly formed, dilated capillaries and a mononuclear infiltrate (Fig. 25-9B).

In the acute weeping stage, the epidermis is necrotic throughout. A massive infiltrate of mononuclear cells extends throughout the dermis. In some lesions, the mononuclear cell infiltrates may be comprised mainly of large, transformed lymphoblasts. Such lesions might be misdiagnosed as a lymphoid neoplasm if careful attention is not given to the changes in the keratinocytes. A lichenoid reaction with a high percentage of histiocytes, a common response to viral infections of the skin, can also be seen. In the later stages, the epidermis shows acanthosis with finger-like downward projections, and the dermis shows vasodilatation and chronic inflammation, followed by resolution. The histology of orf and milkers' nodules is identical.

Histogenesis and Viral Identification. In lesions <2 weeks old, the virus can be grown in tissue cultures of various cell types, including bovine or rhesus monkey kidney cells and human amnion cells or fibroblasts. In older lesions, serologic changes or viral antigen demonstration in lesional material have to be relied on for identification. Electron microscopy reveals that the parapoxvirus is cylindrical in shape and has convex ends. It consists of a dense DNA core surrounded by a less dense, wide capsid and by two narrow, electron-dense outer layers. On average, the virion measures 140 by 310 nm.

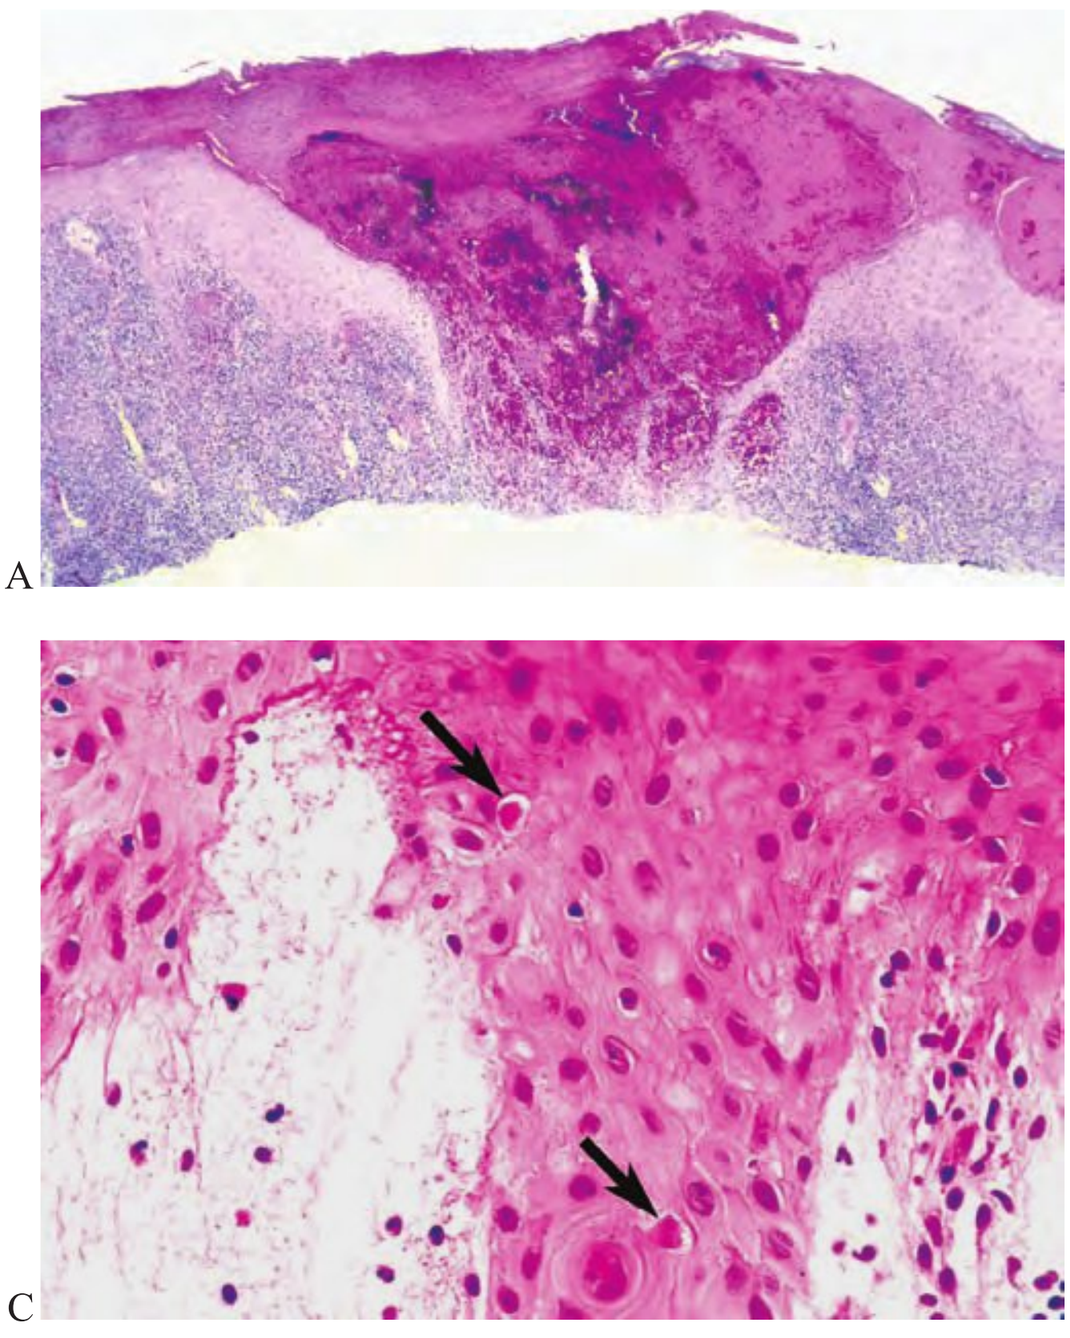

FIGURE 25-9. Orf. A: At scanning magnification, in the target stage, there is central hemorrhage and tissue necrosis with peripheral reticulated degeneration and dense inflammatory infiltrates. B: Reticulated vesicles (a characteristic feature of a viral infection affecting the epidermis), and the dermis contains many newly formed, dilated capillaries and a mononuclear infiltrate. C: Eosinophilic inclusion bodies in the cytoplasm of vacuolated epidermal cells (arrow points to the inclusions) distinguish orf from herpesvirus infections. Intranuclear eosinophilic inclusion bodies are also present in some cases.

Molluscum Contagiosum

Molluscum contagiosum occurs worldwide. It is seen most commonly in children, but it may be found in persons of all ages. The virus is transmitted by direct bodily contact, through minor abrasions, or indirectly via fomites. Among young adults, it is usually a sexually transmitted disease. The incubation period for this virus, as determined by human volunteers who underwent inoculation, ranges from 14 to 50 days.

Molluscum contagiosum may be found anywhere on the body but rarely occur on the palms or soles. It consists of a variable number of small, discrete, waxy, skin-colored, delled, dome-shaped papules, usually 2 to 5 mm in size (Fig. 25-10A). A papule of molluscum contagiosum may appear inflamed. In immunocompetent patients, the lesions involute spontaneously. During involution, there may be mild inflammation and tenderness.

Since 1980, there have been reports of greater severity of molluscum contagiosum in patients infected with HIV. In the setting of immunosuppression, molluscum contagiosum can attain considerable size and be widely disseminated. In immunocompromised patients, particularly those with AIDS, hundreds of lesions of molluscum contagiosum may be observed, showing little tendency toward involution. Furthermore, clinically normal skin in the vicinity of molluscum lesions in HIV-infected persons may be infected by molluscum virus (72). Infection with molluscum contagiosum produces little immunity, with reinfection being relatively common among immunocompromised individuals. In the context of AIDS, a variety of systemic fungal diseases, including cryptococcosis, histoplasmosis, and Penicillium marneffei, can disseminate and produce skin lesions that resemble molluscum contagiosum.

Histopathology. The epidermis is acanthotic in molluscum contagiosum. Many epidermal cells contain large, intracytoplasmic inclusion bodies—the so-called molluscum bodies (Fig. 25-10B). These bodies first appear as single, minute, ovoid eosinophilic structures in the lower cells of the stratum malpighii at a level one or two layers above the basal cell layer. The molluscum bodies increase in size as infected cells move toward the surface. The molluscum bodies in the upper layers of the epidermis displace and compress the nucleus so that it appears as a thin crescent at the periphery of the cell. At the level of the granular layer, the staining reaction of the molluscum bodies changes from eosinophilic to basophilic. In the horny layer, basophilic molluscum bodies measuring up to 35 μm in diameter lie enmeshed in a network of eosinophilic horny fibers. In the center of the lesion, the stratum corneum ultimately disintegrates, releasing the molluscum bodies. Thus, a central crater forms. Secondary infection and ulceration can occur.

The surrounding dermis usually shows little or no inflammatory reaction, except in instances in which the lesion of molluscum contagiosum ruptures and discharges molluscum bodies and horny material into the dermis. During the period of spontaneous involution, a mononuclear infiltrate may be observed in close apposition to the lesion infiltrating between the infected epidermal cells.

Electron microscopic examination reveals that the molluscum inclusion bodies contain—embedded in a protein matrix—large numbers of molluscum contagiosum viruses. The virus of molluscum contagiosum belongs to the poxvirus group. Like the viruses of variola, vaccinia, and cowpox, it is "brick-shaped" and measures approximately 300 by 240 nm. The virus of molluscum contagiosum has not been grown in tissue culture. Molluscum contagiosum virus can be detected directly in tissue specimens by using *in situ* hybridization (73).

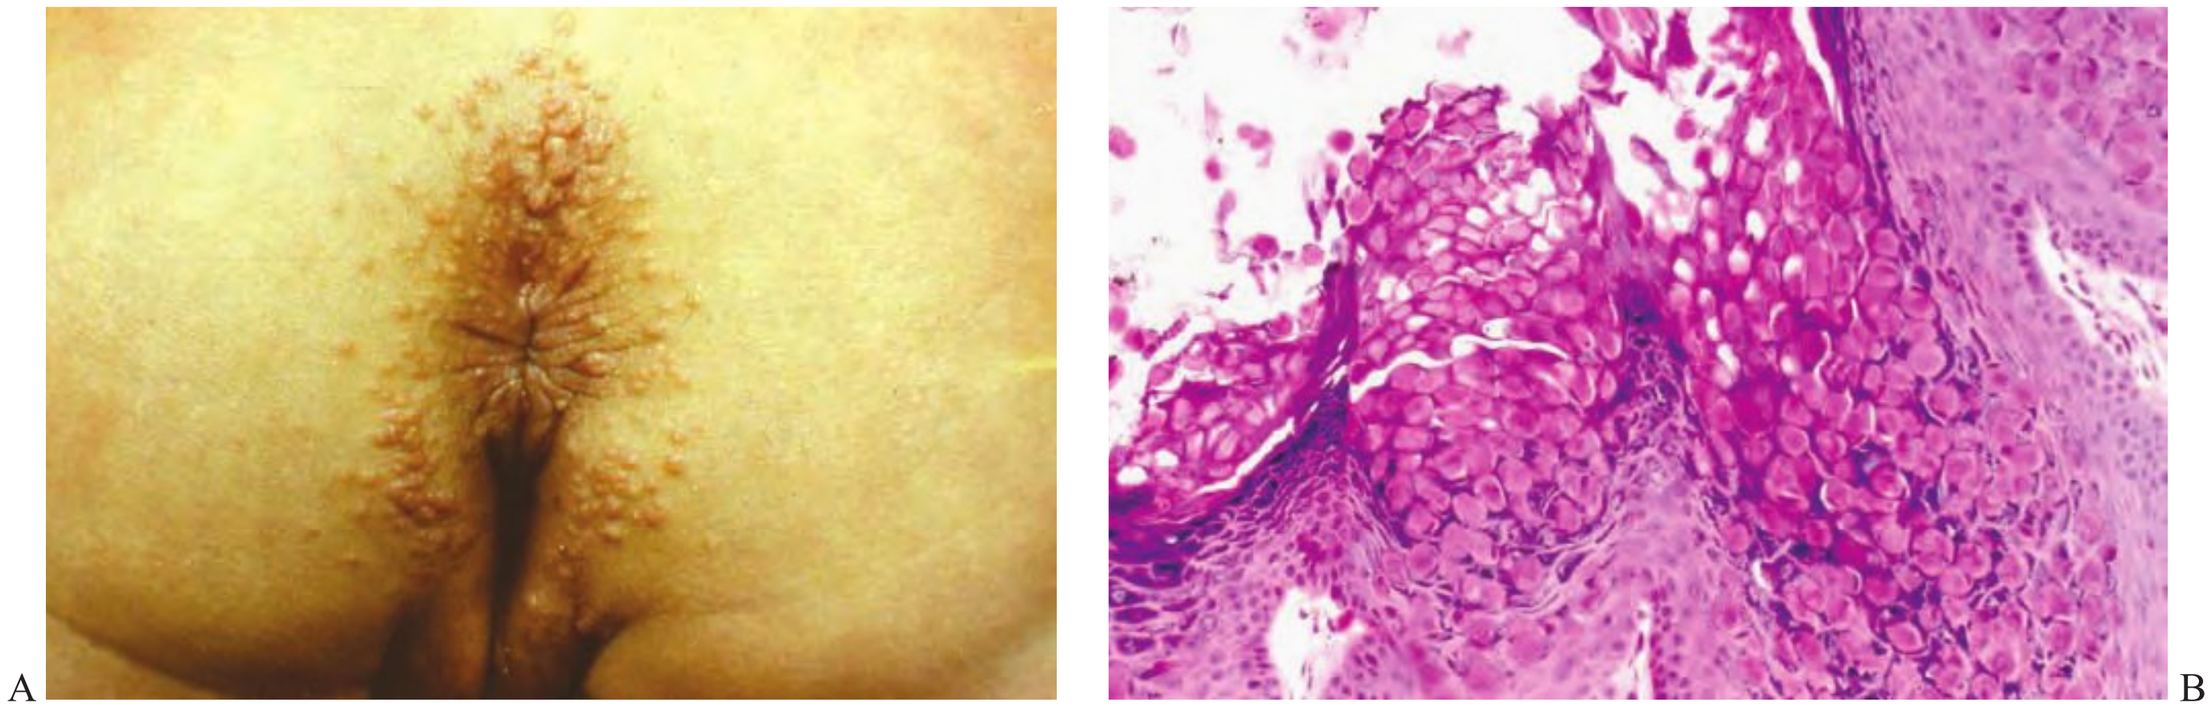

FIGURE 25-10. Molluscum contagiosum. A: Multiple lesions, some with characteristic central umbilication. B: Numerous intracytoplasmic inclusion bodies, so-called molluscum bodies, can be seen forming in the lower epidermis. They increase in size as they move toward the surface.

PAPILLOMAVIRIDAE

The human papillomavirus (HPV) belongs to the Papillomaviridae family. It consists of a group of nonenveloped

double-stranded DNA viruses. An infectious origin for skin warts was first recognized in 1891, and viral particles were isolated from human skin papillomatous lesions in 1949. Since that time, over 80 fully sequenced HPV genotypes have been identified, with another 70 additional genotypes suggested through PCR analysis (74). The genetic heterogeneity is reflected in the differing clinical presentations of HPV infection. The cutaneous and mucosal manifestations of HPV infection include the common wart verruca vulgaris, the genital wart condyloma acuminatum, and less common entities including epidermodysplasia verruciformis (EV) and oral focal epithelial hyperplasia (Heck's disease). HPV is regarded as an oncogenic virus and is well known to be associated with cervical and anogenital cancers (75). Recently, HPV has been implicated in oropharyngeal squamous cell carcinoma (76), lung cancer (77), esophageal cancer (78), and in nonmelanoma skin cancers (79), particularly in immunosuppressed patients (80). The specific viral genotypes show fairly good association with the different clinical presentations listed, although considerable overlap exists.

Verruca vulgaris: 1, 2, 4, 7, 49
Verruca plana: 3, 10, 28, 49
Palmoplantar wart: 1, 2, 3, 4, 27, 29, 57
Condyloma acuminatum (high cancer risk): 16, 18, 31, 33, 51
Focal epithelial hyperplasia: 13, 32
Bowenoid papulosis: 16, 18, 31, 33, 51
Butcher's warts: 7
EV: 3, 5, 8–10, 12, 14, 17, 19–29, 36, 38, 47, 50
Laryngeal carcinoma: 30
Head and neck (oropharyngeal) squamous cell carcinoma: 16
Giant condyloma of Bushke and Loewenstein: 6
Cervical and vulvar dysplasia: 16, 18, 31, 33, 51

The association of particular HPV types with specific groups of warts, however, is not absolute. The value of HPV typing in the clinical setting is not clear. Definitive HPV typing can be obtained through DNA hybridization or amplification of HPV genomic material by PCR. However, positive results cannot be considered definitive in predicting outcome. High-risk HPV types can be missed through sampling errors. In the end, close follow-up is important in the management of HPV infection, particularly when the patient has clinical exposure to potentially high-risk HPV types (81).

All HPV types target squamous epithelial cells. Entry of HPV into squamous epithelium results in three different type of infections: latent infection, in which there is no gross or microscopic evidence of disease; subclinical infection, in which colposcopy or microscopy reveals disease in the absence of clinical disease; and clinical disease. Early HPV genes are expressed in basal epithelial cells. Clinical and histologic evidence of HPV infection usually develops 1 to 8 months after initial exposure. Untreated, these lesions may regress spontaneously, persist as benign lesions, or progress to precancerous lesions and eventually cancer (82).

Verruca Vulgaris

Verruca vulgaris, the common wart, most commonly presents singly or in groups on the dorsal aspects of the fingers and hands as painless, circumscribed, firm, elevated papules with papillomatous ("verrucous") hyperkeratotic surfaces (Fig. 25-11A). The palms and soles are less common sites and present at these sites as mosaic warts. Verruca vulgaris is rarely identified on the oral mucosa. The face and scalp are the most common sites for filiform warts, variants of verruca vulgaris that show threadlike, keratinous projections arising from horny bases.

Verrucae vulgares are circumscribed, firm, elevated papules with papillomatous ("verrucous") hyperkeratotic surfaces. They occur singly or in groups. Generally, they are associated with little or no tenderness. Verrucae vulgares occur most commonly on the dorsal aspects of the fingers and hands. They are also found on the soles of the feet and less often on the palms as mosaic warts. Rarely, verrucae vulgares occur on the oral mucosa. Filiform warts, variants of verruca vulgaris, show threadlike, keratinous projections arising from horny bases. New warts may form at sites of trauma (Koebner phenomenon). Verrucae vulgares are often associated with HPV-2 but may be induced by HPV-1, -4, -7, and -49.

Histopathology. Verrucae vulgares show acanthosis, papillomatosis, and hyperkeratosis (Fig. 25-11B). The rete ridges are elongated and, at the periphery of the verruca, are often bent inward so that they appear to point radially toward the center (arborization). The characteristic features that distinguish verruca vulgaris from other papillomas are foci of vacuolated cells, referred to as *koilocytotic cells*; vertical tiers of parakeratotic cells; and foci of clumped keratohyaline granules (Fig. 25-11C). These three changes are quite pronounced in young verrucae vulgares. The foci of koilocytes are located in the upper stratum malpighii and in the granular layer. The koilocytes possess small, round, deeply basophilic nuclei surrounded by a clear halo and pale-staining cytoplasm. These cells contain few or no keratohyaline granules, even when they are located in the granular layer. The vertical tiers of parakeratotic cells are often located at the crests of papillomatous elevations of the rete malpighii overlying a focus of vacuolated cells. Compared with ordinary parakeratotic nuclei, the nuclei of the parakeratotic cells in verrucae vulgares are larger and more deeply basophilic, and many of them appear rounded rather than elongated. Although no granular cells are seen overlying the papillomatous crests, they are increased in number and size in the intervening valleys and contain heavy, irregular clumps of keratohyaline granules. Dilated capillaries and small areas of hemorrhage may be seen in the thickened horny layer at the tip of the vertical tiers of parakeratotic cells (Fig. 25-11C). In filiform warts, the papillae are more elongated than in verrucae vulgares (Fig. 25-11D).

Although warts are very common, especially in children and adolescents, defective cell-mediated immunity predisposes to the development of some types of warts. The frequency of warts in persons with renal transplants receiving immunosup-

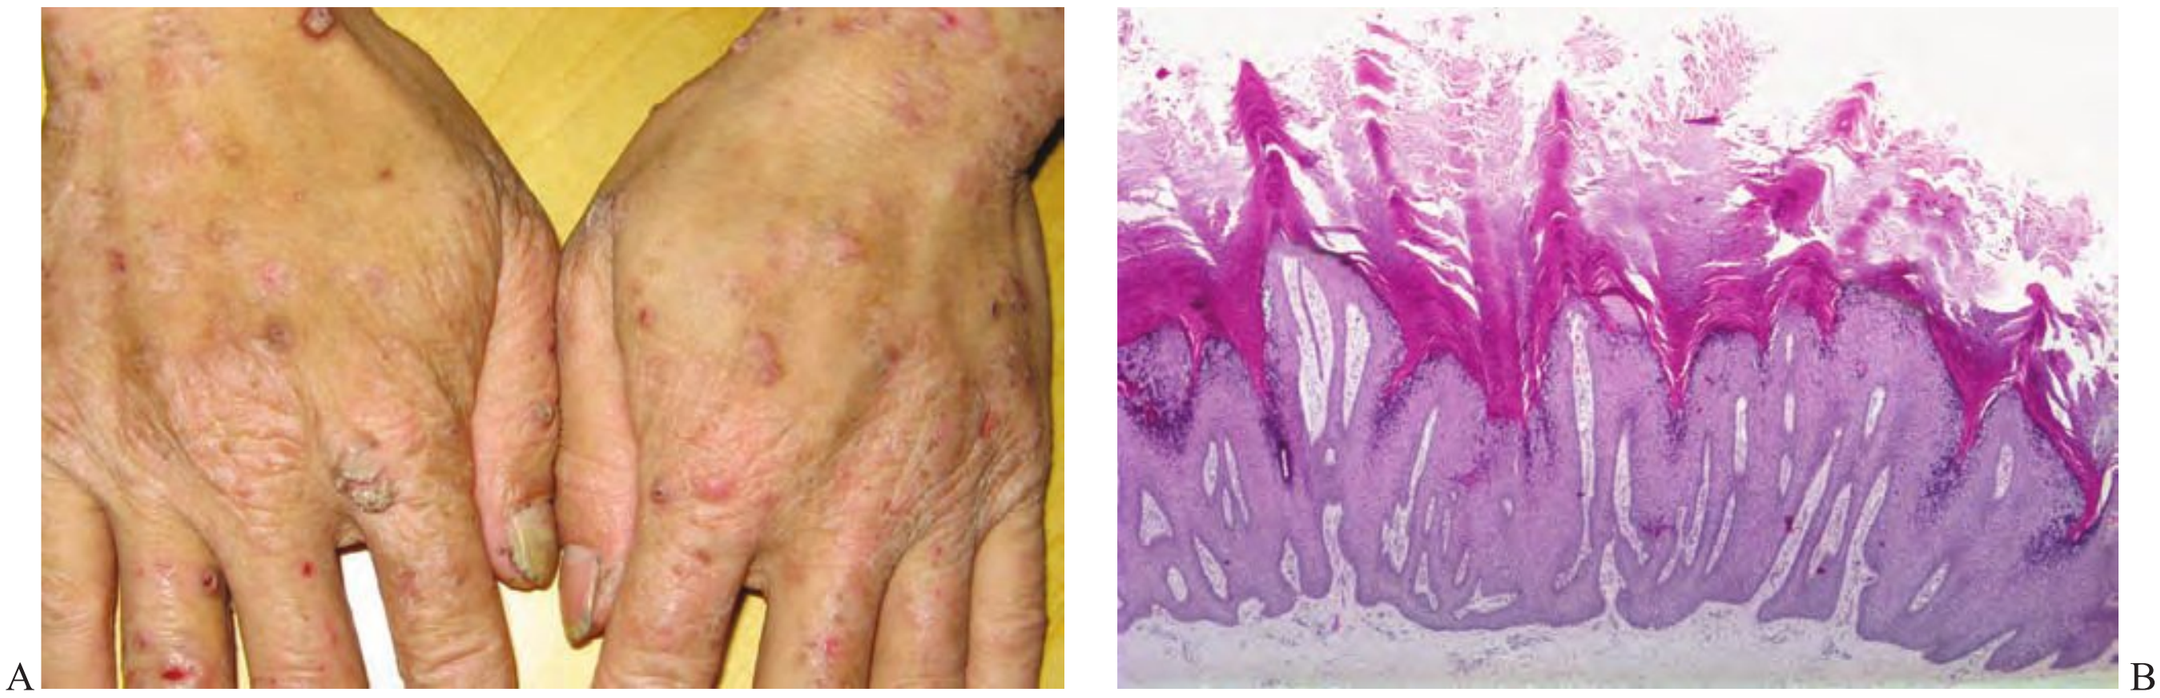

FIGURE 25-11. Verruca vulgaris. A: Multiple lesions most commonly seen on the hands and fingers. B: Low magnification. Hyperkeratosis, acanthosis, and papillomatosis are seen. The rete ridges are elongated and bent inward at both margins and thus appear to point radially to the center. C: High magnification. Groups of large, vacuolated cells lie in the upper stratum malpighii and granular layer. D: Verruca vulgaris of filiform type. There is marked papillomatosis.

pressive therapy is greater than that of the general population (83). In the context of HIV infection, a variety of papillomavirus infections have been reported. Eradication of cutaneous infection becomes increasingly difficult as the degree of immunosuppression becomes more profound.

Histogenesis and Viral Identification. No difference has been noted in electron microscopic appearance among the virus particles in the various types of HPV. However, the quantity varies with the different types. Frequently, virus particles are absent in verrucae vulgares on electron microscopic examination. Negative results of electron microscopic examination do not exclude the presence of HPV. Viral antigens, such as papillomavirus common antigen, can be detected by using immunohistochemistry, and HPV DNA can be amplified from lesions by using PCR with appropriate primers. Viral genomic material can also be identified by *in situ* hybridization. Viral DNA replication occurs in proliferating basal cells, but structural capsid protein forms in the mid-epidermis; thus, mature HPV viral structures, if present, are observed only in the upper epidermis.

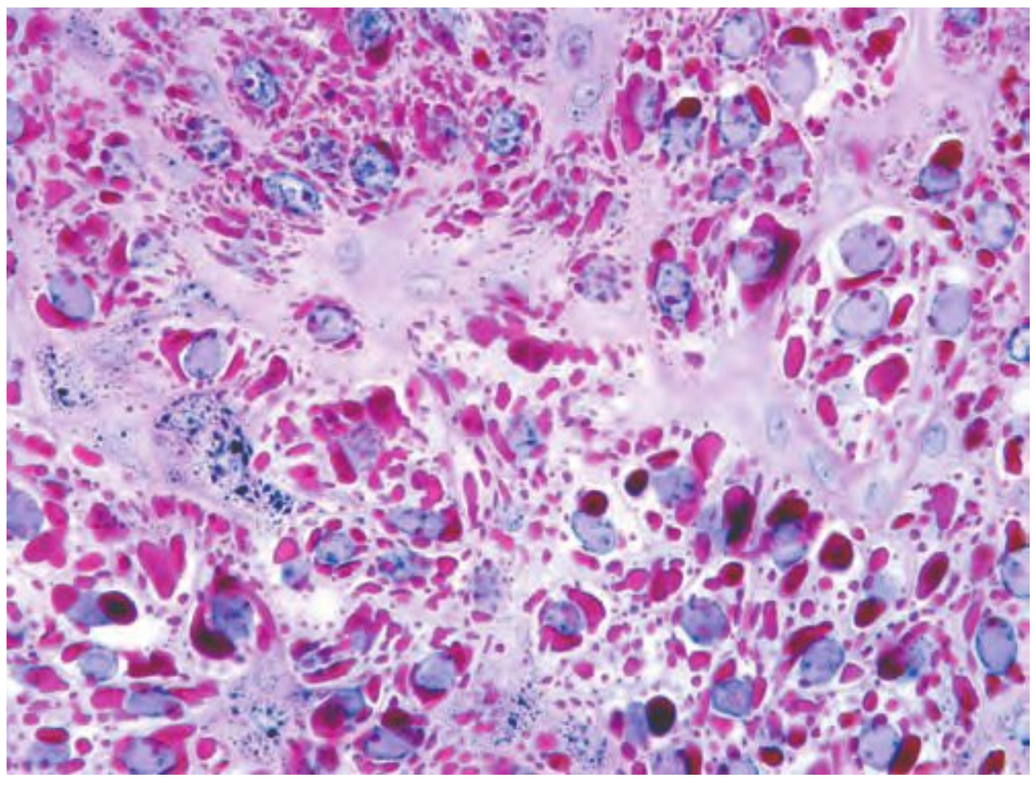
The virus particles are spherical bodies with a diameter of about 50 nm. Each particle consists of an electron-dense nucleoid with a stippled appearance surrounded by a less dense capsid. The wart virus replicates in the nucleus, where the viral

particles are located as dense aggregates in a crystalloid arrangement. Eosinophilic intranuclear bodies are very rare in verrucae vulgares. The wart virus does not grow in tissue cultures and is not pathogenic for any animals.

Deep Palmoplantar Warts

Deep palmoplantar warts can be tender and occasionally swollen and red. Although they may be multiple, they do not coalesce as do mosaic warts, which are verrucae vulgares. Deep palmoplantar warts occur not only on the palms and soles but also on the lateral aspects and tips of the fingers and toes. Unlike superficial, mosaic-type palmoplantar warts, deep palmoplantar warts usually are covered with a thick callus (Fig. 25-12A). When the callus is removed with a scalpel, the wart becomes apparent.

A plantar wart associated with HPV-60 may appear as a nodule on the weight-bearing surface of the sole. The nodule usually is smooth with visible rete ridges but may become hyperkeratotic. If the lesion is incised, cheesy material may be expressed. A pigmented verrucous variant associated with HPV-65 and a whitish keratotic wart associated with HPV-63 have been reported.



Histopathology. Whereas superficial, mosaic-type palmoplantar warts have a histologic appearance analogous to that of verruca vulgaris and represent HPV-2 or HPV-4 infection, deep palmoplantar warts are commonly associated with HPV-1 infection but can also be seen with HPV-60, -63, and -65. These lesions, also known as *myrmecia* ("anthill") or *inclusion warts*, are characterized by abundant keratohyalin, which differs from normal keratohyalin by being eosinophilic. There is prominent hyperkeratosis. Starting in the lower epidermis, the cytoplasm of many cells contains numerous eosinophilic granules, which enlarge in the upper stratum malpighii and coalesce to form large, irregularly shaped, homogeneous "inclusion bodies." They either encase the vacuolated nucleus or are separated from it by perinuclear vacuolization. The nuclei in the stratum corneum persist, appearing as deeply basophilic round bodies surrounded by a wide, clear zone (Fig. 25-12B). In addition to the large intracytoplasmic eosinophilic inclusion bodies, some of the cells in the upper stratum malpighii with vacuolated nuclei contain a small intranuclear eosinophilic "inclusion body." It is round and of about the same size as the nucleolus, which, however, is basophilic (Fig. 25-12C). Regression of plantar warts is often

A

B

C

FIGURE 25-12. Palmoplantar wart (myrmecia). A: The lesions are flat with prominent hyperkeratosis. Vascular thromboses can be seen in some lesions. B: Virally induced proliferation of keratinocytes results in the lesion. The elongated retia are displaced laterally while their tips point to the center in the deep portion. The lesion is covered by thickened keratin, resulting in a tendency to grow inward rather than outward from the surface. C: The epidermal squamous cells contain polygonal, refractile-appearing, eosinophilic, cytoplasmic inclusions. Nuclei also contain round eosinophilic bodies.

associated with thrombosis of superficial vessels, hemorrhage, and necrosis of the epidermis.

Histogenesis and Viral Identification. Under electron microscopic examination, viral particles are first observed in the upper portion of the stratum malpighii within and around the nucleolus. Their number increases, and in cells just beneath the stratum corneum, nucleoli are no longer detected. In many instances, the material of the nucleus appears to be entirely replaced by virus particles except for a thin rim of chromatin closely applied to the nuclear membrane. The particles tend to be arranged in regular or crystalline formations. In the stratum corneum, no normal cell structures are recognizable, but there remain large, compact aggregates of virus particles surrounded by keratinous matter.

Verruca Plana

Verrucae planae are slightly elevated, flat, smooth papules. They may be hyperpigmented. The face and the dorsa of the hands are affected most commonly (Fig. 25-13A). In rare instances, there is extensive involvement, with lesions also on the extremities and trunk. If starting in childhood and occurring in several members of the family, such disseminate cases of verruca plana have been mistakenly held to be instances of EV, from which they differ by the absence of red, "tinea versicolor–like" patches and lack of malignant transformation of some of the exposed lesions.

Histopathology. Verrucae planae show hyperkeratosis and acanthosis but, unlike verrucae vulgares, have no papillomatosis, only slight elongation of the rete ridges, and no areas of parakeratosis. In the upper stratum malpighii, including the granular layer, there is diffuse vacuolization of the cells (Fig. 25-13B). Some of the vacuolated cells are enlarged to about twice their normal size. The nuclei of the vacuolated cells lie at the centers of the cells, and some of them appear deeply basophilic. The granular layer is uniformly thickened, and the stratum corneum has a pronounced basket-weave appearance resulting from vacuolization of the horny cells. The dermis appears normal. In spontaneously regressing warts, there is often a superficial lymphocytic infiltrate in the dermis with exocytosis and apoptosis of cells in the epidermis.

Histogenesis. Verrucae planae are induced by HPV-3 and HPV-10. Electron microscopic examination reveals marked cytoplasmic edema. The tonofilaments are dislodged to the periphery of the cell. The keratohyaline granules appear normal. Viral particles are numerous in the nuclei of vacuolated cells.

Epidermodysplasia Verruciformis

EV is a genetic disease characterized by HPV infection with types not seen in otherwise healthy individuals. It usually begins in childhood and is characterized by a generalized infection by HPV, frequent association with cutaneous carcinomas, and abnormalities of cell-mediated immunity (84). Two forms of EV are recognized. One form is induced by HPV-3 and HPV-10 and characterized by a persistent widespread eruption resembling verrucae planae with a tendency toward confluence into plaques. Some of the cases are familial. There is no tendency to malignant transformation in this form. The other form is primarily related to HPV-5. There is often a familial history with an autosomal recessive or X-linked recessive inheritance. In addition to the plane warts, irregularly outlined, slightly scaling macules of various shades of brown, red, and white, tinea versicolor–like lesions, and seborrheic keratosis–like lesions have been noted (85). The eruption usually begins in childhood. Development of Bowen's disease (squamous cell carcinoma *in situ*) within lesions in exposed areas is a common occurrence, and invasive lesions of squamous cell

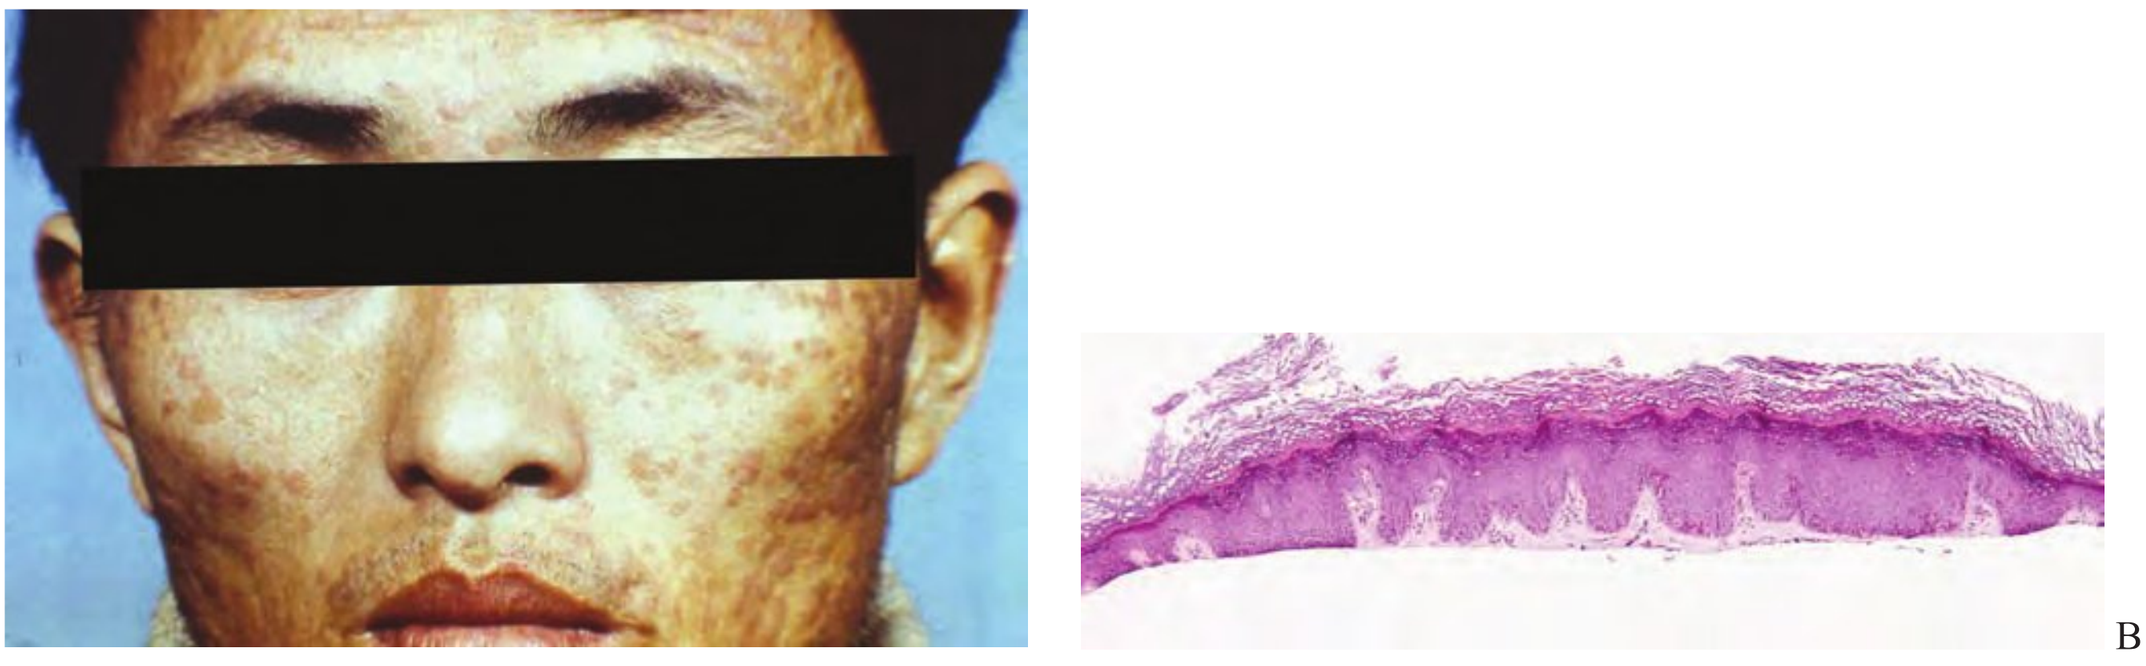


FIGURE 25-13. Verruca plana. A: Flat, smooth, flesh-colored papules, often on the face or hand. B: Hyperkeratosis and acanthosis are observed, but no papillomatosis or parakeratosis. Numerous vacuolated cells lie in the upper stratum malpighii, including the granular layer. The horny layer has a pronounced basket-weave appearance resulting from the vacuolization of the horny cells.

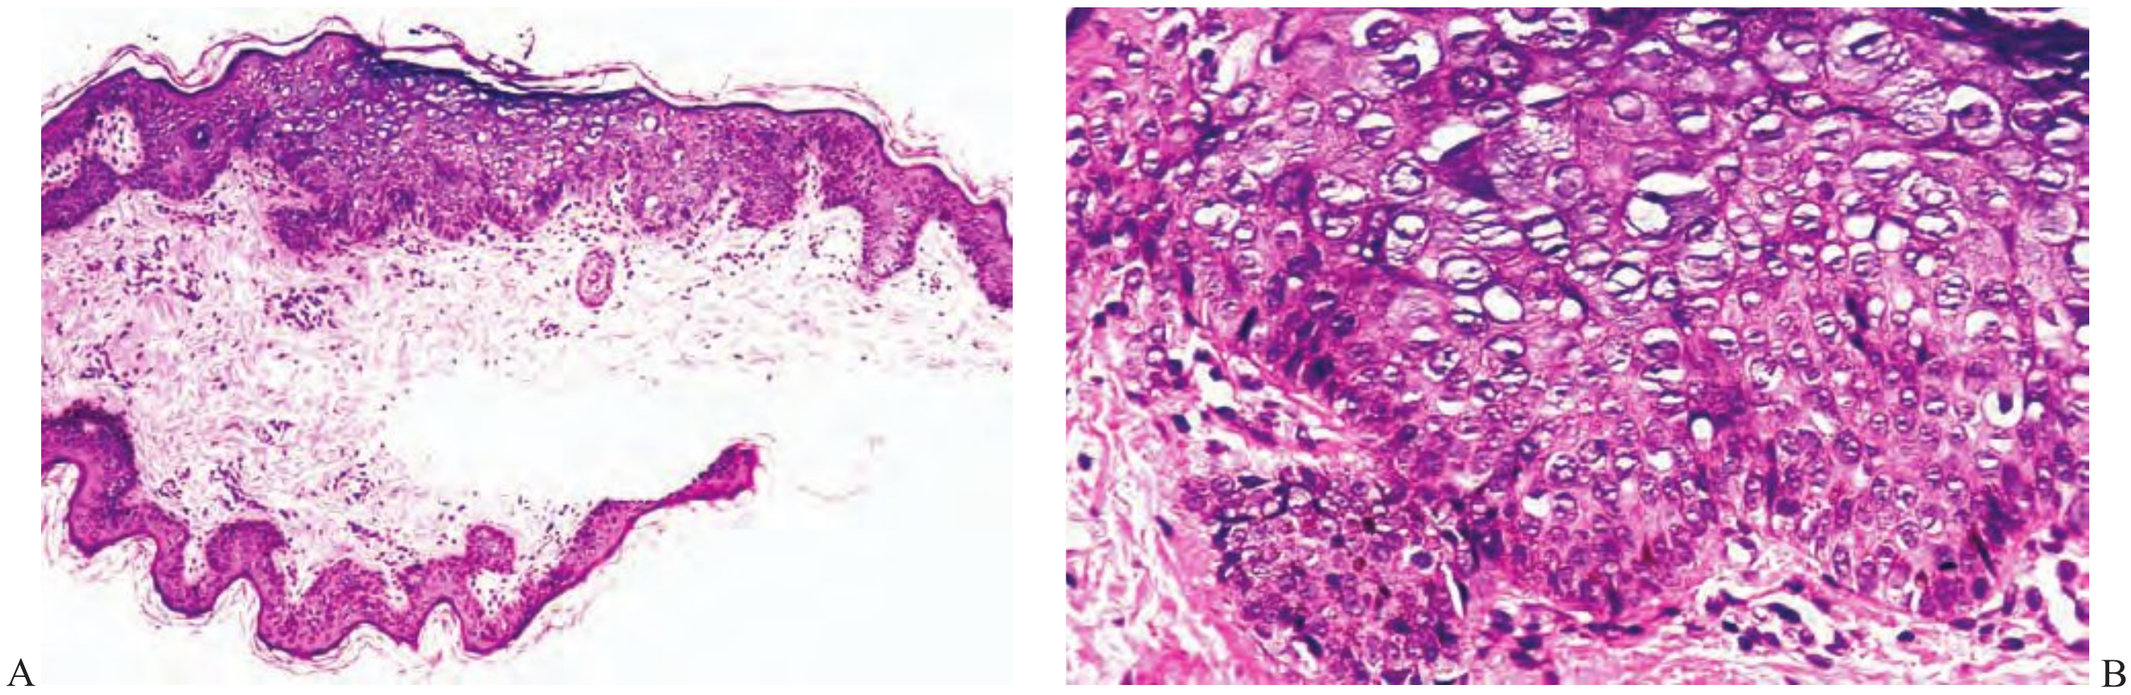

FIGURE 25-14. Epidermodysplasia verruciformis. A: The epidermis is hyperkeratotic and slightly acanthotic. Vacuolated cells are present in the upper stratum malpighii and granular layer. B: Affected keratinocytes have abundant, slightly basophilic cytoplasm. Keratohyalin granules may be prominent, although not in this example. Although some nuclei may appear pyknotic, others appear large, round, and empty.

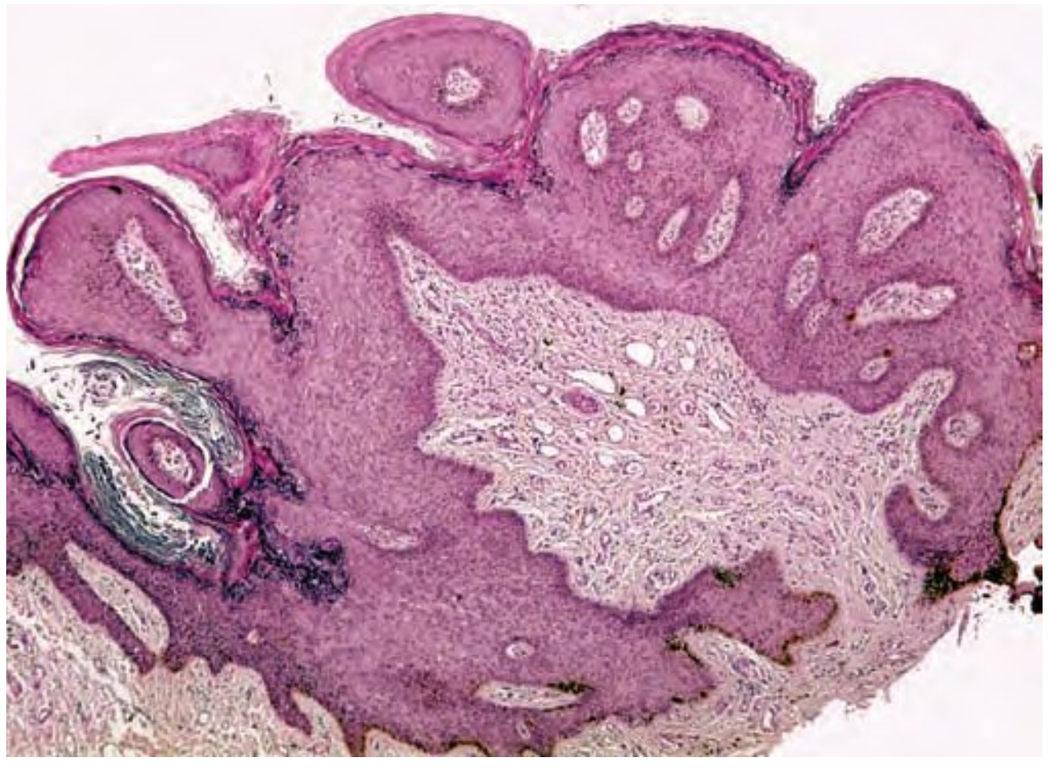
carcinoma are occasionally found. Malignant transformation occurs in about 25% of patients with EV. The oncogenic potential is highest for HPV-5, followed by HPV-8. EV-like lesions can develop in renal transplant patients (86) and HIV-infected persons (87).

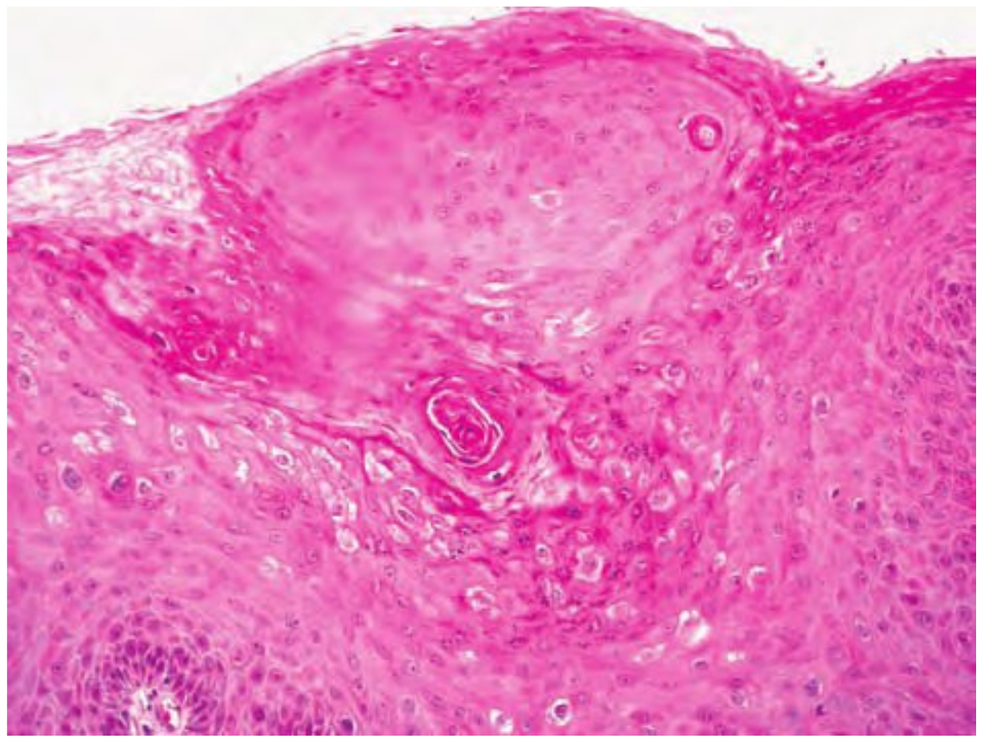
Histopathology. The epidermal changes, although similar to those observed in verruca plana, often differ by being more pronounced and more extensive. Affected keratinocytes are swollen and irregularly shaped. They show abundant, slightly basophilic cytoplasm and contain numerous round, basophilic keratohyalin granules. A few dyskeratotic cells may be seen in the lower part of the epidermis. Although some nuclei appear pyknotic, others appear large, round, and empty owing to marginal distribution of the chromatin (Fig. 25-14). In immunocompromised patients, EV often lacks the histologic features of verruca planae, a focally thickened granular layer is a marker for viral detection, and the risk for dysplasia in such lesions is much higher than in EV not associated with acquired immunosuppression (88).

Histogenesis. In EV skin lesions, many HPV types have been found, and in some individual patients, several types have been identified (89). Electron microscopic examination shows viral particles, often in a semicrystalline pattern within nuclei located in the stratum granulosum. In contrast, the swollen cells in the stratum malpighii show virions in their nuclei in small aggregates only in some cases but none at all in others.

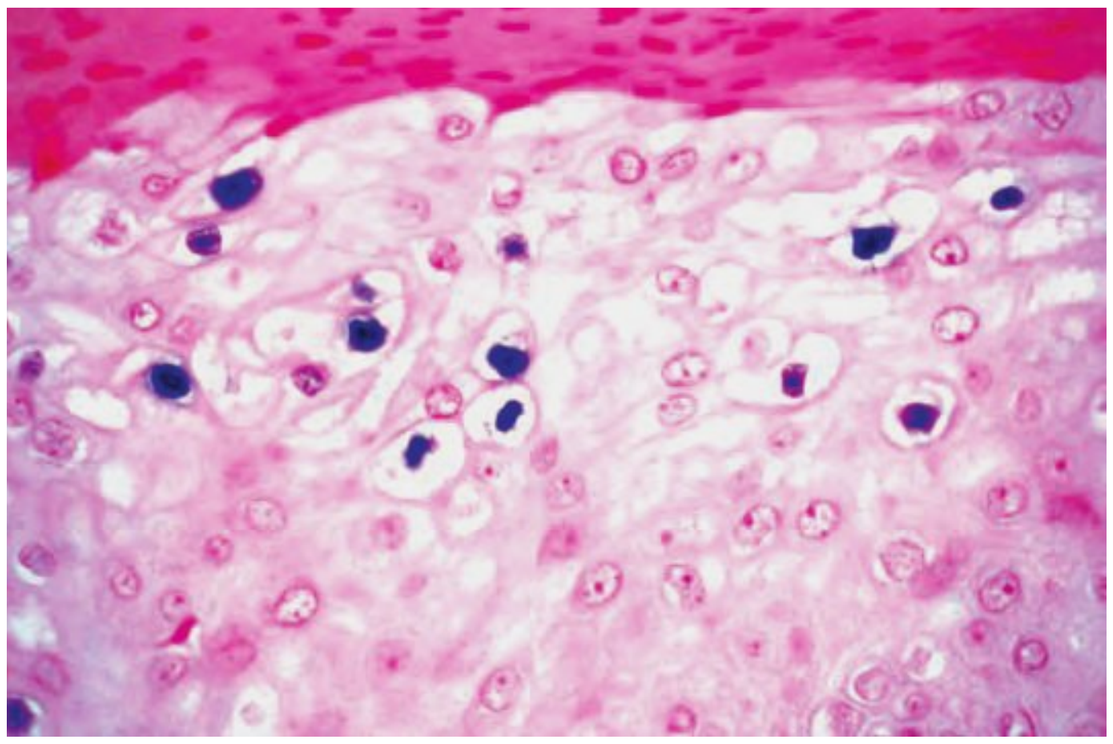
Viral particles are absent in lesions of Bowen's disease or squamous cell carcinoma arising from EV, but rarely these can be observed in the upper layers of the epidermis overlying malignant lesions. However, HPV-5–specific DNA or HPV-8–specific DNA has been demonstrated on several occasions in squamous cell carcinomas arising in lesions of EV. The underlying defect in EV is not clear but may involve oncogene or immunologic dysfunction.



Condyloma Acuminatum



Condylomata acuminata, or anogenital warts, can occur on the penis, female genitals, and in the anal region. Condylomata acuminate are transmitted sexually, and HPV infection is one of the most common viral sexually transmitted diseases in the world, with an estimated 1% prevalence in the sexually active population in the United States. The estimated prevalence of HPV DNA or HPV antigens in young women may be as high as 10% to 11%. Recent studies show that HPV DNA is detectable by PCR in more than 99.7% of cervical cancers, making HPV infection the most important risk factor in the development of this disease (90). Malignant progression is associated with infection by certain HPV types. Anogenital HPV types 6 and 11 rarely progress to invasive disease and are considered low risk. HPV types 16, 18, 31, 33, and 51 have been associated with both *in situ* and invasive processes of the male and female genital regions as well as the vagina and cervix in women. Additional types associated with malignancy include 35, 39, 42–45, 52 and 56. However, even with infection by high-risk types, these lesions most often spontaneously regress with no long-term adverse effects (91). Progression includes a spectrum from Bowen's disease to squamous cell carcinoma, potentially with extension to metastasis.



Condylomata acuminata usually are found on the penis and around the anus in men. In women, frequent areas of infection include the vulva, vaginal introitus, perineal area, perianal area, and cervix. Lesions of the skin consist of fairly soft, verrucous papules that occasionally coalesce into cauliflower-like masses (Fig. 25-15A). Condylomas are flatter on mucosal surfaces.

Histopathology. In condyloma acuminatum, the stratum corneum is only slightly thickened. Lesions located on mucosal surfaces show parakeratosis. The stratum malpighii shows papillomatosis and considerable acanthosis, with thickening

FIGURE 25-15. Condyloma acuminatum. A: Cauliflower-like or filiform lesions in the anogenital region. B: There is papillomatosis and acanthosis (low power). C: Many cells of the stratum malpighii appear vacuolated and have round, hyperchromatic nuclei (high power). D: In situ hybridization shows HPV in the squamous cells. E: Giant condyloma acuminatum with marked acanthosis and more endophytic growth.

and elongation of the rete ridges. Mitotic figures may be present. Usually, invasive squamous cell carcinoma can be ruled out because the epithelial cells show an orderly arrangement and the border between the epithelial proliferations and the dermis is sharp (Fig. 25-15B). The most characteristic feature, important for the diagnosis, is the presence of areas in which the epithelial cells show distinct perinuclear vacuolization. These vacuolated epithelial cells are relatively large and possess hyperchromatic, round nuclei resembling the nuclei seen in the upper portion of the epidermis in verrucae vulgares (Fig. 25-15C). It must be kept in mind, however, that vacuolization is a normal occurrence in the upper portions of all mucosal surfaces; thus, vacuolization in condylomata acuminata can be regarded as being possibly of viral genesis only if it extends into the

deeper portions of the stratum malpighii. Koilocytotic ("raisin") nuclei, double nuclei, and apoptotic keratinocytes may be present but are often less prominent than in uterine cervical lesions.

The diagnosis of HPV infections of the vulva can be complicated by the frequent absence of koilocytosis. HPV detection in lesions that depart from the typical morphology of condyloma can be achieved by *in situ* hybridization (Fig. 25-15D) or molecular tests. In one study, HPV DNA—principally HPV-6—was detected in 18 of 25 vulvar seborrheic keratoses (72%), while 15% of nongenital seborrheic keratoses were positive for this virus. Therefore, a majority of vulva seborrheic keratoses may represent senescent condylomas (92).

Giant Condylomata Acuminata of Buschke and Loewenstein

The Buschke-Loewenstein tumor, also called *giant condyloma acuminatum*, is generally observed in males. The most frequent location is the glans penis and foreskin (where urethral fistulas may result), but they may occur also on the vulva and in the anal region. Clinically, it is a cauliflower-like tumor with resemblance to a large aggregate of condylomata acuminata, especially in the early stage. It is characterized by its large size with the propensity to ulcerate and infiltrate into deeper tissues, contrasting with a microscopically benign pattern. The hallmark of the disease is the high rate of recurrence (66%) and of malignant transformation (56%). Distant metastases are extremely rare. The overall mortality is 20%, all occurring in patients with recurrences (93).

Histopathology. The lesion shows a papillomatous growth characterized predominantly by epithelial hyperplasia, hyperacanthosis, and hyperkeratosis (Fig. 25-15E). Generally, vacuolization of keratinocytes is mild or absent, in contrast to condyloma acuminatum. There is tremendous proliferation of the epidermis with displacement of the underlying tissue, but the ratio of nucleus to cytoplasm is low. The invasive strands of tumor usually possess a well-developed basal cell layer. (See verrucous carcinoma for further discussion.)

Histogenesis. Papillomaviruses induce a variety of proliferative lesions in humans. Of the many types of HPV that have been identified, a subset that includes types 16, 18, 31, 33, and 51 is associated with anogenital cancers (94). These cancers develop from precursor lesions such as condylomata acuminata on the external genitalia, vaginal intraepithelial neoplasia (VIN), and cervical intraepithelial neoplasia (CIN). Viral production occurs in low-grade lesions that are only slightly altered in their pattern of differentiation from normal cells, but the concentration of mature virions in condylomata acuminata is low. The production of viral particles, genome amplification, capsid protein synthesis, and virion assembly is dependent on differentiation and is restricted to suprabasal cells. In more atypical lesions, viral DNA is usually found integrated into host chromosomes and no viral production is noted. The viral DNA encodes nine overlapping genes, early (E1-7) and late (L1-2). Early genes are involved in oncogenic transformation in high-risk HPV types, especially E6 and E7, which enable HPV to use cellular proteins for continued viral replication by arresting the process of keratinocyte differentiation and inactivation of cell cycle regulators such as p53 and retinoblastoma protein (Rb), thus providing the initial step in progression to malignancy (95).

BOWENOID PAPULOSIS OF THE GENITALIA

Bowenoid papuloses are small, red papules of the genitalia. Some lesions are distinctly verrucous in appearance. The lesions are located in men on the glans and shaft of the penis and in women in the perineal and vulvar areas. Generally, the lesions are diagnosed clinically as genital warts, and the histologic finding of "Bowen's disease" appears incongruous.

The lesions have a definite tendency toward spontaneous resolution; some lesions regress, but others may appear and in turn also regress. Still, in some patients, lesions have persisted for prolonged periods. In rare cases, invasive squamous cell carcinoma has been described as arising in a Bowenoid papule.

Some authors regard the disorder as benign and, in particular, as different from Bowen's disease (57), but others have found that Bowenoid papulosis presents a premalignant lesion with a high risk for cervical neoplasia both for female patients and for sexual partners of male patients (96). Invasive squamous cell carcinoma develops in a small number of cases, and it seems that women over 40 years of age have the greatest risk.

Histopathology. Bowenoid papulosis shows the typical features of Bowen's disease. These features consist of full-thickness epidermal atypia with crowding and an irregular, "windblown" arrangement of the nuclei, many of which are large, hyperchromatic, and pleomorphic (Fig. 25-16). Dyskeratotic and multinucleated keratinocytes are also present, as are atypical mitoses. The basement membrane is intact. True koilocytes are uncommon. Bowenoid papulosis may be histologically indistinguishable from *vulvar intraepithelial neoplasia* (VIN III), a term that is synonymous with squamous cell carcinoma *in situ* or Bowen's disease. Some researchers believe that bowenoid papulosis differs from Bowen's disease by virtue of a lesser degree of cytologic atypia. In a few instances, bowenoid papulosis and condylomata acuminata have been found coexisting in the same patient.

Histogenesis. Bowenoid papulosis represents infection by HPV types associated with high risk of malignancy evolution, such as types 16, 18, 31, 33, and 51. As noted previously, these types elaborate oncoproteins that interfere with normal cellular homeostasis.

Differential Diagnosis. Bowenoid papulosis of the genitalia in most instances is differentiated from Bowen's disease on the basis of clinical data, such as onset at an earlier average age, multiplicity of lesions, smaller size of lesions, verrucoid appearance of

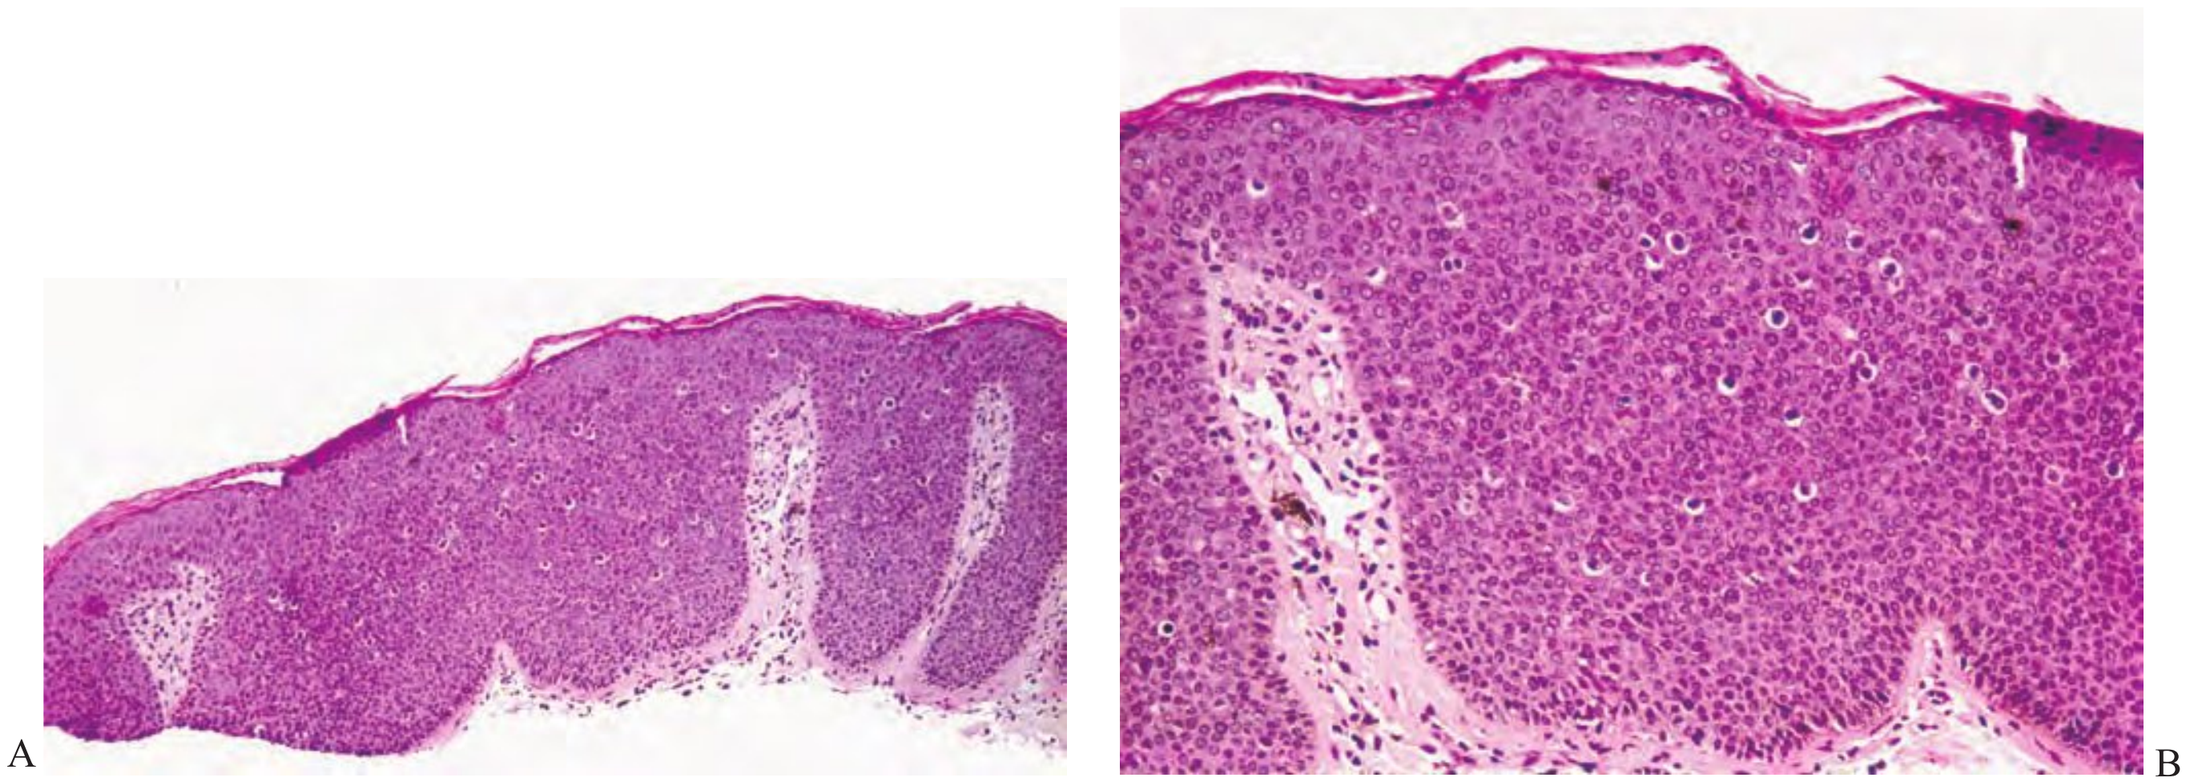

FIGURE 25-16. Bowenoid papulosis. A: The epithelium is irregularly thickened with disorderly maturation, which may impart a "windblown" look at scanning or intermediate magnification. B: The keratinocytic nuclei are crowded, and there is partial arrest of maturation. Mitoses are present above the basal layers, and the nuclei tend to be hyperchromatic and irregular, sometimes with nucleoli.

some lesions, and tendency toward spontaneous regression. Thus, Bowen's disease or squamous cell carcinoma *in situ* (VIN III) cannot be ruled out by biopsy alone in most cases.

Changes induced by recent application of podophyllum resin need to be considered. The changes induced by podophyllum resin consist of necrotic keratinocytes and bizarre mitotic figures and are most pronounced during the first 72 hours after application.

ORAL FOCAL EPITHELIAL HYPERPLASIA

A rare condition described in Native Americans, oral focal epithelial hyperplasia (Heck's disease) has since been found to occur in many countries and races but most commonly among the Eskimos of Greenland (97). It primarily occurs in children, often in small endemic foci, but lesions may occur in young and middle-aged adults. There is no gender predilection. Sites of greatest involvement include the labial, buccal, and lingual mucosa, but gingival and tonsillar lesions have also been reported.

There are numerous soft, white papules 2 to 10 mm in diameter. Individual lesions are broad based or slightly elevated as well as demarcated plaques. Papules and plaques are usually the color of normal mucosa but may be pale or, rarely, white. Most are discrete, but some are confluent. The lesions are asymptomatic. Although the disease is chronic, spontaneous remissions occur. Oral focal hyperplasia has been described in the context of HIV infection (98).

Histopathology. The oral epithelium shows acanthosis with thickening and elongation of the rete ridges. The thickened mucosa extends upward, not down into underlying connective tissues, hence the lesional rete ridges are at the same depth as the adjacent normal rete ridges. The ridges themselves are widened, often confluent, and sometimes club shaped; they are not long and thin as in *psoriasis* and other diseases. Throughout the epithelium, there are areas where the cells show marked vacuolization and stain only faintly. Vacuolization is most pronounced in the upper portion of the epithelium, but it may extend into the broadened rete ridges (Fig. 25-17).

Histogenesis. Electron microscopic examination reveals viral particles with the size of HPV arranged in a crystalline pattern. HPV types 13 and 32 are typical for oral focal epithelial hyperplasia (99).

Differential Diagnosis. The histologic appearance of the affected oral epithelium in focal epithelial hyperplasia is identical to that of oral epithelial nevus, or white sponge nevus.

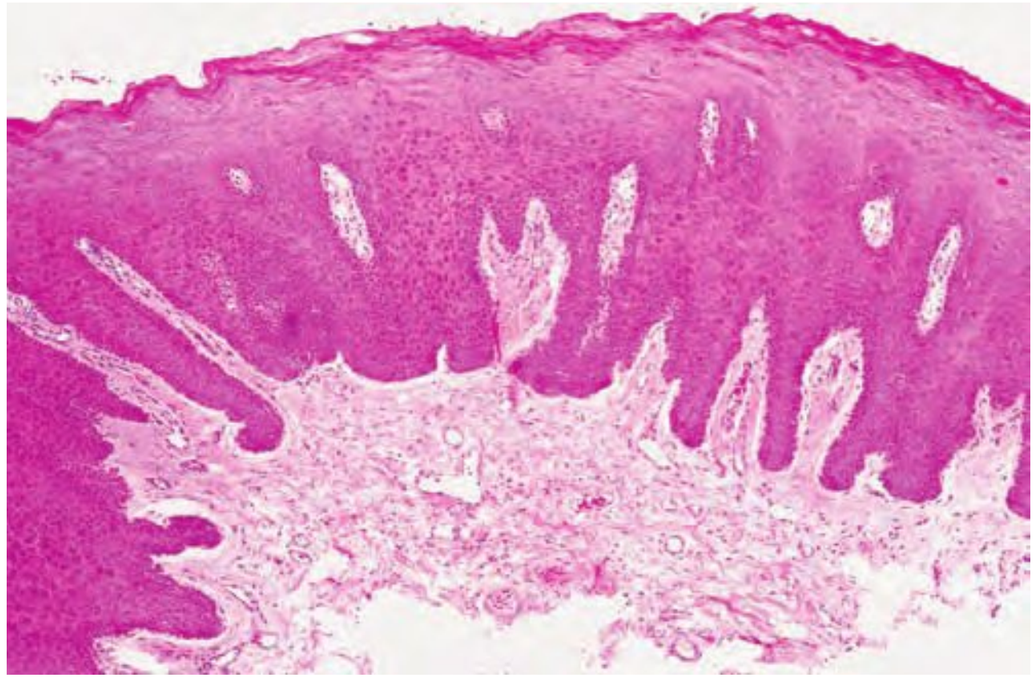

FIGURE 25-17. Oral focal epithelial hyperplasia (Heck's disease). The oral epithelium shows acanthosis with thickening and elongation of the rete ridges. The ridges are widened, often confluent, and sometimes club shaped. Vacuolization is most pronounced in the upper portion of the epithelium.

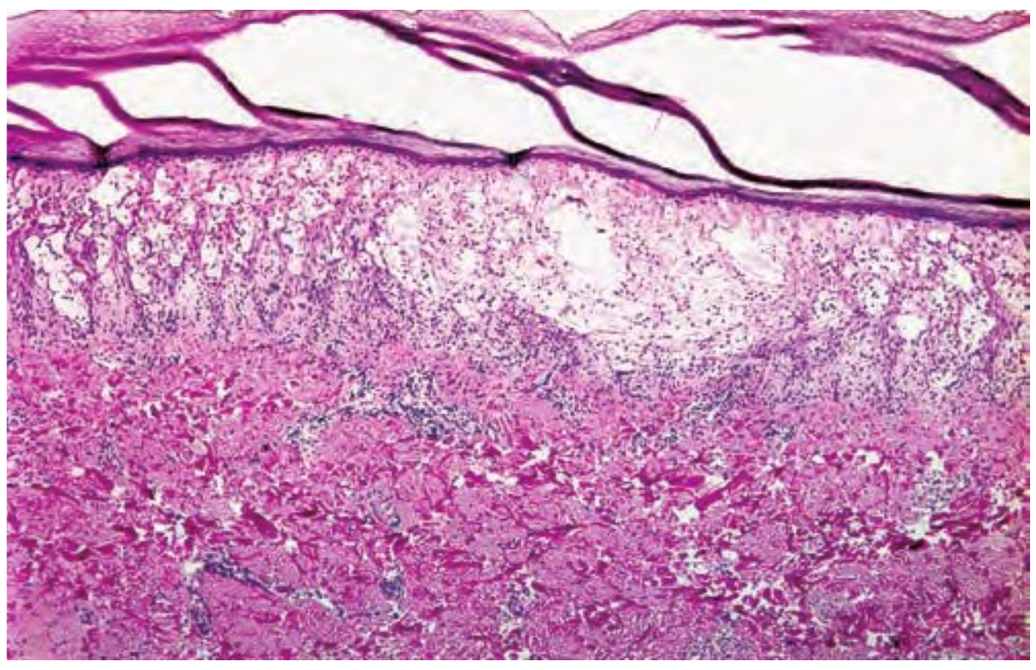
PICORNAVIRIDAE

Picornaviridae consists of single-stranded RNA viruses that are 10 to 30 nm, naked, icosahedral, and contain only four to six genes. They are the smallest of the RNA viruses and are very important in human disease. Picornaviridae infections of humans have been classified into five genera: Enterovirus (polio), Hepadnavirus (hepatitis A), Cardiovirus (encephalomyocarditis), Rhinovirus (common cold), and Apthovirus (foot and mouth diseases). Picornaviridae infection is one of the most common causes of viral exanthem. In addition to nonspecific findings, enterovirus infection also causes distinct syndromes such as hand-foot-and-mouth disease, herpangina, and hemorrhagic conjunctivitis (100).



Hand-foot-and-mouth Disease

Hand-foot-and-mouth disease is caused by a coxsackie virus, which is an enterovirus. In most instances, coxsackie virus type A16 has been isolated; only rarely has another type, such as A5 or A9, been found (101). Hand-foot-and-mouth disease occurs in small epidemics, affecting mainly children and having a mild course that usually lasts less than a week. Transmission is mainly via fecal–oral contact and less commonly by respiratory droplets (102). Symptoms usually appear 3 to 5 days after exposure. After a 1- to 2-day mild prodrome of low-grade fever, sore throat, and malaise, small red macules present on the oral mucosa and progress to 1- to 3-mm small vesicles, where they evolve into small ulcers. Between 25% and 65% of patients may have the classic vesicular lesions on the hands and feet, which present as scattered small vesicles surrounded by an erythematous halo on the palms of the hands (Fig. 25-18A), soles of the feet, and ventral surfaces and sides of the fingers and toes (103). Similar lesions may develop on the rest of the skin.

Histopathology. Early vesicles are intraepidermal, whereas old vesicles may be subepidermal in location. There is pronounced reticular degeneration of the epidermis, resulting in multilocular vesiculation. In the deep layers of the epidermis, some ballooning degeneration may be found. Neither inclusion bodies nor multinucleated giant cells are present (Fig. 25-18B, C).

Histogenesis and Diagnosis. Viral culture has been the gold standard until recently; PCR has become the diagnostic test for rapid and accurate enterovirus infection. The sensitivity of PCR is almost double that of viral culture (104). Electron microscopic examination reveals that within their cytoplasm, some keratinocytes contain aggregates of virus particles exhibiting a crystalloid pattern (105). The coxsackie virus can be cultured from stool and occasionally from skin vesicles. The virus grows well on human epithelial cell and monkey kidney cell cultures.

Neither inclusion bodies nor multinucleated cells are present.

Hepatitis A Virus

The hepatitis A virus is a common cause of hepatitis worldwide. Spread of infection is through the fecal–oral route. Hepatitis A is endemic in developing countries, and most residents are exposed in childhood. In contrast, the adult population in developed countries demonstrates falling rates of exposure with improvements in hygiene and sanitation. Hepatitis A usually presents as fever, jaundice, and hepatomegaly. Extrahepatic manifestations are rarely found in hepatitis A viral infection. Urticaria and scarlatiniform eruption and rare cases of cutaneous vasculitis and cryoglobulinemia have been reported (106).

RETROVIRIDAE

Retroviridae are RNA retroviruses that currently are classified into seven genera, including HIV, the cause of AIDS, and human T-lymphotropic virus.

Acquired Immunodeficiency Syndrome

HIV infects predominantly $CD4^+$ cells, most notably T helper cells, and leads to a profound alteration of immune system function that predisposes patients to numerous opportunistic infections, malignancies, and neurologic diseases. The virus is spread almost exclusively through blood and semen.

Cutaneous findings in HIV disease are frequent and include viral, bacterial, fungal, and noninfectious etiologies (107). Some infections occur in clinically obscure forms because they do not have recognizable morphologic features. In addition, systemic infectious diseases can produce skin lesions, even though the classic organs of involvement for that agent may not include the skin. Dermatologic diseases common to the general population, such as *seborrheic dermatitis*, often have an increased prevalence or severity in these individuals (108). Several skin diseases occur nearly exclusively in HIV-infected individuals, such as oral hairy leukoplakia, bacillary angiomatosis, and KS.

HIV itself produces cutaneous findings shortly after exposure. In addition, gradual deterioration of the immune system renders HIV-infected patients susceptible to numerous cutaneous viral diseases, including herpesviruses, HPV, and molluscum contagiosum (109). Approximately 2 to 6 weeks following HIV exposure, patients may present with a transient illness related to HIV replication and host response. More than 50% of patients report symptoms of acute HIV infection: a macular or morbilliform rash usually involving the trunk is present in 40% to 80% of patients with acute HIV infection (110). Because the standard immunoassay and Western blot are often negative with acute infection, additional tests may be needed when there is a high index of suspicion. P24 antigen assay has fewer false positives and may be a more cost-effective way to diagnose primary HIV infection (111).

Pruritic papular eruption is the most common cutaneous manifestation in HIV-infected patients. Opportunistic viral infections affecting the skin and mucous membranes are also common (40). *Herpetic infections* are one of the most important causes of opportunistic infections in patients with HIV and frequently include cutaneous manifestations. Unlike in the healthy individual, in which case the lesions are often self-limited, herpetic infections cause significant chronic morbidity in immunocompromised patients. As immune function declines, the herpetic lesions may become chronic and progress to painful ulceration. *Herpes zoster* may be complicated by repeated bouts, involvement of multiple dermatomes, chronic verrucous zoster; rarely, herpes zoster may disseminate. *CMV* infection is associated with $CD4^+$ cell counts <100 and has a spectrum of presentations including pulmonary, ocular, gastrointestinal, and neurologic involvement, although CMV skin lesions are uncommon (112). While a majority of adults harbor EBV in latent phase, *oral hairy leukoplakia* is a rare disorder found almost exclusively in HIV-infected individuals. Approximately 25% of HIV-infected individuals may be affected. White, verrucous, confluent plaques that are most commonly located on the lateral aspects of the tongue characterize oral hairy leukoplakia, which do not scrape off with a tongue depressor (113). EBV appears to be necessary for production of this lesion, although HPV and *Candida* are also frequently present. The condition is a result of EBV infection of epithelial cells that leads to hyperkeratotic thickening. *Molluscum contagiosum* generally presents as $CD4^+$ counts fall below $100/mm^3$. While the lesions spontaneously resolve in immunocompetent hosts, they are often extensive and progressive in HIV-infected individuals, who are also subject to so-called giant molluscum contagiosum with lesions ranging from 1 to 6 cm in diameter (114).

Bacterial infections are also common in AIDS. *Staphylococcus aureus* is the most common cutaneous bacterial pathogen in HIV-seropositive patients. HIV-infected patients are also prone to streptococcal impetigo and axillary lymphadenitis. Another unique infectious disease first recognized in the context of HIV infection is *bacillary angiomatosis*. Bacillary angiomatosis is a systemic infectious disease caused by gram-negative *Bartonella henselae* or *Bartonella quintana* (115). Patients may have palpable subcutaneous nodules, which may resemble KS or hemangioma but resolve with appropriate antibiotic therapy. The lesions often are painful, unlike those of KS. HIV-infected patients are susceptible to mycobacterial infections that can sometimes produce unusual skin manifestations. *Syphilis* is common in these individuals and often the presenting infection of HIV disease (116). *Secondary syphilis* assumes a variety of manifestations in HIV-infected patients, including oral erosions, nodules, papules, vesicles, hyperkeratotic plaques, and papulosquamous or maculopapular eruptions.

Patients with HIV are subject to fungal, protozoa, and arthropod infections that produce mucocutaneous findings. Oral candidiasis is often an early clinical manifestation of AIDS and in progressing may cause painful esophagitis. Other infections such as *Cryptococcus*, *Histoplasma*, *Coccidioidomycosis*, *tinea versicolor*, *phaeohyphomycosis*, *nocardiosis*, and *mucormycosis* are not uncommonly seen in these patients (117). *Scabies* mite is the most common parasitic infestation of

HIV-infected individuals (118). Scabies is highly contagious in HIV-infected patients via direct contact. *Demodicidosis* involves the proliferation of *Demodex* mites within the pilosebaceous unit and is reported in association with HIV infection (119). *Disseminated acanthamebiasis* has been reported in these patients and often presents skin manifestations such as pustules, subcutaneous and deep dermal nodules, and ulcers, most often seen on the extremities and face.

Noninfectious cutaneous disorders are also common in HIV infection and can occur at all stages of disease. An explosive episode of *psoriasis* or severe *seborrheic dermatitis* can be the presenting symptom of HIV disease. Seborrheic dermatitis is a common disease affecting 2% to 4% of the general population, but up to 85% of HIV-positive individuals experience seborrheic dermatitis at some time during their diseases. It can be quite severe, with the severity correlating with the patient's clinical status and CD4 count (120). Less common areas such as the chest, back, axilla, and groin are often involved in HIV-seropositive patients. The histology of this eruption is similar to that of idiopathic seborrheic dermatitis, although some feel that distinctive histologic patterns are present (121). While the incidence of psoriasis in HIV disease is similar to the general population, it is often more severe, refractory to treatment, and has a higher prevalence of psoriatic arthritis. *Reiter's syndrome*, characterized by arthritis, urethritis, and conjunctivitis, may be associated with psoriasis in HIV-infected individuals (122). As many as 30% of HIV-infected individuals experience *xerosis* or *acquired ichthyosis* with fine white scales and cracking skin without erythema, which may be diffuse or preferentially affect the anterior tibia, dorsal hand, and forearm (123). Whereas xerosis reveals minimal inflammation microscopically, acquired ichthyosis is histologically similar to ichthyosis vulgaris, often with hyperkeratosis and diminished or absence of the granular cell layer. A nonspecific follicular eruption, named *eosinophilic pustular folliculitis*, is present in a significant number of patients with HIV infection (124). The eruption is chronic and pruritic. An interface dermatitis associated with HIV, observed in a series of 25 patients with AIDS, presents as a more or less widespread eruption of pink or red macules, papules, or plaques. It resembles and may represent a form of drug eruption or erythema multiforme (125).

Adverse cutaneous drug reactions are common in HIV-positive individuals, and they are prone to side effects associated with antimicrobial and antiviral medications (126). For example, after 1 to 2 weeks of trimethoprim-sulfamethoxazole treatment for *Pneumocystis carinii* infection, up to 50% to 60% of HIV-infected patients may develop a morbilliform rash. HIV-infected individuals also have an increased incidence of photosensitivity reactions. *Chronic actinic dermatitis*, a rare photosensitivity reaction, is sometimes the presenting manifestation of HIV seropositivity (127). *Porphyria cutanea tarda* (PCT) is reported more frequently in HIV-infected individuals when compared with the general population. Other lesions, such as pityriasis rubra pilaris, porokeratosis, yellow nail syndrome, alopecia, asteatosis, vasculitis, acrodermatitis enteropathica, and neutrophilic eccrine hidradenitis have been reported.

KS is the most common AIDS-associated cancer in the United States. Over 95% of all KS lesions have been associated with HHV-8 (128). Skin lesions of KS typically present with asymptomatic reddish-purple patches that sometimes progress to raised plaques or nodules. One third of patients experience oral cavity lesions characterized by red-to-purple plaques or nodules. Other tumors such as melanoma (129) and squamous and basal cell carcinoma have been reported in these patients.

Histopathology. The histology of the acute exanthema of HIV infection is rather nonspecific, with a tight perivascular infiltrate of lymphocytes in the dermis. Epidermal changes are usually mild but may include spongiosis, vacuolar change, and/or keratinocyte apoptosis (130,131), or there may be nonspecific lymphocytic infiltrates with mild epidermal changes, primarily spongiosis (110).

The lesions of oral hairy leukoplakia show irregular keratin projections, parakeratosis, and acanthosis. A characteristic finding within the epithelium is vacuolar change of superficial keratinocytes (Fig. 25-8). *Candida* organisms may be demonstrable. Seborrheic dermatitis in patients with AIDS may show nonspecific changes, including spotty keratinocytic necrosis, leukocytoclasia, and plasma cells in a superficial perivascular infiltrate (121). The papular eruption of AIDS may exhibit nonspecific perivascular eosinophils with mild folliculitis, although epithelioid cell granulomas have also been reported (132). The interface dermatitis shows, as the name implies, vacuolar alteration of the basal cell layer, scattered necrotic keratinocytes, and a superficial perivascular lymphohistiocytic infiltrate. The vacuolar alteration and number of necrotic keratinocytes tend to be more pronounced than in drug eruptions (125). The changes found are nonspecific but suggestive of features described in graft-versus-host disease and become more prominent in late-stage disease. *Eosinophilic pustular folliculitis* shows folliculitis with transmigration of eosinophils into the follicular epithelium, mimicking the changes observed in Ofuji's disease. However, in many cases, the histologic picture is less specific, showing only a polymorphous inflammatory response and mild folliculitis (131,133). *Cutaneous acanthamebiasis* shows both pustular and vasculitis changes; the microscopic identification of organisms is difficult because of the macrophage-like appearance of the microbes in routine sections (134). A periodic acid-Schiff (PAS) stain can be used to highlight the organisms.

DISEASES CAUSED BY OTHER VIRUSES

Hepatitis B virus

The hepatitis B virus (HBV) is a double-stranded DNA virus belonging to the Hepadnaviridae family. Transmission of the virus is frequently through intravenous drug use, sexual activity, and maternal–fetal transmission (135). During the acute phase, 15% of the patients will develop urticaria, fever, and malaise (136). Polyarteritis nodosum (PAN) is one of the more serious and common complications of HBV infection (137).

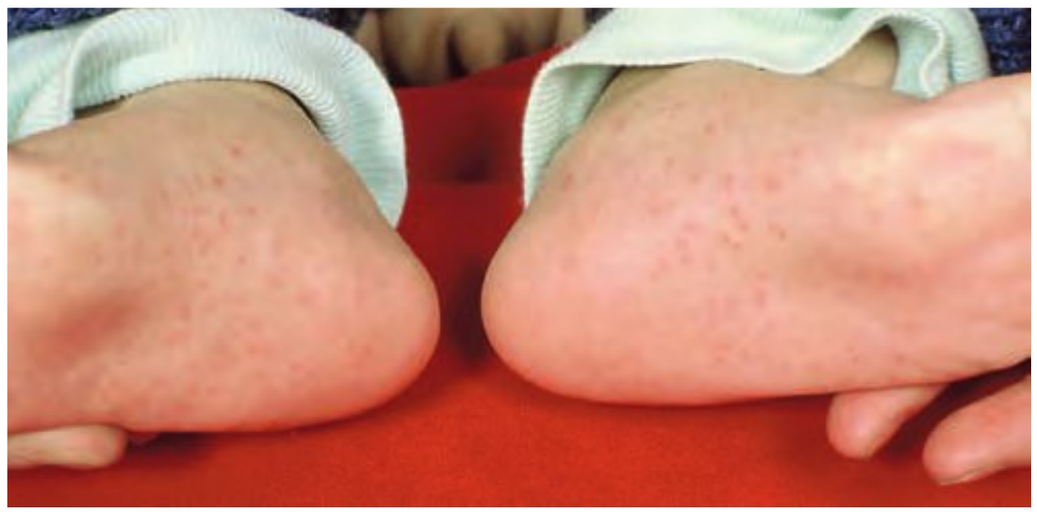

FIGURE 25-19. Papular acrodermatitis of childhood. Numerous erythematous papules are present on the feet of this boy.

About 2 in 500 people with HBV develop PAN, but up to 50% of people with PAN test positive for hepatitis B surface antigen (HBsAg). Cutaneous involvement occurs in 10% to 20% of the persons with PAN, which presents as palpable purpura that progress to large ulcers. Tender, purple, subcutaneous nodules can occur as well as livedo vasculitis (138). There is fibrinoid necrosis of the medium-size vessel wall with a cellular infiltrate composed mainly of $CD8^+$ T cells and macrophages. Depositions of immune complex, IgM, C3, and HBsAg in the vessel walls are observed.

Papular acrodermatitis of childhood (Gianotti-Crosti syndrome) occurs in children infected with HBV but is not common in adults (139). The clinical presentation includes a nonrelapsing erythematous papular eruption localized to the face and limbs (Fig. 25-19), with lymphadenopathy and acute hepatitis (mostly anicteric). The lesions do not affect mucosal surfaces. Papular acrodermatitis of childhood is common in southern Europe and Japan but rare in the United States. This condition can also be associated with CMV, EBV, respiratory syncytial virus, and enterovirus infection (140). The histology is characterized by a mixture of spongiotic and lichenoid dermatitis with a dense perivascular infiltrate.

Serum sickness–like syndrome is considered the most common dermatologic manifestation associated with HBV, which occurs in 20% to 30% of patients during the prodromal phase of the HBV infection. The skin manifestation includes urticaria, angioedema, and rashes. The urticaria lesions show erythrocyte extravasation, endothelial cell swelling, and various degrees of fibrinoid change of postcapillary venules (141). The pathology is induced by deposition of immune complexes, which are composed of HBsAg, IgG, IgM, and C3.

HBV has also been associated with mixed cryoglobulinemia (MC) (142); however, it is much less common than that associated with hepatitis C virus (HCV) infection. A recurrent papular rash on the trunk and extremities (143) and lichen planus (LP) have been reported as complications of hepatitis B vaccination in both adults and children (144).

Hepatitis C Virus

HCV is a single-stranded RNA virus that belongs to Hepacivirus, the third genus of the Flaviviridae family. Individuals with exposure to blood or blood products are at risk of infection with HCV. The prevalence in the United States ranges from 0.5% to 2.0%. *MC* is the most documented extrahepatic manifestation of HCV infection (145). It presents cutaneously as inflammatory, palpable purpura, which is usually confined to the lower extremities, progressing to ulceration. It is established that the majority (80%) of what was previously known as *essential MC* is now known to be related to chronic HCV infection (146). Despite a high prevalence of HCV markers in patients with MC, only an estimated 13% to 54% of patients with chronic HCV will develop MC. It is believed that HCV-IgG and HCV-lipoprotein complexes may act as B-cell superantigens inducing the synthesis of non-HCV reactive IgM with rheumatoid factor–like activity, leading to immune complex formation. Because of the high prevalence of liver abnormalities seen in patients with MC, hepatotropic viruses should be ruled out as causative agents. Histologic features for MC are those of an acute vasculitis involving small- and/or medium-sized dermal vessels. Intravascular hyaline deposits are generally not seen except in the areas beneath the ulcer.

LP is common in patients with HCV, with the prevalence of HCV ranging from 16% to 55% and 0.17% to 4.80% in LP patients and control groups, respectively (147). The lesions of HCV-related LP are similar to those of classic LP. However, a majority of reported HCV-related LP cases have oral involvement. Histologically, LP is characterized by a subepidermal, bandlike lymphohistiocytic infiltrate with interface change, sawtooth rete ridges, and pigmentary continence.

Recent reports have documented a high but variable prevalence of HCV infection in patients with porphyria cutanea tarda (PCT). The prevalence is higher in southern Europe (67% to 91%) and lower in northern Europe (8% to 10%). The prevalence in the United States is reported to be between 50% and 75% (148). In most cases, the HCV exposure and associated liver dysfunction precede the onset of PCT, suggesting that a viral infection can reveal a porphyrin metabolism defect in susceptible patients. Histologically, PCT is characterized by a cell poor subepidermal bulla with increased PAS-positive diastase-resistant hyaline material in the vessel walls and basement membrane.

Other lesions associated with HCV infection include erythema multiforme and erythema nodosum (149), Henoch-Schönlein purpura (150), Behçet's syndrome (151), necrolytic acral erythema (152), PAN (153), prurigo nodularis (154), pyoderma gangrenosum (155), and urticarial vasculitis (156).

Parvovirus B19

Parvovirus is a single-stranded DNA virus belonging to the Parvoviridae family. Parvovirus B19 is the only Parvovirus that clearly causes human disease (157). The virus is highly tropic for erythroid progenitor cells and thus is classified as an erythrovirus. The cellular receptor for B19 is a globoside, also known as *blood group P antigen* (40). Parvovirus infection is ubiquitous and occurs worldwide. Transmission of the virus occurs through the respiratory route in most cases. Two dermatologic conditions have been linked to Parvovirus B19

FIGURE 25-20. Erythema infectiosum (fifth disease). The lesion has the classic slapped-cheek appearance. The bright red erythema appears abruptly over the cheeks and is marked by nasal, perioral, and periorbital sparing.

infection, *erythema infectiosum*, and *papular purpuric "gloves-and-socks" syndrome* (157,158). Infection may also result in nonspecific findings, such as reticular erythema, maculopapular eruptions, purpuric eruptions, palpable purpura, and angioedema. Other dermatologic entities, such as erythema multiforme (159) and papular acrodermatitis of childhood (Gianotti-Crosti syndrome) (160), as well as recently various vasculitic syndromes, including Henoch-Schönlein purpura (HSP), Wegener's granulomatosis, and microscopic polyarteritis, have been linked to B19 infection (161).

The most well-known dermatologic manifestation of Parvovirus B19 is *erythema infectiosum*. This well-recognized exanthema also is called *fifth disease*, with a distinctive "slapped cheek" appearance (Fig. 25-20). Less widely recognized and described only a decade ago, papular purpuric "gloves-and-socks" syndrome is also associated with Parvovirus B19. Clinically, the rash consists of symmetric erythema and edema of the hands and feet, with gradual progression to petechiae and purpura. One of the clinical hallmarks of the rash is the sharp demarcation on the wrists and ankles. Resolution occurs within 1 to 2 weeks, with no permanent sequelae. However, in immunocompromised patients, papular purpuric "gloves-and-socks" syndrome may lead to more serious complications, such as persistent anemia. The histology is not entirely specific. Most cases have revealed interstitial histiocytic infiltrates with piecemeal fragmentation of collagen and a mononuclear cell-predominant vascular injury pattern, showing dilated and irregular-shaped dermal vessels with swelling of endothelial cells. Mild to moderate perivascular infiltrates of mononuclear cells have been noted (162).

Measles

Measles virus is a single-stranded RNA virus that belongs to the Paramyxoviridae family. Measles is an epidemic disease with a worldwide distribution. Measles virus is transmitted via respiratory secretions, predominantly as aerosols but also by direct contact. The symptoms usually last for 10 days and resolve without consequence. However, there is an increased risk of more severe diseases, such as severe pneumonitis or encephalitis, in immunocompromised individuals (163). A biopsy of the rash shows nonspecific histologic change with epidermal spongiosis and mild vesiculation with scattered degenerated keratinocytes (164). Biopsies from AIDS patients with measles show necrosis of clusters of keratinocytes in the upper spinous layer and granular layer of the epidermis. Unlike in erythema multiforme, the necrosis occurs in the basal layer keratinocytes. Multinucleated keratinocytes may or may not be prominent in the measles biopsy. Cytoplasmic swelling of the keratinocytes in the granular layer may be present even when multinucleated cells are sparse (165).

Rubella

Rubella is an enveloped, single-stranded RNA virus that belongs to the Togaviridae family. Rubella, also known as *German measles*, is a viral exanthema of childhood that is generally subclinical and inconsequential. Viremia occurs approximately 1 week before the rash; the rash is seen when circulating antibodies appear. The rash is maculopapular, erythematous, discrete, and pruritic. The face is usually the first area of devolvement, then spreads to extremities. The entire body may be involved within 1 day. The second day, there is clearing of the face and the rash is commonly cleared by the third day. Histologically, the change is not specific with a mild, perivascular lymphocytic infiltrate (166,167).

CHAPTER 26

Walter H.C. Burgdorf
Bernhard Zelger

The Histiocytoses

The histiocytic disorders cover a wide range of primary and secondary, solitary and multiple, benign and malignant disorders unified only by being for the most part uncommon and poorly understood. The "X" in histiocytosis X as originally proposed by Lichtenstein (1) was designed to reflect the unknown; even though we have drifted away from the designation, it to some degree still reflects the state of our knowledge. The word "histiocyte" itself is not particularly helpful. Loosely translated, it means a "cell of the tissue." Medical dictionaries tend to define the histiocyte as a "macrophage" or a "tissue macrophage," but many of the diseases known as histiocytoses are not disorders of macrophages but instead involve dendritic cells. Despite these misgivings, we retain the term histiocytosis, as have major textbooks (2,3) and reviews (4–8).

Recent research has clarified some aspects of the terminology but made others more confusing. There are two major cell lines responsible for the spectrum of diseases considered as histiocytoses. The following markers are useful in identifying these cells (Table 26-1):

1. The bone marrow–derived monocytes, which migrate to tissue, where they differentiate into macrophages or professional phagocytes, known by many names based on their site, such as Kupffer cells in the liver. There are a number of monoclonal antibodies available to identify macrophages; most are directed against CD68. Stains for CD14 and CD163 are also used.
2. The dendritic cells are for the most part bone marrow derived and reside in the skin, lymph nodes, or other organs. Two are relevant for here (9):
   a. The Langerhans cell (LC) is an antigen-processing cell characterized by Birbeck granules, S100 protein, CD1a, and langerin (CD207) positivity. LC initially take up antigens in the epidermis, migrate through the dermis to lymphatics and then lymph nodes, and there present processed antigens in association with major histocompatibility complex molecules to T cells. The more mature form is the interdigitating dendritic cell (IDC), which lacks Birbeck granules, CD1a, and langerin.
   b. The dermal/interstitial dendritic cell is a perivascular cell positive for factor XIIIa (FXIIIa) and fascin that fails to stain for S100 protein or CD1a. FXIIIa can also be expressed by activated macrophages. FXIIIa is the rate-limiting enzyme in the formation of fibrin thrombi and is most prominent in the superficial dermis. It is more likely to be positive in acute and early lesions. The number of different dermal dendritic cells and their precursors has expanded rapidly in recent years, but clinicopathologic correlation is lacking.
3. A source of confusion is the indeterminate cell, whose vague name accurately reflects the current situation. No single definition is agreed on; possibilities cited in the recent literature include the following:
   - A veiled cell, that is, a LC migrating to the dermis
   - A LC precursor (exactly the opposite of a veiled cell)
   - A cell with features of both a macrophage and LC. There is marked overlap between the dermal/interstitial dendritic cells and macrophages. with potential for shifting markers even relatively late in development.

A number of cautions are required. A diagnosis is rarely if ever based on the presence or absence of a single antigen, but instead is based on the clinicopathologic picture. Both macrophages and dendritic cells go through a maturation process, and so their profiles may change. In addition, because monocytes and most dendritic cells arise from a similar bone marrow–derived stem cell, there are overlaps with macrophages expressing S100 protein or even CD1a, but not langerin; similarly, dermal dendritic cells may express macrophage markers. We do not find FXIIIa specific enough to agree that its presence unequivocally identifies dermal cells as of dendritic cell origin. Dermatofibromas that meet all other morphologic criteria for a fibrocytic origin in early lesions regularly stain with FXIIIa.

Histiocytic lesions can usually be diagnosed based on their light microscopic pattern using a much more limited number of stains (Table 26-2). Our detailed classification is presented in Table 26-3. The classification of the Histiocyte Society is designed primarily for childhood disorders (10), whereas that of the World Health Organization concentrates on malignant neoplasms in adults and ignores cutaneous xanthogranulomas (11).

In addition to the diseases to be discussed in this chapter, a wide array of disorders can display similar histologic patterns. Most are discussed elsewhere in this book.

1. Metabolic disorders: In addition to hyperlipoproteinemias and other disorders of fat metabolism, many lysosomal disorders and other storage diseases may feature cutaneous xanthomas or other infiltrates. The diagnosis of these disorders

TABLE 26-1 Markers for "Histiocytes"

Cell type	Useful marker
Monocyte (source of all the rest)	CD14
Macrophage	CD14, CD68, CD163
Sinus histiocytosis macrophage	CD14, CD68, CD163, S100 protein, fascin
Dermal/interstitial dendritic cell	CD14, CD163, FXIIIa, fascin
Langerhans cell	CD1a, langerin, S100 protein

is not a practical question for the dermatopathologist, and they will not be further considered.

2. Infectious diseases. Tuberculosis, lepromatous leprosy, other mycobacterial infections, and leishmaniasis may produce granulomas. Malakoplakia is a chronic granulomatous reaction, presumably to an infectious agent, that occurs occasionally in the skin. The key histologic finding is the presence of intracellular Michaelis-Gutmann bodies.
3. Proliferations. Some lymphomas present with cutaneous granulomatous infiltrates; included in this group are Hodgkin's lymphoma and some forms of T-cell lymphoma. Most diseases diagnosed in the past as histiocytic malignancies are lymphomas. Malignant fibrous histiocytoma and its more superficial cutaneous variant atypical fibroxanthoma are established diagnoses, but their line of differentiation remains controversial. Melanocytic tumors can be confused with macrophage disorders, both clinically and histologically. The red-brown color of xanthogranulomas is similar to that of Spitz nevi. Balloon cell nevi and melanoma are occasionally mistaken histologically for xanthomatous lesions (12). Touton giant cells can sometimes be confused with multinucleated rosette cells in melanocytic nevi (13). Fortunately, immunohistochemical studies readily resolve these potential difficulties (14).
4. Trauma. Most dermatofibromas and some verruciform xanthomas are the result of trauma, be it an insect bite, folliculitis, or another insult. Some xanthomas arise secondary to cutaneous damage from light or after marked inflammation. External objects, such as glass fragments, silica, and many others, may produce cutaneous granulomas, often of the sarcoidal type. A ruptured follicular cyst is also accompanied by a macrophage response.
5. Idiopathic. Unfortunately, most "histiocytic" diseases fit here, and there is little logic to what has been considered a macrophage disorder and what has been cubby holed elsewhere. For example, granuloma annulare has a macrophage infiltrate but is considered a necrobiotic disorder. Both rheumatoid arthritis and sarcoidosis may feature infiltrates of macrophages in the skin and other organs; nonetheless, they are not considered "histiocytoses."

LANGERHANS CELL DISEASE

Langerhans cell disease (LCD) is characterized by a proliferation of Langerhans cells. The clinical spectrum of LCD is broad, with skin involvement a common finding. Whereas LCD has been subdivided into several clinical types, overlaps are the rule, not the exception, and lumping appears more appropriate than splitting. Acute disseminated LCD (Abt-Letterer-Siwe disease) usually occurs in infants (15) but can be seen in older children or adults. The most common manifestations are fever, anemia, thrombocytopenia, enlargement of the liver and spleen, lymphadenopathy, and pulmonary infiltrates. Osteolytic lesions are uncommon except in the mastoid region

of the temporal bone, resulting in a clinical picture of otitis media (16–18).

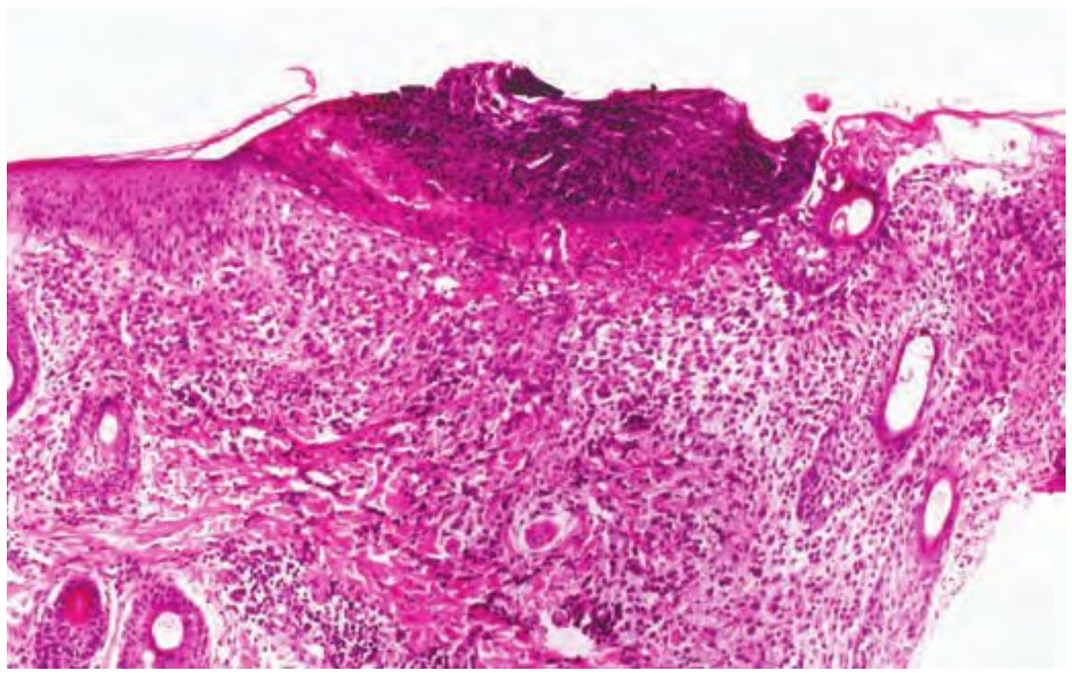
Cutaneous lesions are found in about 80% of cases, often as a presenting sign. Numerous closely set, red-brown papules covered with scales or crusts may be accompanied by petechiae. This type of eruption may be extensive, involving particularly the scalp, face, and trunk, with a striking resemblance to seborrheic dermatitis or Darier's disease. Cutaneous LCD is very pleomorphic; lesions may be vesicular (19), ulcerated, urticarial (20), or, rarely, xanthomatous (21). If there is a diffuse cutaneous eruption, one must anticipate multiorgan involvement. In rare instances, a widespread cutaneous eruption is the only clinical manifestation in infants and even in the elderly, in whom anogenital involvement is common (22,23). The prognosis in such cases is good. Other adults may have similar cutaneous findings but also multisystem disease and do poorly.

Congenital self-healing reticulohistiocytosis (CSHRH) (Hashimoto-Pritzker disease) (24) is another variant of LCD, not a distinct disorder. It is usually present at birth but may not appear until several days or weeks after delivery. Affected infants have scattered papules and nodules. Large nodules tend to become eroded or ulcerated. Usually, the number of lesions varies from several to a dozen; on rare occasions, numerous lesions are widely scattered over the entire skin. In about 25% of cases, a solitary nodule is present. The lesions begin to involute within 2 to 3 months and usually have completely regressed within 12 months (25,26). But the patients should be carefully followed; relapses may occur, including bone involvement, and the occasional case may advance to acute disseminated disease (27). Although acute disseminated LCD may also be present at birth, it is rarely nodular.

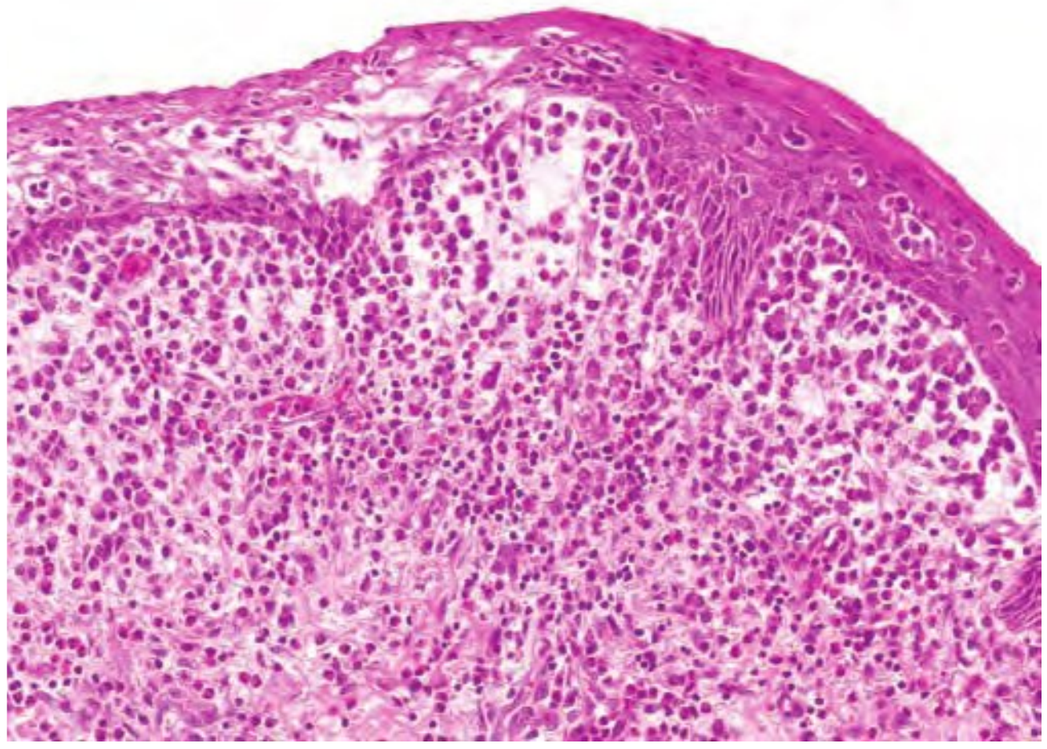
In chronic multifocal LCD, diabetes insipidus, exophthalmos, and multiple defects of the bones, especially of the cranium, represent the classic triad of Hand-Schüller-Christian disease. Any one or even all three of the cardinal symptoms may be absent, and entirely different organs may be involved. For example, enlargement of the liver, spleen, lungs, or lymph nodes may be found. Osteolytic lesions of the long bones may result in spontaneous fractures. Cutaneous lesions occur in about one third of the cases. Three types of skin lesions may be found. Most common are infiltrated nodules and plaques undergoing ulceration, especially in the axillae, the anogenital region, and the mouth. Next in frequency is an extensive eruption identical to that in infants but usually less severe. Finally, in rare instances yellow xanthomas are seen. Patients with LCD also tend to develop more juvenile xanthogranulomas than expected (28,29).

Chronic focal LCD or eosinophilic granuloma represents the fourth and least severe variant. The lesions are either solitary or few. Most common are lesions of the bones, but the skin or the oral mucosa is occasionally involved, either with or without osseous lesions. Involvement of the jaw leading to a loose or floating tooth is a fairly typical occurrence. Although the lesions are usually chronic, some heal spontaneously, and simple surgery is generally curative. In rare instances, cases originally diagnosed as chronic focal disease may progress into multifocal or even disseminated disease.

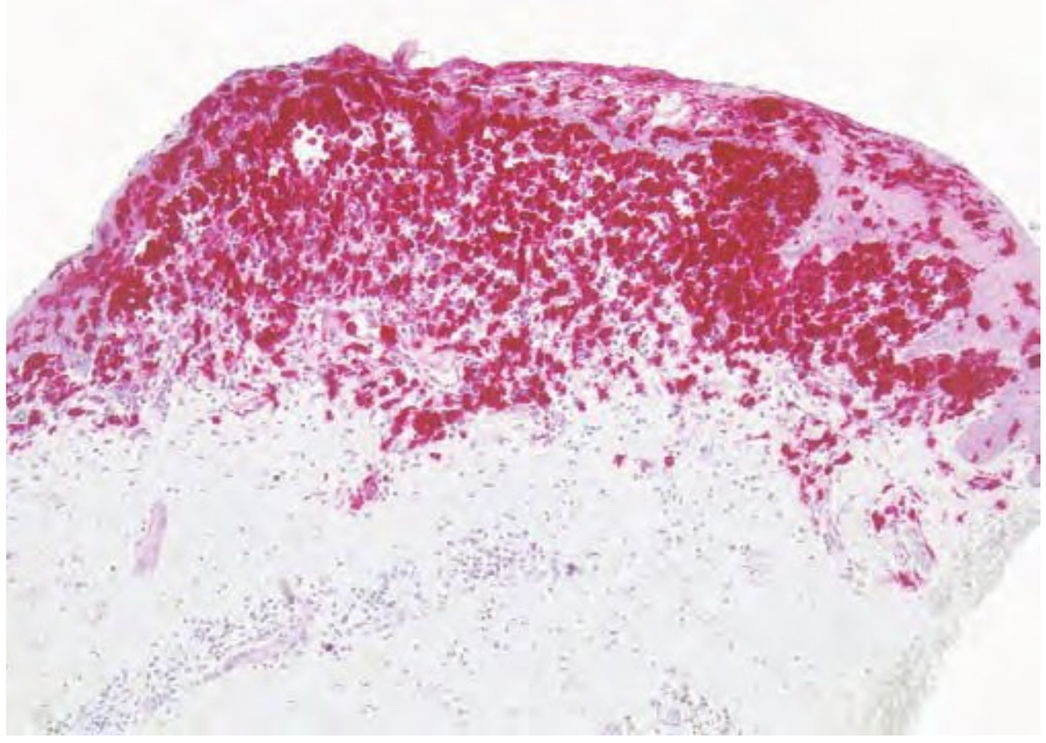
The clinical course and the prognosis of LCD are difficult to predict. The most important parameters in prognosis are those recommended for staging: the age of the patient, the number of organs involved, and the degree of organ dysfunction. Abnormalities of the bone marrow, spleen, liver, or lungs suggest a poor prognosis. Skin involvement alone suggests a favorable outcome. Paradoxically, the presence of skin disease at birth (the nodules of CSHRH) is a good sign, but involvement before the age of 2 years (Letterer-Siwe disease) is a bad one. Histologic features correlate poorly with outcome (30). Patients with disseminated LCD seem to be at risk for a variety of systemic neoplasms, including lymphomas, leukemias, and lung tumors (31). In addition, they may experience secondary macrophage activation syndrome, also known as reactive hemophagocytic lymphohistiocytosis, which is usually fatal. In general, about 10% of patients with multifocal disease die, 30% undergo complete remission, and the remaining 60% embark upon a chronic, shifting course (16,32).



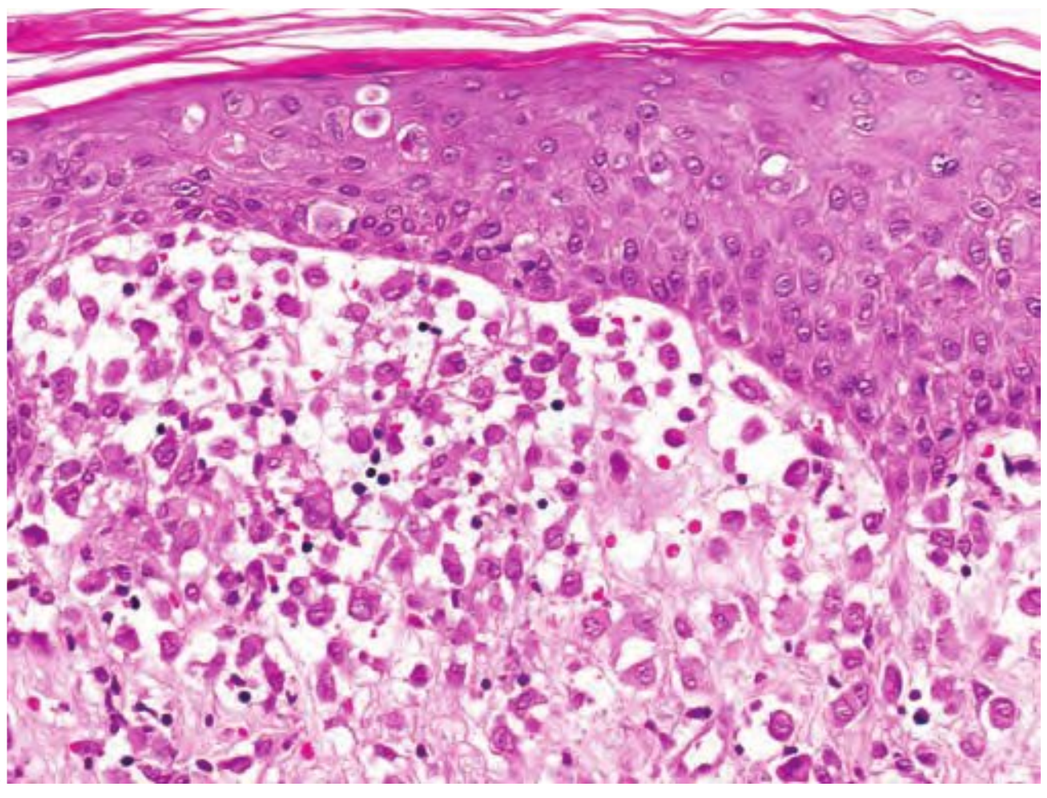
Histopathology. The histologic picture unites the many varied forms of LCD. The key to diagnosis is identifying the typical LCD cell in the appropriate surroundings. The cell has a distinct folded or lobulated, often kidney-shaped, nucleus. Nucleoli are not prominent, and the slightly eosinophilic cytoplasm is unremarkable. A variety of methods can be used to confirm the identity of such cells. For years the gold standard has been to use electron microscopy to search for the typical Birbeck or Langerhans cell granules. Today, S100 protein, CD1a, and langerin can all be identified using paraffin-fixed tissue. Langerin is every bit as specific as Birbeck granules.



Although Lever emphasized three kinds of histologic reactions in LCD —proliferative, granulomatous, and xanthomatous— only the first two are commonly seen. A relationship exists between the type of histologic reaction and the clinical type of disease. In general, the proliferative reaction with its almost pure LC infiltrate is typical of acute disseminated LCD and the granulomatous reaction of chronic focal or multifocal LCD, as the name eosinophilic granuloma suggests. The xanthomatous reaction is seen in Hand-Schüller-Christian disease but primarily in other organs, especially the meninges and bones. Xanthomatous lesions in the skin are decidedly rare (21).



The proliferative reaction is encountered in the skin in petechiae, as well as in almost translucent, hemorrhagic, or crusted papules. It is characterized by the presence of an extensive infiltrate of LC. The infiltrate usually lies close to or involves the epidermis, resulting in ulceration and crusting (Fig. 26-1A). Large, kidney-shaped tumor cells can be seen just below or even impinging on the epidermis (Fig. 26-1B). Staining with S100 protein, CD1a, or langerin shows both the normal and abnormal LC (Fig. 26-1C).



The nodules of CSHRH show densely aggregated LC with abundant eosinophilic cytoplasm (Fig. 26-1D). Some of the LC are large and form giant cells, with diameters up to 50 μm. In some cells, the cytoplasm has a "ground glass" appearance

responsible for the term "reticulohistiocyte," a morphologic pattern seen occasionally in LCD and commonly in macrophage disorders. CHRSH cannot be histologically separated from other lesions of LCD.

The granulomatous reaction is found most commonly in infiltrated plaques and nodules in the genital area, in the axillary region, or on the scalp, as well as in the soft tissue and bone lesions. Extensive aggregates of LC often extend deep into the dermis. Eosinophils are present in various quantities (Fig. 26-1E). Generally, they lie in clusters instead of being diffusely scattered and may develop into microabscesses. Irregularly shaped, multinucleated giant cells are occasionally seen. In addition, some neutrophils, lymphocytes, and plasma cells may be present. Frequently, extravasation of erythrocytes is found.

The uncommon xanthomatous reaction reveals in the dermis numerous foamy cells, as well as varying numbers of LC and some eosinophils. Multinucleated giant cells are frequently present. They are mainly of the foreign-body type but occasionally have the appearance of Touton giant cells. The S100 protein and CD1a staining is likely to be weak or even negative in the foamy cells.

A final question is that of malignant LCD ("malignant histiocytosis X;" not to be confused with malignant histiocytosis). The International Lymphoma Study group identified several examples of Langerhans cell sarcoma (33). In such instances, there may be nodal, extranodal, or systemic involvement by highly atypical LC with frequently mitoses and marked pleomorphism (34). Acute disseminated LCD can reasonably be argued to be a malignancy because it is progressive, destructive, and potentially fatal and shows clonality. Some cases have been identified with marked cytological atypia, including mitoses, and a poor clinical outcome (35–37). Unfortunately, most often the diagnosis has been made retrospectively; cellular morphology is a poor way to predict the course of LCD, except in the case of nodular, frankly anaplastic sarcomas or lymphomas, both of which are rare.

Visceral Lesions. The visceral lesions seen in LCD show the same three types of reactions just described for the skin. The organs most commonly affected are the spleen, liver, lungs, lymph nodes, and bones. In Hand-Schüller-Christian disease, the diabetes insipidus is caused by granulomatous infiltration of the hypothalamus-pituitary axis; the exophthalmos, by retroorbital accumulations of granulomatous tissue; and the multiple defects in the skull, by the osteolytic effect of granulomatous infiltrates. Pulmonary LCD typically occurs in adult smokers, but lung involvement can be seen in children with widespread disease, in whom it is a poor sign.

Pathogenesis. Although the key cell of LCD is very similar to a normal Langerhans cell, there may be subtle differences. The cell of LCD is immature and may express CD68 and HLA-DR in a paranuclear pattern. Birbeck granules are convincing proof of the relationship, but they are present in varying amounts in LCD. Particularly when dealing with a sparsely infiltrated dermatitic picture, the search can be frustrating. In denser infiltrates, one can usually readily find the characteristic organelles.

LCD is most often a clonal process. Different groups have studied female patients with the disease and used a variety of X-linked polymorphisms to demonstrate clonality (38,39). A loss of heterozygosity may also be detected; it appears more likely in high-risk lesions and in those from patients with multisystem disease (40). Despite these studies, many view LCD as a reactive process because of its tendency toward spontaneous remissions and its good response to mild, nontoxic therapeutic regimens. In a fascinating historical review, Nezelof and Basset, who identified the cell of then "histiocytosis X" as a LC, lamented that fact that discovering this association has provided few clues to what causes the disease (41).

Differential Diagnosis. The differential diagnosis for LCD varies with the histologic pattern. The most difficult situation is an early proliferative dermatitic lesion with little epidermotropism and few characteristic cells. Without adequate clinical background, it is easy to make the mistaken diagnosis of superficial perivascular dermatitis. One should keep LCD in mind in all biopsies of dermatitis from infants and freely employ the S100 protein stain for screening. When a nodule or tumor is present, the presence of eosinophils and the sheets of characteristic cells usually lead to the diagnosis. The cutaneous xanthomas are not distinctive, and whereas the foamy cells may stain weakly with S100 protein or CD1a, usually the surrounding infiltrate has enough positive cells to allow a diagnosis. Some cases of CSHRH may be clinically confused with the blueberry muffin syndrome, congenital leukemic infiltrates, or mast cell disease, but the microscopic picture brings clarity.

XANTHOGRANULOMA FAMILY

The xanthogranuloma family is the largest group of cutaneous histiocytic disorders. The source of xanthogranuloma cells is unclear; the two most often proffered candidates are macrophages and dermal/interstitial dendritic cells (42,43). Macrophages seem likely based on CD68 staining and the propensity for xanthomatous transformation (44). The main evidence for dermal/interstitial dendritic cells is FXIIIa positivity, but we question its specificity. Another explanation is alternate activation of macrophages leading to the expression of stabilin-1, a receptor that links exogenous signals to a variety of intracellular vesicular functions. Stabilin-1 can be identified by anti–MS-1 antibodies and seems to be a marker for cutaneous macrophage disorders, as compared to systemic ones (45). Finally, some have suggested that xanthogranuloma cells may arise from plasmacytoid dendritic cells/monocytes (46). We use the term macrophages for the rest of this chapter, fully recognizing that it may be incorrect in some instances.

Xanthogranulomas contain cells with a wide variety of morphologic characteristics, including vacuolated, xanthomatized, spindle-shaped, scalloped, and oncocytic cells (Fig. 26-2 and Table 26-4). A classic xanthogranuloma contains a mixture of these different cell types, but there are some disorders in which one cell type predominates; these disorders may

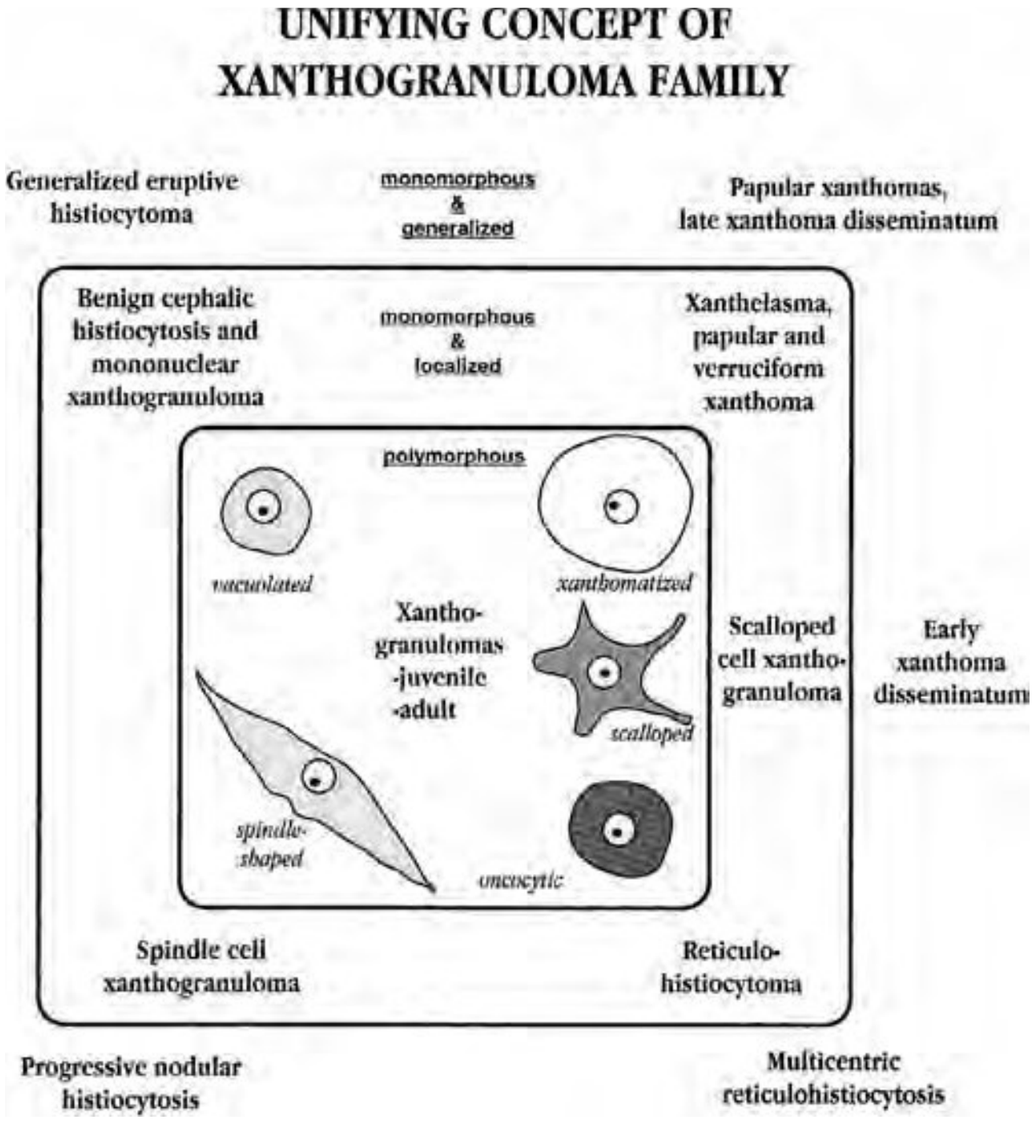

FIGURE 26-2. Unifying concept of the xanthogranuloma family.

be further divided into solitary and multiple forms, as the diagram shows (47).

Juvenile Xanthogranuloma

Juvenile xanthogranuloma (JXG) is a benign disorder in which one, several, or occasionally numerous red-to-yellow nodules are present. Because the lesions are also seen in adults, JXG is admittedly an imperfect term. Because we have used xanthogranuloma to describe a type of lesion and family of disorders, we prefer to retain the designation JXG for these specific lesions.

The papules and nodules are usually 0.5 to 1.0 cm in diameter. Most lesions appear during the first year of life; 20% are present at birth. In children the lesions may grow rapidly but almost always regress within a year. Lesions in adults are not uncommon but are usually solitary and persistent (48–50). JXG may be clinically subdivided into several forms. The micronodular variant is most common; patients are infants with many small nodules. Occasionally a macronodular form is seen with only a few lesions, but these are often several centimeters in diameter. The solitary giant xanthogranuloma may be larger than 5 cm (51). Plaques may also be seen, as well as prominent nasal involvement (the Cyrano sign) (52). There are also subcutaneous or deep JXG (53–55). On occasion JXG develops in patients with LCD; this probably reflects the similarities between the responsible cells.

A number of systemic complications are associated with JXG (56). Ocular involvement including glaucoma and bleeding into the anterior chamber is the most common; it occurs in less than 10% of young patients (57). Oral lesions may occur. An association between JXG, café-au-lait macules, neurofibromatosis I, and juvenile chronic myelogenous leukemia has been reported but must be rare (58,59). JXG has also been identified in many other organ systems, including the central nervous system, kidney, lungs, liver, testes, and pericardium.

In two large series, involving more than 300 patients in pediatric pathology referral centers, 5% of the patients had widespread systemic disease (48,49). These patients are at risk for infections and macrophage activation syndrome, and some may die. Although some of these children present with cutaneous disease, most do not. It is neither necessary nor wise to raise the specter of systemic involvement each time an infant or a child is seen with a solitary cutaneous JXG.

Bone involvement with JXG can be confusing. Erdheim-Chester disease is a rare macrophage disorder almost always seen in adults (mean age greater than 50 years) featuring symmetric lesions of the long bones associated with extraskeletal disease in 50% of cases (60–62). Skin is the third-most-common such site, after kidney and retroperitoneum. Typical findings include xanthelasmas (63) and occasionally red-brown papules or nodules suggesting JXG. The cells in Erdheim-Chester disease mark just as do any other JXG cells. The outlook for patients with extraskeletal diseases is poor, with most dying within 3 to 5 years from renal, cardiac, or pulmonary disease. Thus, when adults have apparent skeletal xanthogranulomas, one must be suspicious of this diagnosis. Rarely, children have been reported with the disease.

Spindle	Rarely seen
Vacuolated	Few

Histopathology: The typical JXG contains macrophages with a variety of cellular features (64). On low power, a well-circumscribed nodule, often exophytic and with an epidermal collarette, is found (Fig. 26-3A). Typically many of the stylized morphologic variants of macrophages can be seen. There is usually a characteristic progression as the lesions mature (65). Early lesions may show large accumulations of vacuolated cells without significant lipid infiltration intermingled with only a few lymphocytes and eosinophils (Fig. 26-3B). When no foamy cells or giant cells are seen, the possibility of JXG is often overlooked (66,67). This mononuclear variant of JXG is identical to lesions found in benign cephalic histiocytosis and generalized eruptive histiocytosis. Usually some degree of lipidization is present, even in very early lesions, manifested by pale cells. In mature lesions, a granulomatous infiltrate is usually present containing foamy cells, foreign-body giant cells, and Touton giant cells, as well as macrophages, lymphocytes,

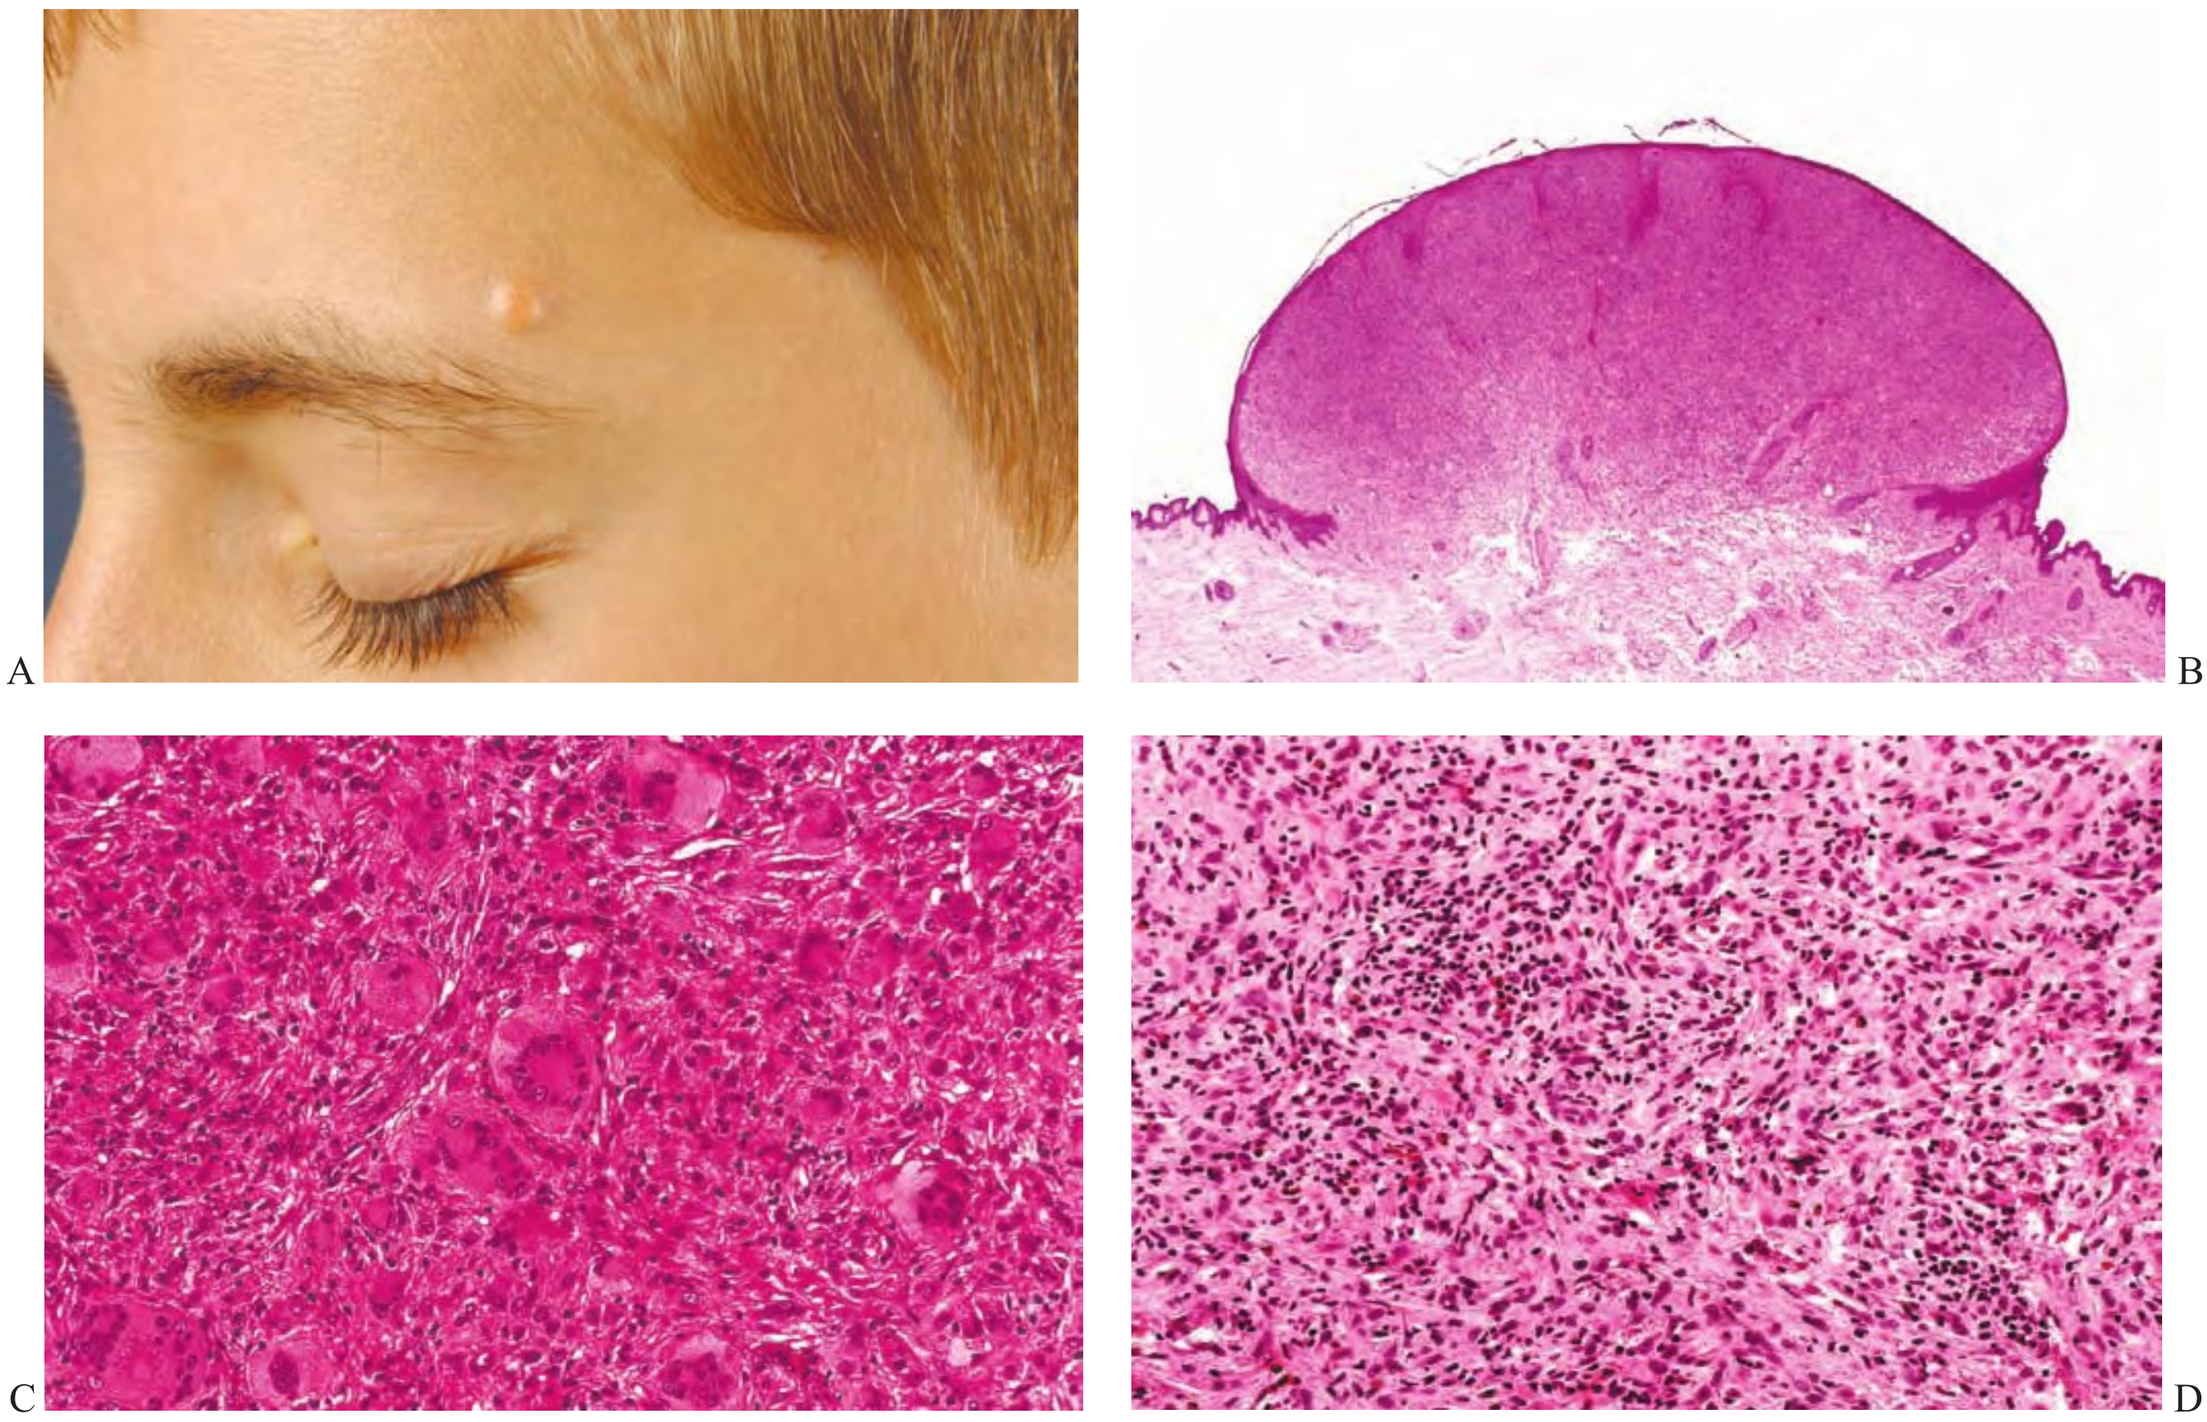

FIGURE 26-3. Juvenile xanthogranuloma. A: Yellow-brown nodule in a typical facial location in a child. B: Elevated nodule with epidermal collarette. At scanning magnification, a pale pink color and a few giant cells can be identified. C: Numerous Touton giant cells; cytoplasm within the wreath of macrophages is slightly more eosinophilic than that at the periphery. D: Numerous mononuclear macrophages admixed with eosinophils without Touton giant cells. (A: Courtesy of Wilfried Neuse, Düsseldorf, Germany.)

and eosinophils (68). The presence of giant cells, most of them Touton giant cells, showing a wreath of nuclei surrounded by foamy cytoplasm is quite typical for JXG (Fig. 26-3C) but not diagnostic because wreath-shaped giant cells can be seen in other disorders, including some melanocytic nevi. Occasionally, Touton giant cells are absent even in mature lesions. Older, regressing lesions show fibrosis replacing part of the infiltrate. Two types of spindle/dendritic cells may be identified; the spindle-cell or fusiform macrophages are dispersed throughout the lesion and are S100 protein negative. LC may be found as bystanders, generally at the periphery of the lesion.

Pathogenesis. The cause of JXG is unknown. The cell of origin is controversial, as discussed previously.

Differential Diagnosis. The clinical differential diagnosis includes Spitz nevi, mastocytomas, and dermatofibromas. The typical histologic picture of JXG is unmistakable. The many variants lead to a baffling array of diagnostic possibilities, which are considered under the individual variants.

Papular Xanthoma

Papular xanthomas (PX) are small red-brown papules often with a yellowish hue. Patients present with one, several, or many papules (69,70). Although the lesions may be generalized, they have neither the distribution pattern of xanthoma disseminatum nor the confluence of diffuse normolipemic plane xanthoma. Plaques are not seen. The patients show no abnormalities of lipid metabolism. Most patients are adults, but occasional cases have been seen in children (71,72). The oral mucosa may be involved.

Histopathology. Nodules containing foamy cells with numerous Touton giant cells are seen in the dermis. Extracellular lipids are not seen. Even when early lesions are biopsied, xanthomatized cells predominate, with only a small component of mononuclear vacuolated macrophages or other cell types (Fig. 26-4A, B).

Pathogenesis. Why some macrophages become xanthomatized in the presence of normal serum lipid levels is not known. Despite the early definition of papular xanthoma as a macrophage disorder without a macrophage precursor phase,

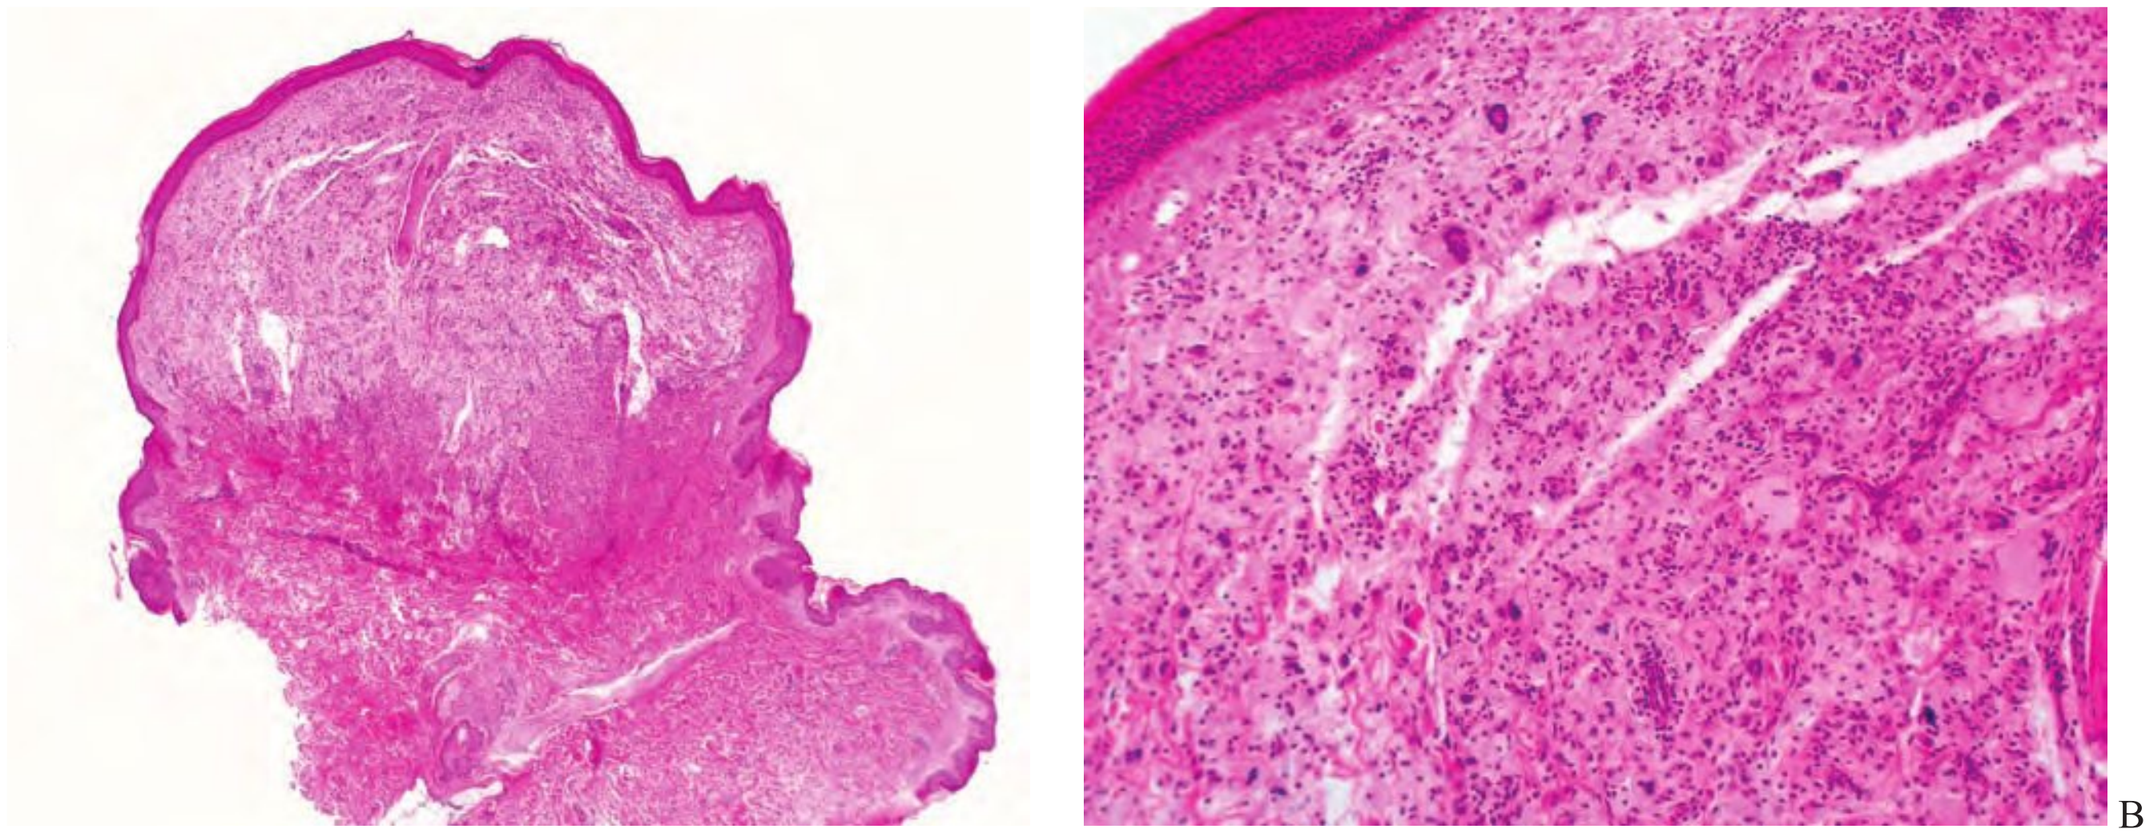

FIGURE 26-4. Papular xanthoma. A: Pale papule without epidermal reaction or clefting. B: Numerous foamy macrophages and Touton giant cells. Extracellular lipids are not present.

there must be macrophages present initially that rapidly become xanthomatized. Neutrophilic papular xanthomas have been described in normolipemic patients with HIV/AIDS. They may develop following similar pathways to the paraneoplastic xanthomas secondary to the massive changes in lymphocyte proliferation. These xanthomas contain neutrophils and nuclear dust in addition to foamy cells.

Differential Diagnosis. Papules made up of predominately foamy cells may also be associated with elevated lipid levels or be a paraneoplastic marker, as in diffuse normolipemic plane xanthoma. Solitary lesions may be mistaken clinically for dermatofibroma, Spitz nevus, and a variety of other benign proliferations.

Scalloped Cell Xanthogranuloma

Scalloped cell xanthogranuloma is not clinically distinct. We identified a number of lesions in which the predominant macrophage is scalloped once we had become aware of this morphologic variant in xanthoma disseminatum and began searching for solitary lesions to fill in our unifying concept scheme (73). The lesions are typically on the head, neck, or back of young men and may be diagnosed as juvenile xanthogranuloma or, less often, melanocytic nevus or basal cell carcinoma. Histologically, scalloped macrophages predominate, although a mélange of other macrophage types may be found (Fig 26-5A, B).

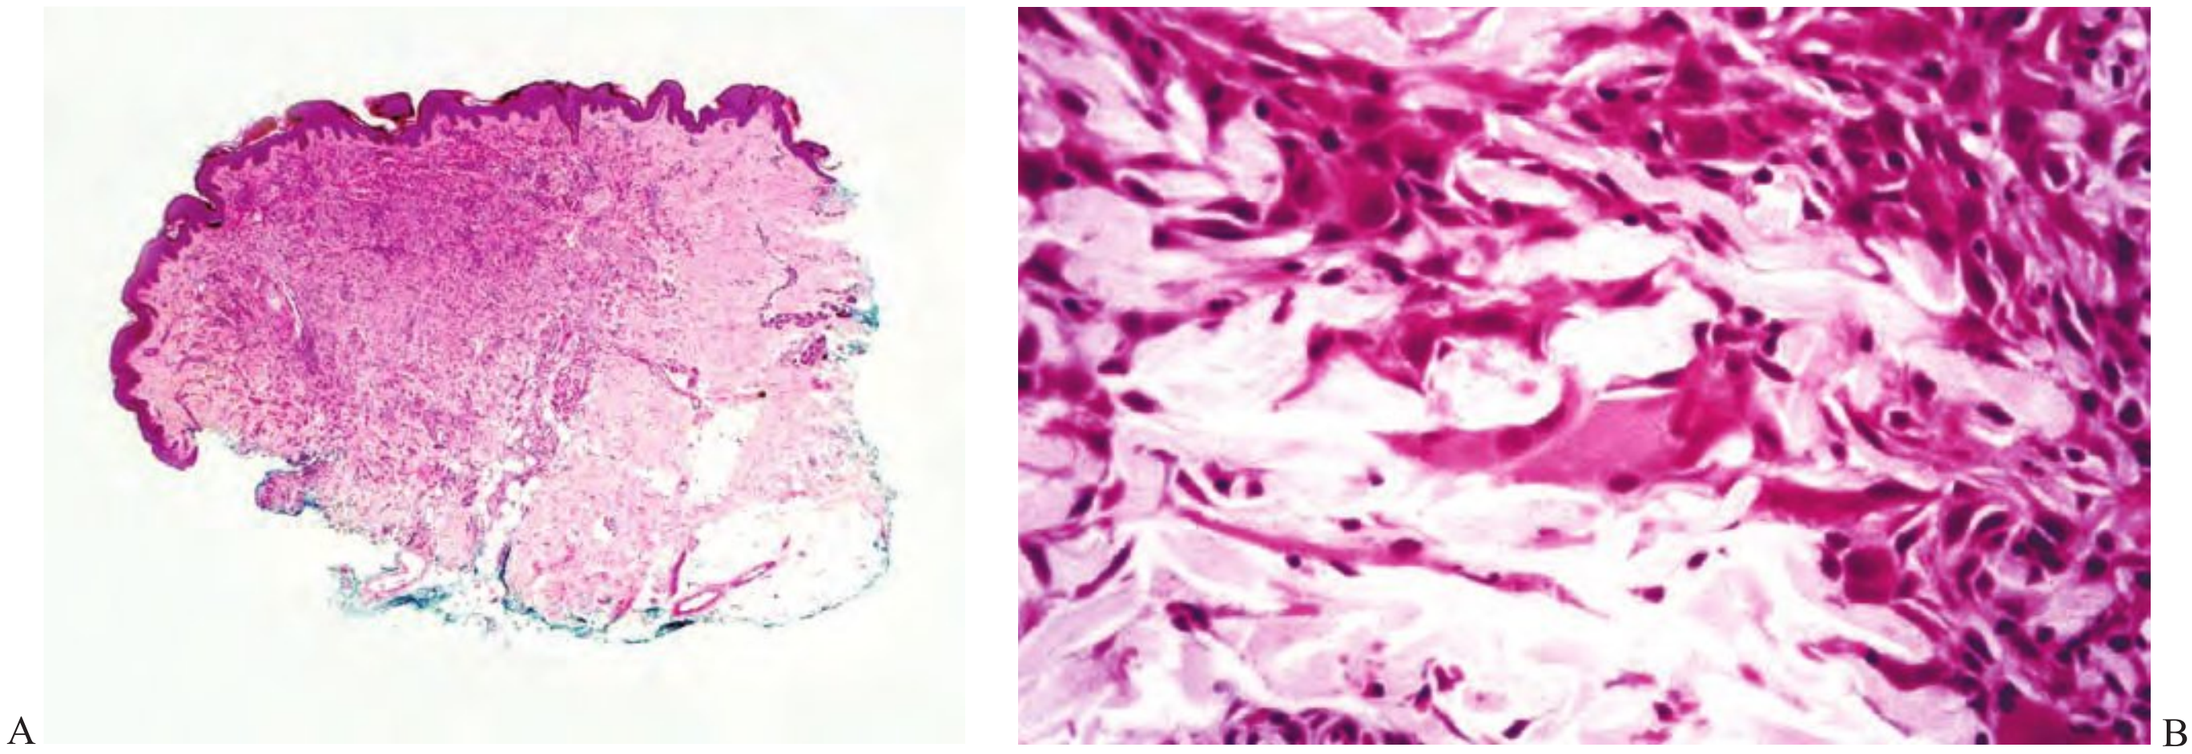

FIGURE 26-5. Scalloped cell xanthogranuloma. A: Small, well-circumscribed dermal nodule without obvious giant cells or pale areas. B: Pale scalloped macrophages seen at the base of the infiltrate. Such cells can also be found in the early lesions of xanthoma disseminatum.

Xanthoma Disseminatum

Xanthoma disseminatum (XD) is a rare but distinctive disorder featuring numerous widely disseminated but often closely set and even coalescing, round to oval, orange or yellow-brown papules and nodules. Lesions are found mainly on the flexor surfaces, such as the neck, axillae, antecubital fossae, groin, and perianal region. Peculiar target lesions may be seen. Often there are lesions around the eyes. The mucous membranes are affected in 40% to 60% of cases. In addition to oral lesions, there may be pharyngeal and laryngeal involvement. Three patterns have been identified; the most typical is the persistent form. Rarely, lesions may regress spontaneously, and even more infrequently in the progressive form there may be significant internal organ involvement. The largest review (74) suggests that most cases begin in childhood, where the diagnosis can be problematic, as, for example, in an infant with mucosal and pituitary lesions. We have only seen the disease in adults.

Diabetes insipidus is encountered in about 40% of cases but usually is less severe than that associated with LCD. Characteristically, internal lesions other than diabetes insipidus are absent. In a few instances multiple osteolytic lesions have been found, especially in the long bones, as well as lung and central nervous system infiltrates.

Histopathology. In early lesions, scalloped macrophages dominate the histologic picture, with few foamy cells. More-developed lesions may still show scalloped cells, but xanthomatization occurs in most cases. Most well-developed lesions contain a mixture of scalloped cells, foamy cells, and inflammatory cells, as well as Touton and foreign-body giant cells (Fig. 26-6) (75).

Pathogenesis. In the past, some authors assumed a relationship between XD and LCD. Although in both conditions xanthomatous lesions and diabetes insipidus may occur, XD occurs in older patients, often has mucosal involvement, and only rarely involves bone. Finally, xanthomatous lesions are expected in XD and rare in LCD.

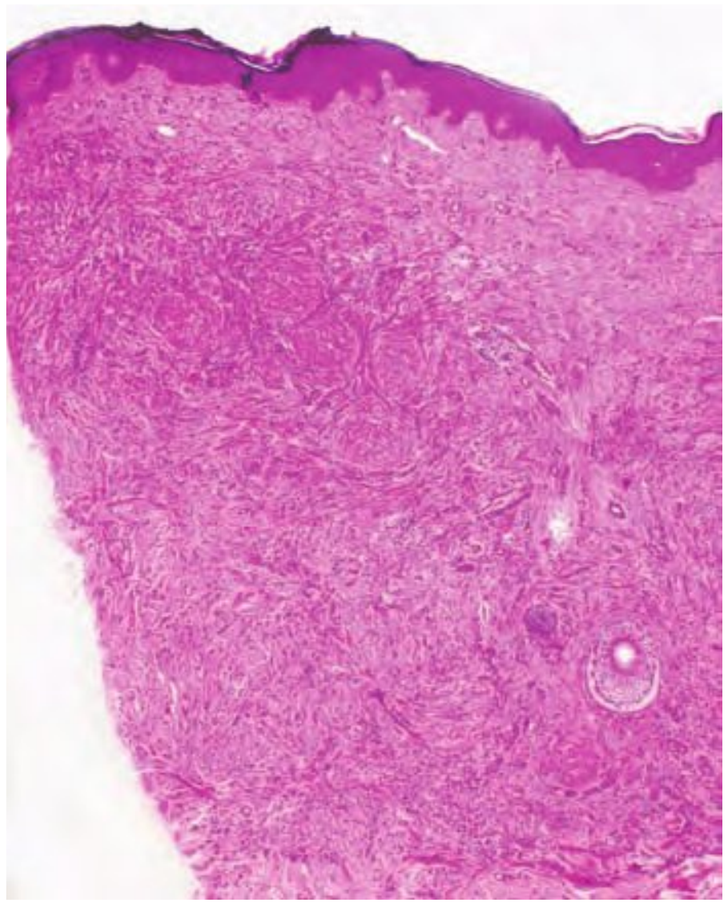

FIGURE 26-6. Xanthoma disseminatum. Combination of spindle cells in the upper dermis and foam cells deeper.

Reticulohistiocytosis and Multicentric Reticulohistiocytosis

We divide what has traditionally been called reticulohistiocytosis into giant cell reticulohistiocytoma (GCRH) and multicentric reticulohistiocytosis (MRH). Both disorders occur almost exclusively in adults. The histologic picture is very similar in the two types, but everything else is different.

GCRH is simply a xanthogranuloma in which the oncocytic macrophages and "ground glass" giant cells predominate. It is never clinically unique but diagnosed as a JXG or dermatofibroma. The clinical features, distribution, and course are identical to those of JXG (76). In greater than 90% of cases, the lesion is single, but occasionally multiple lesions are seen (77). Even patients with multiple lesions show no sign of systemic involvement. The newly suggested term of solitary epithelioid histiocytoma (78) may cause confusion with dermatofibroma/histiocytoma, and so we prefer not to use it.

In multicentric reticulohistiocytosis, a name first coined by Goltz and Laymon (79), the patients tend to be females, usually in the fifth or sixth decade of life, with widespread cutaneous involvement and a destructive arthritis (80–82). Nodules ranging in size from a few millimeters to several centimeters are most common on the extremities. Multiple papules on the face may coalesce, producing a leonine facies. Many small papules along the nail fold create the "coral bead sign." In about half of the patients, nodules are present also on the oral or nasal mucosa. Finally, about 25% also have xanthelasmas.

The polyarthritis may be mild or severe but is almost always present. It may be mutilating, especially on the hands, through destruction of articular cartilage and subarticular bone. In addition, there is an association with hyperlipidemia (30% to 50%), a variety of internal malignancies (15% to 30%) (83,84), and autoimmune diseases (5% to 15%). The disease tends to wax and wane over many years (85).

Histopathology. The characteristic histologic feature in both GCRH and MRH is the presence of numerous multinucleate giant cells and oncocytic macrophages showing abundant eosinophilic, finely granular cytoplasm, often with a "ground glass" appearance (Fig. 26-7A, B). There may be subtle microscopic differences between solitary and multiple lesions (86). In older lesions giant cells and fibrosis are more common. Staining for vimentin and CD45 also appears common, whereas FXIIIa is usually negative (87). Some lesions have been described sharing features with dendritic cells (88).

The polyarthritis present in nearly all instances of MRH is caused by the same type of infiltrate as found in the cutaneous lesions. In early or mild cases, the granulomatous infiltrate is confined to the synovial membrane. Although similar infiltrates have been described in other organs, their clinical significance is unclear.

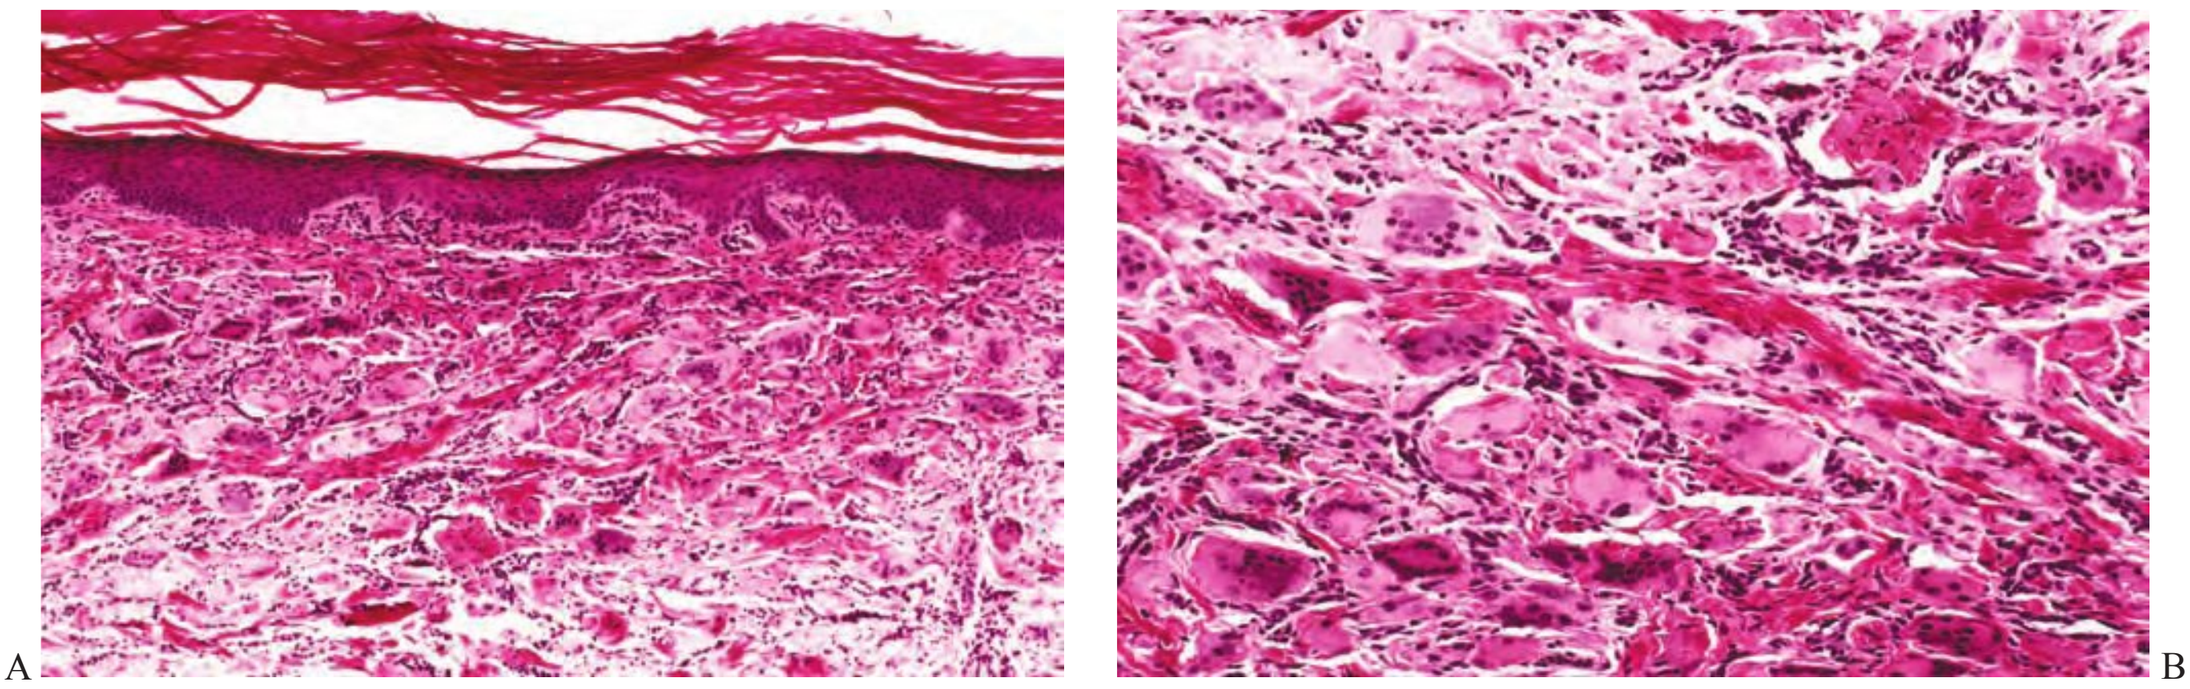

FIGURE 26-7. Multicentric reticulohistiocytosis. A: A diffuse dermal giant cell infiltrate with sparse inflammation and a thinned epidermis. B: Relatively clear giant cells with finely granular cytoplasm ("milk glass" appearance) replacing the upper dermis. The giant cells are large and irregular, containing many haphazardly arranged nuclei.

Pathogenesis. Ultrastructural examination shows abundant mitochondria and lysosomes, which correlate with the ground glass appearance. Similar changes are found in oncocytic thyroid and renal tumors. The cause of the solitary lesions is unknown, just as with JXG.

Differential Diagnosis. It is futile to try and distinguish between a solitary GCRH and JXG. The two lesions are part of a spectrum, and overlaps occur. A single macrophage lesion with ground glass cytoplasm does not make the diagnosis of MRH but instead should simply be viewed as having the same clinical significance as JXG. The clinical differential diagnosis of MRH is lengthy, but a skin biopsy is quite helpful in pointing one in the right direction. Gout, rheumatoid arthritis, sarcoidosis, dermatomyositis, and even lepromatous leprosy may be considered (89).

Spindle Cell Xanthogranuloma

Spindle cell xanthogranulomas are not clinically distinct. They are usually on the head or neck of young adults and identified as JXG or dermatofibromas (90). Deep spindle cell xanthogranulomas may cause puzzlement; in one case, a woman presented with cutaneous JXG and later developed spindle cell xanthogranuloma of the breast (91). Histologically they are even more likely to be misdiagnosed, usually as dermatofibromas or blue nevi. Microscopically they lack melanin and do not have reactive changes in the overlying epidermis or lateral entrapment of collagen so typical of dermatofibromas (Fig. 26-8A, B). They stain with the typical macrophage stains, but also for FXIIIa and smooth muscle actin.

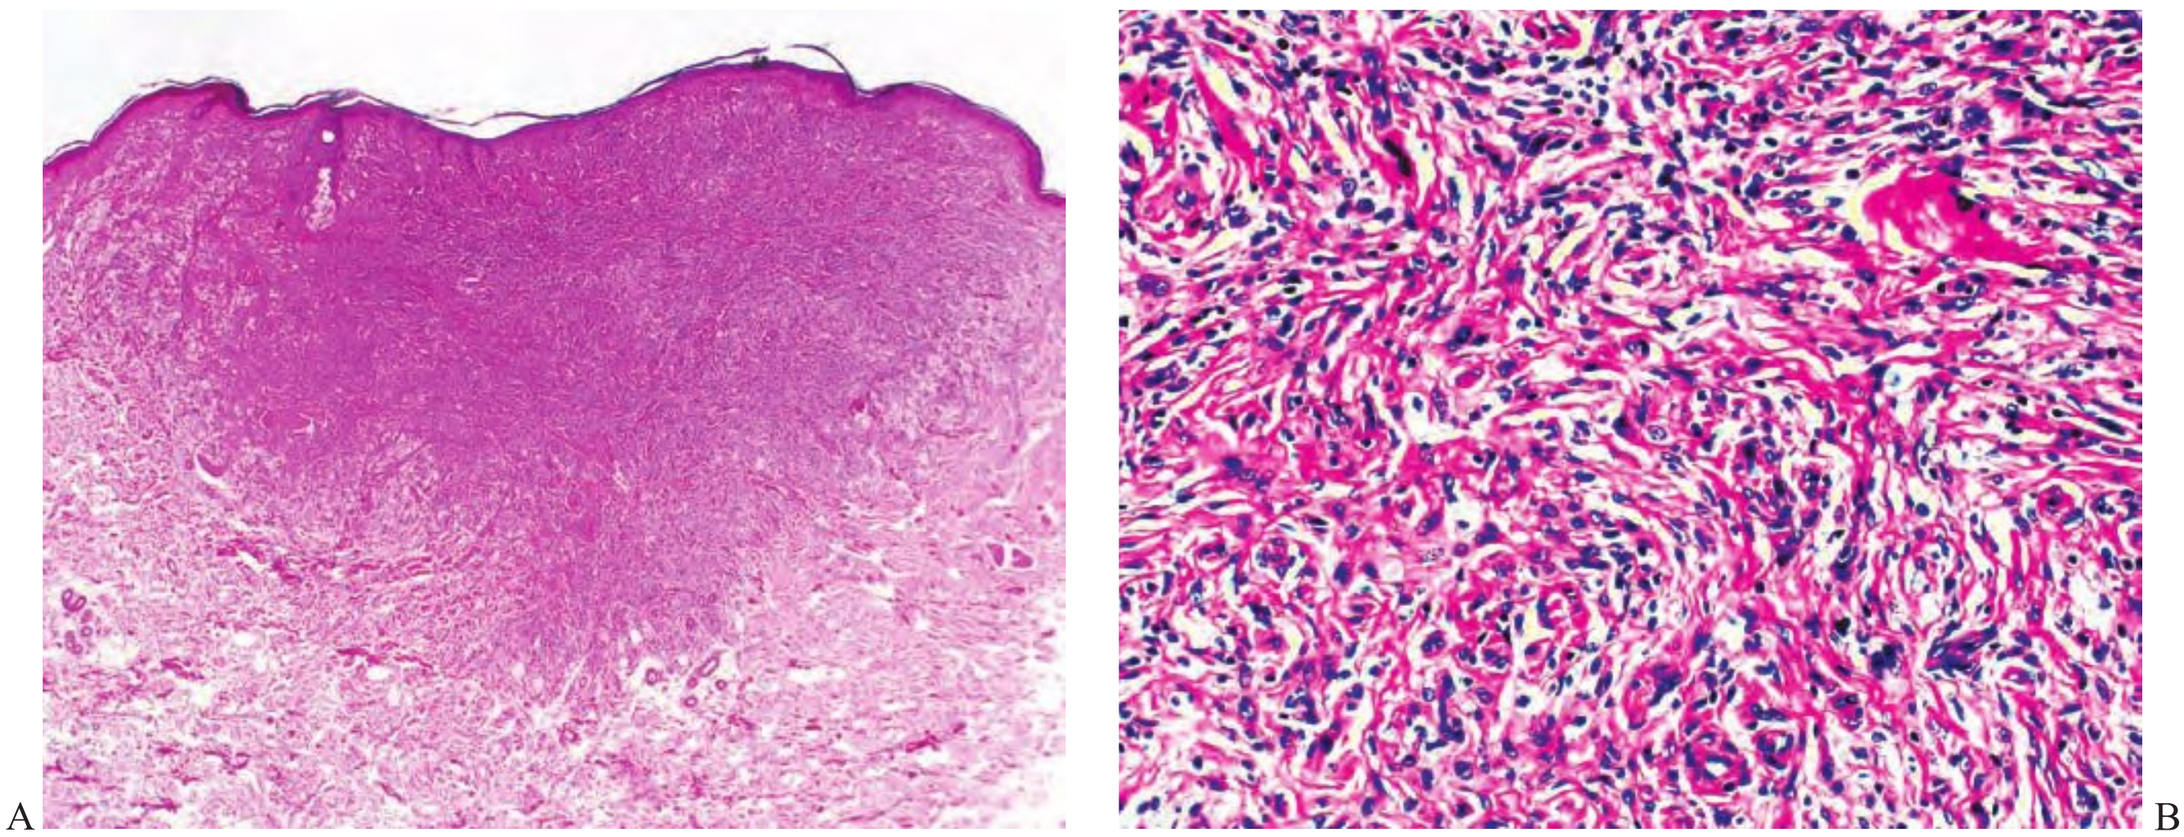

FIGURE 26-8. Spindle cell xanthogranuloma/progressive nodular histiocytosis. A: Dermal nodule with storiform pattern. No evidence of epidermal reaction or peripheral entrapment of collagen. B: Spindled macrophages admixed with a few foamy cells. The lesion was from a patient with progressive nodular histiocytosis.

Progressive Nodular Histiocytosis

Progressive nodular histiocytosis is a rare, clinically distinct disorder. Patients typically have hundreds of lesions of two types: superficial xanthomatous papules 2 to 10 mm in diameter and deep fibrous nodules 1 to 3 cm in diameter. The key to diagnosis lies in these two distinct lesions (92,93). Conjunctival, oral, or laryngeal lesions may occur, as well as rare systemic lesions (94,95). Lesions rarely if ever regress. Familial or congenital cases have not been reported.

Histopathology. Two patterns can be recognized that correlate with the clinical lesions. The smaller papules are xanthomatous with foamy cells and occasional Touton giant cells; they are papular xanthomas. The larger nodules are spindle cell xanthogranulomas (Fig. 26-8A, B).

Differential Diagnosis. When the distinctive clinical picture is present, the diagnosis of progressive nodular histiocytosis should be considered, but no harm is done if the patient is diagnosed with multiple JXG.

Benign Cephalic Histiocytosis

Benign cephalic histiocytosis is a self-healing eruption usually limited to the skin (96). The eruption usually starts during the first 3 years of life and is almost always on the face, although it may become generalized (Fig. 26-9A). The lesions consist of red-to-yellow papules, which after a few years become flat and pigmented and finally resolve. There are overlaps with multiple JXG (97,98). Systemic involvement is rare (99,100).

Histopathology. The infiltrate tends to be sparse and consists of macrophages with regularly shaped nuclei and sparse cytoplasm. Three patterns have been observed: papillary dermal, lichenoid, and diffuse (101). The papillary dermal pattern is most common; there is a cohesive infiltrate of macrophages in the upper

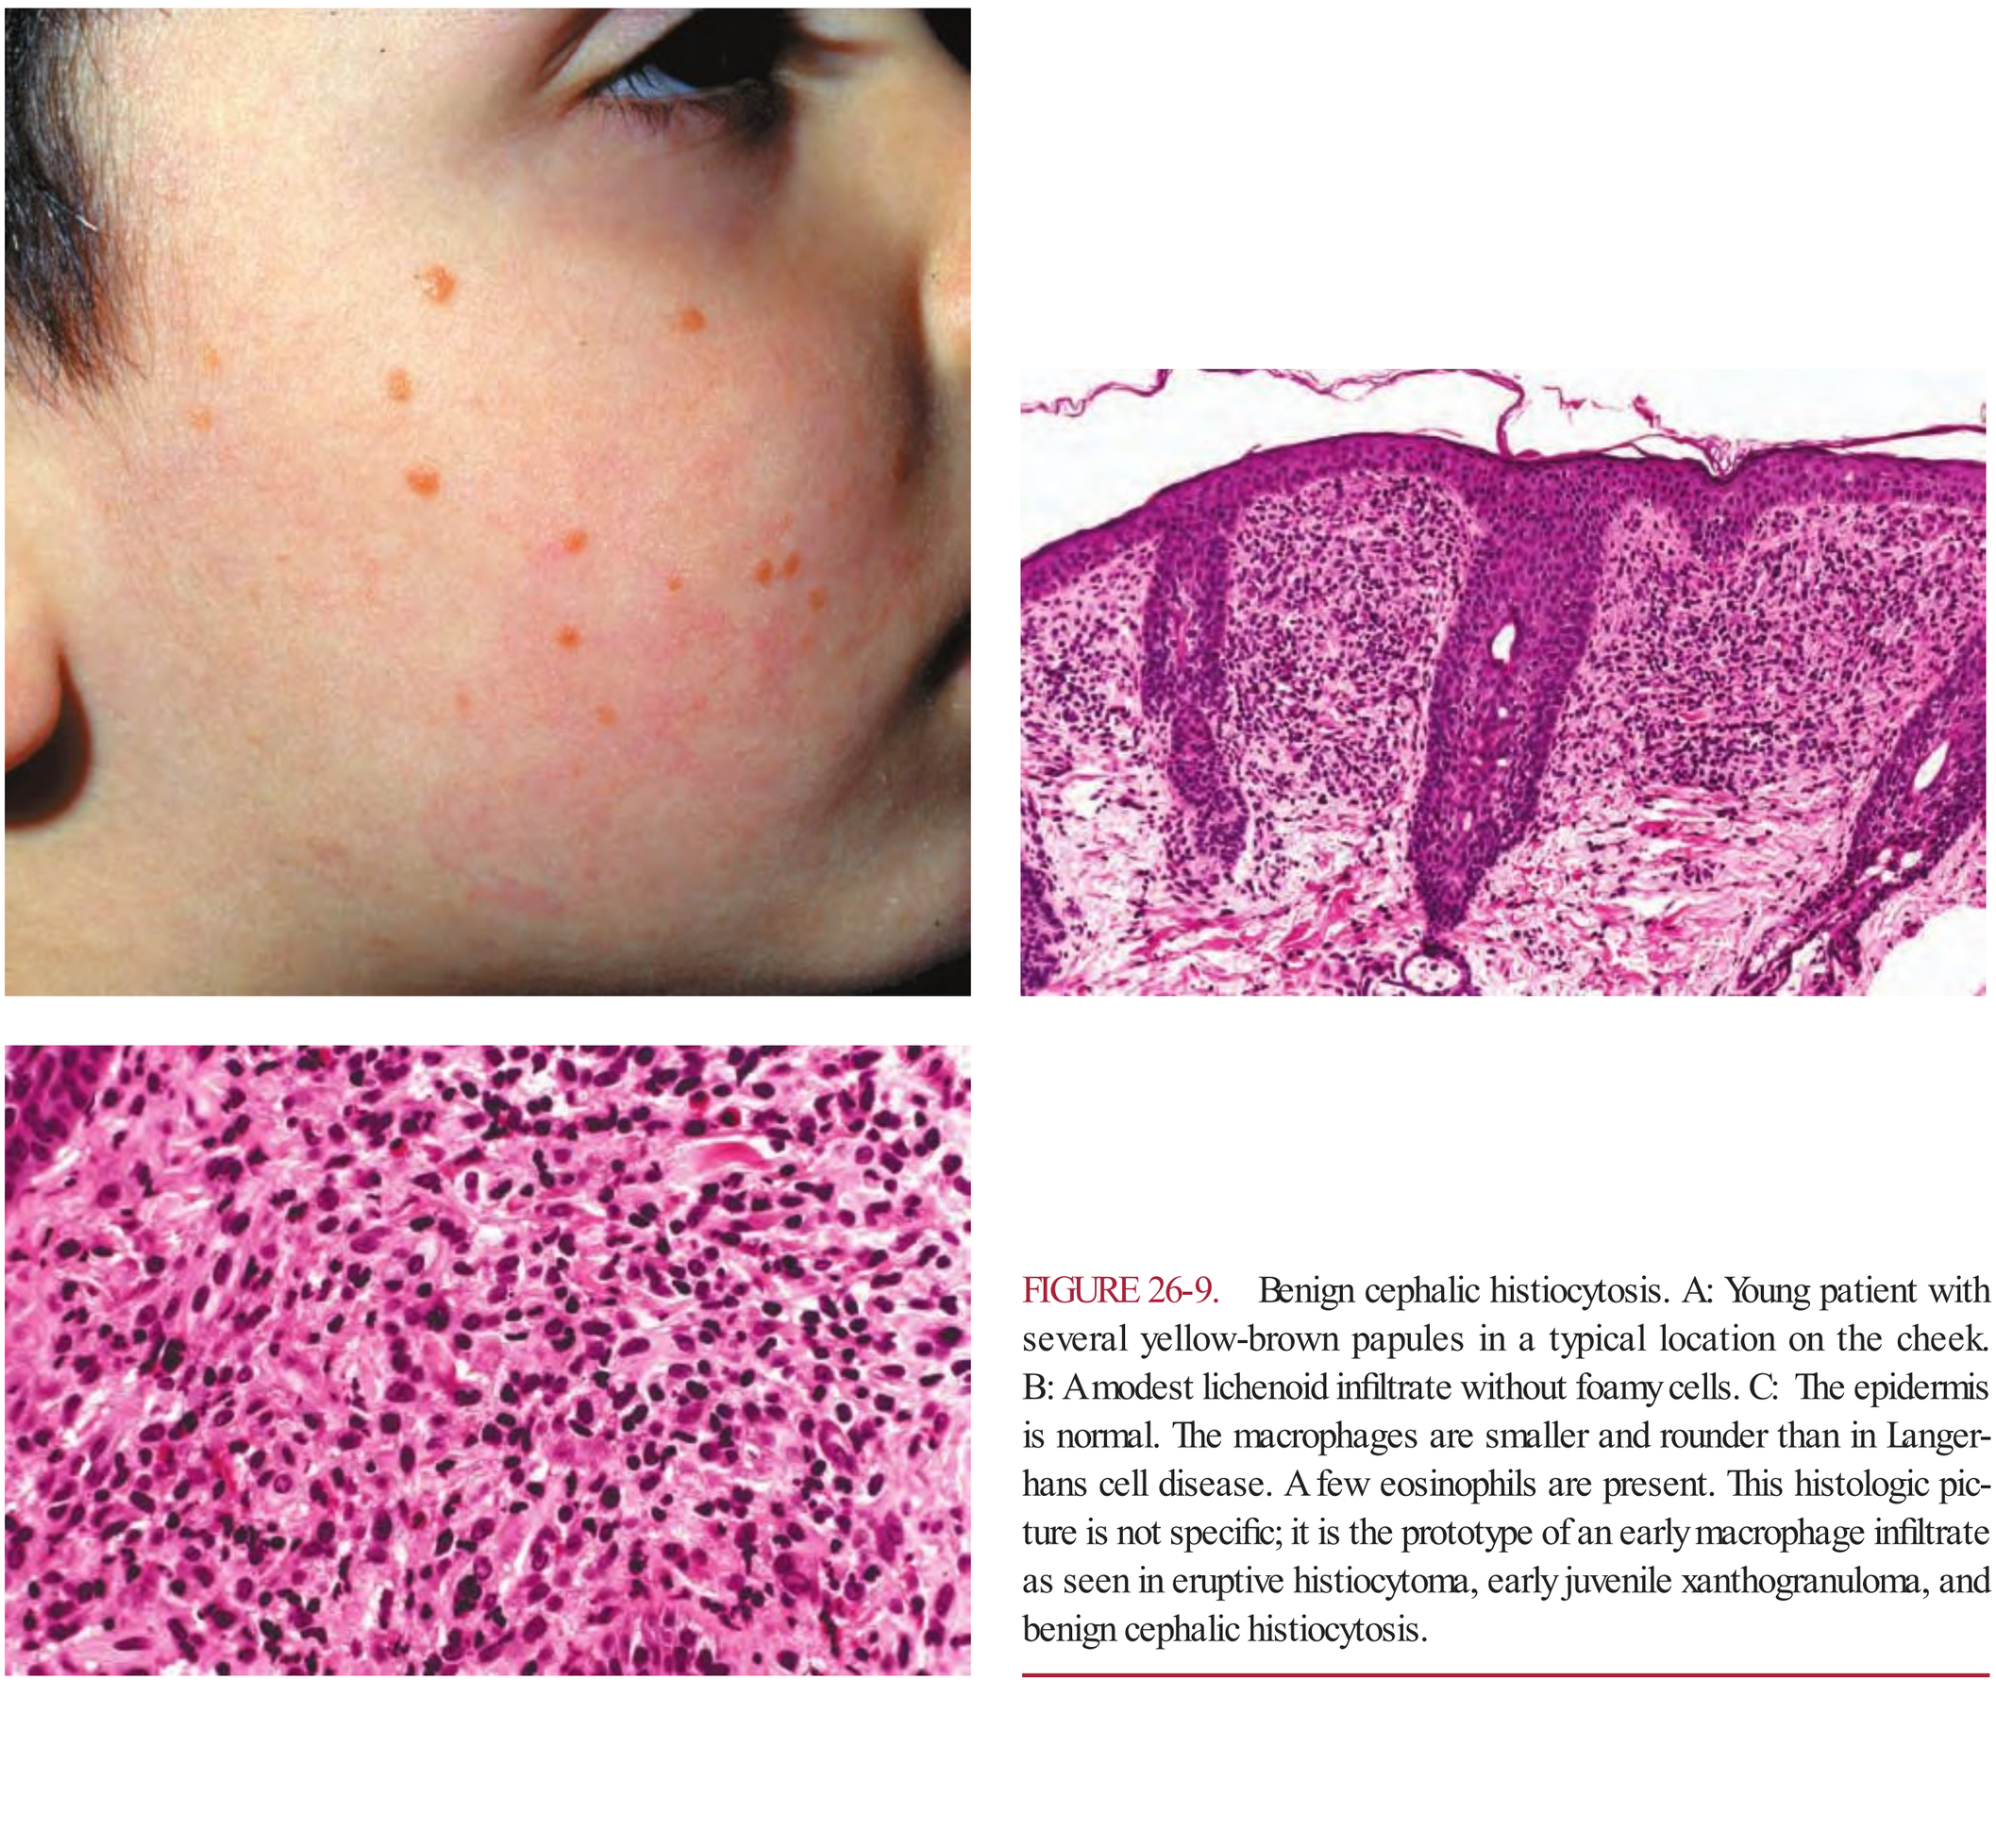

FIGURE 26-9. Benign cephalic histiocytosis. A: Young patient with several yellow-brown papules in a typical location on the cheek. B: A modest lichenoid infiltrate without foamy cells. C: The epidermis is normal. The macrophages are smaller and rounder than in Langerhans cell disease. A few eosinophils are present. This histologic picture is not specific; it is the prototype of an early macrophage infiltrate as seen in eruptive histiocytoma, early juvenile xanthogranuloma, and benign cephalic histiocytosis.

dermis. The cells tend to be large and have an eosinophilic cytoplasm. Foamy cells and epidermotropism are rare; eosinophils are often seen. The diffuse pattern is a minor variant in which the macrophages are sparser and spread throughout the dermis. The lichenoid pattern is easily confused with LCD, but the nuclear changes seen in the latter are not present; crusting and ulceration are also uncommon (Fig. 26-9B, C).

Pathogenesis. The cause of BCH is unknown.

Differential Diagnosis. It is most important to exclude LCD because clinical distinction can on occasion be difficult. Benign cephalic histiocytosis overlaps with generalized eruptive histiocytosis, progressive nodular histiocytosis, papular xanthomas, and multiple JXG. In an instructive case, a child with BCH developed more typical JXG after varicella infection with facial involvement. If the lesions are clinically typical, the diagnosis can be made with some confidence.

Generalized Eruptive Histiocytosis

Generalized eruptive histiocytosis may represent the initial stage of a variety of macrophage disorders, including JXG, xanthoma disseminatum, multicentric reticulohistiocytosis, and progressive nodular histiocytosis (47). Clinically it is characterized by the presence of innumerable flesh-colored to red macules and papules that develop in crops and may involute spontaneously (102). The disease takes a variable course; it may persist, remit, or relapse. As the infiltrates regress, the lesions may evolve into hyperpigmented macules. Although most patients are adults, the condition may arise in infancy (103,104). In rare instances, oral lesions have been observed. There may be an associated underlying disorder, such as a malignancy (105); the eruption may improve when the malignancy is treated (106).

Histopathology. Histologic examination reveals an infiltrate composed of various types of macrophages; most often small vacuolated cells are seen in a perivascular arrangement, but other morphologic variants may be represented or even dominate. Multinucleated giant cells are usually absent (107).

Pathogenesis. The etiology is unknown. These cells appear so rapidly that it is not surprising that they are often undifferentiated. Older lesions may show fibrosis or giant cells. The macrophages may in some cases appear in response to cytokines released by neoplasms, but in general their appearance remains unexplained.

Differential Diagnosis. The sudden onset and the lack of foamy cells or giant cells should suggest the diagnosis.

OTHER HISTIOCYTIC DISORDERS

Indeterminate Cell Histiocytosis

The diagnosis of indeterminate cell histiocytosis (ICH) was first proposed by Wood et al. when they reassessed a previously reported case (108). Clinically, most patients show numerous persistent red-brown papules or nodules that may coalesce.

Histopathology. The histologic picture is quite variable. Most commonly a monomorphous infiltrate of mononuclear cells intermingled with some giant cells and foamy cells is found. In our hands, these cases are positive for S100 protein and CD68, as well as showing focal CD1a reactivity (109). Other lesions more closely resemble LCD but lack the appropriate markers.

Pathogenesis. We do not consider ICH as a single specific entity. In addition, most cases described as ICH have little to do with the several different cells described as indeterminate cells. We suspect that most cases are macrophage disorders—variants of xanthogranuloma in which the predominant cell is derived from an earlier or aberrant lineage (110,111). Other cases, such as those resembling CSHRH, are clearly variants on LCD. Some examples of ICH may be reactive; such infiltrates have been described in nodular scabies (112) and after pityriasis rosea (113). A spindle cell variant has also been described (114).

Dermal Dendrocytoma

Both congenital (115,116) and acquired (117) lesions have been described that feature dermal dendrocytes. Because the available markers have changed greatly over the two decades during which the handful of cases have been described, there is no unifying pattern. In general, there have been dermal spindle cells staining for FXIIIA, fascin, vimentin, and CD34. We suspect that most of these cases represent dermatofibromas or spindle-cell xanthogranulomas.

Rosai-Dorfman Disease

The term "sinus histiocytosis with massive lymphadenopathy" was first used by Rosai and Dorfman in 1969 (118), although Destombes had previously described the disorder in Africa. Massive cervical lymphadenopathy, usually bilateral and painless, is the most common manifestation. Rosai-Dorfman disease (RDD) is generally a benign disorder in spite of its propensity to form large masses and to disseminate to both nodal and extranodal sites. In most patients the disease resolves spontaneously, others have persistent problems, and very few die (119). About 10% of patients with nodal disease have cutaneous involvement. The lesions are typically papules or nodules. The skin and subcutaneous soft tissue are also the most common sites of involvement when patients present with extranodal disease. Such individuals may represent a separate but closely related disorder because very few advance to nodal or systemic disease (120–125). Occasionally the soft tissue lesion may present as a breast mass or panniculitis (126).

Histopathology. The skin lesions contain a polymorphous infiltrate in which lymphocytes and macrophages with clear cytoplasm are most prominent. The low-power view has been compared to that of a "lymph node in the skin" (Fig. 26-10A, B). Occasionally they may be multinucleated or have a foamy

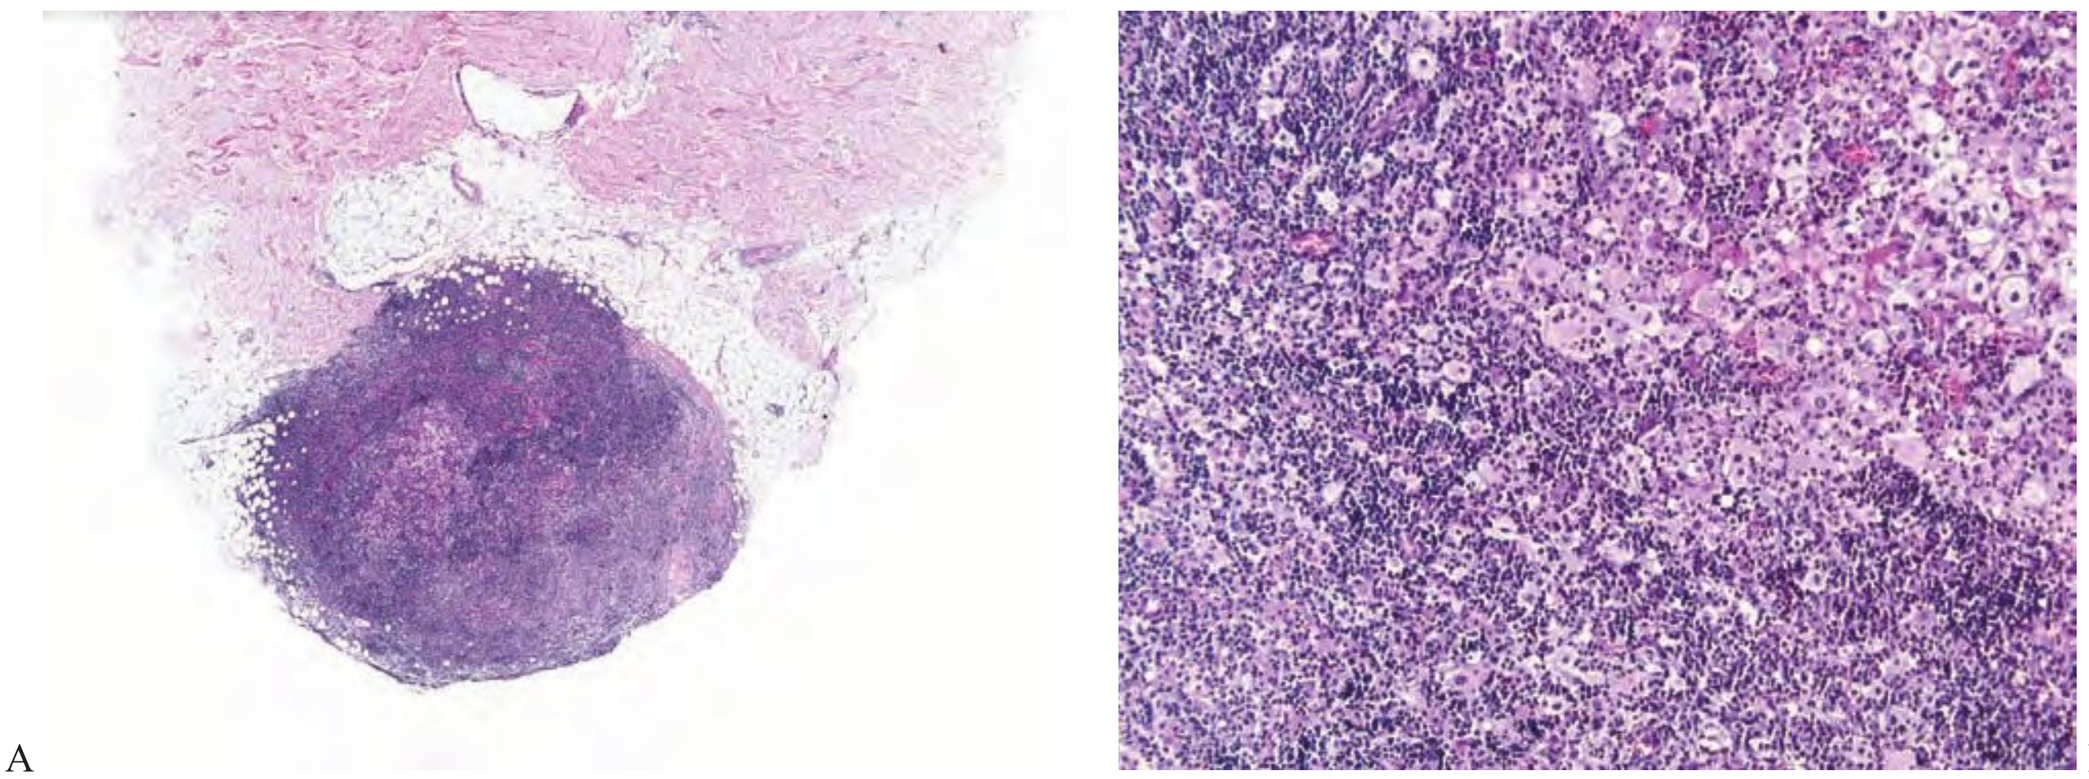

FIGURE 26-10. Sinus histiocytosis with massive lymphadenopathy. A: Subcutaneous nodular infiltrate rich in pale-staining cells centrally. B: Typical pattern of pale sinusoidal macrophages admixed with darker-staining lymphocytes. C: Numerous large macrophages, several of which have ingested lymphocytes, demonstrating emperipolesis. (All courtesy of Michael Flaig, Munich, Germany.)

cytoplasm. The hallmark histologic feature is emperipolesis of lymphocytes (Fig. 26-10C, inset). Emperipolesis differs slightly from phagocytosis in that the lymphocytes are taken up but seem not to be attacked and digested by enzymes. Thus they appear intact. On occasion, red cells can also be taken up. There are also often plasma cells, sometimes leading to deposits of crystalline immunoglobulins. In the lymph nodes, the sinuses are greatly dilated and crowded with inflammatory cells, particularly macrophages. Here they tend to have an abundant foamy cytoplasm and also display emperipolesis. The lymph node changes in autoimmune lymphoproliferative syndrome with defects in Fas-mediated apoptosis are very similar to those of RDD.

Pathogenesis. The cells are unusual activated macrophages that are positive for CD68, other macrophage markers, and fascin but are also S100 protein positive. They are CD1a and langerin negative. Over the years a variety of viruses have been implicated as triggers, including most recently parvovirus B19 (127). The lymph node changes resemble those in patients with autoimmune lymphoproliferative syndrome (128).

HISTIOCYTIC SARCOMA

Even though malignant tumors of macrophage lineage are rare, they are occasionally encountered in the skin. The large International Lymphoma Study Group identified 18 such cases, with 3 involving the skin, both with solitary and multiple lesions (33). There were also 3 cases of widespread systemic disease, corresponding to the old term of malignant histiocytosis. The tumors consist of large cells with frequent mitoses and varying degrees of pleomorphism. Multinucleate giant cells, foamy cells, and spindle-shaped cells may be encountered. Erythrophagocytosis is absent or inconspicuous, whereas emperipolesis is even rarer. The diagnosis must be supported by CD68 positivity, which is also accompanied by positive lysozyme staining in 90% of cases. Other macrophage markers

may also be positive, as well as S100 protein. Markers for dendritic cells, T cells, and B cells must be negative. Rare cases with overlap phenotypes have been reported (129). On electron microscopy, lysosomes are found but Birbeck granules and desmosomes are absent. Histiocytic sarcoma is an aggressive disease; only patients with solitary extranodal disease such as a single skin lesion are occasionally cured.

XANTHOMAS ASSOCIATED WITH LIPID ABNORMALITIES

Even though we place xanthomas among the macrophage disorders, we have left those associated with lipid abnormalities as a separate category because they are generally viewed as such by both clinicians and pathologists. Xanthomas are a cutaneous clue to the possible presence of hyperlipidemia, defined as an elevated fasting cholesterol level of greater than 200 mg/dL or a triglyceride level of greater than180 mg/dL. Today the high-density-lipoprotein (HDL)-cholesterol is also measured and used to calculate the low-density-lipoprotein (LDL)-cholesterol level. The desirable LDL-cholesterol level is less than 130 mg/dL. If abnormalities are detected, lipoprotein analysis is also usually performed. Hyperlipidemia may be unexpectedly identified during routine evaluations or searched for because of a family history of lipid abnormalities, cardiovascular disease, or the presence of one of its many secondary causes.

Once hyperlipidemia is identified, one must first exclude these secondary causes, which include diabetes mellitus, hypothyroidism, nephrotic syndrome, biliary disease, alcohol abuse, and a variety of medications, including estrogens, corticosteroids, and retinoids. In the 1960s Frederickson classified the primary hyperlipidemias on the basis of their electrophoretic lipoprotein phenotype. He considered not just cholesterol and triglycerides, but also the main lipoprotein classes in which they were transported throughout the body—chylomicrons, very low-density lipoproteins (VLDLs), LDLs, and HDLs. This traditional scheme is still used for a first diagnostic orientation but does not allow pathophysiologic classification of the lipoprotein disorder for two reasons:

1. The protein component of lipoproteins, known as apoproteins, has been extensively characterized and subdivided. The different apoproteins bind lipids, regulate enzymes, and identify cell receptors. For example, a patient may have normal amounts of cholesterol but decreased levels of HDL, which is essential for the removal of intracellular cholesterol.
2. The specific genetic defect has been identified for most disorders; the best known of which is familial hypercholesterolemia in which there is an absent or functionally defective LDL receptor.

Most patients with lipoprotein abnormalities do not have xanthomas, but the presence of xanthomas and especially the identification of extracellular lipids on histologic examination of the lesion should alert the clinician to the need for an internal evaluation. The type of xanthoma is primarily a clinical diagnosis and correlates poorly with the exact lipid abnormality. With these limitations in mind, Table 26-5 gives a brief overview of the relationship between xanthomas and hyperlipidemias (130).

TABLE 26-5 Algorithm for Cutaneous Xanthomas

When an infiltrate with foamy cells is found:
1. Is extracellular lipid present?
   If YES, marker for underlying hyperlipidemia
2. Check serum lipid levels
   a. If abnormal, diagnosis confirmed
   b. If normal, consider
      (i) Xanthogranulomas (papular xanthoma, xanthoma disseminatum)
      (ii) Noncholesterol lipid disorders (sitosterolemia, cholestanolemia)
      (iii) Paraneoplastic disorders
      (iv) Postinflammatory, posttraumatic lesions
      (v) Storage disorders and other rare syndromes

The xanthomas may clinically be divided into eruptive xanthomas, tuberous xanthomas, tendon xanthomas, and plane xanthomas. We view xanthelasmas as a morphologic variant of plane xanthoma more closely related to the macrophage disorders but discuss it here for the sake of continuity. Eruptive xanthomas are almost always associated with chylomicronemia and are most commonly seen in secondary forms of hyperlipoproteinemia. Eruptive xanthomas consist of small, soft, yellow papules with a predilection for the buttocks and the posterior aspects of the thighs (Fig. 26-11A). They come and go with fluctuations in the chylomicron level in the plasma. The lipid in these lesions is primarily triglycerides. Triglycerides are more rapidly metabolized than cholesterol. This may explain the more transient nature of eruptive xanthomas than other xanthomas.

Tuberous and tuberoeruptive xanthomas are found predominantly in cases with an increase in LDL and VLDL remnants. They are large nodes or plaques located most commonly on the elbows, knees, fingers, and buttocks. Most of the lipid in these xanthomas is in the form of cholesterol.

Tendon xanthomas occur in patients with excessive plasma LDL levels, such as familial hypercholesterolemia and familial apolipoprotein B-100 protein defect, as well as in phytosterolemia and cholestanolemia (cerebrotendinous xanthomatosis). The Achilles tendons and the extensor tendons of the fingers are most frequently affected.

Plane xanthomas typically develop in skin folds and especially in the palmar creases, where they are diagnostic for dysbetalipoproteinemia. Diffuse plane xanthomas are typically seen as multiple grouped papules and poorly defined yellowish plaques in normolipemic patients, often with paraproteinemia, lymphoma, or leukemia. On the other hand, intertriginous plane xanthomas suggest homozygous familial hypercholesterolemia. The palmar xanthomas associated with cholestasis (primary biliary cirrhosis and biliary atresia) are plaquelike and tend to extend past the creases.

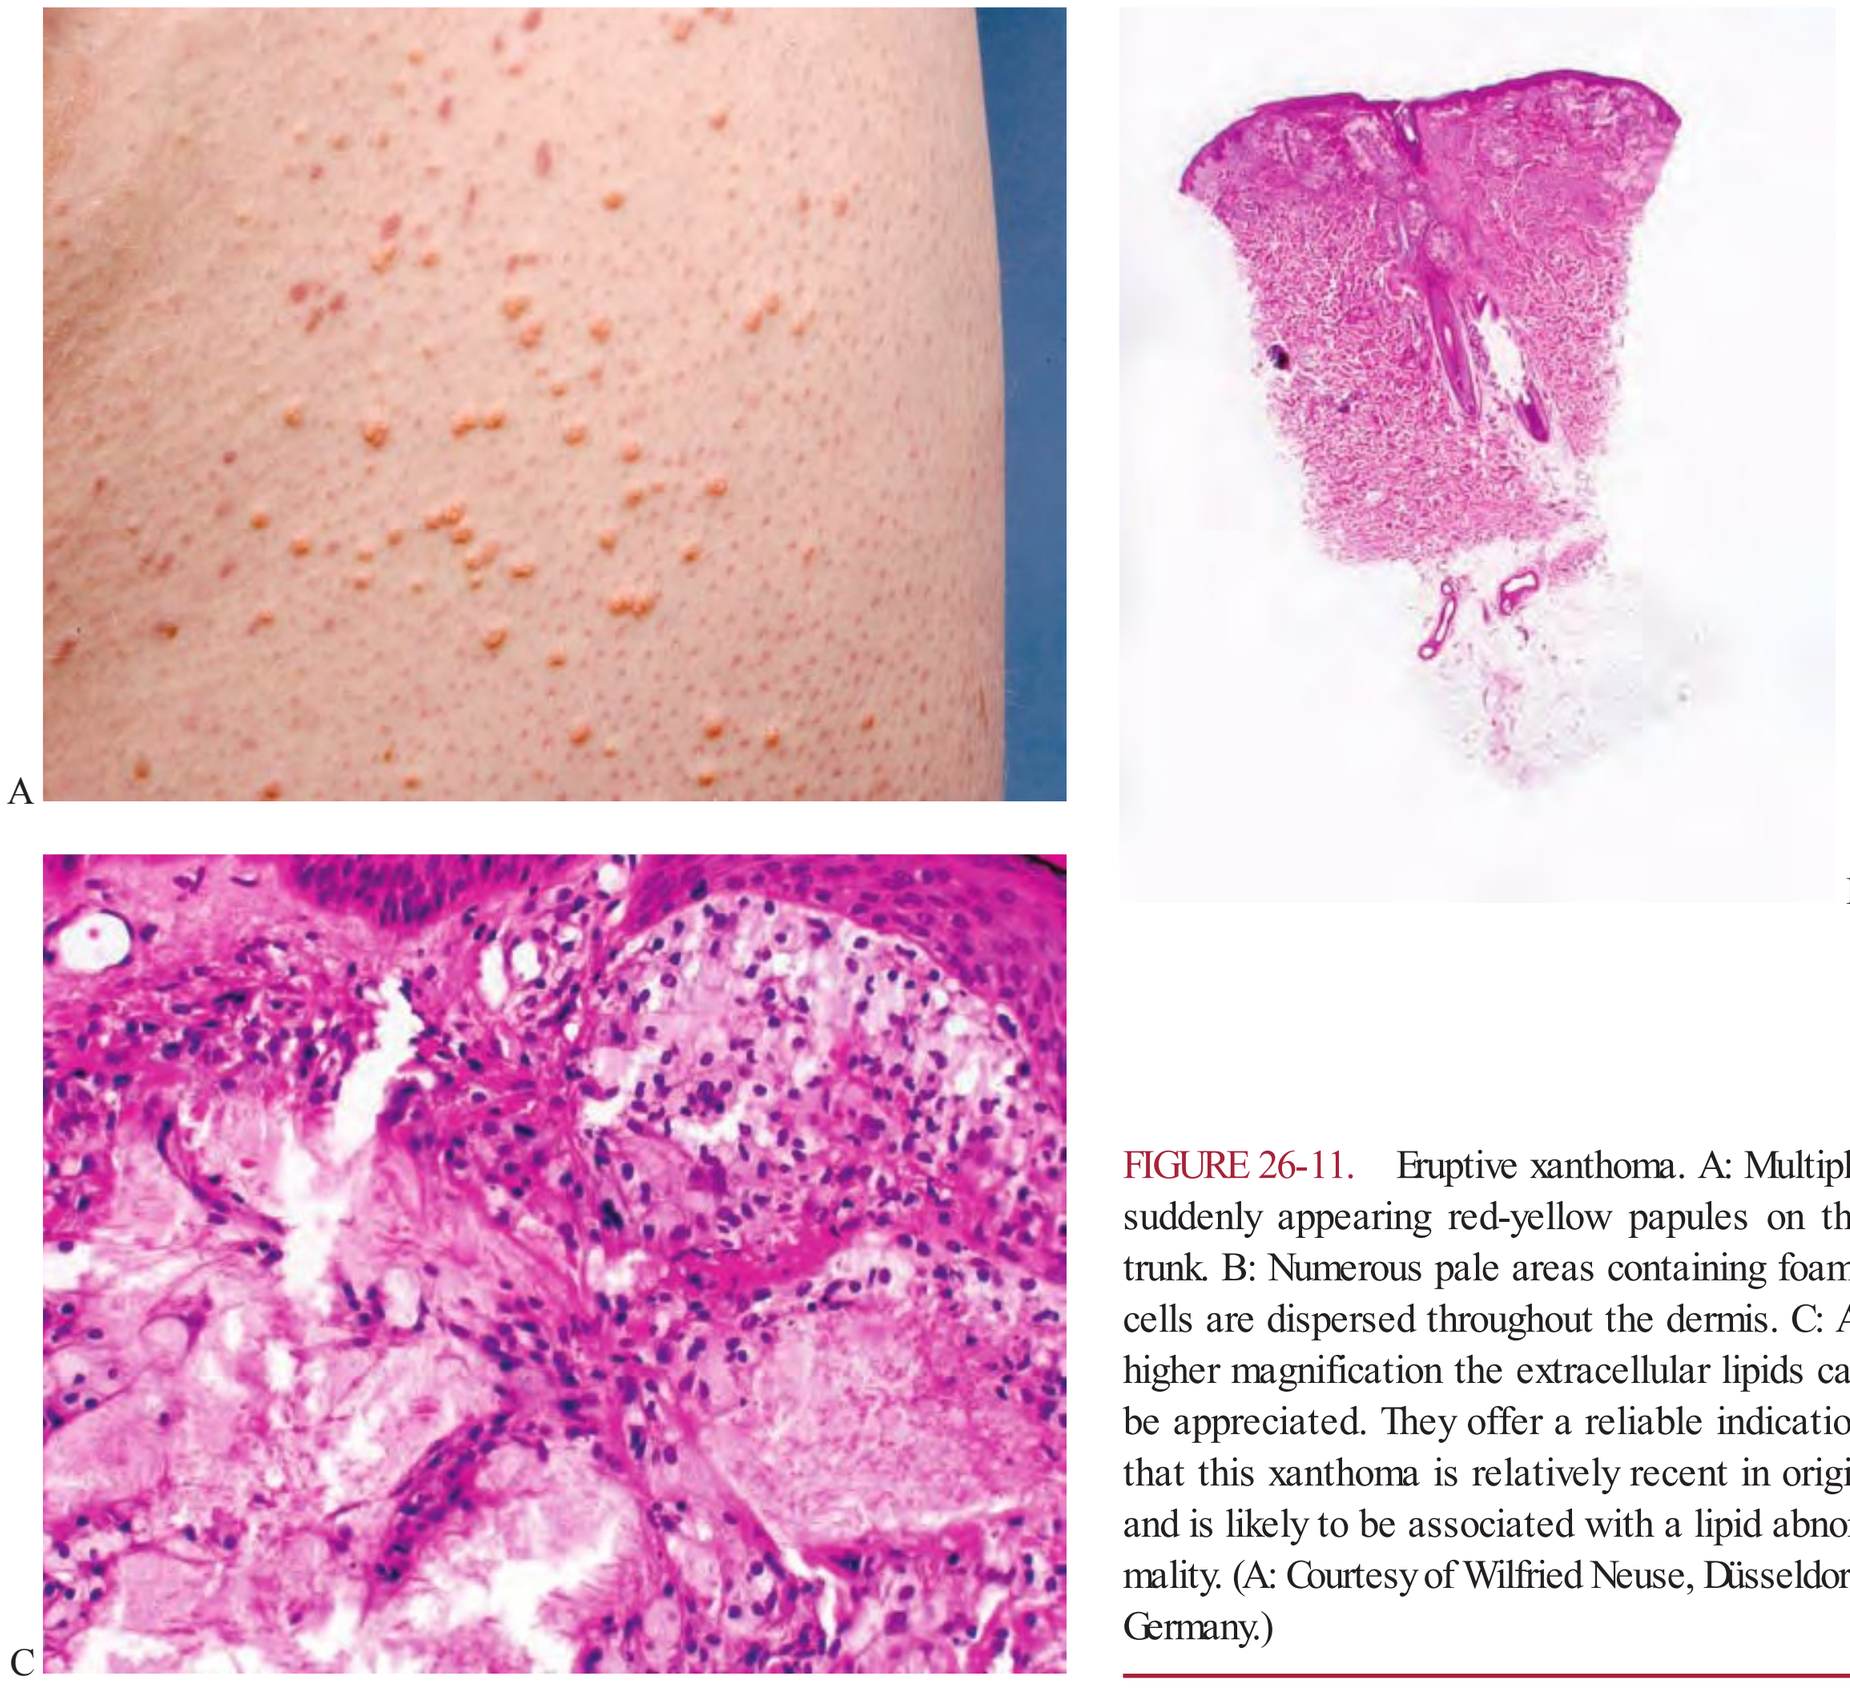

FIGURE 26-11. Eruptive xanthoma. A: Multiple suddenly appearing red-yellow papules on the trunk. B: Numerous pale areas containing foamy cells are dispersed throughout the dermis. C: At higher magnification the extracellular lipids can be appreciated. They offer a reliable indication that this xanthoma is relatively recent in origin and is likely to be associated with a lipid abnormality. (A: Courtesy of Wilfried Neuse, Düsseldorf, Germany.)

Xanthelasmas consist of slightly raised, yellow, soft plaques on the eyelids. Although xanthelasmas are the commonest of the cutaneous xanthomas, they are also the least specific because they most frequently occur in persons with normal lipoprotein levels. We argue that xanthelasmas belong in the family of macrophage disorders because they rarely show extracellular lipids, frequently have giant cells, and do not typically disappear with appropriate lipid-lowering therapy.

Histopathology. The histologic appearance of xanthomas of the skin and the tendons is characterized by foamy cells, macrophages that have engulfed lipid droplets (131). Most of the xanthoma cells are mononuclear, but giant cells, especially of the Touton type with a wreath of nuclei, may be found. The most diagnostic finding suggesting that a xanthomatous lesion reflects an underlying lipid abnormality is the presence of free lipids that have not yet been taken up by macrophages. The lipid droplets can be better seen if frozen or formalin-fixed sections are stained with fat stains such as scarlet red or Sudan red. There may be varying degrees of fibrosis, giant cells, and clefts, depending on the type and site of xanthoma sampled, but most are surprisingly similar. All xanthomas are characterized by a degree of fixation artifact. Formalin fixation and paraffin embedding remove lipids so that only their shadows are left behind. Larger extracellular deposits of cholesterol and other sterols leave behind clefts.

In the past, much emphasis was placed on the refractile nature of xanthomatous deposits. Frozen or formalin-fixed frozen sections can be examined under polarized light. Cholesterol esters are doubly refractile, whereas other lipids are not. Thus tendon and tuberous xanthomas tend to be doubly refractile, whereas other xanthomas are not. Chronic lesions are far more likely to show fibrosis.

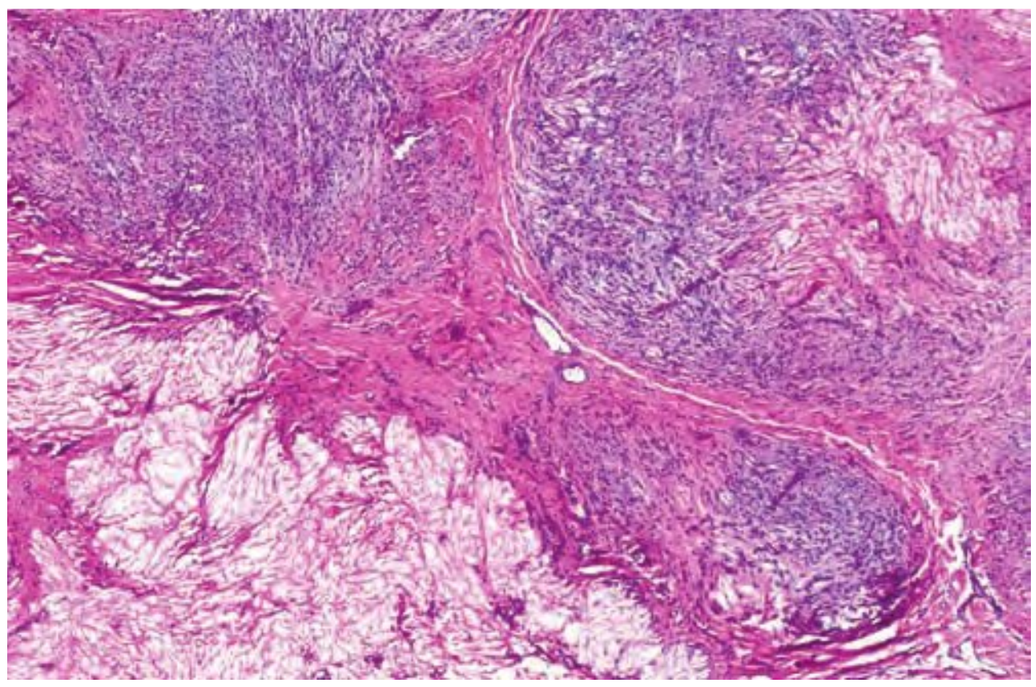
Some differences exist in the histologic appearance of the various types of xanthoma. Eruptive xanthomas, when of recent origin, often show a considerable admixture of nonfoamy cells, among them lymphocytes, macrophages, and neutrophils, whereas the number of well-developed foamy cells may still be small (Fig. 26-11B, C) (132). Because the rapid transport of lipid, especially triglycerides, into the tissue overwhelms the

capacity of the macrophages, extracellular lipids are usually found (Fig. 26-10A, B). These pools of lipid surrounded by macrophages mimic granuloma annulare histologically. Fully developed eruptive xanthomas are rich in foamy cells. Some may show urate crystals, causing confusion with gout (133).

Tuberous xanthomas consist of large and small aggregates of foamy cells. In early lesions, there usually is a slight admixture of nonfoamy cells, among them lymphocytes, macrophages, and neutrophils. In well-developed lesions, the infiltrate is composed almost entirely of foamy cells. Ultimately, collagen bundles replace many of these cells. Cholesterol clefts may be found (Fig. 26-12). Tendon xanthomas are identical to tuberous xanthomas in histologic appearance but may be even larger and are often submitted without their overlying skin.

Plane xanthomas should be suspected when the overlying epidermis is thickened with hyperkeratosis and a stratum lucidum, indicating a palmar location (Fig. 26-13A, B). Plane xanthomas from other sites have no unique features.

Xanthelasmas located on the eyelids differ from tuberous xanthomas by the fairly superficial location of the foamy cells and the nearly complete absence of fibrosis. Superficial striated muscles, vellus hairs, small vessels, and a thinned epidermis all suggest location on the eyelid and serve as clues to the histologic diagnosis of xanthelasmas (Fig. 26-14A, B). Metastatic adenocarcinoma to the eyelids, most often of breast origin, and primary adnexal carcinomas (sebaceous and signet ring) can be mistaken for xanthelasmas.



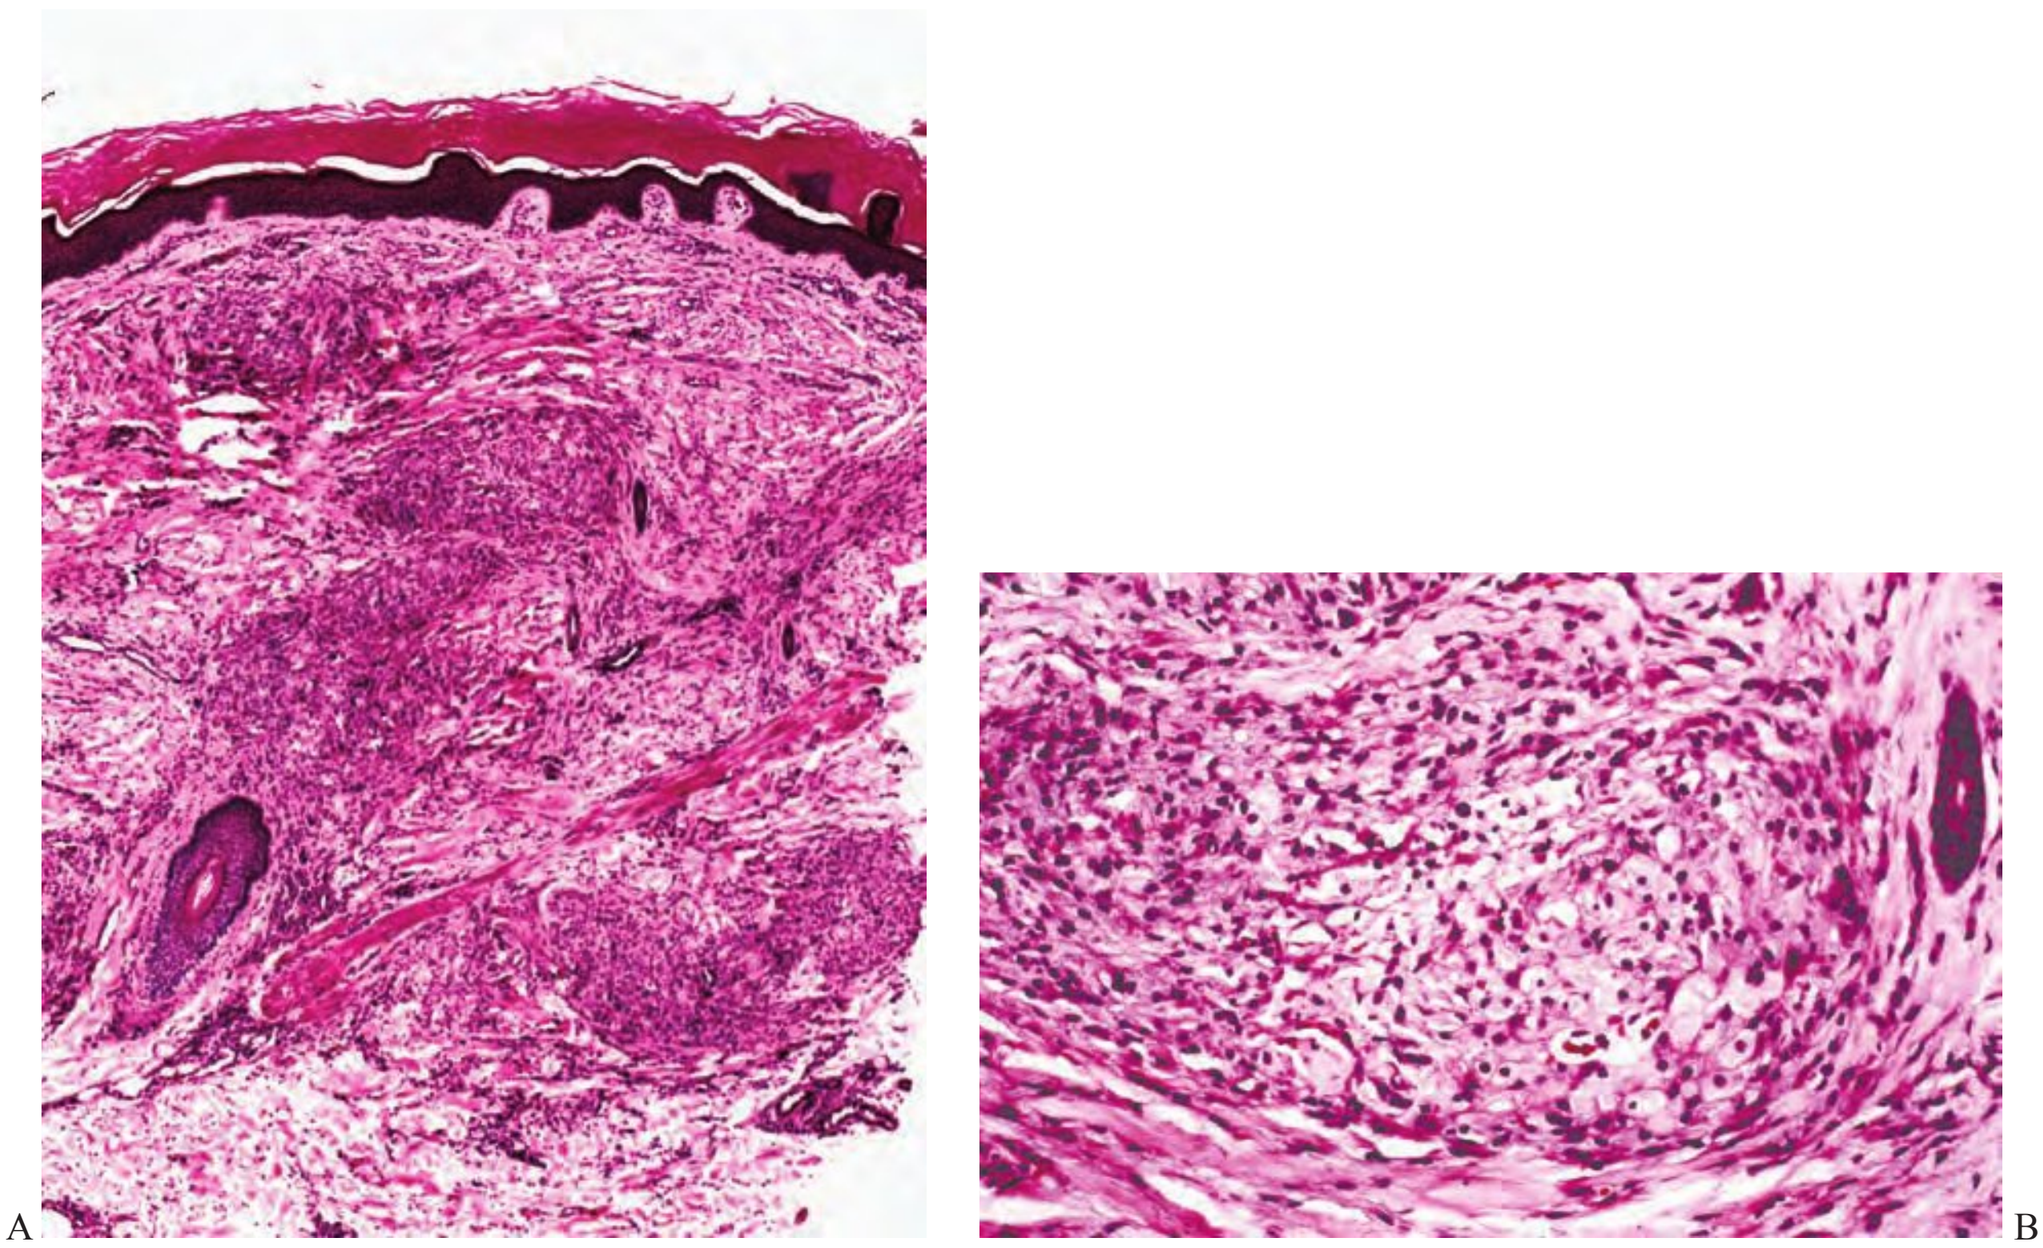


FIGURE 26-12. Tuberous xanthoma. Diffuse deposits of cholesterol probably occupied the pale area at the lower left, whereas clefts are more prominent in the upper right side.

Pathogenesis. Whereas the pathogenesis of many forms of hyperlipidemia is well understood, the formation of xanthomas is a complex process of dysregulation of macrophage sterol flux. Elevated levels of cholesterol-rich LDL and VLDL remnants tend to predispose to xanthomas. Under physiologic conditions, about 80% of LDL-cholesterol is taken up by specific LDL receptor–mediated endocytosis. The remaining LDL is removed from the circulation by the scavenger receptor pathways of

A B

FIGURE 26-13. Plane xanthoma. A: Acral skin with dermis replaced by multiple pale bulbous infiltrates. B: At higher power, numerous foamy macrophages with their nuclei displaced to the cell periphery can be seen.

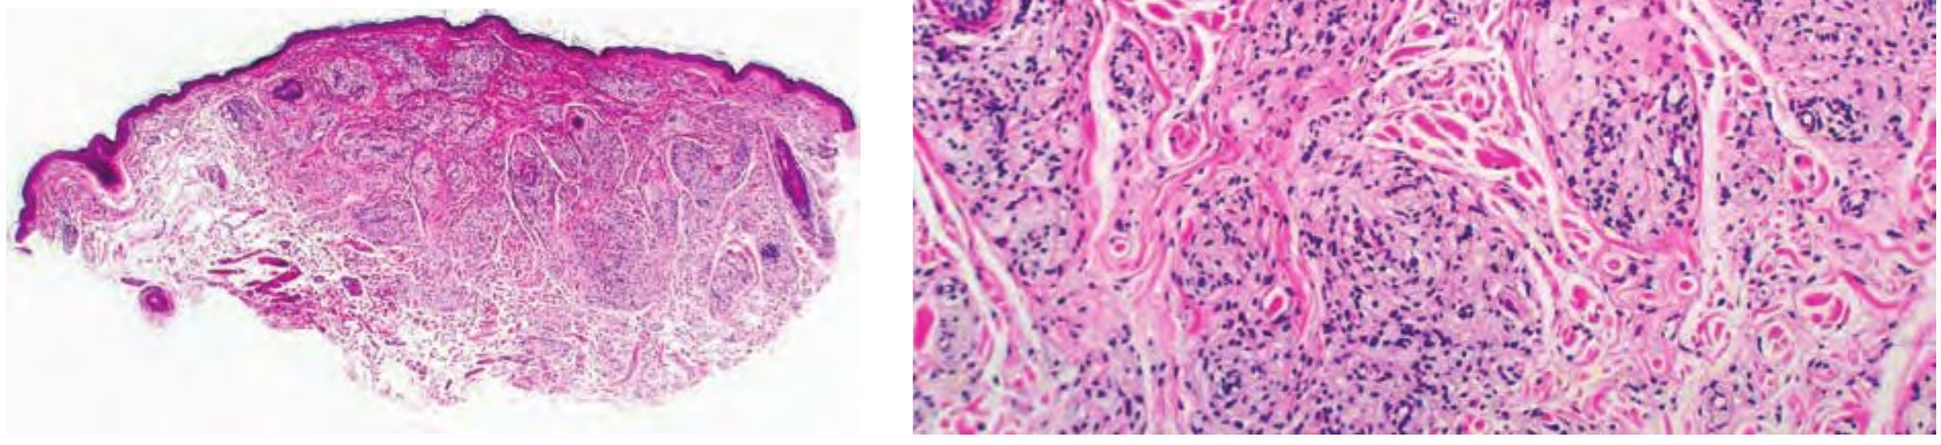

FIGURE 26-14. Xanthelasma. A: The thin epidermis and muscle fibers at the base are a clue to the eyelid location. B: Lobules of foamy cells in this location allow the specific diagnosis of xanthelasmas.

macrophages. In familial hypercholesterolemia and familial dysbetalipoproteinemia, the accumulating LDL and VLDL remnants are predominantly scavenged by macrophages, a pathway without feedback regulation, leading to continuous cellular lipid accumulation and foamy cells. Thus these xanthomas are caused by an increased load of altered sterol-rich lipoproteins.

On the other hand, xanthomas can also be caused by disturbed mechanisms of macrophage cholesterol reflux. Specific ATP-binding cassette (ABC) transporters play the key role in macrophage sterol efflux, regulation of HDL metabolism, and reverse cholesterol transport. Defective ABCA1 transporter has been shown to be the molecular cause of Tangier disease and familial HDL deficiency. Thus both overload of macrophages with altered and aged lipoproteins (increased scavenger pathway) and defective cholesterol efflux from macrophages (abnormal transporters) appear to play a crucial role in xanthoma formation.

NORMOLIPEMIC XANTHOMAS

A wide number of disorders must be considered if xanthomas are identified in a normolipemic patient. They can arise because of the presence of the following:

1. Another source of excess sterol (such as cholestanol in cerebrotendinous xanthomatosis or sitosterol in phytosterolemia). In both cases, tuberous and tendon xanthomas are most common, with marked amounts of extracellular lipids.
2. An abnormal apoprotein, which selectively binds cholesterol or triglyceride that is present nonetheless in normal amounts. These disorders are for convenience grouped with the traditional lipid-related xanthomas.
3. Lymphoproliferative disease (diffuse plane xanthomas and necrobiotic xanthogranuloma).

In some instances there is no lipoprotein abnormality or associated lymphoproliferative disease; many are idiopathic and others posttraumatic. In addition to those xanthomas in the xanthogranuloma family (xanthoma disseminatum and papular xanthoma) and rarely in LCD, one must consider verruciform xanthoma, postinflammatory and posttraumatic xanthomas, and a variety of rare syndromes.

Necrobiotic Xanthogranuloma with Paraproteinemia

Necrobiotic xanthogranuloma with paraproteinemia can usually be recognized clinically and histologically (134–136) but may overlap with diffuse normolipemic plane xanthoma. Large, often yellow, indurated plaques are found with atrophy, telangiectasia, and occasionally also ulceration. The most common location is periorbital; in one review, 21 of 22 patients had skin findings in this area (137). The thorax is also commonly involved. Systemic involvement includes a cardiac myopathy with giant cell infiltrates and hematologic malignancies (138).

Histopathology. Infiltrates containing macrophages, foamy cells, and often also an admixture of other inflammatory cells are present either as focal aggregates or as large, intersecting bands occupying the dermis and subcutaneous tissue (Fig. 26-15A). The intervening tissue shows extensive necrobiosis (degeneration of collagen imparting unique staining characteristics) (Fig. 26-15B). Another characteristic finding is B-cell follicles. A distinctive feature is the presence of numerous large giant cells, both of the Touton type with a peripheral rim of foamy cytoplasm and of the foreign-body type (Fig. 26-15C). Cholesterol clefts are also common. Sometimes all other features are present, but no necrobiosis is found (139).

Pathogenesis. In most patients, serum protein electrophoresis shows an immunoglobulin G monoclonal gammopathy that

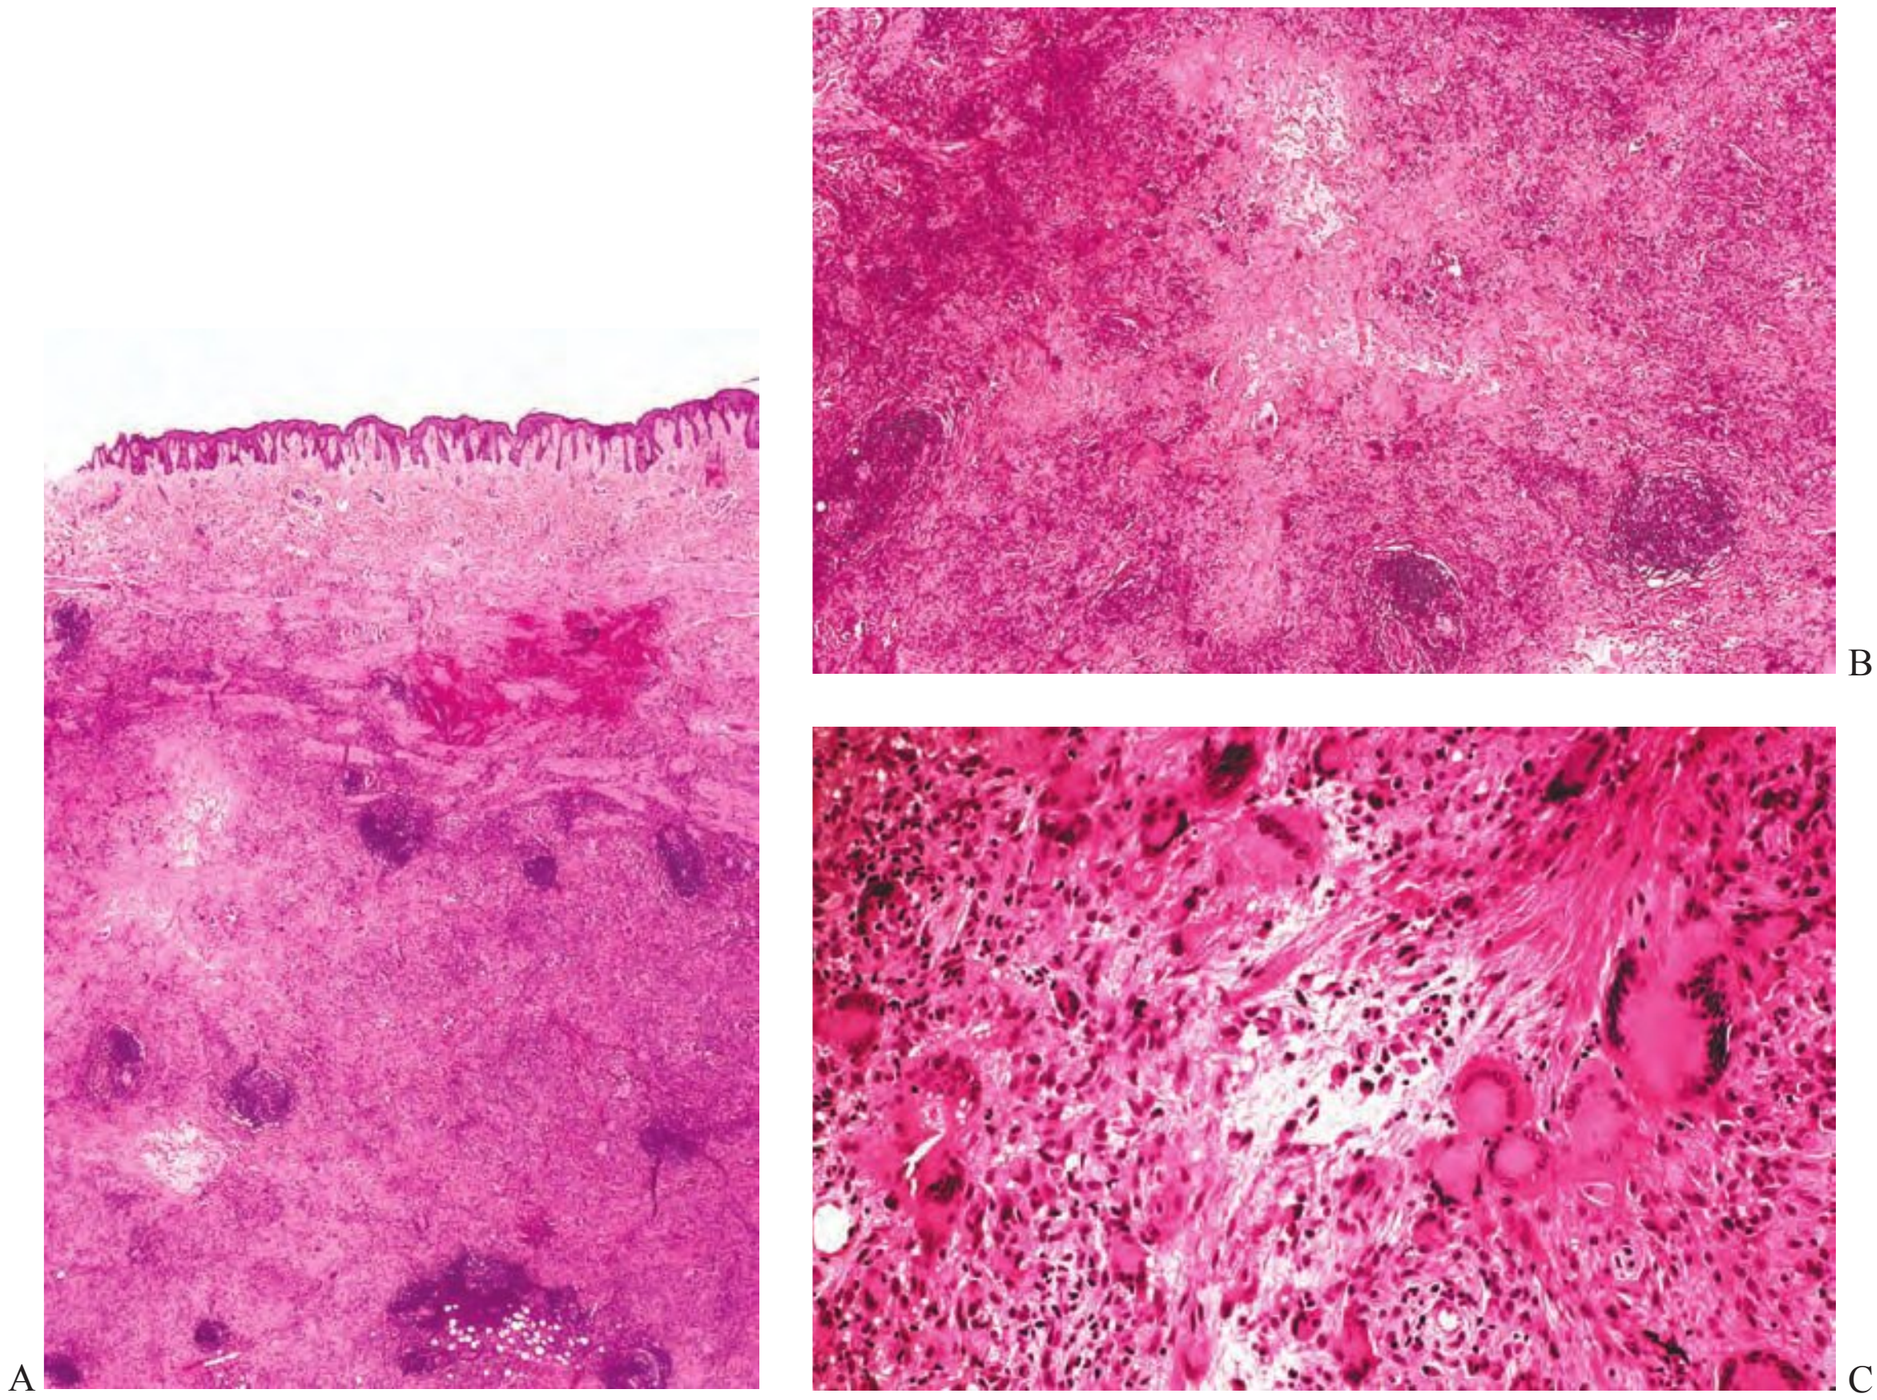

FIGURE 26-15. Necrobiotic xanthogranuloma. A: Low-power view showing a diffuse infiltrate with amorphous necrobiotic areas, cellular regions rich in giant cells, and a nodular lymphocytic infiltrate. B: Higher magnification, showing prominent B-cell follicles and pale necrobiotic regions. C: Another view, showing numerous bizarre foreign-body and Touton giant cells and extensive necrobiosis.

usually consists of κ light chains. Bone marrow examination has revealed multiple myeloma. The xanthomas seen in POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes, which may include xanthomas and angiomas; see Chapter 33) may have a similar etiology.

Differential Diagnosis. Other necrobiotic disorders, especially necrobiosis lipoidica diabeticorum and subcutaneous granuloma annulare or rheumatoid nodule, may be considered. In necrobiotic xanthogranuloma, the necrobiosis is far more extensive and often occurs in broad bands, associated with extensive infiltrates of Touton giant cells, foamy macrophages, and lymphocytes. Vascular involvement is rare, but panniculitis is common. Thus the cellularity and extent of necrobiosis usually serve as reliable clues, as does the usual periorbital location.

Diffuse Normolipemic Plane Xanthoma

In diffuse normolipemic plane xanthoma (DNPX), another rare disorder, one observes papules, patches, or, most commonly, even larger diffuse areas of orange-yellow discoloration of the skin (140–142). Whereas the smaller lesions are distinct, the diffuse areas have a poorly defined border. The face, particularly the periorbital areas, and the upper trunk are sites of predilection. The disorder may mimic xanthelasmas initially but progresses to involve wide areas of skin. The lesions usually persist indefinitely. By definition, the patient has no lipid abnormalities. Many but not all cases of diffuse normolipemic plane xanthoma are associated with hematologic disorders, most commonly paraproteinemias, including multiple myeloma, benign monoclonal gammopathy (often immunoglobulin A), Castleman's disease, and cryoglobulinemia (143). The skin disorder may precede the hematologic problem by many years (144,145).

Generalized papular xanthomas and eruptive normolipemic xanthomas are probably variations on the same theme; both have been reported in association with many of the conditions associated with diffuse normolipemic plane xanthomas. In addition, DNPX has many features in common with necrobiotic xanthogranuloma, including the presence of large patches and plaques, periorbital involvement, and association with paraproteinemias.

Histopathology. Histologic examination reveals large sheets and clusters of foamy cells, diffusely scattered throughout the dermis, as well as singly and in small groups, (Fig. 26-16). In some areas, the foamy cells lie in thin streaks between collagen bundles,

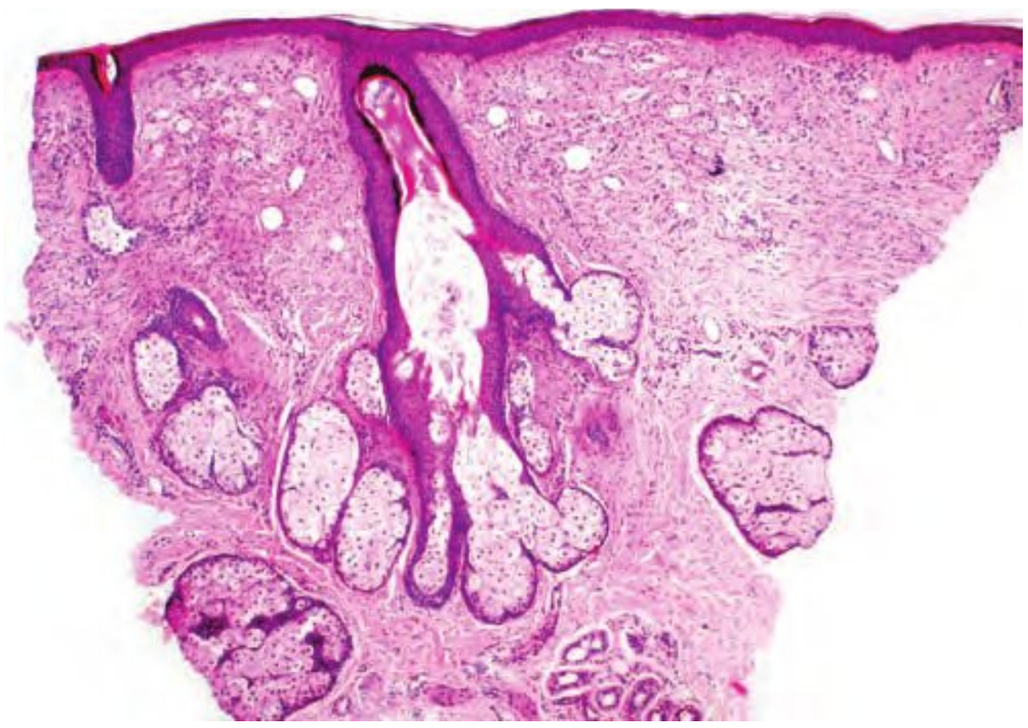

FIGURE 26-16. Diffuse normolipemic plane xanthoma. Accumulations of foamy cells in the superficial dermis.

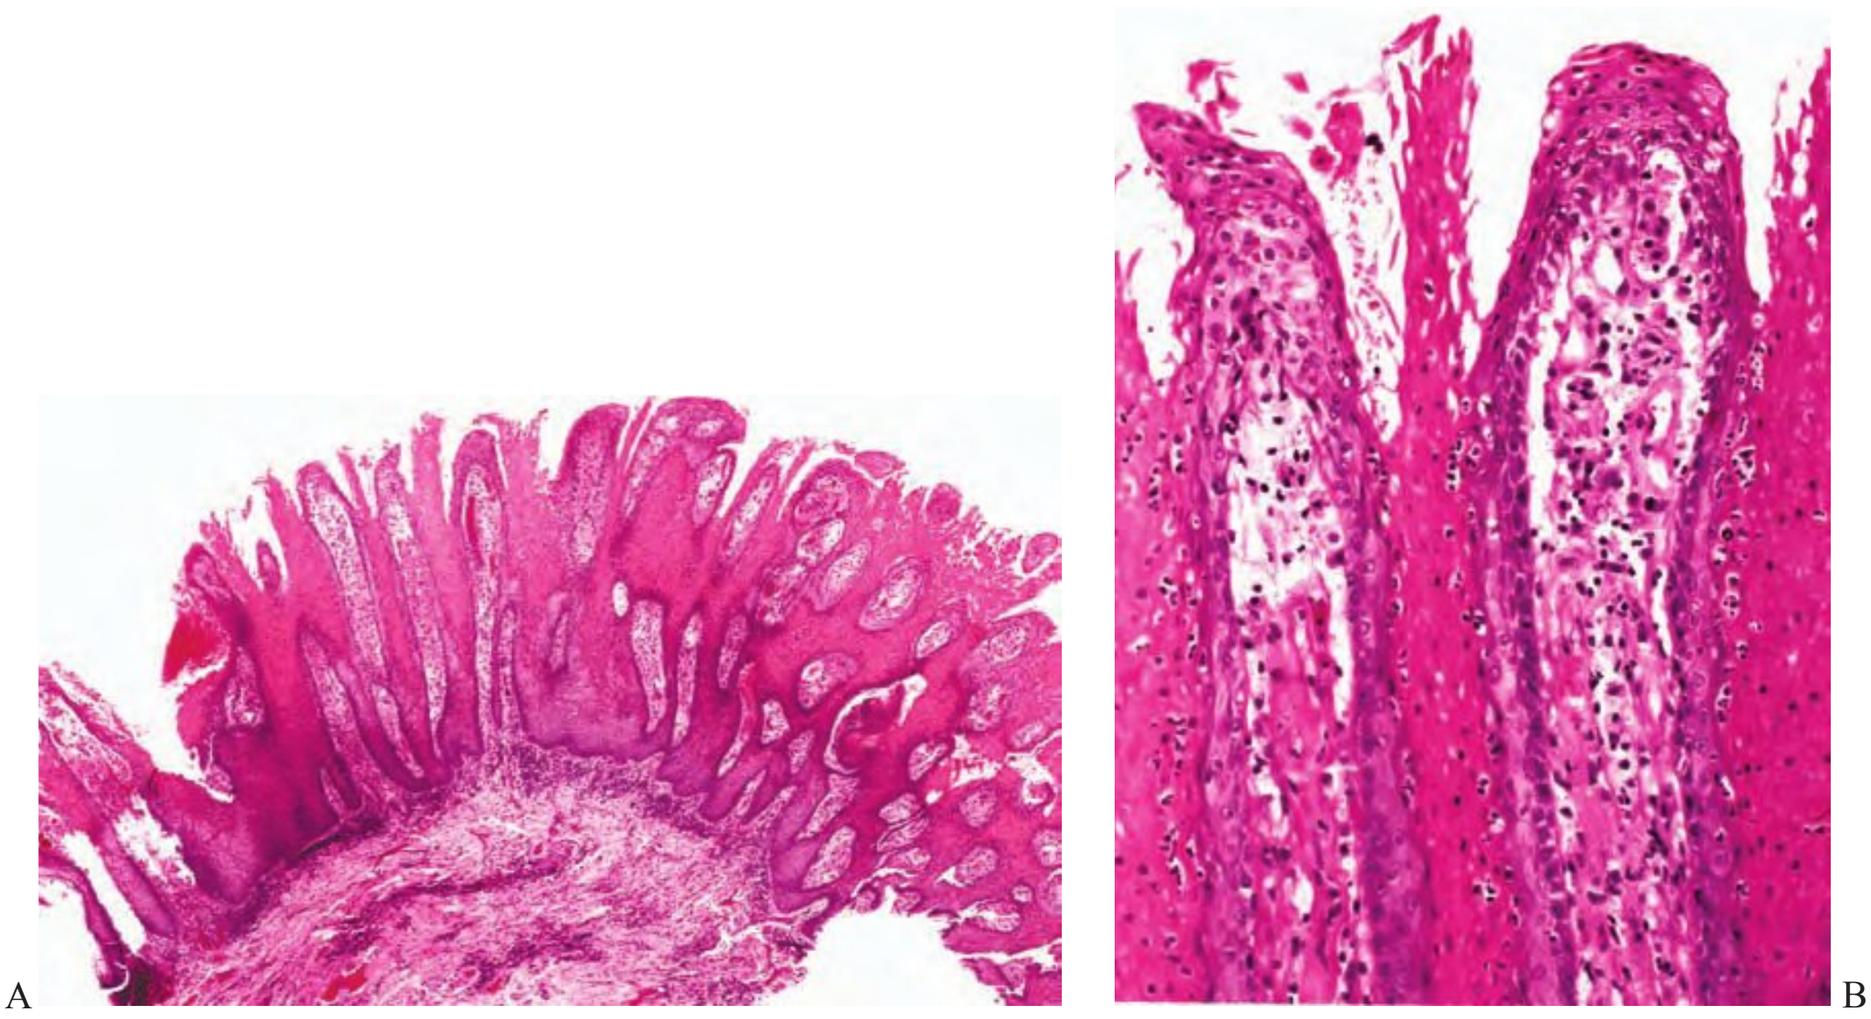
and occasionally a perivascular arrangement is noted. There may be an admixture of macrophages and lymphocytes; rarely, Touton giant cells are seen. Scattered foamy cells have been observed even in clinically normal skin.

Pathogenesis. The mechanism of xanthoma formation is unclear. Possible explanations include the secretion of cytokines or immunoglobulins by the underlying lymphocytic proliferation, which in turn could stimulate macrophages or alter lipoprotein activity. This theory fails to explain why the skin involvement so often occurs first. The immunohistochemical phenotyping of the macrophages has yielded variable results.



Differential Diagnosis. A single lesion cannot be distinguished from other small xanthomas. If marked necrobiosis or giant cell formation is present, necrobiotic xanthogranuloma should be considered.

Verruciform Xanthomas

Verruciform xanthoma (VX) occurs most commonly in the oral cavity, where it was first described by Shafer (146). Lesions are typically solitary, asymptomatic hyperkeratotic papillomatous nodules. Most cases involve the gingival or alveolar mucosa, although other oral sites may be affected (147). Although the process is usually benign, it has been associated with carcinoma *in situ* (148).

In addition, VX may occur in the skin in several settings (149). The most predictable situation is as part of a CHILD nevus, one type of epidermal nevus (congenital hemidysplasia with ichthyosiform erythroderma and limb defects; see Chapter 6) (150). Idiopathic cutaneous VX is usually anogenital or perioral; trauma is probably the triggering agent. Similar changes have been seen in sun-damaged skin, again associated with carcinoma *in situ* (151). VX has been reported secondary to a variety of inflammatory lesions, including discoid lupus erythematosus (152), lichen planus, and bullous diseases, and following psoriasiform inflammation in AIDS (153).

Histopathology. The low-power picture is that of a verruca, often leading to a mistaken diagnosis. There is marked elongation of the rete ridges extending to a uniform level in the dermis (Fig. 26-17A). An infiltrate of foamy cells is confined to the elongated dermal papillae located between the rete ridges

A B

FIGURE 26-17. Verruciform xanthoma. A: Papilloma with marked elongation and thinning of the dermal papillae. There is prominent hyperkeratosis, with a modest lymphocytic infiltrate at base. B: Higher magnification showing foamy cells in the papillae with polymorphonuclear leukocytes in the adjacent crust.

(Fig. 26-17B). Sometimes the xanthomatous cells may appear granular. The vessels in the papillae are also more prominent. The overlying epithelium is parakeratotic, and candidal hyphae or bacteria may be found.

Pathogenesis. Degenerating keratinocytes or perhaps even melanocytes are believed to be the source of the lipid material (154). Although human papilloma virus has been searched for, it has not been unequivocally identified in more than a few scattered cases. Trauma and inflammation are the two best-established triggers. The foamy cells are positive for macrophage markers and express scavenger receptors similar to those found in xanthomas associated with hyperlipidemia (155).

Miscellaneous Xanthomas

It is difficult to make rhyme or reason of the many other causes of normolipemic xanthomas. One recurrent theme is trauma, as in VX. Xanthoma have developed in areas of chronic inflammation, such as atopic dermatitis (156), persistent light eruption, mycosis fungoides (157), or even contact dermatitis (158), although the illustrations in many of these reports fail to convincingly demonstrate a nodule made up of foamy cells.

Pigmentary Disorders of the Skin

CONGENITAL DIFFUSE MELANOSIS

Congenital diffuse melanosis, also termed *melanosis diffusa congenita* (1) or *generalized cutaneous melanosis* (2,3), is thought to be recessively inherited, appears at or shortly after birth, and demonstrates progressive diffuse hyperpigmentation. The pigmentation is most intense on the abdomen and back and may be reticulate in the axillae and groin. Thin nails (3) and yellow-white hair (1) have been noted.

Histopathology. Increased melanization is seen in both the basalar and midepidermal keratinocytes, along with melanophages in the superficial dermis.

Histogenesis. On electron microscopic examination, Braun-Falco and colleagues (1) noted increased numbers of single melanosomes in the keratinocytes, and Klint and associates (3) described dispersion of melanosomes throughout the keratinocyte cytoplasm.

RETICULATE PIGMENTARY ANOMALIES

Numerous cutaneous disorders have been documented that are characterized by hyperpigmentation that is clinically seen in a reticulate, retiform, or fishnet-like pattern. These disorders are unified by the presence of increased melanin within the epidermis and exclude postinflammatory pigmentary alterations and conditions displaying reticulation secondary to vascular phenomena, such as livedo reticularis.

Dyskeratosis congenita is characterized by an acquired reticulated brown hyperpigmentation, beginning in the first decade of life, which spreads across the neck, upper chest, and arms. This syndrome demonstrates genetic and clinical heterogeneity but is most commonly associated with nail dystrophy, leukoplakia, bone marrow failure, and a predisposition to malignancy (4).

Progressive cribriform and zosteriform hyperpigmentation begins in the second decade of life with tan cribriform macular hyperpigmentation of the lower half of the trunk or thighs in a dermatomal distribution (5,6). Linear and whorled nevoid hypermelanosis has a similar clinical appearance, except the pigmentation appears within the first year of life and is present along the lines of Blaschko.

Several entities are characterized by the presence of acral hyperpigmentation. *Acropigmentation symmetrica of Dohi* (dyschromatosis symmetrica hereditaria) is a progressive autosomal dominant disorder that appears as reticulate hyperpigmented and hypopigmented macules on the face and dorsa of the hands and feet, progressing to cover acral areas (7,8). *Reticulate acropigmentation of Kitamura* is an autosomal dominant disorder that presents as slightly depressed hyperpigmented macules on the dorsal hands and feet that evolve to a reticulate pattern as the individual ages. There is progression to involve the extremities, lateral neck, and occasionally the trunk and face. There has been an association with palmar and plantar pits (9).

Reticulate acropigmentation of Kitamura and *Dowling-Degos disease* (reticulate pigmented anomaly of the flexures) may appear together (10), supporting the concept that they are different expressions of one disorder. In Dowling-Degos disease, a dominantly inherited dermatosis, heavily pigmented macules are arranged in a reticulate pattern with a tendency to coalesce on flexural skin, including the axillae, lateral neck, inframammary and inguinal folds, antecubital and popliteal fossae, and intergluteal clefts. Other sites that may be involved include the genitalia, inner thighs, chest, face, and abdomen. Extensive areas of the skin may be affected. Pitted perioral scars, hyperpigmented comedones, hidradenitis suppurativa, multiple cysts and abscesses, and keratoacanthomas have been associated (11). *Galli-Galli disease* is considered an acantholytic variant of Dowling-Degos disease, but they are clinically indistinguishable (12).

The *Naegeli-Franceschetti-Jadassohn syndrome* (Naegeli's reticular pigmented dermatosis) and *dermatopathia pigmentosa reticularis* are autosomal-dominant inherited disorders that share key clinical features, such as reticulate pigmentation of the skin, absence of dermatoglyphics, palmoplantar keratoderma, hypohidrosis, and other hair and nail abnormalities. Dermatopathia pigmentosa reticularis is distinguished from Naegeli-Franceschetti-Jadassohn syndrome by lifelong persistence of skin hyperpigmentation, partial alopecia, and absence of dental anomalies (13).

Histopathology. Most of these conditions demonstrate hyperpigmentation of the basalar keratinocytes with either a normal or slightly increased number of melanocytes. Dyskeratosis

congenita is characterized by occasional atrophy of the epidermis, mild interface vacuolization with melanophages in the upper dermis, and telangiectasias of superficial vessels (14). Reticulate acropigmentation of Kitamura and, to a greater degree, Dowling-Degos disease demonstrate digitated elongations of the hyperpigmented rete ridges with a tendency to spare the suprapapillary epithelium. In Dowling-Degos disease, these thin, branching, heavily pigmented downward proliferations also involve the infundibula of follicles, and in some instances, horn cysts may be seen (11). Galli-Galli disease demonstrates similar thin, branching hyperpigmented rete ridges with foci of acantholysis (12). Although there is no preceding inflammatory dermatosis in dermatopathia pigmentosa reticularis, clumps of melanin-laden melanophages are seen in the papillary dermis in a patchy distribution without overlying epidermal hyperpigmentation (15).

Histogenesis. These conditions are thought to be inherited, although all of the genes responsible for their expression have not been definitively identified. Dyskeratosis congenita is a genetically heterogeneous disease of defective telomere maintenance that may demonstrate X-linked, autosomal recessive, or autosomal dominant patterns of inheritance (16). Dowling-Degos disease has been linked to mutations of the keratin 5 gene (17,18).

LINEAR AND WHORLED NEVOID HYPERMELANOSIS

Linear and whorled nevoid hypermelanosis is an occasionally familial disorder that appears within the first few weeks of life and progresses over 1 to 2 years before stabilization (19). This process presents with multiple hyperpigmented linear streaks and whorls composed of small homogeneous tan to brown macules that follow the lines of Blaschko (20,21). The pattern is the inverse of that found in hypomelanosis of Ito (21) and must be differentiated from resembling conditions including incontinentia pigmenti, epidermal nevus, and zebra-like hyperpigmentation (21,22).

Histopathology. There is hyperpigmentation of the basalar keratinocytes with prominent melanocytes and mild elongation of the rete ridges (19,21,22). Pigmentary incontinence with melanophages in the papillary dermis is variably present (22,23).

Histogenesis. The genetic abnormality has not been defined, but developmental somatic mosaicism has been proposed as an explanation for this patterned hypermelanosis (21,22).

MELASMA

Melasma is an acquired, localized, usually symmetrical hyperpigmentation of the face occurring in women. The forehead, cheeks, upper lip, and chin are affected. It often is associated with pregnancy or the ingestion of oral contraceptives and aggravated by sunlight.

Histopathology. An epidermal and a dermal type can be recognized, although frequently there is a combination of the two types. Melanin is significantly increased in all epidermal layers, and melanosomes are increased in number and more widely distributed among keratinocytes in lesional skin. Melasma skin often has more free melanin and melanophages in the dermis (24,25).

ADDISON'S DISEASE

Addison's disease represents a hypofunction of the adrenal cortex and is characterized by progressive weakness, malaise, weight loss, hypotension, joint and back pain, and darkening of the skin and mucous membranes (26). In some cases, hyperpigmentation is the initial clinical manifestation (27). The hyperpigmentation is generalized but most pronounced on sun-exposed skin, sites of friction, palmar creases, recent scars, and genital skin (26). Patchy oral mucosal pigmentation is often present.

Histopathology. The histologic findings simulate the normal findings in patients with naturally dark skin and are therefore not diagnostic. Increased amounts of melanin are seen in the basalar keratinocytes and often in the keratinocytes in the upper spinous layer. The number of melanocytes is not increased. Variable numbers of melanophages may be seen in the papillary dermis (28).

Histogenesis. Most commonly, Addison's disease is the result of an autoimmune destruction of the adrenal glands, with subsequent inadequate production of cortisol and aldosterone. Addison's disease is often associated with other autoimmune diseases, such as autoimmune glandular syndromes, insulin-dependent diabetes, vitiligo, and thyroid disease (26). Other causes of adrenal hypofunction include damage of adrenal glands by tuberculosis, metastatic carcinoma, and deep fungal infections.

The hyperpigmentation in Addison's disease is caused by an increased release of melanocyte-stimulating hormone (MSH) from the pituitary gland. Adrenocorticotropic hormone (ACTH) and MSH synthesis and secretion in the pituitary gland are linked. The increased production of ACTH and MSH in Addison's disease is a compensatory, feedback-controlled response to low adrenal gland activity.

POSTINFLAMMATORY PIGMENTARY ALTERATION

Pigment alteration in the skin from a preceding inflammatory disorder can produce clinical hypopigmentation, hyperpigmentation, or both. It occurs commonly in processes that affect the dermal–epidermal interface such as fixed drug eruptions, lichen planus, benign lichenoid keratosis, and erythema multiforme. In some individuals, the alteration can be

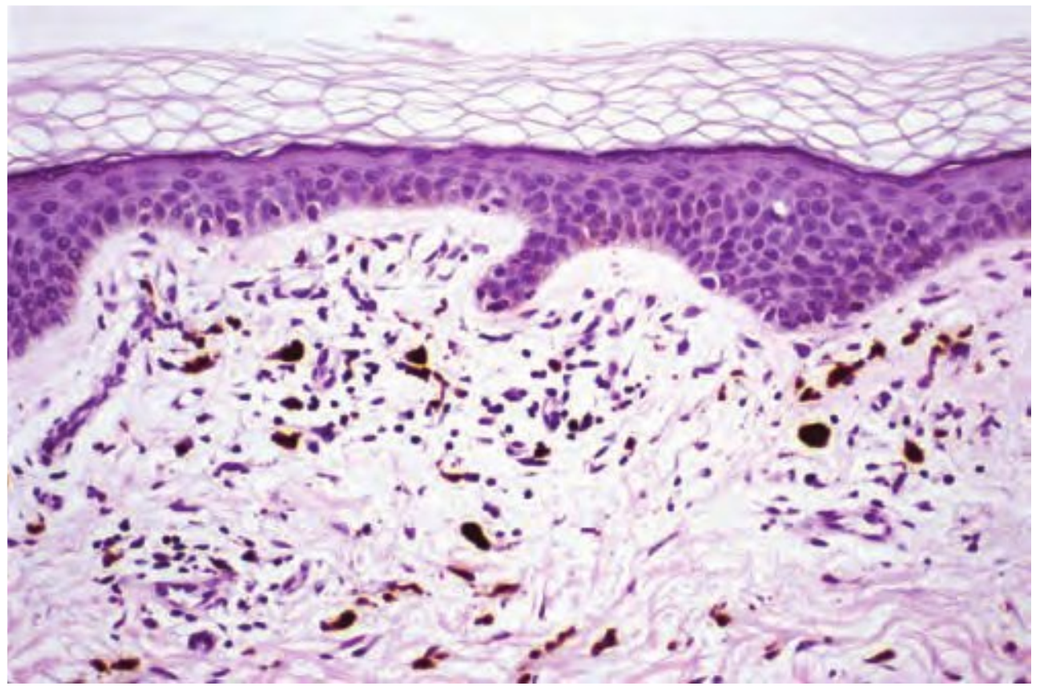

FIGURE 27-1. Postinflammatory hyperpigmentation. There are numerous melanophages in the papillary dermis along with a mild perivascular lymphocytic infiltrate. The epidermis is normal.

dramatic, producing dark pigmentation resembling primary melanocytic lesions or marked hypopigmentation resembling vitiligo. Wood's light examination accentuates epidermal melanin and is useful as a clinical tool in defining the nature and extent of pigmentary alteration.

Histopathology. Epidermal melanin is increased in clinical hyperpigmentation and decreased in clinical hypopigmentation. In both clinical forms of pigmentary alteration, melanophages are present in the superficial dermis, along with a variably dense infiltrate of lymphohistiocytes around superficial blood vessels and in dermal papillae (29) (Fig. 27-1). Necrotic keratinocytes and coarse collagen bundles in the papillary dermis are occasionally seen (29,30).

BERLOQUE DERMATITIS AND PHYTOPHOTODERMATITIS

Localized hyperpigmented patches produced by furocoumarin-containing oil of bergamot found in perfumes have a distinctive clinical presentation. The patches assume droplike shapes resembling pendants (French: *berloque*) and are usually located on the sides of the neck or retroauricular areas. Contact with plants containing furocoumarins may also produce hyperpigmented patches and include lime, wild and cow parsnip, wild carrot, bergamot orange, and fig (31).

Histopathology. Features identical to postinflammatory hyperpigmentation are found, including increased epidermal melanin and melanophages in the superficial dermis. Variable chronic inflammation is present.

CHEMICAL DEPIGMENTATION

Chemicals are capable of producing depigmentation resembling vitiligo. Hydroquinones and phenols are the most common causes and are found in bleaching agents, adhesives, cosmetics, photographic processing materials, and antioxidants used in the manufacture of rubber (32,33). Depigmentation may also occur in body sites remote from chemical contact, presumably from systemic absorption or inhalation.

Histopathology. Features indistinguishable from vitiligo are found (32). Decreased or absent melanocytes are present with a variable superficial perivascular lymphocytic infiltrate.

IDIOPATHIC GUTTATE HYPOMELANOSIS

Idiopathic guttate hypomelanosis is a commonly acquired disorder of unknown cause that produces few to numerous sharply circumscribed, 2- to 6-mm white macules. These lesions occur predominantly on the legs and forearms of persons over 30 years of age (34).

Histopathology. In sections stained with Fontana-Masson, the melanin content in lesional skin is markedly reduced. The lesional borders are sharply demarcated. Within the hypomelanotic epidermis, the melanin granules are irregularly distributed, and there is a significant reduction in the number of melanocytes (35,36).

Histogenesis. On electron microscopic examination, the scattered residual melanocytes in lesional skin are round and less dendritic with fewer melanosomes that are incompletely melanized (37).

PROGRESSIVE MACULAR HYPOPIGMENTATION

Progressive macular hypopigmentation is a disorder of unclear etiology that is characterized by hypopigmented macules on the central trunk, predominantly in young adults. These lesions are asymptomatic and occur without previous inflammation or skin disease. The lesions may be discrete or eventually become confluent (38).

Histopathology. Histologic features of lesional and nonlesional skin may be indistinguishable. A subtle decrease in melanin content may be present in lesional skin, and staining with Fontana Masson may demonstrate reduction in melanin within the basal cell layer (38,39).

Histogenesis. *Propionibacterium acnes* has been cultured and identified histologically in follicles of lesional skin but not follicles or interfollicular areas of healthy appearing adjacent skin. It has been proposed that the bacteria may interfere with melanogenesis in these skin lesions (39).

PSORALEN AND ULTRAVIOLET A–INDUCED PIGMENT ALTERATIONS

Psoralen and ultraviolet A (PUVA) therapy consists of the oral ingestion or topical application of a furocoumarin-containing psoralen compound followed by patient exposure to high-intensity

UVA radiation in a controlled-light-box setting. It is widely used for treating psoriasis and cutaneous T-cell lymphoma and less commonly used for a variety of other dermatoses including repigmentation therapy of vitiligo.

A spectrum of clinical and histologic changes is seen during and after PUVA therapy. Acutely, the phototoxic erythema peaks at 48 to 72 hours. Hyperpigmentation (tanning) is delayed for several days and more pronounced and longer lasting than that induced by ultraviolet B (UVB) exposure (40). Prolonged therapy leads to photoaging with cutaneous atrophy, fine wrinkling, mottled hyperpigmentation and hypopigmentation, telangiectasias, and loss of elasticity (41). Stellate lentigines or PUVA freckles often develop after prolonged therapy (42). There is also a dose-dependent increase in the risk of squamous cell carcinoma (43), especially in the genital areas (44).

Histopathology. The histologic changes of PUVA-induced acute phototoxicity are similar to a sunburn, with numerous pink apoptotic cells ("sunburn cells") scattered throughout the epidermis. Early in the therapeutic course, the melanocytes in the basalar epidermis and keratinocytes in the mid spinous layer are heavily melanized. Prolonged therapy leads to gradual flattening of the rete ridges, telangiectasias, increased papillary dermal acid mucopolysaccharide deposition, thinning and basophilic degeneration of elastic fibers, and hyperplasia and fragmentation of elastic fibers (45). Hyperpigmented skin without other clinical changes frequently demonstrates small foci of keratinocytic nuclear atypia and loss of the normal maturation pattern (46). Actinic keratoses, Bowen's disease, and squamous cell carcinomas may develop. PUVA freckles or lentigines show increased numbers of melanocytes and elongation of the rete ridges with focal atypical melanocytes (47).

Histogenesis. On electron microscopy, melanosomes are diffusely distributed throughout the epidermis (48). There is basement membrane thickening with focal dissolution. Elastic fibers in the dermis appear homogenized and fragmented (49). In the deep dermis, there is reduplication of the basal layer of capillaries and increased pinocytosis of endothelial cells (50).

DRUG-INDUCED PIGMENTARY ALTERATIONS

Drug-induced pigmentary alterations are quite common. Implicated agents include nonsteroidal anti-inflammatory drugs, antimalarials, tetracyclines, psychotropics including phenothiazines, antineoplastic agents including cytotoxics, heavy metals including gold, amiodarone, amitriptyline, and clofazimine (51,52). A variety of pathogenic mechanisms are seen, including increased production of melanin leading to hyperpigmentation of basalar keratinocytes, vacuolar change at the dermal–epidermal junction with pigmentary incontinence and dermal melanophages, binding of the drug to melanin and deposition of stable complexes, and deposition of the drug itself as granules in the dermal extracellular matrix or in macrophages. In addition, drugs may induce the synthesis of special pigments, such as lipofuscin, or damage blood vessels leading to red blood cell extravasation and hemosiderophages (51,52). Clinical features vary from generalized hyperpigmentation to specific patterns attributed to individual drugs such as the flagellated streaks attributed to bleomycin (53).

Histopathology. Minocycline may cause generalized bluish-brown pigmentation in a photodistribution due to increased basalar keratinocytic melanin, blue-black pigmentation of acne and other scars due to hemosiderin deposition in dermal macrophages, or gray-blue pigmentation of the anterior legs and arms due to deposition of drug complexes and protein extracellularly in the dermis and deposition on elastic fibers.

Antimalarial agents deposit pigment granules in dermal macrophages and extracellularly (51). Phenothiazines commonly deposit electron-dense granules in dermal macrophages. The granules are composed of a drug metabolite and melanin leading to progressive blue pigmentation on sun-exposed skin (54). Amiodarone may provoke a photoallergic reaction with blue-gray pigmentation due to the deposition of lipofuscin granules in macrophages around superficial dermal blood vessels. These are accentuated by periodic acid-Schiff (PAS) staining. Lipofuscinosis may also be caused by antibiotics (51).

Chemotherapy agents commonly produce both generalized and localized hyperpigmentation of the basalar keratinocytes. Bleomycin, busulfan, doxorubicin, daunorubicin, fluorouracil, cyclophosphamide, and carmustine additionally may demonstrate melanophages in the superficial dermis (53). Globules of mercury have been found in dermal and subcutaneous abscesses after oral ingestion (55).

PIGMENTARY PRESENTATIONS OF CUTANEOUS AND SYSTEMIC DISEASES

Mycosis fungoides may present with hypopigmented (56,57) or hyperpigmented (58) lesions. The former occurs in children and young adults, is slowly progressive, and often is present for many years before diagnosed. Sarcoidosis (59) may display hypopigmented skin lesions but usually demonstrates some degree of clinical induration. Darier's (60) disease may also present with hypopigmentation. Although pigmented variants of basal cell carcinoma are not uncommon, pigmented Bowen's disease (61), pigmented Paget's disease (62), and depigmented extramammary Paget's disease (63) can be difficult to recognize clinically. Skin metastases from breast carcinoma may be pigmented and can even simulate malignant melanoma (64). As well, generalized hyperpigmentation may be the presenting sign of metastatic malignant melanoma and primary pituitary tumors.

Histopathology. The histologic changes are those of the primary dermatosis. In hypopigmented mycosis fungoides, variable melanin pigmentary incontinence occurs (57), whereas hyperpigmented mycosis fungoides shows striking melanin pigment in the basal layer and giant melanin pigment granules throughout the spinous layer (58). No alteration of melanocytes is

present in hypopigmented sarcoidosis, and no appreciable change in melanin pigment is noted (59). Decreased melanin pigment is seen in the basal layer of hypopigmented Darier's disease (60). Pigmented Bowen's disease shows abundant melanin pigment in basal keratinocytes, highly dendritic melanocytes, and numerous melanophages (61). Pigmented Paget's disease and pigmented epidermotropic metastatic breast carcinoma demonstrate dendritic melanocytes at the dermal–epidermal junction with variable melanin pigment in the cytoplasm of tumor cells (62). Normal numbers of melanocytes are present in depigmented extramammary Paget's disease, but epidermal melanization is markedly reduced (63). In generalized hyperpigmentation from metastatic melanoma or endocrinopathy, variable epidermal pigment and melanophages are present.

Histogenesis. Electron microscopy of hypopigmented mycosis fungoides shows degenerative changes in melanocytes. The melanocytes demonstrate dilatation of rough endoplasmic reticulum, mitochondrial swelling, incompletely melanized melanosomes, and vacuolization and disintegration of the cytoplasm (65). Giant melanosomes are seen in keratinocytes of hyperpigmented mycosis fungoides, and melanin granules are also present in the cytoplasm of tumoral and Langerhans cells (58). Fewer melanosomes are present within keratinocytes in hypopigmented sarcoidosis, and melanocytes feature variable degenerative changes (59).

ALBINISM

Albinism is a heritable disorder causing a generalized lack of pigmentation of the skin, hair, and eyes. Involvement of only the eyes is known as *ocular albinism* and is X-linked recessive. Oculocutaneous albinism (OCA) affects both the eyes and skin and is autosomal recessive.

There are at least 10 types of OCA based on the degree of tyrosinase activity, hair color, and associated systemic disorders. Tyrosinase is a copper-containing enzyme responsible for the biosynthesis of melanin. Mutations in the tyrosinase gene result in inactivity of the enzyme (tyrosinase-negative OCA) and cause the most severe subtype (66,67). In tyrosinase-positive OCA, synthesis of melanin pigment is reduced, and patients acquire some melanin pigment in the hair, skin, and eyes beginning in childhood. Hair color varies from yellow (yellow-mutant OCA) to red (rufous OCA) to platinum (pt OCA) to brown (brown OCA) to black (blacklocks-albinism-deafness syndrome [BADS]). Associated systemic disorders include platelet defect and ceroid storage (Hermansky-Pudlak syndrome), defects in immunity (Chédiak-Higashi and Griscelli syndromes), and microphthalmia and mental retardation (Cross syndrome). Cutaneous malignancies, particularly squamous cell carcinoma, are frequent in all forms of albinism.

Prenatal diagnosis of OCA can be made by analysis of fetal skin biopsy for the tyrosinase gene in fetal cells obtained by amniocentesis (68).

Histopathology. Histologic examination of skin from patients with OCA shows the presence of basal melanocytes in the epidermis and hair bulb; however, Fontana-Masson stain fails to show any melanin. In patients with the tyrosinase-positive type of albinism, the epidermal melanocytes form pigment if sections of skin are incubated with dopa.

Hermansky-Pudlak syndrome is a disorder in melanosome formation that histologically demonstrates giant melanosomes in the epidermis along with melanophages in the dermis (69,70).

Histogenesis. OCA is a disorder of melanin synthesis within the melanosome. Electron microscopic examination in OCA shows normally structured melanocytes in the epidermis; however, there is a reduction in the melanization of melanosomes (71). For example, in tyrosinase-positive albinism, there are fewer melanized stage III and IV melanosomes, whereas in tyrosinase-negative albinism, the melanosomes contain no melanin and represent stage I and II melanosomes. Melanosome transfer to keratinocytes is not altered.

The tyrosinase gene has been localized in the long arm of chromosome 11 (72). Mutations in the protein-coding region of the gene are responsible for the tyrosinase-negative OCA. In contrast, tyrosinase-positive OCA has been mapped to the P gene on chromosome 15, and mutations of this gene are associated with a wide range of clinical manifestations (73).

PIEBALDISM (PATTERNED LEUKODERMA)

Piebaldism is an autosomally dominant disorder characterized by irregularly shaped depigmented patches that are present from birth and are associated in about 85% of the cases with a white forelock arising from a depigmented area in the center of the forehead. Depigmentation has a predilection for the ventral skin, that is, the center of the face, the ventral chest, and the abdomen. Small islands of hyperpigmentation, 1 to 5 cm in diameter, are usually present within the depigmented areas. The condition used to be called *partial albinism*, but this term is no longer used because of the difference in pathogenesis between OCA and piebaldism.

Waardenburg syndrome, also dominantly inherited, is a variant of piebaldism that is characterized by lateral displacement of the inner canthi of the eyes, heterochromia of the irides, and congenital deafness. About half of the patients have a white forelock, and approximately 12% have patches of depigmentation from birth.

Histopathology. The depigmented skin and hair usually have significantly reduced to no melanocytes (74,75). Melanocytes are normal in number in associated hyperpigmented areas (75). In some cases, white forelock epidermis may show a few melanocytes that are dopa positive (76).

Histogenesis. Electron microscopic examination of the depigmented skin usually reveals a complete absence of melanocytes (76). In some instances, an occasional melanocyte is seen with unmelanized ellipsoidal or spherical melanosomes. Electron microscopy of plucked forelock hair reveals absence of melanin

in the cortex, cuticle, and inner root sheath (76). The small hyperpigmented islands show many abnormal spherical, granular melanosomes.

A mutation of the *KIT gene* that encodes melanocytic migration into the hair follicle and epidermis during embryonic development has been implicated in piebaldism (72). In the Waardenburg syndrome, four types have been described involving three transcription factors, MITF, SOX-10 and PAX-3, all of which affect expression of the KIT gene (77).

VITILIGO

Vitiligo is an acquired, disfiguring, patchy, total loss of skin pigment. Stable patches often have an irregular border but are sharply demarcated from the surrounding skin. There may be surrounding hyperpigmented skin. In expanding lesions, there may rarely be a slight rim of erythema at the border and a thin zone of transitory partial depigmentation. Hairs in patches of vitiligo are often white. The scalp and eyelashes are rarely affected. In generalized vitiligo, the face, upper trunk, dorsal hands, periorificial areas, and genitals are most commonly affected in a symmetrical fashion. Localized disease can occur as a linear, dermatomal patch (segmental vitiligo). Induction with trauma (Koebner phenomenon) and association with halo nevi occurs with generalized but not segmental vitiligo.

In *Vogt-Koyanagi-Harada syndrome*, an aseptic meningitis is often the initial symptom, followed by uveitis and dysacousia. Patches of vitiligo involving the skin, and frequently the eyelashes and scalp, develop. There is often an association with alopecia areata.

Histopathology. The most prominent feature in vitiligo is the alteration of melanocytes at the dermal–epidermal junction. With silver stains or the dopa reaction, well-established lesions of vitiligo are totally devoid of melanocytes. The periphery of expanding lesions, which are hypopigmented rather than completely depigmented, still show a few dopa-positive melanocytes and some melanin granules in the basal layer (78). In the outer border of patches of vitiligo, melanocytes are often prominent and demonstrate long dendritic processes filled with melanin granules. Early lesions show a superficial perivascular and occasionally lichenoid mononuclear cell infiltrate at the border. Focal areas of vacuolar change at the dermal–epidermal junction in association with a mild mononuclear cell infiltrate have been seen in the normal-appearing skin adjacent to vitiliginous areas (79,80). In long-standing lesions, degenerative changes in cutaneous nerves and adnexal structures have been reported (81).

Histogenesis. Electron microscopic studies (80,82) and immunohistochemistry studies using a panel of 17 monoclonal antibodies directed against melanocytes (83) confirm the complete absence of melanocytes in areas of long-standing vitiligo (Fig. 27-2). In the hypopigmented zone of expanding lesions, most melanocytes show signs of degeneration. Some studies have demonstrated peripheral damage to keratinocytes and melanocytes (84). A combination of hair follicle split-dopa stains and hair follicle split-scanning electron microscopy showed inactive, dopa-negative melanocytes in the outer root sheaths of normal hair follicles. These inactive melanocytes are also present in the outer root sheaths of hair follicles from vitiliginous patches. Treatment of vitiligo stimulates these inactive melanocytes in the middle and lower parts of the outer root sheaths to divide, proliferate, and migrate upward to the dermal–epidermal junction of overlying skin. Melanocytes then radiate to form the pigmented islands clinically visible in repigmented lesions (85,86).

Autoimmune mechanisms with an underlying genetic predisposition are the most likely cause of vitiligo, although neurohumoral and autocytotoxic hypotheses are alternative theories or contributing mechanisms. Antibodies to melanocytes have been found by immunoprecipitation in the sera of patients with vitiligo but not in normal sera (87). As well, sera from patients with vitiligo causes damage to melanocytes in cell cultures, suggesting that the antibodies present in these sera may be involved in the pathogenesis of vitiligo (88). Patients with metastatic malignant melanoma may develop vitiligo, which is postulated to be secondary to the development of antibodies that react with both melanocytes and melanoma cells, as a result of cross-antigenicity (89). Vitiligo patients also have an increased association of known autoimmune disorders including thyroiditis, pernicious anemia, Addison's disease, diabetes, and alopecia areata. A recent study suggests that variants of the *NALP1 gene*, a regulator of the innate immune system, confers susceptibility to autoimmune and autoinflammatory diseases that are associated with vitiligo (90). Evidence of cellular mechanisms in the pathogenesis include the finding of T cells expressing a cutaneous lymphocyte-associated antigen typical of skin-homing T cells that are found at the edge of vitiligo patches. This finding is consistent with a hypothesis that lesional T cells rather than circulating antimelanocytic antibodies may be responsible for the patchy destruction of cutaneous melanocytes in vitiligo (91). Another study showed striking aberrations of T-cell subtypes in active areas of vitiligo when compared with static patches of disease (92).

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome is a rare autosomally recessive disorder characterized by cutaneous, ocular, neurologic, and hematologic abnormalities. There is a greatly increased susceptibility to bacterial infections and a unique "accelerated phase" that often leads to death (93). The accelerated phase is manifested by fever, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia, and widespread lymphohistiocytic organ infiltrates. Viruses, particularly Epstein-Barr virus, have been associated with triggering the accelerated phase. Giant lysosomal granules in the cytoplasm of circulating white blood cells are typical.

Chédiak-Higashi syndrome is a subtype of OCA, and patients demonstrate fair skin with susceptibility to severe

FIGURE 27-2. Vitiligo. A: Patchy loss of pigment in a patient with vitiligo. B: There is a total loss of melanocytes in the depigmented skin near the border of this patch. C: S-100 protein immunoperoxidase staining confirms the loss of melanocytes, although Langerhans and dermal dendritic cells stain positively.

sunburn, silvery colored hair, and pale irides with photophobia and nystagmus. Severe and recurrent infections of the respiratory tract and skin are common.

Histopathology. Light microscopic features of skin sections show normal findings (94). Fontana-Masson stain shows sparse melanin granules, some of which are grouped and others of which are larger than normal (94). Similar large, irregularly shaped melanin granules are scattered in the upper dermis within melanophages. Hair shafts also demonstrate abnormal aggregates of melanin (95).

The giant lysosomal granules can be demonstrated in peripheral blood, in skin (melanocytes or Langerhans cells), and other organs. A blood smear stained with Giemsa or Wright stain shows the granules are azurophilic. They are found in all white blood cell lines but are most easily seen in neutrophils.

Histogenesis. Within melanocytes, electron microscopic examination reveals giant melanosomes of irregular shape surrounded by a limiting membrane. They further increase in size by fusing with other giant particles. Within the giant melanosomes, a granular matrix and filaments showing periodicity and varying degrees of pigmentation are observed. The largest melanosomes show signs of degeneration leading to vacuolization and the formation of residual bodies. In addition, normal melanosomes are present in the melanocytes and are transferred to keratinocytes; however, they are packaged into abnormally large lysosomes. Similar abnormally large, membrane-bound lysosomes are found in the hair. The giant melanosomes in melanocytes and the giant lysosomes in keratinocytes form because of a defect in membrane or microtubule function. Hypopigmentation occurs because the melanosomes within keratinocytes are found within a relatively few large lysosomes rather than dispersed throughout the cell cytoplasm.

The giant granules in the cytoplasm of white blood cells develop by the fusion of primary lysosomes with one another and with cytoplasmic material. Even though microorganisms are phagocytized into phagocytic vacuoles in a normal fashion, their intracellular killing is delayed because of the unavailability of primary lysosomes to discharge their bacterial enzymes into the phagocytic vacuoles. Also, cathepsin G, a potent antimicrobial protease in neutrophils, is absent in Chédiak-Higashi syndrome.

Mutations in the *CHS1/LYST gene* are associated with Chédiak-Higashi syndrome. CHS1 protein is thought to be a cytosolic protein with a role in vesicle transport (70,96).

Xiaowei Xu

Benign Pigmented Lesions and Malignant Melanoma

Melanocytic proliferations are composed of one or more of three related types of cells: melanocytes, nevus cells, and melanoma cells, each of which may be located in the epidermis, the dermis, or occasionally also in the subcutis. Melanocytes are solitary dendritic cells that generally are separated from one another by other cells (keratinocytes or fibroblasts). Localized proliferation of melanocytes may occur, giving rise to benign or malignant melanocytic neoplasms, characterized by melanocytes that lie in contiguity with one another to form a tumor. Benign tumors of melanocytes are generally called melanocytic nevi, whereas malignant tumors are called malignant melanomas, and the cells of these lesions are called nevus cells and melanoma cells, respectively. Although the term "melanoma" was at one time taken to include benign pigmented lesions, this is now considered to be synonymous with "malignant melanoma," and the two terms are used interchangeably in this chapter. Major morphologic differences among melanocytes, nevus cells, and melanoma cells are summarized in Table 28-1.

Melanocytic lesions are important primarily because of malignant melanoma, which is the most common potentially lethal neoplasm of the skin. The incidence of melanoma has risen dramatically over the last several decades. However, the mortality has risen less dramatically than the incidence, likely due to earlier diagnosis. There is considerable geographic variation in the incidence of melanoma, related to exposure to sunlight and the susceptibility of the population. Thus, the global incidence is highest in the Australian tropics but very low in most other tropical countries, with their less susceptible populations.

Benign melanocytic nevi occur in all ethnic groups, although there is evidence for shared etiologic factors with melanoma, with a greater incidence in susceptible populations living in sunny climates. Nevi and other benign pigmented lesions are occasionally of cosmetic significance, especially in the case of giant or so-called "garment" congenital nevi. Other than cosmetically, nevi are important primarily in relation to melanoma. Thus, nevi are important as simulants of melanoma, as potential precursors of melanoma, and as markers of individuals at increased risk for melanoma. Because nevi are simulants of melanoma both clinically and histologically, criteria that distinguish between nevus and melanoma are of critical importance. This differential diagnosis, especially at the histologic level, is the primary topic of this chapter.

BENIGN PIGMENTED LESIONS

Benign pigmented lesions composed of epidermal melanocytes include freckles, solar lentigines ("actinic" or formerly senile lentigo), the melanotic macules of Albright's syndrome, and Becker's melanosis. The café-au-lait patches of neurofibromatosis have been described elsewhere. Benign pigmented lesions derived from dermal melanocytes include the Mongolian spot, the nevi of Ota and of Ito, and the blue nevus. Benign tumors of nevus cells are called melanocytic nevi. They can be divided into junctional nevi, including lentigo simplex, compound nevi, and intradermal nevi. There are special variants of melanocytic nevi, the more important of which include the Spitz nevus, the pigmented spindle cell nevus, the congenital melanocytic nevus, and the dysplastic nevus.

Dermal Melanocytoses and Hamartomas

It is important to distinguish dermal melanoses (implying only increase in dermal melanin pigment) caused by the presence of melanocytes in the dermis (melanocytoses) from those produced by the presence of melanin within nonmelanocytic cells (e.g., macrophages) within the dermis. Clinically, the two different processes may have very similar appearances (1). In this section we consider the former condition. Dermal melanosis associated with metastatic melanoma is discussed in a later section of this chapter (Generalized Melanosis in Metastatic Melanoma), whereas inflammatory disorders associated with pigmentary alterations are discussed in Chapter 27.

Mongolian Spot

The typical Mongolian spot occurs in the sacrococcygeal region as a uniformly blue discoloration resembling a bruise. It consists of a noninfiltrated, round or ovoid, rather ill-defined patch of varying size. It is found very frequently in Mongoloid and Negroid infants, but it also occurs occasionally in Caucasoid infants. It is present at birth and usually disappears spontaneously within 3 to 4 years (2).

Occasionally, Mongolian spots occur outside the lumbosacral region as aberrant Mongolian spots, such as on the middle or upper part of the back; they may then be multiple and bilateral and persist. Extensive and persistent Mongolian spots are commonly seen in patients with bilateral nevus of Ota (3).

TABLE 28-1 Melanocytes, Nevus Cells, and Melanoma Cells

Melanocytes	Nevus cells	Melanoma cells
Cytoplasm is dendritic	Rounded or spindle	Rounded or spindle
Cells are solitary	Arranged in clusters	In clusters and large sheets
Nuclei are small and regular	Nuclei of most cells are small and regular	Most nuclei are large, irregular, and hyperchromatic
Mitoses are rare	Mitoses are rare	Mitoses are usually present

Histopathology. In the Mongolian spot, the dermis shows in its lower half or two thirds greatly elongated, slender, often slightly wavy dendritic cells containing melanin granules that are distributed within the dendrites, rendering them visible. These cells are present in a low concentration and lie widely scattered between the collagen bundles, and like the collagen bundles, they generally lie parallel to the skin surface. No melanophages are seen.

Nevi of Ota, Ito, and Hori; Dermal Melanocyte Hamartoma

Nevi of Ota and Ito and dermal melanocyte hamartoma are types of dermal melanocytosis that differ from the Mongolian spot by usually having a speckled rather than a uniform blue appearance and by showing a greater concentration of dermal melanocytes, with location in the upper rather than in the lower portion of the dermis (3,4).

The *nevus of Ota* is most often a unilateral discoloration of the face composed of blue and brown, partially confluent macules. The periorbital region, temple, forehead, malar area, and nose are usually involved. Because of this usual distribution, Ota called the lesion nevus fuscocaeruleus ophthalmomaxillaris. There is frequently also a patchy blue discoloration of the sclera of the ipsilateral eye and occasionally also a similar discoloration of the conjunctiva, cornea, and retina. In some instances, the oral and nasal mucosa is similarly affected. In about 10% of the cases, the lesions of the nevus of Ota are bilateral rather than unilateral. They may be present at birth; they may also appear during the first year of life or during adolescence but only rarely in childhood. They have a tendency toward gradual extension. Malignant change in the cutaneous lesions of a nevus of Ota is extremely rare (3).

In the nevus of Ota, the involved areas of the skin show a brown to slate-blue, uniform or mottled discoloration, usually without any induration. Occasionally, however, some areas are slightly raised. In some patients, discrete nodules varying in size from a few millimeters to a few centimeters and having the appearance of blue nevi are found within the areas of discoloration. Persistent Mongolian spots are quite common in association with the nevus of Ota. Extensive Mongolian spots are typically found in bilateral cases of nevus of Ota (3).

The *nevus of Ito* differs from the nevus of Ota by its location in the supraclavicular, scapular, and deltoid regions. It may occur alone or in association with an ipsilateral or bilateral nevus of Ota (5). Like the nevus of Ota, it has a mottled, macular appearance.

Nevus of Hori is a form of acquired dermal melanocytosis. It is also known as acquired bilateral nevus of Ota-like macules and acquired symmetric dermal melanocytosis (6–8). The patients present with speckled blue-brown or gray macules that are located bilaterally in the malar region. The vast majority of the reported cases have been seen in Asian women. Histology reveals dendritic pigmented melanocytes in the mid and upper dermis. The dermal pigment stains positively with Fontana Masson staining, and the melanin-containing cells are 3,4-dihydroxy-L-phenylalanine (DOPA) positive. Electron microscopy has revealed a predominance of stage IV melanosomes and melanocyte dendrites encircling elastic fibers.

In the *dermal melanocyte hamartoma*, there may be a single, very extensive area of gray-blue pigmentation present from the time of birth. Histologic and ultrastructural examinations reveal numerous dermal melanocytes (9). The involvement may be nearly generalized (10). In other instances, there are several coalescing blue macules that have gradually extended within a circumscribed area from the time of childhood (11).

Histopathology. The noninfiltrated areas of the nevus of Ota, as well as the nevus of Ito and the dermal melanocyte hamartoma, show, like the Mongolian spot, elongated, dendritic melanized melanocytes scattered among the collagen bundles. However, in these three forms of dermal melanocytosis, the melanocytes generally are more numerous and more superficially located than in the Mongolian spot. Although most of the dendritic melanocytes lie in the upper third of the reticular dermis, melanocytes may also occur in the papillary layer and may extend as far down as the subcutaneous tissue. Melanophages are seen in only few lesions (9,10). A histologic classification of Ota's nevus has been proposed according to the distribution of the dermal melanocytes from superficial to deep. This correlates with the color and location of the nevus and probably with response to therapy (12).

Slightly raised and infiltrated areas show a larger number of elongated, dendritic melanocytes than do noninfiltrated areas, thus approaching the histologic picture of a blue nevus, and nodular areas are indistinguishable histologically from a blue nevus (13).

Malignant changes in lesions of nevus of Ota have been reported in a handful of cases (14). The histologic appearance of the tumors may be that of a malignant or cellular blue nevus (15). In a few instances, a primary melanoma of the choroid, iris, orbit, or brain has developed in patients with a nevus of Ota involving an eye (16,17). A benign or low-grade lesion termed a melanocytoma of the meninges may also occur (18).

Histogenesis of the Dermal Melanocytoses. The blue color of the dermal melanocytoses depends on the phenomenon whereby light passing through the skin is scattered as it strikes dark particles, such as melanin. Owing to this scattering phenomenon, which is termed the Tyndall effect, the colors of light that have a longer wavelength, such as red, orange, and yellow, tend to be less scattered and therefore continue to travel in a forward direction, but the colors of shorter wavelength, such as blue, indigo, and violet, are scattered to the side and backward to the skin surface. This phenomenon is also responsible for the distinctive color of blue nevi and of blood in veins.

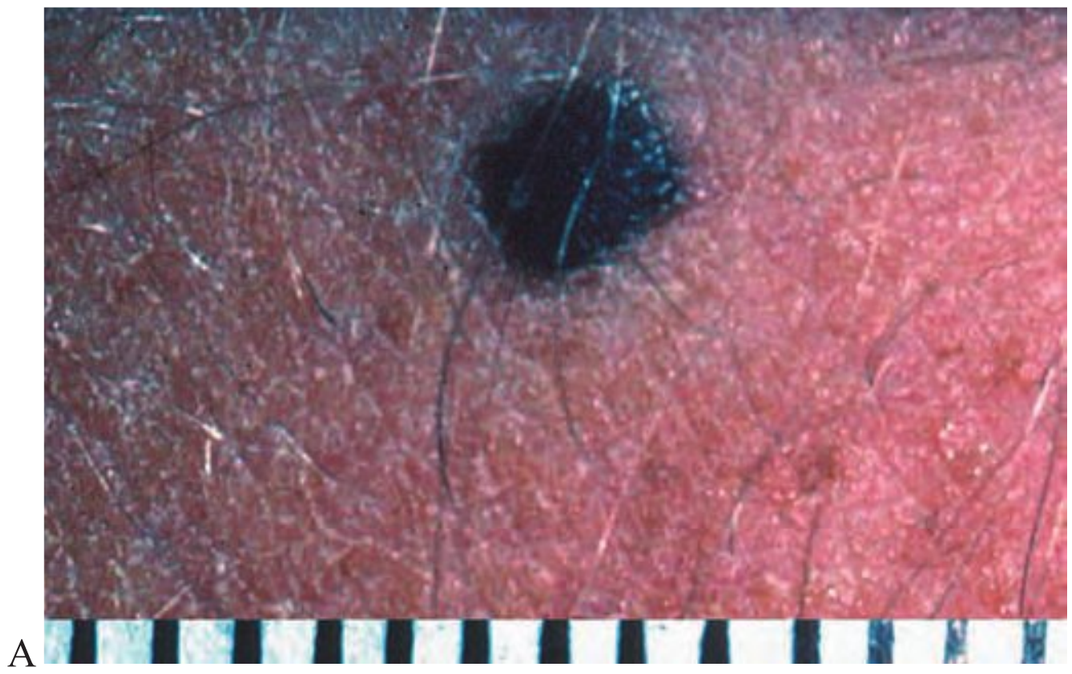
The Mongolian spot is believed to be the result of the delayed disappearance of dermal melanocytes during embryogenesis. On electron microscopy, the dermal melanocytes are seen to contain numerous fully melanized melanosomes. Only a few melanocytes show premelanosomes as evidence of ongoing melanogenesis (2).

Because the concentration of melanocytes in the nevi of Ota and Ito and in the dermal melanocyte hamartoma is greater than in the Mongolian spot, it has been suggested that these lesions are nevoid or hamartomatous, rather than reactive or neoplastic. Although the lesional cells are considered to be melanocytes, the DOPA reaction may be negative, likely due to all of the melanogenic enzyme having been consumed in heavily pigmented melanocytes (9).

Blue Nevi

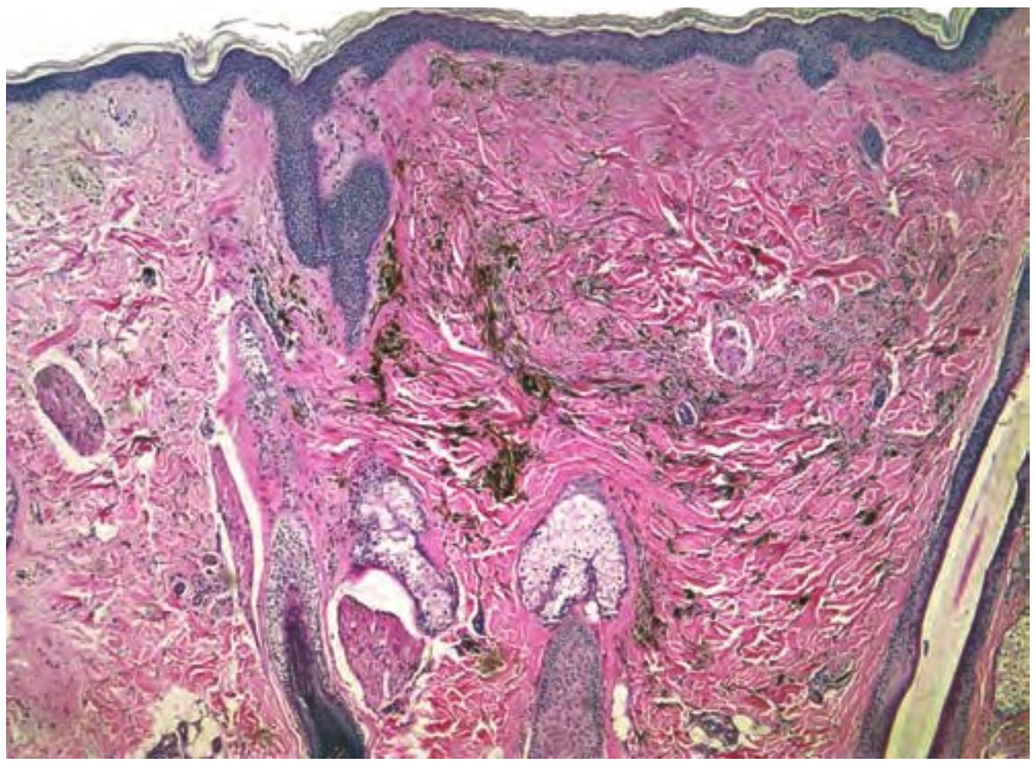
Blue nevi are benign, localized pigmented lesions that generally occur on the skin, although, occasionally, they may be observed in mucous membranes (19). On the skin, three types of benign blue nevi are recognized: the common blue nevus, the cellular blue nevus, and the combined nevus. In addition, there are malignant blue nevi, discussed in a later section.

Histologically, the common feature of blue nevi is the presence of pigmented spindle and dendritic melanocytes in a focal area of the reticular dermis, associated (unlike the dermal melanocytoses) with alterations in the dermal collagen architecture. This deeply situated pigment differs from that in acquired nevi, which is typically superficial only, and accounts for the blue color of these lesions due to the light-scattering Tyndall effect.



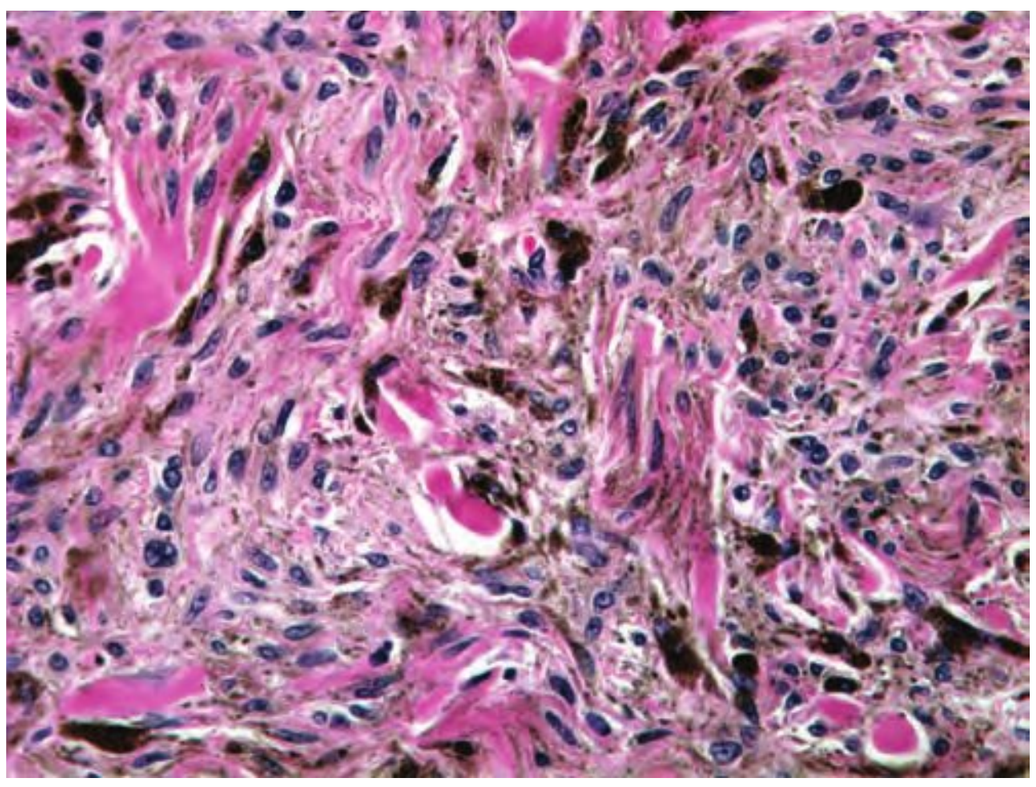
In a recent study, persistence and recurrence of blue nevi were discussed, demonstrating that blue nevi of all histologic types and combinations are capable of persistence with clinical recurrence (20). The persistence usually is histologically similar to the original but in some cases is more "cellular" and/or atypical. Limited follow-up of these cases has not demonstrated frankly malignant behavior. Clinical recurrence may also be associated with malignancy of a blue nevus–like lesion, but this study demonstrated that tumor progression to malignancy is not necessarily the case. In the absence of necrosis en masse, marked cytologic atypia, and frequent mitotic figures, recurrence of a blue nevus or a cellular blue nevus is likely to be a benign phenomenon (20). However, we recommend complete excision and follow-up for such recurrent lesions.

Common Blue Nevus

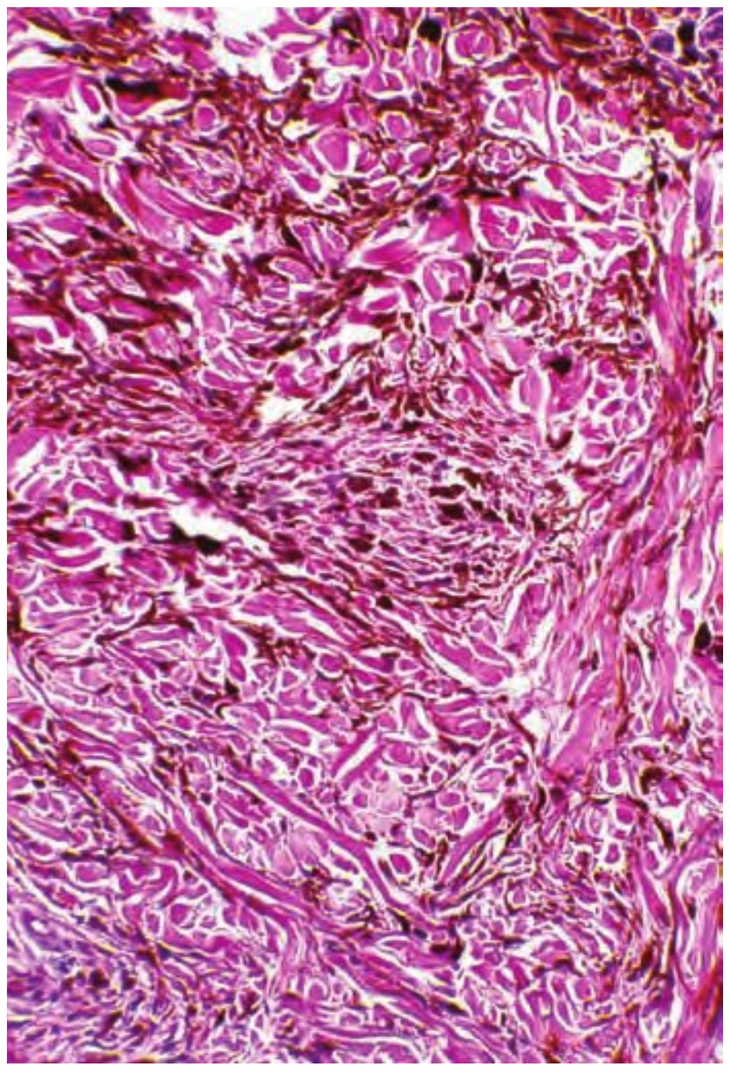


The common blue nevus occurs as a small, well-circumscribed, dome-shaped nodule of slate-blue or blue-black color (Fig. 28-1A). The lesion rarely exceeds 1 cm in diameter. Common blue nevi are frequently found on or near the dorsa of the hands and feet, as well as on the scalp. Usually, there is only one lesion, but there may be several. A rare manifestation is the plaque type of blue nevus, which shows numerous macules and papules within a circumscribed area. This type of lesion may be present at birth or may become clinically apparent later in life (21). Malignant degeneration has not been reported in the common blue nevus.

Histopathology. In the *common blue nevus*, the melanocytes have a similar appearance to those in the Mongolian spot and in the nevus of Ota but they are typically larger and their density is much greater. Greatly elongated, slender, often slightly wavy melanocytes with long, occasionally branching dendritic processes lie grouped in irregular bundles in the dermis (Fig. 28-1B–D). The bundles of cells may extend into the subcutaneous tissue or lie close to the epidermis. However, the epidermis is normal, except in the combined nevus (see section Combined Nevus). The greatly elongated melanocytes lie predominantly with their long axis parallel to the epidermis. Most of them are filled with numerous fine granules of melanin, often so completely that their nuclei cannot be visualized. The melanin granules also characteristically fill the long, often wavy, occasionally branching dendritic processes. Wavy fiber bundles similar to nerves may be present, indicative of schwannian differentiation (22). Occasionally, lesional cells are seen in the perineurium of authentic nerves, a finding that is not indicative of malignancy. Melanophages may be seen near the bundles of melanocytes but are usually not numerous or dense. The melanophages differ from the melanocytes by being more round to ovoid, by showing no dendritic processes, and by containing larger granules. The melanocytes of blue nevi are positive for S100 and HMB-45 (23) and for Melan-A (24). The number of fibroblasts and the amount of collagen are generally increased in blue nevi, resulting in disruption of the normal architecture of the connective tissue. In some lesions, the collagen is unusually prominent, and these have been termed *desmoplastic blue nevi* (or cellular blue nevi) (25,26).



If melanocytes are relatively sparsely distributed and minimally pigmented, these lesions may be mistaken for a fibrohistiocytic lesion such as a *dermatofibroma*. A few blue nevi are hypopigmented or even amelanotic (27,28), requiring immunohistochemistry for their confirmation. Although blue nevi are usually strictly dermal, rare *compound blue nevi* have been described in which there are pigmented dendritic melanocytes in the epidermis near the dermal–epidermal junction (29). Junctional melanocytes may also be seen in the setting of combined nevi (see later discussion). Recurrences of benign blue nevi after excision have been described; although this phenomenon is



A

B

C

D

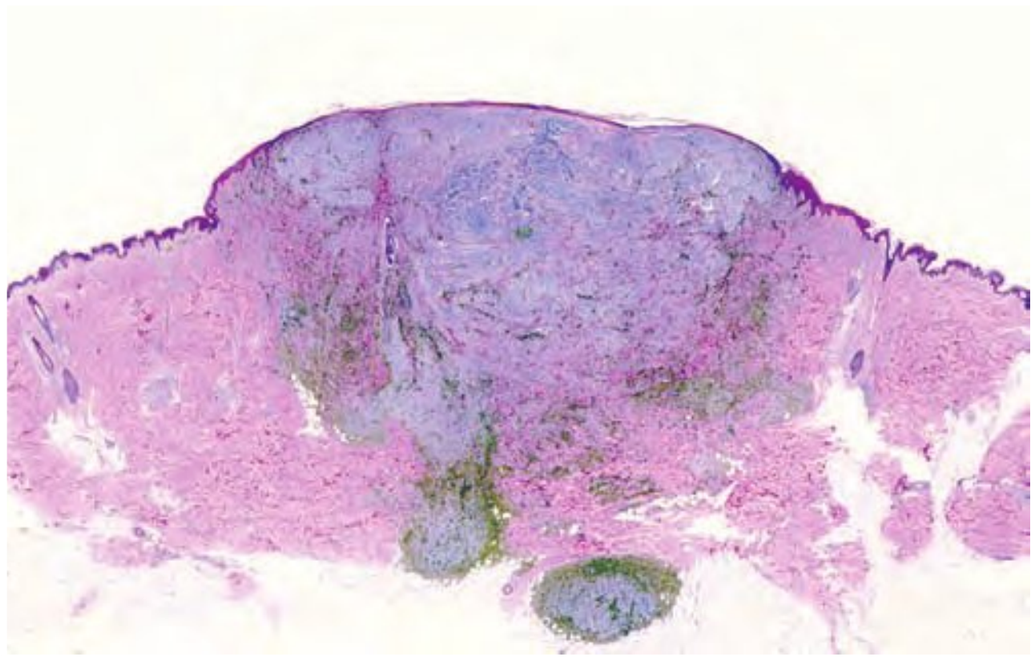


FIGURE 28-1. A: Blue nevus. A relatively small, well-circumscribed, slightly elevated blue-black pigmented lesion. B: Spindle-shaped or dendritic melanocytes are placed among reticular dermis collagen bundles, which are often, as here, slightly thickened. C: Unlike the cells of most common or congenital nevi that involve the reticular dermis, the cells of blue nevi are usually heavily pigmented, with coarsely divided melanin granules. D: Especially at the periphery of the lesion, the cells are arranged as single cells placed among collagen bundles rather than sheets or fascicles.

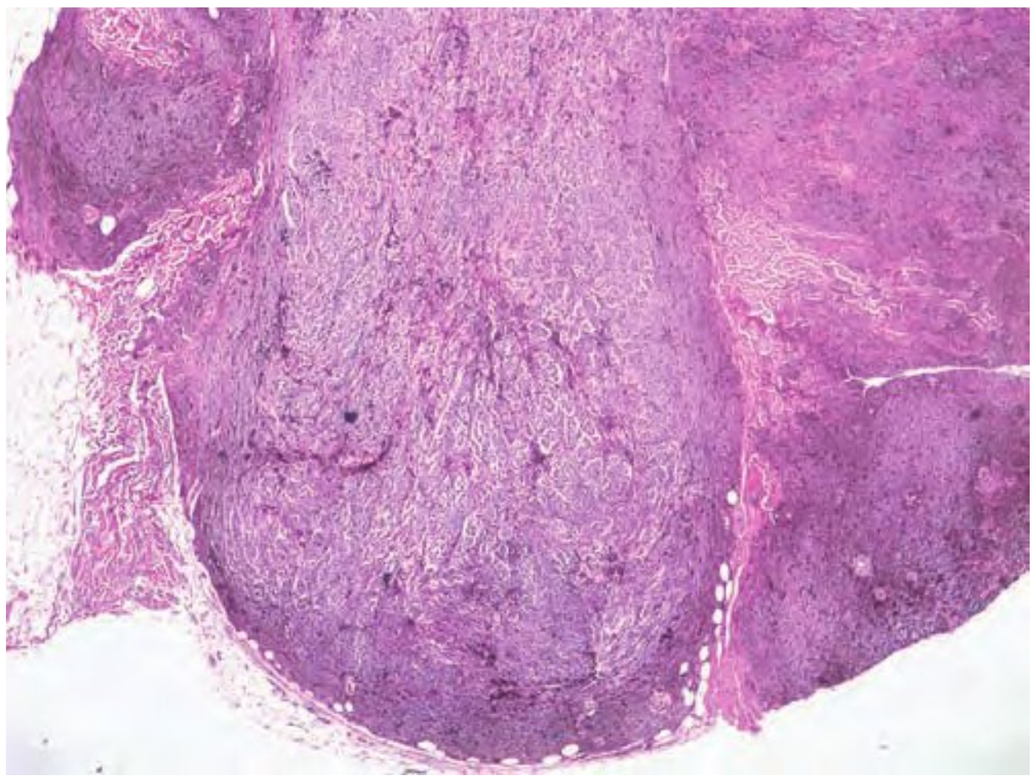
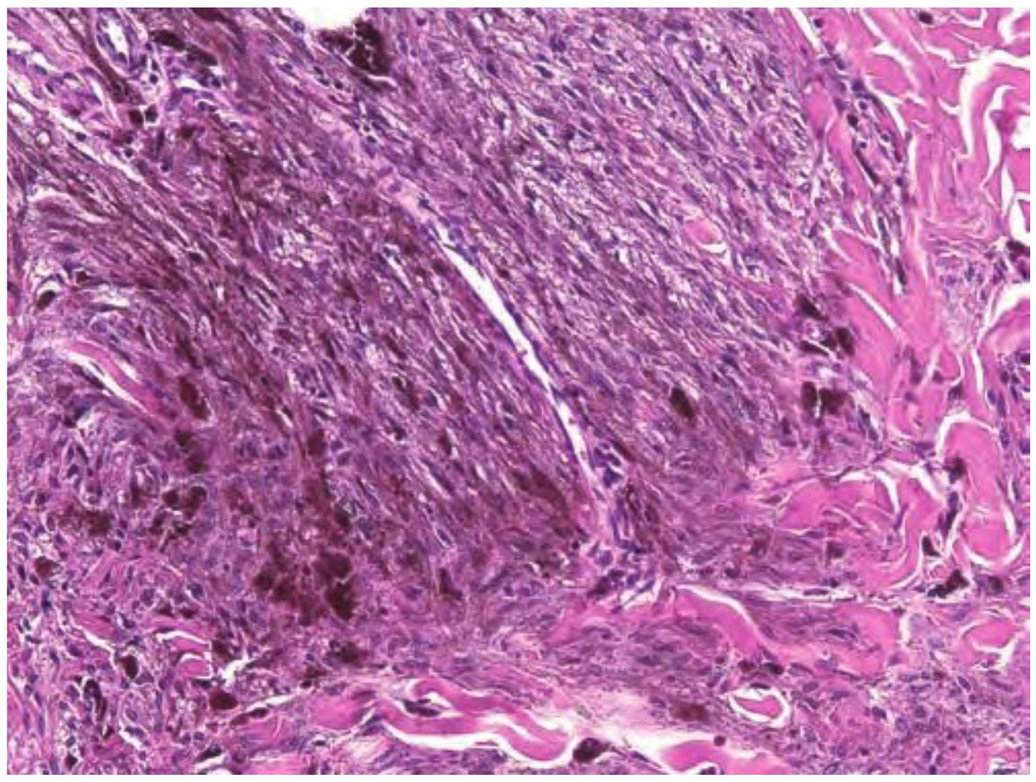
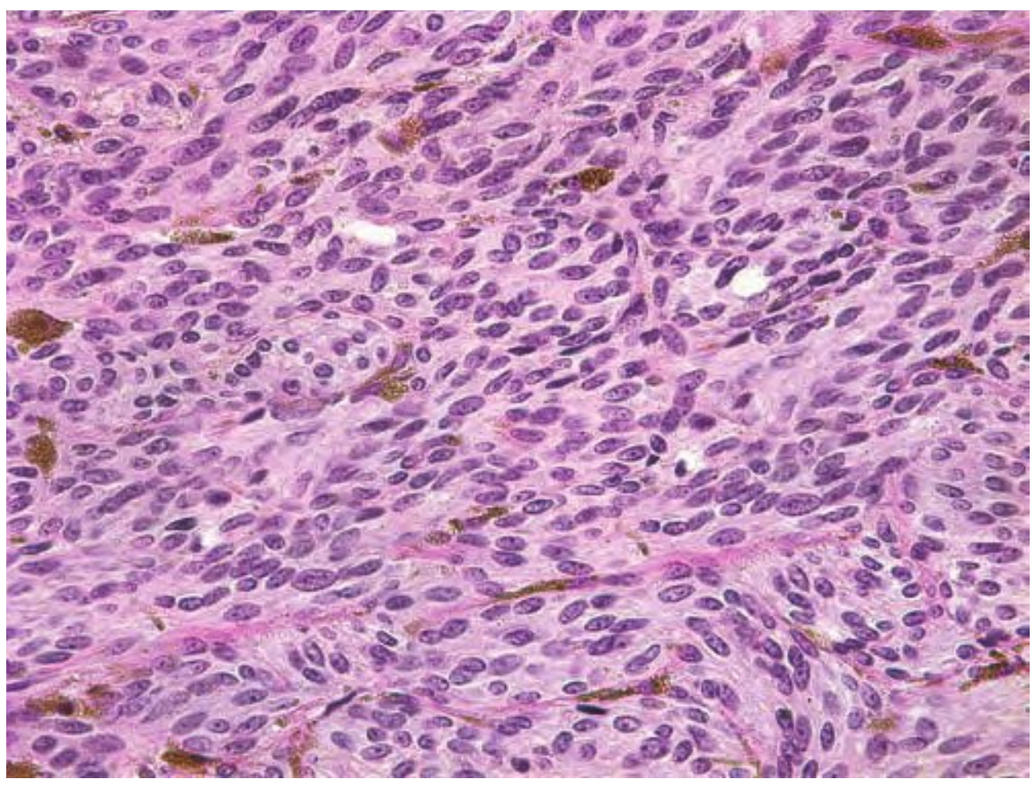


suggestive of malignancy and the recurrences tend to be more cellular than the original lesions, the behavior may be benign in the absence of compelling indicators of malignancy, such as necrosis, high-grade atypia, and mitoses (20).



Cellular Blue Nevus



The cellular blue nevus (CBN) consists of a blue nodule that is usually larger than the common blue nevus. It generally measures 1 to 3 cm in diameter, but it may be larger. It shows either a smooth or an irregular surface. About half of all cellular blue nevi have been located over the buttocks or in the sacrococcygeal region (30–32). Although rare, malignant degeneration of cellular blue nevi can occur (31) (see section Malignant Blue Nevis).

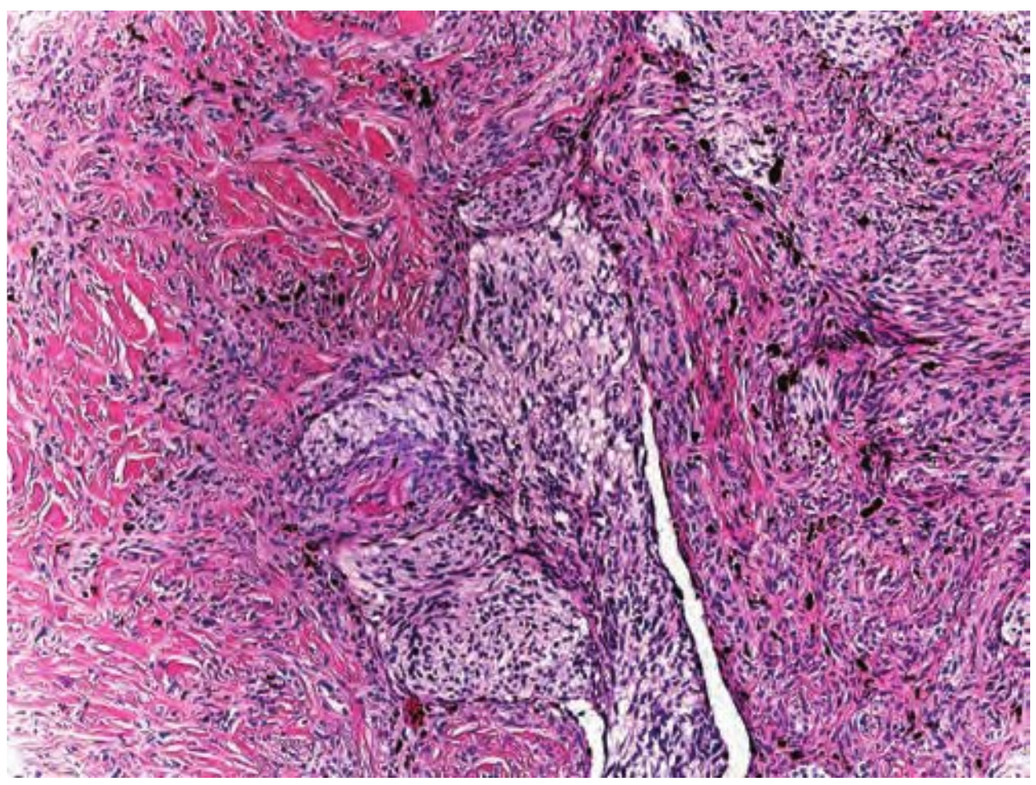
Histopathology: The profile of a CBN is often distinctive at scanning magnification, with a bulky, heavily pigmented cellular tumor often spanning the reticular dermis and not associated with an overlying *in situ* melanoma (Fig. 28-2A–E). In

A

B

C

D



E

FIGURE 28-2. A: Cellular blue nevus. Usually broader at its surface than its base, the cellular blue nevus spans the reticular dermis, usually involving the superficial panniculus. Often, there is a region of increased cellularity that may form a bulbous expansion at the base. A small satellite lesion, as seen here, is an unusual finding. B: The bulbous expansion where the lesion meets the panniculus at the base is a characteristic but not invariable finding. C: Spindle cells usually predominate in cellular blue nevi. They lie in contiguity with one another, unlike the cells of common blue nevi, most of which are separated from one another by collagen bundles. D: In other areas, it is common to find sheets of cuboidal cells with pale cytoplasm in a cellular blue nevus. E: This mixed-biphasic pattern is a distinctive feature of many cellular blue nevi, with ovoid islands of polygonal cells with somewhat clear cytoplasm alternating with spindle cells, the latter often pigmented. Mitoses are very rare in most examples. Changes at the periphery may be indistinguishable from those of a common blue nevus.

lesions that enter the subcutis there is often a cellular nodule at the base, connected to the overlying tumor in a dumb-bell pattern. Areas of deeply pigmented dendritic melanocytes, as seen also in the common type of blue nevus, are admixed with cellular islands composed of closely aggregated, rather large, spindle-shaped or more-epithelioid cells with ovoid nuclei and abundant pale cytoplasm often containing little or no melanin. Melanophages with abundant melanin may be present between the islands. Although pigment is usually prominent, amelanotic CBN have been described (33). Four histologic subtypes have been recognized: mixed-biphasic, alveolar, fascicular or neuronevoid (also known as the monophasic spindle cell type), and atypical varieties (31). In the common mixed-biphasic type, there are clusters of epithelioid cells with somewhat clear cytoplasm, between which there are fascicles of spindle cells (Fig. 28-2E). Pigment is usually more prominent in the latter. The alveolar type is distinctive, characterized by rounded nests of clear spindle cells embedded in a matrix of dendritic and spindle-shaped, more heavily pigmented melanocytes similar to those of the mixed-biphasic pattern. The monophasic spindle cell type is somewhat more problematic and may overlap with *pigmented epithelioid melanocytomas*, *spindle cell tumorigenic melanomas*, and *malignant blue nevi* (see the respective sections). The absence of an overlying *in situ* component may help to rule out a melanoma. Attributes that may suggest malignancy in a CBN are discussed in the section on malignant blue nevi. They include frequent mitoses, high-grade cytologic atypia, and spontaneous tumor necrosis or ulceration.

Lesions termed *atypical cellular blue nevi* have become recognized as a variant of cellular blue nevi, characterized by unusual features including architectural atypia (infiltrative margin and/or asymmetry) and/or cytologic atypia (hypercellularity, nuclear pleomorphism, hyperchromasia, occasional mitotic figures, and/or subtle necrosis) (30,31,34). Although most of these lesions have a benign course, a few cellular blue nevi (not necessarily all "atypical") have been locally aggressive (35,36) or have metastasized at least to regional lymph nodes (37,38), and a guarded prognosis is appropriate in the presence of more than a few mitoses (see section Superficial Atypical Melanocytic Proliferation of Uncertain Significance). The absence or scarcity of mitotic figures and the absence of areas of necrosis or of high-grade atypia are evidence against a diagnosis of malignant blue nevus, and the presence of areas of dendritic blue nevus–type cells elsewhere in the tumor and the lack of a characteristic intraepidermal (*in situ* melanoma) component argue against a diagnosis of melanoma.

In several instances in which cellular blue nevi were excised with regional lymph nodes under the mistaken diagnosis of melanoma or because of an "atypical" or "uncertain" diagnosis, moderately or severely atypical cells of cellular nevus were found in the regional lymph nodes, often in the marginal sinuses or in the capsule (39), but sometimes more massively involving the node (38). It is sometimes assumed that these cells do not represent true metastases but were passively transported to the lymph nodes and lodged there as inert deposits. However, some examples of this phenomenon in our experience have shown high-grade uniform atypia, necrosis, and fairly numerous mitoses, apparently indicative of an active neoplasm. Some of these lesions may best be interpreted as metastatic tumors of uncertain potential (see later section).

Combined Nevus

The term *combined nevus* is applied to the association of a blue nevus with an overlying melanocytic nevus (40) or to other combinations of benign nevi (41). Clinically, combined nevi often present with a focal area of deep pigmentation.

Histopathology: In a combined nevus, one component is often a congenital pattern nevus in which pigmented spindle cells form a focal collection of fascicles among nests of ordinary nevus cells. The fascicles tend to be organized along the lines of a blue nevus, which may be either a common or a cellular blue nevus. The other component may be an overlying nevus of the junctional, compound, or intradermal type, or, rarely, a Spitz nevus (41). Such lesions may simulate melanoma clinically because of the appearance of a very darkly pigmented spot within a background nevus. Histologically, the pigmented spindle cells of the blue nevus component may give rise to suspicion based on apparent asymmetry of pigment distribution, but mitoses and high-grade atypia are absent, and the pigmented cells often blend with the background nevus rather than displacing or destroying it. Furthermore, it is extremely unusual for a melanoma to arise in the dermal component of a nevus in the absence of a characteristic intraepidermal component.

Histogenesis of Blue Nevi. There is general agreement that the cells of the common blue nevus are melanocytes, which may show evidence of Schwannian differentiation. This occasional resemblance to neural tumors had led to suggestions of neural origin for blue nevi (42). However, the lesional cells of blue nevi and their variants react positively with antibodies to the S100, HMB-45, and Melan-A/MART-1 antigens, the last two in this context being quite specific for melanocytic differentiation, and also serving to help differentiate these lesions from desmoplastic melanomas, which are typically negative for these markers (26,43). In addition, melanosomes are present by electron microscopy (EM 48), and the electron microscopic DOPA reaction indicates that the spindle-shaped cells of the cellular blue nevus have melanogenic potential (44).

Freckles and Hyperpigmentations

By definition, a freckle (ephelide) is a small, flat, tan or brown lesion that histologically shows increased pigment in keratinocytes but no increase in the number of melanocytes. Hyperpigmentations may be described as larger, macular, pigmented lesions that show increased melanin pigment in keratinocytes without melanocytic proliferation. Lentigines are macular hyperpigmentations that differ from freckles and hyperpigmentations in that the number of epidermal melanocytes is increased within the basal cell layer. However, in common parlance, the term "freckle" is often used to refer both to ephelides and to solar lentigines, as well as other forms

of macular hyperpigmentations. Ephelides appear early in childhood and are associated with fair skin type and red hair. Solar lentigines appear with age and are a sign of photodamage. Both lesions are strong risk indicators for melanoma and nonmelanoma skin cancer. Melanocortin-1–receptor (MC1R) gene variants are also associated with fair skin, red hair, and melanoma and nonmelanoma skin cancer. In a large case–control study, carriers of MC1R gene variants had a markedly increased risk of developing ephelides, whereas the risk of developing severe solar lentigines was moderately increased, suggesting that MC1R is a major gene controlling susceptibility to the development of these forms of macular hyperpigmentations (45).

Ephelide (Freckle)

Freckles, or ephelides, are small, red-brown macules scattered over skin exposed to the sun. Exposure to the sun deepens the pigmentation of freckles, in contrast to lentigo simplex, whose already deep pigment does not change. Ephelides, simple lentigines, and solar lentigines are difficult to distinguish from one another clinically and are considered together in most clinical and epidemiologic studies. Taken together, these lesions constitute a significant risk factor for the development of melanoma (46).

Histopathology. Freckles show hyperpigmentation of the basal cell layer, but in contrast to lentigo simplex, there is no elongation of the rete ridges and, by definition, no obvious increase in the concentration of melanocytes. However, in a quantitative study of lesions from children, melanocyte frequencies in freckles were significantly greater than in adjacent nonpigmented skin. Cellular atypia of melanocytes and reactivity of melanocytes for HMB-45 were noticed in some freckles (47). It is likely that freckles represent a hyperplastic and hyperactive response of melanocytes to ultraviolet (UV light).

Histogenesis. On electron microscopy, the melanocytes within freckles are found to be essentially similar to those of dark-skinned persons. Melanocytes of the surrounding epidermis, by contrast, show constitutionally few and minimally melanized melanosomes, many of which are rounded rather than elongated (48). Such rounded melanosomes (so-called pheomelanosomes) are characteristic of the lightly pigmented skin of individuals with red hair and/or blue eyes and a cutaneous phenotype that is prone to freckles. As noted earlier, the tendency to develop freckles appears to be closely related to MC1R gene polymorphisms (45).

Melanotic Macules of Albright's Syndrome

Albright's syndrome usually is characterized by unilateral polyostotic fibrous dysplasia, precocious puberty in females, and melanotic patches. The patches generally are large and few, are located on only one side of the midline, often on the same side as the bone lesions, and have a jagged, irregular border, like the coast of Maine, in contrast to the smooth, coast of California–type of border of the café-au-lait patches of neurofibromatosis.

Histopathology. Except for hyperpigmentation of the basal layer, there is no abnormality, and both the number and the size of the melanocytes are normal (49).

Differential Diagnosis. The melanotic macules of Albright's syndrome only rarely show the "giant" melanin granules (macromelanosomes) that are commonly seen in some of the melanocytes and keratinocytes within the café-au-lait patches of *neurofibromatosis*. Histologically, the melanotic macules may be indistinguishable from ephelides without correlative clinical information.

Mucosal Melanotic Macules (Mucosal Lentigines)

These benign lesions present as a pigmented patch on a mucous membrane. Common locations include vermilion border of the lower lip, the oral cavity, the vulva, and, less often, the penis. These lesions may simulate melanoma clinically, but histologically there is no contiguous melanocytic proliferation and no significant atypia. Because there may be a slight increase in number of melanocytes, although there is no nest formation, the term genital lentiginosis has been proposed for those lesions affecting genital paramucosae (50). The lesions may be synonymously referred to as mucosal lentigo or mucosal melanotic macule.

In the common location on the vulva (vulvar lentigo), this process may appear quite alarming clinically, presenting as a broad, irregular, and asymmetric patch of brown to blue-black hyperpigmentation, often meeting the "ABCD" criteria for melanoma discussed later (51). Similar lesions may also be seen on penile skin (50). The lesions may be multicentric, with alternating areas of normal and pigmented mucosa resembling areas of partial regression of a melanoma. The lesions are entirely macular, which would be unusual in an invasive melanoma. The so-called labial lentigo (also known as labial melanotic macule or labial melanosis), a hyperpigmented macule of the lip, is closely related to the lesions of genital skin. It is rarely biopsied because the clinical appearances are characteristic and do not suggest malignancy. These lesions are uniformly pigmented light to dark brown, usually completely macular, and usually less than about 6 mm in diameter. These macules are biologically indolent (52).

Histopathology. On initial inspection, a biopsy specimen may appear normal. The findings include mild acanthosis without elongation of rete ridges and hyperpigmentation of basal keratinocytes, often best recognized in comparison with surrounding epithelium, in association with scattered melanophages in the dermis. Although melanocytes may be normal in number, in most instances they are slightly increased (50,53). Because of this slight increase in number, the lesions are termed lentigines (as opposed to ephelides) by strict histologic criteria (50). In contrast to true melanocytic neoplasms (nevi or melanomas), the cell bodies of the lesional melanocytes are separated by those of keratinocytes, that is, there is no contiguous proliferation of melanocytes. Occasionally, especially in the penile and vulvar lesions, there are prominent dendrites of melanocytes ramifying among the hyperpigmented keratinocytes. There

may be associated mild keratinocytic hyperplasia, and scattered melanophages in the papillary dermis, resulting from pigmentary incontinence, may account for the blue-black color and the pigmentary variegation that may simulate melanoma clinically.

Differential Diagnosis. The histologic distinction from radial-growth-phase melanoma is easy because of the absence of neoplastic (contiguous) melanocytic proliferation and cytologic atypia of melanocytes (54).

Pathobiology. The process appears likely to be one of reactive hyperplasia with some features of postinflammatory hyperpigmentation rather than a neoplasm (55). The phenomenon is benign, with associated lesional growth stabilization over time.

Becker's Melanosis

Becker's melanosis, also called Becker's pigmented hairy nevus, occurs most commonly as a large, unilateral patch showing hyperpigmentation and hypertrichosis on the shoulder, back, or chest of a male adult (56). Usually, the patch is sharply but irregularly demarcated. Occasionally, however, the lesion presents as coalescing macules instead of a solitary patch. The lesion commonly appears during the second decade of life. In some instances, Becker's melanosis affects areas other than the shoulder and chest. In addition, it may be multiple and bilateral and may occasionally be found in women.

In one report, nine cases of melanoma in association with Becker's nevus were described (57). Five of these were on the same body site as the nevus. It remains to be determined whether these reports represent a greater incidence than chance would suggest.

The hairiness always appears after the pigmentation, and, quite frequently, no hypertrichosis is seen. It is therefore possible that cases described as progressive cribriform and zosteriform hyperpigmentation represent a variant of Becker's melanosis without hypertrichosis (58).

Of interest is the association of a pilar smooth muscle hamartoma with Becker's melanosis. In such cases, the area of Becker's melanosis may show slight perifollicular papular elevations or slight induration (59).

Histopathology. The epidermis shows slight acanthosis and regular elongation of the rete ridges. There is hyperpigmentation of the basal layer, and melanophages are seen in the upper dermis. The number of melanocytes is increased within the basal cell layer. This increase is particularly evident when melanocytes are stained for dopa-oxidase activity in both involved and uninvolved skin nearby (60). The pilar structures appear normal or increased in number.

An increase in smooth muscle fibers exists in nearly all cases, although it may be slight (61). In cases with an associated smooth muscle hamartoma, irregularly arranged, thick bundles of smooth muscle are present in the dermis (59). The term Becker nevus syndrome has been proposed for a phenotype characterized by the presence of a particular type of organoid epithelial nevus showing hyperpigmentation, increased hairiness, hamartomatous augmentation of smooth muscle fibers (smooth muscle hamartoma), and other developmental defects such as ipsilateral hypoplasia of breast and skeletal anomalies including scoliosis, spina bifida occulta, and ipsilateral hypoplasia of a limb (62).

The few melanomas that have been described in association with Becker's nevus have been of the superficial spreading type, originating in the epidermis (57).

Lentigines

Lentigines are macular hyperpigmentations in which the number of epidermal melanocytes is increased and there are no nests of melanocytes as are present, by definition, in nevi. The term "lentigo" is derived from the Latin "*lenz*," meaning lens or lentil (63). Thus, the term in its original usage is clinical, referring to a small ovoid or lens-shaped pigmented spot. The term has come to be applied to larger pigmented lesions, especially those that recapitulate to a greater or lesser extent the histologic features of a lentigo simplex: basal proliferation of melanocytes arranged as single cells rather than in nests, typically but not always associated with elongation of the rete ridges. This pattern of melanocytic proliferation is termed "lentiginous." Lentiginous melanocytic proliferation is seen in the macules of solar lentigo and lentigo simplex and in the macular or plaque components of lentiginous junctional and compound nevi, of lentiginous dysplastic nevi, and of lentiginous melanoma, including lentigo maligna, acral and mucosal-lentiginous types.

Solar Lentigo (Actinic Lentigo)

Solar lentigines commonly occur as multiple lesions in areas exposed to the sun, such as the face and extensor surfaces of the forearms, but most commonly on the dorsa of the hands. The lesions increase in number with age, in contrast to nevi, which decline in number (64). Therefore, they are often referred to as senile lentigines (65). However, sun exposure, rather than age, is the eliciting factor (66). Thus, the lesions do not occur on sun-protected skin, even in the elderly. Solar lentigines are commonly seen in sun-exposed Caucasoids. They are not indurated, possess a uniform dark brown color, and have an irregular outline. They vary in diameter from minute to more than 1 cm and may coalesce. Solar lentigines, like ephelides, are risk markers for the development of melanoma (67) and are commonly numerous in the skin around melanomas, as seen in melanoma reexcision specimens. Lesions termed "sunburn freckles" by some clinicians may overlap clinically and histologically with actinic lentigines. They are blotchy macular areas of tan hyperpigmentation, often of the order of 1 cm in diameter, that often appear on the shoulders or other sun-exposed areas of a young person after a severe sunburn (68). Other potentially related lesions are intensely dark, perfectly macular reticulated lesions that have been called reticulated lentigo (69) or ink spot lentigo (70).

Solar lentigines differ from ephelides in that they are more prevalent, increase in prevalence and number with age (ephelides tend to decline in number), are most prevalent on

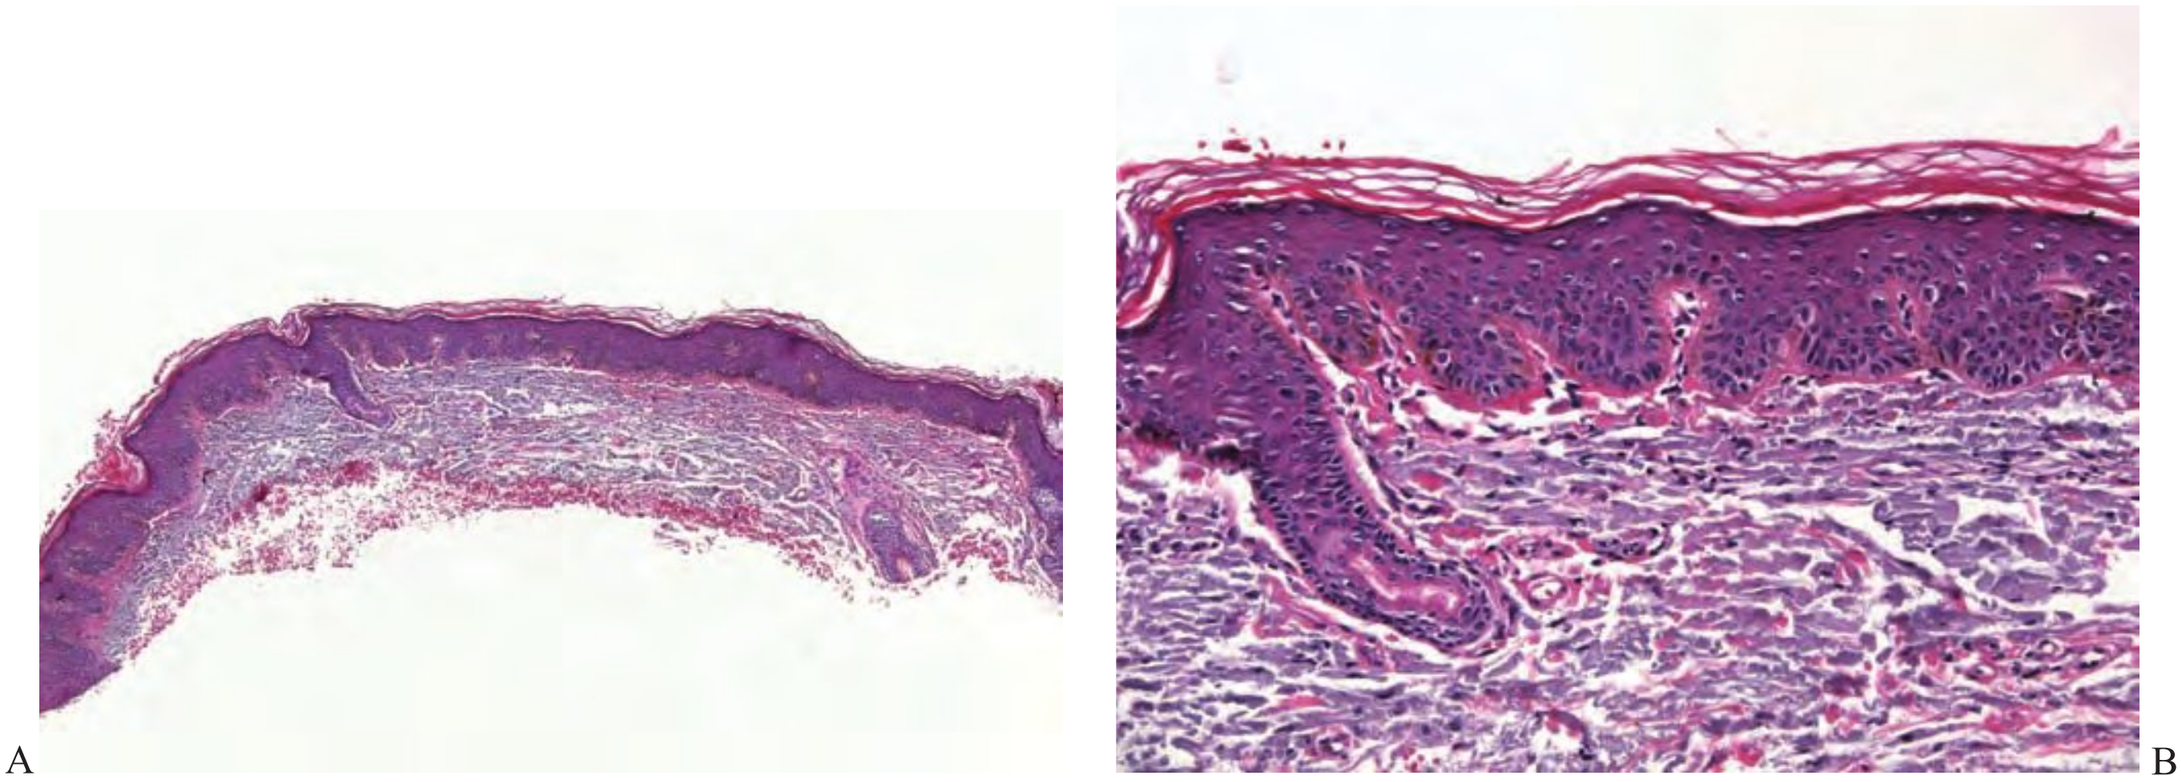


FIGURE 28-3. A: Actinic lentigo. Scanning magnification showing a localized area of elongated rete ridges in elastotic, actinically damaged skin. B: Actinic lentigo. Higher magnification shows basal hyperpigmentation and slight to moderate prominence of melanocytes, without contiguous proliferation. Sometimes there is slight atypia of randomly scattered melanocytes (mild random atypia).

the trunk, and occur more frequently in males than in females, unlike ephelides, which are more evenly distributed and are not related to sun exposure (71,72).

Solar lentigines and relatively flat seborrheic keratoses may resemble each other in clinical appearance, and both are commonly referred to as "liver spots" or "age spots." Seborrheic keratoses in general show more hyperkeratosis clinically. In contrast, lentigo maligna differs from solar lentigo in clinical appearance by its irregular distribution of pigment, often in a finely reticulated pattern, and by its greater asymmetry and border irregularity.

A recent microarray analysis of solar lentigines demonstrated upregulation of genes related to inflammation, fatty acid metabolism, and melanocytes and downregulation of cornified envelope–related genes; the authors suggested that solar lentigo may be induced by the mutagenic effect of repeated UV light exposures, leading to enhancement of melanin production along with decreased proliferation and differentiation of lesional keratinocytes on a background of chronic inflammation (73). It has been postulated that abnormal pigment retention in keratinocytes may be the primary disorder in solar lentigines (74).

Prolonged treatment with psoralen and ultraviolet light A (PUVA) can induce formation of pigmented macules ("PUVA lentigines") in the irradiated areas. These are similar to solar lentigines, but their color is darker and their pigment is more irregularly distributed (75).

Histopathology. The rete ridges are subtly or more significantly elongated. They either appear club shaped or are tortuous and show small, budlike extensions. The elongated rete ridges are composed, especially in their lower portion, of deeply pigmented basaloid cells intermingled with melanocytes, which are arranged mostly as single cells. Epidermal maturation may appear subtly perturbed in some lesions. The melanocytes appear significantly increased in number in some cases but only slightly or not at all increased in others (Fig. 28-3) (76). They possess a heightened capacity for melanin production, as shown by the fact that, on staining with DOPA, they display more numerous as well as longer and thicker dendritic processes than the melanocytes of control skin (77). The upper dermis shows elastosis and often contains scattered melanophages and occasionally a mild, perivascular lymphoid infiltrate.

Solar lentigines differ histologically from ephelides by definition, in having an increased number of epidermal melanocytes. However, in some lesions, the proliferation may be demonstrable only by formal counting (78). In contrast to lentigo simplex, lentiginous nevi, and lentiginous melanomas, the melanocytic proliferation is not contiguous and is nonnested.

In some lesions, the rete ridges are elongated to such an extent that strands of basaloid cells form anastomosing branches, resulting in a reticulated pattern closely resembling that seen in the reticulated pigmented type of seborrheic keratosis. However, unlike seborrheic keratoses, solar lentigines do not form horn cysts (76).

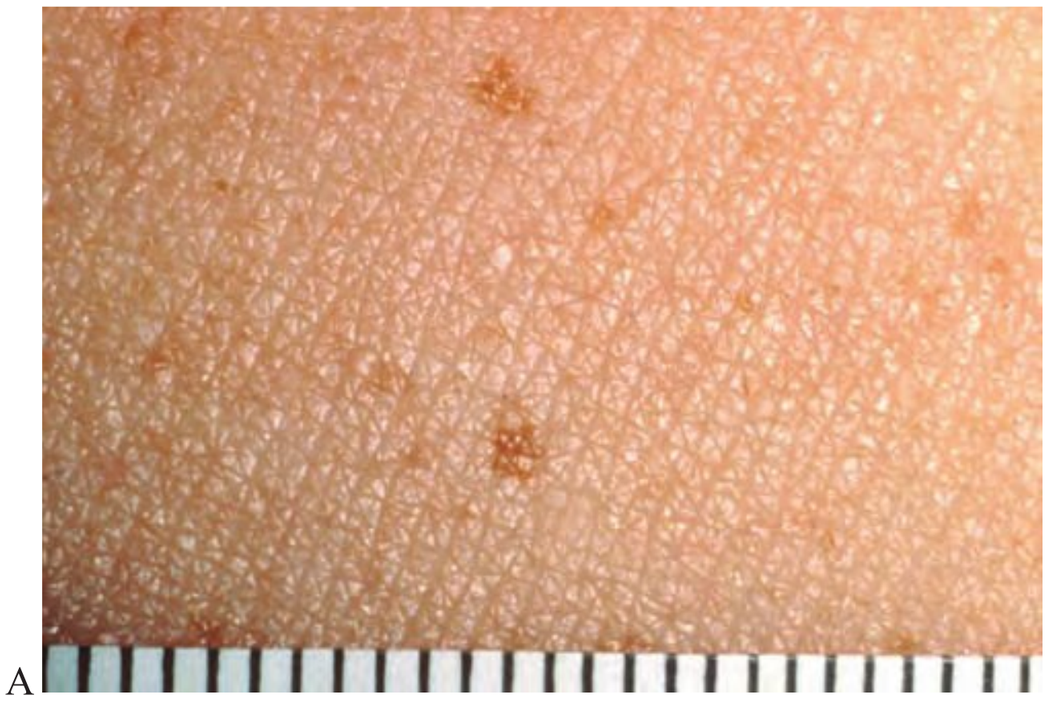
PUVA-induced pigmented macules represent actinic lentigines on the basis of irregular elongation of their rete ridges. They show an increased number of large melanocytes that may appear slightly atypical (79).

Large-cell acanthoma, which presents as a slightly scaly, tan macule on photodamaged skin, is identified histologically by having epidermal keratinocytes with nuclei roughly twice the size of adjacent keratinocytes but with minimal nuclear pleomorphism. There are clinical, histologic, and immunohistochemical overlapping characteristics with solar lentigo, suggesting that large-cell acanthoma should be considered as a related condition (80).

In the reticulated or "ink spot" lentigo, histologic evaluation, including electron microscopy and DOPA-incubated vertical sections, demonstrated lentiginous hyperplasia of the epidermis, marked hyperpigmentation of the basal layer with "skip" areas that involved the rete ridges, and a minimal increase in the number of melanocytes (70).

Histogenesis. By electron microscopy, the basal layer of keratinocytes contains increased melanosomes and melanosome complexes, and the melanosome complexes within keratinocytes appear larger than those found in uninvolved skin. Even in the upper layers of the epidermis, including the horny layer, numerous melanosomes are present, largely in a dispersed state rather than as complexes (74,76).

Differential Diagnosis. In lentigo simplex (see later discussion), the rete ridges are elongated, but, in contrast, the lesional melanocytes are more obviously increased in number and focally lie in contiguity with one another around the tips and sides of the rete but not between the rete. Lentigo maligna shows flattening or absence of the rete ridges together with contiguous and continuous proliferation and uniform atypia of its melanocytes; like lentigo simplex, however, it may be associated with a dermal lymphocytic infiltrate. In actinic lentigo, the rete are elongated and the lesional melanocytes do not lie in contiguity with one another, even though they may be increased in number. There is minimal cytologic atypia and no pagetoid spread of melanocytes above the basal layer. In contrast to a pigmented actinic keratosis, there is no keratinocytic atypia and usually no parakeratosis.



Lentigo Simplex and Related Lesions

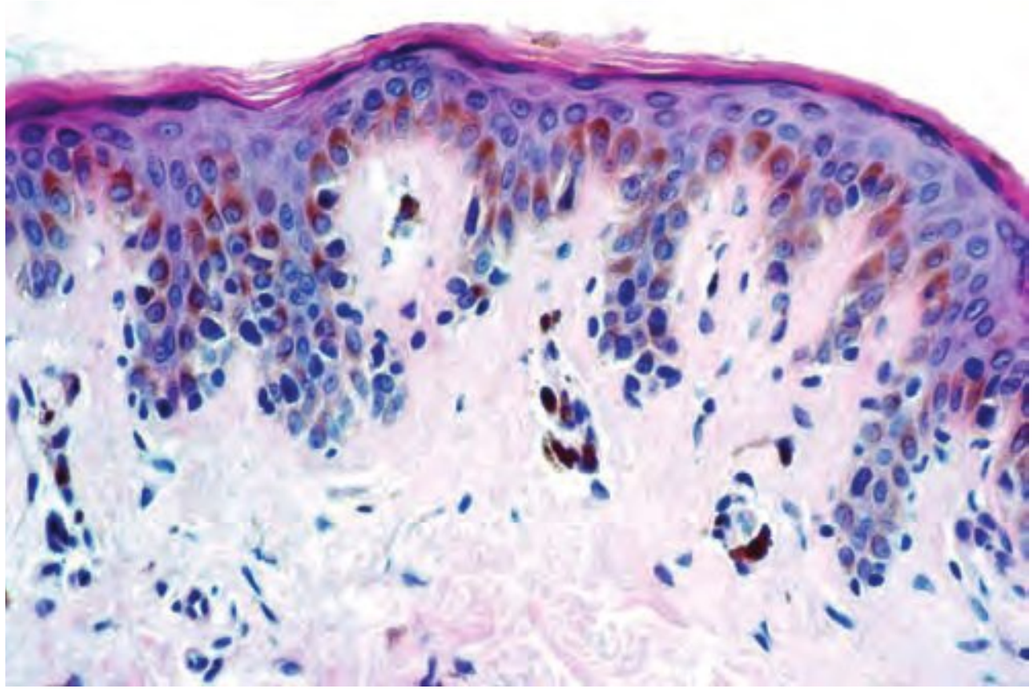
Simple lentigines are macular hyperpigmentations in which the number of epidermal melanocytes is increased. In solar lentigines, as described previously, the cell bodies are separated from one another by those of keratinocytes, and the proliferation may be termed noncontiguous. The proliferation may be described as contiguous if the cell bodies at least focally touch one another, as in lentigo simplex (and also in lentiginous nevi and in lentiginous melanomas).

Lentigo simplex most frequently arises in childhood, but it may appear at any age (81). Usually there are only a few scattered lesions in lentigo simplex, without predilection for areas of sun exposure. They are small, symmetric, and well-circumscribed macules that are evenly pigmented but vary individually from brown to black (Fig. 28-4A). They are not indurated and usually measure only a few millimeters in diameter. Clinically a lentigo simplex is indistinguishable from a junctional nevus. Special forms of lentigo simplex are lentiginosis profusa, the multiple lentigines syndrome or LEOPARD syndrome, and speckled lentiginous nevus, also referred to as nevus spilus.

Lentiginosis profusa shows innumerable small, pigmented macules either from birth or starting in childhood or early adulthood without any other abnormalities. The mucous membranes are spared. There may be a family history (82,83). *Agminated* or *segmental lentigines* have been defined as a circumscribed group of small, pigmented macules arranged in a small or large group, often in a segmental pattern, each macule consisting of a lentiginous intraepidermal proliferation of melanocytes (84,85). The *speckled lentiginous nevus*, or *nevus spilus*, consists of a light brown patch or band present from the time of birth that in childhood becomes dotted with small, dark-brown macules (86,87).

The multiple lentigines syndrome, a dominant trait, is characterized by the presence of thousands of flat, dark-brown macules on the skin but not on the mucous surfaces. The

A



B

FIGURE 28-4. A: Lentigo simplex. Clinically, the lesions are small (usually less than 2 mm), fairly symmetric, and well circumscribed. It is not possible to distinguish clinically among ephelides, simple lentigines, and lentiginous junctional nevi. (Clinical photograph by Peter Wilson.) B: Lentigo simplex. Melanocytes are present in contiguity near the tips and sides of elongated rete ridges ("lentiginous proliferation"). There is no continuous proliferation between the rete. The presence of at least a single nest would define a lentiginous junctional nevus ("jentigo").

lentigines begin to appear in infancy and gradually increase in number. Although most macules vary from pinpoint dots to 5 mm in diameter, some dark spots are much larger, up to 5 cm in diameter. Features of this rare syndrome, known also by the mnemonic LEOPARD, in addition to the lentigines (L), may include electrocardiographic conduction defects (E), ocular hypertelorism (O), pulmonary stenosis (P), and abnormalities of the genitalia (A) consisting of gonadal or ovarian hypoplasia, retardation of growth (R), and neural deafness (D). Not all of these manifestations are present in every case. Cardiomyopathy may also be present and associated with significant mortality (88). Another syndrome associated with lentigines is known by the mnemonic NAME or LAMB or as myxoma syndrome (lentiginous nevi, atrial and/or mucocutaneous myxomas, myxoid neurofibromas, ephelides, blue nevi). It has been proposed that these mnemonics be dropped because the particular features encompassed within this syndrome are unclear, and the term cutaneous lentiginosis with atrial myxomas is an adequate description of this syndrome (89). The Carney complex, a familial multitumoral syndrome, comprises spotty skin pigmentation (lentigines and blue nevi), myxomas (heart, skin, and breast), endocrine overactivity usually manifested by endocrine tumors (adrenal cortex, pituitary, testis, and thyroid), schwannomas, and two unusual pigmented tumors, epithelioid blue nevus (skin) and psammomatous melanotic schwannoma (involving skin, viscera, or nerve tissue). Carney complex has been linked to chromosome 2p16 and the PRKAR1A gene at 17q22-24 (90).

The *Peutz-Jeghers syndrome* (PJS) shows dark-brown macules clinically resembling lentigines in the perioral region. Similar macules are seen on the vermilion border and the oral mucosa and, often, the dorsa of the fingers. Although a few cases of this dominantly inherited disorder have shown only the pigmentary anomaly, there are usually multiple polyps in the gastrointestinal tract, mainly in the small intestine (91,92). Although early reports did not demonstrate a predisposition to cancer in patients with this syndrome, more recent studies have described an increased risk for both gastrointestinal and extragastrointestinal cancers. Women with PJS have an extremely high risk for breast and gynecologic cancer. Recently, a PJS susceptibility gene, encoding the serine threonine kinase STK11 (also called LKB1), was identified in this syndrome (93). A complex of PJS-like pigmentation without polyposis, designated as isolated mucocutaneous melanotic pigmentation, has recently been described and also appears to be associated with increased risk of cancer in diverse organs (94).

Histopathology. Lentigines, in general, show a slight or moderate elongation of the rete ridges, an increase in the concentration of melanocytes in the basal layer, an increase in the amount of melanin in both the melanocytes and the basal keratinocytes, and melanophages in the upper dermis. The melanocytes in the epidermis lie in focal contiguity with one another near the tips and sides of the elongated rete, but the proliferation is not continuous between the rete (Fig. 28-4B). There are no nests by definition. In some instances, melanin is also seen in the upper layers of the epidermis, including the stratum corneum. A mild inflammatory infiltrate may be intermingled with the melanophages within the underlying papillary dermis. In lesions otherwise clinically characteristic of lentigo simplex, small nests of nevus cells are commonly seen at the epidermal–dermal junction, especially at the lowest pole of rete ridges. The lesions then combine features of a lentigo simplex and a junctional nevus, leading to their descriptive diagnosis as jentigo (84), or lentiginous junctional nevus. Because of the existence of these transitional forms, the lentigo simplex is regarded as a potential precursor of what may become a melanocytic nevus, and is discussed as such in the next section.

In *lentiginosis profusa* and the *multiple lentiginosis syndromes*, as a rule, the lesions are "pure" lentigines without the formation of nevus cell nests. In larger macules, however, there may be junctional nevus cell nests, and there may even be nevus cell nests in the upper dermis (95).

In *speckled lentiginous nevus*, or *nevus spilus*, the light-brown patch or band shows the histologic features of lentigo simplex. The speckled areas show junctional nests of nevus cells at the lowest pole of some of the rete ridges, diffuse lentiginous melanocytic proliferation, and dermal aggregates of nevus cells. Various types of nevi (e.g., junctional nevi, blue nevi, and Spitz nevi) may present in the same lesion over time, and histologic features of congenital melanocytic nevi may be present within the spots, suggesting that these lesions may be considered as variants of congenital nevi (87).

In the lesions of *Peutz-Jeghers syndrome*, the basal cell layer shows marked hyperpigmentation. Although the number of melanocytes may appear to be slightly increased, no increase has been found in DOPA-stained sections (96). The intestinal polyps appear to be hamartomas because glands are intermingled with smooth muscle bundles (93).

The presence of occasional giant melanin granules has been described in various forms of lentigines and lentiginous nevi, as well as in other conditions associated with hyperpigmentation, including the café-au-lait spots of neurofibromatosis and, less commonly, in café-au-lait spots without neurofibromatosis; on occasion, they have even been found in normal skin of healthy persons (97,98). Thus, they have no diagnostic specificity. Giant melanin granules vary in size from 1 to 6 mm. Because of their size and heavy melanization, the larger granules are readily recognized by light microscopy. Although seen largely within melanocytes, they also occur in keratinocytes and melanophages to which they have been transferred, although many are too large for conventional donation by affected melanocytes to keratinocytes. On electron microscopy, the giant melanin granules have been termed macromelanosomes, and are regarded as autolysosomes, referred to as melanin macroglobules, representing lysosome-mediated accumulation of melanosomes to form massive rounded to ellipsoid melanized bodies (99).

Table 28-2 summarizes some of the salient clinical and histologic features observed in the various forms of hyperpigmentations and lentigines.

TABLE 28-2 Hyperpigmentations and Lentigines

	Clinical	Basal layer	Melanocytes	Features
Ephelide	Sun-exposed skin, decrease with age, darker with exposure	Increased melanin	No increase by routine histology	HMB-45 reactivity, rounded melanosomes
Melanotic macule, Albright's syndrome	Fibrous dysplasia, precocious puberty, Albright's syndrome	Increased melanin	Normal in number and size	—
Mucosal lentigines	Lower lip, genital skin	Increased melanin	Appear normal to slightly increased	Mild acanthosis, pigment incontinence
Becker's melanosis	Unilateral, hypertrichosis	Increased melanin	Increased	Elongation of rete, smooth muscle fibers in dermis
Solar lentigo	Sun-exposed skin, increase with age	Increased melanin	Appear normal to increased, no contiguity	Elongated rete, solar elastosis
Lentigo simplex	Early onset, not related to sun exposure	Increased melanin	Increased, in focal contiguity	Elongated rete
Lentiginosis profusa	Many lesions at birth or childhood	Increased melanin	Increased, in focal contiguity	Elongated rete, nevus nests in some lesions
Multiple lentiginosis syndromes (LEOPARD, LAMB)	Many lesions, dominant trait	Increased melanin	Increased, in focal contiguity	Elongated rete, nevus nests in some lesions
Speckled lentiginous nevus	Macule at birth, becomes speckled	Increased melanin	Increased, in focal contiguity	Elongated rete, nevus nests in speckled areas
Peutz-Jeghers lentigines	Perioral, dominant trait, GI polyps	Increased melanin (marked)	No increase by DOPA stain	

DOPA, 3,4-dihydroxy-L-phenylalanine; GI, gastrointestinal; LAMB, lentiginous nevi, atrial and/or mucocutaneous myxomas, myxoid neurofibromas, ephelides, blue nevi; LEOPARD, lentigines, electrocardiographic conduction defects, ocular hypertelorism, pulmonary stenosis, and abnormalities of the genitalia consisting of gonadal or ovarian hypoplasia, retardation of growth, and neural deafness.

Melanocytic Nevi

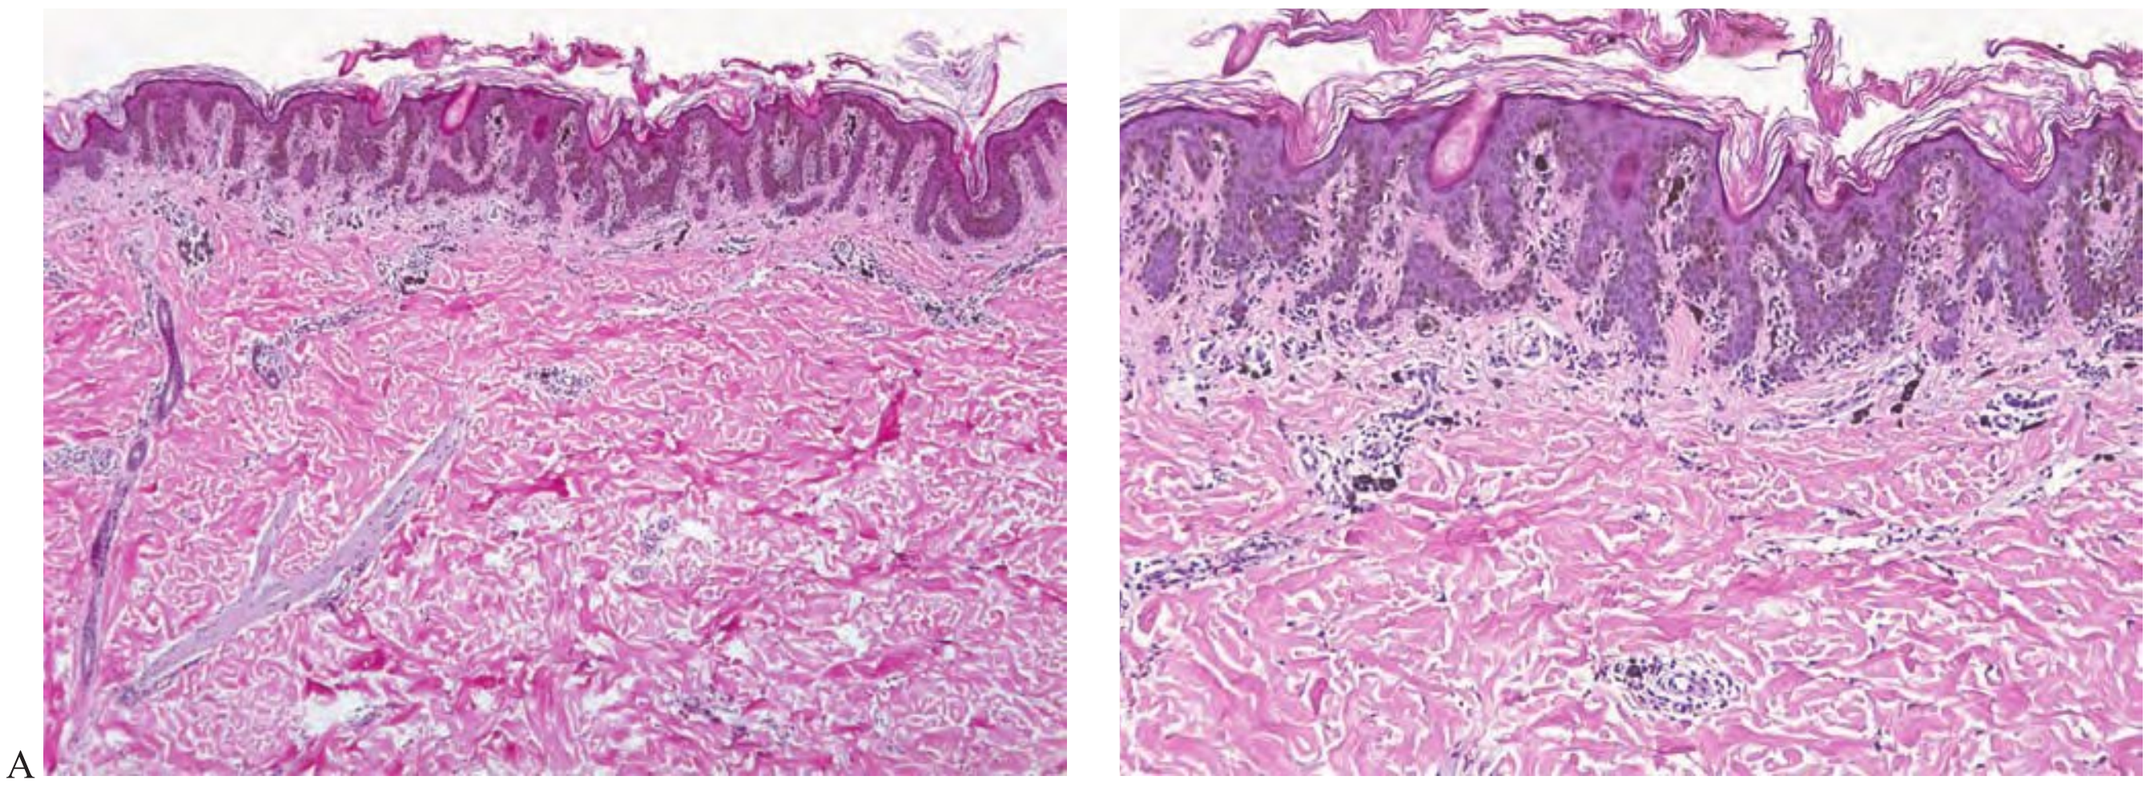
Common Melanocytic Nevus

Although the term "nevus" may refer to a variety of hamartomatous and/or neoplastic lesions in the skin, the unqualified term in common usage and in this chapter refers to a *melanocytic nevus*, which is generally considered to be a benign neoplastic proliferation of melanocytes, leading to a localized pigmented or nonpigmented lesion usually less than 5 mm in diameter. Nevi vary considerably in their clinical appearance. In addition to the pathologic variants, which will be discussed separately, five clinical types may be recognized: (a) flat lesions, (b) slightly elevated lesions, often with a raised center and a flat periphery, (c) papillomatous lesions, (d) dome-shaped lesions, and (e) pedunculated lesions. The first three types are always pigmented; the last two may or may not be pigmented. Any of the elevated lesions may be surrounded by a flat periphery, within which changes of melanocytic dysplasia may be seen histologically ("nevus with dysplasia"). Dome-shaped lesions often contain several coarse hairs. Although exceptions occur, one can predict to a certain degree from the clinical appearance of a nevus whether on histologic examination it will prove to be a junctional nevus (confined to the epidermis), a compound nevus (epidermal and dermal), or an intradermal nevus. Most small, flat lesions represent either a lentigo simplex or a junctional nevus; flat lesions or lesions with a flat periphery 5 mm or more in diameter with irregular indefinite borders and pigment variegation are clinically dysplastic nevi, although if these changes are severe, melanoma may need to be ruled out. Most slightly elevated lesions and some papillomatous lesions represent compound nevi (especially if they are pigmented); and most papillomatous lesions and nearly all dome-shaped and pedunculated lesions that are not pigmented represent intradermal nevi (100).

Melanocytic nevi are only rarely present at birth (see section Congenital Melanocytic Nevus). Most nevi appear in adolescence and early adulthood. In this age period, they may occur episodically and, rarely, as widespread eruptive nevi (101–103). New nevi arise occasionally in midlife and rarely in later life. Except for occasional cosmetic significance, nevi are important only in relation to melanoma, for which they are risk markers, simulants, and potential precursors (67,104,105).

A general concept of clinical importance for melanocytic nevi is that, unlike melanoma, which inexorably progresses over time, nevi enlarge to a point, stabilize, and then involute, becoming less frequent in the elderly than in younger age groups (64). This clinical attribute is directly related to the importance of heightened suspicion that is aroused when a previously stable nevus undergoes change in size or pigmentation.

Histopathology



Melanocytic nevi are defined and recognized by the presence of nevus cells, which, even though they are melanocytes, differ from ordinary melanocytes by being arranged at least partially in clusters or "nests." Other defining characteristics of nevus cells include a tendency to rounded rather than dendritic cell shape and a propensity to retain pigment in their cytoplasm rather than to transfer it to neighboring keratinocytes (106). Nevus cells show considerable variation in their appearance and often are not pigmented, so that they are often recognizable as nevus cells more by their arrangement in clusters or nests than by their cellular features. As the result of a characteristic shrinkage artifact, nevus cell nests often appear partially separated from their surrounding stroma and, in some nevi such as the spindle and epithelioid cell variant, from surrounding epithelium.

Although a histologic subdivision of nevi into junctional, compound, and intradermal nevi is generally accepted, it should be realized that these are transitional stages in the life cycle of nevi, from junctional to compound to intradermal, and finally to involuting lesions.

Lentigo Simplex. Lentigo simplex, as described earlier, may be regarded as an early or evolving form of melanocytic nevus. Histologically, these are small (usually less than 2 mm) and are characterized by an increased number of nevoid melanocytes present in contiguity with one another near the tips and sides of elongated rete ridges. This pattern, characteristic of lentigines, is therefore described as lentiginous melanocytic proliferation. The lack of nests at the histologic level distinguishes the lentigo from a nevus, by definition. However, transitional forms between a simple lentigo and a lentiginous junctional nevus (a lentigo with a few nests) are commonly observed, and the two histologic entities are indistinguishable clinically, giving rise to the term nevoid lentigo (86) or jentigo (84). The former term has been used more or less synonymously with lentigo maligna (81,107), and therefore we prefer the term lentiginous junctional nevus for these very common lesions (Fig. 28-5) (69).

Junctional Nevus. In a junctional nevus, nevus cells may lie in well-circumscribed nests either entirely within the lower epidermis or bulging downward into the dermis but still in contact with the epidermis, perhaps in the process of dropping off to form a compound nevus. The nevus cells in these nests generally have a regular, rounded to cuboidal appearance, although they are occasionally spindle shaped. In addition, a varying number of diffusely arranged single nevus cells is seen in the lowermost epidermis, especially in the basal cell layer. In many lesions, single cells are about as common as nests, recapitulating the histology of a simple lentigo. Such lesions in our practice are termed lentiginous junctional nevi (Fig. 28-5). Varying amounts of melanin granules are seen in the nevus cells. Some of the nevus cells, on staining with silver, show dendritic processes containing melanin granules, making them indistinguishable from melanocytes, but in general the degree of dendritic differentiation is markedly reduced compared to melanocytes. The nested and single melanocytes are arranged mainly at the tips and sides of rete ridges; continuous proliferation of single cells between the rete, confluence of nests, or pagetoid extension of cells into the suprabasal epidermal layers may be architectural indicators of dysplasia or evolving *in situ* melanoma.

Although nevus cells only occasionally penetrate into the upper layers of the epidermis ("pagetoid extension"), aggregates

A B

FIGURE 28-5. A: Lentiginous junctional nevus. Most examples are less than 4 mm, usually about 2 to 3 mm, in diameter. A dermal component, if present in a lentiginous nevus, lies in the center of the lesion, and the epidermal component extends beyond its shoulder. B: In the epidermis, single cells and nests of nevus are arranged near the dermal–epidermal junction near the tips and sides of elongated rete ridges (a lentiginous pattern). There is minimal or no atypia. There is no continuous proliferation of melanocytes in the suprapapillary regions of the epidermis between the rete ridges. These architectural features are repeated but exaggerated in dysplastic nevi, which in addition exhibit mild to moderate random cytologic atypia and more conspicuous stromal reactions.

of melanin granules may be seen in the stratum corneum in deeply pigmented junctional nevi. Often, the rete ridges are elongated as in lentigo simplex (see section Lentigo Simplex and Related Lesions), and single cells, as well as nests of nevus cells, are seen at the bases of the rete ridges. Not infrequently, as in lentigo simplex, the upper dermis contains an infiltrate of melanophages and mononuclear cells. These lesions that combine features of lentigo simplex and junctional nevus are exceedingly common, and, as indicated, may be termed lentiginous junctional nevi. Lesions with these features but larger than 5 mm clinically or 4 to 5 mm in a histologic section often prove to have cytologic atypia and to be dysplastic nevi (see section Dysplastic Nevus).

In children, some junctional nevi may show considerable cellularity with some degree of cellular enlargement, pleomorphism, and pagetoid cells above the basal layer. They may also often show fine, dusty melanin particles and a dense inflammatory infiltrate (92,108). Some of these lesions may represent Spitz nevi or dysplastic nevi (see respective sections). Others may correlate with a tendency for ordinary junctional nevus cells to be enlarged, or epithelioid, in younger individuals. The small size of the lesion, the sharp lateral demarcation, the lack of severe or uniform atypia and of mitoses, and the fact that in children melanomas are very rare help in the distinction from melanoma. However, if the criteria mentioned are present, the diagnosis of melanoma should be considered, even in a child.

Compound Nevus. Clinically, a compound nevus is a pigmented papule (Fig. 28-6A) or a plaque. In most nondysplastic

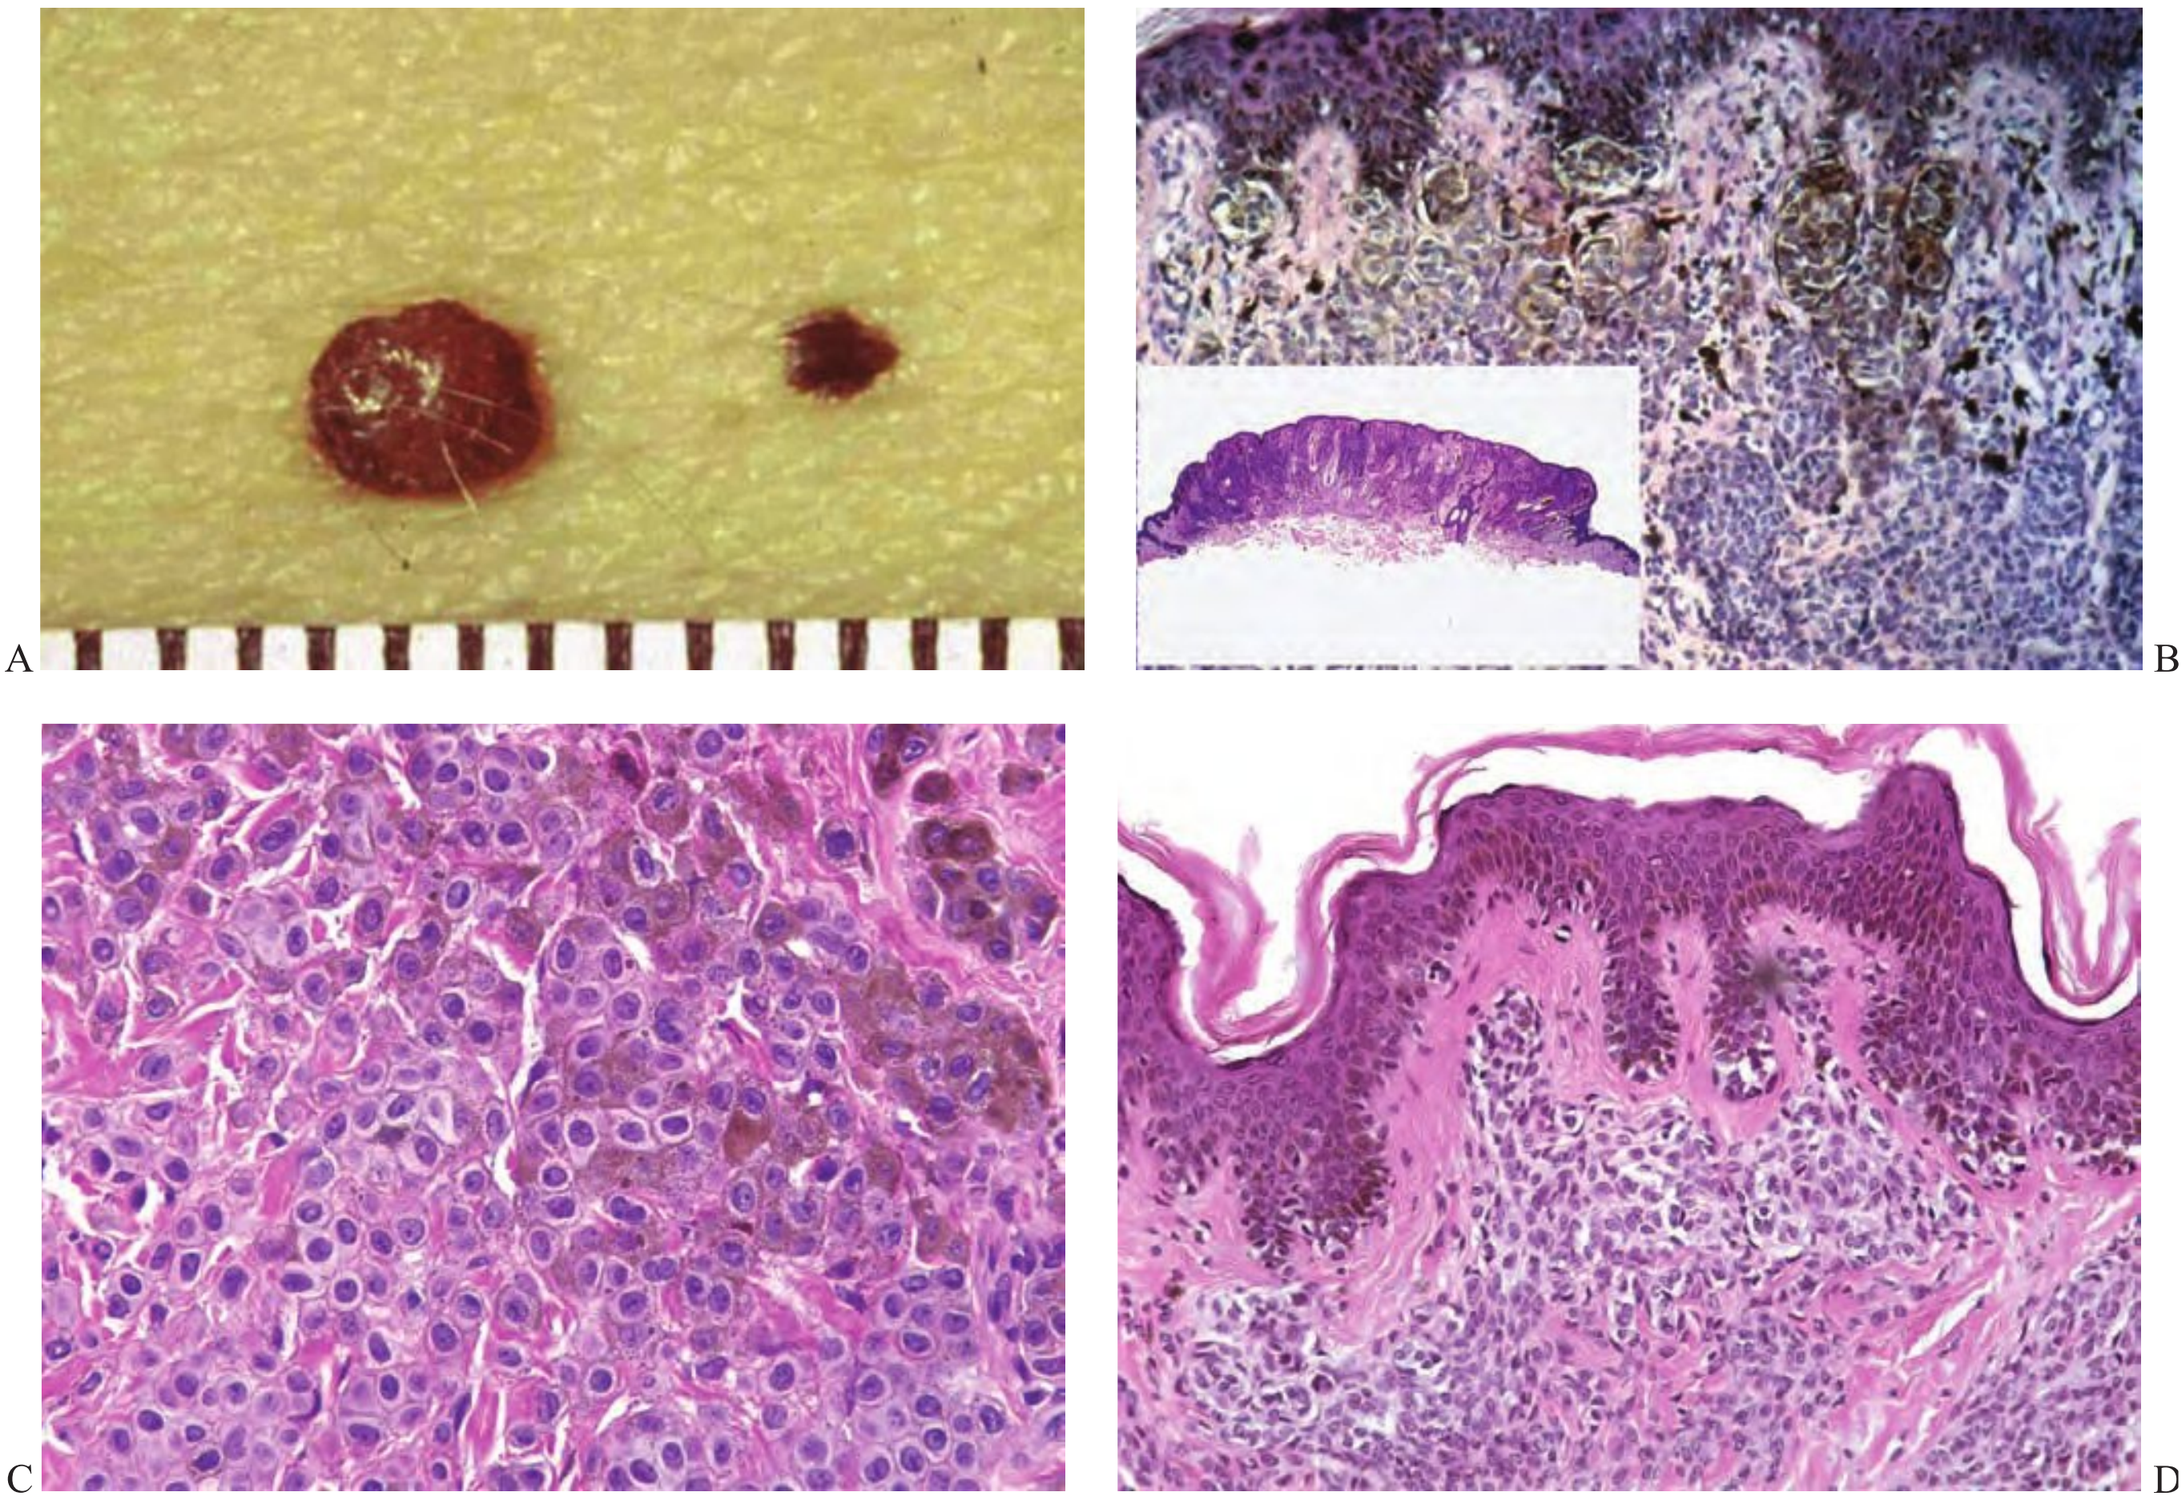


FIGURE 28-6. A: Compound nevi. Each lesion is a true papule without any adjacent macular component. The lesion on the right is a pigmented compound nevus. The lesion on the left has little pigment and clinically is a predominantly dermal nevus. B: Histologically, the lesion is a true papule without an adjacent junctional component (inset). Nests of nevus cells are present at the dermal–epidermal junction. It is believed that these nests become separated from the epidermis to lie in the dermis, piling on one another in an accretive pattern of growth and resulting in gradual elevation of the epidermis above its original position to form the papule. Pigment is present mostly in junctional and superficial dermal nevus cells. C: Dermal nevus with type A nevus cells. The type A cells have visible cytoplasm in contact with that of neighboring nevus cells. The nuclei are small, without atypia or prominent nucleoli. There are no mitoses. D: Lentiginous compound nevus. In this as in many nevi, nests are admixed with single cells in the junctional component, a lentiginous pattern. The cells in the dermis are small, lymphocyte-like type B cells. (continued)

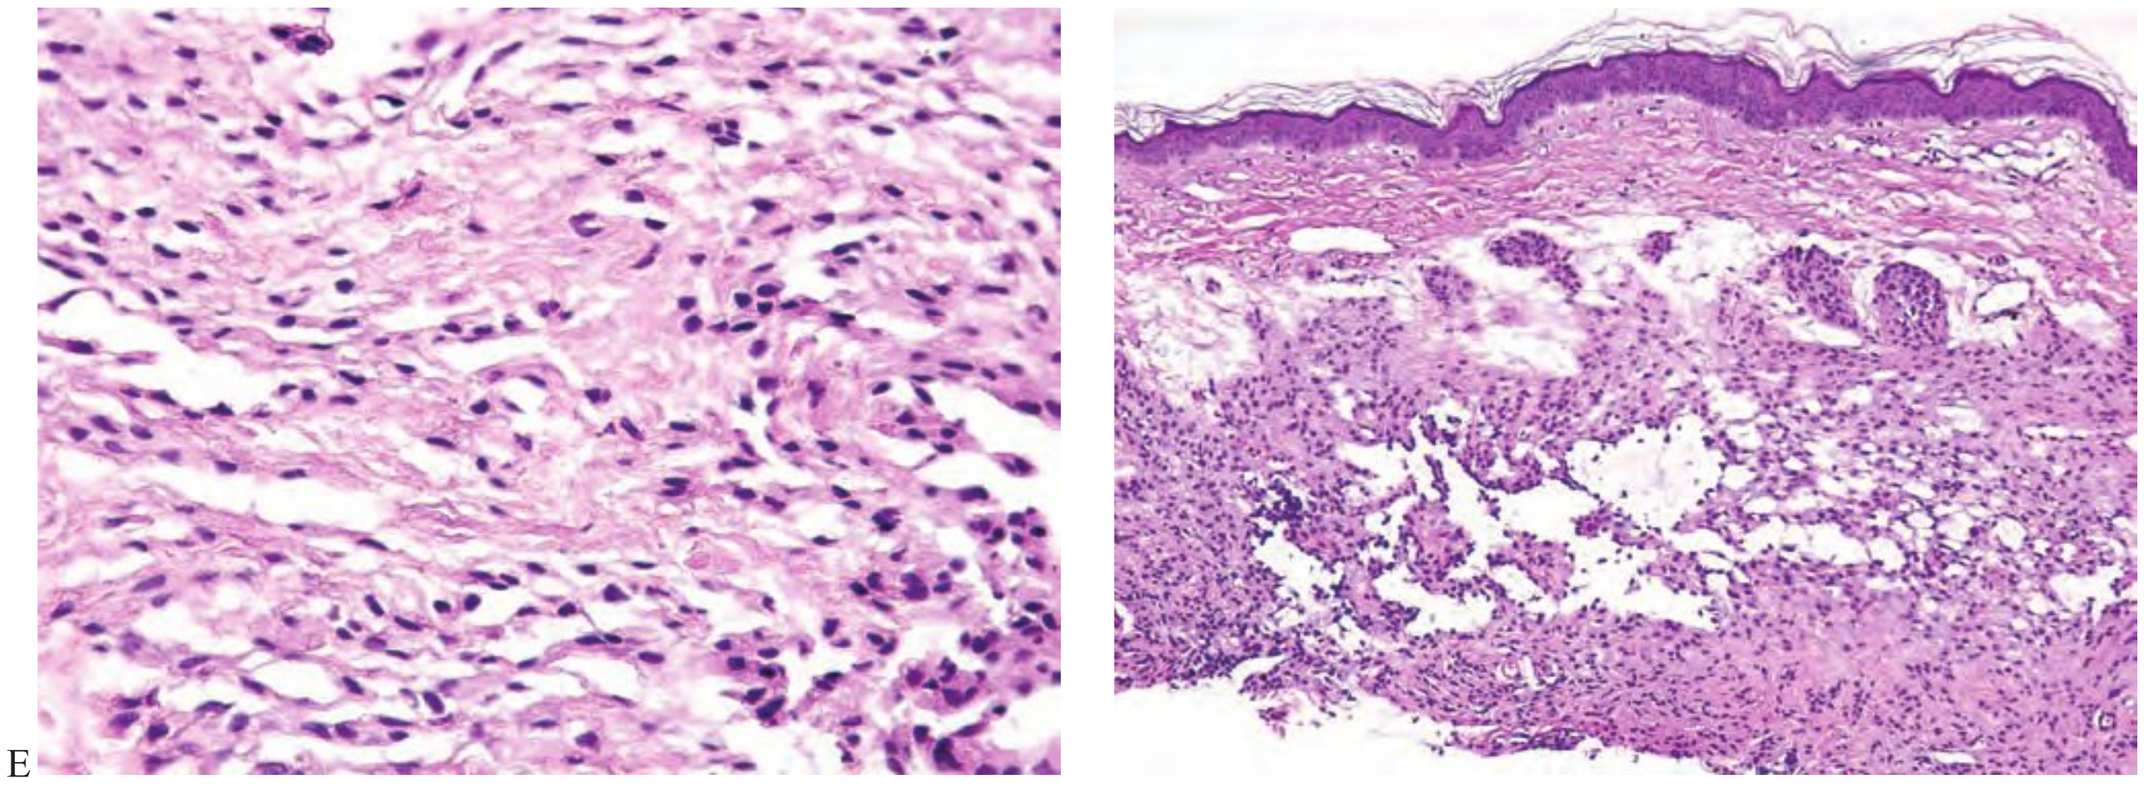

FIGURE 28-6. Continued. E: Type C dermal nevus cells at the base of a nevus. The cells at the base of a nevus tend to be spindled in shape and to have collagen between the individual cells. If they extend into the reticular dermis, they tend to disperse as individual cells among the superficial collagen fibers, a pattern that is also characteristic of Spitz nevi. F: Dermal nevus with pseudolymphatic spaces. The type B nevus cells at the top of the lesion have small nuclei and scant cytoplasm, reminiscent of lymphocytes. The spaces are a common artifact in dermal or compound nevi. They may simulate lymphatic invasion of a melanoma but are completely benign. The cells at the base of the lesion are predominantly type C cells. G: Neurotized dermal nevus cells at the base of a dermal nevus. The structures at the base of a neurotized dermal nevus may be reminiscent of nerve fibers or neural organs such as Wagner-Meissner corpuscles.

compound nevi, there is no adjacent macular component. Histologically, a compound nevus possesses features of both a junctional and an intradermal nevus. Nevus cell nests are present in the epidermis, as well as appearing to "drop off" from the epidermis into the superficial dermis and, in many lesions, the reticular dermis (Fig. 28-6B). This time-honored theory of *abtropfung* or dropping off of nevus cells proposed by Unna has been challenged by the finding that junctional nevi are at least as common in adults as in children (109). Nevus cells in the upper, middle, and lower dermis may present characteristic morphologic variations called types A, B, and C, respectively (42,110). Usually, the type A nevus cells in the upper dermis are round to cuboidal, show abundant cytoplasm containing varying amounts of melanin granules, and tend to form nests. Type A cells with especially abundant cytoplasm, as may occur in children and young adults, may be termed epithelioid cells (Fig. 28-6C). Melanophages are occasionally seen in the surrounding stroma. The cells in the middermis usually are type B cells; they are distinctly smaller than the type A cells, display less cytoplasm and less melanin, and generally lie in well-defined aggregates or cords. They may to some extent resemble lymphoid cells (Fig. 28-6D). Type C nevus cells in the lower dermis tend to resemble fibroblasts or Schwann cells because they are usually elongated and possess a spindle-shaped nucleus. They often lie in strands and only rarely contain melanin (Fig. 28-6E). Occasionally they form aggregates that resemble Meissner corpuscles. Occasional nevi show abnormal stratification within the deeper dermis of otherwise benign type A nevus cells, resulting in the designation of inverted type A nevus.

The decrease in cell size, melanization, and progression from nests to cords to more neuroid spindle cells with dermal descent seen in nevi is often referred to as maturation and is regarded as evidence of benignity because the size of the cells in a melanoma usually does not decrease with depth. The process of nevus cell maturation has alternatively been regarded as one of senescence or atrophy (111), perhaps driven by the tumor suppressor p16, which is activated in response to the effects of an activated oncogene such as BRAF or NRAS in a phenomenon termed oncogene-induced senescence (112). If dermal nevus cells are confined to the papillary dermis, they often retain a discrete or "pushing" border with the stroma. However, nevus cells that enter the reticular dermis tend to disperse among collagen fiber bundles as single cells or attenuated single

files of cells. This pattern of infiltration of the dermis differs from that in most melanomas, in which groups of cells tend to dissect and displace the collagen bundles in a more expansive pattern (113). Lesions in which nevus cells extend into the lower reticular dermis and the subcutaneous fat or are located within nerves, hair follicles, sweat ducts, and sebaceous glands may be termed congenital pattern nevi because they share morphologic features with congenital nevi but are not necessarily present at birth (114) (see section Congenital Melanocytic Nevus).

Intradermal Nevus. Intradermal nevi show essentially no junctional activity. The upper dermis contains nests and cords of nevus cells. Multinucleated nevus cells may be seen in which small nuclei lie either in a rosette-like arrangement or close together in the center of the cell. These nevus giant cells differ significantly in appearance from the irregularly and even bizarrely shaped giant cells that are seen frequently in Spitz nevus and occasionally also in melanoma. As a result of shrinkage during tissue processing, clefts may form between some nests of nevus cells and the surrounding epidermis, as well as stroma, the latter leaving a defect that simulates a lymphatic space and thus mimics lymphatic invasion (Fig. 28-6F) (115).

Whereas the nevus cell nests located in the upper dermis often contain a moderate amount of melanin (particularly type A cells), the type B and C nevus cells in the midportion and the lower dermis rarely contain melanin. Type C cells appear spindle shaped, are arranged in bundles, and are embedded in collagenous fibers having a loose, pale, wavy appearance similar to that of the fibers in a neurofibroma, resulting in a "neurotized nevus." Such formations have been referred to as neuroid tubes. In other areas, the nevus cells lie within concentrically arranged, loosely layered filamentous tissue, forming so-called nevic corpuscles that resemble Meissner's tactile bodies (Fig. 28-6G). Neurotized nevus cells express the marker S100A6 protein, a form of S100 found in Schwann cells, supporting the hypothesis that maturation in these lesions recapitulates some features of Schwann cell differentiation (116).

Occasional intradermal nevi are devoid of nevus cell nests in the upper dermis and contain only spindle-shaped nevus cells embedded in abundant, loosely arranged collagenous tissue. These nevi may be referred to as neural nevi. The differentiation from a solitary neurofibroma may be difficult in routinely stained sections, but distinction might be possible with an immunohistochemical technique using myelin basic protein, which is positive only in neurofibroma (117) (see Histogenesis). Neurofibromas also tend to contain small nerve twigs and axons that can be highlighted with glial fibrillary acidic protein staining (118), a feature not typical of neurotized nevi.

Some intradermal and, less commonly, compound nevi show hyperkeratosis and papillomatosis, which may be associated with a lacelike, downward growth of epidermal strands and with horn cysts. Such nevi resemble seborrheic keratoses in their epidermal architecture. In other instances, large hair follicles are observed. Rupture of a large hair follicle may manifest itself clinically in an increase in the size of the nevus associated with an inflammatory reaction, leading to clinical suspicion of a melanoma. Histologic examination in such instances shows a partially destroyed epidermal follicular lining with a pronounced inflammatory infiltrate containing foreign-body giant cells as a reaction to the presence of keratin in the dermis. Occasionally, intradermal nevi contain scattered large fat cells within the aggregates of nevus cells. This is likely to be a regressive phenomenon in which fat cells replace involuting nevus cells (119) or, alternatively, (and more likely) true adipocyte metaplasia within the stroma of the nevus.

Some intradermal nevi, including variants of spindle and epithelioid cell nevi, induce marked deposition of coarse, sometimes hyalinized collagen. Such nevi are described as sclerosing variants. This change occasionally may confound diagnosis but is not of biological significance.

In occasional otherwise typical dermal nevi (or in the dermal component of compound nevi), rare mitoses are found in the dermis. This phenomenon has been described in children (108) and in association with pregnancy (120). If there are no other indicators of malignancy, we report these cases as "nevi with mitoses" and generally recommend complete excision. The possibility of nevoid melanoma (see later section) should be seriously considered in such lesions (121).

Pathogenesis of Acquired Melanocytic Nevi

For many years, Masson's theory of the dual origin of nevus cells was widely accepted (42). He believed that the nevus cells in the upper dermis developed from epidermal melanocytes, whereas the nevus cells in the lower dermis developed from Schwann cells, as suggested by the frequent presence of nerve-like structures in the latter. The fact that both melanocytes and Schwann cells are derived from the neural crest seemed to support Masson's view, as did the presence of a nonspecific cholinesterase reaction in both deep nevus cells and Schwann cells and the absence of melanin in the deep nevus cells (122). However, in favor of a melanocytic origin of these deep dermal nevus cells was the presence of melanosomes with dopa-oxidase activity even in deeply situated nevus cells that had a neuroid appearance on light microscopy (123). An electron microscopic examination of neuroid structures in nevi revealed that these nevic corpuscles contained no Schwann cells or axons but were instead composed exclusively of cells that contain premelanosome-like dense bodies in their perikaryon (124). Furthermore, myelin basic protein has been found to be regularly present by immunoperoxidase in Schwann cells and absent in all types of melanocytic nevi (117). In addition, melanocyte-specific markers like Melan-A/MART-1, HMB-45, tyrosinase, and others are often positive in nevi but typically absent in neural cells and neurofibromas (125).

Another important point in favor of a single origin of the nevus cell is to be found in the life cycle of nevi. Although there are exceptions, most nevi appear in childhood, adolescence, and early adulthood, and, with advancing age, there is a progressive decrease in the number of nevi (126). The evolution and involution of nevi correlate with their histologic appearance. Junctional proliferation of nevus cells is present in almost every

nevus in children but decreases with age. Intradermal nevi, by contrast, are most unusual in the first decade of life, and their proportion increases progressively with age. The incidence of fibrosis, fatty infiltration/metaplasia, and neuroid changes increases with age. Thus, the formation of cylindrical neuroid structures represents the end stage of differentiation and not a source of origin of intradermal nevi (126,127).

Concerning the relationship between epidermal melanocytes and nevus cells, some authors believe that these two types of cells have a different embryologic genesis, with the nevus cell originating from a neural crest precursor cell referred to as a nevoblast (128). Most authors regard the two cell types as identical, however (129). It would seem that the morphologic features by which nevus cells differ from melanocytes, such as the absence of dendrites as seen by light microscopy, their arrangement in cell nests, their larger size, and their tendency to retain pigment, are secondary adjustments of the cells. Electron microscopy has shown that the fine structure of nevus cells is comparable to that of epidermal melanocytes (130) (EM 46, 47). Cultured nevus cells, whether derived from congenital or acquired lesions, have been found to be highly dendritic, as are epidermal melanocytes (129). In conclusion, it seems established that nevus cells differ from Schwann cells and are benign neoplastic variants of melanocytes.

The molecular pathology of nevi is beginning to be understood. In a recent study of the BRAF oncogene, which had previously been found to be mutated in a high percentage of metastatic melanomas (131), mutations resulting in the V599E amino acid substitution were found in 68% of melanoma metastases, 80% of primary melanomas, and, unexpectedly, 82% of nevi (132). Activating mutations of the oncogene NRAS (mutually exclusive with BRAF mutations) have also been described in melanoma-associated nevi and in congenital nevi (133–136). These data suggest that mutational activation of the RAS/RAF/MAPK mitogenic pathway in nevi is a critical step in the initiation of melanocytic neoplasia but alone is insufficient for melanoma tumorigenesis (132). High levels of the tumor suppressor gene product p16INK4 in benign nevi may represent the mechanism whereby the cell cycle remains regulated in nevi, even in the presence of activating oncogene mutations (112,137–139).

Balloon Cell Nevus

Balloon cell nevi are histologic curiosities that possess no clinical features by which they can be differentiated from other nevi. They are quite rare.

Histopathology. Balloon cells may be seen within the epidermis singly or in groups or may be absent from the epidermis. In the dermis, they lie arranged in lobules of varying size, often with an admixture of ordinary nevus cells and often with transitional forms between the ordinary and ballooned nevus cells (Fig. 28-7). The balloon cells may be multinucleated and are considerably larger than ordinary nevus cells. Their nuclei are small, round, and usually centrally placed. Their cytoplasm appears empty, finely granular, or vacuolated, often with a few small melanin granules. There may be melanophages that are solidly packed with pigment. Stains for lipids, glycogen, and acid or neutral mucopolysaccharides are negative in the balloon cells. Electron microscopic examination reveals in balloon cells numerous large vacuoles formed by enlargement and coalescence of degenerating melanosomes (140,141). Balloon cell nevus is differentiated from balloon cell melanoma by the usual criteria. The large adipocytes present in some intradermal nevi as a result of fatty infiltration or stromal metaplasia differ from balloon cells by routine histology by having a flattened nucleus located at the periphery of the cell. In the differentiation from clear cell hidradenoma and other clear cell tumors, the absence of periodic acid-Schiff–positive glycogen and keratin in balloon cell nevus might be helpful; balloon nevus cells also stain for S100 protein, and although eccrine neoplasms (and adipocytes) may also express this marker, they will also usually be positive for Melan-A/MART-1 and negative for keratin markers.

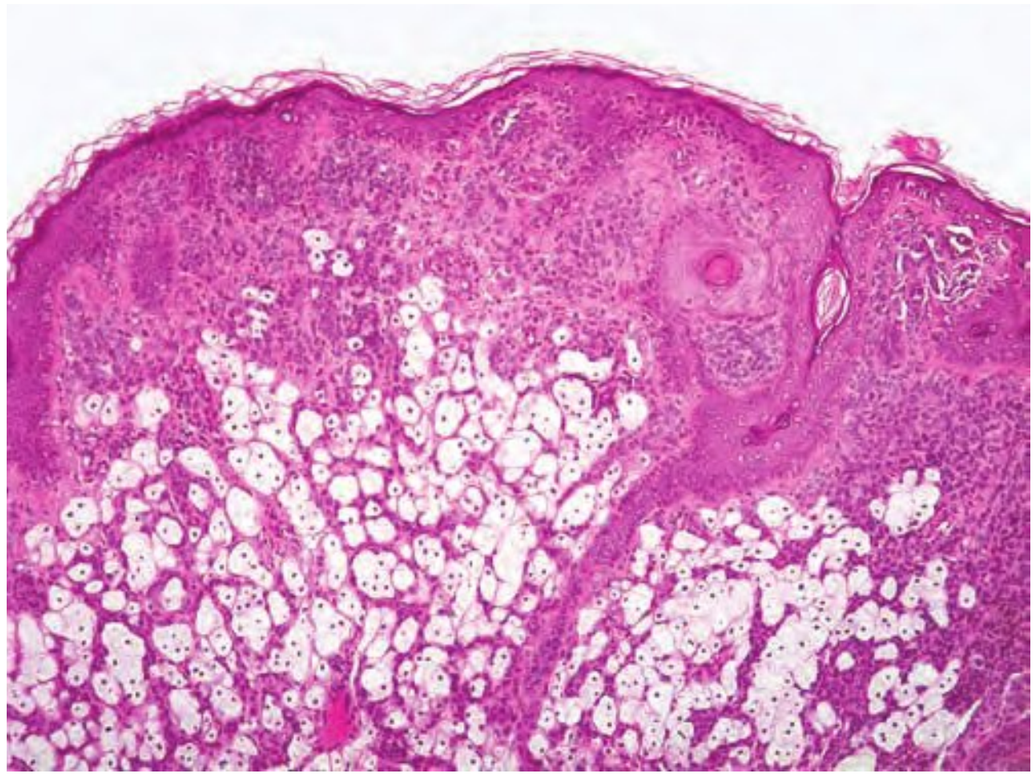

FIGURE 28-7. Balloon cell nevus. Large cells with pale cytoplasm are admixed with mature nevus cells. There is no high-grade atypia or mitotic activity.

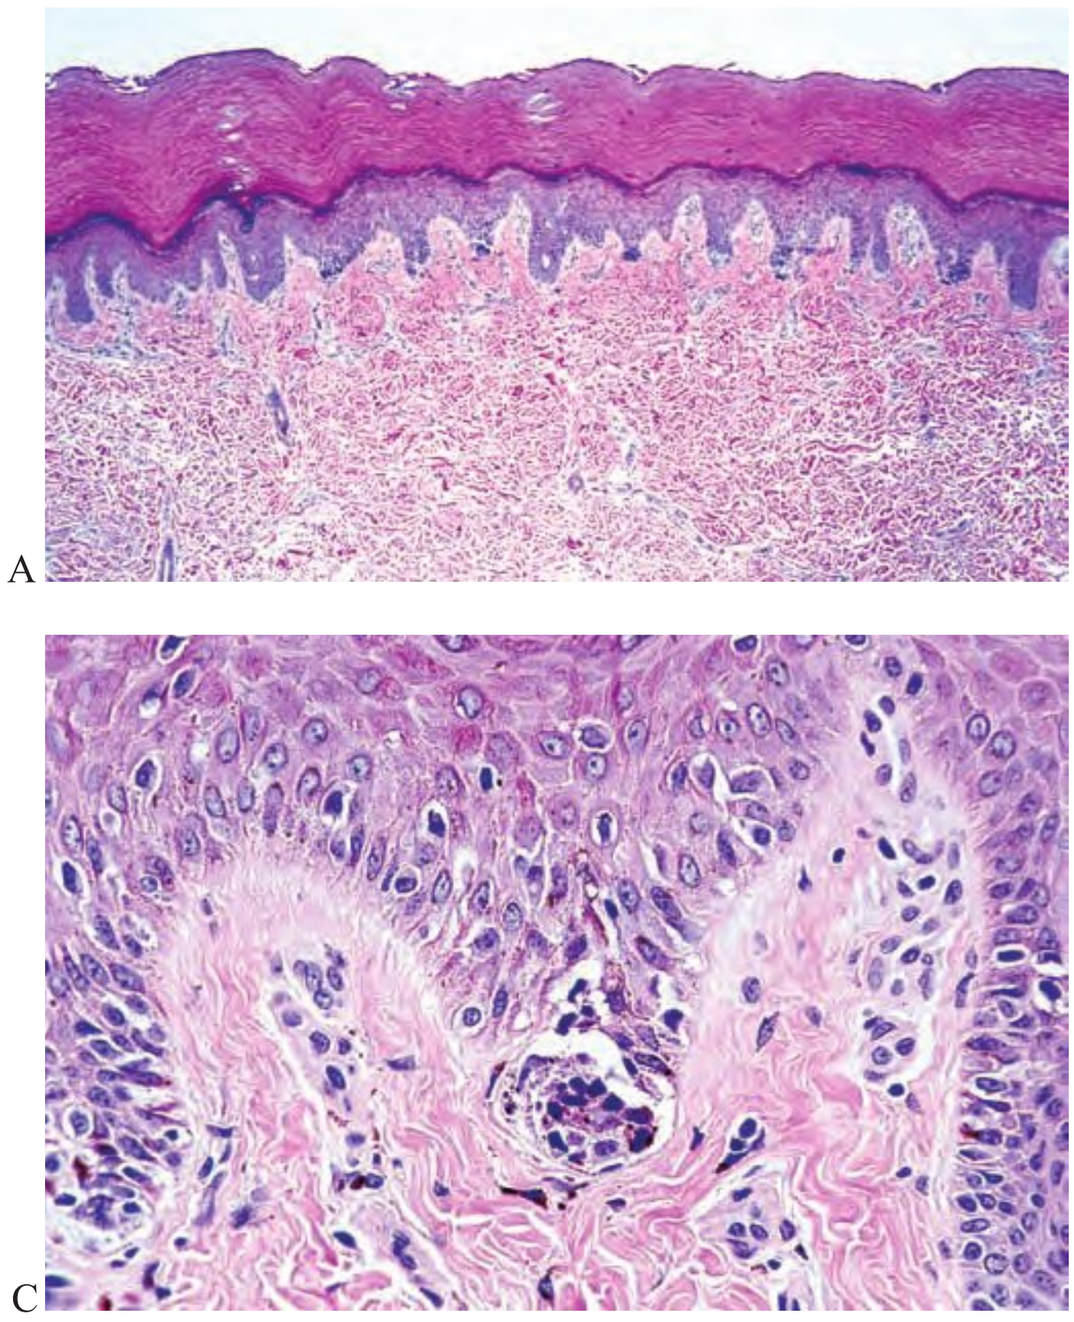
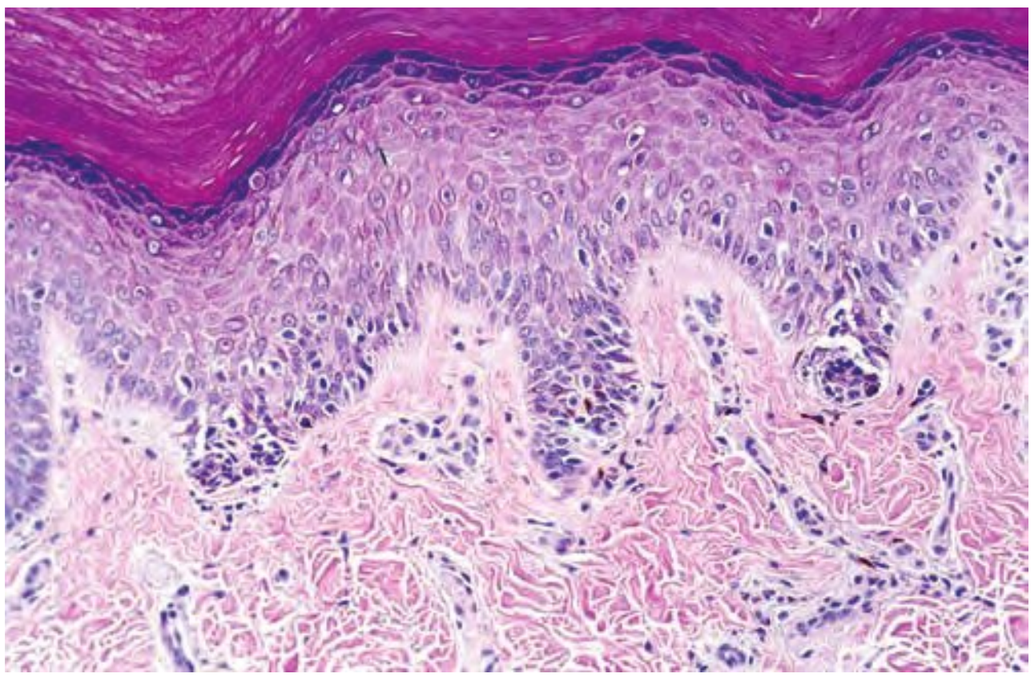
Nevi of Special Sites

There is apparent variation in the morphology of common nevi by site. In a study of Australian schoolchildren, gender differences in nevus density on the back and lower limbs were similar to gender differences for melanoma, with back lesions favoring males and lower-extremity lesions favoring females. Small nevi (2 to 4 mm) were most dense on the arms, whereas large nevi (5 mm or greater) were most dense on the posterior trunk, where they were related to age, male sex, and freckling. The findings were considered to support the hypothesis of site-specific differences in nevus proliferative potential (142). Nevi in certain locations may exhibit features that are unusual in the vast majority of common nevi on the trunk, limbs, or face and scalp. These special-site nevi have been best defined in acral locations (palmar, plantar, and subungual nevi) and in genital



skin. Nevi in skin flexural areas (ear lobe, axilla, umbilicus, inguinal creases, pubis, scrotum, and perianal area) may also show unusual features, similar to those to be described for acral nevi (143). Recently, the skin of the ears, the skin of the breast, and the skin of the scalp in adolescents have been added to this seemingly ever-expanding list of "special" sites (144–147). In general, the "special" features of the nevi are seen in only a minority of the nevi from these sites; the other nevi are quite unremarkable.

Nevi of Acral Skin



Melanocytic nevi are present on the skin of the palms or soles in as many as 4% to 9% of the population (148). Clinically, they are usually small, symmetric, well-circumscribed brown macules with a tendency to dark ridging along dermoglyphics that can be clinically striking and may impart a seemingly irregular border. They are usually stable, and are more often junctional than are nevi of the trunk.

Histopathology. Acral nevi tend to be more cellular than most common nevi, and the nevus cells may be arranged in predominantly lentiginous rather than nested patterns in the epidermis. Recently, pagetoid proliferation ("pagetoid melanocytosis") of lesional nevus cells in the epidermis above the basal layer was described in benign acral nevi (149–152). These features may perhaps account for recommendations in the older literature to remove acral nevi because of suspicion of melanoma. However, there is no evidence that these lesions, when devoid of true dysplasia, are common precursors or risk markers for acral melanomas.

Acral nevi may simulate and must be differentiated from melanoma, and this may be difficult especially in small biopsies. Clemente and colleagues studied a series of acral nevi and identified a subset that they termed acral-lentiginous nevi (150). The distinctive features of these nevi compared to other acral nonlentiginous nevi included several features also seen in acral-lentiginous melanomas: poor lateral circumscription, elongation of rete ridges, continuous junctional proliferation of melanocytes, the presence of scattered melanocytes within the upper epidermis, and the presence of junctional melanocytes with abundant pale cytoplasm and round to oval, sometimes hyperchromatic nuclei with prominent nucleoli. In lentiginous compound acral nevi, the nevus cells in the dermis, unlike melanoma cells, mature to the lesional base. There is no high-grade uniform cytologic atypia, no extensive and high-level pagetoid melanocytosis in the epidermis, and no mitoses (Fig. 28-8). There may be patchy lymphocytes and occasional melanophages in the dermis. Some of these features may suggest dysplastic nevus. However, the rete ridge pattern of keratinocytes in most acral nevi does not show the uniform elongation with occasional accentuation of anastomosing rete that characterizes dysplastic nevi, the complete array of stromal changes of dysplastic nevi are not observed in most acral nevi, and atypia of melanocytes, as a rule, is minimal or absent. In case of doubt, it may be appropriate to evaluate the patient's other nevi, especially if there is a family or personal history of melanoma. An acral-lentiginous lesion that extends to

A

B

C

FIGURE 28-8. A: Acral-lentiginous nevus. The lesion is small, quite well circumscribed, and entirely contained within the biopsy specimen. B: Acral-lentiginous nevus. Nests of nevoid to small epithelioid melanocytes predominate near the dermal—epidermal junction. They tend to be small, evenly spaced, and discreet. C: Acral-lentiginous nevus. Although a few lesional cells may be present above the junction in a pagetoid pattern, there is no severe uniform atypia or mitotic activity, and there is no continuous proliferation of single cells between the nests.

specimen borders should be evaluated carefully, and clinicopathologic correlation should be obtained to ensure that the specimen does not represent the periphery of a larger lesion. In such cases it may be judicious to recommend complete excision, to rule out additional pathology, and to preclude persistence or recurrence of the lesion. Finally, because a nevus is acral does not preclude the unusual possibility that it is also dysplastic, but this diagnosis must rely on the presence of cytologic and stromal criteria for dysplastic nevus in addition to those commonly encountered in nevi of acral sites.

Melanonychia Striata (Longitudinal Melanonychia)

Melanonychia striata refers to a pigmented band extending in the long axis of the nail. Such bands are common in blacks and Asians and therefore regarded as normal (153,154). However, the sudden appearance of melanonychia striata is cause for concern, particularly in whites, requiring a punch biopsy of the nail matrix (155). An exception is the melanonychia striata seen in the Laugier-Hunziker syndrome, which may affect one, several, or all fingernails in association with pigmented macules of the lips or the buccal mucosa. This type of melanonychia is always benign (153,156).

For carrying out the biopsy, longitudinal bilateral releasing incisions are made along the medial and lateral sides of the posterior nail fold. Next, the entire posterior nail fold is reflected proximally to expose and make visible the very end of the pigmented streak, which is usually within the matrix of the nail. Then the biopsy specimen is taken with a 3- or 4-mm punch through the nail plate and matrix down to the phalangeal bone (157,158).

Histopathology. Histologic examination in most instances shows merely basal cell layer hyperpigmentation without an obvious increase in the number of melanocytes. Such lesions have been termed melanotic macules (159) or nail matrix activation, referring to an increased production of melanin with a normal number of melanocytes (160). In a study of 18 cases, 10 were melanotic macules, 1 case was melanoma *in situ*, another showed keratinocytic atypia, and 3 were subungual hemorrhages (161). In other cases, a junctional nevus, a compound nevus of acral type as described earlier, or an acral-lentiginous melanoma, either *in situ* or invasive, may be found. The junctional or compound nevi tend to be of the lentiginous acral nevus pattern described earlier. Longitudinal melanonychia may also be associated with pigmented Bowen's disease (155). Longitudinal melanonychia in children is almost always benign: In a study of 40 cases in children younger than the age of 16 years, the histologic diagnosis was nevus in 19 cases (junctional in 17 cases and compound in 2), lentigo in 12 cases, and simple hyperpigmentation ("functional melanonychia") in 9. None of the patients in this series had melanoma (162). Subungual melanomas, although very rare, do occasionally occur in children (163).

Nevus of Genital Skin

Some clinically unremarkable nevi located on or near genital skin may present with histologic features that simulate some aspects of melanomas. The lesions have no clinical significance except the possibility of diagnostic error. They have been termed atypical melanocytic nevi of the genital type and are most often seen on the vulva of young (premenopausal) women, but they may also been seen on perineal skin (164–166). Similar lesions also occur uncommonly on the male genitalia (167). The lesions are often removed incidentally. They are typically symmetric papular lesions, usually less than 1 cm in diameter, and uniformly pigmented with discrete, well-circumscribed borders. The atypical features appear to represent a histologic curiosity seen in a minority of vulvar nevi. In a comparative histologic study of vulvar and common nevi most of the vulvar lesions were unremarkable (168). Vulvar nevi themselves are quite uncommon; in patients in a gynecology practice, the prevalence was only 2.3% (169). An interesting variant pattern of nevi has been described in association with lichen sclerosus et atrophicus, most commonly on skin of the vulva, perineum, or rarely elsewhere. These nevi had features in common with persistent ("recurrent") melanocytic nevi and can mimic malignant melanoma. This activated melanocytic phenotype seen in lichen sclerosus–associated melanocytic nevi suggests a stromal-induced change (165). The clinical differential diagnosis for atypical genital nevi also includes early genital lentigines, as described previously.

Histopathology. The scanning magnification impression is typically that of a small, well-circumscribed papular lesion composed of nevus cells arranged in clusters in the papillary dermis and arranged mainly in nests in the epidermis, where the cells do not extend beyond the shoulder of the dermal component, as typically occurs in compound dysplastic nevi (Fig. 28-9). The nevus cells may be large, with prominent nucleoli and abundant cytoplasm containing finely divided ("muddy") melanin pigment. The epidermal nests may vary considerably in size and shape, tending to become confluent. The nests tend to be variable in size, shape, and position, originating from the sides as well as the tips of rete, and often oriented parallel to the surface. The melanocytes within the nests are often dyshesive. Single cells and nests of nevus cells may occasionally be seen within the epithelia of skin adnexa. The epidermis occasionally is irregularly thickened, resulting in an asymmetric silhouette. Some of the features seen in atypical vulvar nevi may arouse a suspicion of melanoma. However, the lesions are comparatively small and well circumscribed, without significant junctional proliferation of atypical melanocytes beyond the major dermal component, as is seen in most mucosal melanomas. Moreover, there is little or no pagetoid spread of single or nested melanocytes into the epidermis, there is no necrosis and usually no ulcer, and, of importance, there is no mitotic activity in the dermis (168). Stromal patterns more characteristic of melanoma (diffuse fibroplasia) or dysplasia (concentric fibroplasia) are generally lacking in these lesions (166). The diagnosis of melanoma in vulvar skin should be made with caution (but is sometimes unavoidable) in a premenopausal woman. Occasional vulvar nevi do exhibit high-grade cytologic atypia, however, and although the biological behavior of such lesions in

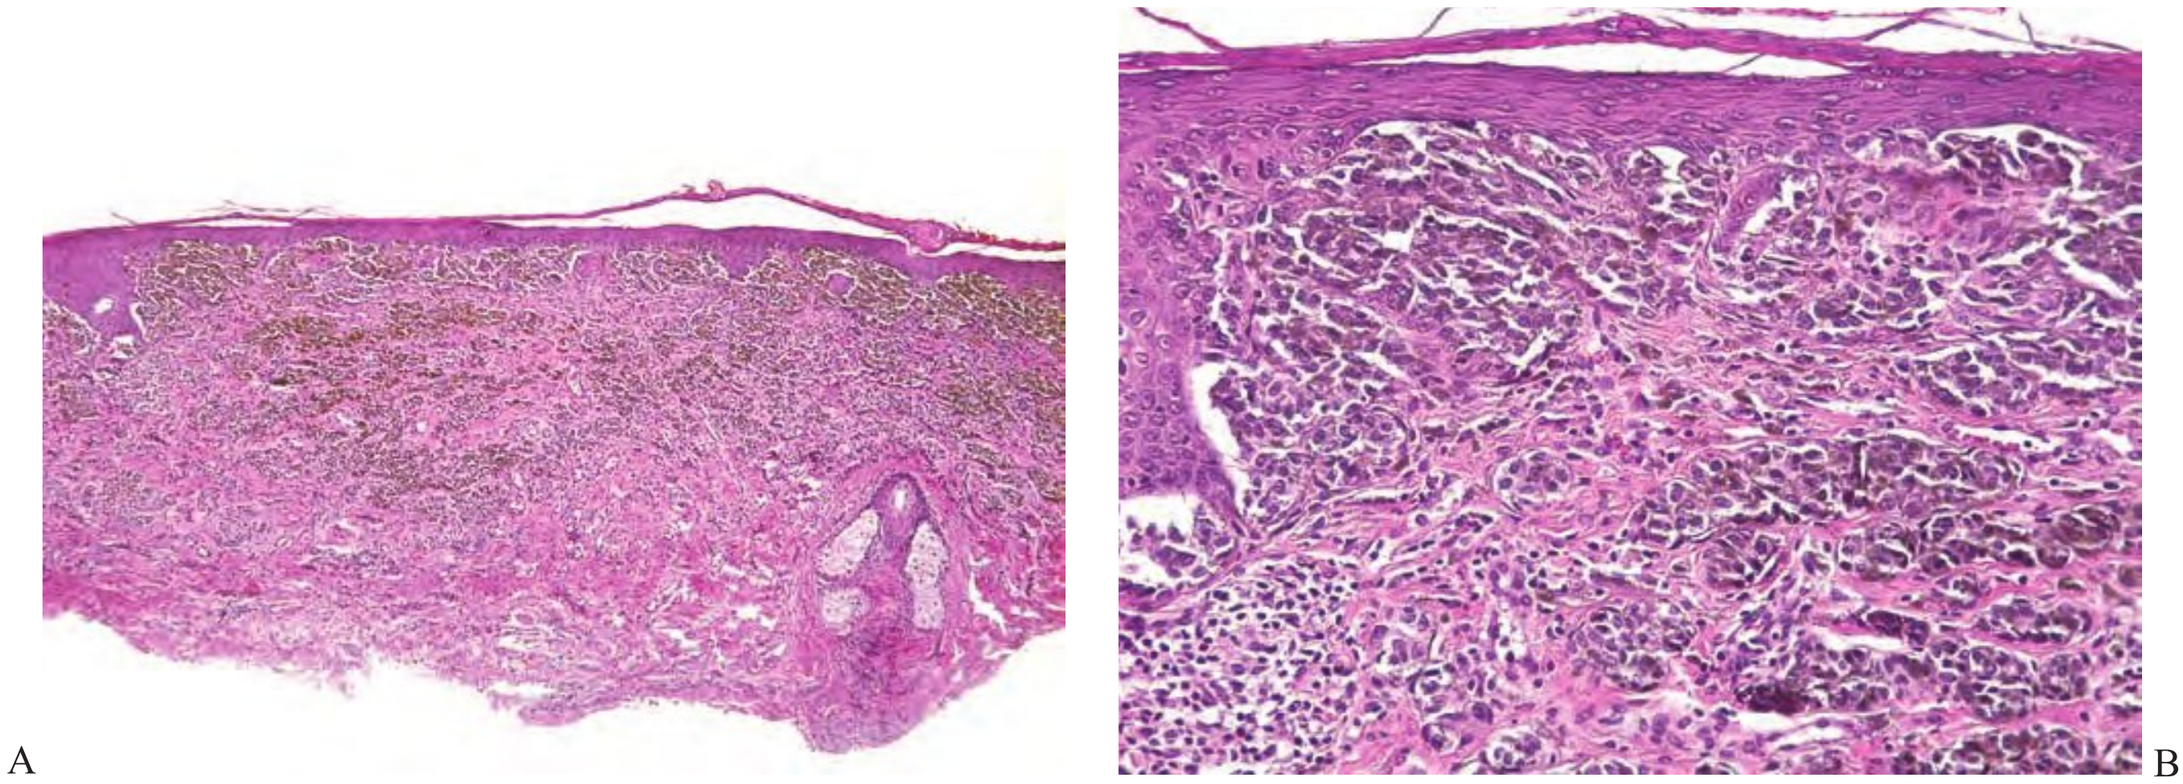


FIGURE 28-9. A: Nevus of genital skin. Nevi on genital skin may exhibit atypical features at high power but are usually relatively small and symmetric and thus benign in their appearance at scanning magnification and also clinically. B: Atypical features in genital nevi may include nests that tend to be large and confluent and to vary a good deal in size and shape and cells that tend to be large, with macronucleoli, and dyshesive from one another. Mitoses are rare or absent, and there is no adjacent in situ or microinvasive radial-growth-phase component.

young to middle-aged women has not been fully studied, it is prudent to excise such lesions modestly to prevent local persistence or recurrence in scar tissue.

In an apparently unrelated phenomenon, atypical nevi have been described in association with lichen sclerosus et atrophicus. These lesions resembled persistent or recurrent melanocytic nevi (so-called pseudomelanoma; see later section) (165).

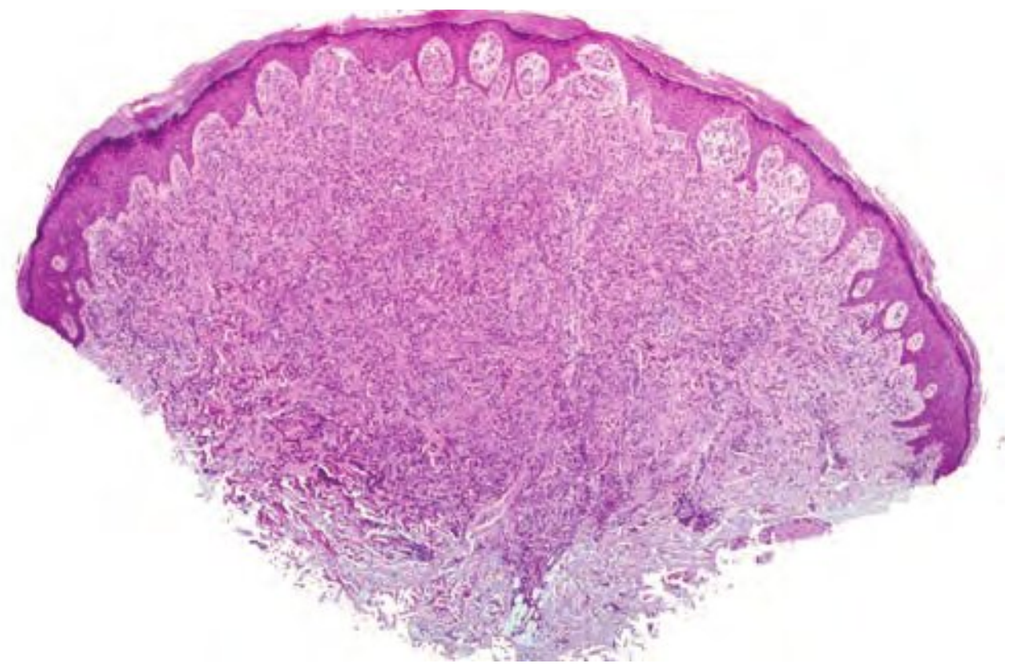
Nevi of Flexural Sites

Based on histologic findings, it has been suggested that nevi in flexural sites may differ histologically from those at other sites, in general resembling the appearances of nevi of genital skin and potentially simulating melanoma. In a study of 40 melanocytic nevi of flexural sites (axilla, umbilicus, inguinal creases, pubis, scrotum, and perianal area), 22 of them had a nested and dyshesive pattern similar to the genital pattern nevi. This pattern was characterized by the confluence of enlarged nests with variation in size, shape, and position at the dermoepidermal junction and by the diminished cohesion of melanocytes. Nevi of breast skin may show similar features. These changes in flexural nevi, like those in other "special sites," should not be overinterpreted as indicative of melanoma (143); by the same token, authentic dysplastic nevi and melanomas may occur in these sites and should not be underdiagnosed (170).

Spitz Nevus

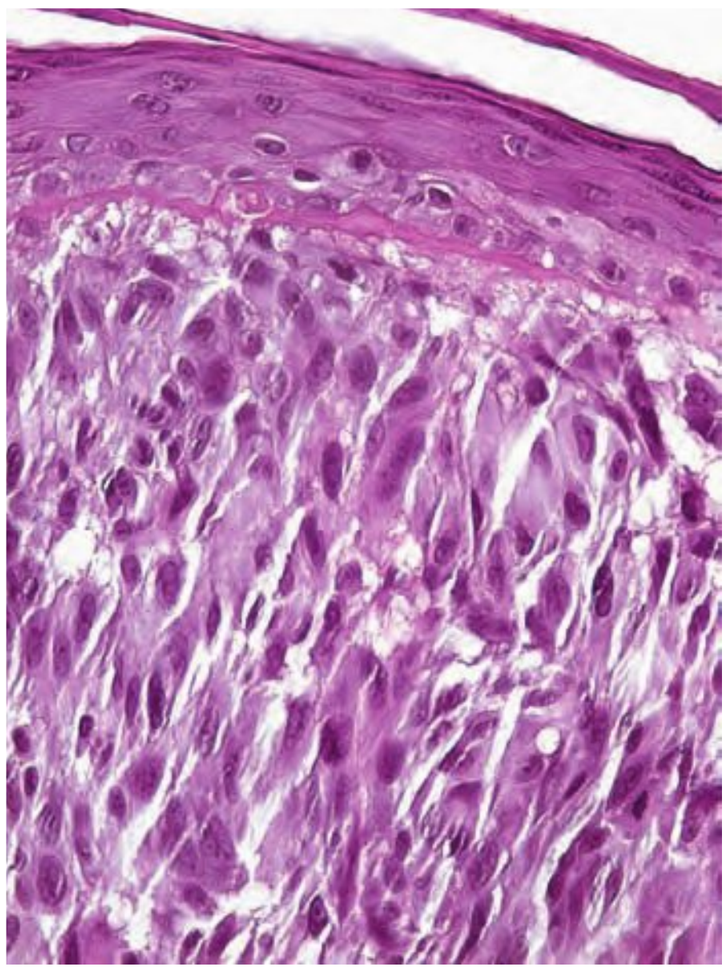
The Spitz nevus, named after Sophie Spitz, who first described it in 1948 (171), is known also as *benign juvenile melanoma* (a term that should be discouraged) and *spindle* and/or *epithelioid cell nevus*. The lesion was originally believed to occur largely in children, but it is now well recognized in young to early middle-aged adults (172,173). Rarely, it is present at birth (174). Because of a degree of unpredictability in the behavior of a subset of cases, particularly when lesions occur in adults, the term "Spitz tumor" has been suggested as preferable to "nevus," except in the most typical cases (175,176).

The lesion usually is solitary and is encountered most commonly on the lower extremities and face (177). In a recent comparative study, Spitz nevi were found to predominate on the thighs in persons younger than 40 years of age, whereas, in contrast, on the trunk melanomas were more frequent in persons 40 years of age or older (178). In most instances, the lesion consists of a dome-shaped, hairless, small pink nodule. Most Spitz nevi are small: in 95% of the patients, the size of the tumor is less than 1 cm, and in 75% it is 6 mm or less (179). The color is usually pink because of a scarcity of melanin and in some lesions associated vascularization of the stroma, and it is then often diagnosed clinically as a pyogenic granuloma, an angioma, or a dermal nevus. However, it may be tan and, in some cases, brown or even black. Ulceration is seen only rarely— in our experience, most commonly in lesions from young children. After an initial period of growth, most Spitz nevi are stable.



In rare instances, multiple tumors are encountered. These may be either agminated (grouped) in one area (180) or widely disseminated (181) (Fig. 28-10A). In a case of *agminated Spitz nevi*, a mosaic pattern of chromosomal translocation was demonstrated in lesional fibroblasts, suggesting a local event in embryogenesis (180).

Histopathology



Spitz nevi/tumors are usually compound, but they can be intradermal or entirely junctional. Ackerman's term "nevus of

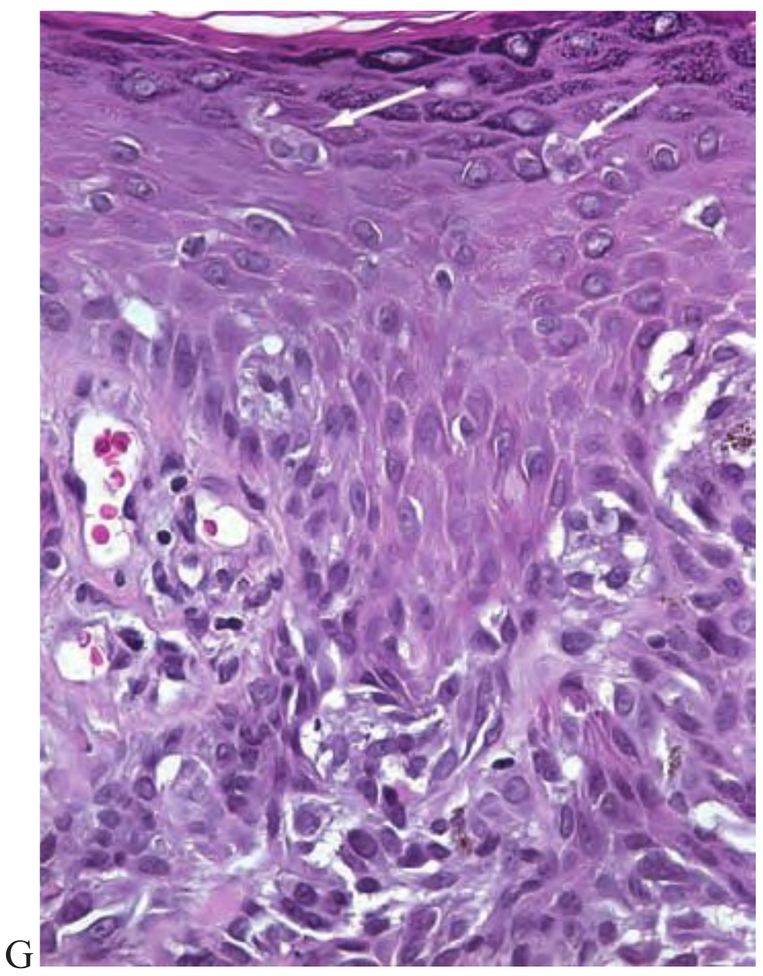

FIGURE 28-10. A: Agminated Spitz nevi. Most Spitz nevi are single lesions. In this example of agminated, or grouped, Spitz nevi, each individual lesion is a characteristic Spitz nevus—relatively small, symmetric, well-circumscribed tan papules. B: Most Spitz nevi are small, circumscribed, symmetric papules at scanning magnification and clinically. This lesion is somewhat larger than most examples. C: Spitz nevi are defined by the presence of large cells, with abundant amphophilic cytoplasm, which may be spindled or polygonal in shape (large spindle and/or epithelioid melanocytes). The nuclei in a given Spitz nevus are more homogeneous than in most melanomas, usually large but with open chromatin and smooth nuclear membranes, and with prominent nucleoli. D: Maturation from larger cells near the surface to smaller cells at the base is an important feature of Spitz nevi. (continued)

E

F

G

FIGURE 28-10. Continued. E: Spitz nevus with globoid eosinophilic bodies (Kamino bodies). Although not pathognomonic, these structures are highly characteristic of Spitz nevi. F: At the base of a Spitz nevus, the lesional cells become smaller and "dispersed" among the reticular dermis collagen fibers. This is the same lesion as in panels D & E. Note the diminution in size (maturation) of the lesional cells at the base. G: Pagetoid extension of some cells of a Spitz nevus into the epidermis, as seen here, is not diagnostic of a melanoma if other attributes of melanoma are not observed. This pagetoid melanocytosis is not uncommon at least focally in lesions of young children.

large spindle and/or epithelioid cells" reflects the characteristic cytologic appearances that provide the essential definition for the lesion (173). Because of the large size of the lesional cells often with considerable nuclear and cytoplasmic pleomorphism and the frequent presence of an inflammatory infiltrate, the histologic picture often resembles that of a nodular melanoma. There is no doubt that, before the recognition of Spitz nevi as an entity, many cases were diagnosed as melanoma. Even today, differentiation from a melanoma can often be very difficult and occasionally even impossible. Features that aid in the distinction may be summarized as architectural pattern and cytologic features (Fig. 28-10A–G).

In terms of their architectural pattern, Spitz nevi resemble common nevi. They are usually compound, but, as stated earlier, they can be intradermal or entirely junctional. They are small, symmetric, and well circumscribed. It is somewhat unusual for the intraepidermal component to extend beyond the dermal component, and such a finding should prompt consideration of associated dysplasia or melanoma (182). The epidermal component is arranged in nests often formed by spindle cells that tend to be oriented vertically and, though large, do not show significant variation in size and shape or tend to become confluent. The cytoarchitecture or spindle cells aligned in parallel within the junctional nests is character-

istic and forms the basis for the descriptive term by which the nests are considered to be "raining down." In Spitz nevi with junctional activity, there are often artifactual semilunar clefts separating nests of nevus cells at the epidermal–dermal junction from adjacent and overlying epidermal cells. Not so commonly seen in melanoma, this feature represents a useful diagnostic feature (182).

Although there may be diffuse junctional activity, permeation of the epidermis by tumor cells (pagetoid melanocytosis) is relatively slight. If present, it usually consists of single nevus cells or small groups of cells and is generally limited to the lower half of the epidermis (Fig. 28-10G) (173). In a few Spitz nevi, however, pagetoid migration of lesional cells into the epidermis may be quite marked, especially in young children. These pagetoid Spitz nevi appear clinically as a small (less than 0.4 cm) pigmented macule in young patients. Features favoring nevus over melanoma include small size, circumscription, symmetry, even distribution of cells, and lack of marked cytologic atypia (183). Pagetoid involvement of the suprabasal epidermis is not a common feature of Spitz nevi in adults; in such a case the diagnosis of melanoma should be considered (184). Occasionally, nests of lesional cells are seen in transit through the epidermis, described as transepidermal elimination of nevus cells (185,186).

The epidermis involved by Spitz nevi is often hyperplasic, with elongated rete ridges. Occasionally, this hyperplasia is sufficiently florid to be termed pseudoepitheliomatous, representing a possible source of confusion with squamous cell carcinoma, especially in a superficial biopsy (187). However, the epidermis may be thinned and even ulcerated, especially in very young children. A pattern termed consumption of the epidermis, defined as "thinning of the epidermis with attenuation of the basal and suprabasal layers and loss of rete ridges in areas of direct contact with neoplastic melanocytes," has been suggested as an additional criterion for differentiating melanoma from nevi. This feature is seen in many melanomas but is absent in most Spitz tumors (188). Found in fewer than half of the patients, diffuse edema, stromal hyalinization, and telangiectasia in the papillary dermis, if present, are of slight diagnostic importance. The edema may cause a loose arrangement of the nevus cell nests (182).

Important cytologic features of Spitz nevi include especially the presence of large spindle cells and epithelioid cells (Fig. 28-10C). Spindle cells or epithelioid cells may predominate, or the two types of cells may be intermingled ("large spindle and/or epithelioid cells") (173). Apart from the shape of their cell bodies, the spindle cells and the epithelioid cells in any given Spitz nevus resemble one another in nuclear and in cytoplasmic consistency, suggesting that they may represent dimorphic expression of a single cell type. The cells are large, with abundant amphophilic cytoplasm that may contain scant, finely divided melanin pigment, although in most of the cells, pigment is typically absent. The nuclei are large, with pale, delicate, and evenly dispersed chromatin, regular, smooth nuclear membranes, and prominent eosinophilic or amphophilic nucleoli. The size of the lesional cells, more than any other feature, sets the Spitz nevus apart from the common nevus (189) and also from most melanomas. Bizarre giant cells may be seen in both melanoma and Spitz nevi, the difference being that, in the latter, they usually have regular nuclei of similar size, whereas in melanoma the nuclei are usually more pleomorphic. Mitoses are absent in about half of the cases. This is helpful in ruling out melanoma in these lesions. Usually, there are only a few mitoses, but occasionally, they are quite numerous in the epidermal compartment. A dermal mitotic rate of greater than two mitoses per square millimeter, abnormal mitoses, or mitoses close to the base of the dermal component (within the lower half of the dermal component) are unusual in Spitz nevi (190) and may warrant a diagnosis of melanoma or a descriptive diagnosis of melanocytic tumor of uncertain potential. Atypical mitoses are uncommon, and if they are found, the lesion should be interpreted with great caution (182,190). The complete absence of mitoses in 50% of Spitz nevi is very helpful in ruling out melanoma in these cases.

Of special importance is maturation of the cells with increasing depth, so that they become smaller and look more like the cells of a common nevus (Fig. 28-10D–F) (182). Also important is the uniformity of the lesional cells from one side of the lesion to the other: At any given level of the lesion from the epidermis to its base, the lesional cells look the same. Although large superficially, the cells at the base of most Spitz nevi are small, and they tend to disperse as single cells or files of single cells among reticular dermis collagen bundles. Involvement of the reticular dermis is highly characteristic of Spitz nevi, and as they descend into this part of the dermis, some of the cells become separated from the apparent border of the lesion to form outlier cells (179) that can be revealed, for example, by a stain for S100 antigen. Other benign nevi also tend to infiltrate in this way if they involve the reticular dermis (191). Melanomas, in contrast, tend to form solid tongues or fascicles of tumor cells that separate and displace the collagen bundles in the reticular dermis without forming outlier cells.

A useful although not pathognomonic cytologic criterion for Spitz nevi is the presence within the epidermis of red globules resembling colloid bodies in 60% to 80% of cases. They may form larger bodies through coalescence. These "Kamino bodies" are most commonly seen in the basal layer above the tips of dermal papillae (Fig. 28-10E). Similar-appearing eosinophilic globules have been noted in the epidermis in only 2% of melanomas and 0.9% of ordinary nevi, in which they are, however, less conspicuous because they do not coalesce (192,193). Although often these bodies may resemble apoptotic cells, formal studies have found no evidence of active apoptosis and have related the eosinophilic material to hyalinized collagen or basement membrane–like material (194).

Melanin is in many instances completely or nearly absent in Spitz nevi. In a few cases, melanin is moderate or dense. Some of these pigmented Spitz nevi are better classified as pigmented spindle cell nevi, related lesions that are discussed in the next section. An inflammatory infiltrate is found in many Spitz nevi and may be quite heavy. Its distribution can be bandlike, mainly at the base, as in some melanomas. Often,

however, the infiltrate is patchy around blood vessels and is seen throughout the lesion (172,179,182).

On comparing Spitz nevi occurring in adults with those of children, it appears that pure epithelioid cell Spitz nevi are rare in adults. In addition, lesions in adults often are more pigmented than in children (195). Furthermore, desmoplastic Spitz nevi seem to occur predominantly in adults (173).

In some examples of Spitz nevi (and also in some nevi with smaller cells that may not meet criteria for Spitz nevi), diffuse fibrosis is present (196–198). These *desmoplastic Spitz nevi* generally show no junctional activity, nesting, or pigmentation. The nevus cells are predominantly spindle shaped and compressed by a desmoplastic stroma. However, they differ from a dermatofibroma by the presence of epithelioid and often also multinucleated cells. Desmoplastic melanoma almost always shows an associated lentiginous *in situ* component, in contrast to the rarity of junctional activity in desmoplastic Spitz nevi. Furthermore, desmoplastic melanomas are almost invariably negative (in their spindle cell component) for the HMB-45 and Melan-A (MART-1) melanocytic markers, which in contrast are usually positive in Spitz nevi (199,200).

Hyalinizing Spitz nevi are related lesions that present with spindle or epithelioid nevus cells embedded in a paucicellular hyalinized collagenous stroma. Some of these lesions have been mistaken histologically for metastatic carcinomas (201).

Angiomatoid Spitz nevi present histologically with large spindle and/or epithelioid nevus placed among "angiomatoid" densely arranged, small blood vessels lined by plump endothelial cells embedded in a collagenous stroma. The Spitz nevus cells may be quite inconspicuous among the vessels in some cases. There have been no reported cases of recurrence or metastases (202).

Histogenesis. On electron microscopic examination, Spitz nevi show in their upper portion melanocytes with numerous melanosomes; in their lower portion, the number of melanosomes in the melanocytes decreases. Melanization is incomplete in most melanosomes, and there is evidence of lysosomal degradation of melanosome complexes (203). The paucity of melanin in most Spitz nevi is thus explained. Biological marker studies have shed little or no light on the mechanisms whereby Spitz nevi appear to have the capacities for relatively rapid invasive and tumorigenic proliferation in the dermis but to lack the capacity for metastasis.

Diagnostic and Prognostic Markers. Morphometric and immunohistochemical studies have shown differences between Spitz nevi and melanomas, but none of these adjuncts to histologic diagnosis is in standard use. By immunohistochemistry, Spitz nevi react not only with differentiation markers for melanocytes such as S100 antigen, but also with HMB-45 and Melan-A/MART-1, the former a melanosomal antigen often expressed in proliferating melanocytic lesion (as well as melanoma), and the latter a more specific marker of melanocytic lineage (125,199,200). Spitz nevi tend to show a more orderly pattern of stratification of HMB-45 reactivity from superficial to deep compared to melanomas (199). A recent study demonstrated interesting differences in S100A6 protein expression between Spitz nevi and melanomas (204). Like nevi and unlike melanomas, Spitz nevi show a tendency toward diminution of nuclear size and/or DNA content (205,206), as well as for reactivity with certain antigens, from the superficial to the deep portions of the nevus (199). This stratification may be regarded as an expression of maturation/senescence that is diagnostically and no doubt also biologically important in the distinction between Spitz nevi and melanomas.

Nuclear size or volume assessed morphometrically has provided fairly good discrimination in some hands, especially when measured at the base of the tumor or when combined with a "maturation parameter," namely the ratio of nuclear area between the deep and superficial portions (207). Cell proliferation marker studies using PCNA or cyclin antibodies have in general shown Spitz nevi to be intermediate between common nevi and melanomas, but the specificity has been insufficient for diagnostic use (208–210). Perhaps of some potential practical utility is the absence of aneuploidy as judged by cytofluorometry (211,212) or DNA fluorescence *in situ* hybridization (FISH) (213,214), a feature that is specifically associated with Spitz nevi compared to melanomas in several studies. However, these methods have not been applied to a sufficiently large and well-characterized series of difficult cases for which they are most needed, but also for which their utility is likely to be most limited. In one such study, de Wit et al., using FISH, were able to identify only three of five lesions that had been originally diagnosed as Spitz nevi but later reclassified as melanoma because of the occurrence of metastasis (215). In another recent study, 5 of 22 Spitz nevi had an aneuploid cell population, so that the presence of aneuploidy cannot be considered diagnostic of melanoma (216).

In a recent study by Bastian et al. using FISH on tissue arrays, copy-number increases often associated with oncogenic mutations involving the HRAS gene on chromosome 11p were found in about 10% of cases (217). Tumors with 11p copy-number increases were larger, predominantly intradermal, and had marked desmoplasia, characteristic cytologic features, and an infiltrating growth pattern. HRAS activation by either mutation or copy-number increase alone could explain several of the histologic features that overlap with those of melanoma. It is speculated that HRAS activation in the absence of cooperating additional genetic alterations may drive the partially transformed melanocytes of these atypical Spitz nevi into senescence or a stable growth arrest (217), likely as a result of p16 activation in a process termed oncogene-induced senescence (218). There are no data to suggest that Spitz nevi with HRAS activation are at special risk for progression to melanoma; however, the biological potential of these lesions is not completely understood.

Differential Diagnosis. The distinction between Spitz nevi/tumors and benign nevi is usually trivial except for dysplastic nevi, which may be indicators of an individual at increased risk for melanoma. In cases of doubt in this regard, we add a note to the effect that the differential diagnosis may include a dysplastic

nevus and recommend that the patient be evaluated for other risk factors, such as multiple dysplastic nevi and a family or personal history of melanoma. Occasional examples of histiocytic tumors such as epithelioid histiocytomas or juvenile xanthogranulomas may be confused with epithelioid Spitz nevi or with melanomas, especially when foam cells or Touton giant cells are inconspicuous (219). It has been demonstrated that Melan-A and tyrosinase markers are sensitive and specific in making the diagnosis of a melanocytic lesion, whereas histiocytic markers such as CD68 and factor XIIIa are likely to be positive in the histiocytic lesions (see Chapter 26) (220–222).

The differential diagnosis with melanoma is of course of much greater importance. Differentiation of a Spitz nevus from a nodular melanoma can be difficult and even impossible in some cases because all of the changes seen in the Spitz nevus may also be observed in melanoma. This differential has been discussed extensively in previous sections. Crotty et al. considered that the presence of symmetry, Kamino bodies, and uniformity of cell nests or sheets from side to side favor a Spitz nevus, whereas the presence of abnormal mitoses, a dermal mitotic rate of greater than 2/mm^2, and mitotic figures within 0.25 mm of the deep border of the lesion favor a melanoma (190). We would add to this list the characteristic dispersion pattern of single cells at the base, which favors a Spitz or other benign nevus.

There are cases on record that were diagnosed as instances of Spitz nevus but later proved to be melanoma (215). Other cases, regarded by some as malignant Spitz nevi, have metastasized to regional lymph nodes but not beyond (223). These lesions, which are often large, ulcerated, deeply infiltrative, and mitotically active, can alternatively be signed out descriptively as melanocytic tumors of uncertain potential. Others regard these lesions as spitzoid melanomas, some considering that the prognosis for these tumors may be better than expected for an ordinary melanoma with similar microstaging attributes (175). The diagnosis of a Spitz nevus depends on an assessment of multiple morphologic features, which are summarized in Table 28-3. Given that so-called metastasizing Spitz nevi/tumors have been associated with long-term survival (224–228), it may be appropriate to regard the metastases as metastatic melanocytic tumors of uncertain potential rather than unqualified metastatic malignant melanoma. However, in our practice, such individuals would be offered a consideration of adjuvant protocols for metastatic melanoma.

TABLE 28-3 Spitz Nevus Versus Melanoma

Spitz nevus	Melanoma
Pattern features	
Usually <6 mm diameter	Usually >6 mm
Usually symmetric	Often but not always asymmetric
Single attenuated cells between reticular dermis collagen bundles at base	Nests and fascicles rather than single cells in the reticular dermis
Epidermal hyperplasia, hyperkeratosis, and hypergranulosis may be prominent	Epidermal reaction is often minimal
Usually little or no pagetoid spread of lesional cells into the epidermis	Usually obvious pagetoid spread into the epidermis
Epidermal component usually does not extend beyond the lateral border	Lateral extension (radial growth phase) is common except in nodular melanoma
Ovoid nests of lesional cells oriented perpendicular to the epidermis	Nests variable in size, shape, and orientation
Discontinuous junctional proliferation	May be continuous proliferation
Little or no pigment	Often heavily pigmented, or irregularly scattered pigmented cells within the lesion
Small uniform nests in the dermis at base	Larger variable nests at base
Cytologic features	
Nuclear chromatin is open, with prominent nucleoli	Nuclei may be hyperchromatic and clumped
Nuclear membranes are regular	Irregular nuclear membranes
Single and confluent eosinophilic globoid bodies in epidermis and superficial dermis	If present, globoid Kamino bodies are inconspicuous and usually single
Mitoses absent or low mitotic rate	Mitoses rarely absent, rate often high
Atypical mitoses rare or absent	Atypical mitoses common
Mitoses rare in lower third of lesion	Mitoses common in lower third of lesion
Cells uniform from side to side	Greater tendency to cellular variability
Cells mature with descent to base	Little or no maturation

Because of the difficulty of making an absolutely certain differentiation from melanoma, it is advisable as a precautionary measure that lesions diagnosed as Spitz tumors/nevi be excised completely, especially in persons at or beyond puberty, particularly because such lesions are usually small. Although the issue is debatable (229), exceptions to this general rule might include those lesions for which there are cosmetic or other contraindications to excision and for which the diagnosis of Spitz nevus is certain despite the partial nature of the biopsy (230). In addition, one should never exclude a diagnosis of melanoma based on age alone because melanomas may arise in children, although this is rare. Spatz et al. provided criteria for grading risk in Spitz tumors, considering metastasizing cases in childhood. These criteria included diagnosis at age greater than 10 years, diameter of the lesion greater than 10 mm, presence of ulceration, involvement of the subcutaneous fat (level V), and mitotic activity of at least 6/mm^2 (176). As noted earlier, it is not always possible to make an unequivocal distinction between a melanoma or a Spitz tumor/nevus, and in these doubtful cases we will often use the descriptive term "melanocytic tumor of uncertain potential" (MELTUMP) and provide a differential diagnosis that might in cases of extreme doubt include microstaging attributes that would apply if the lesion were interpreted as a melanoma (231).

Pigmented Spindle Cell Nevus

This tumor, first described by Richard Reed in 1973 (232), may be regarded as a variant of the Spitz nevus (167,173) or as a distinctive clinicopathologic entity (233). In our experience and that of others, most cases differ significantly from classical Spitz nevi, but some present with overlapping features, indicative of a close relationship between the two entities (234–236). Although this distinction has no clinical significance, in that each is a benign lesion, it is important to rule out melanoma, and this is facilitated by an understanding of the differences between these two common melanoma simulants.

The lesions are usually 3 to 6 mm in diameter, deeply pigmented, and either flat or slightly raised. Most patients are young adults, and the most common location is on the lower extremities. Pigmented spindle cell nevi are uncommon after the age of 35 years. A classic presentation is that of a newly evolved black plaque on the thigh of a young woman. Because of the heavy pigment and the history of sudden appearance, a diagnosis of melanoma is often suspected clinically. In contrast, Spitz nevi are usually submitted with a benign clinical diagnosis, such as an angioma or a dermal nevus. Like Spitz nevi, the lesions are generally stable after a relatively sudden appearance and a short-lived period of growth.

Histopathology. The pigmented spindle cell nevus is characterized by its relatively small size and its symmetry and by a proliferation of uniform, narrow, elongated, spindle-shaped, often heavily pigmented melanocytes at the dermal–epidermal junction (233–235,237). The nests of spindle cells are vertically oriented and tend to blend with adjacent keratinocytes rather than forming clefts as in Spitz nevi. Eosinophilic globules (Kamino bodies) may be present (Fig. 28-11) (238). The tumor cells often form bundles that are separated by elongated rete ridges. In the papillary dermis, the nevus cells lie in compact clusters, pushing the connective tissue aside. Numerous melanophages are characteristically diffusely present within the underlying papillary dermis. Involvement of the reticular dermis, common in Spitz nevi, is unusual in pigmented spindle cell nevus. Some lesions show upward epidermal extension of junctional nests of melanocytes. Single-cell upward invasion of the epidermis in a pagetoid pattern may be present but is usually not prominent (152,234). Features that may lead to a diagnosis qualified as atypical pigmented spindle cell nevus include architectural abnormalities including poor circumscription and pagetoid melanocytosis, prominent cytologic atypia, or a prominent epithelioid cell component (234). There may also be considerable overlap with dysplastic nevi (234). The significance of these atypical variants appears to lie in their greater chance of being misdiagnosed as melanoma because all reports of pigmented spindle cell nevi emphasize their benign behavior after excision.

Differential Diagnosis. The most important differential diagnosis is with melanoma of the superficial spreading type. In contrast to these melanomas, pigmented spindle cell nevi are smaller, symmetric, and show sharply demarcated lateral margins. The tumor cells appear strikingly uniform from side to side. If lesional cells of pigmented spindle cell nevi descend into the papillary dermis, they mature along nevus lines, in contrast to melanomas. Mitoses may be present in the epidermis in either lesion but are uncommon in the dermis in pigmented spindle cell nevi. Abnormal mitoses are exceedingly uncommon. Pagetoid melanocytosis is usually not prominent, and the spindle cell cytology differs from that of the epithelioid cells that predominate in most superficial spreading melanomas. Lentigo maligna melanomas may have spindle cells in their vertical-growth-phase component, but the epidermal component is usually composed of smaller, nevoid, albeit atypical, cells. Some pigmented spindle cell nevi may present overlapping features with dysplastic nevi but can usually be distinguished on the basis of their irregularly thickened epidermis, their vertically oriented nests, and the uniformity of cell type, the absence of cytologic dysplasia, and the absence of typical stromal alterations (e.g., lamellar fibrosis). In cases of extreme doubt, we may classify the lesions as superficial atypical melanocytic proliferation of uncertain significance (SAMPUS) and provide a differential diagnosis of melanoma *in situ* or dysplastic nevus. In the former case, a reexcision procedure is recommended, whereas in the latter case we recommend assessment of melanoma risk factors and perhaps follow-up, especially if the patients have other clinically atypical nevi or a family or personal history of melanoma (231). Some rare examples of lesions with larger expansile intradermal nodules may be difficult to distinguish from melanoma, and a descriptive diagnosis may be appropriate (MELTUMP; see later section).

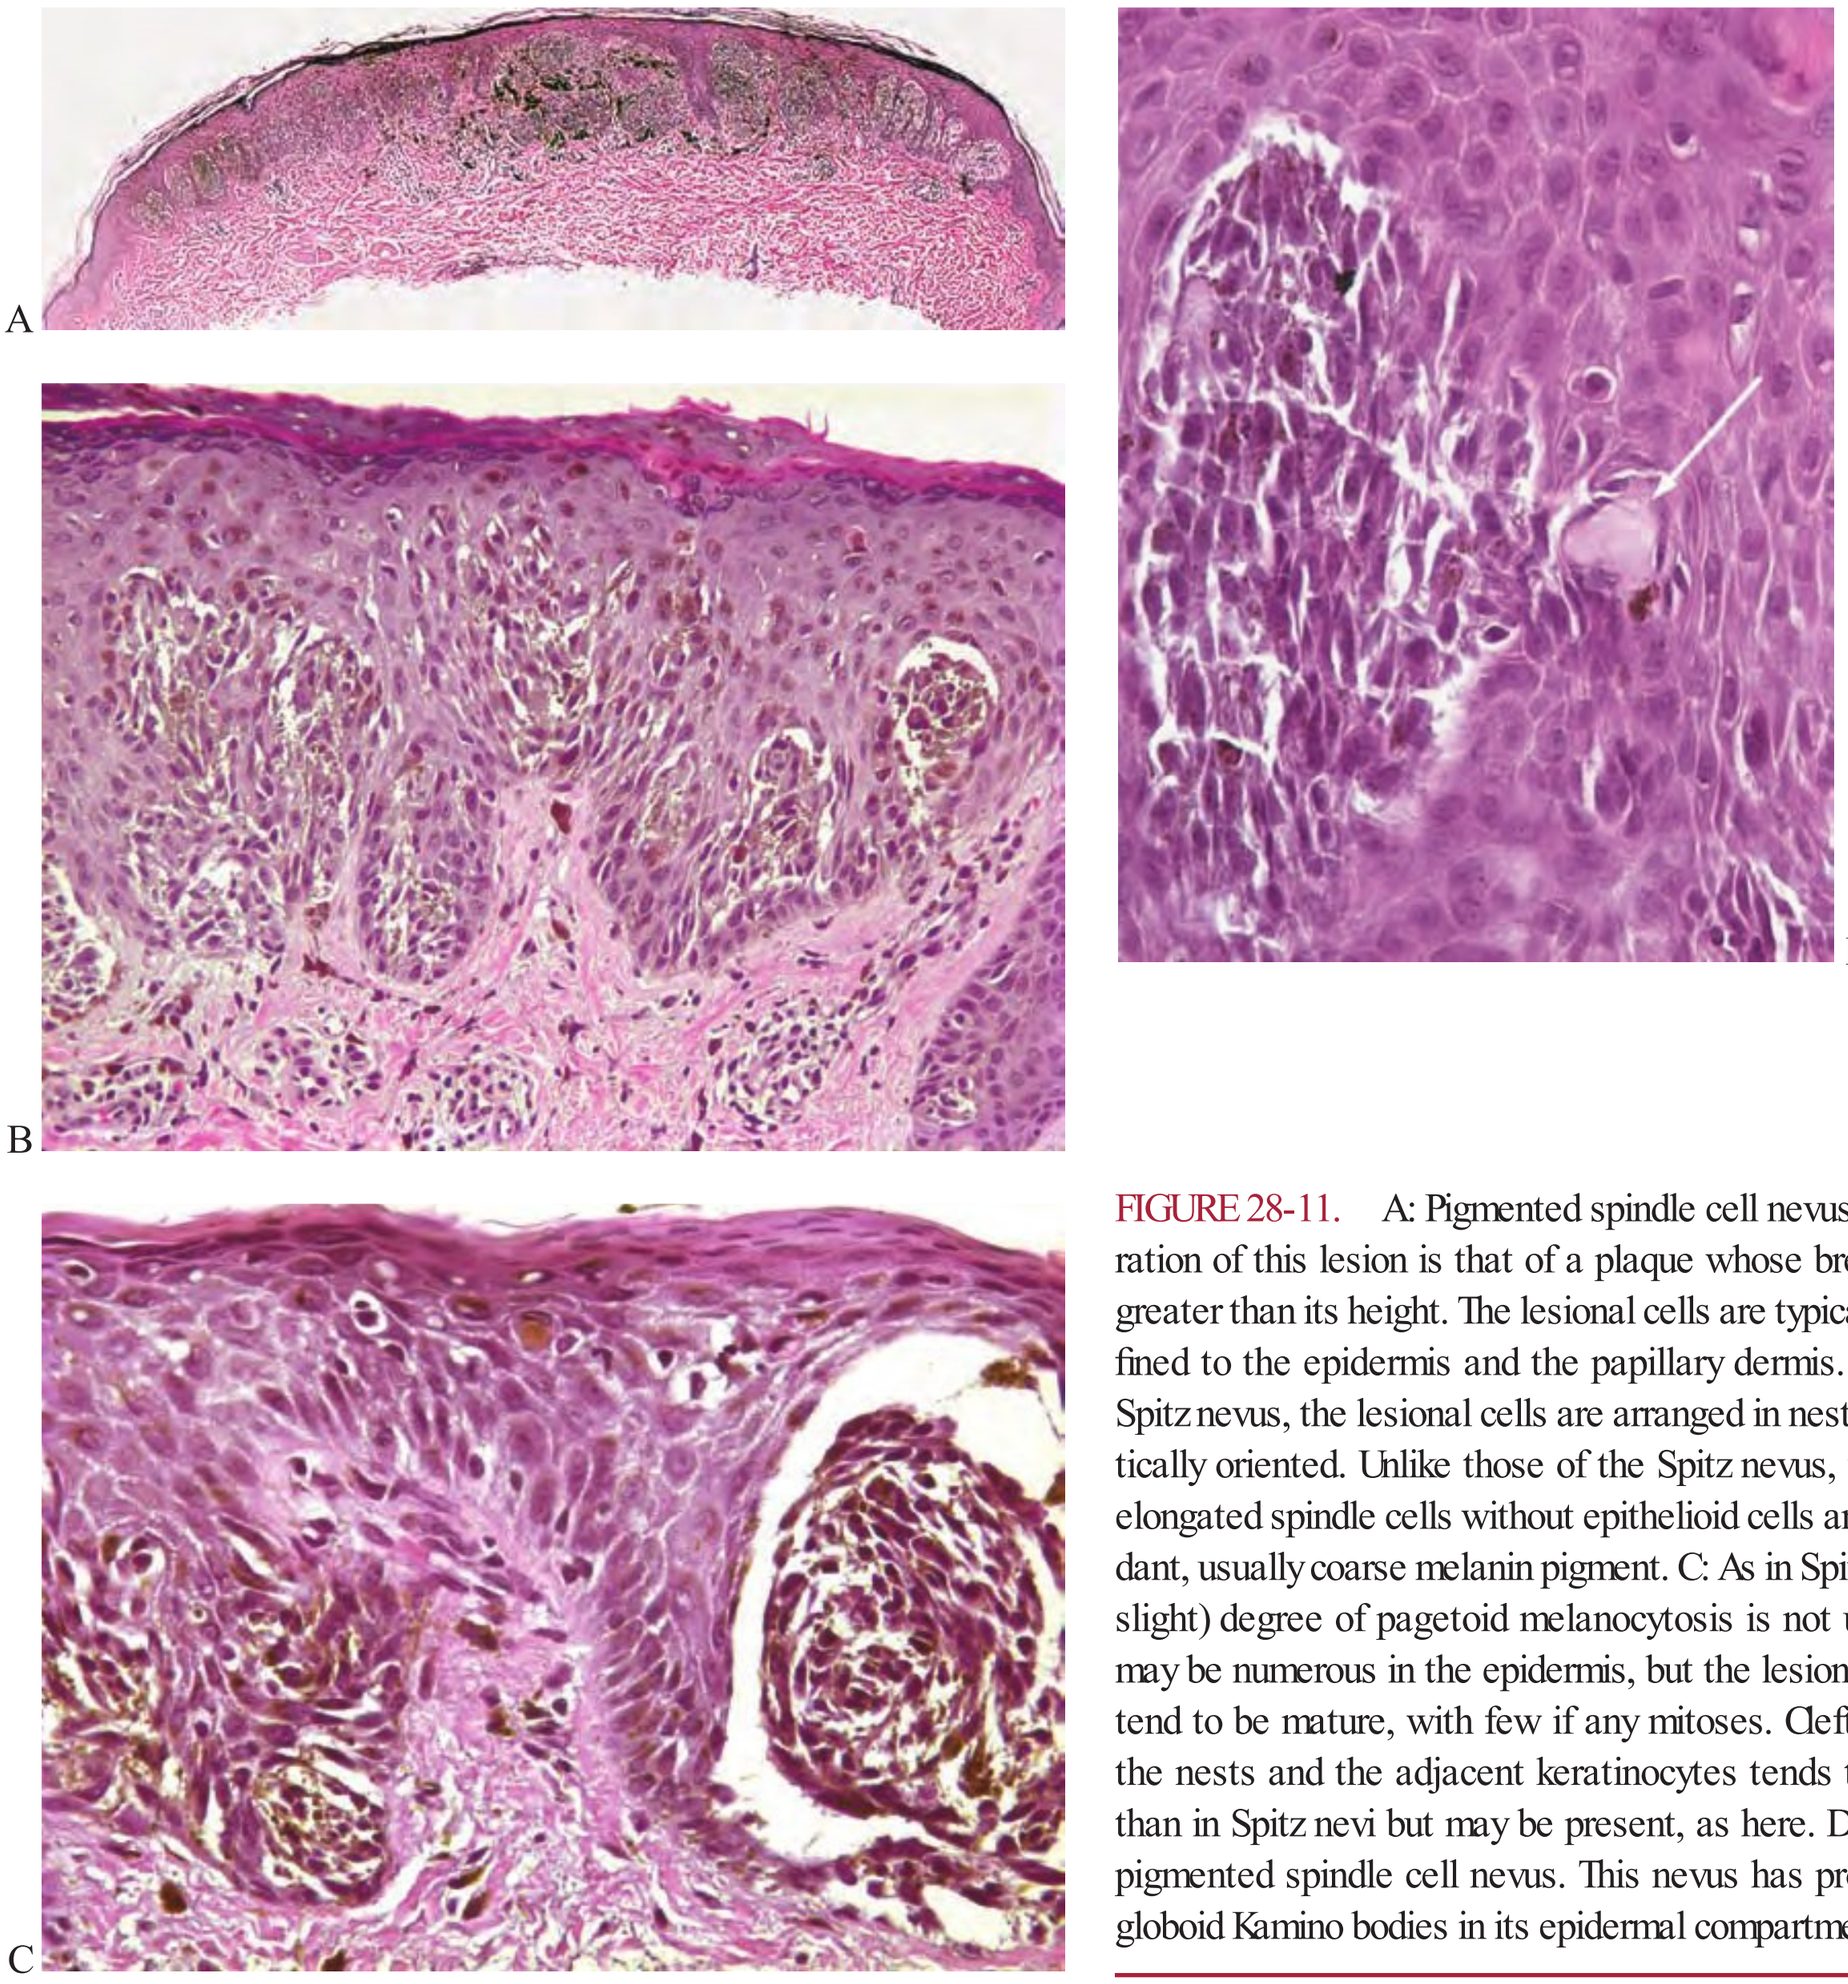

FIGURE 28-11. A: Pigmented spindle cell nevus. The typical configuration of this lesion is that of a plaque whose breadth is considerably greater than its height. The lesional cells are typically junctional or confined to the epidermis and the papillary dermis. B: As in the classic Spitz nevus, the lesional cells are arranged in nests that tend to be vertically oriented. Unlike those of the Spitz nevus, the cells are narrow, elongated spindle cells without epithelioid cells and they contain abundant, usually coarse melanin pigment. C: As in Spitz nevi, some (usually slight) degree of pagetoid melanocytosis is not unexpected. Mitoses may be numerous in the epidermis, but the lesional cells in the dermis tend to be mature, with few if any mitoses. Clefting artifact between the nests and the adjacent keratinocytes tends to be less prominent than in Spitz nevi but may be present, as here. D: Kamino bodies in a pigmented spindle cell nevus. This nevus has prominent eosinophilic globoid Kamino bodies in its epidermal compartment.

Congenital Melanocytic Nevus

A congenital melanocytic nevus may be defined as a lesion present at birth and containing nevus cells. Congenital nevi are found in about 1% to 2% of newborn infants (239,240), and thus, although such lesions are rare when compared to the total number of all noncongenital nevi, their occurrence is a relatively common clinical event. In many instances, congenital nevi are larger than acquired nevi, measuring more than 1.5 cm in diameter (241). However, only a few are of considerable size. Those measuring more than 20 cm in greatest diameter are referred to as *giant congenital melanocytic nevi* (Fig. 28-12A) (242). *Nongiant congenital melanocytic nevi* are usually slightly raised and often pigmented, and they may show a moderate growth of hair. They may be classified as "small" (less than 1.5 cm in diameter) or "intermediate" (greater than 1.5 cm and less than 20 cm, or amenable to local excision) (242,243). A number of variants have been described, such as the *cerebriform congenital nevus*, which presents as a skin-colored, convoluted mass (244); the *spotted grouped pigmented nevi*, showing closely set brown to black papules (245); the *congenital acral melanocytic nevus*, which consists of a blue-black patch on the sole or the distal portion of a finger clinically resembling an acral-lentiginous melanoma (246); and the *desmoplastic hairless hypopigmented nevus*, which presents clinically as a hard, ligneous, progressively hypopigmented and alopecic giant congenital nevus and is characterized histologically by intense dermal fibrosis, scarce nevus cells, and hypotrophic or absent hair follicles (247). Giant congenital melanocytic nevi often have the distribution of a garment ("garment nevi"). They usually are deeply pigmented and are covered with a moderate growth of hair. Often, there are many scattered satellite lesions of a similar appearance (248). These

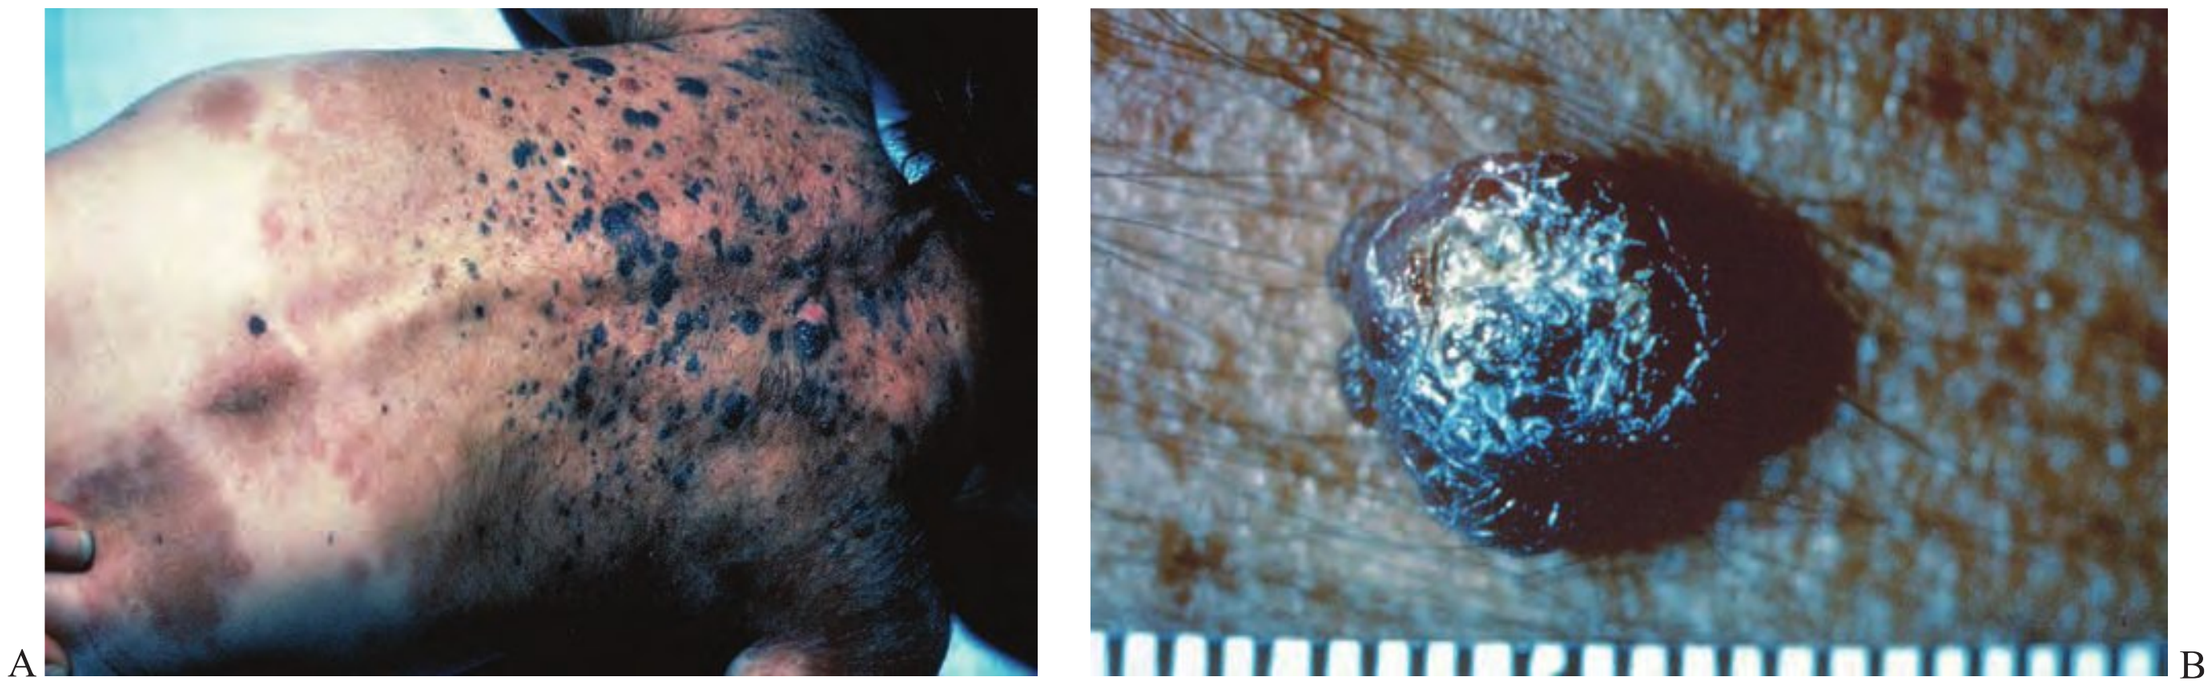

FIGURE 28-12. A: Giant congenital nevus (clinical). These lesions have also been called "garment nevi" because of their coverage of such large areas of skin. Focal areas of increased pigmentation, sometimes associated with palpable nodularity, are not uncommon in giant congenital nevi. Such foci should be followed carefully, and any lesions showing evidence of progressive changes should be excised to rule out melanoma. B: Melanoma in a giant congenital nevus. This nodule developed on the back of the patient illustrated in panel A at the age of 4 years. The patient died within about 2 years of metastatic melanoma.

satellite nevi are benign, in contrast to the satellite metastases that may be associated with melanomas. Leptomeningeal melanocytosis is occasionally found in cases in which the giant congenital nevus involves the neck and scalp. There may be not only epilepsy and mental retardation, but also a primary leptomeningeal melanoma (249). In one study, magnetic resonance findings of meningeal melanosis were identified in 14 of 43 asymptomatic children with giant congenital melanocytic nevi. These findings are consistent with an increased lifetime risk of central nervous system melanoma (250).

Incidence of Cutaneous Melanoma. The lifetime incidence of melanoma arising either in a giant congenital nevus or, as seen rarely, in one of the many smaller satellite nevi is estimated to lie between about 6% and 12% (251–267). Thus, the majority of patients with giant congenital nevi will never develop melanoma. In one study, increasing numbers of satellite lesions and larger lesional diameters were associated with melanoma and neurocutaneous melanosis (267). The melanoma may be present at birth, or it may arise in infancy or any time later in life (Fig. 28-12B). The mortality of such melanomas is substantial. In a cohort study in which 33 patents with giant congenital nevi were followed, 2 fatal melanomas developed, representing a relative risk approximately 1,000-fold greater than that in the general population (254), whereas in another study of 80 pediatric cases, 4 melanomas (3 of them fatal) occurred after an average follow-up of about 5 years (255). In follow-up data on 170 patients in the New York University Registry of Large Congenital Melanocytic Nevi, four melanomas had developed, including extracutaneous melanomas in the central nervous system and one retroperitoneal melanoma (254,265,267). In a review of the literature, approximately 70% of the melanomas that occurred in patients with giant congenital nevi developed before puberty (254). It is therefore generally agreed that it would be desirable for giant melanocytic nevi to be excised, if feasible. However, complete excision is often not possible, and melanomas may develop in extracutaneous sites. Thus, clinical surveillance is considered to be an acceptable alternative in such situations (258,265).

The incidence of melanoma in nongiant congenital nevi—those less than 20 cm in greatest diameter—is unknown, but it is probably greater than that in a comparable area of normal skin. It is likely that the risk is related to the lesion's size (252). The excision of all nongiant congenital nevi, where feasible, is advised by many (252,268) although not all authors (242,269). Most of the melanomas observed in these nongiant lesions occurred after puberty (253).

Histopathology

The histologic appearance of giant congenital nevi differs from that of acquired nevi in terms of their greater size and depth and in the involvement of skin appendages and sometimes even deeper tissues (e.g., galea aponeurotica and cranial nerve extension in scalp lesions) (Fig. 28-13). Nongiant congenital nevi may have the same histologic appearance as acquired nevi or may show features of congenital nevi (Fig. 28-14) (114,270,271). The features in nongiant congenital nevi are neither sensitive nor specific for truly congenital origin of a nevus: a recent histologic study with comparison with clinical data showed that 32 nevi with the histologic criteria of congenital nevi were actually acquired, and that 179 nevi present at birth did not fulfill these criteria. However, such studies are complicated by the possibility that some congenital nevi may be clinically covert at birth and thus regarded as acquired. In the case of deep and large (giant) congenital nevi, in contrast, the clinicopathologic correlation was 100% (272). Cytologically, the cells of congenital nevi are similar to those of acquired nevi. The nevus cells are typically positive for the melanocytic markers S100, HMB-45, and

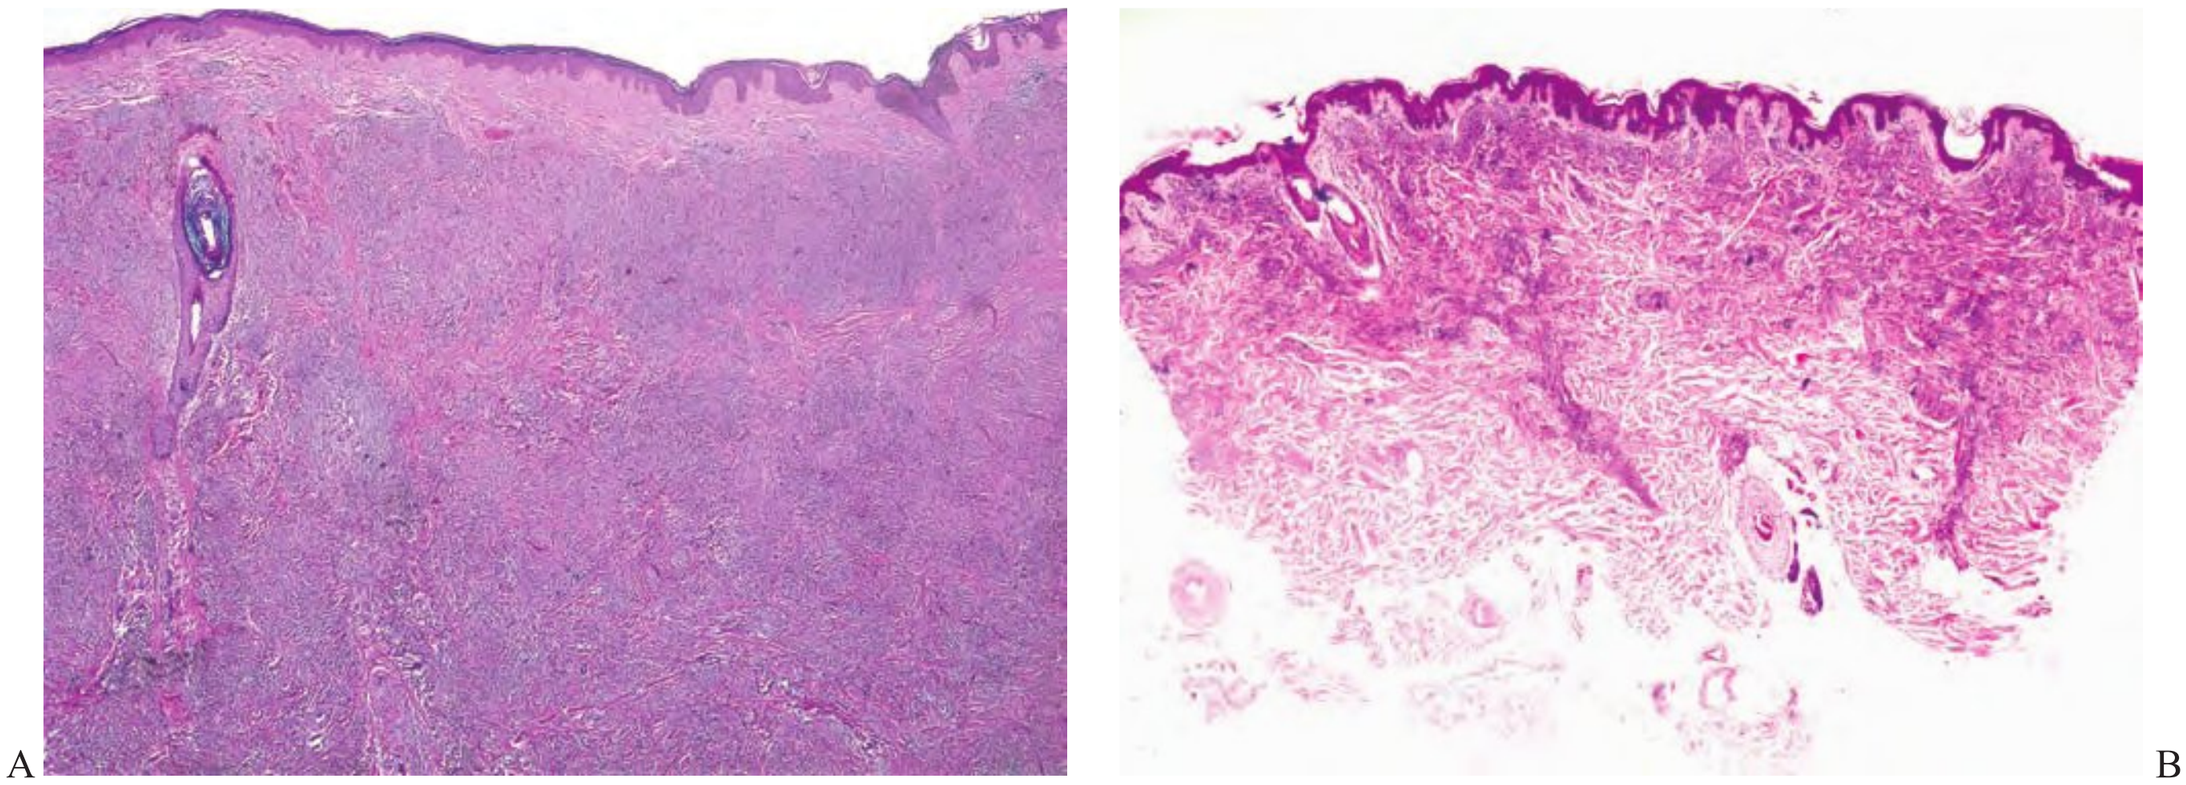

FIGURE 28-13. A: This nevus is very broad (many centimeters, extending well beyond the borders of the image) and deep, that is, the lesional cells extend from the epidermis through the reticular dermis and into the fat. B: In another giant congenital nevus, sheets of nevus cells are placed among reticular dermis collagen bundles. The dermal component of giant congenital nevi is often variably cellular, and in addition to nevic differentiation there may be evidence of schwannian or even heterotopic elements.

Melan-A, the last of which has the best combination of sensitivity and specificity (125).

Nongiant (Small and Intermediate) Congenital Melanocytic Nevi. At one time these were believed to be superficial at birth and to show deep involvement later (241). However, a serial study showed no change in pattern in follow-up biopsies (273). This and other studies have shown various patterns in the distribution of the nevus cells independent of the age of the patient. Thus, nongiant congenital nevi may be junctional, compound, or intradermal nevi, and their location in the dermis may be either superficial, which may include junctional involvement, or superficial and deep (273,274). They may differ from acquired nevi by one or more features: (a) presence of melanocytes, often in nests, around and within hair follicles, in sweat ducts and glands, in sebaceous glands, in or in intimate association with vessel walls, in arrector pili muscles, and in the perineurium of nerves; (b) extension of melanocytes between collagen bundles singly or in double rows; and (c) extension into the deepest reticular dermis and into the subcutis (Fig. 28-14) (241). However, many nongiant congenital nevi show none of these features. For example, some documented congenital nevi have been entirely junctional (273), whereas the likelihood of deep dermal involvement appears to increase with the size of the lesion (275) and is actually uncommon in lesions smaller than 3 cm (271). Conversely, the presence of most of the features mentioned has been documented in nevi that indubitably became clinically apparent after birth ("tardive" congenital nevi) (276). Thus, nevi with the constellation of

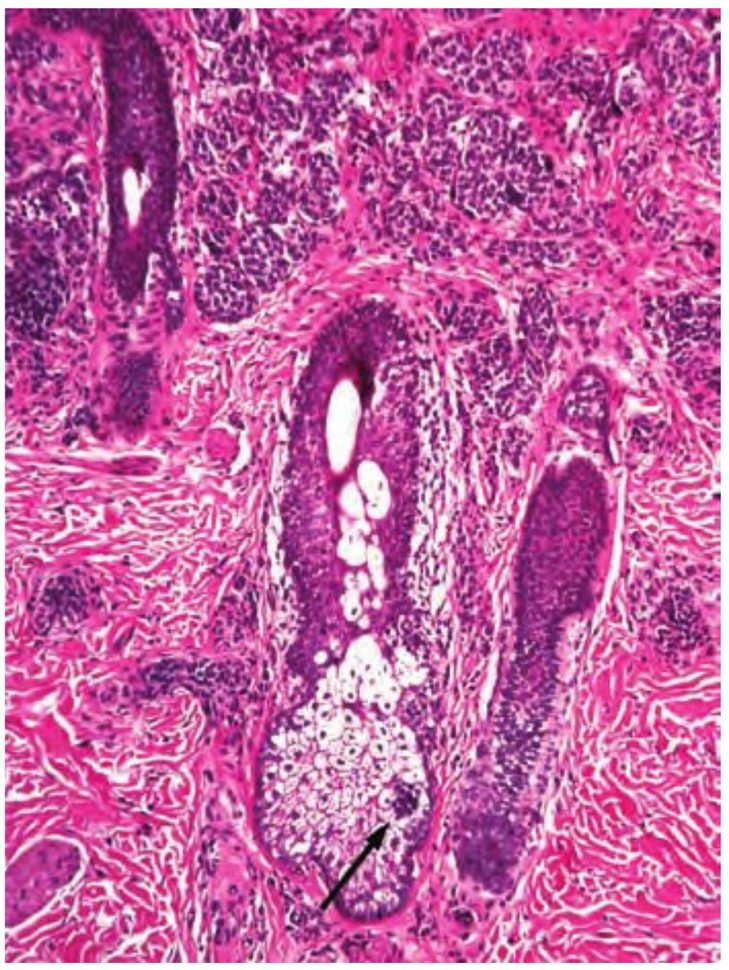

FIGURE 28-14. Compound nevus with congenital pattern features. Nevus cells extend around skin appendages and between fibers of the reticular dermis. The presence of nevus cells within skin appendages (as here in the sebaceous unit) is a quite specific feature indicating true congenital onset of a nevus. The extension of nevus cells into the upper reticular dermis and around skin appendages is quite characteristic of congenital nevi. However, acquired nevi may also exhibit this deep pattern, and, conversely, congenital nevi are not always deep.

features described may be characterized as nevi with congenital pattern features, but not all of these lesions are truly congenital in origin. It appears that most congenital nevi have mutation of NRAS, in contrast to most acquired nevi, which have mutated BRAF. The lesions appear to undergo oncogene-induced senescence, similar to acquired nevi (277). In another contrast, most of the "congenital pattern" nevi that are actually acquired have BRAF mutations, possibly related to sun exposure (278). It remains to be seen whether such nevi have any special significance as risk markers or potential precursors of melanoma (264).

Among the special forms of nongiant congenital nevi, the *cerebriform congenital nevus* usually presents as an intradermal nevus with neuroid changes simulating those seen in neurofibroma (244). Lesions called *spotted grouped pigmented nevi* also are intradermal nevi. They are either eccrine centered or follicle centered. If they are eccrine centered, each eccrine sweat duct is tightly enveloped by nevus cells, whereas hair follicles are involved only slightly (245). If they are follicle centered, nevus cell nests are found mainly around the hair follicles. In the *acral nevus of congenital origin*, a compound nevus is seen with considerable pigmentation in the upper dermis, and aggregates of nonpigmented nevus cells are seen around blood vessels and eccrine glands in the lower dermis (246). In a lesion called *desmoplastic hairless hypopigmented nevus*, there is intense dermal fibrosis, scarce nevus cells, and hypotrophic or absent hair follicles. Follow-up biopsies have documented the progressive nature of the fibrosis and nevus cell depletion (247).

In some congenital melanocytic nevi, changes are observed that may simulate a melanoma. In a recent study, features that could simulate malignant melanoma in a congenital nevus included (a) asymmetry and poor circumscription, (b) an increased number of single melanocytes, which predominated over nests of melanocytes in some high-power fields, (c) single melanocytes not equidistant from one another, (d) scattered single melanocytes present above the dermoepidermal junction, and (e) confluence of nests of melanocytes, all features in common with malignant melanoma (279). In our experience, such changes are generally slight in degree, and severe uniform cytologic atypia or frequent mitoses are not observed.

Giant Congenital Melanocytic Nevi. These are often are more complex than nongiant congenital nevi. Three patterns may be found within them: a compound or intradermal nevus, a neural nevus, and a blue nevus pattern (249). In most instances, the compound or intradermal nevus component predominates, whereas, in others, the neural nevus component predominates. In the latter case, formations such as neuroid tubes and nevic corpuscles are present. These areas may show considerable similarity to a neurofibroma. A component resembling a blue nevus or a cellular blue nevus is found in some of the giant pigmented nevi, usually as a minor component. In rare instances, however, the entire congenital lesion consists of a giant blue nevus, which, in one patient with a lesion of the scalp, was reported to extend to the dura (35) and in another had infiltrated the brain (36). Nevus cells may be present in lymph nodes draining skin containing a giant congenital nevus; this phenomenon should not be mistaken for involvement by a melanoma. In general, the nodal nevus cells lie in capsular or sinusoidal septal collagen, and the cells lack atypia (280).

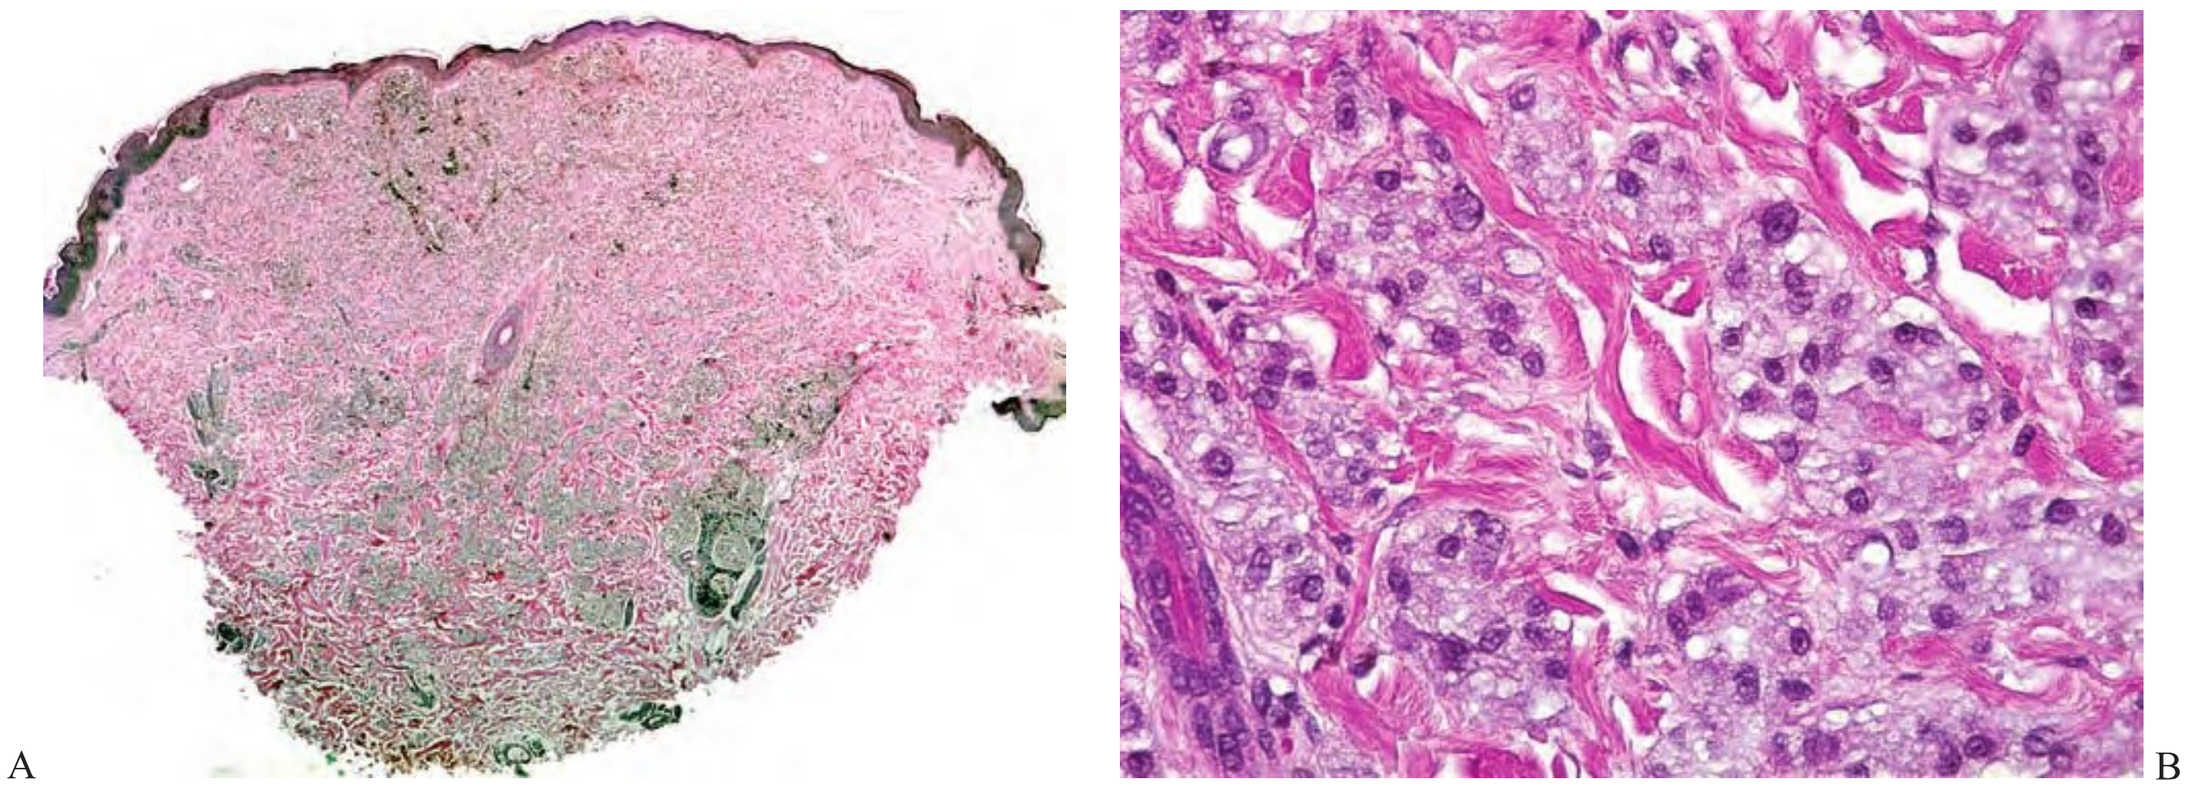
Melanoma in Congenital Nevi. The pattern of occurrence of melanoma in giant congenital nevi was studied in a review of 34 patients who had primary cutaneous melanomas within their nevi; in 2 additional patients, melanoma developed at cutaneous sites other than within their nevi. All patients in whom melanoma developed within the nevi had nevi in axial locations; however, 91% of the nevi were axial. No melanoma was found that had arisen in any of the 26 nevi confined to the extremities. In addition, no melanoma was found that had arisen in thousands of satellite nevi (260). If a melanoma arises in a congenital nevus, it usually originates at the epidermal–dermal junction and the appearances are those of an ordinary form of melanoma, usually of the superficial spreading or nodular types (see section Classification of Melanoma). Most of the congenital nevi associated with such melanomas are small and superficial (281). Occasionally, however, a melanoma in a giant congenital nevus, in contrast with nearly all other cutaneous melanomas, arises deep in the dermis or subcutis (282–285).

Histologically, in our experience, some of the melanomas in giant congenital nevi have consisted largely of undifferentiated blastic cells resembling lymphoblasts and containing little or no melanin, whereas others are comprised or large epithelioid cells similar to those of many melanomas. Other patterns of malignancy that have been described in congenital nevi have included neoplasms with the appearance of a neurosarcoma (286), lesions that have been termed malignant blue nevus (287–289), neoplasms with heterologous mesenchymal elements including rhabdomyoblasts (290) and lipoblasts, undifferentiated spindle cell cancers, and well-differentiated neoplasms termed minimal deviation melanomas (289). It has been emphasized that peculiar differentiation is to be expected in neoplasms of giant congenital nevi, and that alarmingly cellular neoplasms may not behave aggressively (289). Thus, pathology does not always readily predict outcome. This is especially true in our experience when melanomas arise in the first few months of life.

Cytologic and architectural atypia may occasionally be seen in congenital nevi, and criteria for the distinction of these lesions from melanoma are similar to those discussed in the differential diagnosis of dysplastic nevi and superficial spreading melanomas in later sections. In an interesting study, abnormal DNA content was found to correlate with cytologic atypia in giant congenital nevi (291). It is possible that the presence of atypical foci could increase the risk of malignant transformation.

Melanomas in small congenital nevi are typically of the usual superficial spreading type. In a recent study, 40 of 190 cases of melanoma were associated with preexisting nevi; of these, 15 had congenital features with a largest diameter of 1.5 cm, that is, small congenital pattern nevi. These 15 cases were melanomas of the superficial type with a mean tumor thickness lower than that of melanomas not associated with nevi

(0.33 vs. 1.50). Thus, a relatively high percentage of small congenital pattern nevi was found to be associated with melanomas, indicating that they may be considered as potential melanoma precursors. Nevertheless, the risk of progression of any given lesion is very low (264).



Proliferative Nodules in Congenital Nevi. Although melanomas may occur in the dermal component of congenital nevi, cellular proliferative nodules that occur in these nevi often do not behave in a clinically aggressive fashion (292). Such lesions may arise as one or more relatively small nodules that develop sometimes rapidly within a preexisting congenital nevus, particularly in infancy and early childhood. In a clinical pathologic study of a cohort of 26 cases, with a mean of 5-year follow-up on 16 patients, the lesions had an invariably benign clinical course. The features that are useful to differentiate cellular proliferative nodule from melanoma include (a) lack of high-grade uniform cellular atypia, (b) lack of necrosis within the nodule, (c) rarity of mitoses, (d) evidence of maturation in the form of blending or transitional forms between the cells in the nodule and the adjacent nevus cells, (e) lack of pagetoid spread into the overlying epidermis, and (f) no destructive expansile growth (293). If some of these features are present to a slight degree, the descriptive diagnosis of melanocytic tumor of uncertain potential may be appropriate (see later section). Cases of cellular nodules in congenital nevi demonstrate chromosome loss with patterns that differ from the findings in frank melanomas (294), and most of them have mutations of NRAS rather than BRAF, considered to be characteristic of lesions that develop in the absence of sun exposure (278).

Leptomeningeal Melanocytosis. There is a diffuse infiltration of the leptomeninges with pigmented melanocytes. In addition, the blood vessels entering the brain and spinal cord may be surrounded by melanocytes, and there may be areas of infiltration of the brain or spinal cord with melanocytes. Leptomeningeal melanoma can infiltrate the leptomeninx and form multiple nodules in the brain (295,296).

Deep Penetrating Nevus (Plexiform Spindle Cell Nevus)

This is a distinctive entity that has some features of combined nevus, blue nevus, and Spitz nevus (297,298). In the first report of 70 cases from a referral center, many cases had previously been misdiagnosed histologically as melanomas. Similar lesions have also been described as plexiform spindle cell nevi (41,299,300). Most of the lesions occurred in the second and third decades (range 3 to 63 years). The head, neck, and shoulder were the most frequent sites of involvement, with no occurrences on the hands or feet. The lesions ranged from 2 to 9 mm and were darkly pigmented papules and nodules, often diagnosed clinically as blue nevi or cellular blue nevi. In a mean follow-up of 7 years, none recurred or metastasized. Occasional recurrences, but no metastases, have since been described (301). On cross section, the lesions extended at least halfway into the dermis, with a smooth, dome-shaped elevation of the epidermis. It is possible that lesions termed nevi with focal atypical epithelioid component or clonal or combined nevi may represent a superficial variant (301). These distinctions are of little or no importance; the key distinction is from melanoma.

Histopathology. At scanning magnification, the lesions are circumscribed and pyramidal in shape, with a broad base abutting the epidermis and an apex extending into or toward the fat (Fig. 28-15). Nests of nevus cells at the dermal–epidermal junction are usually present. The dermal component is composed of loosely arranged nests or plexiform fascicles of large

A B

FIGURE 28-15. A: Deep penetrating nevus. At scanning magnification, the lesion is pyramidal, with its base applied to the epidermis and its apex in the reticular dermis. B: The lesional cells in the dermis are arranged in clusters. They may be heavily pigmented, and there may be scattered large, hyperchromatic, and pleomorphic nuclei, constituting random cytologic atypia. Mitoses are absent or very rare.

pigmented spindle and epithelioid cells interspersed with melanophages. There is a tendency to formation of narrow spindle cells at the periphery of the nests, reminiscent of sustentacular cell differentiation. In many cases there is an admixture of smaller, more conventional nevus cells. The lesional cell nests tend to surround skin appendages and to infiltrate the collagen at the periphery of the lesion. The cells do not tend to mature with descent into the dermis. Some lesions have a patchy mild lymphocytic infiltrate.

At higher magnification, nuclear pleomorphism may be striking in some lesions, with variation in size and shape, hyperchromasia, and nuclear pseudoinclusions. The atypia tends to be confined to randomly scattered cells rather than being uniform or present in a majority of the cells. Nucleoli are usually inconspicuous, but a few large eosinophilic nucleoli may be observed. Of importance, mitoses are absent or very rare, with no more than one or two in multiple sections of any given lesion. The cytoplasm is abundant and contains finely divided brown melanin pigment. The lesional cells react positively for S100 protein and HMB-45 antigen (300).

Differential Diagnosis. Deep penetrating nevi can be distinguished from *nodular melanoma* by architectural and cytologic features. Most bulky tumorigenic melanomas exhibit a more striking pattern of epidermal involvement, with spread of atypical cells into the epidermis and, often, with ulceration. Melanomas are likely to be more broad than deep, whereas deep penetrating nevi tend to be vertically oriented like Spitz nevi. Tumorigenic melanomas usually exhibit a more destructive pattern of infiltration, with displacement and compression of the stroma, and often with necrosis. Most also display marked nuclear atypia with frequent and often abnormal mitoses. A few nodular spindle cell melanomas have lower-grade nuclear atypia, and in these cases the presence of more than a few mitoses may be decisive. A study found rates of expression of the cell cycle proliferation marker PCNA to be somewhat higher in deep penetrating nevi than in ordinary banal nevi but considerably lower than in melanomas (302).

Benign lesions that may show some tendency to overlapping features with deep penetrating nevi include *common and cellular blue nevi*, as well as *spindle and epithelioid cell nevi*, and *clonal or combined nevi* (301). Although deep penetrating nevi can usually be distinguished from these benign lesions, the distinction from melanoma is of greatest importance. Neural involvement is not an indicator of malignancy in these lesions. Although most deep penetrating nevi will have a banal clinical course, sufficient numbers have not been studied to ensure this with certainty, and we generally recommend modest complete excision of such lesions. As with Spitz nevi, this approach also minimizes the possibility of local recurrence of a nevus variant with intrinsically unusual features in scar tissue, a situation at potential risk for overdiagnosis and overtreatment as outright melanoma.

Halo Nevus

A halo nevus, also known as Sutton's nevus or nevus depigmentosa centrifugum, represents a pigmented nevus surrounded by a depigmented zone or halo (Fig. 28-16A). The nevus may be of almost any of the types described in the preceding sections, and a similar halo reaction may be seen rarely in relation to primary or metastatic melanoma (303). In the common type of halo nevus, which is characterized histologically by an inflammatory infiltrate and is therefore referred to as inflammatory halo nevus, the central nevus only rarely shows erythema or crusting; however, it undergoes involution in most instances, a process that extends over a period of several months. The area of depigmentation shows no clinical signs of inflammation and, even though it may persist for many months and even years, it ultimately repigments in most cases. Halo nevi tend to progress through several clinical stages. The classic early lesion is a brown nevus with a surrounding, usually symmetric rim of vitiligo-like depigmentation. The central nevus may then lose its pigment and appear pink with a surrounding halo; the central papule may then disappear, leading to a circular area of macular depigmentation, or the depigmented area may repigment, leaving no trace of its prior existence. In unusual lesions, darkening of the central nevus rather than lightening has been described (304). Most persons with halo nevi are children or young adults, and the back is the most common site. Not infrequently, halo nevi are multiple, occurring either simultaneously or successively.

Besides the more common inflammatory halo nevus with histologically apparent inflammation, there also are cases of non-inflammatory halo nevi in which histologic examination shows no inflammatory infiltrate (305). In such instances, the nevus does not involute. In addition, there is the so-called halo nevus phenomenon, also referred to as halo nevus without halo. In these instances, the nevus shows histologic signs of inflammation analogous to a halo nevus but without presenting a halo clinically (306). Such nevi may or may not involute. An association with Turner's syndrome has been recently described (307).

Halo dermatitis around a melanocytic nevus refers to a temporary inflammatory reaction surrounding a nevus (Meyerson's eczematous nevus) (308). There is a papular compound nevus that becomes surrounded by an eczematous halo. Histologically, the epidermis adjacent to the nevus is spongiotic. An analogous phenomenon of "nevocentric" erythema multiforme has also been described in which cytotoxic/interface alterations predominate (309). Similar changes may be seen around atypical or dysplastic nevi (310).

Histopathology. An inflammatory halo nevus in its early stage shows nests of nevus cells embedded in a dense inflammatory infiltrate, in the upper dermis, and at the epidermal–dermal junction (Fig. 28-16B–D). Later, scattered nevus cells tend to predominate over nests. Even when melanin is still present in the nevus cells, these cells often show evidence of damage to their nucleus and cytoplasm, and some frankly apoptotic nevus cells are commonly observed. Some cells, especially superficially, may have enlarged ovoid nucleoli, changes that may be regarded as a form of "reactive atypia." High-grade nuclear atypia is not observed. Of importance, the lesional cells tend to show evidence of maturation, becoming smaller

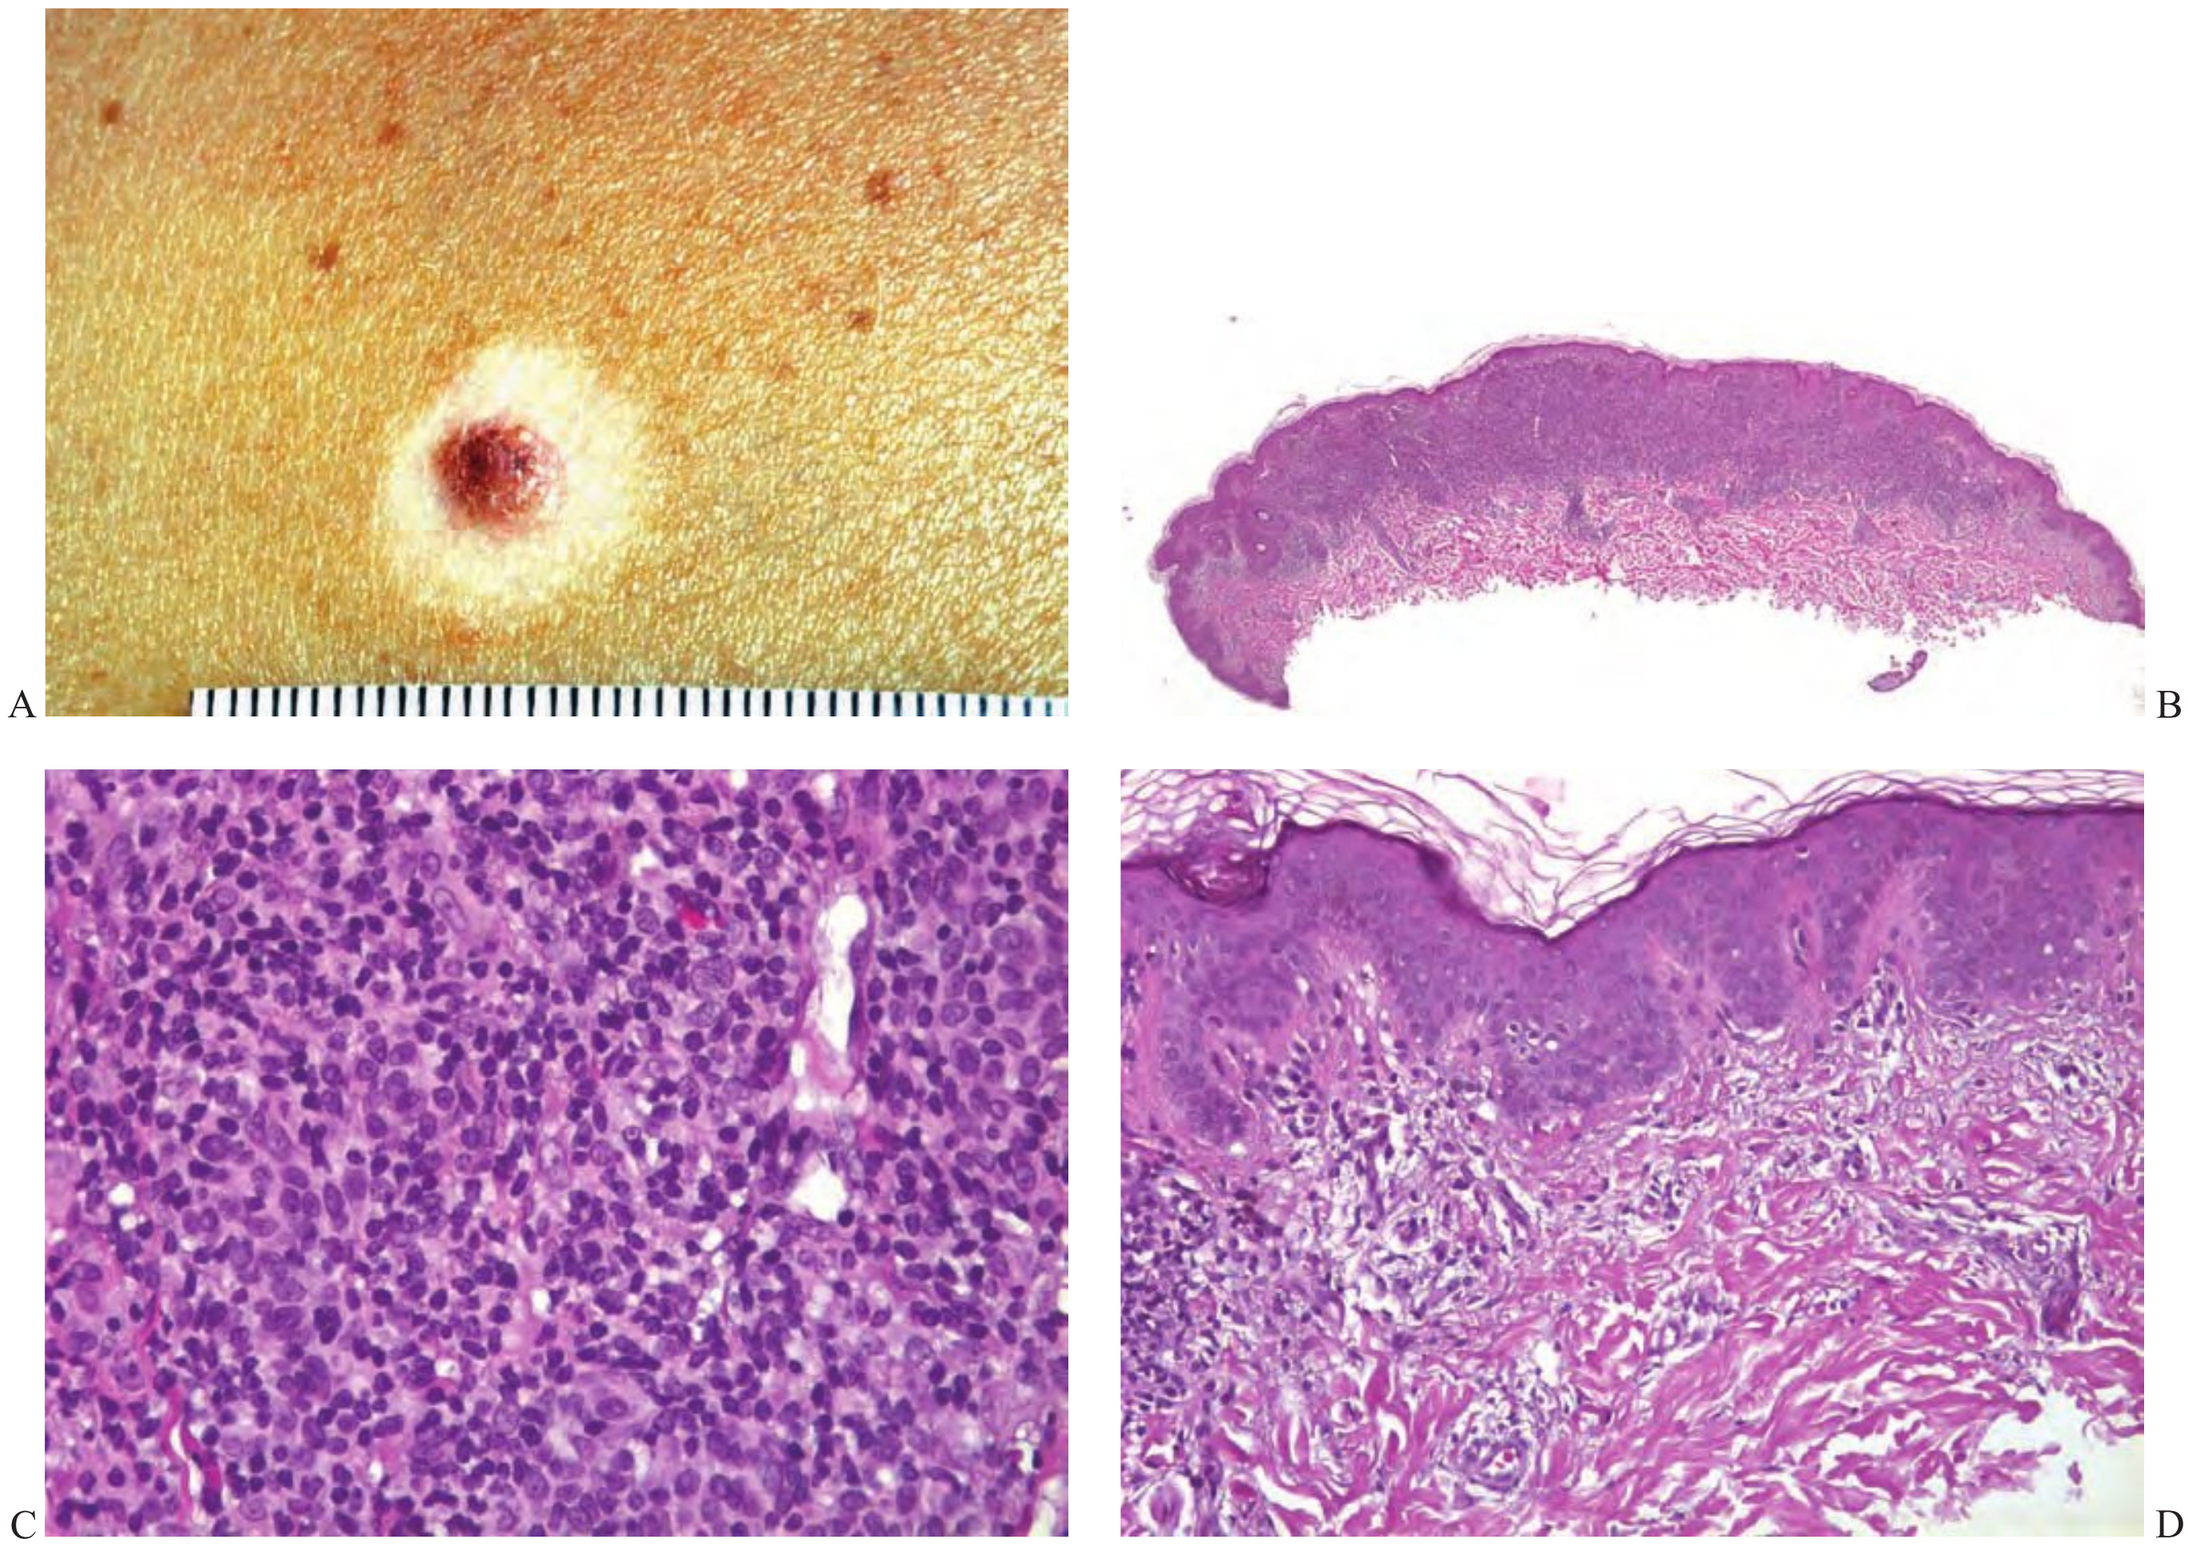


FIGURE 28-16. A: Halo nevus clinical. The halo develops around a preexisting unremarkable compound nevus. B: Halo nevus. A dense infiltrative lymphocytic response blurs the silhouette of the lesional nevus cells in the dermis at scanning magnification. C: Halo nevus. Small lymphocytes are diffusely placed among the dermal nevus cells, which may appear swollen and slightly atypical (reactive atypia). Severe or uniform atypia or mitotic activity should suggest the possibility of melanoma. D: Halo nevus. At the periphery of the nevus, the halo is a region where pigment and melanocytes are reduced or absent, and there may be a subtle lymphocytic infiltrate at the dermal–epidermal junction, as here.

with descent from superficial to deep within the lesion. Nevus cell mitoses are rare, and if present should prompt consideration of the possibility of melanoma. In this regard, it may be difficult to differentiate nevus cell mitoses from those attributable to the reactive mononuclear cells, a problem we have found to be lessened by use of a combined (dual) Mib-1 (Ki-67) and Melan-A/MART-1 stain. Most of the cells in the dense inflammatory infiltrate are lymphocytes. However, some of them are macrophages, in which varying amounts of melanin are contained. As the infiltrate invades the nevus cell nests, it often is difficult to distinguish between the lymphoid cells of the infiltrate and the type B nevus cells in the middermis because they, too, may have the appearance of lymphoid cells. Immunohistochemical studies using S100 or a more specific marker such as Melan-A may be very helpful in identifying the nevus cells in the infiltrate (311). The infiltrate tends to extend upward into the lower portion of the epidermis. In most instances, the infiltrate is characterized by dense cellular packing without vasodilation or intercellular edema and by sharp demarcation along its lower border.

At a later stage, only a few and finally no distinct nevus cells can be identified. Gradually, after all nevus cells have disappeared, the inflammatory infiltrate subsides. Despite the clinical evidence of regression and the inflammatory infiltrate, which consists predominantly of T cells (312), fibrosis is not a prominent feature (313).

In both the inflammatory and the noninflammatory halo nevus, the epidermis of the halo first shows a reduction in the amount of melanin on staining with silver and fewer DOPA-positive melanocytes than are seen in the normal epidermis. Ultimately, there is complete absence of melanin and also a negative DOPA reaction. Especially in early lesions, lymphocytes

may be seen rosetting around damaged melanocytes in the halo.

Histogenesis. Immunohistochemical staining for S100 protein helps in the identification of nevus cells within the inflammatory infiltrate because their number may be small and it may be difficult to differentiate them from the lymphocytes of the infiltrate (311). However, Langerhans cells and some histiocytes also react with S100 protein, and therefore a more specific marker such as Melan-A is preferable. Electron microscopic study reveals that nevus cells and melanocytes within reach of the infiltrate are damaged and ultimately disappear. In the nevus, many nevus cells appear vacuolated and contain only few melanosomes, but large aggregates of melanosomes are seen within macrophages (314,315).

In the depigmenting halo, the melanocytes show various kinds of degeneration, such as vacuolization and coagulation of the cytoplasm and autophagocytosis of melanosomes (316). It has been suggested that an initial noncellular stage of inhibition of both the melanocytes and the nevus cells may be responsible for the development of the depigmented halo, preceding the appearance of a dermal lymphomacrophagic infiltrate that ultimately leads to the destruction of the nevus (314). Both in halo nevi and in vitiligo, the depigmentation takes place through disappearance of the melanocytes. However, despite occasional patients who present with both lesions, halo nevus is likely not a form of vitiligo (317). The abundance of potential antigen-presenting cells and lymphocytes (including $CD8^+$ T cells) in the regressing nevus at the site of depigmentation suggests that these cells participate in the destruction of nevus cells and melanocytes in the halo phenomenon (318). In an interesting study of the lymphoid elements infiltrating halo nevi, oligoclonal expansion of T cells was observed in all patients, and in one patient, T cells using the same T-cell receptor b-chain were observed in distinct halo nevi, demonstrating a local expansion of common clones that are most likely activated by shared antigens within the nevi (319).

Differential Diagnosis. It can be difficult to differentiate early lesions of inflammatory halo nevus from a melanoma; both types of lesions may have a dense cellular infiltrate in the dermis, and, in halo nevi, the nevus cell nests, as a result of having been invaded by the cellular infiltrate, may appear atypical, which we consider to be reactive. The danger of misinterpretation is greatest in halo nevi without a halo, the so-called halo nevus phenomenon. However, the inflammatory infiltrate in halo nevi is more pronounced than in melanoma and extends diffusely through the lesion rather than being concentrated at the periphery as in most examples of tumorigenic melanoma. The diagnosis of melanoma rather than halo nevus is likely in a complex lesion that has an adjacent *in situ* or microinvasive component. Whether or not such an adjacent component is present, attributes of the nodule itself that should prompt consideration of melanoma include larger size, asymmetry, increased cellularity, lack of lesional cell maturation, uniform high-grade nuclear atypia, and mitotic activity.

If no identifiable nevus cells are present, the diagnosis of halo nevus may be suggested by the presence of melanophages in the dense cellular infiltrate and by the absence of melanin in the epidermis on staining with silver. However, one should also consider the possibility of a regressed squamous lesion or melanoma.

Recurrent Nevus (Pseudomelanoma)

Recurrence of a nevus may show clinical hyperpigmentation that on biopsy may show histologic changes suggestive of melanoma (320–324). Recurrence may follow incomplete removal of a nevus, particularly by a shave biopsy or electrodessication, or the nevus may apparently have been completely excised. A similar phenomenon has been described in relation to Spitz tumors (325). The term persistent nevus is sometimes used because it is considered that the clinical recurrence must have arisen from nevus cells that were not removed by the prior procedure. However, we have also considered the possibility that the "recurrent" pigmentation might be the result of a reactive hyperplasia and nevoid transformation of melanocytes in the epidermis above the healing biopsy site as a consequence of melanocyte growth factors known to be elaborated by scar tissue (e.g., c-kit ligand or fibroblast growth factors). In any event, at a clinical level, recurrence of apparently completely excised nevi is common. In a prospective follow-up study, 28% of all nevi and 41% of hairy nevi were reported to have recurred within 12 months after shave excision (326). The pigmentation in recurrent nevi is confined to the region of the scar and typically presents within a few weeks of the surgical procedure (320). After this rapid appearance, the pigment is stable. In contrast, recurrent melanoma does not respect the border of the scar and extends over time into the adjacent skin. Paradoxically, recurrent melanoma occurs more slowly, over months or years, but progresses inexorably.

Histopathology. Although most recurrent nevi are not cytologically atypical, in a few instances they contain atypical melanocytes, both singly and in nests, arranged mainly along the epidermal–dermal junction, but occasionally also extending into the upper dermis and also into the epidermis in a pagetoid pattern (Fig. 28-17) (152). The junctional nests are often composed of pigmented epithelioid melanocytes forming irregular nests, possibly as a result of their growth within an atrophic epidermal layer that interfaces with scar tissue. Deep remnants of the nevus may be seen in the reticular dermis beneath the scar (324). A lymphocytic infiltrate with melanophages may be seen in the upper dermis. The fibrosis of the scar may mimic and be mistaken for regressive fibrosis in a melanoma, especially in a superficial shave biopsy, where the bases of the scar cannot be visualized. Nevus cells in the dermis tend to show evidence of maturation, and the Ki-67 proliferation rate is low (327). Distinction from melanoma may be difficult without a pertinent history. However, the presence of scarlike fibrosis in the upper dermis where fibroblasts/myofibroblasts and collagen bundles lie parallel to the epidermal layer and of remnants of a melanocytic nevus beneath the zone of fibrosis, as well as the

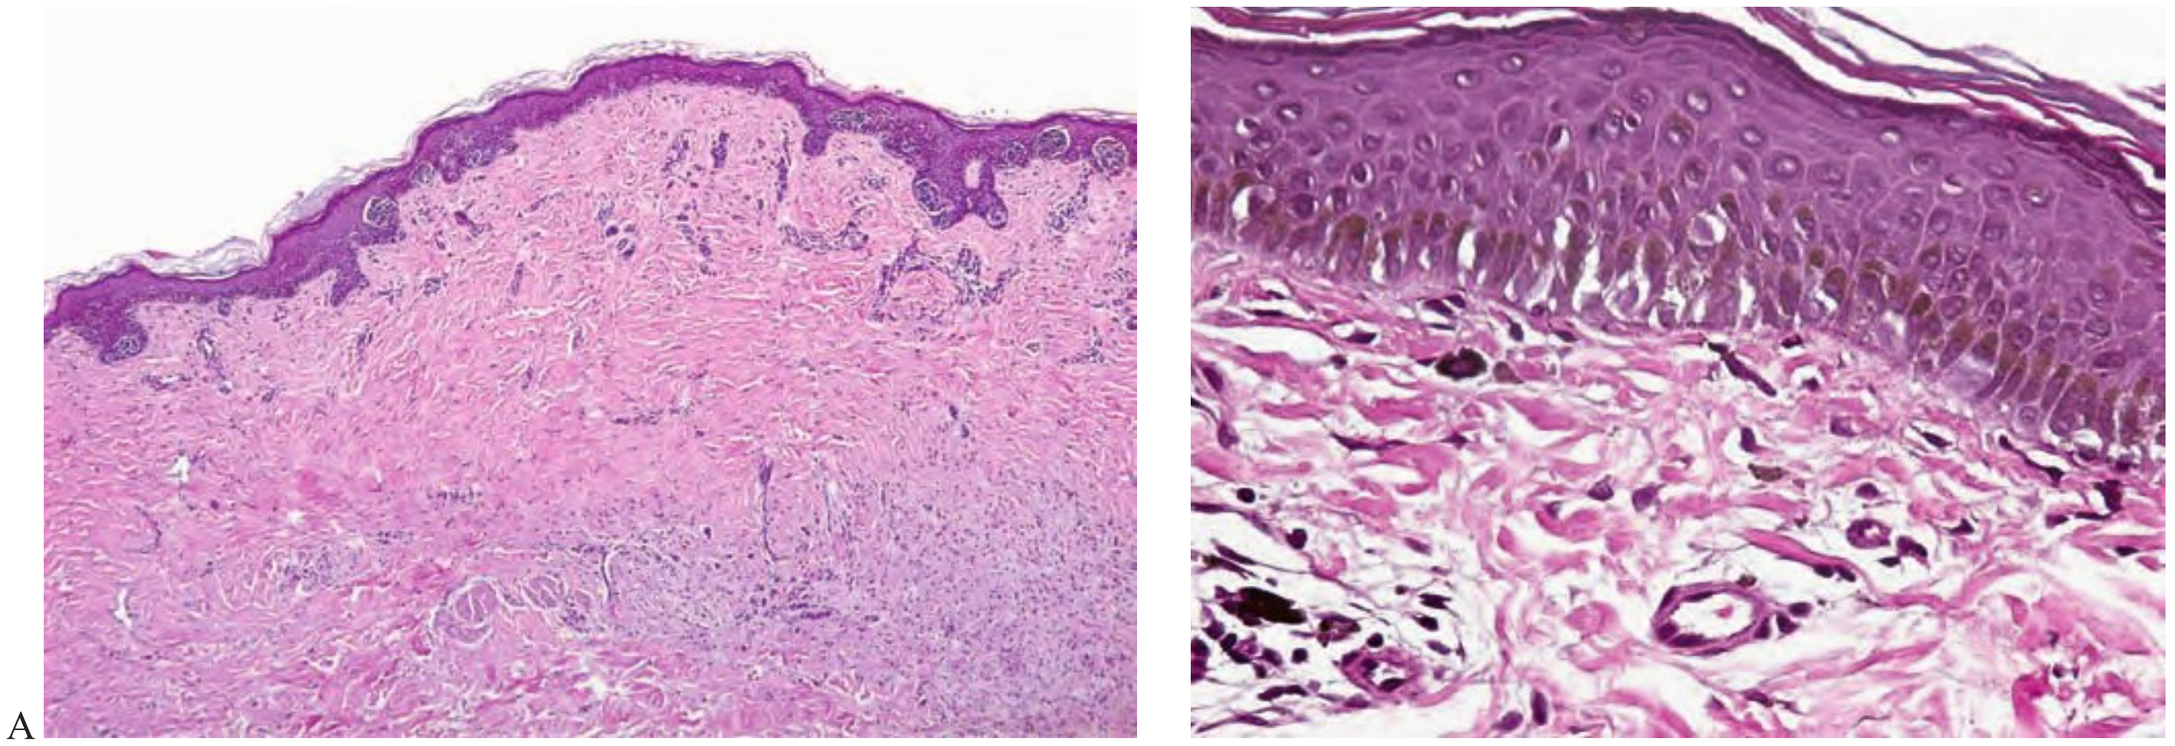

FIGURE 28-17. A: Recurrent and persistent melanocytic nevus. Recurrent pigmentation may occur after complete excision of a nevus or in the scar of a partial removal, as in this example, where the pathology of the recurrent nevus is seen only above the scar, and residual dermal nevus cells of the persistent original nevus are present to the right of the scar and beneath it. B: The cells of the recurrent nevus in the epidermis are variably enlarged, and they may be arranged with single cells predominating in foci and extending up into the epidermis in a pagetoid pattern, which is usually, as here, relatively subtle. Severe uniform atypia with extensive pagetoid proliferation should suggest the possibility of recurrent melanoma. The prior biopsy should be reviewed, if possible.

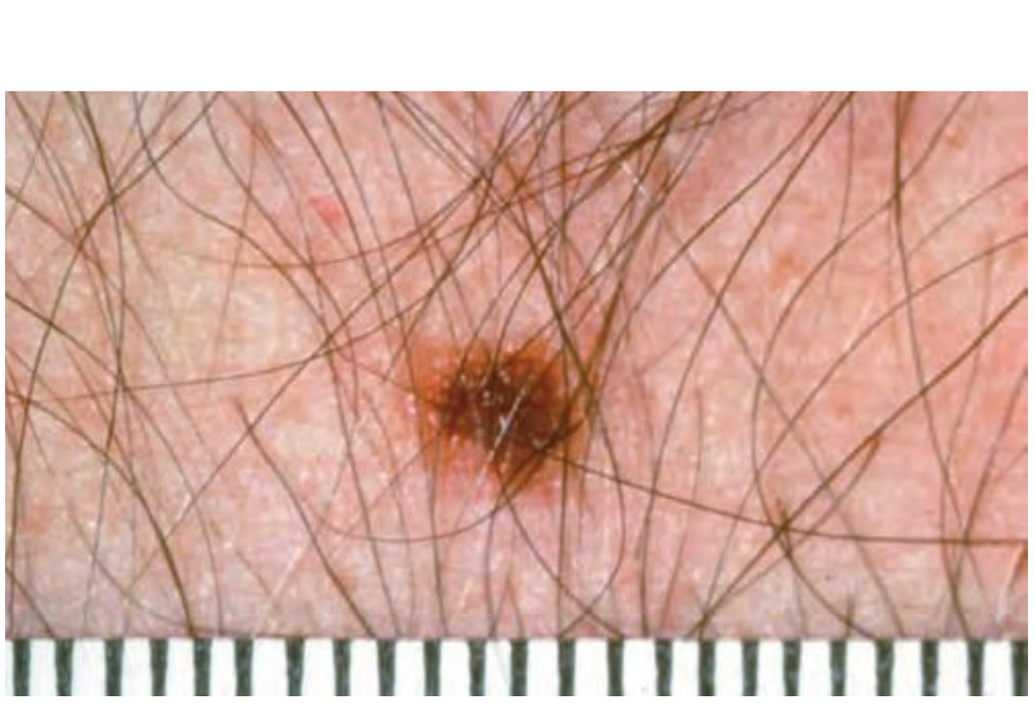
sharp lateral demarcation of the melanocytic proliferation devoid of lateral extension beyond the scar, usually make a correct diagnosis possible. As is true clinically, the recurrent nevus is confined to the epidermis above the scar, whereas recurrent melanoma may extend into the adjacent epidermis. However, persistent nevus, after a partial biopsy, may also involve skin adjacent to a scar. In this instance, ordinary criteria for the distinction between melanomas and nevi apply, as discussed later. In any problematic case in which the diagnosis is in doubt, the original biopsy should be obtained for review. This is particularly important in view of the possibility that genuinely dysplastic primary lesions, after initial biopsy, may also exhibit recurrent nevus–type changes.

Histogenesis. The nevus cells in some recurrent lesions may originate from residual nevus cells located either at the periphery of the lesion or along the outer root sheath of hairs. Recurrences that follow complete excision may be due to activation of melanocytes, possibly related to a subclinical field of melanocytes with a lowered threshold for nevus cell transformation that surrounded the original lesion. The confinement of these reactive changes to the regenerating epidermis above the biopsy scar suggests that the process may be related to growth factors involved in wound healing. Some of these, such as fibroblast growth factors and c-kit ligand, are well known to be trophic for melanocytes *in vitro* (328).

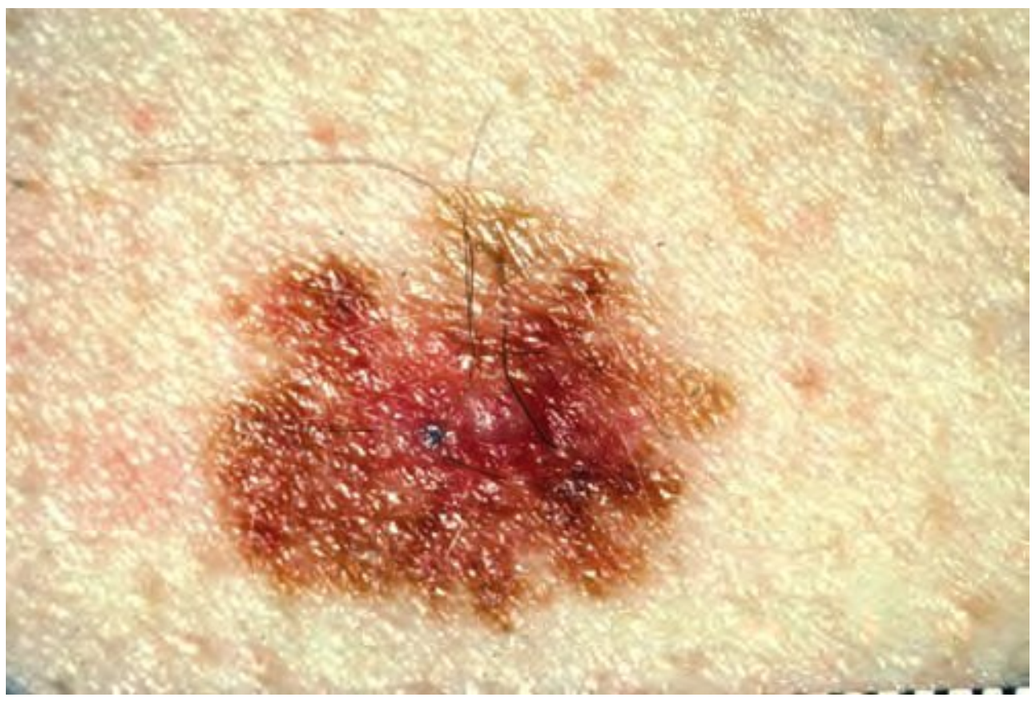
It is important to note that although previous biopsy is the most common cause of the recurrent nevus phenomenon, trauma to a lesion, potentially unrecognized by the patient, may also produce similar changes. Accordingly, whenever traumatic scar formation is noted in the dermal component of a nevus with overlying abnormalities of intraepidermal melanocytic proliferation, this possibility should be considered.

Dysplastic Nevus



Dysplastic nevi were first described under the designations of B-K mole syndrome or atypical mole syndrome as multiple lesions occurring in patients with one or several melanomas and in some of their relatives (329,330). It soon became apparent that multiple moles, in addition to their familial occurrence, can also occur as a sporadic phenomenon in patients with a melanoma. This was referred to as the dysplastic nevus syndrome (331). Subsequently, cases of multiple dysplastic nevi without melanoma were reported (332). This was followed by the recognition that dysplastic nevi frequently occur as solitary lesions and are quite common, being found in 5% to 20% of various populations, depending on the criteria used (333). Although the nature and number of moles appear to be under genetic control (334), dysplastic nevi do not constitute a single-gene–related genetic syndrome, and in today's usage, it is more appropriate simply to characterize individuals as having dysplastic nevi, with some estimate of their number and degree of clinical atypia, rather than as having a particular form of dysplastic nevus syndrome.

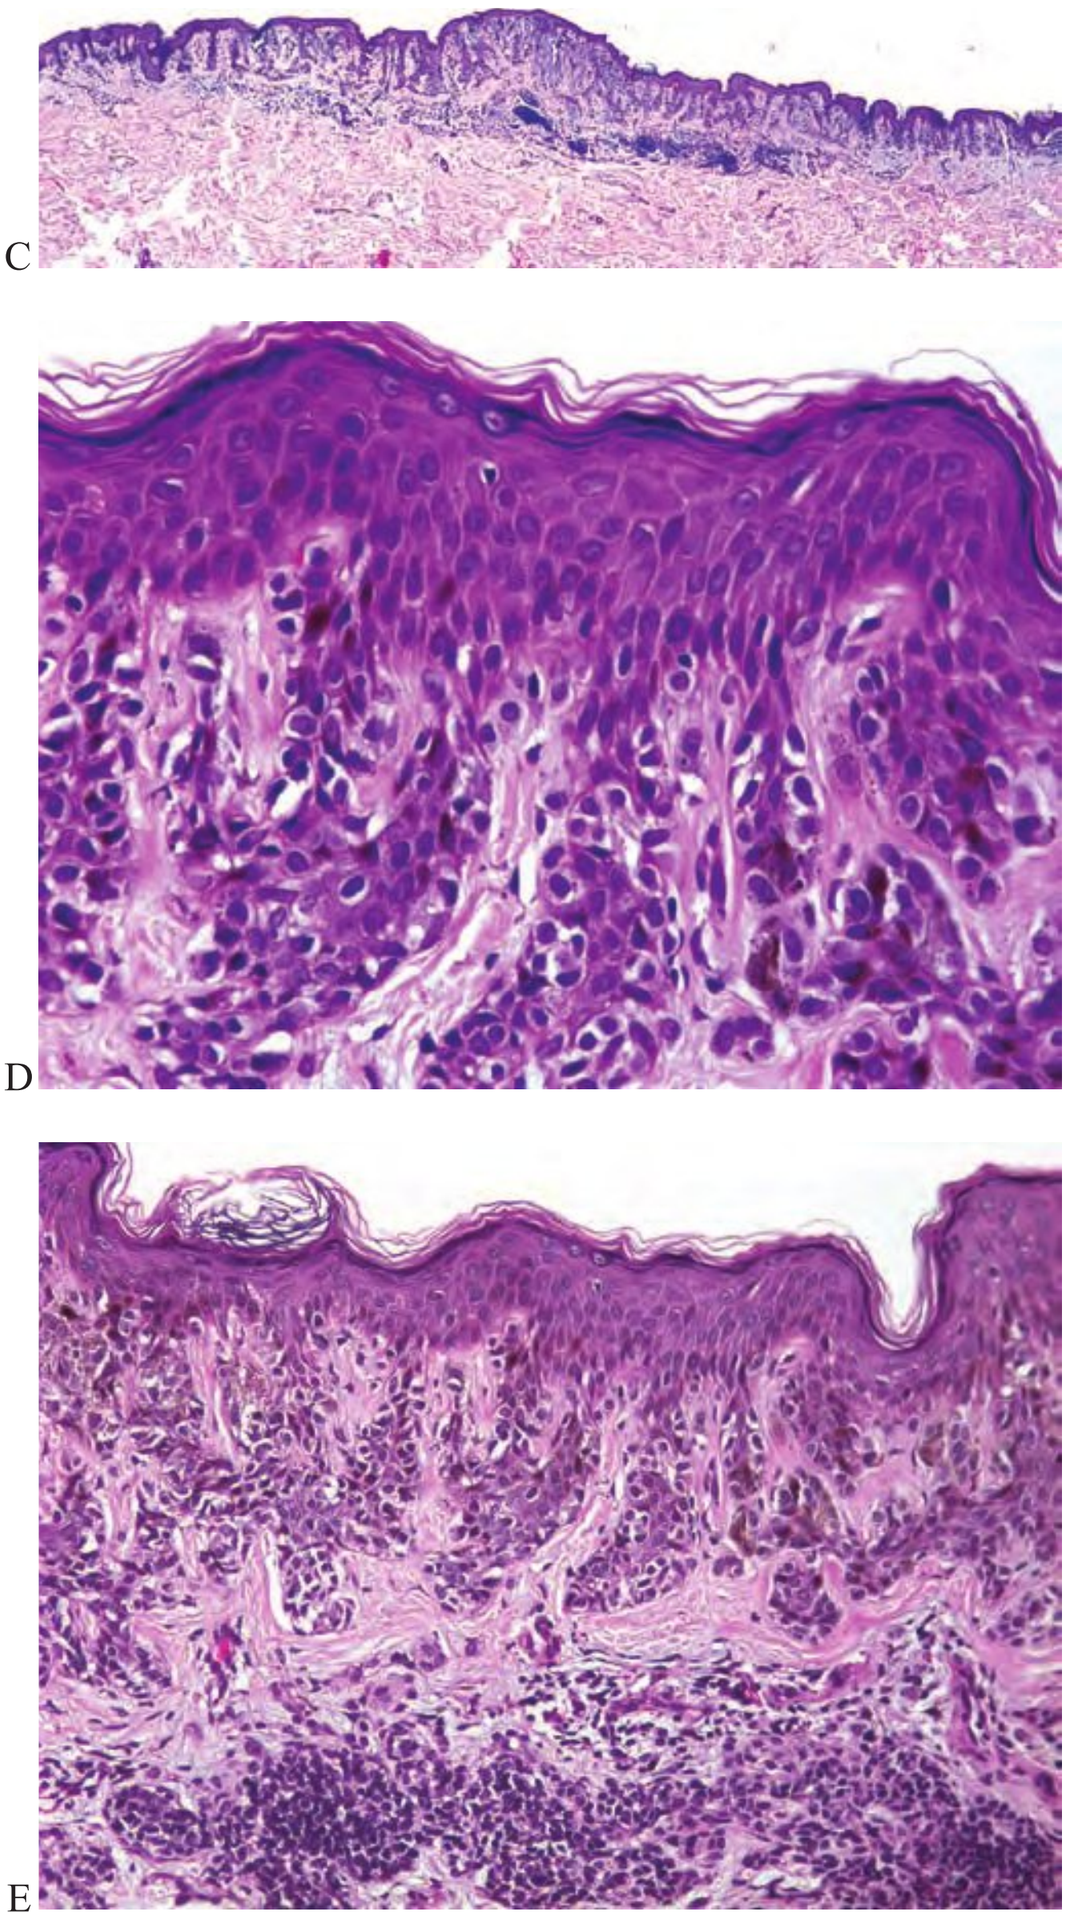
Dysplastic nevi, clinically and histologically, can be placed into a continuum extending from a common nevus to a superficial spreading melanoma (335). They may be located anywhere on the body but are found most commonly on the trunk. A suitable rigorous definition of a clinically dysplastic nevus includes (a) the presence of a macular component either as the entire lesion or surrounding a papular center; (b) large



size, 5 mm or more; (c) irregular or ill-defined "fuzzy" border; and (d) irregular pigmentation within the lesion (Fig. 28-18A, B) (67,336). When defined in this manner, clinically recognized dysplastic nevi are a central risk factor for cutaneous melanoma; in a large case–control study, 1 clinically dysplastic nevus was associated with a 2-fold risk for melanoma, whereas 10 or more conferred a 12-fold increased risk (67). A recent meta-analysis of 46 studies concluded that a large number of common nevi was confirmed as an important risk factor with a substantially increased relative risk of 6.9 associated with the presence of 101 to 120 compared to less than 15 nevi, whereas only 5 (vs. 0) atypical (dysplastic) nevi were associated with a comparable relative risk of 6.4 (337).

Histopathology. When dysplastic nevi were first described in association with melanoma, it was considered that dysplastic nevi by definition always contained cytologically atypical melanocytes (333). Later, it was argued by some that an abnormal pattern of lentiginous melanocytic growth was a sufficient criterion without requiring atypia (338). It was even stated that "most compound nevi that are confined to the epidermis and the papillary dermis are dysplastic nevi" (338). Subsequently, the term Clark's nevus was coined to encompass all nevi with lentiginous junctional components (either alone or adjacent to a dermal component), irrespective of lesional size or of the presence or absence of cytologic atypia (339). This definition would include the very common small lentiginous junctional and compound nevi. Thus, the term Clark's nevus is not synonymous with the term dysplastic nevus. Because of controversy regarding its use and definition, use of the term dysplastic nevus was discouraged by a National Institutes of Health (NIH) panel, which proposed the synonymous term "nevus with architectural disorder and melanocytic atypia" (340). This clumsy term is used by a minority of dermatopathologists, with a majority favoring the dysplastic nevus nomenclature (341). Specificity in distinguishing dysplastic from nondysplastic nevi is likely to be increased by the inclusion of size and cytologic atypia as criteria, as was done in the original reports. In our practice, small lesions or lesions with architectural features of dysplastic nevi but without cytologic atypia may be reported as compound nevi or as lentiginous compound nevi, or the NIH descriptive terminology may be used. Criteria for assessing melanocytic dysplasia may be summarized in two categories: architectural features and cytologic features (333). These features are closely but not perfectly correlated (Fig. 28-18) (342).

In the architectural pattern of melanocytic dysplasia, the lesions are either entirely junctional, or there is a prominent junctional component that is symmetrically distributed at the shoulders or junctional edges that extend laterally beyond a central dermal component (Fig. 28-18C). At higher magnification, nested and lentiginous proliferation of nevus cells in the epidermis is the dominant feature in the junctional component. There is elongation of the rete ridges and an increase in the number of junctional melanocytes, arranged in nests with long axes tending to lie in parallel to the epidermal surface. These nests tend to lie near the tips and sides of elongated rete ridges and to form bridges via apparent fusion of nests between adjacent rete (Fig. 28-18D). There may be scattered single cells in lentiginous array as well, but these do not predominate, and there is no continuous proliferation of single cells between the rete. The melanocytes in the junctional nests are frequently spindle shaped, but they may be large and epithelioid and show abundant cytoplasm with fine, dusty (finely divided)



A

B

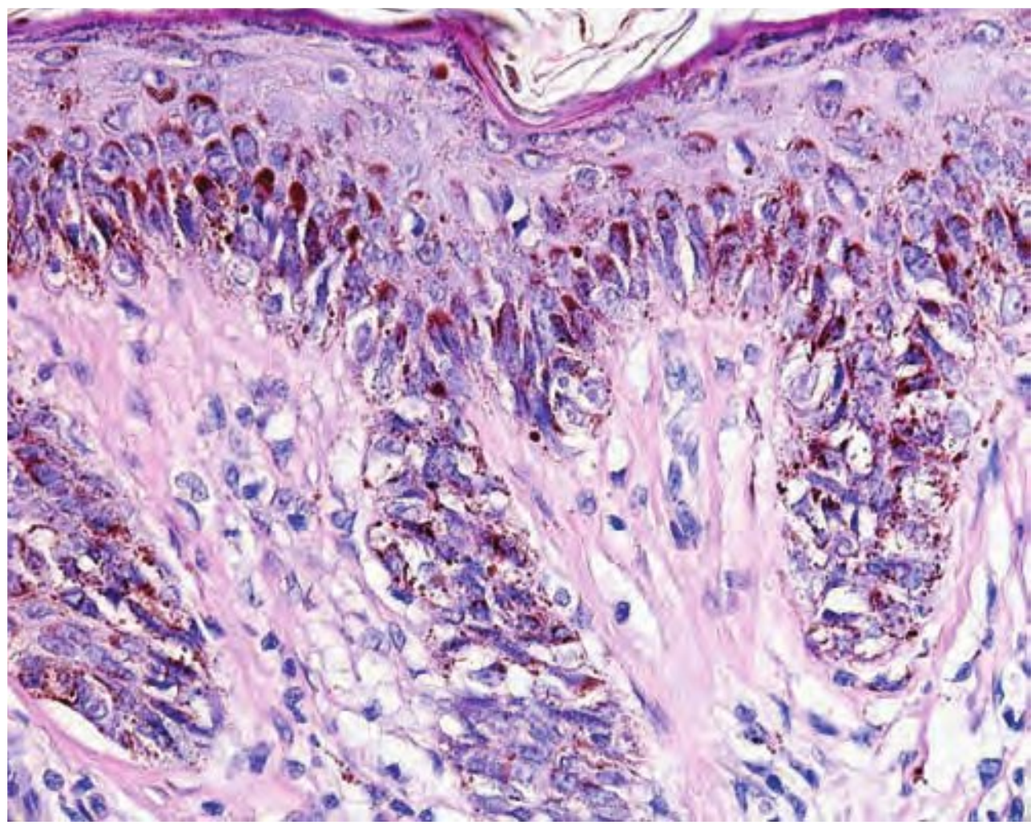


FIGURE 28-18. A: Junctional dysplastic nevus. A lesion that meets minimal clinical criteria. The diameter is almost exactly 5 mm, the lesion is entirely flat, there is mild pigmentary variegation, and the border is ill defined or "fuzzy." B: Compound dysplastic nevus. This lesion is relatively broad and quite irregular in outline, with variegated shades of tan and brown pigmentation. There is a papular compound portion near the center, and the periphery is flat, with an ill-defined "fuzzy" border in some areas but a more discrete border in others. This morphology overlaps with that of a radial-growth-phase melanoma of the superficial spreading type, and a lesion such as this should be considered carefully for excision to rule out a possible melanoma. (continued)

C

D

E

F

FIGURE 28-18. Continued. C: At scanning magnification, the lesions are broad and symmetric. If a dermal component is present, as here in the center of the lesion, the epidermal component (which is always present) extends beyond its shoulder. D: In the junctional compartment of the nevus (the shoulder just mentioned), the epidermal rete ridges are elongated but delicate, and there are nests of lesional cells that tend to be oriented parallel to the surface and to bridge between adjacent elongated rete. The lesional cell nuclei tend to be moderately enlarged compared to most banal type A nevus cells, and a minority of them have slightly irregular nuclei that are either hyperchromatic or have prominent nucleoli (random mild to moderate cytologic atypia). E: In the center of the nevus, there are orderly dermal nevus cells that are usually confined to the papillary dermis or may enter the upper reticular dermis. The junctional component in such a lesion tends to resemble that at the shoulder. F: Severe melanocytic dysplasia with changes suggestive of evolving melanoma in situ. There is a tendency to confluence and lack of definition of nests and to continuous extension of the proliferation in the suprapapillary plates between the rete. Cytologic atypia in the form of nuclear irregularity and the presence of nucleoli, though moderate in degree, is relatively uniform.

melanin granules. If the lesion is compound, nests of melanocytes in the papillary dermis show a uniform appearance and evidence of maturation with descent into the dermis, as seen in an ordinary compound nevus. In these compound dysplastic nevi, the intraepidermal component extends by definition beyond the lateral border of the dermal component, forming a shoulder to the lesion histologically and a "target-like" or "fried-egg" pattern clinically. Pagetoid extension of melanocytes into the epidermis is absent or slight and limited to the lowermost layers. A lymphoid inflammatory infiltrate, usually only of a mild or moderate degree and intermingled with melanophages, is present in the dermis beneath areas of junctional activity. The papillary dermis is also characteristically fibrotic, and typically lamellae of collagen encircle affected rete (concentric fibroplasia) and/or form stacked layers within dermal papillae (lamellar fibroplasia). The nevus cells in the dermis are mature, usually of the type B variety (Fig. 28-18E). They are often in continuity with similar cells in the papillary dermis, or in some cases they may enter the upper reticular dermis (compound dysplastic nevus with congenital features) (343). Most dysplastic nevi are clinically stable (344), so that they are not active in the sense of continuing growth.

Cytologically, in addition to the lentiginous melanocytic hyperplasia, melanocytic nuclear atypia is required for the diagnosis. This atypia is characterized by irregularly shaped, large, hyperchromatic nuclei in some melanocytes. Most atypical melanocytes lie singly or in small groups, and the atypia involves only a minority of the lesional cells ("random" cytologic atypia) (Fig. 28-18D). Focal extension of atypical-appearing melanocytes into the lower spinous layer may be seen, but if this is prominent, the possibility that transformation into melanoma *in situ* may have occurred

TABLE 28-4 Criteria for Dysplastic Nevus Grading

Atypia	None	Mild	Moderate	Severe	Melanoma
Lateral circumscription	+++	++	+	+	+/−

Based on Arumi-Uria M, McNutt NS, Finnerty B. Grading of atypia in nevi: correlation with melanoma risk. Mod Pathol 2003;16:764–771.

should be seriously considered. A borderline lesion may be a severely dysplastic nevus or an early superficial spreading melanoma that is still *in situ* or microinvasive. Because such early melanomas are curable after simple excision (345), this distinction does not carry the implication of increased mortality, as long as the lesion is entirely removed. For lesions with severe dysplasia in which the differential diagnosis includes the possibility of early melanoma, conservative reexcision is recommended for lesions that have been minimally or incompletely excised.

Melanocytic dysplasia appears to be a quantitative trait, and several authors have produced guidelines for grading dysplasia. McNutt and his colleagues recently published a detailed schema for grading lesions from nevi without atypia to melanoma. This schema has been correlated with biology, in that patients with more atypia in their nevus biopsies are more likely to have had a primary melanoma. Table 28-4, adapted from Arumi-Uria et al. (346), presents key grading features in schematic form. The critically important criteria for distinguishing between nevi and melanoma are given in more detail in Table 28-5. The features of severe dysplasia in this study included nests predominating over single cells in the epidermis, only rare upward migration of cells in the center and not at the periphery of the lesion, and a dermal component that tended to be abundant, with more crowding of the dermal nests. Cytologically, the nuclei are usually larger than those of keratinocytes, and there was often an admixture of cells that include large, bizarre, hyperchromatic nuclei. Confluent ("uniform") atypia was not observed. Nucleoli were often prominent. The grading for each lesion was based on a combination of these architectural and cytologic features (346). Similar criteria for grading of dysplastic nevi have been published and illustrated by others (343,347–349). In general, in our opinion, lesions that show significant overlap with criteria for melanoma such as those listed here should be graded as severe dysplasia, with an indication, if appropriate, that evolving melanoma *in situ* cannot be ruled out (Fig. 28-18F). In cases of extreme doubt, a descriptive diagnosis such as superficial atypical melanocytic proliferation of uncertain significance may be used, with a differential diagnosis and often with a recommendation for therapy (231). Such lesions should be managed by complete excision, with, at a minimum, a clear margin of normal skin around the scar and any residual lesion. If melanoma *in situ* cannot be ruled out, current guidelines recommend consideration of excision with a 5-mm margin.

The diagnosis of melanocytic dysplasia has been found to be reproducible by two international multidisciplinary groups that used agreed-on criteria (350,351). In another study, including participants whose published criteria differed in their requirements for atypia and for a size criterion, it was concluded that the participating pathologists used different diagnostic criteria, but that their usage was consistent (352). It has been suggested that histologic criteria may be more specific when applied to larger lesions, and that cytologic atypia may play a key role in the identification and significance of these lesions. Slight melanocytic atypia may be subtle and poorly reproducible and also may be of modest clinical significance. On the other hand, the diagnosis of higher-grade dysplasia (severe dysplasia) is likely to be both more reproducible and of substantially greater biological significance (336,353). In our practice, for purposes of management of the lesion itself, we tend to distinguish between mild to moderate lesions and lesions that at least focally show severe dysplasia (e.g., moderate to severe, or severe). Severe dysplasia shares sufficient characteristics with melanoma (Table 28-4) to suggest that it should be managed as a lesion with potential for local recurrence, with complete excision and clear margins. Via such an approach, dysplastic nevi may essentially be segregated into low-grade and

TABLE 28-5 Dysplastic Nevus Versus Radial-Growth-Phase Melanoma

Dysplastic nevus	Radial-growth-phase melanoma
Pattern features	
May be <6 mm in diameter, not often >10 mm	Usually 6 mm, often >>10 mm
Somewhat symmetric	Often highly asymmetric
Often symmetrically arranged about shoulders of a mature dermal nevus	If dermal nevus is present, it is likely to be asymmetrically placed
Uniformly elongated narrow, delicate rete ridges	Irregularly thickened epidermis, often with effaced rete ridges
No alteration of stratum corneum	May be hyperkeratotic
Nests predominate over single cells in the epidermis	Single cells predominate, except in late lesions
Little or no pagetoid spread of lesional cells into epidermis	Usually obvious pagetoid spread into epidermis, extending to stratum corneum
Patchy lymphocytic infiltrate in papillary dermis	Brisk, bandlike infiltrate
No regression	Regression common
Last lesional cells at the lateral border are often in a nest	Last cells are often single and may be above the basal zone
Cytologic features	
Scattered atypical epithelioid cells with dusty melanin pigment, nucleoli, anisokaryosis ("random atypia")	Epithelioid cells with dusty pigment, nucleoli, anisokaryosis predominate ("uniform atypia")
Most cells are not atypical	Most cells are atypical
No mitoses in epidermis or dermis	Intraepidermal mitoses in about one third of cases; no mitoses in dermis
Cells in dermis, if any, are smaller than those in epidermis	Cells in dermis are similar to those in epidermis

high-grade lesions, providing a less complicated approach to diagnosis and therapy. On the other hand, in Shors et al.'s recent case–control study (354), reviewed in more detail in the next section, any dysplasia beyond mild was associated with increased melanoma risk, suggesting that patients with moderate or severe dysplasia, but perhaps not mild dysplasia (in the absence of other risk factors), should be offered follow-up. Further refinement of criteria for dysplastic nevus diagnosis will likely occur in the near future as a result of these studies.

Pathobiology. After the early descriptions of dysplastic nevi as markers of high risk for melanoma in hereditary melanoma kindreds, it was widely assumed that identification of individuals in the community at high risk for melanoma required biopsy of a nevus to rule out dysplasia. Subsequent studies have shown that risk is best assessed by the clinical evaluation of the patients' entire cutaneous phenotype. The total number of nevi and the number of large nevi (355), light skin color, and high freckle density (356) are all risk factors for development of melanoma, but the strongest risk factor is the presence and number of dysplastic nevi (67). Family history of melanoma is another significant risk factor (345,357), as is a personal history of prior melanoma (358). In members of hereditary melanoma kindreds, the lifetime risk for melanoma approaches 100% in members who have clinically dysplastic nevi, corresponding to approximately 100-fold relative risk compared to the general population (358–360). In people without a family history of melanoma, the relative risk as determined in multiple cohort and case–control studies from different geographic regions is of the order of 3- to 10-fold, depending on the number of dysplastic (clinically atypical) nevi on their skin (67,337,355,361–383). These data are based on clinical evaluation of nevi, which does not necessarily correlate well with histologic atypia (384). Even when a biopsy can be obtained, usually only one or two nevi are sampled, whereas clinical examination considers the whole phenotype.

Nevertheless, it is clear that histologic atypia in dysplastic nevi is associated with melanoma risk. In one study, histologically verified clinically dysplastic nevi were associated with a relative risk of 4.6 for melanoma (363). In a multiobserver study in which biopsies had been taken from 24 melanoma cases and 21 random controls, four of six observers (who had each used different criteria) found an increased prevalence of histologic dysplasia ranging up to a 3.5-fold increase in cases compared to controls (352). An interesting study Sagebiel et al. found that the degree of dysplasia in a nevus biopsy correlated with increasing age of the patient, with frank melanomas occupying the oldest age category (343). More recently, as discussed earlier (Table 28-4), Arumi-Uria et al., in a very large single-institution study, demonstrated a clear relationship between the degree of atypia in clinically atypical (dysplastic) nevi submitted for biopsy and the chance that a patient has had a melanoma, demonstrating that the risk of melanoma is greater for persons who tend to nevi with high-grade histologic atypia (346). Finally, this vexed question seems to have been settled in a case–control study carried out by Shors et al., who studied nevi from 80 melanoma cases and spouse controls and found that dysplastic nevi with moderate to severe histologic dysplasia were a risk factor for melanoma, with an adjusted

risk ratio of 3.99 (354). In future work, this group will have the opportunity to identify the criteria that best fit with risk, providing an evidence-based approach to refining the histological diagnosis of a dysplastic nevus.

Although melanomas in patients with dysplastic nevi may arise within a preexisting dysplastic nevus, the majority arise *de novo*. Histologic changes of an associated dysplastic nevus are seen at the periphery of melanomas in approximately 20% to 30% of cases (105,281,385–388), supporting the view that at least some cutaneous melanomas have their origin in a dysplastic nevus. Even so, most dysplastic nevi are clinically stable (344) and will never evolve into melanomas. This paradox is explained by the fact that dysplastic nevi are vastly more common than melanomas in the general population and provides a rationale against indiscriminate excision of clinically stable dysplastic nevi for prophylaxis of melanoma.

In keeping with their role as potential precursors and as simulants of melanoma, dysplastic nevi tend to occupy an intermediate position between nevi and melanomas in laboratory studies. In cell cycle proliferation marker studies, the reactivity of dysplastic nevi is intermediate although closer to that of common nevi than of melanoma (389,390). Electron microscopic studies of dysplastic nevi have shown abnormal spherical and partially melanized melanosomes similar to those seen in superficial spreading melanomas (391,392). Although most *in situ* hybridization or immunohistochemical studies have shown reactivity similar to common nevi, dysplastic nevi have reacted in an intermediate manner with some markers (393–395), whereas the reactivity with others has been more akin to that of melanomas (396) or nevi (397). Interesting studies have shown that the amount of red pheomelanin is greater in dysplastic nevi than in common nevi or normal skin (398). Because pheomelanin may be a generator of toxic free radicals after UV irradiation, this attribute may increase the risk of genetic mutations in these lesions that may contribute to continued tumor progression (399). Genetic changes in nevi and dysplastic nevi are beginning to be cataloged. For example, loss of heterozygosity at the 9p locus (which contains the p16/CDKN2A tumor suppressor gene) was found in 64% of dysplastic nevi and 50% of benign nevi, although homozygous deletion of p16 was found in 29% of dysplastic nevi but never in benign nevi (400). Recent studies have demonstrated aberrations in DNA repair pathways in dysplastic nevi (401) and microsatellite instability in melanomas and nevi, including dysplastic nevi (402,403). These findings are consistent with DNA repair deficiency in patients with dysplastic nevi and tend to correlate with patient groups ordered according to increasing melanoma risk (403).

Differential Diagnosis and Management. The major importance of biopsy in an individual with dysplastic nevi is to rule out the possibility of melanoma in a problematic lesion. Key features in making this distinction are reviewed in Table 28-5. Lesions in which some features of dysplasia are observed but not judged to be diagnostic may be reported as lentiginous (junctional or compound) nevi or nevus with architectural disorder with an interpretive note. Such a note may indicate that additional evaluation of the patient could be appropriate to assess melanoma risk, and that periodic surveillance could be appropriate, especially if there are other clinically atypical (dysplastic) nevi or a family or personal history of melanoma (404).

In conclusion, in patients with dysplastic nevi, periodic surveillance of the patient and evaluation of first-degree relatives may be indicated for early diagnosis of melanoma. This is especially so if the clinically dysplastic lesions are numerous and/or markedly atypical and in individuals who have a personal or family history of melanoma. There is evidence that surveillance and/or education of individuals at increased risk for melanoma can result in the diagnosis of melanomas in their early, curable stages (405). The major role of biopsy and of histologic examination of nevi in such individuals is to rule out melanoma in a clinically suspicious or changing lesion. However, histologic atypia also correlates with a patient's risk of developing a melanoma. Atypia is heterogeneous in these lesions (in contrast to the uniform atypia that characterizes most melanomas), and so complete excision biopsy is recommended (which can include shave or punch excisions, as long as the entire lesion is included in the specimen) (406). Lesions whose biopsy shows severe dysplasia or changes suggestive of evolving melanoma *in situ* (see Table 28-5) should be considered for conservative reexcision if their margins are close or involved (404).

MALIGNANT MELANOMA

Most malignant melanomas arise in the epidermis and these may be *in situ* (entirely within the epidermis) or invasive (extending from the epidermis into the dermis). Occasional invasive melanomas are entirely dermal at presentation. Invasive melanoma may be *tumorigenic* ("*vertical growth phase*") or *nontumorigenic* ("*radial growth phase*"). Melanoma *in situ* and nontumorigenic invasive melanoma can be divided into (a) lentigo maligna, (b) superficial spreading, (c) acral-lentiginous, and (d) mucosal lentiginous types. Tumorigenic melanoma may arise in relation to a preexisting nontumorigenic component of any of the foregoing types, in which case it is named accordingly. Alternatively, tumorigenic melanoma may arise *de novo*, without evidence of an adjacent *in situ* or microinvasive component at the time of detection, in which case it is termed (e) "nodular melanoma." However, some but all of these lesions probably arise initially via a nontumorigenic intraepidermal component that fails to develop or persist as the tumorigenic component evolves. Important variants of tumorigenic melanoma include (f) desmoplastic melanoma and (g) neurotropic melanoma. Other unusual forms of tumorigenic melanoma are discussed later.

All major types of melanoma originate almost invariably from melanocytes at the epidermal–dermal junction. Although the lesions are commonly associated with a preexisting nevus,

TABLE 28-6 Classification of Melanoma

Radial growth phase (RGP)
Nontumorigenic melanoma
  In situ or microinvasive
    Superficial spreading melanoma (SSM): 67% of all melanomas (410)
    Lentigo maligna melanoma (LMM): 9% (410)
    Acral-lentiginous melanoma (ALM): 4% (410)
    Unclassified radial growth phase (URGP): 5% (410)
Vertical growth phase (VGP)
Tumorigenic melanoma
  No RGP compartment
    Nodular melanoma (NM): 10% of all melanomas (410)
  RGP compartment present (may be SSM, LMM, ALM, URGP): 90% (410)
    Usual vertical growth phase: 96% (414)
    Desmoplastic: 3%, most are also neurotropic (414)
    Neurotropic, not desmoplastic: 1% (414)
Other variants (nevoid/ minimal deviation, balloon cell, amelanotic, spindle cell, malignant blue nevus, melanoma in congenital nevus, clear cell sarcoma, malignant melanocytic schwannoma, etc.): low frequency, no definitive frequency estimates exist

Based on 1996 and 2006 World Health Organization classifications (412,413).

more than half of them arise either *de novo* or have completely supplanted the precursor nevus at the time of presentation. The majority of cutaneous melanomas are believed to be caused by sunlight exposure, either intermittent (sunburn episodes) in the more common superficial spreading melanomas or chronic in the lentigo maligna melanomas. The cause of acral and mucosal melanomas is unknown.

Classification of Melanoma

There are two major categories of melanoma, which represent sequential stages or phases of stepwise tumor progression (407). In the nontumorigenic radial or horizontal growth phase, the neoplastic melanocytes (melanoma cells) are confined to the epidermis (melanoma *in situ*) or to the epidermis and papillary dermis without evidence of proliferation in the dermis and without formation of an expansile tumor mass. These lesions may be confined to the epidermis (*in situ* melanoma), or there may be a few cells in the dermis (microinvasive melanoma). This phase may be followed after varying lengths of time by the focal appearance of the mitogenic and/or tumorigenic vertical growth phase, or a phase of dermal invasion with capacity for not only cell survival, but also proliferation in the dermis and usually with expansile tumor formation. Thus, a fully evolved melanoma may have two major lesional compartments: the nontumorigenic, *in situ* or microinvasive radial growth phase, placed within which there may be a contiguous tumorigenic vertical-growth-phase compartment. In addition, dermal and/or epidermal compartments of an associated nevus may be recognized in some melanomas. Variants of each of the major compartments have been described and are listed in Table 28-6 (407–411).

About 5% to 10% of melanomas in different series fall into "unclassified" or "other" categories (410,411). The fact that categorization of an individual case is occasionally difficult does not mean that classification of melanoma, after accounting for tumor thickness and site, is unnecessary, as has been stated (415). Even though in the tumorigenic stage the prognosis is similar for all four types of melanoma, depending largely on the depth of invasion, the duration of the *in situ* phase preceding lentigo maligna melanoma is, on the average, longer than that of superficial spreading melanoma (416). Furthermore, there are differences in the apparent etiology of the various forms of melanoma and in their molecular biology (417,418). In a recent important study, attributes traditionally used in the classification of melanomas into the aforementioned clinicopathologic subtypes correlated strongly with the mutation status of the tumors studied. An algorithm involving an initial separation based on melanoma cell nesting and scatter, followed by consideration of cell size and age, predicted BRAF mutation with an error estimate of 13%, demonstrating that parameters routinely available and traditionally used by practicing pathologists allow good prediction of BRAF mutation status. It was concluded that this "strong association between genetic alterations and morphological findings further supports the existence of biologically distinct melanoma types, and the use of genetic factors to develop and clarify improved clinically applicable classification systems" (419). Finally, the separate description of the morphologic variants has nosologic and pedagogic value, facilitating accurate diagnosis by enabling the recognition of the variant patterns.

Morphology of Tumorigenic and Nontumorigenic Melanoma

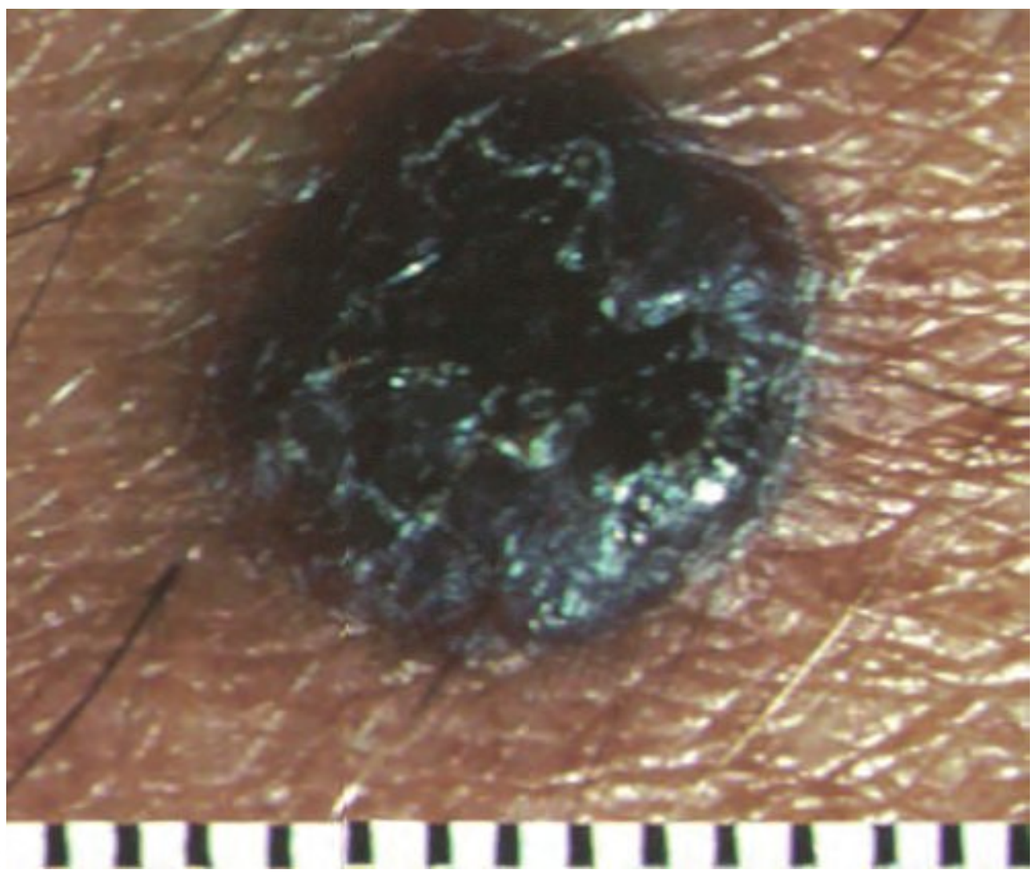
In their nontumorigenic stage, melanomas tend to expand more or less inexorably along the radii of an imperfect circle as viewed clinically. The clinically derived term "radial" growth has no intuitive histologic meaning, and the histologic term "horizontal growth phase" has been suggested as an alternative. The major clinical diagnostic criteria have been summarized as the ABCD criteria (420), which include lesional *asymmetry* (one half of a lesion does not match the other in shape or in color distribution), lesional *border* irregularity (lesions tend to have an indented coastline like the map of a small island), lesional *color* variegation (the surface is multicolored and may include shades of tan, brown, blue-black, gray-white, and other variations), and lesional *diameter* generally greater than 6 mm (although some melanomas are smaller) (Fig. 28-19). These criteria, although useful, are imperfect; recent guidelines have emphasized the value of the "ugly duckling" sign of the changing or different-looking mole in the practice of skin self-examination (421). In view of this, the letter E could be added to the criteria to indicate the "evolving" nature of a changing melanocytic lesion.

Histologically, most of the lesional cells in nontumorigenic melanomas are located in the epidermis. Microinvasion is here defined as the presence of a few lesional cells in the papillary dermis, without tumorigenic proliferation, which is defined later. Microinvasive lesions are not specifically distinguishable from *in situ* melanomas on clinical grounds. It has been questioned whether microinvasive or *in situ*, nontumorigenic melanomas lack competence for metastasis; in a database of 624 clinical stage I invasive melanoma cases followed 10 years or more, the 8-year survival rate from 161 microinvasive or *in situ* (pure radial growth phase) melanomas was 100 ± 1%. In the same database, the patients with lesions having only radial growth phase were 4.3 years younger than those additionally having vertical growth phase, consistent with the hypothesis that the radial growth phase is antecedent and relatively indolent (345,422).

Clinically, the tumorigenic vertical growth phase is qualitatively different from the plaquelike radial growth phase. The tumor appears as an expanding papule within a previously indolent plaque lesion and grows in three dimensions in a balloon-like fashion to form a nodule (Fig. 28-19B). Typically, the ABCD criteria do not apply to the tumor nodule itself, which is commonly symmetric with smooth borders. The color is often

A

B



C

FIGURE 28-19. A: Superficial spreading melanoma, nontumorigenic, radial growth phase only (microinvasive), with focal regression. The lesion is large, asymmetric, with irregular border, and variegated colors including reddish-brown and focal areas of blue-black, as well as a focal grayish area of partial radial-growth-phase regression (near the middle of the lesion). This morphology could overlap with that of the severely dysplastic nevus in Fig. 28-18B. Each of these lesions is sufficiently atypical that it should be considered for excision for pathologic diagnosis. B: Acral-lentiginous melanoma, tumorigenic, with extensive radial growth phase, partial regression of the radial growth phase, and a bulky ulcerated tumorigenic vertical-growth-phase nodule. C: Nodular melanoma. The tumorigenic vertical-growth-phase nodule, lacking an adjacent radial growth phase by definition, is relatively small, symmetric, and uniform in color. The focally ulcerated surface may lead to presenting symptoms of bleeding and oozing, which are signs of a relatively advanced melanoma.

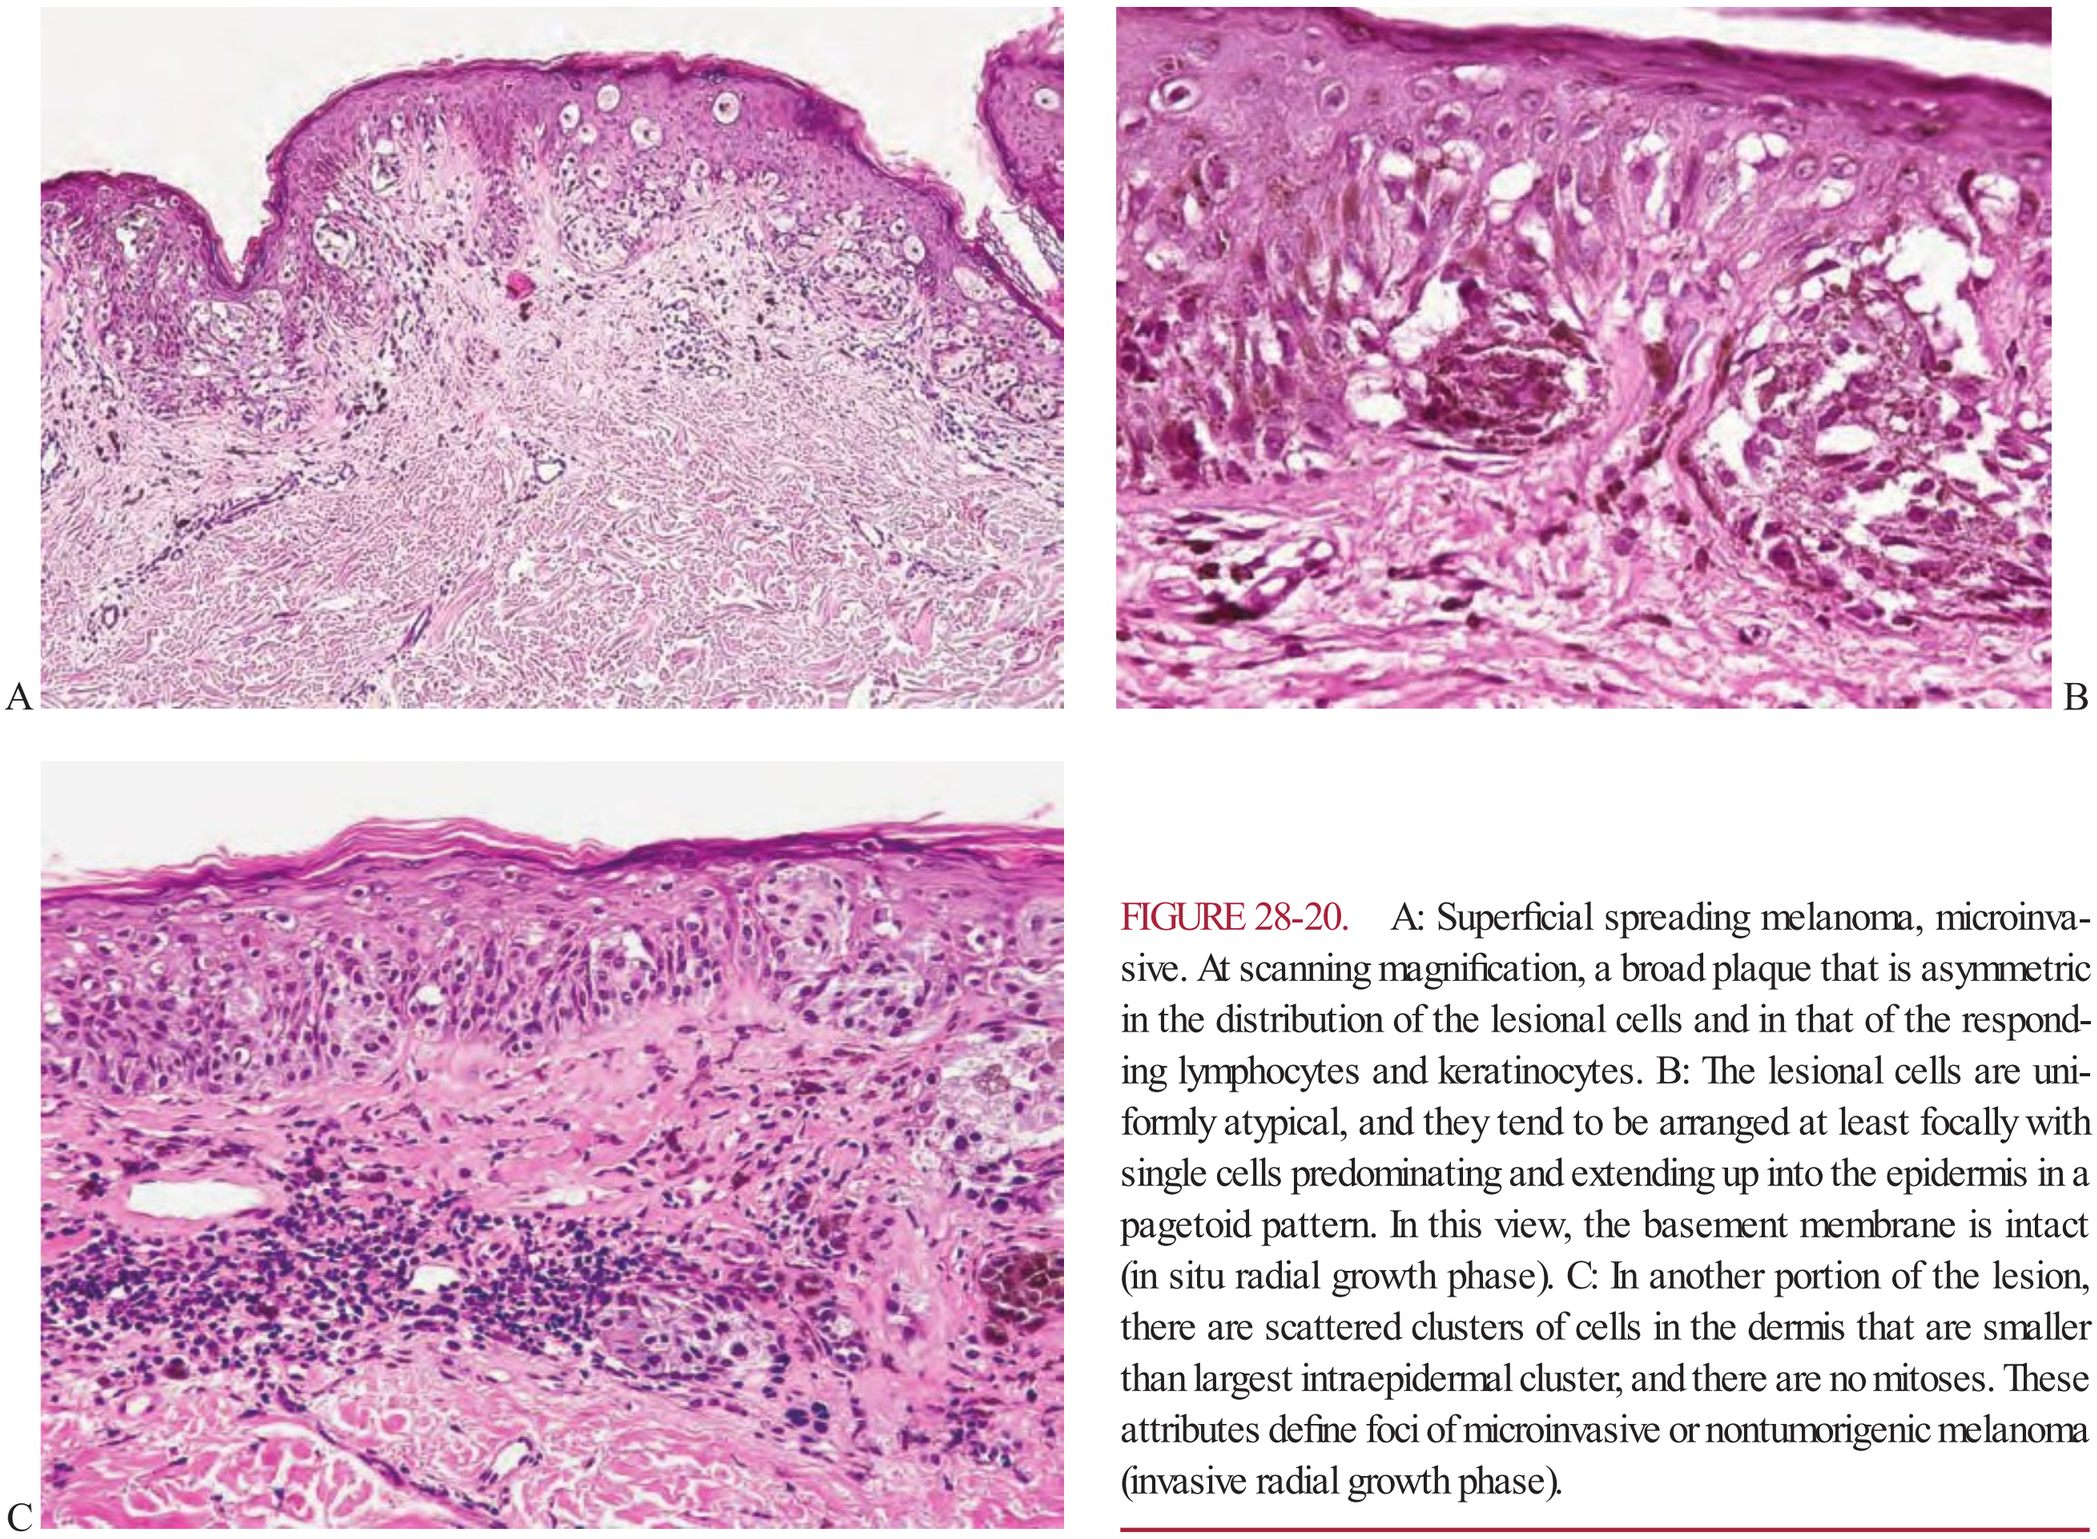


FIGURE 28-20. A: Superficial spreading melanoma, microinvasive. At scanning magnification, a broad plaque that is asymmetric in the distribution of the lesional cells and in that of the responding lymphocytes and keratinocytes. B: The lesional cells are uniformly atypical, and they tend to be arranged at least focally with single cells predominating and extending up into the epidermis in a pagetoid pattern. In this view, the basement membrane is intact (in situ radial growth phase). C: In another portion of the lesion, there are scattered clusters of cells in the dermis that are smaller than largest intraepidermal cluster, and there are no mitoses. These attributes define foci of microinvasive or nontumorigenic melanoma (invasive radial growth phase).

quite uniform and may be pink rather than blue-black, and the diameter of the tumor nodule itself is often less than 6 mm, even in a quite high-risk lesion. For these reasons, clinical diagnosis of melanoma may be subtle in a nodular melanoma that lacks an adjacent nontumorigenic compartment (Fig. 28-19C).

The major histologic feature that distinguishes a tumorigenic melanoma is the capacity for proliferation of melanoma cells in the extracellular matrix of the dermis to form an expansile mass. In contrast, nontumorigenic melanoma cells may proliferate inexorably in the epidermal compartment and may invade the dermis but do not proliferate there (Fig. 28-20). The lack of metastatic capacity in nontumorigenic melanomas may be explained by considering that cell proliferation in the extracellular matrix of a distant site is essential to the development of a metastasis. Thus, it is likely that a tumor that cannot proliferate in the matrix at its local site of origin would not do so in a metastatic site either. Operational definitions for tumorigenic and nontumorigenic melanoma and for radial and vertical growth phase are as follows (422,423):

Tumorigenic melanoma. A mass of melanoma cells is present in the dermis, defined as at least one cluster (nest) in the dermis that is larger than the largest intraepidermal cluster (indicative of a tumor with capacity for expansile growth in the dermis) (Fig. 28-21).

Nontumorigenic melanoma. No mass of melanoma cells is present in the dermis (there is no cluster larger than the largest intraepidermal cluster) (Fig. 28-20C).

Vertical growth phase (VGP). A lesion is classified as vertical growth phase if it is tumorigenic or if there are any dermal mitoses even in the absence of architectural criteria for tumorigenic growth. The presence of any mitoses in the dermal component of the melanoma is indicative of a tumor with capacity for expansile growth in the dermis and defines the concept of typical vertical growth phase even in the absence of a frank tumor mass (Fig. 28-21).

Radial growth phase *(RGP).* A lesion is classified as radial growth phase only ("pure" RGP, or "radial growth phase confined") if it is nontumorigenic and there are no dermal mitoses. Alternatively, the radial growth phase may be present as a compartment of a complex primary melanoma in which the foregoing histologic criteria apply only to that portion of the melanoma adjacent to the VGP (Fig. 28-21). "Pure" RGP melanoma may be defined as the absence of VGP in a primary melanoma (Fig. 28-20).

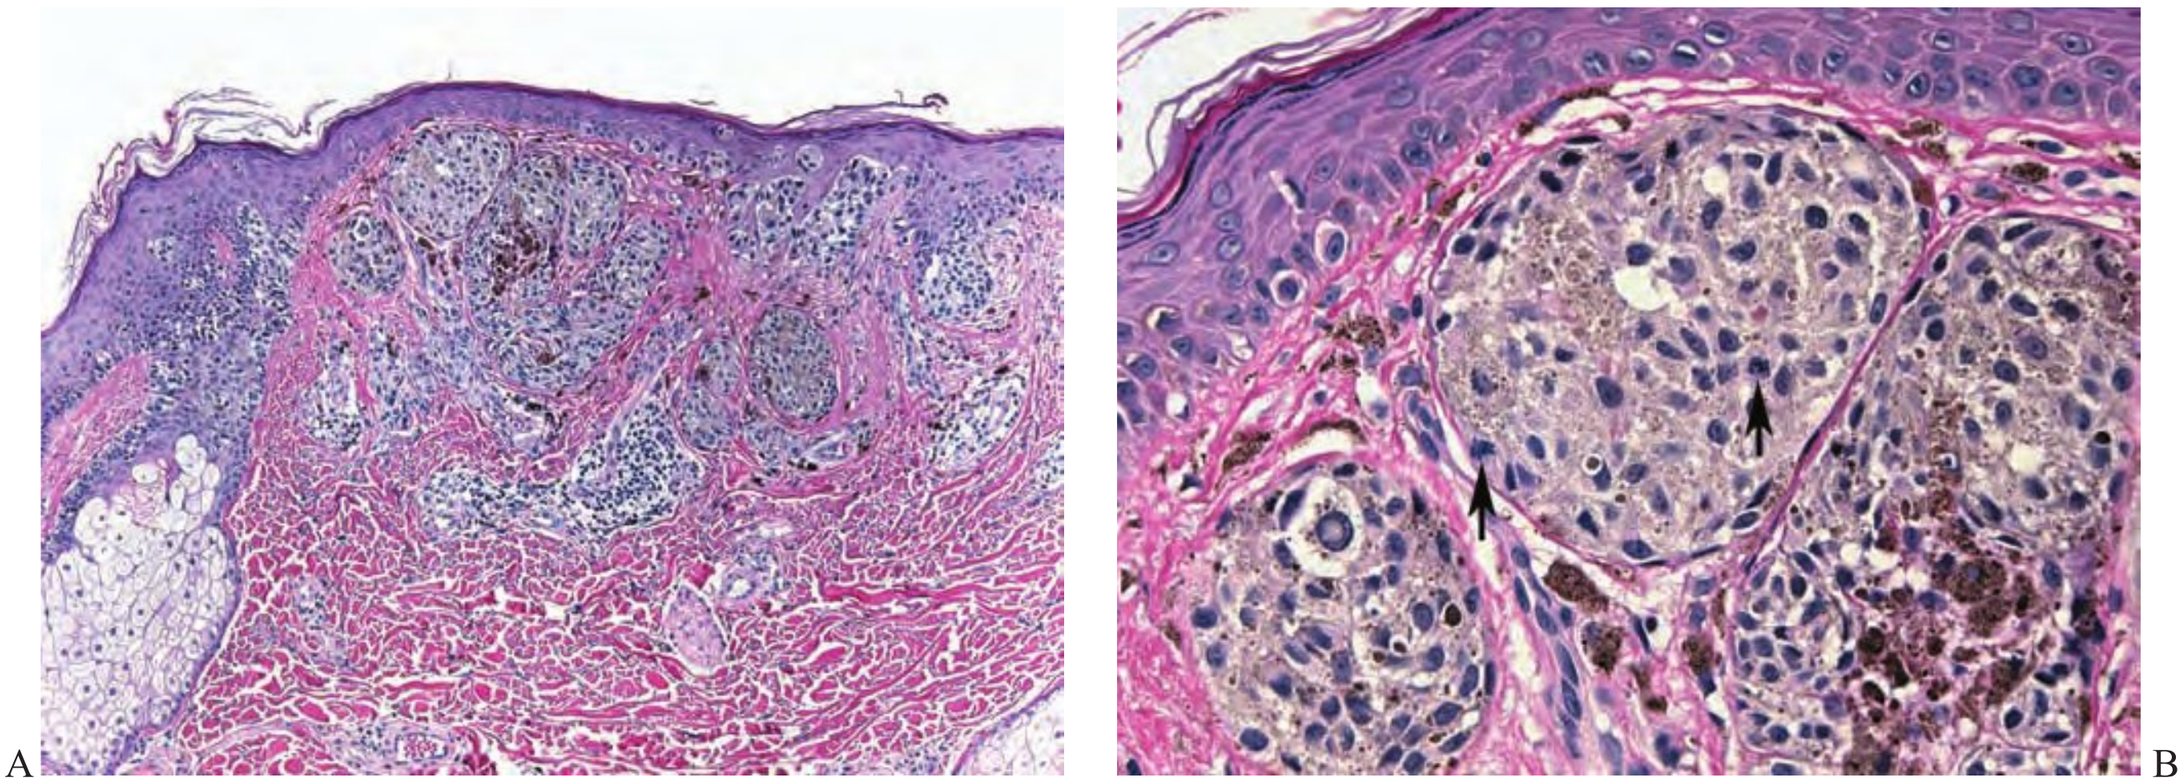

FIGURE 28-21. A: Melanoma with early tumorigenic vertical growth phase. This lesion is Clark level II because the papillary dermis is expanded but not quite filled by the proliferation. The Breslow thickness is approximately 0.5 mm. Several of the clusters of cells in the dermis are slightly larger than the largest clusters in the epidermis, indicative of tumorigenic proliferation in the dermis. The cells in the epidermis are smaller than those in the dermis and they extend laterally as a predominantly in situ radial-growth-phase compartment in the primary melanoma. B: At high magnification, there is uniform atypia, and there are scattered lesional cell mitoses in the early vertical growth phase. The melanin pigment is finely divided or "dusty."

In rare instances, a mass is formed in the dermal component of a melanoma by the accretive piling up of clusters of cells in the absence of any single cluster of cells that is larger than the largest intraepidermal cluster (Fig. 28-22). Reed et al. described these lesions as "variant vertical growth phase" or "accretive vertical growth phase" (232). These lesions are nontumorigenic. However, if any mitoses are present in such a lesion, it would meet the criteria for vertical growth phase defined earlier. The prognostic significance of variant vertical growth phase is uncertain. Most examples are thin, with a good prognosis as judged by prognostic models. In our experience, rare instances of metastasis have been associated with the presence of variant vertical growth phase; the overall metastatic rate is exceedingly low, comparable with that associated with other nontumorigenic melanomas.

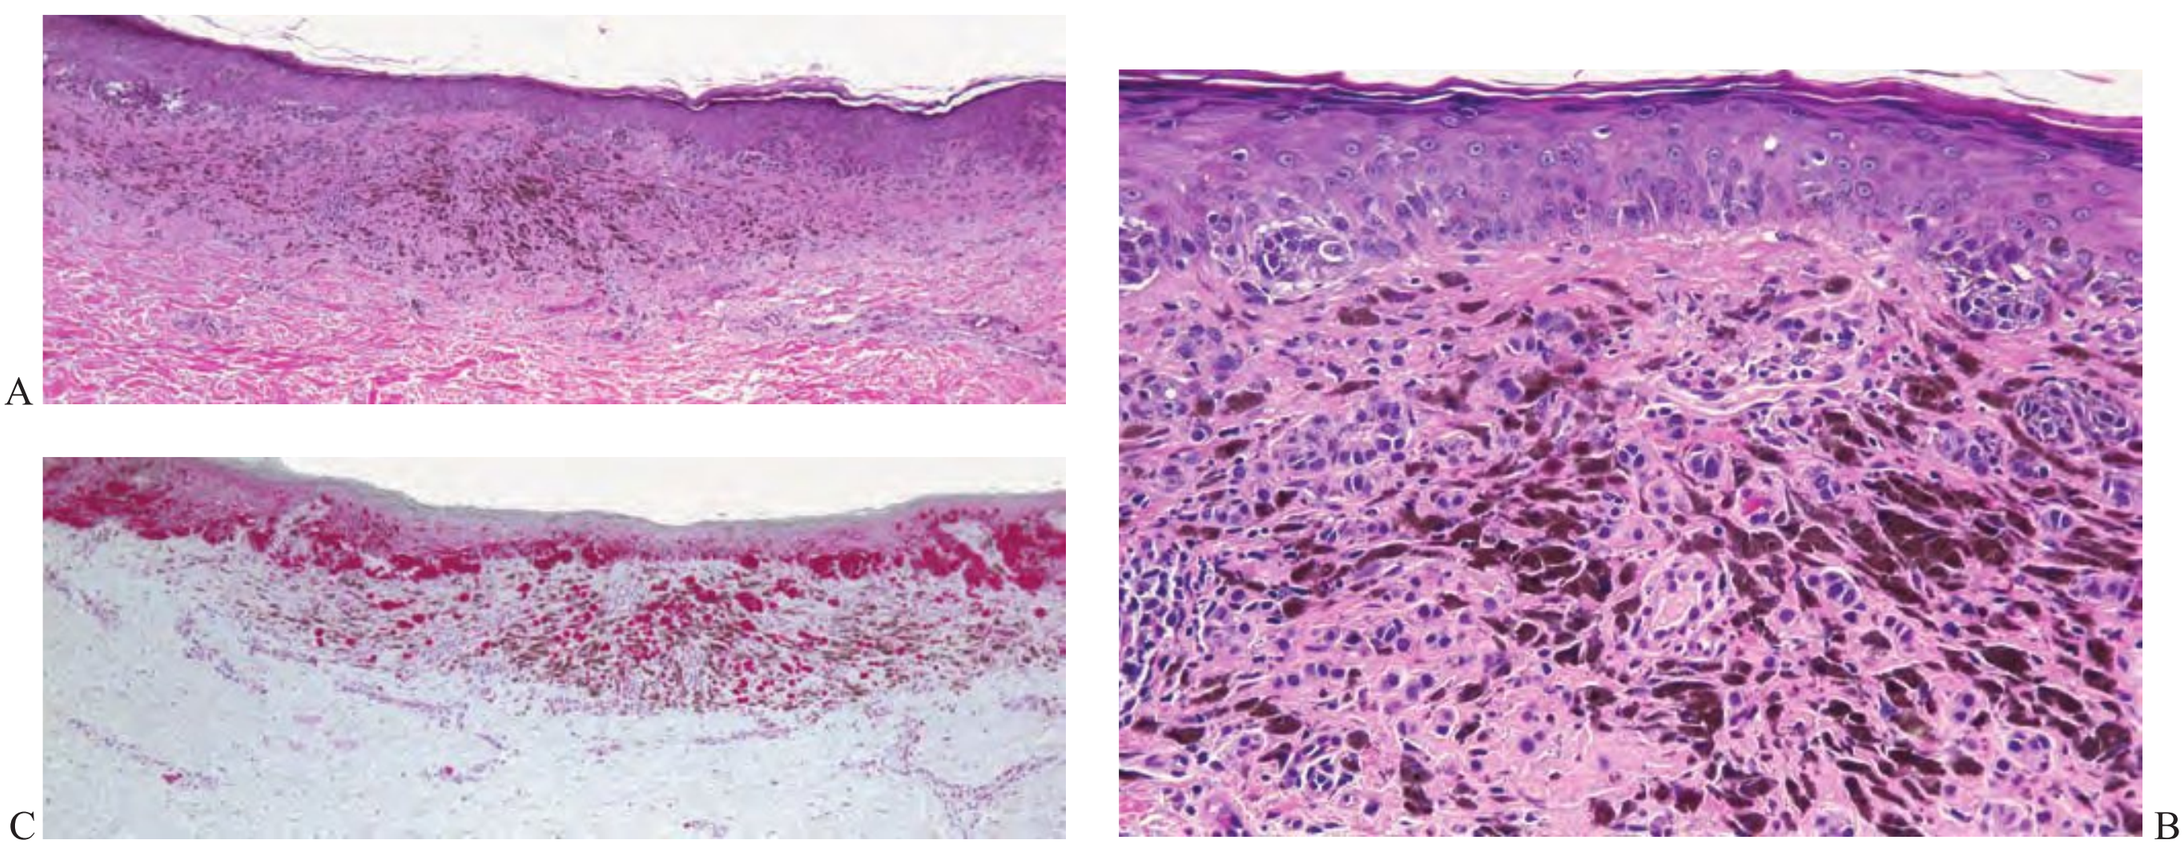

FIGURE 28-22. A: Melanoma with variant vertical growth phase ("accretive VGP"). There is a region in the center of the lesion where the papillary dermis is expanded by a small mass. B: The mass appears to have been formed by the accretive growth of numerous small nests, none of which is larger than the largest intraepidermal nest. C: A Melan-A stain graphically demonstrates the smaller nests in the dermis and the larger nests in the epidermis.

In a study conducted by the Pathology Panel of the Cancer Research Campaign in the United Kingdom, the level of agreement for recognition of vertical growth phase was "good" as judged by formal kappa analysis and was improved after discussion of standardized criteria among members of the reviewing panel (424). Subsequently, two additional studies confirmed this finding (425,426).

Molecular Pathology of Melanoma. Knowledge of the molecular pathology of melanoma has expanded dramatically since the discovery in 2001 of a high frequency of mutation of the oncogene BRAF in primary and metastatic melanomas (131). In a one study, mutations resulting in the activating V599E amino acid substitution were found in 68% of melanoma metastases, 80% of primary melanomas, and, unexpectedly, 82% of nevi (132). Activating mutations of the oncogene NRAS have also been described in melanomas and in tumor-associated and congenital nevi (133–135). Lesions that have mutated NRAS tend not to have mutated BRAF and vice versa (427). These data suggest that mutational activation of the RAS/RAF/MAPK mitogenic pathway in nevi is a critical step in the initiation of melanocytic neoplasia but alone is insufficient for melanoma tumorigenesis (132). The CDKN2A tumor suppressor gene product p16 is highly expressed in nevi (428,429), presumably restraining the proliferative pressure in these lesions despite the activating oncogene mutations, in a phenomenon termed "oncogene-induced senescence" (277). Loss of this suppressor in melanomas, in the context of activated mitogenic signaling pathways, may represent an important mechanism of progression (137).

The Nontumorigenic Compartment of Primary Malignant Melanoma (Radial Growth Phase)

The following sections describe the morphology of the nontumorigenic compartments of the different forms of melanoma. Next, we discuss the morphology of the tumorigenic vertical growth phase, which tends to be similar among the different forms. Typically, about 90% of all melanomas have a nontumorigenic compartment, and about half of these also have a tumorigenic focus; about 10% of melanomas, termed nodular melanomas, have a tumorigenic but no *in situ* or invasive radial-growth-phase compartment.

Two major patterns of nontumorigenic melanoma can be distinguished: pagetoid and lentiginous. The *lentiginous* pattern recapitulates the pattern of focally contiguous proliferation of nevus cells in the simplest melanocytic neoplasm, lentigo simplex. However, there is more uniform and complete contiguous basal replacement, and thus the proliferation is continuous, at least in part, between adjacent rete ridges. *Pagetoid* spread, graphically described as "buckshot scatter" of melanocytes within the epidermis, is the best-known pattern of melanomas. However, many melanomas, including many of the lentiginous ones, are entirely or partly lacking in pagetoid proliferation. In many melanomas, as in nevi, nests of melanocytes are present at the dermal–epidermal junction. These tend to differ from those in nevi in being more variable in size, shape, and orientation and in their more irregular spacing along the junction (430).

Not all superficial melanocytic proliferations can be reliably and reproducibly distinguished as either a superficial melanoma or as a nevus. In such cases, we provide a descriptive designation, such as superficial atypical melanocytic proliferation of uncertain significance, with a differential diagnosis. For example, a problematic lesion with dysplastic features and a small focus of pagetoid extension of slightly atypical melanocytes into the epidermis may be signed out as "junctional nevus with severe dysplasia and focal changes suggestive of evolving melanoma *in situ*." Because the differential diagnosis in these lesions includes melanoma *in situ*, which could locally persist, recur, and grow inexorably, although without metastatic potential at the time of diagnosis, we recommend a reexcision procedure for such lesions. The dimensions of such a procedure could follow guidelines for melanoma *in situ*, or at a minimum should be discussed with the patient and include a margin of normal tissue around the scar and any residual lesion.

Superficial Spreading Melanoma

Superficial spreading melanoma, also referred to as pagetoid melanoma (409), is the most frequent form of melanoma (about 70% of all cases), and may therefore be regarded as the "common" or "prototypic" form of melanoma. These lesions were described in the past as "atypical melanocytic hyperplasia" (431) or "precancerous melanosis," a term that dates to one of the earliest descriptions of melanoma by Dubreuilh in 1912 (432). The lesions, which occur in a relatively young to middle-aged patient population, may occur on exposed skin but are more commonly found on intermittently exposed skin and are rare on unexposed skin. In contrast to lentigo maligna, superficial spreading melanoma is believed to be associated with acute intermittent rather than chronic continuous sun exposure, which is often recreational rather than occupational (433). The most frequently involved sites are the upper back, especially in men, and the lower legs, especially in women. The lesions are slightly or definitely elevated, with a palpable border and an irregular outline. There is often variation in color that includes not only tan, brown, and black, but also pink, blue, and gray. White areas may be seen at sites of spontaneous regression (Fig. 28-19A). Microinvasion may be clinically unapparent, but the onset of tumorigenic vertical growth is indicated by the development of a papule followed by nodularity and sometimes also ulceration, the latter usually a late feature. In rare instances the lesion has a verrucous surface, in which case differentiation from a seborrheic keratosis may be difficult (434). In its early stage of development, superficial spreading melanoma may be indistinguishable clinically from a dysplastic nevus. Although dermoscopy can improve clinical diagnostic specificity (435), histologic examination remains the gold standard and is necessary for accurate diagnosis (435,436).

Histopathology. Architectural pattern features of importance in the diagnosis include the large diameter of the lesions, poor circumscription (the last cells at the edge of the lesion tending to be small, single, and scattered), and asymmetry (one half of the lesion does not mirror the other half) (430). The epidermis is irregularly thickened and thinned, in contrast to the uniformly elongated rete ridge pattern of a dysplastic nevus (Fig. 28-20A). Rather uniformly rounded, large melanocytes are scattered in a pagetoid pattern throughout the epidermis. The large cells lie predominantly in nests in the lower epidermis and singly in the upper epidermis. The nests tend to vary a good deal in size and shape and to become confluent. Dermal melanophages and a dermal infiltrate are regularly present. The lymphocytic infiltrate may be patchy and perivascular as in a dysplastic nevus but is typically dense and bandlike, especially in invasive lesions.

Cytologically, the lesional cells are rather uniform and have abundant cytoplasm containing varying amounts of melanin that often consists of small, "dusty" granules. They are almost entirely devoid of readily visible dendrites. The nuclei tend to be large and hyperchromatic, with irregular nuclear membranes and irregularly clumped chromatin (Fig. 28-20B). This uniform cytologic atypia is of considerable diagnostic importance and contrasts with the random cytologic atypia of dysplastic nevi.

When the lesion is *in situ*, the basement membrane is intact (as in the field seen in Fig. 28-20B) and there are no lesional cells in the dermis. In an invasive but nontumorigenic lesion (invasive radial growth phase or microinvasive melanoma), cells similar to those in the epidermis are present in the dermis in the form of small nests, with no nests larger than those in the epidermis, and with no dermal mitoses (Fig. 28-20C). When tumorigenic vertical growth phase is present, there is at least one, or often more than one, cluster of cells in the dermis that is larger than the largest intraepidermal nest, and/or there may be lesional cell mitoses in the dermis (Fig. 28-21A, B).

Histogenesis. On electron microscopic examination, melanosomes are present in great numbers in the large pagetoid tumor cells. Their shape is largely spheroid, rather than ellipsoid as in normal melanocytes and in the tumor cells of lentigo maligna (437). They often also show other abnormalities, such as absence of cross-linkages of the filaments within the melanosomes. Melanization within the melanosomes is variable but often incomplete (438). This accounts for the finely divided "dusty" character of the pigment in the cells of many melanomas. As already mentioned, it is likely that most superficial spreading melanomas have mutually exclusive activating mutations of the oncogene BRAF or NRAS. In a recent genotype–phenotype study, melanomas that had prominent nesting and pagetoid scatter of melanocytes—criteria similar to those for superficial spreading melanoma—were more likely than other melanomas to be associated with BRAF or NRAS mutations (419). These evolving genetic data will lead to refinement of the clinicopathologic melanoma classification system in the near future.

Differential Diagnosis. A junctional nevus differs from superficial spreading melanoma in radial growth phase by a lack of atypia in the tumor cells, particularly in their nuclei, by a lack of pagetoid upward extension of tumor cells, by the absence of a significant inflammatory infiltrate in the upper dermis, and often but not always by a sharper lateral demarcation. Salient features in the important distinction from junctional melanocytic dysplasia have been reviewed (Table 28-5), and include, at scanning magnification, larger size, asymmetry, an irregularly thickened and thinned epidermis, and a bandlike lymphocytic infiltrate in superficial spreading melanoma. At higher power, indicators of melanoma include the presence of high-level and extensive pagetoid melanocytosis (large neoplastic cells scattered among benign keratinocytes), high-grade and/or uniform cytologic atypia, and lesional cell mitoses (the latter present in about one third of cases). A junctional Spitz nevus, especially the uncommon pagetoid Spitz nevus, may simulate superficial spreading melanoma quite closely. Distinguishing features include generally smaller size, the presence of large spindle and/or epithelioid cells, the presence of Kamino bodies, and the lack of "consumption" or thinning of the epidermis above the lesion, as previously discussed (see section Spitz Nevus). The so-called nevi of special sites, including flexural sites, ears, scalp, and breast, may also simulate this form of melanoma in particular, and these should be seriously considered when a biopsy from one of these sites is examined (see also page 715). Caution should be exercised when what at first appears as melanoma *in situ* is restricted to the epidermis that overlies a surgical or traumatic scar because this must be differentiated from the recurrent nevus phenomenon [see section Recurrent Nevus (Pseudomelanoma)]. Helpful features include the precise spatial restriction of the atypical intraepidermal focus to the zone overlying (but not extending horizontally beyond) the scar, the presence of residual nevus cells, and the absence of true uniform cytologic atypia. Whenever possible, it is important to also review the initial biopsy in such cases. The differential diagnostic distinction from lentiginous melanomas is of less consequence because the management is the same. In lentigo maligna, the epidermis is atrophic and pagetoid melanocytosis is less prominent, and contiguous replacement of the basal cell layer by atypical melanocytes is the dominant pattern. Problematic cases can be reported as malignant melanoma (*in situ* or microinvasive, etc.) without designation as to type.

When tumorigenic vertical growth phase is present, it does not differ appreciably from that in any other form of melanoma, except for the adjacent radial growth phase (Fig. 28-23). Classification of such complex tumorigenic primary melanomas is based on the morphology of the radial growth phase.

Among the nonmelanocytic neoplasms that must be differentiated from a superficial spreading melanoma *in situ* are *Paget's disease* and pagetoid examples of *Bowen's disease* (*squamous cell carcinoma in situ*). Paget's disease (discussed in detail in Chapter 30) usually shows remnants of compressed basal cells beneath the tumor cells, whereas in superficial spreading melanoma the lesional cells extend to the basement membrane. In Paget's disease, the tumor cells may stain positively for carcinoembryonic

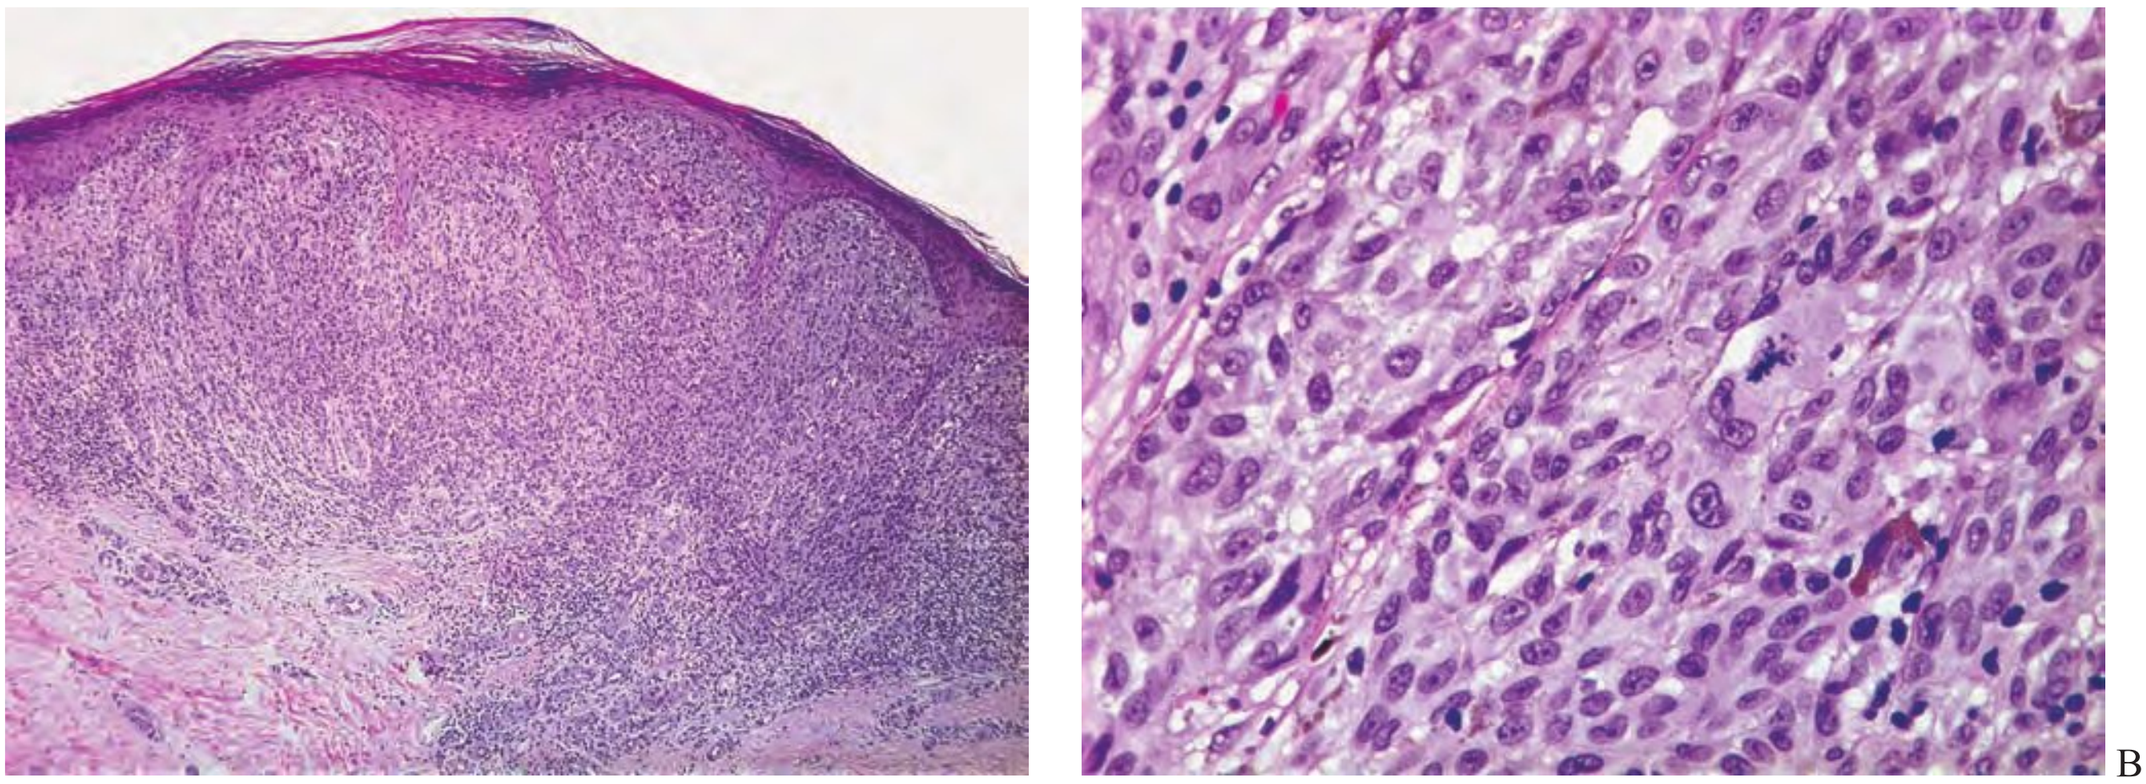

FIGURE 28-23. A: Malignant melanoma, tumorigenic. At scanning magnification, there is a bulky ulcerated tumor nodule, which is eccentrically placed in contiguity with a broad plaque, the nontumorigenic radial-growth-phase compartment (not shown, to the right of the image field). B: The tumorigenic nodule is composed of uniformly atypical, mitotically active, fully malignant melanocytes (melanoma cells).

antigen and keratin and are negative for HMB-45 and Melan-A. S100 reactivity, although unusual, may occasionally be observed in Paget's disease. Pagetoid Bowen's disease (discussed in Chapter 29) shows, as a rule, a well-preserved basal cell layer, except in areas in which dermal invasion has taken place, and immunohistochemically the atypical cells stain positively with antikeratin antibodies (e.g., AE1/AE3) (439). They do not stain with S100 or with Melan-A or HMB-45. It should be noted that the cells of Paget's disease and of Bowen's disease may contain melanin pigment because of transfer from reactive melanocytes in the adjacent skin.

A final pitfall in evaluating nonmelanocytic mimics of intraepidermal melanoma involves the variable tendency of keratinocytes within the uppermost epidermal layers to exhibit perinuclear retraction presumably due to cytoplasmic glycogenation combined with tissue processing. Some body sites (e.g., areola and along the milk line) may be particularly prone to this change, perhaps in part the result of so-called "clear cells of Toker." These cells may produce the false appearance of true pagetoid spread in an otherwise benign or dysplastic melanocytic lesion, thus inciting consideration of a diagnosis of superficial spreading melanoma. However, keratinocytes so altered are recognizable at high magnification as cells with nuclei surrounded by clear spaces (retraction clefts) that themselves are bordered by a rim of cytoplasm and joined by desmosomes, in contrast to pagetoid melanoma cells, which lack desmosomes and whose nuclei are directly enveloped by relatively clear cytoplasm that may be surrounded by a thin, clear mantle of retraction that separates the cell from adjacent keratinocytes.

Lentigo Maligna Melanoma

Lentigo maligna, previously referred to as *melanosis circumscripta preblastomatosa of Dubreuilh* and also as *melanotic freckle of Hutchinson* [or *Hutchinson's melanotic freckle* (*HMF*), a term used currently in Australia for this condition], accounts for about 10% of melanomas and typically occurs on the chronically exposed cutaneous surfaces of the elderly, most commonly on the face, and occasionally on the back, the forearms, or the lower legs (440). The term "lentigo maligna" may be regarded as synonymous with "lentigo maligna melanoma *in situ*" for most purposes. It is controversial whether lentigo maligna should be regarded as a form of melanoma *in situ* in all cases or whether some cases should be regarded as precursor lesions (lentigo maligna) of *in situ* melanoma (melanoma *in situ*, lentigo maligna type) (441). In any case, these lesions, like other melanomas *in situ*, do not metastasize after complete excision, although they may persist and recur if not adequately excised. The lesion evolves slowly over many years, starting as an unevenly pigmented macule that gradually extends peripherally and may attain a diameter of several centimeters. It has an irregular border and, as long as it remains *in situ* or microinvasive, shows no induration. While extending in some areas, it may show spontaneous regression in others, resulting in irregular depigmented areas. The color varies from light brown to brown with minute dark-brown or black flecks. Fine reticulated lines are usually also present and help in distinguishing the lesions from actinic lentigines. In contrast to superficial spreading melanoma, the border is usually impalpable and indistinct. For this reason, the accurate clinical delineation of the border of a lentigo maligna melanoma can be problematic, and this not uncommonly results in unexpected positive or close margins in resection specimens. Occasionally, a lesion of lentigo maligna lacks melanin pigmentation (442–444). The clinical appearance then resembles that of a solar keratosis or Bowen's disease or of an inflammatory patch, such as lupus.

It has been suggested that the risk of progression from lentigo maligna to invasive lentigo maligna melanoma may be about 5% (445), although some cases may progress rapidly (446). After adjustment for tumor thickness and other factors, lentigo maligna melanoma (LMM) has the same prognosis as other forms of melanoma (447). However, its demographics and associations differ from those of the most common form of melanoma, superficial spreading melanoma (SSM). For example, patients with LMM have fewer nevi but more actinic keratoses than patients with SSM, consistent with a hypothesis of chronic sun exposure in the etiology of LMM (448). In addition, especially in older individuals, lesions that lack nesting and pagetoid scatter of melanocytes—criteria similar to those described for lentigo maligna melanoma—are less likely to be associated with BRAF or NRAS mutations than when these attributes are present, as in SSMs (419). In contrast, the oncogene KIT has been found to be mutated in 28% of melanomas on chronically sun-damaged skin (449). These evolving genetic data will lead to refinement of the clinicopathologic melanoma classification system in the near future.

Histopathology

Architectural Features. In its earliest stage, lentigo maligna may show at its periphery only hyperpigmentation with slight melanocytic proliferation, mainly in the basal cell layer. Toward the center of the lesion, there is a more pronounced increase in the concentration of basal melanocytes and some irregularity in their arrangement. Until there is contiguous proliferation of lesional melanocytes, these changes are not specific and may overlap with those of actinic lentigines. The epidermis is frequently flattened, in contrast to SSM, in which it is irregularly thickened and thinned, or actinic lentigines, in which there is elongation of the rete. This feature, although of diagnostic importance, is less prominent than in superficial spreading melanoma (Fig. 28-24). Noteworthy is the tendency of the basal layer of follicular infundibula to also be involved by the lentiginous proliferation of atypical melanocytes in lentigo maligna.

Some nesting of melanocytes in the basal layer may be seen, but this is not usually pronounced until invasion of the dermis is developing (450). The atypical melanocytes within the nests usually retain their spindled shape, and they often "hang down" like rain droplets from the interface (410). Except in areas of nesting, the melanocytes tend to retain their dendritic processes. If the melanocytes are heavily melanized, some dendrites may be visible even in sections stained with hematoxylin-eosin; otherwise, staining with silver demonstrates the dendrites.

The upper dermis, which almost always shows severe elastotic solar degeneration, contains numerous melanophages and a rather pronounced, often bandlike, inflammatory infiltrate. Invasion may be demonstrable in these areas of dermal inflammation. Because invasion in a lentigo maligna melanoma (as in other melanomas) is a focal process, one should ensure that the specimen is adequately grossed and sectioned in order not to miss such areas. The presence or absence

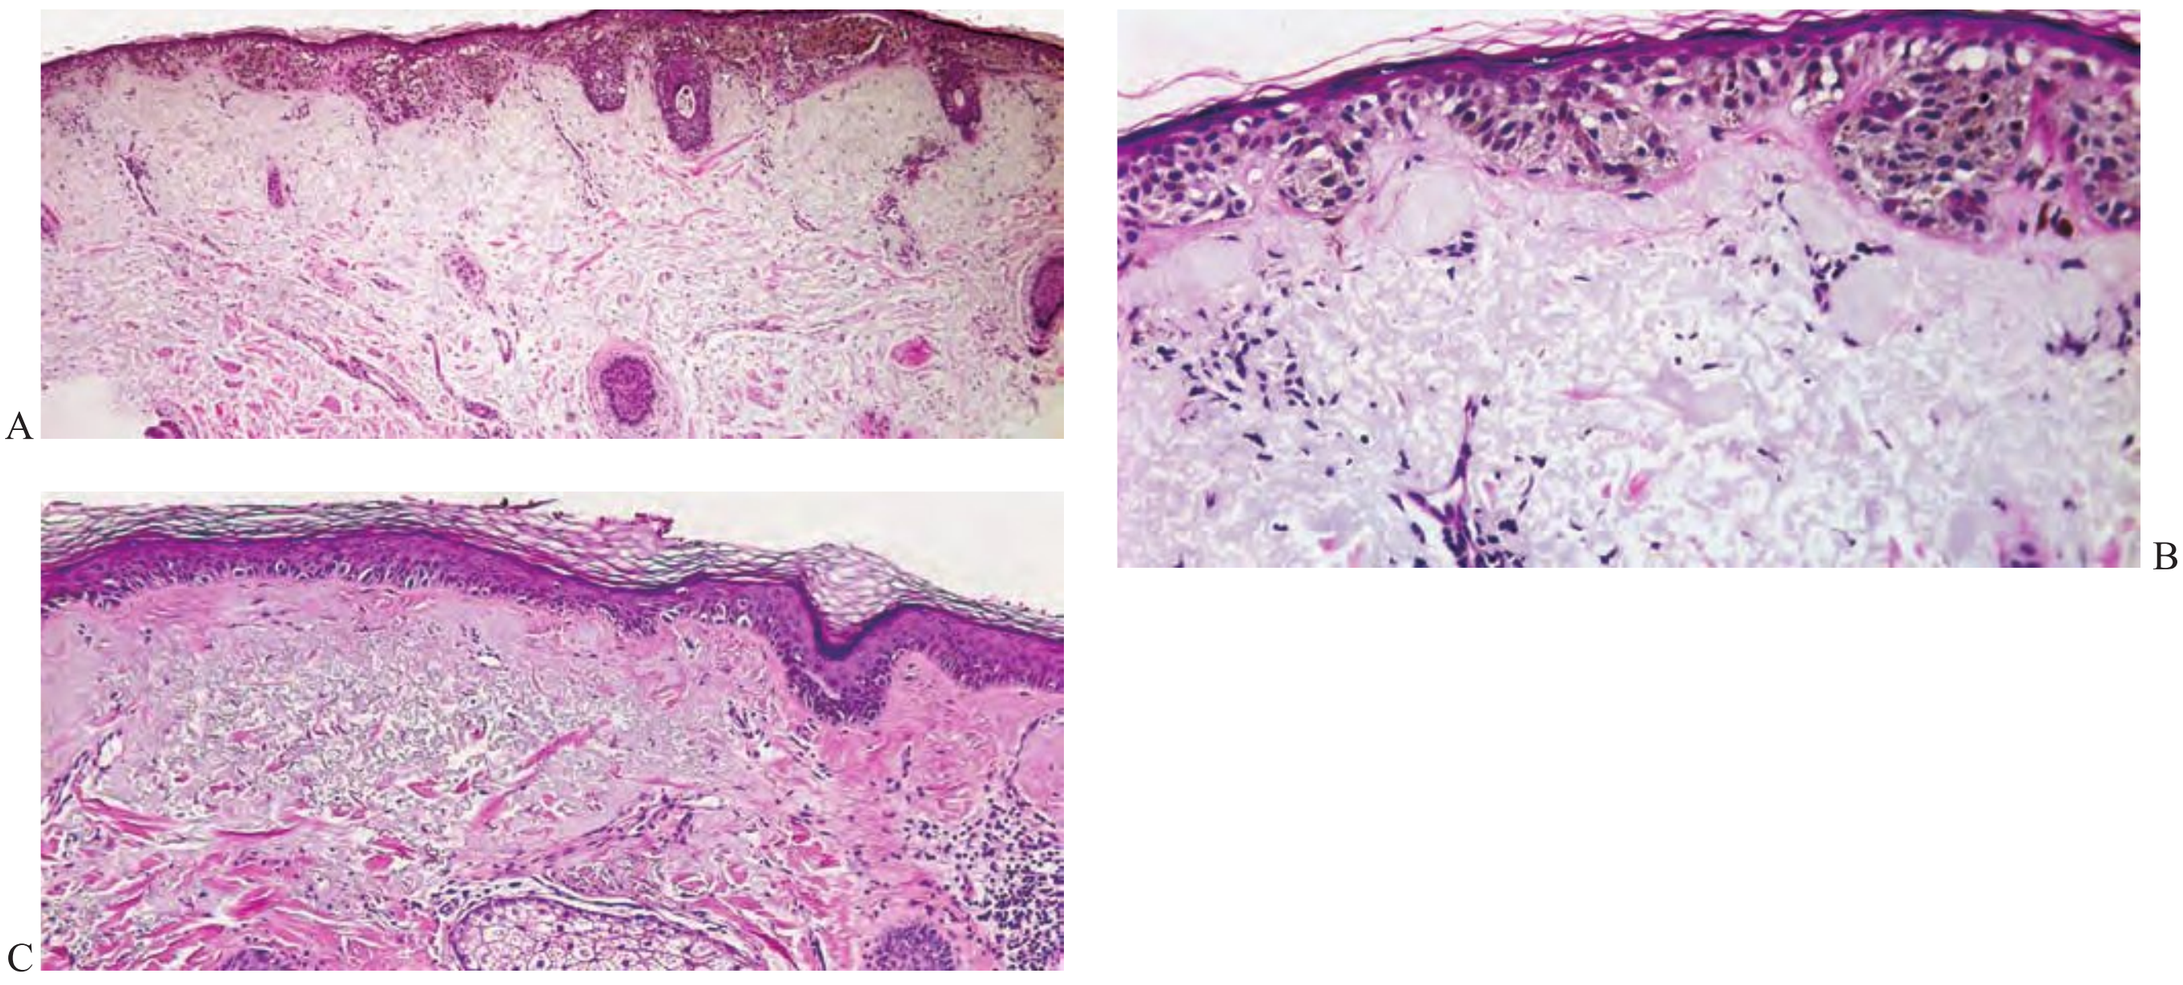

FIGURE 28-24. A: Lentigo maligna melanoma in situ. At low magnification, the lesions are broad and asymmetric in the distribution of lesional and host responding cells. B: The epidermis is atrophic, and there is usually severe actinic elastosis in the dermis. C: As in superficial spreading melanoma, the lesional cells exhibit moderate to severe uniform cytologic atypia. There is usually some evidence of pagetoid proliferation in lentigo maligna melanoma, especially near areas of invasion. However, especially at the periphery of the lesion, this is much less prominent, and the lesional cells are smaller than in superficial spreading melanoma.

of tumorigenic vertical growth phase is recognized using criteria already presented. The possibility of a desmoplastic vertical-growth-phase component (see later section) should be kept in mind because this may be a subtle finding. In case of doubt, an S100 stain can be crucial in demonstrating the lesion.

Cytologic Features. In fully evolved lesions of lentigo maligna, the lesional melanocytes in the epidermis show a marked increase in concentration, so that they come to lie in contiguity with one another, and their number in some areas exceeds that of the basal keratinocytes. Many of them are elongated and spindle shaped. Their nuclei appear atypical, being enlarged, hyperchromatic, and pleomorphic. However, the chromatin pattern is often not as open or "vesicular" as that seen in the more epithelioid cells of superficial spreading melanoma in its radial phase of growth. Frequently, atypical melanocytes extend along the basal cell layer of hair follicles, often for a considerable distance, frequently extending to the base of a shave biopsy specimen. Usually, the proliferating melanocytes contain moderate melanin, and melanin is present also in keratinocytes. There is usually some upward pagetoid extension of atypical melanocytes.

In summary, the properties of contiguous proliferation and uniform cytologic atypia in a broad, poorly circumscribed lesion are clearly of major importance in the diagnosis of *in situ* or microinvasive lentigo maligna melanoma. These features are shared with superficial spreading melanoma, whereas focal pagetoid melanocytosis, although often present, is less prominent. It should also be remembered that some individuals with chronic sun damage may show diffuse, clinically covert, noncontiguous lentiginous proliferation of somewhat atypical melanocytes within the epidermal basal cell layer, and thus correlation with clinical appearance may be critical to determining the biological significance of low-grade atypical melanocytic hyperplasias. Mitotic figures are uncommonly present in the epidermal compartment of lentigo maligna melanoma; if present in the dermis, they are indicative of vertical growth phase. When tumorigenic vertical growth supervenes, it is often of the spindle cell type, including the desmoplastic and neurotropic variants.

Pathogenesis. As an explanation for the somewhat distinctive behavior of lentigo maligna, the theory has been offered that it is derived from spindle-shaped junctional melanocytes and thus represents a melanocyte-derived melanoma, in contrast to the superficial spreading melanoma that is derived from rounded junctional nevus cells and can be regarded as a nevus cell–derived melanoma (451). Electron microscopy provides some support for this concept. The melanocytes of lentigo maligna are large, synthetically active cells with many dendrites. The melanosomes are essentially normal, except that they appear somewhat more elongated than those present in normal melanocytes (437,451). This is in contrast to superficial spreading melanomas, in which the melanosomes show considerable abnormalities. In a study of several immunohistochemical markers comparing lentigo maligna and superficial spreading melanomas, melanocytes of the latter showed greater proliferative activity, as reflected by PCNA staining, higher levels of basic fibroblast growth factor, and more blood vessels. In addition, staining for p53, considered to be a marker of chronic solar damage, is significantly greater in lentigo maligna than in superficial spreading melanomas (452). These results were considered to be in accordance with the biological behavior of superficial spreading and lentigo maligna melanomas, that is, the longer *in situ* phase of the latter (418). Although progression of lentigo maligna is often slow, some cases progress more rapidly, and complete excision of these lesions is recommended to prevent the development of a more dangerous melanoma (453).

Differential Diagnosis of Lentigo Maligna. Lentigo maligna may be associated with fields of atypical lentiginous melanocytic proliferation that in a small biopsy may not permit an outright diagnosis. Recognition of this fact is important in suggesting the potential utility of additional sampling, particularly for clinically suspicious lesions. Lentigo maligna with junctional nest formation may also be mistaken for a superficial dysplastic nevus, especially in a partial biopsy specimen. It is important in such lesions to note the occurrence of the proliferation in an atrophic epidermis devoid of elongation of rete ridges, the uniform (rather than random) atypia of the lesional cells, and, if present, the presence of follicular extension by the atypical melanocytes. As mentioned, invasion in lentigo maligna melanoma may be extremely subtle, particularly when the involved cells exhibit desmoplastic or small-cell (nevoid) features. Close attention to subtle yet uniform atypia, aided by immunohistochemical approaches to support melanocytic (e.g., versus fibroblastic) lineage, may be helpful in such problematic lesions.

Acral-lentiginous Melanoma

Acral melanoma occurs on the hairless skin of the palms and soles and in the ungual and periungual regions, the soles being the most common site (411,454). Acral melanoma is uncommon in all ethnic groups, but it is the predominant form of melanoma in individuals with darker skin. In groups such as Asians, Hispanics, Polynesians, and blacks, in whom the overall incidence of melanoma is low, most melanomas are of the acral type. However, the absolute incidence of acral melanoma in these groups is similar to that in whites, who have a much higher incidence of melanoma overall (455). These considerations suggest that different etiologic factors, likely not involving sunlight, are operative in acral than in other sites. Although the survival rate of patients with acral melanomas in most series is relatively poor (456,457), this is likely due to their typically advanced microstage and/or stage at diagnosis.

Clinically, *in situ* or microinvasive acral-lentiginous melanoma shows uneven pigmentation with an irregular, often indefinite border. The soles of the feet are most commonly involved. If the tumor is situated in the nail matrix, the nail and nail bed may show a longitudinal pigmented band, and the pigment may extend onto the nail fold (Hutchinson's sign). Tumorigenic vertical growth may be heralded by the

onset of a nodule, with development of ulceration (Fig. 28-19B). However, some acral melanomas may be deeply invasive while remaining quite flat because the thick stratum corneum seems to act as a barrier to exophytic growth.

Histopathology. The lesions are termed lentiginous because the majority of the lesional cells are single and located near the dermal–epidermal junction, especially at the periphery of the lesion (Fig. 28-25). However, usually some tumor cells can be found in the upper layers of the epidermis, especially near areas of invasion in the center of the lesions. The histologic picture differs from that of lentigo maligna because of irregular acanthosis, the lack of elastosis in the dermis, and the frequently dendritic character of the lesional cells (458). Early *in situ* or microinvasive lesions may show, especially at the periphery, a deceptively subtle histologic picture consisting of an increase in basal melanocytes and hyperpigmentation with only focal atypia of the melanocytes. However, in the center of the lesions, there is usually readily evident uniform, severe cytologic atypia. There may be a lichenoid lymphocytic infiltrate that may largely obscure the dermal–epidermal junction, and in some cases this may be so dense as to simulate an inflammatory process. In most of the lesions, both spindle shaped and rounded, pagetoid tumor cells are seen, and, in many cases, pigmented dendritic cells are prominent. Pigmentation is often pronounced, resulting in the presence of melanophages in the upper dermis and of large aggregates of melanin in the broad stratum corneum. As in lentigo maligna, when tumorigenic vertical growth phase is present, it is often of the spindle cell type and not uncommonly desmoplastic and/or neurotropic. In other instances, the invasive and tumorigenic cells in the dermis may be deceptively differentiated along nevoid lines.

Biology of Acral Melanoma

Curtin et al. studied melanomas and nevi for copy-number alterations by comparative genomic hybridization and found that melanomas of the palms, soles, and subungual sites were distinguished by the presence of multiple gene amplifications, about 50% of which were found at the cyclin D1 locus (459). Such amplifications are significantly less frequent in other cutaneous melanoma types and, if present, arise later in progression. Single basal melanocytes with similar gene amplifications were then identified in the histologically normal appearing skin immediately adjacent to a melanoma. These field cells

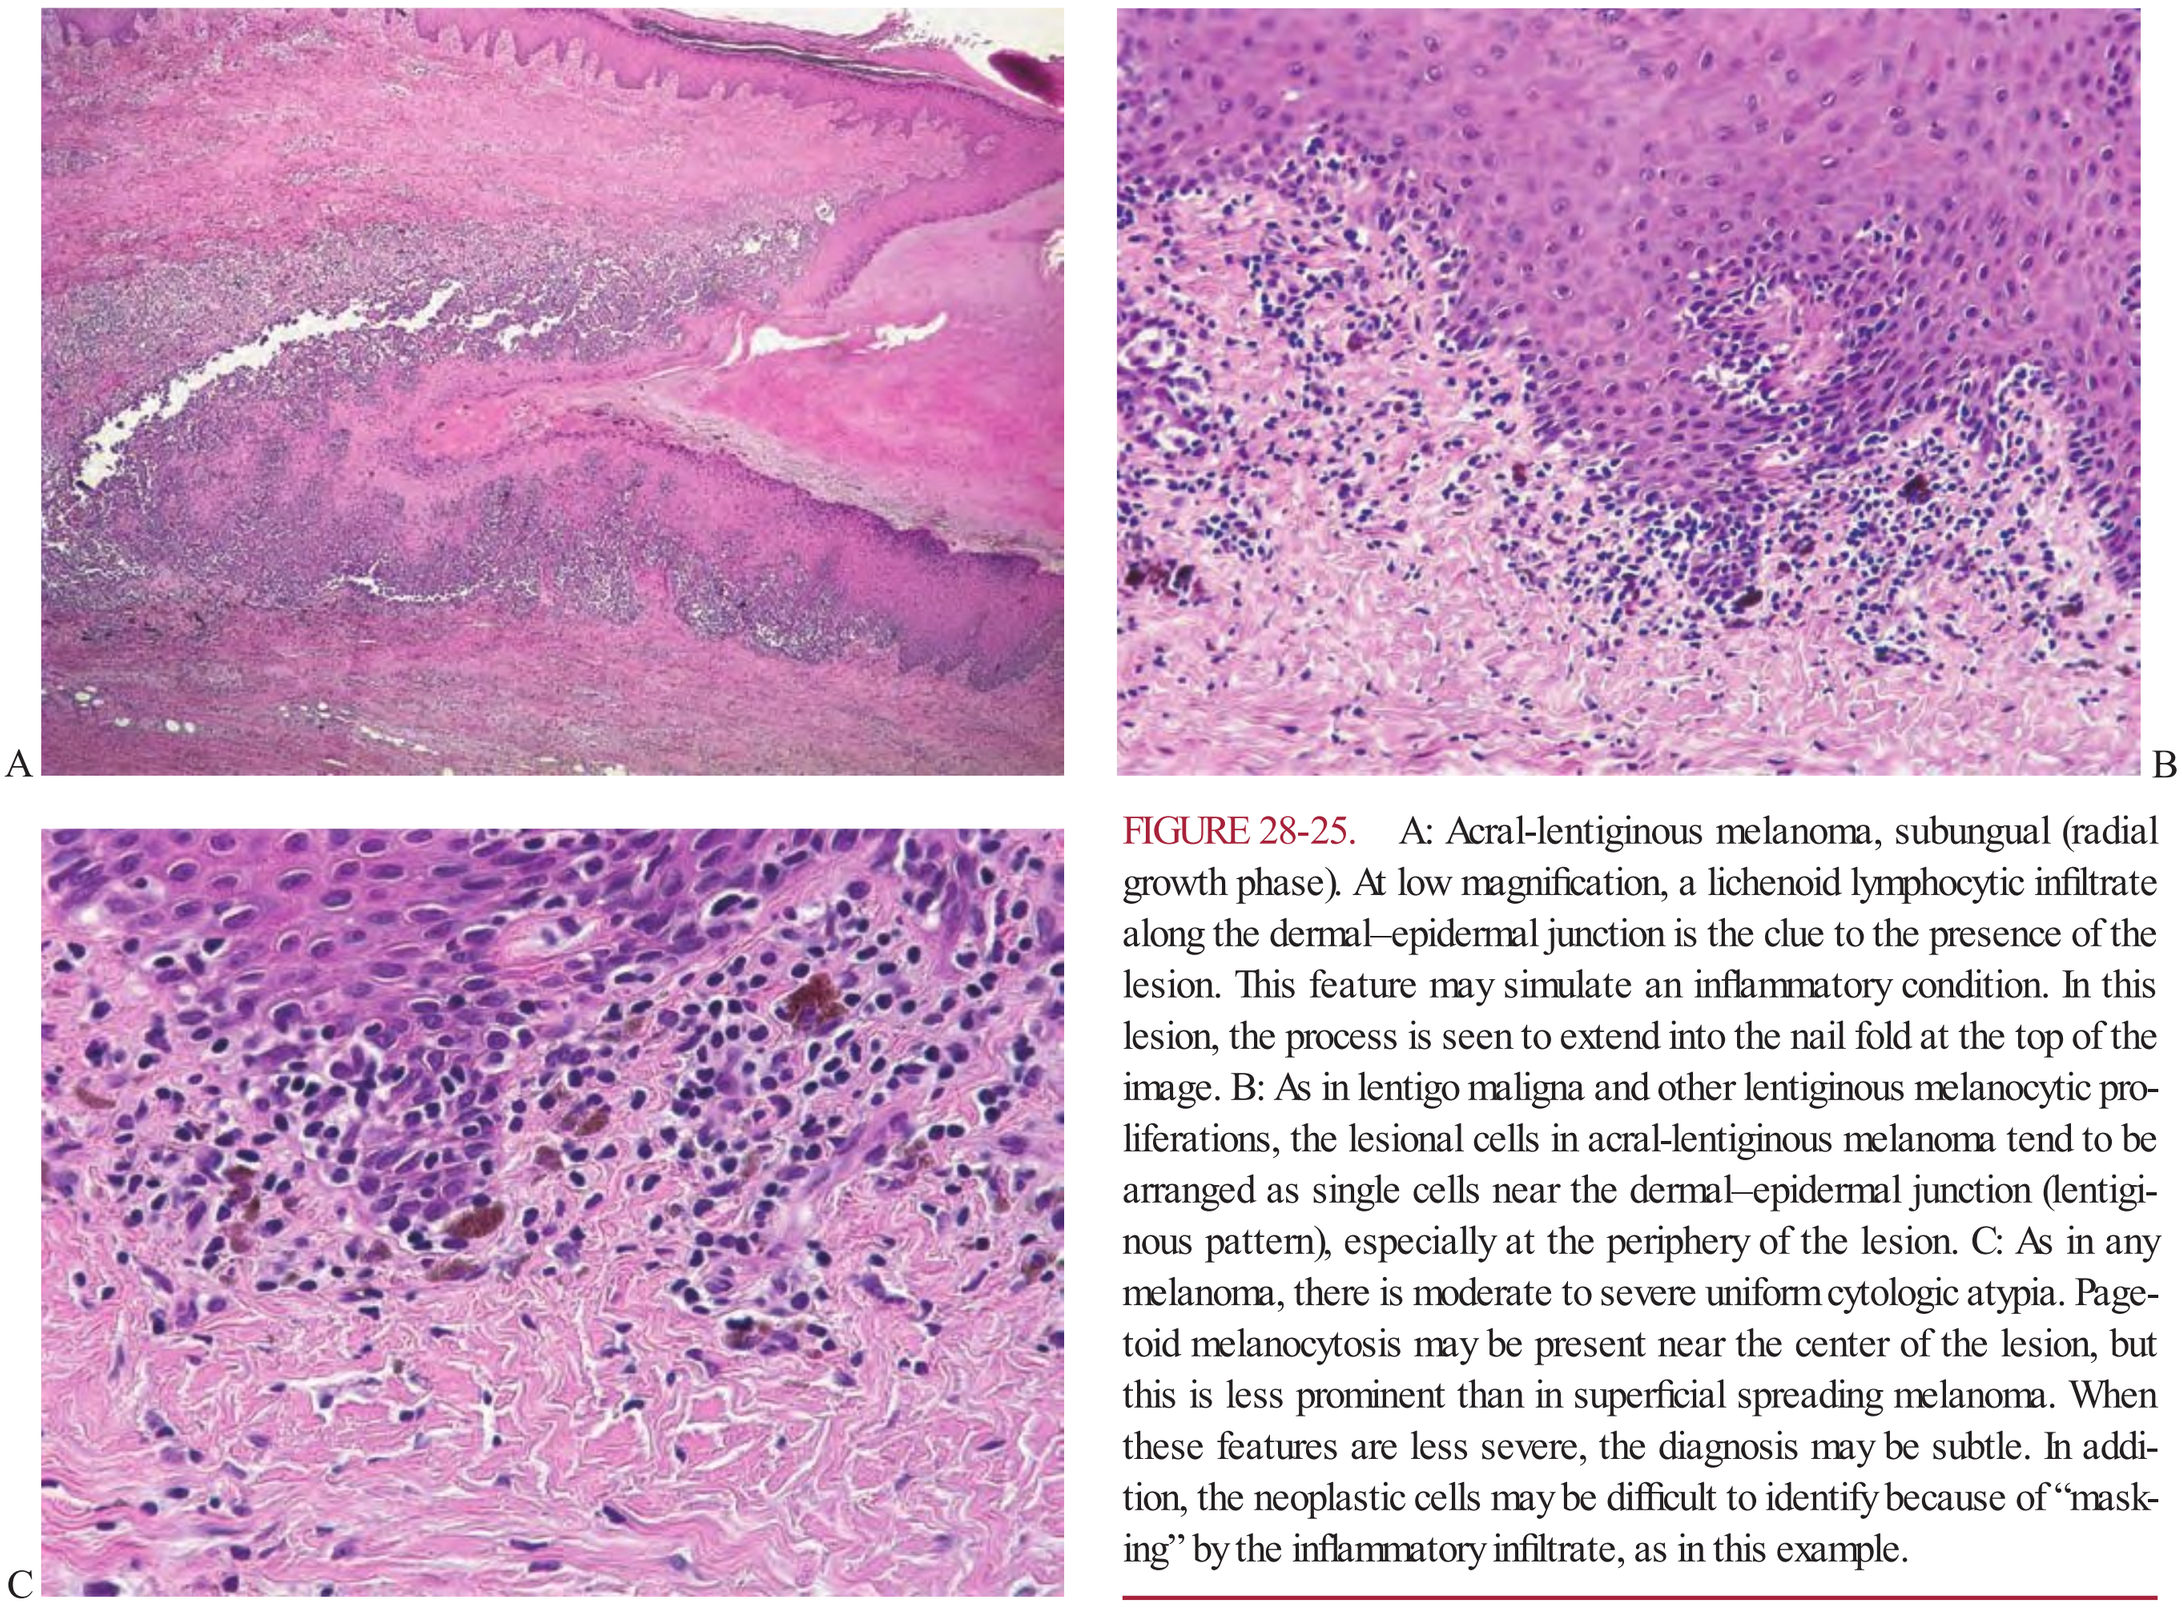

FIGURE 28-25. A: Acral-lentiginous melanoma, subungual (radial growth phase). At low magnification, a lichenoid lymphocytic infiltrate along the dermal–epidermal junction is the clue to the presence of the lesion. This feature may simulate an inflammatory condition. In this lesion, the process is seen to extend into the nail fold at the top of the image. B: As in lentigo maligna and other lentiginous melanocytic proliferations, the lesional cells in acral-lentiginous melanoma tend to be arranged as single cells near the dermal–epidermal junction (lentiginous pattern), especially at the periphery of the lesion. C: As in any melanoma, there is moderate to severe uniform cytologic atypia. Pagetoid melanocytosis may be present near the center of the lesion, but this is less prominent than in superficial spreading melanoma. When these features are less severe, the diagnosis may be subtle. In addition, the neoplastic cells may be difficult to identify because of "masking" by the inflammatory infiltrate, as in this example.

appear to represent subtle melanoma *in situ* and may represent minimal residual disease that could lead to local recurrences if not excised. If the biological significance of these cells in terms of local recurrence can be confirmed, their identification may lead to recommendations for management of these lesions in the future (459). Acral melanomas in general do not express the mutations of BRAF or NRAS that are frequent in the more common superficial spreading melanomas. In contrast, activating mutations of the KIT oncogene were found in 36% of acral melanomas in a recent study (449), a finding that could have therapeutic implications in metastatic tumors.

Differential Diagnosis of Acral Melanoma. The major consideration in the differential diagnosis of acral-lentiginous melanoma is the benign acral-lentiginous nevus, which was discussed earlier (150,151). Features that distinguish this lesion from melanoma include smaller size, greater symmetry, lack of pagetoid lateral spread, absence of high-grade uniform atypia (not always present, however, in some melanomas), absence of mitotic activity in the dermal component, and evidence of dermal nevocytic differentiation (150,151).

Mucosal Lentiginous Melanoma

After the skin and eyes, melanoma is most apt to arise in the juxtacutaneous mucous membranes, such as the oral mucosa (460), nose and nasal sinuses (461), vagina (462), and anorectal mucosa (463). Mucosal melanomas are analogous to acral melanomas in histologic appearance and aggressiveness, which has led to the use of the histologic term mucosal-lentiginous melanoma (464).

Superficial Atypical Melanocytic Proliferation of Uncertain Significance (SAMPUS)

Even though histology is the gold standard for melanoma diagnosis, it is not always possible to make absolute distinctions among melanomas with a predominantly junctional component and their benign simulants because of conflicting, uncertain, or unreliable criteria. A common problem is the distinction between a severely dysplastic nevus and an early melanoma *in situ* or an invasive but nontumorigenic melanoma, and this problem is especially difficult when one of the so-called "special sites" is involved (see section Nevi of Special Sites). When the process is entirely *in situ*, the descriptive term atypical intraepidermal melanocytic proliferation (AIMP) or some similar variant has commonly been used (465–467). When atypical cells are also present in the dermis, this term is obviously inappropriate or at least incomplete, and for some of these lesions we use the descriptive term superficial atypical melanocytic proliferation of uncertain significance (231). For *in situ* lesions, the more traditional term AIMP can be used, or the lesions can be referred to as intraepidermal atypical melanocytic proliferation of uncertain significance (IAMPUS). In any event these terms are descriptive diagnoses, not definitive diagnoses, and should always be accompanied by a differential diagnosis. For example, for a problematic lesion of the breast, we might use the term SAMPUS and in a note express a differential diagnosis that might include a nevus with severe dermal and epidermal dysplasia, a nontumorigenic melanoma, or an unusual presentation of a special-site nevus. The first lesion could have significance as a marker of risk for melanoma, the second could have locally recurring but not metastatic potential, and the last could have no significance at all for the patient. If melanoma is in the differential, we provide sufficient information for American Joint Committee on Cancer (AJCC) staging as a guide to therapy. If the lesion has a potential tumorigenic and/or mitogenic dermal component, and therefore potential competence for metastasis, the term "melanocytic tumor of uncertain malignant potential" is used, as discussed in a later section.

The Tumorigenic Compartment of Primary Malignant Melanoma (Vertical Growth Phase)

The morphology of the variant forms of nontumorigenic melanoma has been discussed. A tumorigenic vertical growth phase may develop in association with any of these to form a complex primary melanoma. In such cases, the histology shows a tumorigenic compartment adjacent to or within the confines of a nontumorigenic compartment. Nodular melanoma differs from these complex melanomas in that it is a tumorigenic melanoma with no clinically or histologically evident adjacent nontumorigenic compartment (410). The morphology of the usual or common forms of vertical growth phase are described later under "common forms of tumorigenic melanoma including nodular melanoma."

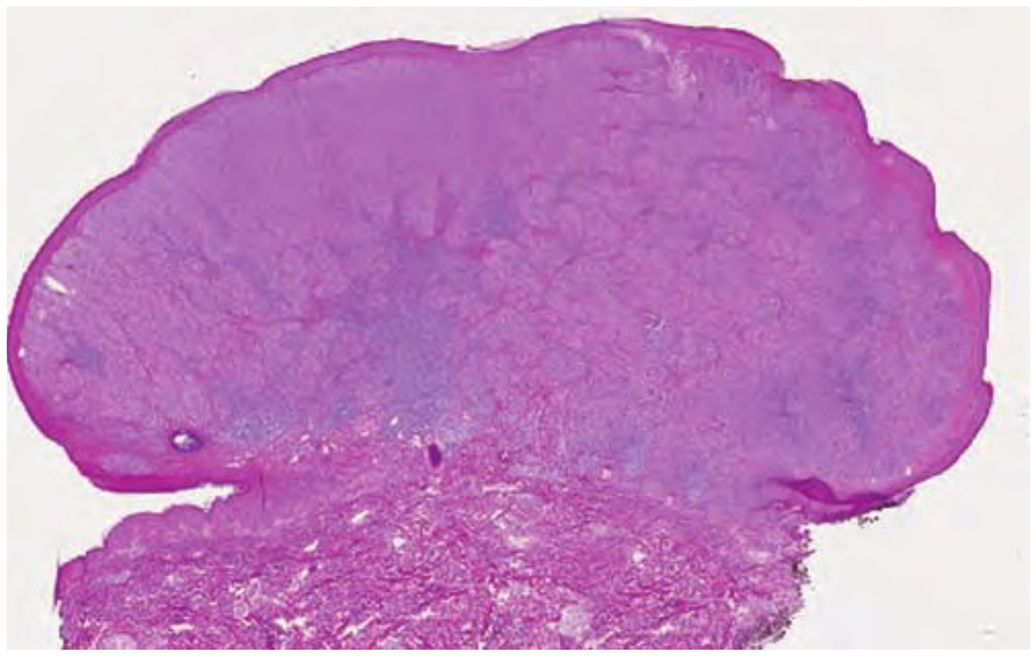
Occasional melanomas exhibit variant patterns that may lead to diagnostic confusion because they may be more characteristically seen in nonmelanocytic tumors. Several variants of melanoma deserve at least a brief description in the following sections: desmoplastic, neurotropic, polypoid, verrucous, balloon cell, signet cell, myxoid, so-called animal-type, nevoid, and minimal deviation melanoma. Other variants, which will not be described here, include small-cell, adenoid/papillary, and pleomorphic (fibrohistiocytic) melanomas (468), melanomas with rhabdoid cytoplasmic features (469,470), and the rare bone-forming or osteogenic melanoma (471).

Common Tumorigenic Melanoma Including Nodular Melanoma

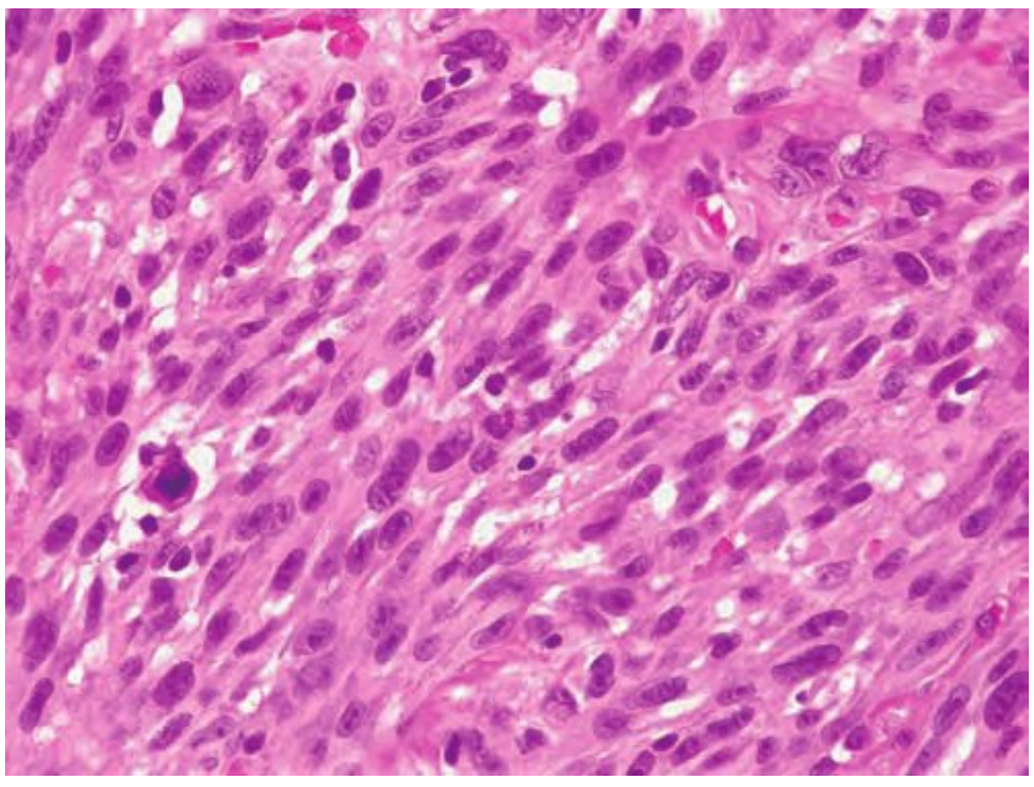
Nodular melanoma by definition contains only tumorigenic vertical growth (sometimes associated with a precursor) and, because of this, has a poorer prognosis on the average than superficial spreading melanoma. However, when other risk factors such as thickness are controlled, the prognosis of nodular melanoma is not worse than that of other forms of melanoma (472). Nodular melanomas occur in slightly older patients than the common superficial spreading melanoma and are relatively more frequent in men (410). A nodular melanoma starts as an elevated, variably pigmented papule that increases in size quite rapidly to become a nodule and often undergoes ulceration. Certain rare primary dermal melanomas comprised of cytologically malignant melanocytes and lacking an *in situ*

component may be considered also in this category (473). The ABCD criteria reviewed earlier do not apply to nodular melanomas, which often present clinically as quite small, symmetric, and well-circumscribed papules or nodules (Fig. 28-19C). These may be conspicuously pigmented, oligomelanotic, or even amelanotic. The tumorigenic nodule that may develop in nodular melanoma does not differ clinically or histologically from that which may occur in relation to a preexisting nontumorigenic melanoma. Indeed, nodular melanomas may represent examples of telescoped tumor progression in which the antecedent radial phase has been so short lived as to be unapparent (474). The clinical importance of the nodular subtype has been emphasized recently; these lesions are more likely to present at a biologically advanced stage despite a comparatively short clinical history (475,476). The mutation profile of nodular melanoma is closer to that of superficial spreading melanoma than to the other subtypes, in that BRAF or NRAS are commonly mutated (477).

Histopathology of Nodular Melanoma and Common Vertical Growth Phase (Tumorigenic Melanoma)



Architectural Features. In a typical tumorigenic melanoma, there is contiguous proliferation of neoplastic melanocytes in the dermis forming a tumor mass that is larger (usually much larger) than the largest nest in the overlying epidermis. Asymmetry is often apparent at the cytologic level as variation in cell size, shape, and pigmentation and in the distribution of the host response, such that one half of the lesion is not a mirror image of the other. However, the silhouette of the entire lesion may be quite symmetric, especially in a nodular melanoma that lacks an adjacent nontumorigenic component (Fig. 28-26A). Conversely, if a nontumorigenic radial-growth-phase compartment is present, asymmetry is likely to be more apparent at both the clinical and histologic levels. The tumor mass comprises uniformly atypical, cytologically fully malignant mitotically active cells usually growing in confluent nests or in sheets (Fig. 28-26B). Usually, the tumor mass fills and expands the papillary dermis (level III) or invades between coarse collagen fibers of the reticular dermis (level IV). Most level III melanomas and most melanomas greater than 0.75 mm in thickness are tumorigenic, whereas most level II or thin melanomas have no cluster in the dermis that is larger than the largest intraepidermal cluster and are therefore nontumorigenic. The epidermis is frequently ulcerated, or there is an adherent scale-crust. It is often stretched and attenuated in a phenomenon that usually does not occur in Spitz tumors and that has been termed consumption of the epidermis (188). Alternatively the epidermis may be irregularly hyperplastic and even show pseudoepitheliomatous hyperplasia, a pattern that has been termed verrucous melanoma (478).



Perhaps the best-known single criterion for melanoma is the upward pagetoid extension of tumor cells into the epidermis overlying the melanoma. However, this pagetoid melanocytosis or pagetoid spread is not specific for melanoma (152). Although in nodular melanoma, permeation of the epidermis with tumor cells may be absent or may be limited to that portion overlying the dermal tumor, lateral extension of melanoma cells in the epidermis and papillary dermis beyond the confines of the dermal tumor is seen in the adjacent nontumorigenic compartment of complex primary melanomas [SSM, LMM, acral-lentiginous melanoma (ALM)]. This phenomenon greatly aids in histologic recognition of these tumors, and, conversely, the recognition of nodular melanomas, which lack this adjacent component, may be difficult. For this reason, nodular melanoma may be difficult or impossible to distinguish from a metastatic melanoma in the skin, and when such a tumor is amelanotic, the distinction from other cutaneous neoplasms may be impossible without immunohistochemistry.

The amount of inflammatory infiltrate in tumorigenic melanomas varies. As a rule, early invasive malignant and many *in situ* melanomas show a bandlike inflammatory infiltrate, often intermingled with melanophages, at the base of the tumor. In tumors that extend deep into the dermis, the inflammatory infiltrate is quite variable, but it is often only slight to moderate rather than pronounced. Lymphocytes extending among tumor cells are often associated with morphologic evidence of damage to individual tumor cells (apoptosis). These tumor-infiltrating lymphocytes (TILs) have been shown to have independent favorable prognostic significance (472). The infiltrate is a predominantly T-cell response (479). TILs extracted from melanomas (mostly metastatic cases) may be cytotoxic and may be directed against immunogenic melanoma-associated antigens (480).

Cytological Features. The tumor cells in the dermis show great variation in size and shape. Nevertheless, two major types of cells can be recognized; an epithelioid and a spindle-shaped cell type. Many tumors show both types of cells, but usually one type predominates. Generally, the lentiginous forms of melanoma (e.g., LMM and ALM) tend to show a predominance of spindle-shaped cells in their invasive dermal components, whereas superficial spreading and nodular melanomas tend to be composed largely of epithelioid cells (472). The epithelioid type of cell tends to lie in alveolar or nested formations and the spindle-shaped type of cells in irregularly branching formations. The alveolar formations of the epithelioid cells are surrounded by thin fibers of collagen containing a few fibroblasts. Tumors in which spindle cells predominate may resemble sarcomas or other spindle cell tumors but in most cases differ from them by the presence of junctional melanocytic activity.

The uniformly atypical nuclei of the cells that constitute the tumor nodule are larger than those of melanocytes or nevus cells, with irregular nuclear membranes, hyperchromatic chromatin, and, often, prominent nucleoli that tend to be irregular in size, shape, and number. The atypia is considered to be uniform if more than 50% of the cells have these

A 

B 

C

FIGURE 28-26. A: Tumorigenic melanoma, nodular type (vertical growth phase without radial growth phase). The nodules of tumorigenic melanomas tend to be symmetric at scanning magnification, although there may be an uneven distribution of pigment and of the lymphocytic response within many of the lesions. When there is no adjacent nontumorigenic radial-growth-phase component, as here, the lesion is termed nodular melanoma. If a radial-growth-phase component is present, the melanoma is classified according to the type of that compartment [e.g., superficial spreading (or acral-lentiginous, etc.) melanoma with tumorigenic vertical growth phase]. B: The lesional cells of nodular melanoma exhibit severe uniform cytologic atypia, usually with readily evident mitoses. In any given high-power field such as this, the appearances are indistinguishable from those of a vertical growth phase associated with a superficial spreading, lentigo maligna, or acral-lentiginous melanoma or from those of a metastasis (compare Fig. 28-23B, panel B in the present figure, and Figs. 28-31C, 28-36, and 28-39B). C: Nodular melanoma, S100 immunohistochemical stain. The brown reaction product in the lesional cells is striking, even at scanning magnification. Note the absence of S100-positive lesional cells in the adjacent skin.

characteristics, but more often than not, all or most of the cells are atypical. In addition to this uniform moderate or severe cytologic atypia, there is also a diagnostically important failure of the melanocytes in the deeper layers of the dermis to decrease in size (absence of maturation) (Fig. 28-21). This must not be confused, however, with the presence of an intradermal nevus beneath a melanoma, a fairly common feature. Not uncommonly, melanoma cells will recapitulate nevic cell maturation (so-called pseudomaturation), but in these instances the smaller cells at the base retain nuclear characteristics of malignant cells, and there will be cytologic continuity between these nevoid cells and the overlying more atypical lesional cells.

Mitotic figures are usually present in the lesional cells of the dermal and epidermal compartments of tumorigenic melanomas [they are present in the epidermal lesional cells in about one third of nontumorigenic melanomas and in the dermal compartment of 85% of tumorigenic melanomas (472,481)] (Fig. 28-23). Mitoses may also be seen in adjacent hyperplastic keratinocytes. The nuclei of these hyperplastic epidermal keratinocytes may be enlarged with prominent nucleoli, although they are not irregular or hyperchromatic. In contrast, mitotic figures are rarely seen in

benign nevi other than Spitz nevi, and even in the latter lesions the rate is usually low or zero (179).

Differential Diagnosis. Great difficulty may be encountered in the differentiation of a nodular melanoma from an atypical dermal or compound nevus. The actual incidence of a wrong diagnosis is not inconsiderable, judging from the frequency with which pathologists disagree in their opinions. When there is doubt, the uncertainty should be acknowledged and the differential diagnosis should be clearly indicated so that appropriate therapeutic intervention can be planned. Incisional biopsies are a common source of interpretive difficulty. The site of melanocytic lesions that have been partially removed by shave or punch biopsy should be excised to assure complete removal if there is any doubt at all about the diagnosis.

The most important attributes that differentiate the tumorigenic vertical growth phase of melanoma from nevi include *asymmetry*, *lack of maturation* of lesional cells with descent into the dermis, *mitotic activity*, and *uniform cytologic atypia*. Apoptotic tumor cells, which often accompany mitotically active lesions, may also be of assistance.

Considerations in the important distinction between thin melanomas and dysplastic nevi are discussed in the section Dysplastic Nevus and are presented in Table 28-5. The most important differential diagnostic consideration for nodular melanoma is the Spitz nevus. The criteria for this distinction are presented in Table 28-3 and discussed in the section Spitz Nevus.

In some instances, it may be difficult to recognize a highly undifferentiated melanoma as such. The specific identification of a tumor as melanoma depends on the identification of melanin or on appropriate immunohistochemical reactivity in an appropriate setting. The amount of melanin present varies greatly in melanomas. In some tumors, considerable melanin is found not only within the tumor cells, but also within melanophages located in the stroma. In others, there may be no evidence of melanin in hematoxylin-eosin stains. However, a Fontana-Masson silver stain usually reveals at least a few cells containing melanin (482). Some melanomas are completely devoid of pigment (amelanotic melanoma). Although amelanotic melanomas tend to be aggressive lesions, the prognosis is not different from that of pigmented melanomas when other staging and microstaging attributes are taken into consideration (483). If appropriate tissue is available, the DOPA reaction may be positive in at least part of the tumor (484), and electron microscopy shows some melanosomes and premelanosomes in nearly all cases (468,482,485). However, in practice, these methods have been largely supplanted by immunohistochemical techniques (468,482).

Immunohistochemistry. Most of the problems in distinguishing amelanotic or oligomelanotic tumorigenic melanomas from other tumors can be resolved by immunohistochemistry, using a panel of antibodies including S100, HMB-45, keratin (low and intermediate molecular weight such as AE1/3), and leucocyte common antigen (LCA) (43,486–489). On immunohistochemical testing, S100 protein is nearly always positive in melanoma (489). A keratin stain should be done in addition to staining for S100 protein to rule out not-uncommon S100-positive carcinomas (490). A few studies have reported positive keratin reactivity in melanomas, but this is unusual when standard methods are used in paraffin sections (490–492). Reactivity of melanomas, mostly metastatic, has been described with polyclonal but not monoclonal carcinoembryonic antigen, and occasional melanomas react with the epithelial marker epithelial membrane antigen (492). Melanomas, unlike most carcinomas, express vimentin, an intermediate filament that is usually associated with mesenchymal tissues (493). Lymphomas are usually positive with LCA, whereas S100 and HMB-45 are negative. The anaplastic large cell type of non-Hodgkin's lymphoma, which could present primarily in the skin, is quite likely to be confused with melanoma, and these tumors are usually positive for the CD30 (Ki-1) antigen, as well as LCA (CD45) (494). Occasional examples of histiocytic tumors such as epithelioid histiocytomas or juvenile xanthogranulomas may be confused with nodular melanomas, especially when foam cells or Touton giant cells are inconspicuous (219). It has been concluded that Melan-A and tyrosinase markers are sensitive and specific in making the diagnosis of a melanocytic lesion (222).

Several more specific but less sensitive antigens, of which the antigen recognized by HMB-45 (gp100) is prototypic, are used in addition to S100 in making the distinction between melanoma and nonmelanoma tumors. Like S100, HMB-45 is positive in many benign melanocytic tumors, and thus it is not specific for melanoma. Its sensitivity of about 70% overall is less than that of S100, for which the sensitivity is close to 100% but the specificity is low (490,491). HMB-45 expression is generally negative in desmoplastic and to a lesser extent other spindle cell melanomas (495). The specificity of the HMB-45 antigen depends on the context in which it is used. Benign melanocytic lesions that may react with HMB-45 include the junctional component of most nevi and the dermal components of dysplastic nevi, blue nevi, cellular blue nevi, deep penetrating nevi, and Spitz nevi. Thus, HMB-45 cannot be used to distinguish benign from malignant melanocytic neoplasms. If, on the other hand, the diagnostic differential is between melanoma and carcinoma, lymphoma, or sarcoma, the diagnostic specificity of a positive test is very high, albeit not 100%.

Use of HMB-45 has been augmented and in some institutions supplanted by other markers. Melan-A (MART-1) is an antigen initially recognized by T cells in melanoma patients, and, like HMB-45, is associated with the pigmentary apparatus. The sensitivity of this antigen is somewhat greater than that of HMB-45, and its specificity is about the same. The Melan-A antibody labels reactive cases strongly and clearly but is less sensitive in spindle cell melanomas and usually negative in the spindle cells of desmoplastic melanomas (488,496). It also must be noted that although Melan-A has more specificity than HMB-45 for detecting cells of melanocytic lineage, it also reacts with normal melanocytes and with nevus cells, limiting its utility as a potential marker for malignancy. Other markers

that have been studied recently include the melanoma-associated antigen (MAGE) series (497), microphthalmia-associated transcription factor (MITF) (498–500), and others. In a recent study, Xu et al. evaluated reactivity for alternative markers in 14 HMB-45–negative, nondesmoplastic melanomas (501). Melanocyte-specific transcription factor was positive in 9, Melan-A in 9, tyrosinase in 6, and MAGE-1 in 11. In 8 desmoplastic malignant melanomas, MAGE-1 was positive in 3, and all other markers were negative. The five markers tested were negative in all but two schwannomas, one with focal melanocyte-specific transcription factor and the other with tyrosinase and weak MAGE-1 reactivity. It was concluded that MAGE-1, melanocyte-specific transcription factor, tyrosinase, and Melan-A may be useful markers in the diagnosis of malignant melanocytic lesions when HMB-45 is negative (501).

In another study, a "panmelanoma cocktail" composed of HMB-45, MART-1, and tyrosinase labeled 98% of all melanomas but only 60% of desmoplastic melanomas, all of which were positive for S100. The panmelanoma cocktail is more specific than S100 and might be considered as a complementary marker to polyclonal S100 antibody, except for desmoplastic melanoma (502).

The markers discussed in the foregoing provide little information as to the benign or malignant nature of a lesion. However, the pattern of staining with HMB-45 can be of some assistance: melanomas tend to have more diffuse staining, whereas staining in benign lesions tends to be top-heavy, no doubt reflecting a form of maturation or senescence (503). In addition, the S100 subunit S100A6 has been of some use in distinguishing between Spitz tumor and melanomas, with a strong and diffuse staining pattern favoring the former (204). Finally, proliferation markers as well as other nuclear markers such as p53 (504), cyclin D (505), ploidy markers (506), and structures called nuclear organizer regions have been advocated (394). The most useful of these is Ki-67 (Mib-1). A high Ki-67 rate of, say, 10% or more of reactive cells would favor a malignant diagnosis, whereas a low rate of 2% or especially zero activity would favor a benign diagnosis (507). In our experience, although we often order a Ki-67 study to assess proliferative activity, most diagnostically equivocal tumors fall into the gray zone of Ki-67 reactivity between these cut-points. Other markers have not been studied in sufficient detail for us to recommend their use.

Desmoplastic and Neurotropic Melanoma

Desmoplastic melanomas present attributes of melanocytic, fibroblastic, and schwannian differentiation, often mixed within a single lesion (508). The lesions occur on chronically sun-damaged skin, usually in elderly patients. The lower lip is a relatively common site, sometimes in younger patients (509). Other cases occur, often in relation to lentiginous melanomas, in acral and mucosal sites (510–514). In a large series of 280 cases, the male-to-female ratio was 1.75:1, and the median patient age was 61 years. The median tumor thickness was 2.5 mm, and 44% of cases were amelanotic. Five-year survival was 75%. Significant predictors of overall survival were a high mitotic rate and tumor thickness. All of the desmoplastic melanomas exceeded 1.5 mm in thickness and were Clark level IV or V. There was a significant increase in local recurrence when neurotropism was present. The rate of local recurrence was not higher for desmoplastic melanoma than for other cutaneous melanomas (515).

Desmoplasia is most often seen in a spindle cell vertical growth phase of lentigo maligna melanoma (516) or acral-lentiginous melanoma (454,517). However, desmoplastic changes can be seen occasionally in tumors with rounded or undifferentiated melanoma cells. The collagen in desmoplastic melanomas is arranged as delicate fibrils that extend between the tumor cells and separate them from one another. The relationship between tumor cells and stroma is thus similar to that seen in sarcomas, in contrast to most melanomas, in which an epithelial pattern of collagen fibers surrounding groups or clusters of tumor cells may be demonstrated, for example, with a reticulin stain. Of interest, neurotized nevi may also show the pattern of individual cells surrounded by collagen that characterizes desmoplastic melanomas, and the arrangement of the cells of desmoplastic melanomas in wavy fiber bundles comprised of S-shaped or serpentine cells may also recall the schwannian patterns of neurofibromas, neurotized nevi, and malignant schwannomas.

Histopathology. In desmoplastic melanoma, scanning magnification usually demonstrates an alteration of the architecture of the dermis, which may be subtle or more prominent. Frequently, this alteration extends throughout the full thickness of the reticular dermis into the fat. Typically, nodular clusters of lymphocytes and occasional plasma cells are present in the tumor or at its periphery, serving as a valuable scanning magnification clue (Fig. 28-27A). At higher magnification, the melanoma cells are usually elongated and amelanotic and are embedded in a markedly fibrotic stroma, so that it is often difficult to decide which are fibroblasts and which are melanoma cells. This problem is enhanced by the relative absence of nuclear atypia in many of the neoplastic spindle cells, although close scrutiny will usually reveal cells with nuclear hyperchromasia and contour irregularities not typical of resting or activated benign mesenchymal cells (Fig. 28-27B). Because of the frequent absence of melanin, differentiation from a fibrohistiocytic or a neural lesion may be difficult. Staining with S100 protein antibody usually marks many of the spindle-shaped cells, indicating that they are not fibroblastic (Fig. 28-27C) (518), but nevi, neurofibromas, and neurogenic sarcomas are also typically S100 positive. The HMB-45 or Melan-A antigens are usually not demonstrable in the spindle cell compartment of desmoplastic melanomas, but they may be focally demonstrable in superficial dermal or *in situ* epithelioid melanocytes (Fig. 28-27D). Indeed, Melan-A reactivity in a spindle cell lesion (in the spindle cells themselves) may be taken as evidence against the diagnosis of a desmoplastic melanoma (24). Similarly, HMB-45 reactivity would also support a diagnosis of a deep spindle cell proliferation other than desmoplastic melanoma (e.g., a relatively amelanotic blue

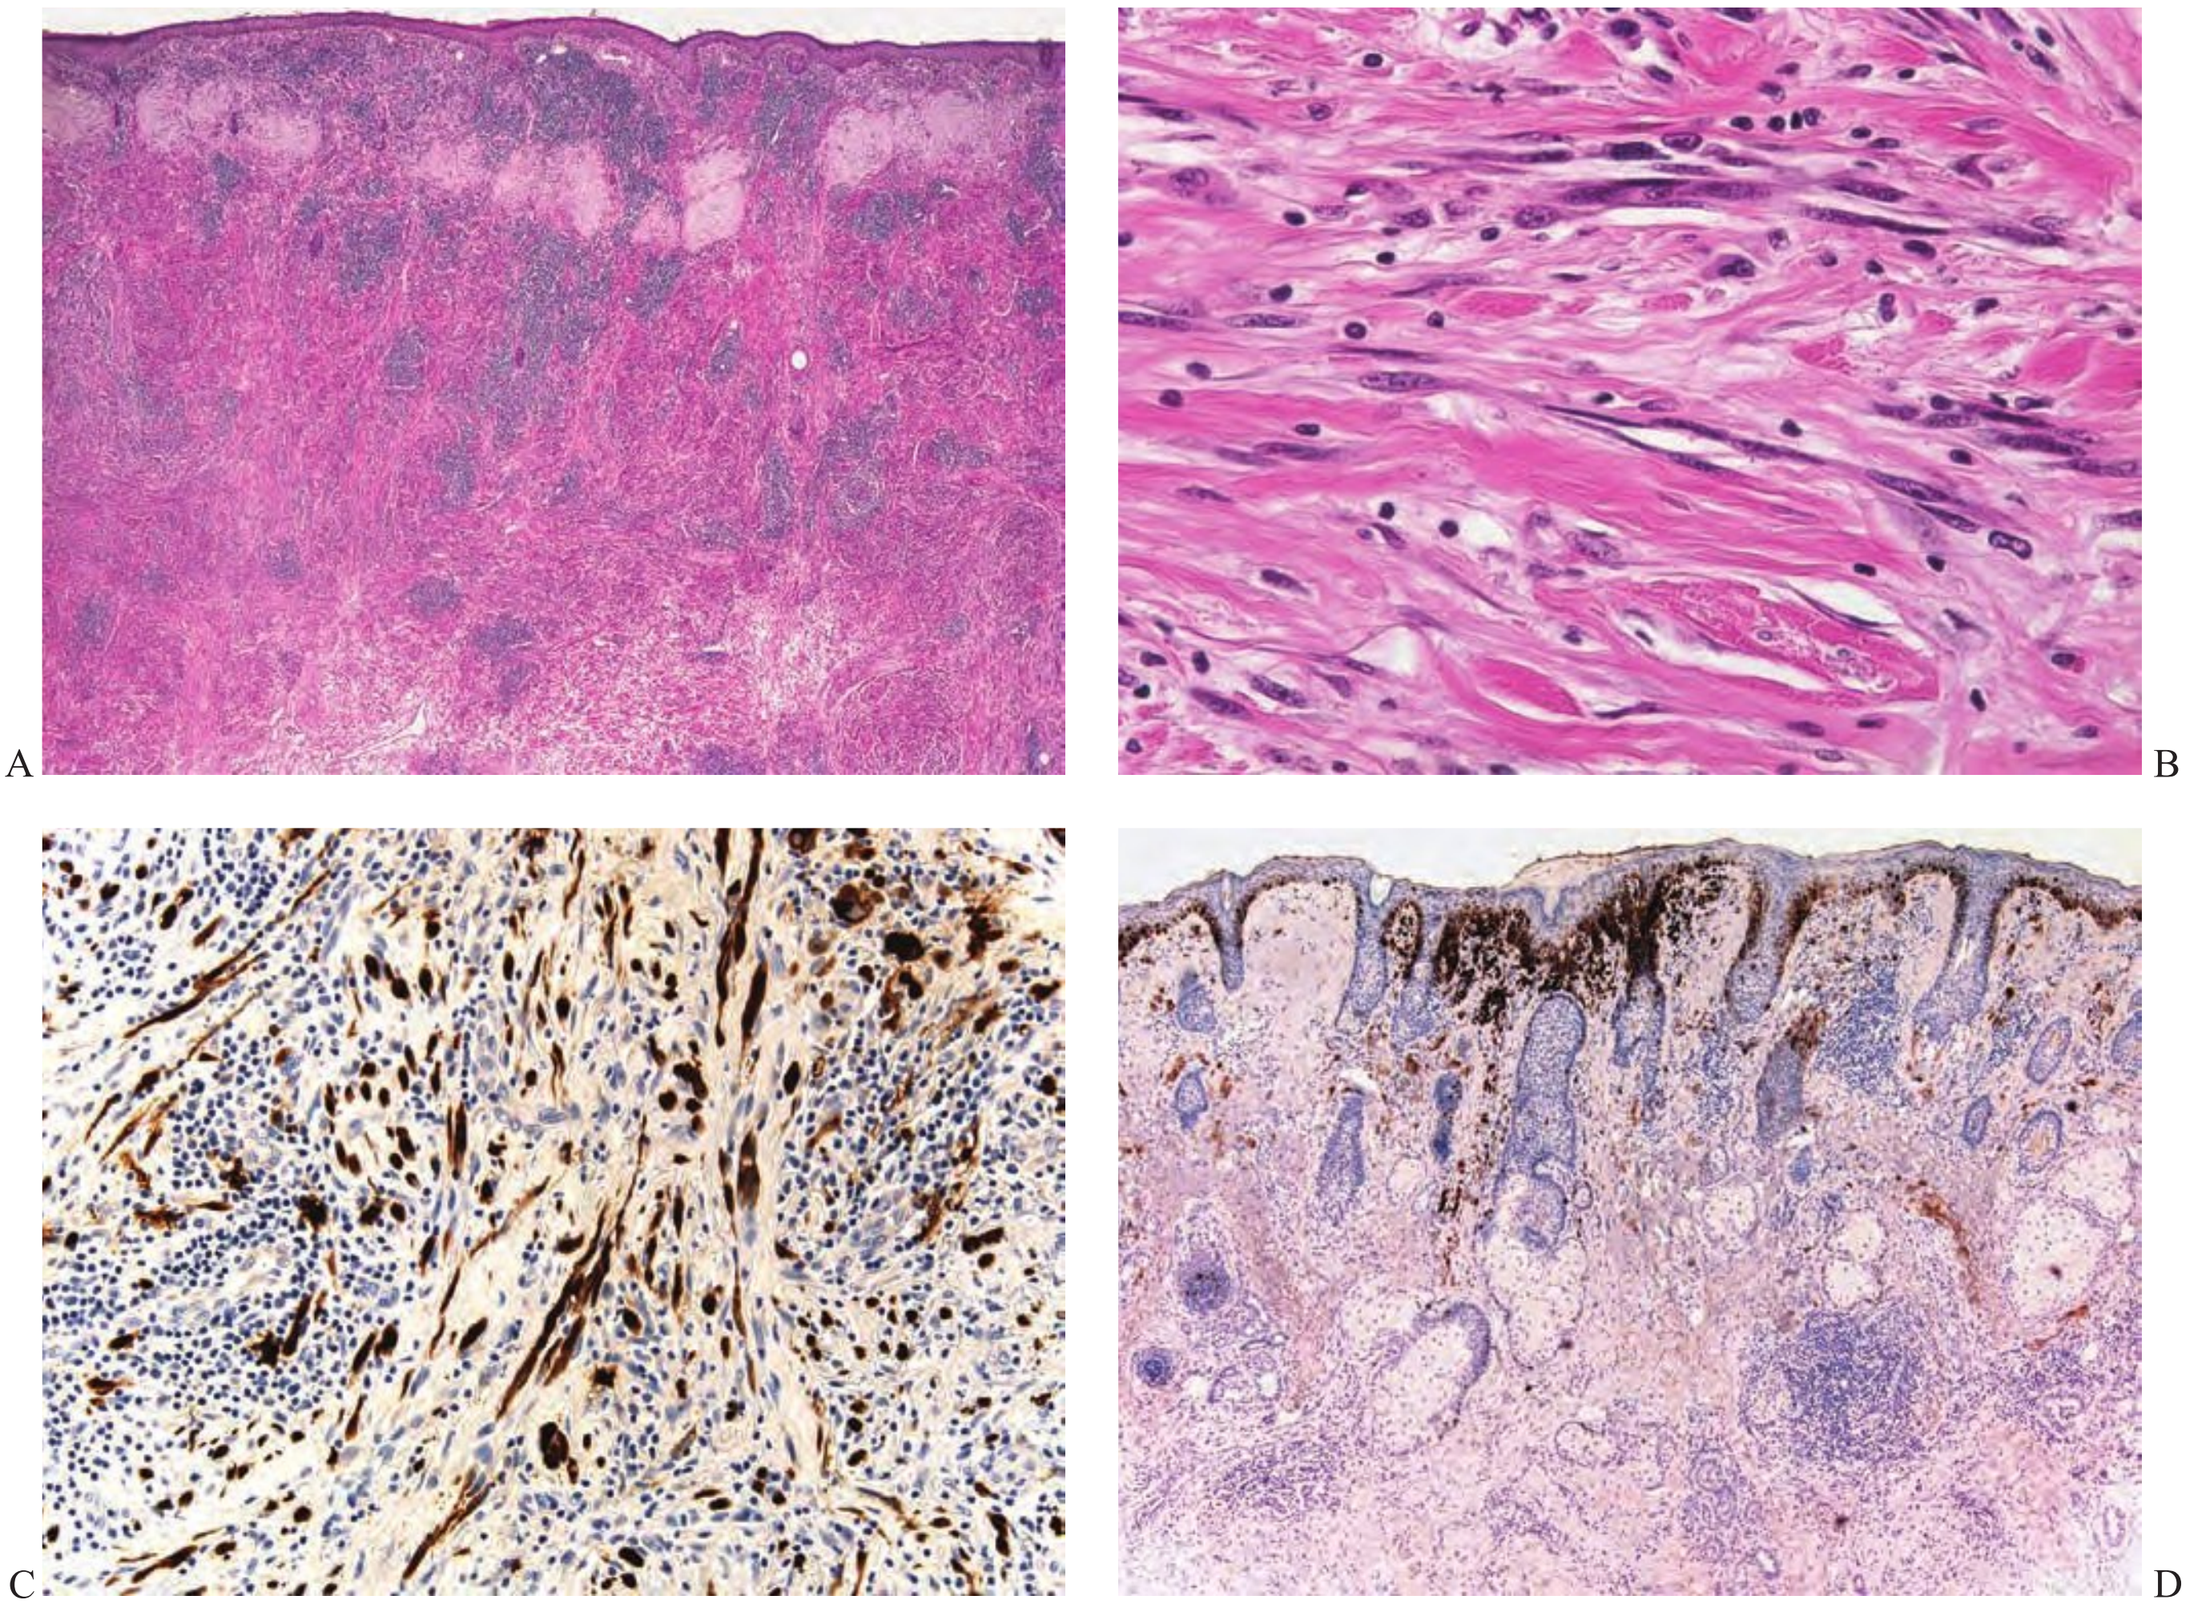


FIGURE 28-27. A: Desmoplastic melanoma. At scanning magnification, the architecture of the reticular dermis is altered by a cellular infiltrate including nodule clusters of lymphocytes, appearances that can simulate an inflammatory infiltrate. B: Desmoplastic melanoma. Atypical spindle cells arranged in loose fascicles extend into the deeper dermis and subcutis, beneath the epithelioid cell component. This subtle proliferation is easily overlooked, resulting in potential "undercalling" of the diagnosis and microstage. C: Desmoplastic melanoma. The spindle cells are S100 positive. S100 stain is of great value in delineating the boundaries of desmoplastic melanomas but should be interpreted cautiously because it is not specific for melanoma cells. D: Desmoplastic melanoma. An immunohistochemical study for Melan-A focally stains the in situ and superficial dermal epithelioid cell component of the melanoma. The deeper spindle cells are uniformly negative.

nevus). The distinction from a *neurogenic sarcoma* may be very difficult or impossible in such cases when there is no pigment and there is no characteristic superficial radial growth phase component (519) . Some of these lesions might alternatively be regarded as *superficial malignant epithelioid schwannomas*. The prognostic implications are similar, whichever diagnostic term is used. When such a lesion is marked by strong and diffuse S100 positivity, we usually make a diagnosis of desmoplastic melanoma, even in the absence of an *in situ* component or pigment. Desmoplastic melanomas have been shown to produce fibrogenic cytokines, neurotrophins, and neurotrophin receptors, which together can account for their desmoplastic and neurotropic propensities (520–522). Occasionally lesions termed *osteogenic desmoplastic melanoma* have been described and may be difficult to differentiate from an osteosarcoma (523). Aside from the diagnostic challenges posed by these differentiation patterns, such lesions may provide evidence of the inherent plasticity of a subpopulation of melanoma stem cells that drives the tumorigenic potential of advanced lesions.

Although the reported survival rate for desmoplastic melanoma in the early literature was poor, this is likely because many of these cases had already recurred at the time the diagnosis was made. A report of a series of desmoplastic melanomas that had been prospectively diagnosed and definitively treated

at their initial presentation showed that the survival rate was no different than for usual forms of melanoma when thickness, mitotic rate, host response, and other risk factors were controlled. Indeed, the probability of survival is relatively good for prospectively diagnosed and definitively treated desmoplastic melanoma because, despite the considerable thickness of many of these lesions, the prognostically important mitotic rate and lymphocytic responses are often favorable (414). In a recent report, expression of N-cadherin was correlated with a worse prognosis (524). By routine histology, desmoplastic melanomas have been classified into two types: Pure desmoplastic melanomas are characterized by predominant fibrosis and have a better 5-year survival of 90% compared to 70% in mixed tumors, in which fibrosis was well developed only in parts of an otherwise nondesmoplastic (i.e., epithelioid) melanoma (525). In a comparative study, whereas desmoplastic melanomas were more locally aggressive than thickness-matched controls, positive sentinel nodes were limited to patients with thick primary tumors, and survival rates were similar to those for patients with other melanomas of similar thickness (526).

Neurotropic melanoma is often a variant of desmoplastic melanoma (515,519,527–530). There are fascicles of spindle cell melanoma that have invaded cutaneous nerves, often extending within the fiber itself (endoneurial invasion) as opposed to the perineural invasion that is more characteristic of neurotropic carcinomas. The involvement of nerves may therefore be quite subtle, with the first clue being the impression of slight hypercellularity within a given nerve branch. The neurotropism usually occurs in association with a spindle cell vertical component with fibrosis (Fig. 28-28). However, some neurotropic melanomas lack these latter features of desmoplastic melanoma. Many of these are spindle cell tumorigenic melanomas of acral-lentiginous or lentigo maligna type, but some are composed of epithelioid cells. Desmoplastic and spindle cell melanomas tend to express a high level of p75 neurotrophin receptor antigen, as well as other neurotrophins and their receptors, which may contribute to the high predisposition for perineural extension in the desmoplastic subset of spindled melanomas (521,522) and could be useful in diagnosis. Neurotropism in a primary melanoma is associated with increased risk for local recurrence, even after standard definitive therapy, and may also be associated with increased mortality (414).

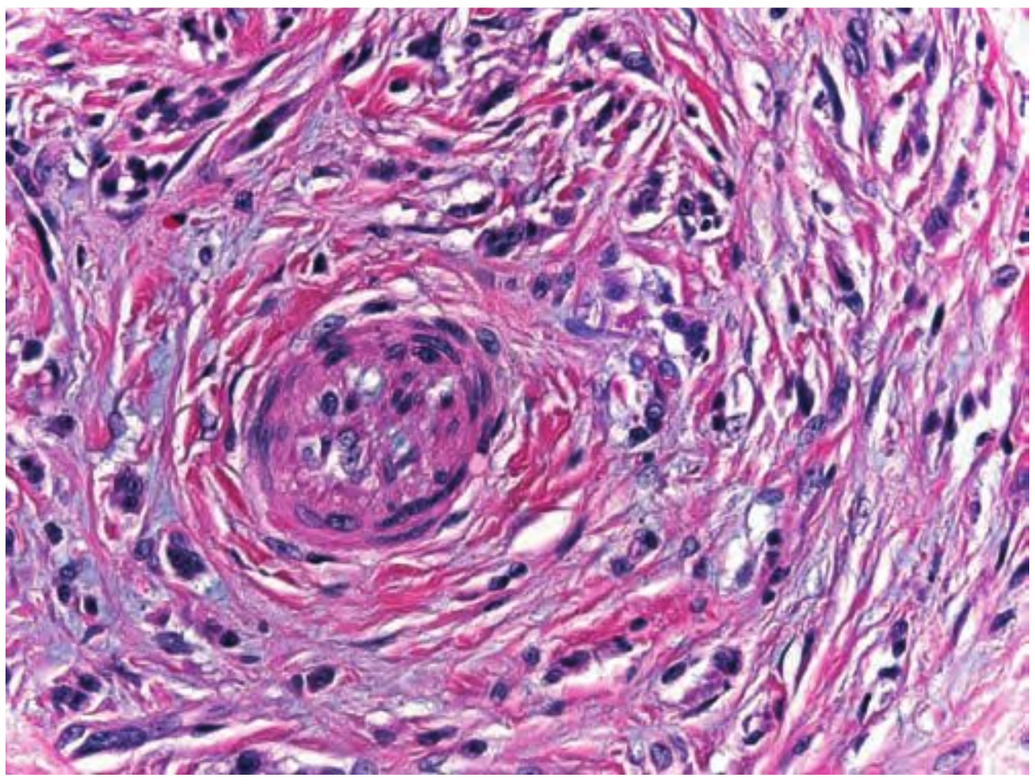

FIGURE 28-28. Neurotropism in a desmoplastic melanoma. A nerve in the center of the image contains atypical neoplastic spindle cells both in the nerve itself (endoneurial invasion) and in the perineurium (perineural invasion). The adjacent stroma contains neoplastic spindle cells separated by desmoplastic stroma.

Reexcision Specimens. Evaluation of reexcision specimens for desmoplastic and neurotropic melanomas can present considerable difficulties. S100 staining can be useful, but it has been demonstrated that S100-positive cells may be present in benign scars (531–533). It is important that these procedures encompass a margin of normal tissue around the scar, both for completeness of excision and because of the difficulty of excluding subtle melanoma involvement of the scar. In this regard, it is helpful to remember that residual melanoma is likely to present at the periphery of the scar and to infiltrate normal tissue adjacent to it. The specimens should be carefully coated with India ink or colored dyes, and the inked margin should be carefully scrutinized for residual invasive melanoma and for subtle neurotropic involvement of small nerves. A clue to the presence of melanoma, both in nerves and in the stroma, is the presence of clusters of lymphocytes, which sometimes may almost completely obscure the tumor cells themselves. Moreover, persistent S100-positive spindle cell melanoma cells tend to occur in small clusters and fascicles rather than as single, often dendritic cells, as is the case with S100-positive dendritic cells of hematopoietic lineage that may be detected in scar tissue.

Immunohistochemistry. As previously discussed, desmoplastic and to a somewhat lesser extent other spindle cell melanomas tend to differ from the more common epithelioid cell melanomas in their immunohistochemical reactivity. Although S100 is almost always positive, the more specific markers such as HMB-45 and Melan-A/MART-1 are usually negative, except for occasional reactivity of a minor epithelioid cell component that is sometimes present in the epidermis or superficial dermal component of the neoplasm (Fig. 28-27D). In a study of 20 desmoplastic melanomas, all 20 were positive for S100 protein, 7 were positive for MITF, 6 for HMB-45, and 11 for tyrosinase (500). In another study, only 4 of 13 spindle cell and desmoplastic melanomas (all positive with anti-S100 and negative with HMB-45) were immunoreactive with Melan-A/MART-1 (2 focally, 2 diffusely) (488). Thus, S100 reactivity is of key importance in distinguishing these tumors from fibroblastic lesions. However, it is of no use in the distinction from neural tumors or from desmoplastic nevi. In contrast, Melan-A/MART-1 reactivity is usually present in desmoplastic nevi, including sclerotic blue nevi, and such reactivity may be very helpful in ruling out a desmoplastic melanoma in some such lesions (26), although not pathognomonic.

Differential Diagnosis. It is very important to differentiate desmoplastic melanoma from benign conditions, including benign melanocytic and neural tumors, fibrous and fibrohistiocytic tumors, and other spindle cell malignancies. Neurotized nevi and neurofibromas share serpentine spindle cell and wavy fiber bundle patterns of schwannian differentiation with desmoplastic melanomas but lack an *in situ* melanoma component and lack atypia and mitotic activity, as well as lymphocytic infiltrates, in the dermal component. According to a study by Harris et al., similarities between desmoplastic nevi and desmoplastic melanomas included the presence of atypical cells and HMB-45 expression in the superficial portion of the lesions (196). The infrequent location on the head or neck, the absence of mitotic figures, a significantly lower number of Ki-67–reactive cells, and the presence of HMB-45 expression in the deep area of the lesions helped to distinguish desmoplastic nevi from desmoplastic melanoma (196). The diagnosis of desmoplastic melanoma should be made with great caution if the dermal spindle cell component is positive for Melan-A (24). Fibrous tumors such as connective tissue nevi (534) or cellular dermatofibromas can be distinguished by immunohistochemical studies, including negative S100 staining. Other considerations include low-grade malignancies such as fibromatoses and dermatofibrosarcoma protruberans and fully malignant lesions such as leiomyosarcoma and malignant schwannoma. The latter group of lesions may overlap biologically as well as morphologically, and their management is the same, namely complete excision and follow-up. Because spindle cell melanomas may be confused with other malignant spindle cell neoplasms (e.g., malignant tumors of neural cells, smooth muscle, fibrohistiocytic cells, and spindle cell variants of squamous cell carcinoma), particularly when careful search fails to reveal evidence of *in situ* growth, immunohistochemical screening by the panel approach is recommended in such instances. Rarely, spindle cell melanomas may form vessel-like structures and, when such lesions occur on the scalp of elderly individuals, produce confusion with angiosarcoma. Immunohistochemical identification of S100 protein and exclusion of CD31 endothelial reactivity may be helpful in such instances (535). Misdiagnosis of desmoplastic melanomas as one or another of the benign lesions listed is not uncommon because attributes of malignancy such as anaplasia or frequent mitoses are often not prominent features of desmoplastic melanomas. The large size and asymmetric silhouette of many of these lesions differ from what is seen in most benign lesions. An important, sometimes subtle clue to the diagnosis at low power is the frequent presence of a lymphocytic infiltrate, distributed as nodular aggregates of infiltrating lymphocytes throughout the tumor, which are not seen in neurofibromas, nevi, or most fibrohistiocytic lesions. Lymphocytes may also be clustered about nerves involved by tumor cells in neurotropic melanomas. Other helpful diagnostic attributes, which may not be readily evident unless sought because of a high index of suspicion, include the presence of an atypical intraepidermal melanocytic component, which may be subtle and not always diagnostic of frank melanoma, and usually the presence on diligent search of at least a few mitoses in the dermal component of the lesion.

Polypoid Melanoma

Also termed pedunculated melanoma, this term designates a melanoma that presents as a protruding nodule connected to the underlying skin by a pedicle or stalk (536). The surface of the nodule often shows erosion or ulceration (537). Because these tumors are bulky, the prognosis is often poor but probably not worse than predicted by other risk factors (538). By convention, polypoid melanomas, even when the greatly expanded papillary dermis is not filled, are considered to represent level III invasion unless tumor cells extend into the reticular dermis (level IV).

On histologic examination, the nodule is filled with melanoma cells, whereas the underlying stalk or pedicle may be free of tumor cells and in other cases the tumor may infiltrate the pedicle and the dermis adjacent to the pedicle.

Verrucous Melanoma

These melanomas present as a markedly hyperkeratotic, tumorigenic nodule that may simulate a verruca, verrucoid benign keratosis, or a verrucous carcinoma clinically (408,434,478,539,540). Histologically as well, the lesions are associated with marked keratosis and verrucous hyperplasia of keratinocytes that may assume pseudoepitheliomatous proportions and raise a question of squamous cell carcinoma unless the underlying neoplastic melanocytes are appreciated (541). Some other lesions are misdiagnosed histologically as benign nevi or seborrheic keratoses (478), highlighting the potential importance of histologic sampling of changing or symptomatic nevic or keratosis-like lesions. Verrucous changes of adjacent keratinocytes are sometimes observed adjacent to acral and especially subungual melanomas, which are often mistaken clinically for warts on initial presentation if pigment is not prominent. In such instances, an inadequate biopsy that does not include the underlying neoplasm could appear to be consistent with a wart.

Balloon Cell Melanoma

Usually in addition to more characteristic melanoma cells of the epithelioid type, some melanomas contain aggregates of "balloon cells" (542). These balloon cells, characterized by their abundant, clear cytoplasm, may show relatively little nuclear atypia and thus may resemble those seen in a balloon cell nevus. The clear cytoplasm is the result of vacuolar degenerative alterations affecting melanosomes and may expand the cytoplasm in a manner that compresses the nucleus, partially obscuring its size and cytologic features helpful in identifying a malignant phenotype. However, the overall architecture of the lesion and the presence of at least foci of detectable cytologic atypia, usually with mitotic activity, identify the tumor as a melanoma. Immunohistochemistry (Melan-A, HMB-45, and/or tyrosinase reactivity) may sometimes be required to distinguish the lesions from other clear cell or foamy tumors, such as renal cell carcinoma or xanthoma, respectively (543).

Transitions from the melanoma cells to balloon cells are usually seen. The metastases of a balloon cell melanoma may or may not be composed largely of balloon cells, and balloon cell metastases have been described from a melanoma that did not contain them in the primary tumor (544). In addition, a metastatic balloon cell melanoma has been described in the absence of a known primary (545). Thus, this possibility should be considered in the differential diagnosis of metastatic clear cell tumors. The cells exhibit immunopathologic reactivity characteristic of melanoma.

Signet Cell Melanoma

Melanomas that contain prominent signet-ring cells may be confusing and must be distinguished from adenocarcinomas, tumors of vascular endothelium or adipose tissue, lymphomas, and epithelioid smooth muscle tumors (546–548). The signet cell morphology may be recognized in the primary tumors or only in metastatic sites. Similar cells may be seen in benign nevi, and a somewhat similar change may also occur as a result of freezing artifact (547). Immunohistochemistry may be used to confirm the diagnosis of a melanocytic lesion and rule out competing possibilities. In evaluating these results, it should be recognized that expression of both carcinoembryonic antigen (only seen using polyclonal antibodies) (549,550) and keratin (492) has been described in melanomas.

Myxoid Melanoma

A histologic pattern of prominent myxoid stroma has been described in some primary and metastatic melanomas (551,552). In addition, a myxoid clear cell sarcoma has been described (553). The differential diagnosis may be very broad, including lipoblastic, myoblastic, fibroblastic, neurogenic, or chondroblastic tumors with myxoid stroma (551). If the diagnosis is suspected, immunohistochemistry can be done to support the diagnosis. Fontana stain may reveal melanin pigment, and electron microscopy in a few cases has shown melanosomes.

Animal-Type Melanoma (Macrophagic Melanoma)

Rare tumors comprised of asymmetric, predominantly dermal nodules of heavily pigmented cells mimic melanocytic neoplasms seen in horses and laboratory animals and thus have been termed animal-type melanomas (554). The tumor cells are heavily stuffed with melanin granules, often obscuring the nucleus, and for this reason the tumors have been referred to as "melanophage-like" (555). Behavior of these lesions is unpredictable. In two published series totaling 20 cases (554,556), the lesions were described as blue-black nodules with irregular borders from 1.0 to 4.0 cm in size located on the scalp, lower extremities, back, and sacrum. Sections showed confluent dermal sheets of round or short, spindle-shaped, heavily melanized cells whose nuclei, where discernible, were large with irregularly thickened membranes, coarse, somewhat hyperchromatic chromatin, and prominent, often spiculated nucleoli. Mitoses were infrequent. Four lesions had an epidermal component. One patient suffered metastases to regional lymph nodes, liver, and lungs with lethal effect, whereas all of the others were alive with variable follow-up, despite 5 of them having regional lymph node metastases, 1 having hepatic metastases, and 3 having local satellite metastases. In a more recent study of 14 cases, the term pigment-synthesizing melanoma was suggested for these lesions, which were considered to be a distinctive, possibly low-grade form of melanoma (556).

Pigmented Epithelioid Melanocytoma

This is a recently described melanocytic tumor that may resemble and thus encompass animal-type melanoma, as well as epithelioid blue nevi as seen in the Carney complex and some cellular blue nevi (557). This lesion is considered to represent a distinctive tumor that affects males and females equally, with a median age of occurrence of 27 years (range 0.6 to 78 years). Multiple body sites may be affected, with extremities being the most common. Histologically there is a deep dermal nodule of heavily pigmented epithelioid and/or spindled melanocytes (Fig. 28-29), and some lesions occur in association with combined nevi. Ulceration may be present in occasional lesions, a finding generally not present in epithelioid blue nevi. These lesions may be identical to animal-type melanoma, and, in this study, also may be difficult to distinguish from some epithelioid blue nevi. Although tumor cells may be deceptively bland and mitoses and necrosis inconspicuous or absent, regional lymph node involvement has been seen in 46% of cases studied. However, there were no deaths. Metastases were not observed in the cases of epithelioid blue nevi seen in association with the Carney complex, which is a multiple neoplasia syndrome featuring cardiac, endocrine, cutaneous, and neural tumors, as well as a variety of pigmented lesions of the skin and mucosae including lentigines, epithelioid blue nevi, and psammomatous melanocytic schwannoma (558). Extranodal spread is rare in pigmented epithelioid melanocytoma, and even with involvement of draining lymph nodes, the clinical course may be remarkably indolent. Similar lesions have been recently designated as pigment-synthesizing melanomas and regarded as a low-grade form of melanoma that may lack some of the signs of more aggressive melanomas of similar bulk, such as frequent mitoses, ulceration, and high-grade atypia (556). Further study with extended outcome analyses of animal-type melanoma, epithelioid blue nevi, and their relationship to the category of pigmented epithelioid melanocytoma is indicated to clarify the biological potential of this difficult category of melanocytic neoplasms.

Minimal Deviation Melanoma

Recognized by only some authors, this lesion is referred to as borderline type when it is limited to the papillary dermis and as minimal deviation type when it extends into the reticular dermis (232,559). These tumors are considered to exhibit less cytologic atypia than the common forms of melanoma, although the architectural characteristics of melanoma are usually present. Accordingly, they may be considered to show morphologic overlap between an atypical nevus and a melanoma with fully evolved anaplasia. The lesions in their vertical phase consist of uniformly expansile nodules, and the

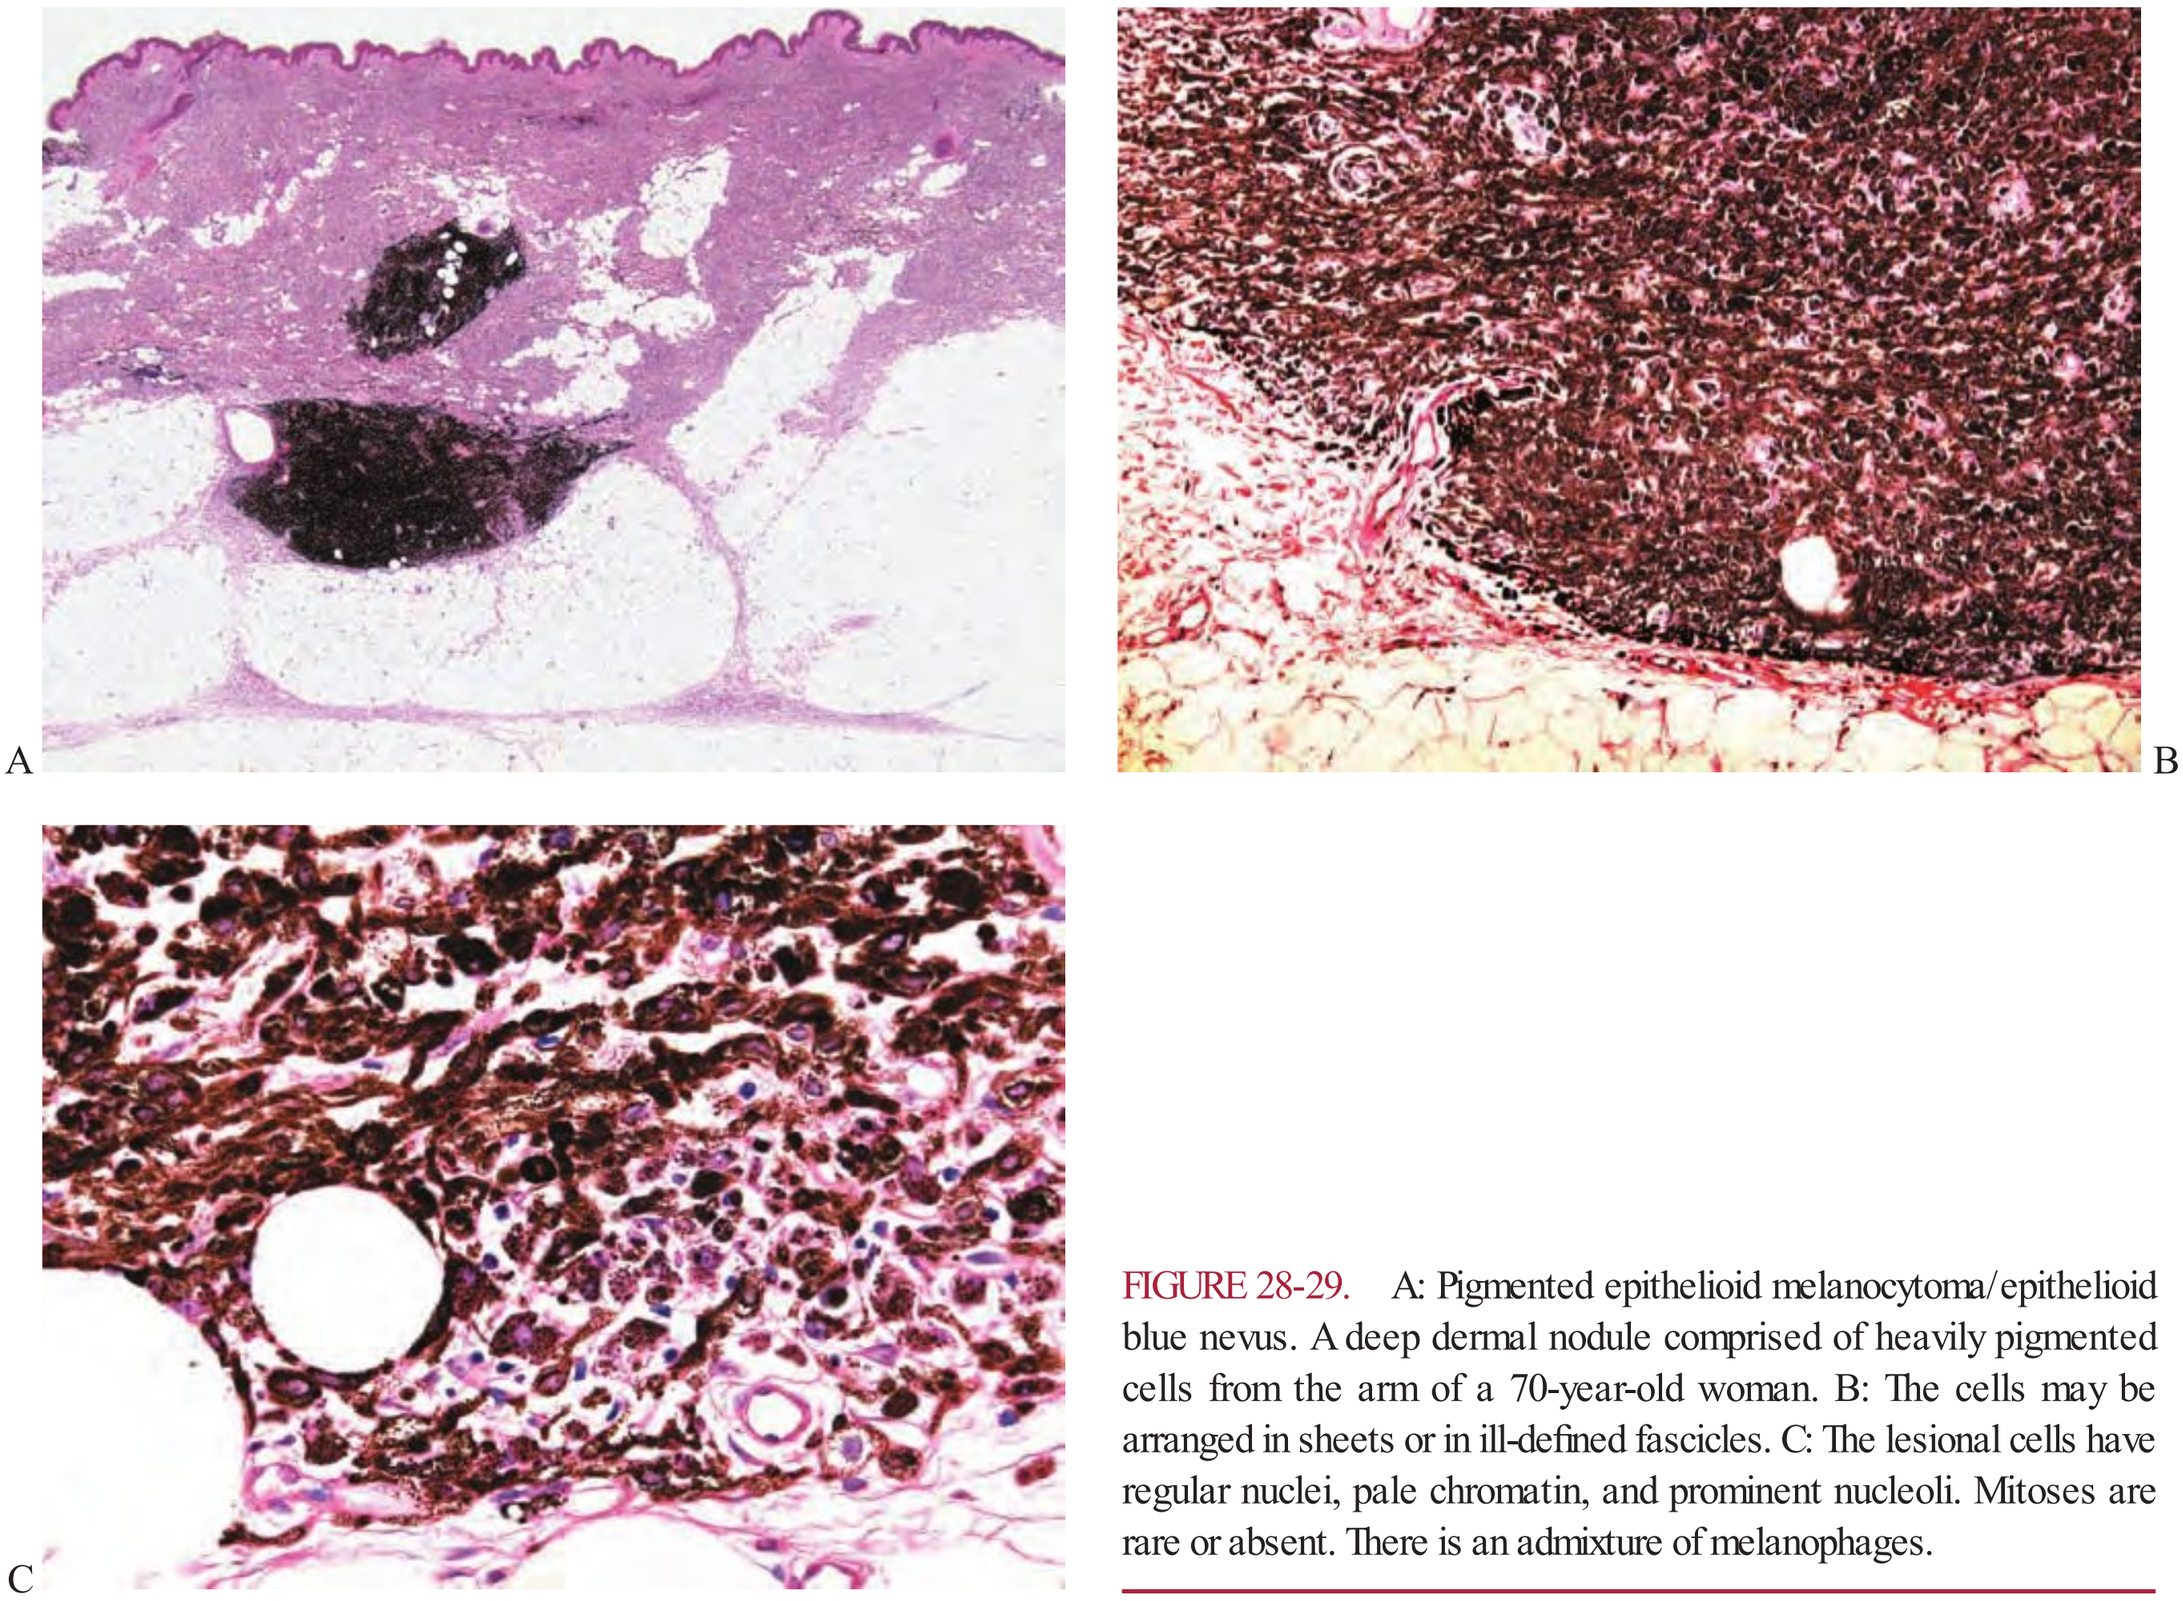

FIGURE 28-29. A: Pigmented epithelioid melanocytoma/epithelioid blue nevus. A deep dermal nodule comprised of heavily pigmented cells from the arm of a 70-year-old woman. B: The cells may be arranged in sheets or in ill-defined fascicles. C: The lesional cells have regular nuclei, pale chromatin, and prominent nucleoli. Mitoses are rare or absent. There is an admixture of melanophages.

cells in the nodules tend to be arranged in uniform patterns. If the tumor cells are epithelioid in type, they may resemble cells of ordinary acquired nevus. In the spindle cell variants, the tumor cells may resemble the cells of a Spitz nevus or, if pigmented or arranged in compact fascicles, a pigmented spindle cell nevus. Because of the resemblance to nevus cells, the term nevoid melanoma has also been used. However, nevoid melanoma (discussed in the next subsection) technically differs from most so-called borderline/minimal deviation melanomas by virtue of a more nevoid architecture, albeit formed by mitotically active cells. In one study, expression rates of the proliferation marker Ki-67 in borderline/minimal deviation melanomas were intermediate between those seen in nevi and in superficial spreading melanomas (560). Even though recurrences, metastases, and death may occur, most minimal deviation melanomas are believed to be biologically not as aggressive as common melanomas. However, prognosis is probably more accurately predicted by multivariable prognostic models.

Nevoid Melanoma

Although related to minimal deviation melanoma, this term has been used somewhat differently. Nevoid melanomas have been defined as lesions that, to a greater or lesser extent, mimic a benign nevus histologically, often with an emphasis on a nevoid architecture (in contrast to minimal deviation melanoma, in which melanoma architecture tends to be preserved) (561,562). Usually, the resemblance is most apparent at scanning magnification, on which lesions may appear symmetric, nested, and devoid of radial growth, features that can lead to a missed diagnosis if sufficient attention is not paid to cytologic and subtle architectural features (563). Discriminating attributes include high cellularity with "sheetlike" growth, cellular atypia, mitoses, infiltration of adnexa, infiltrative growth in the deeper dermis, and the absence of maturation (Fig. 28-30). Tumor thickness was the most important prognostic criterion (562). Nevoid melanomas are generally considered to have the same biological potential as other melanomas with similar microstaging attributes (121,562). Key to the recognition of a nevoid melanoma is a high index of suspicion and the identification of mitotic activity and cytologic atypia in the dermal component of the lesion (121,562,563). According to McNutt, reactivity of the intradermal component for HMB-45 antigen, without antigen retrieval, or for Ki-67 antigen can show that the dermal cells have an activated and hyperproliferative phenotype and, in combination with histologic criteria, can help to support a diagnosis of nevoid malignant melanoma (564).

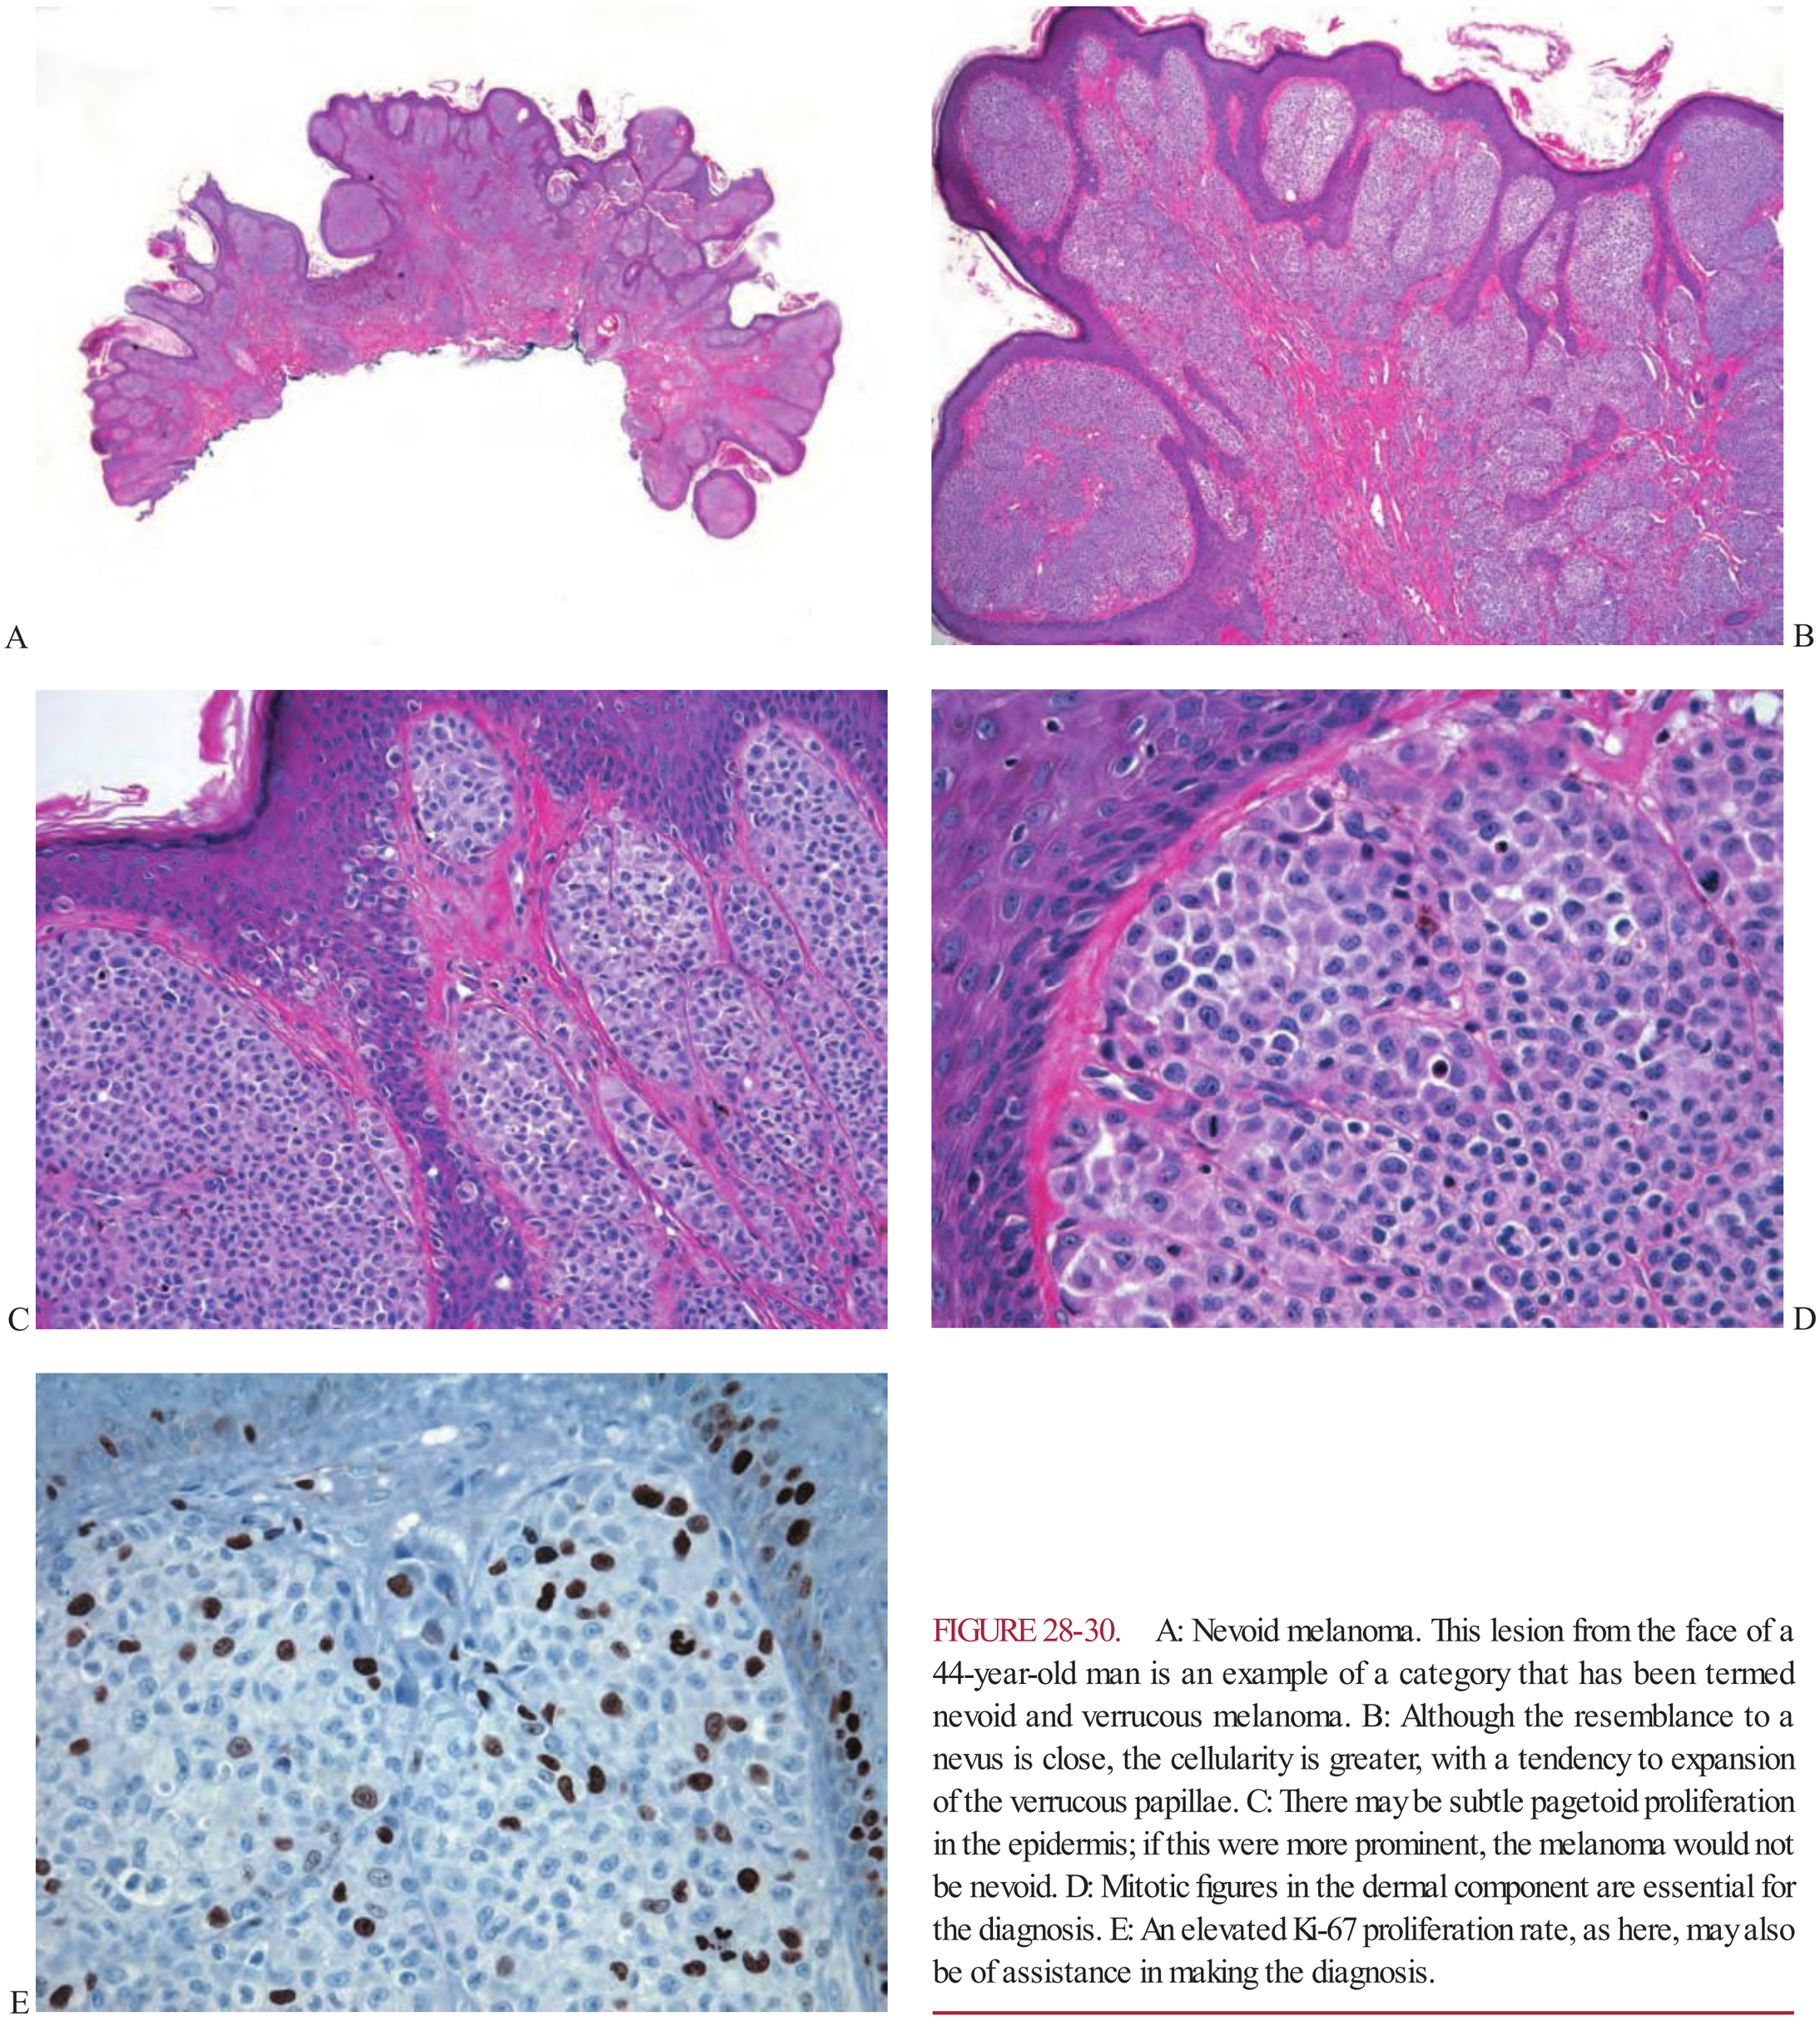

FIGURE 28-30. A: Nevoid melanoma. This lesion from the face of a 44-year-old man is an example of a category that has been termed nevoid and verrucous melanoma. B: Although the resemblance to a nevus is close, the cellularity is greater, with a tendency to expansion of the verrucous papillae. C: There may be subtle pagetoid proliferation in the epidermis; if this were more prominent, the melanoma would not be nevoid. D: Mitotic figures in the dermal component are essential for the diagnosis. E: An elevated Ki-67 proliferation rate, as here, may also be of assistance in making the diagnosis.

Epidemiology, Prognosis, and Management of Melanoma

Risk Factors for the Development of Melanomas

Phenotypic risk factors for the development of melanoma can offer clues to the etiology and pathogenesis of the disease. These have been identified through case–control studies and through follow-up of cohorts of patients, often from high-risk melanoma clinics. The major risk factors include age, family or personal history of prior melanoma, the presence of potential precursors such as nevi and dysplastic nevi, a history of exposure to the sun, a skin susceptibility to solar damage, and the

presence of indicators of chronic solar damage. Type I skin that burns easily and tans poorly is a risk factor, as are behavioral factors, such as living in a sunny climate, a history of weekend and vacation sun exposure, and a history of sunburn episodes. The presence of indicators of exposure to the sun and of susceptibility to solar damage such as freckles and actinic skin changes are also strongly associated with melanoma risk (46,565). Even more closely correlated with risk is the presence on the skin of potential precursors, including attributes of nevi such as the total number of banal nevi, the presence of large nevi, and, especially, the presence and number of dysplastic nevi (337). Among these risk factors, melanocytic nevi and indicators of acute, intermittent sun exposure are more strongly related to superficial spreading and nodular melanoma (566,567), whereas skin type, ethnic background, and measures of total accumulated exposure to the sun (chronic, continuous sun exposure) are more strongly related to lentigo maligna melanoma (568). Age is also a strong risk factor, operating in a continuously progressive fashion in lentigo maligna melanoma and perhaps also in acral and mucosal melanomas, in contrast to a more complex pattern for superficial and nodular melanoma (455). Many of these factors are under genetic control, and a family history of melanoma constitutes another major risk factor, especially as the number of melanomas in a family increases. Only a relatively small proportion of these familial melanomas is attributable to the presence of a major high-penetrance melanoma risk gene, such as CDKN2A (p16) or CDK4, both of which are tumor suppressors that act through the retinoblastoma (Rb) pathway (569–571). Other genes contributing to risk may have lower penetrance but may be present in more individuals in the population, thus accounting for a more substantial proportion of cases (i.e., a higher attributable risk). Examples of such genes include the melanocortin receptor MC1R, which controls skin pigmentation (572), and DNA repair genes (573).

Preexisting Melanocytic Nevus

It is well known that melanomas can develop in congenital nevi and in dysplastic nevi. Histologically, remnants of a banal nevus are found in a substantial number of melanomas, on the order of about 10% to 35%, and evidence of associated melanocytic dysplasia may be seen in up to about 40% (105,281,385–388,574–576). Analysis has demonstrated that this relationship is likely to be nonrandom (577). Remnants of a dysplastic nevus adjacent to a radial growth phase (usually of the superficial spreading type) can be distinguished from the latter using the criteria presented in Table 28-3. Remnants of a dermal component of a nevus deep to a melanoma can be distinguished from the melanoma cells by the following criteria (Fig. 28-31): (a) The dermal nevus cells are smaller; (b) they are arranged in nests that tend to be small and uniform in size and shape; (c) there may be evidence of maturation from superficial to deep within the nevus but not the melanoma cell population; (d) there is no evidence of continuous differentiation from a more obviously malignant superficial component to the nevoid cells at the base of the tumor; (e) there is no high-grade atypia, and there are no mitoses in the dermal nevus cells; and (f) nevus cells tend to disperse as single cells if they enter the reticular dermis, whereas melanoma cells tend to infiltrate as sheets or clusters (Fig. 28-32). This paradoxically less invasive pattern is related to the greater proliferative capacity of melanoma cells: Invasion probably initially involves single cells that then proliferate to form the final pattern of sheets or fascicles in the reticular dermis. For the same reason, cutaneous metastases tend to be sharply demarcated, expansive lesions (113). Occasional examples of differentiated dermal melanoma cells may meet some of these criteria and thus present difficulties of interpretation (see section Nevoid Melanoma).

It has recently been demonstrated that in some cases, loss of heterozygosity at the 9p21 locus (the locus of the cell cycle control gene CDKN2A) is detected simultaneously in a melanoma and its associated nevus (578). Recent studies have also demonstrated the same mutations in the oncogene NRAS in melanomas and in their associated nevi studied by microdissection (579). These results are consistent with a causal relationship for the development of melanoma within a preexistent associated nevus and also support the hypothesis that these genetic alterations play an important necessary but not sufficient role in development of some early melanomas because they are found in histologically benign melanoma-associated nevi (578).

In addition to dysplastic nevi and banal dermal nevi, superficial and deep congenital pattern nevi are also commonly associated with melanomas (281). An exception to the general rule that melanoma arises at the epidermal–dermal border is observed occasionally in congenital nevi, in which a melanoma may arise deep in the dermis. However, these proliferations should be distinguished from benign cellular/proliferative nodules that may occur in congenital nevi (293). In very rare instances, a melanoma may develop within or beneath an intradermal nevus, resulting in a dermal nodule of atypical cells (580).

Multiple Primary Melanomas

People who have had a cutaneous melanoma are at risk of developing additional melanomas, with an incidence of approximately 5% in the first 10 years after diagnosis (581). The occurrence of multiple and familial melanomas has already been pointed out in relation to dysplastic nevi (582–586). A prior melanoma is a strong risk factor for subsequent melanoma, especially in young patients and in familial melanoma kindreds (358,360). It is important to differentiate an additional melanoma from a metastatic melanoma, especially from an epidermotropic metastasis (563,587) because the prognosis of an independent primary is likely to be much better than that of a metastasis. This may be difficult, however, because some epidermotropic metastases closely mimic primary melanomas, and, accordingly, correlation with clinical parameters (e.g., more than one lesion) may be critical in differentiating a second primary from a metastasis in such

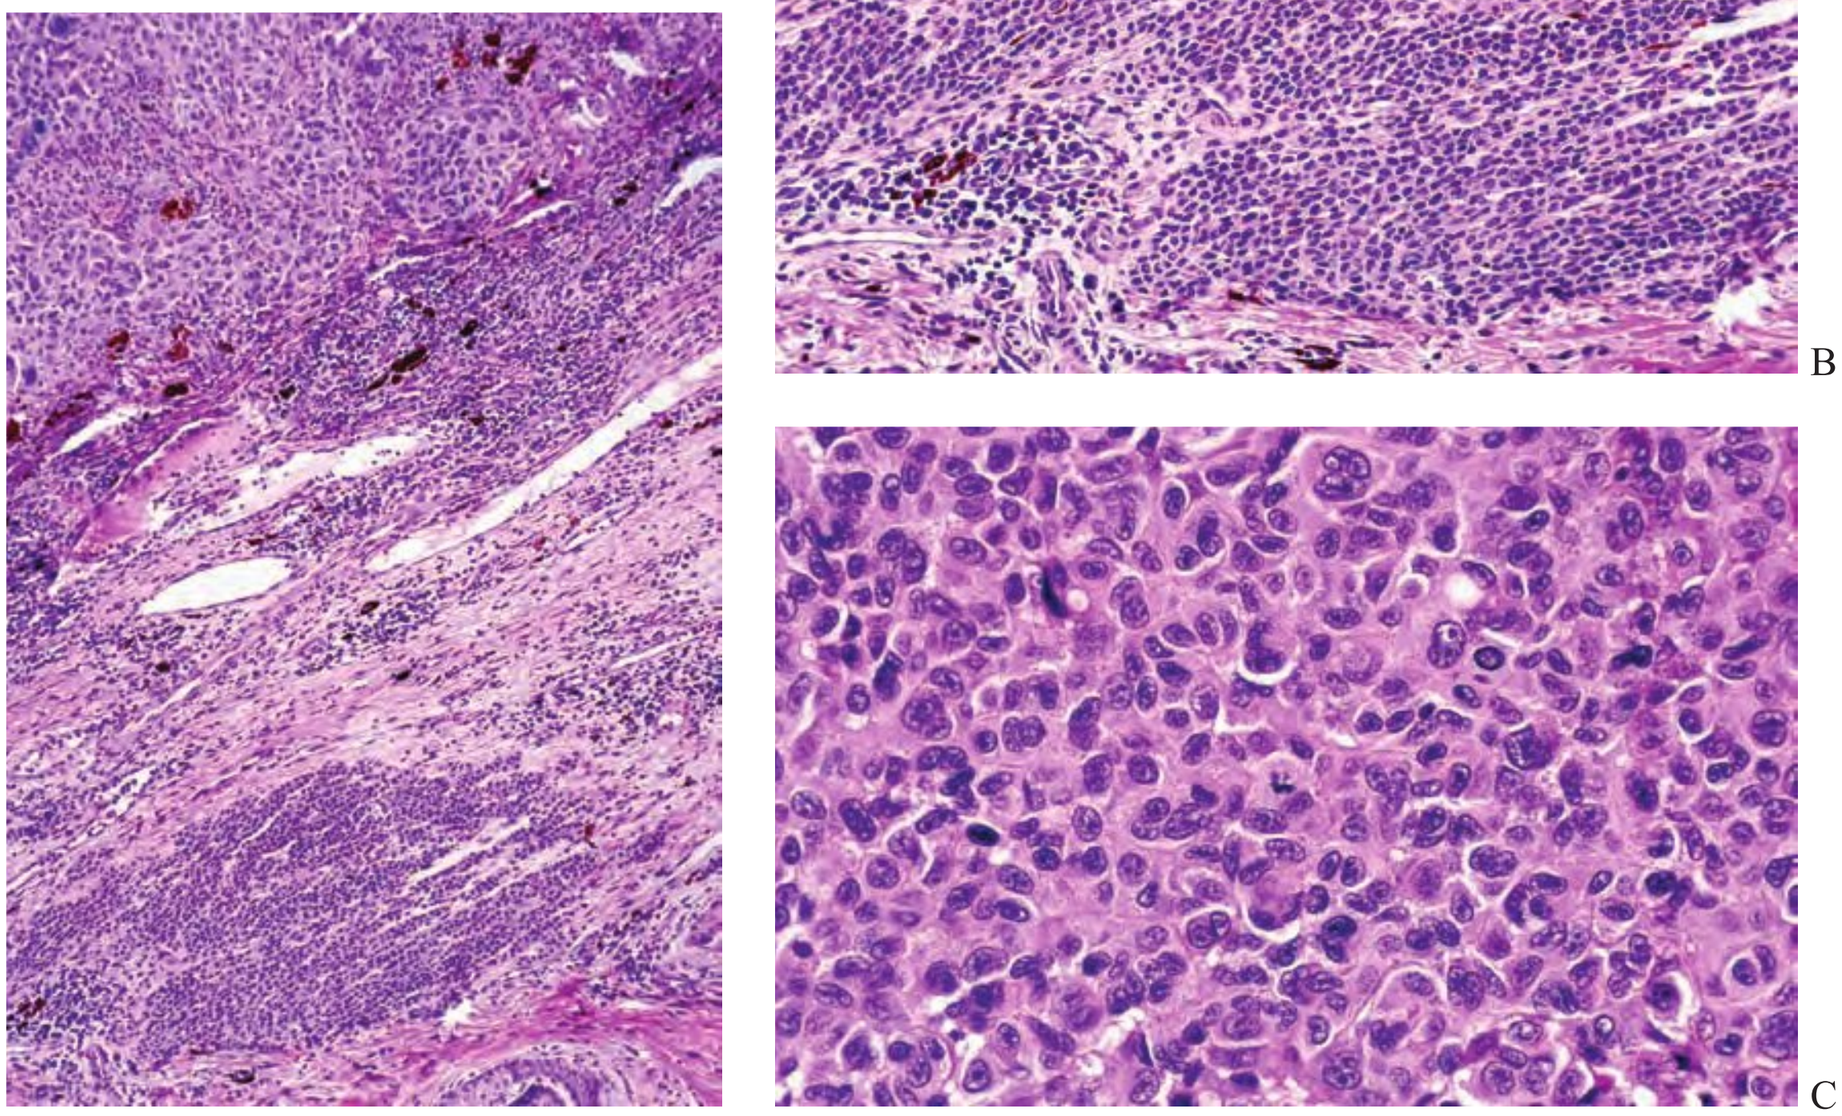

FIGURE 28-31. A: Nevus cells deep to a tumorigenic melanoma. A collection of smaller cells is present at the interface of the papillary and reticular dermis deep to a tumor of vertical-growth-phase melanoma. B: The nevus cells are smaller than the cells of the tumorigenic melanoma. C: The tumorigenic melanoma cells have large, hyperchromatic nuclei with irregularly clumped nuclear chromatin and with mitotic figures.

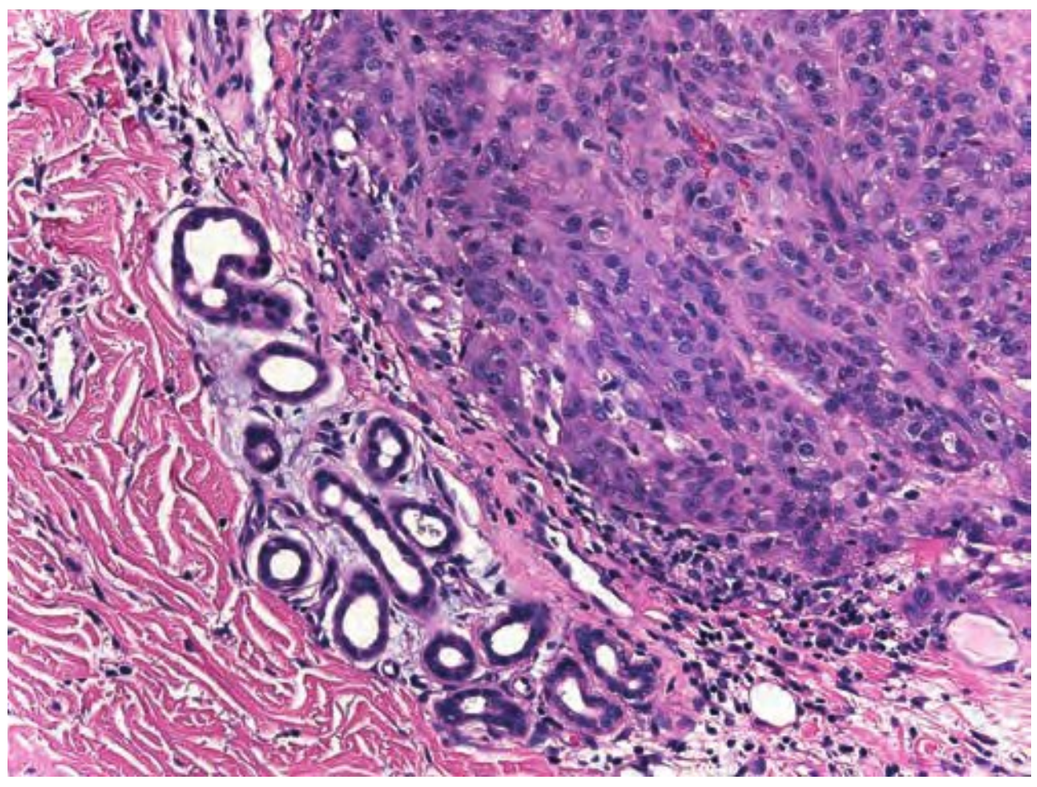

FIGURE 28-32. Infiltration of tumorigenic melanoma at the base of the lesion. The cells tend to be arranged in clusters or sheets. In benign nevi, the cells in the papillary dermis may be clustered, but when they enter the reticular dermis they tend to disperse as single cells (compare with Fig. 28-10F).

instances. Individuals with multiple primary melanomas have also been found to have a modestly increased incidence of a family history of melanoma, dysplastic nevi, and basal cell carcinoma, an earlier age of onset, and a relatively small incidence of CDKN2A mutations (588–591). Therefore, in addition to the multiple primary melanoma index case, other family members can benefit from screening and regular surveillance of their skin.

Malignant Melanoma in Infancy and Childhood

Malignant melanoma is a disease primarily of adults. The incidence of *prepubertal melanoma* is very low. In a few instances, it has occurred as multiple metastases resulting from transplacental transmission (592). Occasionally, a melanoma arises in infancy or childhood in a giant congenital nevus (Fig. 28-12B) (253,257,258,262). Outside of these situations, three patterns of primary melanoma have been described in children (593). In most instances, the melanoma shows a histologic picture similar to that in adults, and the prognosis depends on thickness and other microstaging attributes. In other cases, the tumors are composed of small blastic malignant cells, and the

course is usually aggressive, although sometimes unpredictably so, especially in tumors that arise in congenital nevi. In a few instances, the histologic picture is reminiscent of that seen in Spitz nevi (593–595). In some of these cases, metastases occur that are limited to the regional lymph nodes and the child survives after adequate treatment (223,593). However, spitzoid melanoma with a fatal outcome in a child has been reported (593). These lesions may be considered to represent a special category of spitzoid melanomas of childhood, in which there may be a relatively high incidence of regional metastasis but a relatively low (but not zero) risk of more distant progression (596). Some of these lesions may be best termed melanocytic tumors of uncertain malignant potential because criteria for reliable distinction between benign and malignant examples of these lesions are not well defined (231). This designation may also be relevant to even overt melanomas in children because such lesions appear to overall show a better prognosis than would be anticipated in adulthood.

Biopsy of Melanoma

The question of whether an incisional biopsy is permissible in a lesion that is highly suspected of being a melanoma has been widely discussed. Some authors have opposed the performance of an incisional biopsy because of a belief that it might cause metastatic spread (597). In other studies, no deleterious effect of a preceding biopsy was noted (598–601). It is difficult in studies of this sort to control for other risk factors, which might be expected to be more prevalent in the larger tumors for which an incisional biopsy might be contemplated.

Because a correct diagnosis and accurate prognostic staging are more likely to be accomplished when the entire tumor can be studied, an excisional biopsy is advisable whenever feasible, and only in occasional instances such as very large lesions is an incisional biopsy indicated (602). If a tumorigenic vertical growth phase is present, it should be entirely contained within the biopsy, if possible. A shave biopsy or curetting is not optimal because it may result in inadequate material for diagnosis; it may also make impossible a determination of the depth of penetration of the tumor, which is very important for prognosis and for planning of the extent of surgical procedures (see Prognosis). Shave or punch biopsies that completely encompass the lesion are, of course, acceptable. However, a positive deep margin is commonly found in a shave biopsy, and this may compromise the ability accurately to diagnose and stage the lesion (603).

Multivariable Prognostic Models

The gold standard for considering any putative prognostic marker to be clinically important is its inclusion as an independent variable in a multivariable analysis. Many such studies have been published for the traditional histopathologic and clinical variables reviewed here. Based on these multivariable analyses, prognostic models have been published, either requiring the use of a calculator to determine a regression function or, more simply, using published tables to provide a quantitative probability estimate (472,604–621). Although these models are useful in planning therapy and especially in the development and execution of clinical trials, thickness and ulceration are the factors in predominant use for planning of therapy for stage I melanoma. Prognostic modeling may be considered as a form of staging of the primary tumor (so-called microstaging).

Staging of Melanoma

The purpose of staging is to define subsets of cases with a similar prognosis for management and investigational purposes. The five-stage (0 to IV) clinicopathologic staging system of the AJCC primarily considers aspects of the tumor (T), the presence and size of nodal metastases (N), and the presence and sites of distant metastases (M) to determine a stage based on all three attributes (TNM). The 5-year survival for newly diagnosed localized primary melanoma cases (stages 0 to II) is about 80%, compared to 35% survival when lymph nodes are involved (stage III). Using the prognostic models to be discussed, subsets of cases with more or less favorable prognosis can be identified. When distant metastases are present, the survival at 5 years is on the order of 10% (613,622).

TNM Staging System for Melanoma

The TNM system of tumor staging considers factors related to the primary tumor, to regional lymph nodes (and other regional soft tissues), and to distant metastases to result in a classification that is associated with the probability of survival. The factors considered in the primary tumor (T) category include some of the microstaging attributes discussed earlier. Thus, the TNM classification combines staging and microstaging information in a single format. In the current system (which became official with the publishing of the sixth edition of the *AJCC Cancer Staging Manual* in 2002) (613,622,623), the T attributes are classified pathologically after excision of the melanoma (pT), as described later (622). The TNM model therefore considers pathologic attributes of the primaries, but staging for metastases is defined in part clinically. For example, lymph node metastases are defined in terms of the number of lymph nodes involved, as well as volume, and are coded as micrometastasis if lymph node metastasis has been diagnosed at sentinel node biopsy or at elective lymphadenectomy and as macrometastasis if clinically positive and pathologically confirmed by therapeutic lymphadenectomy (622). Among macrometastases, the size of nodes is no longer used in staging, based on evidence that the number of nodes but not their size is significant prognostically (624–629). In other prognostic models, it has been demonstrated that microstaging of the primary tumor retains prognostic significance in melanoma patients who are clinically negative but pathologically positive for metastases to regional nodes (630–632), and this is also reflected in the new AJCC staging system, in which ulceration retains significance in some patients with nodal metastases. The new system has been reviewed by Schuchter (633).

The latest revision (2002) of the TNM categories is presented in Table 28-7, and the final stage groupings are given in

TABLE 28-7 Melanoma TNM Classification (622,623)

T classification

	Thickness (mm)	Ulceration/Clark level status
T1	≤1.0	a: without ulceration and level II/III b: with ulceration or level IV/V
T2	1.01–2.0	a: without ulceration b: with ulceration
T3	2.01–4.0	a: without ulceration b: with ulceration
T4	>4.0	a: without ulceration b: with ulceration

N classification

	Number of metastatic nodes	Nodal metastatic mass
N1	1	a: micrometastasis* b: macrometastasis†
N2	2–3	a: micrometastasis* b: macrometastasis† c: in-transit met(s)/satellite(s) without metastatic nodes
N3	4 or more metastatic nodes, or matted nodes, or in-transit met(s)/satellite(s) with metastatic node(s)	

M classification

	Site	Serum lactate dehydrogenase
M1a	Distant skin, subcutaneous, or nodal metastases	Normal
M1b	Lung metastases	Normal
M1c	All other visceral metastases	Normal
	Any distant metastasis	Elevated

*Micrometastases are diagnosed after sentinel or elective lymphadenectomy.
†Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

Table 28-8 (613,622,623). Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, clinical staging should be used after complete excision of the primary melanoma, with clinical assessment for regional and distant metastases. Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage 1A patients do not require pathologic evaluation of their lymph nodes. There are no stage III subgroups for clinical staging. The definitions have been recommended by the AJCC Melanoma Staging Committee and approved by both the AJCC Executive Committee and the TNM Committee of the International Union Against Cancer (Union Internationale Contra Cancer, UICC). The revised melanoma staging system has been approved by the World Health Organization Melanoma Program as well as the European Organization for Research and Treatment of Cancer Melanoma Group (634). These new definitions incorporate substantial revisions from previous (1983 and 1997) versions of the melanoma staging categories and classifications (623,635,636).

The TNM staging system incorporates clinical and pathologic attributes of the primary neoplasm (microstaging attributes) in the definition of the stage groups. Tumors in stage groups I and II are nonmetastatic, and stage III may or may not be associated with distant metastasis (Table 28-8). Stage IV is always metastatic. Because these stages are different from those defined in other staging systems, it is clear that the system in use (e.g., AJCC stage X) should be clearly specified when staging is used as a basis for therapy or prognosis.

The staging system is primarily based on survival studies done in several collaborating institutions. Survival rates for 17,600 patients categorized according to the AJCC staging system are shown in Table 28-9. Survival times were calculated from onset of primary melanoma diagnosis and are considered

TABLE 28-9 Survival Rates for Melanoma by TNM and Staging Categories (622,623)

censored for patients who were alive at the last follow-up or who died without evidence of melanoma (613,622).

Pathology of Microstaging Attributes in Common Use

As discussed, the 2002 AJCC staging system, which is used worldwide, incorporates several attributes of primary and metastatic melanomas, such as Breslow's thickness, Clark's levels of invasion, and the presence or absence of ulceration in the primary tumor. These and other attributes that may contribute to the assessment of prognosis are discussed in the following sections.

Vertical Growth Phase

The morphology of vertical growth phase has already been presented. Here we discuss its significance as a prognostic attribute in relatively thin melanomas with vertical growth and in level II melanomas ostensibly without vertical growth. In one series, metastases occurred in 2% of melanomas less than 0.76 mm thick. The cases that metastasized all had tumorigenic vertical growth phase. The rate of metastasis for tumorigenic melanomas less than 0.76 mm in thickness was 15%, whereas in nontumorigenic (radial growth phase) melanoma of any thickness (most are less than 1 mm), the metastatic rate was zero (345,422). In rare instances of metastasizing thin melanomas, vertical growth phase is absent; most if not all of these cases in our experience and in the literature have had extensive partial or complete regression (see later section) (472,637–640). As already mentioned, two reproducibility studies were done for vertical growth phase in thin melanomas, and they concluded that this determination can be reliably made by practicing pathologists (426,641). A recent study investigated prognostic factors in metastasizing thin, level II melanomas and concluded that vertical growth phase (i.e., the focal presence of tumorigenic or mitogenic growth) was the only statistically significant factor. It was proposed that growth phase evaluation should be added to the recommendations for melanoma histologic reporting, at least for level II superficial spreading melanomas (425). Even though vertical growth phase is the most common explanation for metastasizing thin melanoma (345,425), not all such lesions contain this feature (642).

Clark's Levels of Invasion

Although tumor thickness is now considered to be the most important prognostic attribute, the levels of invasion as defined by Clark (408,643) have prognostic value, at least in certain subsets of cases (644,645) or more broadly, depending on the databases studied (621,646). They also have descriptive value. The different levels appear to reflect the sequential acquisition of new properties by evolving tumors and should be included in pathology reports (646,647). They are defined as follows, with survival rates for prospectively diagnosed and definitively treated clinical stage I cases in parentheses (648):

- Level I (100% 10-year disease-free survival): There is confinement of the melanoma cells to the epidermis and its

appendages. These *in situ* melanomas (AJCC stage 0) presumably lack the capacity to invade through a basement membrane.

- Level II (96% survival): There is extension into the papillary dermis, with at most only a few melanoma cells extending to the interface between papillary and reticular dermis. These melanomas are microinvasive but lack the capacity to form tumors in all but a few cases. Almost all of the level II tumors that metastasize have a small tumorigenic papule (VGP), as previously defined.
- Level III (86% survival): There is extension of the tumor cells throughout the papillary dermis, filling it and impinging on the reticular dermis, without, however, invading it. These melanomas are competent to form tumors in the papillary dermis, a loose mesenchyme that is specialized to support epithelium.
- Level IV (66% survival): Tumors are not only invasive and tumorigenic but also have the capacity to invade the dense, sparsely vascular mesenchyme of the reticular dermis.
- Level V (53% survival): Tumors invade the subcutaneous fat. Observer agreement for Clark level has been found to be fair to good (649).

To avoid confusion, it must be emphasized that the original descriptions of Clark and coworkers were often interpreted to equate level II invasion with radial growth and levels III, IV, and V invasion with vertical growth. Based on the current recognition that the occasional level II lesion may show focal tumorigenic or mitogenic growth (equated with an early form of vertical growth and some potential for metastasis), the Clark schema embodies the acknowledgment that not all level II melanomas are pure radial growth. Moreover, such a system also provides for the extremely unusual situation in which a deeper level (e.g., a thin, level IV lesion) could be devoid of tumorigenic or mitogenic growth and thus have prognostic attributes more in keeping with a nonmetastasizing lesion.

Breslow's Thickness of the Tumor

Tumor thickness is the most important factor in predicting survival for stage I patients. Breslow, in 1970, first measured tumor thickness objectively with a micrometer (650,651). The depth of invasion is measured from the top of the granular layer to the deepest extension of the tumor; in ulcerated lesions, measurement is from the ulcer base overlying the deepest point of invasion. In the initial report, metastasis did not occur in lesions less than 0.76 mm in greatest thickness. Since then, there have been reports of metastases from "thin" melanomas, although this continues to be rare (652,653). Metastasis from "thin" melanomas or from level II melanomas appears usually to be explained by the presence of tumorigenic and/or mitogenic vertical growth phase (425,621). In a computer simulation studying the biology of progressive tumor growth, tumor thickness was related not only to time (the most important factor), but also to tumor cell motility, a decreased rate of tumor cell loss, and pronounced proliferation in the tumor cells, attributes that are also believed to correlate with aggressiveness of tumors (654). In this regard, it may be important to realize that individual melanomas may grow over time at highly variable rates, and it is potentially inaccurate to extrapolate and generalize about *in vivo* melanoma growth based on the behavior and doubling times exhibited by cultured melanoma cells *in vitro* or by clinical metastases at the end stage of the melanoma's evolution.

In determining the depth of penetration, whether by level or by measurement, the following rules were suggested by Lever and Schaumberg-Lever (655): (a) Melanocytes in junctional nests are not considered invasive, even though they may push into the papillary dermis. (b) If deep nests of melanoma cells arise from the epithelium of cutaneous appendages, they are not used in measurement from the surface. (c) A column of melanocytes extending from the lower border of the lesion into the deep dermis at nearly a right angle is not measured because it is likely that the column arises from an appendage; this supposition can usually be verified by serial sections or keratin stains (Fig. 28-33) (656). Observer agreement for Clark level has been found to be excellent (649).

One potential problem with level designation occurs in determining whether the existence of rare malignant cells surrounded by thickened collagen bundles at the interface of the papillary and reticular dermis constitutes true level IV involvement. This is more than a theoretical concern, in that level IV involvement in lesions that are less than 1 mm thick may trigger sentinel node sampling at some centers. There is no definitive answer to this dilemma, and in practice we generally recommend that such lesions be diagnosed with the descriptive statement that early level IV invasion cannot be excluded.

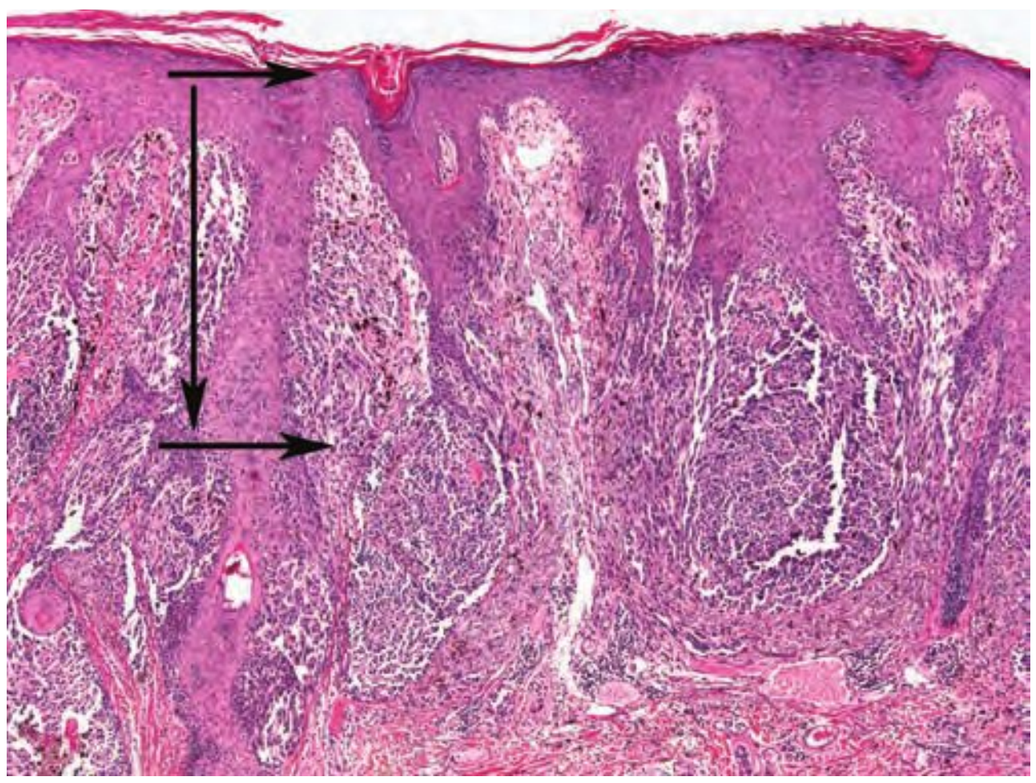

FIGURE 28-33. Extension of melanoma down a hair follicle. In a lentigo maligna melanoma, at right center, a hair follicle is largely replaced by melanoma cells that are confined to the epidermis and adventitial dermis of the follicle. This melanoma is nontumorigenic. Invasive cells at the base of the follicle should not be used for thickness measurement. Arrows indicate where measurement should be taken perpendicular from the top of the granular layer to the deepest invasive tumor cell.

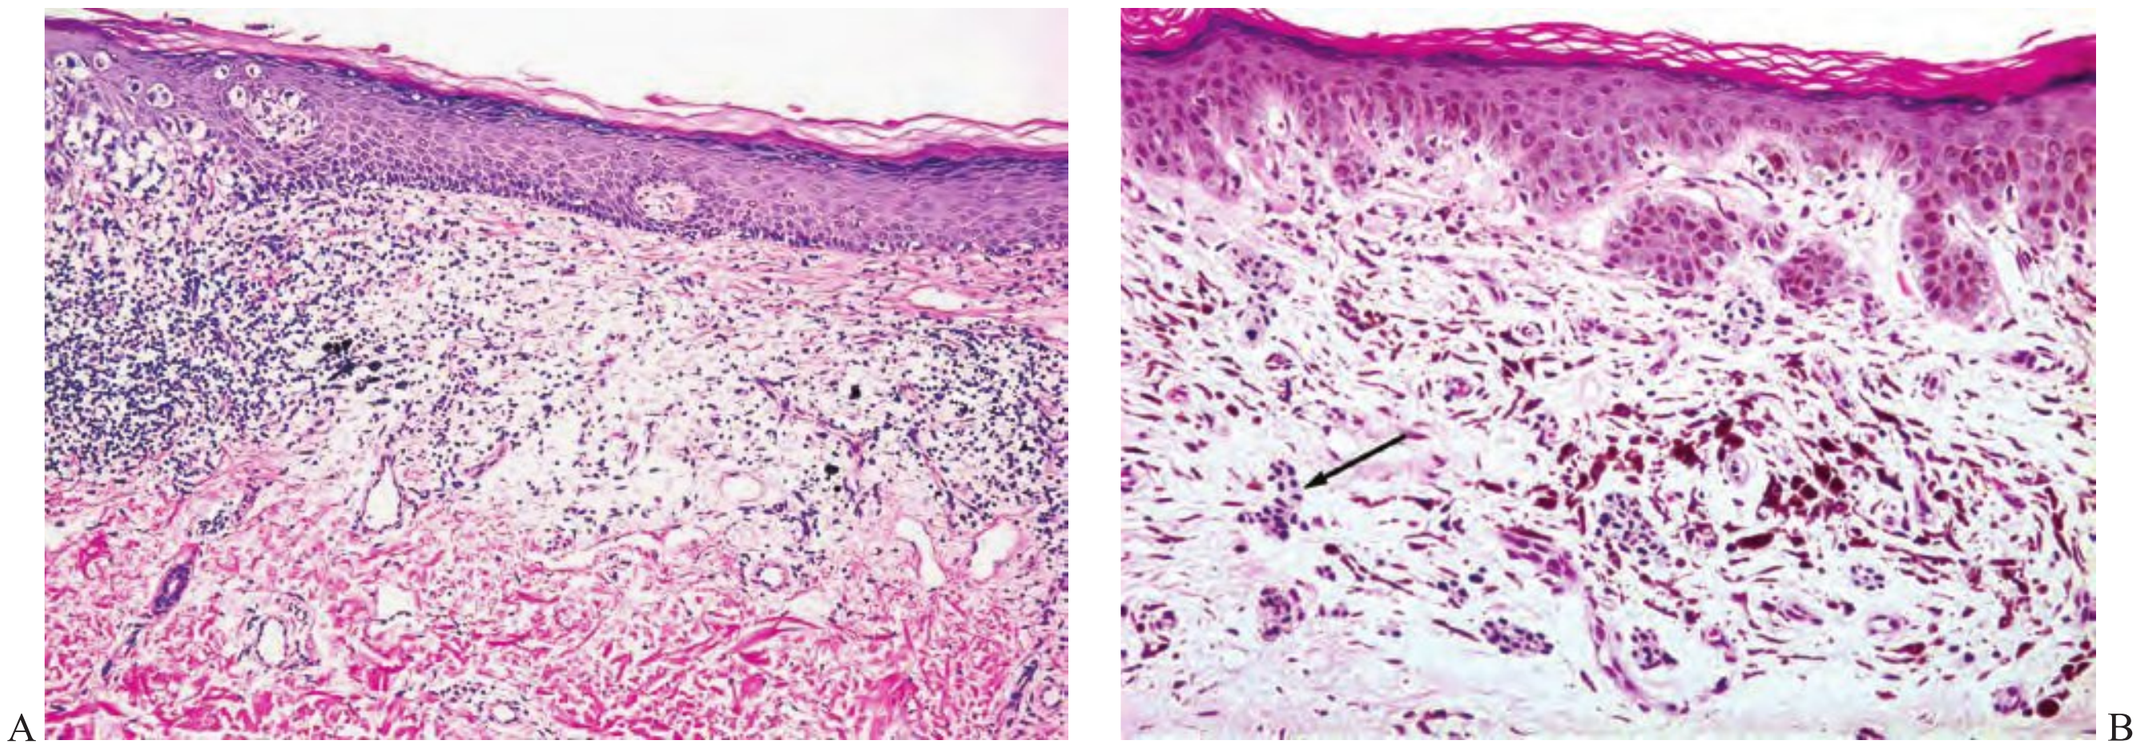

FIGURE 28-34. A: Partial regression of the radial growth phase. At left, there are melanoma cells in the epidermis and papillary dermis. To the right, there is fibrosis with lymphocytes and melanophages in the papillary dermis. B: In another area of partial radial-growth-phase regression, the papillary dermis is widened by fibroblasts with lymphocytes and melanophages. Remnants of a nevus are seen in the regressive fibroplasia (arrow), apparently unaffected by the regression process.

Partial and Complete Regression of Melanoma

Partial regression is common in melanomas. Usually, it is observed in the nontumorigenic compartment ("RGP regression"). Regression is defined as a focal area in which there is delicate, often edematous fibroplasia of the papillary dermis, often accompanied by proliferation of dilated blood vessels, and usually with a sprinkling of melanophages and lymphocytes, with melanoma present in the epidermis and/or papillary dermis to one or both sides but not within the area of regression (Fig. 28-34). Fibrogenic cytokines have been demonstrated in these areas of regression (313). Paradoxically, partial regression of the radial growth phase has been associated in some series with poorer prognosis (472,638–640,657), perhaps because a more significant dermal component had been present and had metastasized before it regressed. Interobserver agreement for regression as a prognostic attribute has been found to be poor in several studies (658,659), perhaps because of failure to agree on criteria.

In contrast to the apparent negative correlation of radial-growth-phase regression with prognosis, tumor-infiltrating lymphocytes within the vertical growth phase, which may be considered as a potentially different form of immunologic regression ("VGP regression") are associated with improved survival rates (Fig. 28-35A) (472,660–662). Regression of the vertical growth phase has not been well described. Occasion-

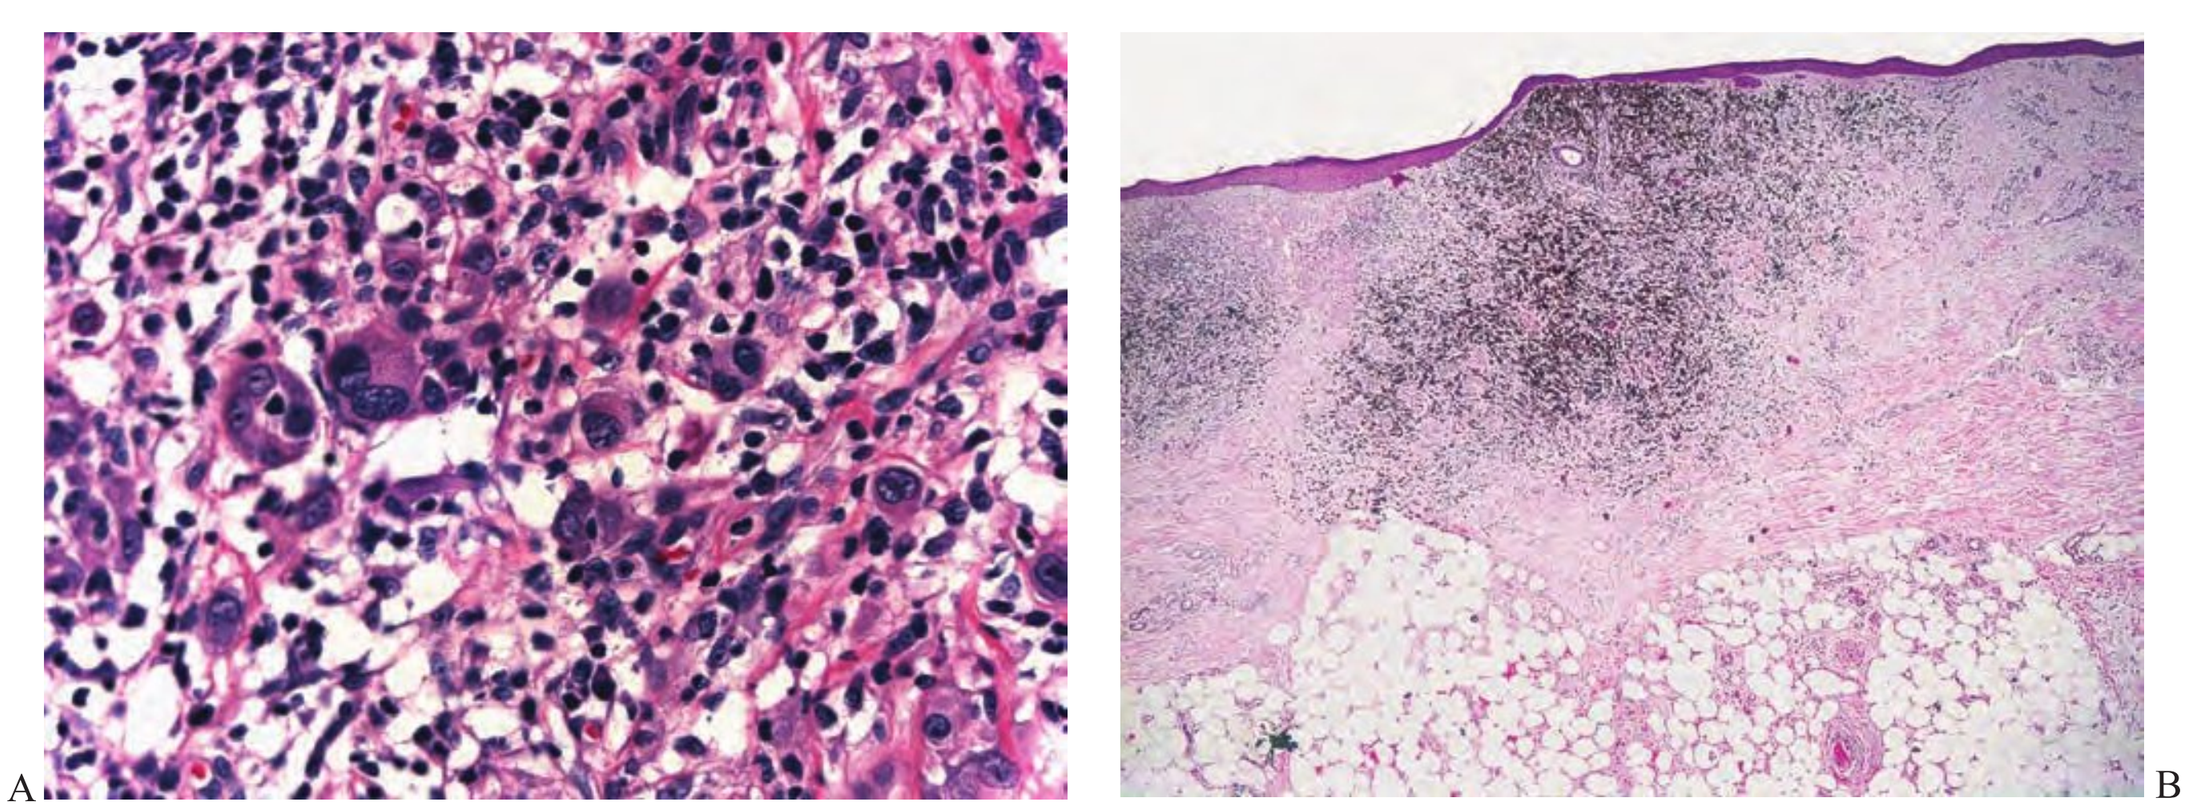

FIGURE 28-35. A: Tumor-infiltrating lymphocytes at the base of the vertical growth phase of a primary melanoma. Lymphocytes that are among the tumor cells, often associated with evidence of apoptosis of the cells, are a favorable prognostic attribute. B: Tumoral melanosis. A localized collection of pigmented melanophages is present in the dermis, consistent with regression of a tumorigenic melanoma or of another pigmented tumor.

ally, one sees an area of fibrosis and melanophages apparently partially replacing a portion of a tumor nodule, and, very infrequently, this process may proceed to completion, resulting in a collection of melanophages in the dermis that could represent the residual evidence of a preexisting tumor nodule. This phenomenon has been aptly referred to as tumoral melanosis (Fig. 28-35B) (663). Not all of these cases are due to regression of a melanoma; pigmented basal cell carcinomas or other pigmented skin tumors may regress and produce similar findings (664).

In occasional cases of metastatic melanoma with no obvious primary tumor, clinical examination may reveal a hypopigmented or irregularly hyperpigmented atrophic patch in the skin of the nodal drainage region (665). Some other cases of apparently regressed primary melanoma may present as clinically pigmented, variegated lesions, clinically suspicious for melanoma. Some of these have presented with concomitant metastases, but some, in our experience, have not been associated with metastasis. Although the diagnosis of melanoma cannot be made with certainty in these latter cases, we have seen at least one case in which metastatic melanoma developed after a period of follow-up. In the case of depigmented lesions histologic examination shows telangiectasia and some pigmented macrophages in the papillary dermis, and in the case of still pigmented lesions an irregular band of melanophages and inflammatory cells in the upper part of the dermis. In some cases, serial sections may reveal a few melanoma cells in the dermis or in the subcutaneous tissue. It is presumed that in patients who present with metastatic melanoma without a clinically overt primary lesion, such completely regressed primary sites may be responsible, although they may evade detection. In such instances, it is important not to implicate other detectable melanocytic lesions (e.g.. dysplastic nevi, melanoma *in situ*) as primary sources of metastasis by default.

Tumor-Infiltrating Lymphocytes

The presence of TILs that are actually among and in contact with the tumor cells of the vertical growth phase has been shown to have powerful independent prognostic significance (Fig. 28-35A) (472,660,666–668). The presence of TILs in lymph node metastases is also associated with better survival (669). The prognosis is best for tumors with a "brisk" TILs response, defined as lymphocytes forming a continuous band beneath the tumor or diffusely throughout its substance. Tumors with "absent" TILs have the worst prognosis, and a "nonbrisk" response (discontinuous band) is associated with an intermediate prognosis. It has been demonstrated that the TIL response is a strong independent predictor of sentinel lymph node involvement in a model that also included thickness, ulceration, and male sex (670). The presence of a noninfiltrative lymphocytic infiltrate around the tumor, usually at its base, is not associated with prognosis (472). The lymphocytic infiltrate tends to diminish with increasing thickness of the primary melanoma and is usually scant in deeply invasive tumors. The histologic determination of the TIL response has been shown to be reproducible (671).

Mitotic Rate

Mitotic rate has been associated with prognosis in multiple studies (599,608,619,672–674,693,695,695a,695b). However, other well-conducted, large studies have not identified this relationship in multivariable models (612,673–678). The differences among these studies may have to do with differences in the determination of mitotic rate or with interactions between mitotic rate and other variables such as ulceration. In some large studies, mitotic was not systematically considered (613,622,679). When it is determined in the tumorigenic compartment of primary melanomas, the mitotic rate has been shown to have powerful independent significance (472). Areas where mitoses are counted should include those where they appear to be the highest (the "hot spot"). The prognosis is best when the mitotic rate is zero and worst when the rate is greater than 6 mitoses per square millimeter (472). The presence of mitoses may also be useful in identifying thin melanomas with a propensity to metastasize (Fig. 28-21B) (673,674,680). Interobserver agreement for tumor mitotic rate has been found to be excellent (649). In a recent series of studies, the property of mitogenicity, or the presence of any dermal mitoses, has been found to be a significant independent prognostic factor in patients with thin AJCC stage I melanomas (617,621,681). Mitogenicity is of course one of the attributes that define the presence of vertical growth phase (682). Especially in these thin tumors, where the volume of the dermal component is small and accurate quantitation is difficult, this attribute is likely to be more reliably recorded by pathologists.

Ulceration

Ulceration is defined by the loss of continuity of the epithelium over the surface of the tumor (Fig. 28-36). Evidence of a host reaction to the ulceration is also required to exclude epithelial loss due

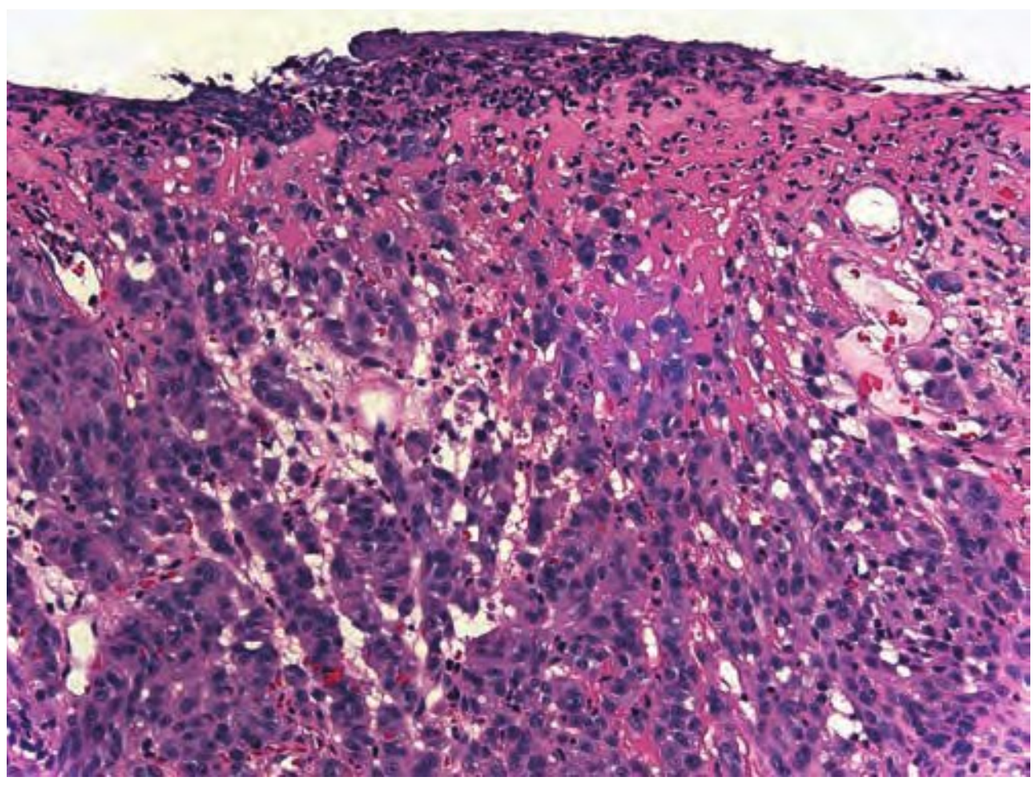

FIGURE 28-36. Ulcerated melanoma. An ulcer is defined as an area of loss of continuity of epithelium over the surface of the lesion, with evidence of a host reaction. The example here shows a neutrophilic and fibrinous exudate on the surface of the ulcer.

to biopsy trauma (683). Even with a host response, it may be difficult or impossible to determine whether ulceration is secondary to the tumor or a result of excoriation or environmental trauma. Nonetheless, this attribute has prognostic significance in most multivariable analyses (607,612,613,667,678,684–692). Other studies, particularly those in which mitotic rate is an independent variable, have not identified ulceration as an independently significant prognostic attribute (472,608,693–695). In the AJCC staging data, ulceration in stage I reduces the 5-year survival rate from 88% to 83% (613). A potentially useful prognostic algorithm has been published in which ulceration is the primary stratifying variable (472,609). Ulceration is a key substratifying variable in the latest AJCC staging system for melanoma (see tables presented earlier) (613). Interobserver agreement for ulceration has been found to be excellent (649,683).

Vascular or Lymphatic Invasion

Although often correlated with survival as a single variable (472), the presence of vascular or lymphatic invasion has infrequently been found to correlate with survival in large series of cases studied by multivariable analysis (696,697). In a recent publication, two types of vascular invasion were studied: vascular invasion with tumor cells within blood or lymphatic vessels (Fig. 28-37) and uncertain vascular invasion, with melanoma cells present within the wall of the vessel, immediately adjacent to the endothelium. The presence of either type of vascular involvement significantly reduced the survival associated with melanoma. Angiotropism, defined as cuffing of the external surface of vessels with tumor cells, also known as extravascular migratory metastasis, has also been associated with aggressive behavior (698). In a multivariate analysis, vascular involvement was the second-most-important factor (after tumor thickness) in the primary tumor in predicting survival (699). Vascular invasion also appears to be a strong predictor of the likelihood of a positive sentinel lymph node (700) and of development of in-transit metastases in follow-up (701). Lymphovascular invasion may also be seen in metastases, and its presence should lead to a consideration of a metastasis simulating a primary, such as an epidermotropic metastatic melanoma (702).

New markers are available that distinguish between vascular and lymphatic channels in paraffin sections and increase the sensitivity of detection of lymphovascular invasion. Use of the marker of lymphatic vessels D2-40 demonstrates an increased number of lymphatic vessels in melanomas compared to nevi and may be used to increase the frequency and specificity of detection of lymphatic invasion in melanomas (703). Tumor vascularity has also been correlated with survival in some studies (704,705). However, in another matched-pair analysis, tumor vascularity was found not to correlate with survival rates (706).

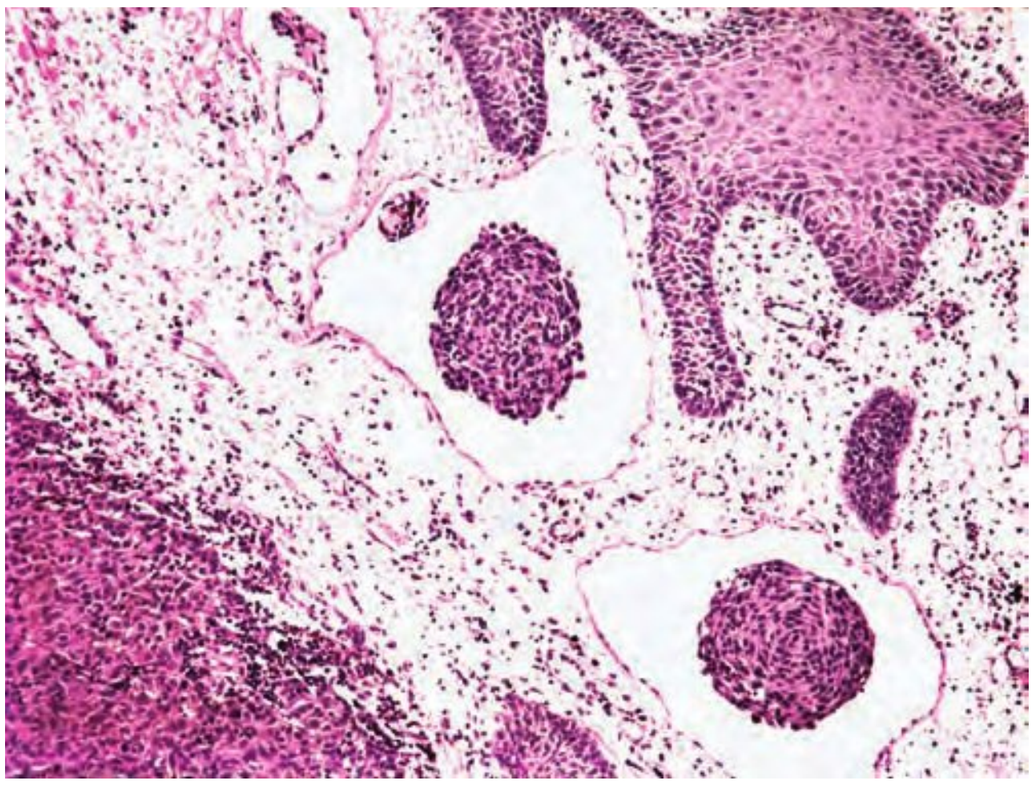

FIGURE 28-37. Lymphatic invasion. Although not often recognized except in very thick tumors, lymphatic invasion is probably an adverse prognostic attribute.

Satellites

Satellites are defined as discontinuous foci of tumor (metastases) located within 5 cm of a primary melanoma, whereas in-transit metastases are beyond 5 cm but still regional. The presence of satellites is a significant staging attribute in the current AJCC staging system, defining a lesion as stage IV, with a poor prognosis (613,622,679,697). Microscopic satellites are independently associated with worse prognosis (707,708). These are defined as tumor nests, greater than 0.05 mm in diameter, in the reticular dermis, panniculus, or vessels beneath the principal invasive tumor mass but separated from it by normal tissue on the section in which the Breslow measurement was taken (Fig. 28-38). In a recent study, the presence of microscopic satellites was associated with a greater likelihood of sentinel node positivity (709).

Other Clinicopathologic Prognostic Factors

Various factors in addition to thickness of the tumor have been cited as influencing the prognosis of clinical stage I melanoma, but many of them are directly related to thickness. In different clinicopathologic databases, multivariate analyses have led to prognostic models that differ somewhat in the predictive variables that are shown to have independent significance. Several features, however, have appeared in two or more of the studies.

Histogenetic Type. Among the histologic factors, the type of tumor, whether nodular or superficial spreading, does not, in most studies, independently affect the prognosis (447,472,710), despite a suggestion in some studies that the prognosis for lentigo maligna melanoma may be slightly better (711). Nodular melanomas, on average, are thicker than superficial spreading melanomas and thus have a worse prognosis overall (712,713). However, the prognosis is the same for nodular and other types of melanoma of similar thickness, and in multivariable analyses, nodular type is not an independent predictor (472,608,667, 711). The scarcity or absence of melanin in the tumor cells (amelanotic melanoma), indicative of poor differentiation, affects the prognosis adversely in some series but does so most likely because of correlations with tumor thickness and other variables (Fig. 33-28) (472). As already discussed, differences among these histogenetic types appear to reside more in the areas of etiology and pathogenesis than in prognosis or behavior. However, emerging data are demonstrating that the underlying oncogenic genotype of the different clinicopathologic entities may vary in a more or

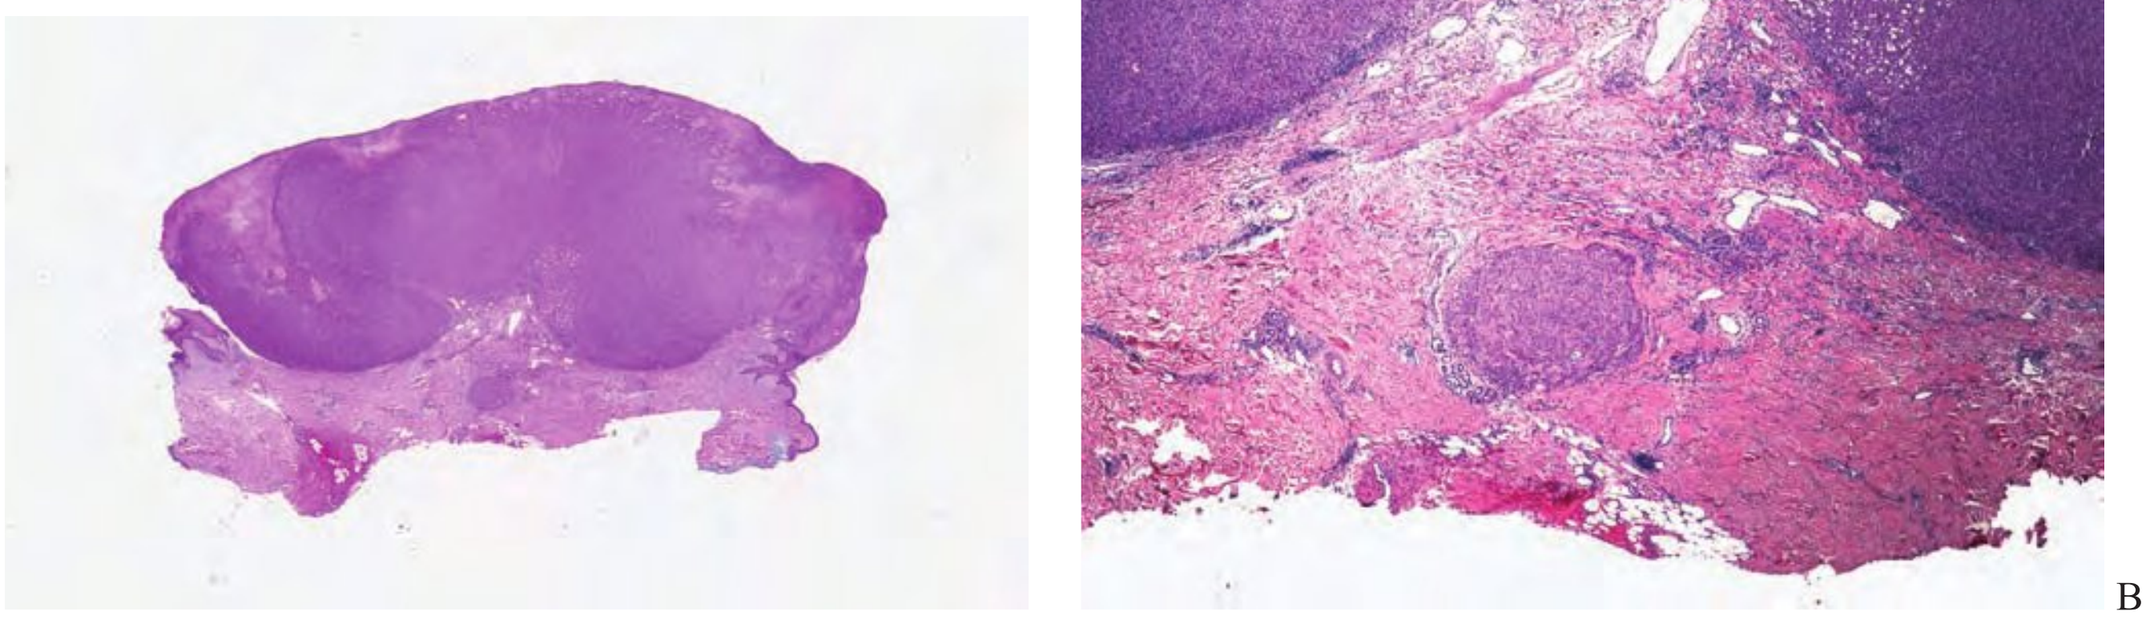

FIGURE 28-38. A: Microscopic satellite present at the base of a bulky tumorigenic vertical-growth-phase melanoma. B: The satellite is located in the superficial reticular dermis.

less predictable manner, so that assessment of characteristics of tumors that predict genotype profiles may be relevant to pathology in the future as therapies directed against these oncogenes are developed (419,449,459).

Lesional Location. Among the favorable clinical factors is location of the tumor on the hair-bearing portions of the limbs, in contrast to location on the trunk, neck, and head or palms and soles (612,667,687,714–717). In one of these studies, lower trunk, thigh, lower leg, foot, lower arms, hands, and face were identified as intermediate sites, with the remaining sites representing higher risk (714). In other studies, however, the palms and soles and the distal lower extremity were included in the higher-risk sites (472,717).

Gender. There is general agreement that women have a better prognosis than men, owing partly, but not entirely, to the higher incidence in women of lesions on the extremities, where the prognosis is favorable compared to the trunk (472,612, 667,716,718–720). The age of the patient has an adverse prognostic effect in some series (612,614,667,716,718,721).

Biological Markers

Biological markers derived from the study of the primary tumors or of host attributes may be expected to add to the precision of present prognostic models. The most consistently useful marker studied appears to be the proliferation marker Mib-1 (Ki-67), which has been found to be significantly related to mortality risk in a number of studies (680, 722–728). Other markers, in general, have not been studied in sufficiently large series of cases or have not been reproduced in other data sets, and no marker is in general use for this purpose.

Local Excision

Formerly, the margin of resection of the primary tumor was regarded by most authors as optimal at about 5 cm beyond the perimeter of the lesion (729). However, a much narrower margin is now acceptable. Margin width recommendations were reviewed by an NIH consensus conference in 1992 (730). A margin of 0.5 to 1.0 cm was recommended for excision of a melanoma *in situ*, with a margin of 1 cm for melanomas less than 1.0 mm thick and a 2- to 3-cm skin margin for thicker lesions (731–733). A worldwide cooperative study showed that in patients with primary melanomas no thicker than 2 mm, excisions with margins of 1 cm gave results as good as excisions with margins of 3 cm (734). A critical review of the literature revealed no evidence of an adverse effect on outcome in terms of survival from melanoma with narrowing of margins to 1 cm. A slightly increased rate of local recurrence was observed in some studies, especially with thicker primary tumors. This analysis therefore did not support the use of resection margins greater than 1 cm for invasive melanoma of any thickness (735). Others have considered similar or lesser margins (736,737). This hypothesis may be worthy of testing in a future randomized trial (738). Detailed therapeutic guidelines for melanoma are available online from the National Comprehensive Cancer Network (http://www.nccn.org).

In examining a resected specimen for melanoma, we generally serially embed the area of the biopsy scar and sample the specimen margin with perpendicular sections. The specimen is first inked to identify the true margin surface. After taking the initial margin section, the specimen is bread-loafed macroscopically, and any remaining lesions suspicious for possible satellites are also submitted for histologic examination. The margin widths discussed earlier are clinical margins, measured from the clinically visible periphery of the melanoma. Therefore, careful histologic examination of the excised tumor and its margins is mandatory because margins may be involved in spite of a clinically normal appearance. It is not necessary, however, to measure the margin width histologically in the resection specimen, as long as the width is adequate. In our practice, we generally alert the clinician when the margin width is less than 0.1 cm (less than 1 mm) in a resection specimen. The dermis and

subcutis should also be evaluated carefully (grossly and microscopically for the presence of satellites, which may have prognostic significance, and which may occasionally be present at the margin). Satellites are rare in relation to thin tumors, but in one study, they were detected in 22% of the reexcision specimens from melanomas greater than 2.25 mm in thickness (739). The presence of neurotropism should also be carefully sought and reported in melanoma resection specimens, especially of course if this neural invasion extends to the specimen margin.

Therapeutic and Elective Lymph Node Dissection

A clinically positive lymph node in a patient with primary cutaneous melanoma should be biopsied, and if the node is histologically positive, a full regional node dissection should be done as a therapeutic procedure (therapeutic regional lymph node dissection) with curative intent and to gain local control (740). For clinically negative lymph nodes, the role of elective regional lymph node dissection is controversial. Theoretically, regional nodes could be regarded as necessary filters that must be bypassed by all melanomas that metastasize systematically. However, it is clear that many melanomas metastasize by the hematogenous route to distant organs without ever involving regional nodes. Thus, lymph node involvement in many cases may be simply a marker of a melanoma that has already metastasized.

The incidence of regional lymph node involvement increases with the thickness of the tumor. Involvement of the regional lymph nodes is extremely rare in melanomas with a thickness of less than 0.76 mm. It is therefore generally agreed that elective regional lymph node dissection is not indicated for these melanomas (most of which are nontumorigenic) (741–743). For tumors 0.76 mm thick or thicker, the data are conflicting (742–747), and recent therapeutic trials have not completely resolved the issues (690,748,749). The next generation of trials of selective lymphadenectomy will likely be more conclusive (see next section).

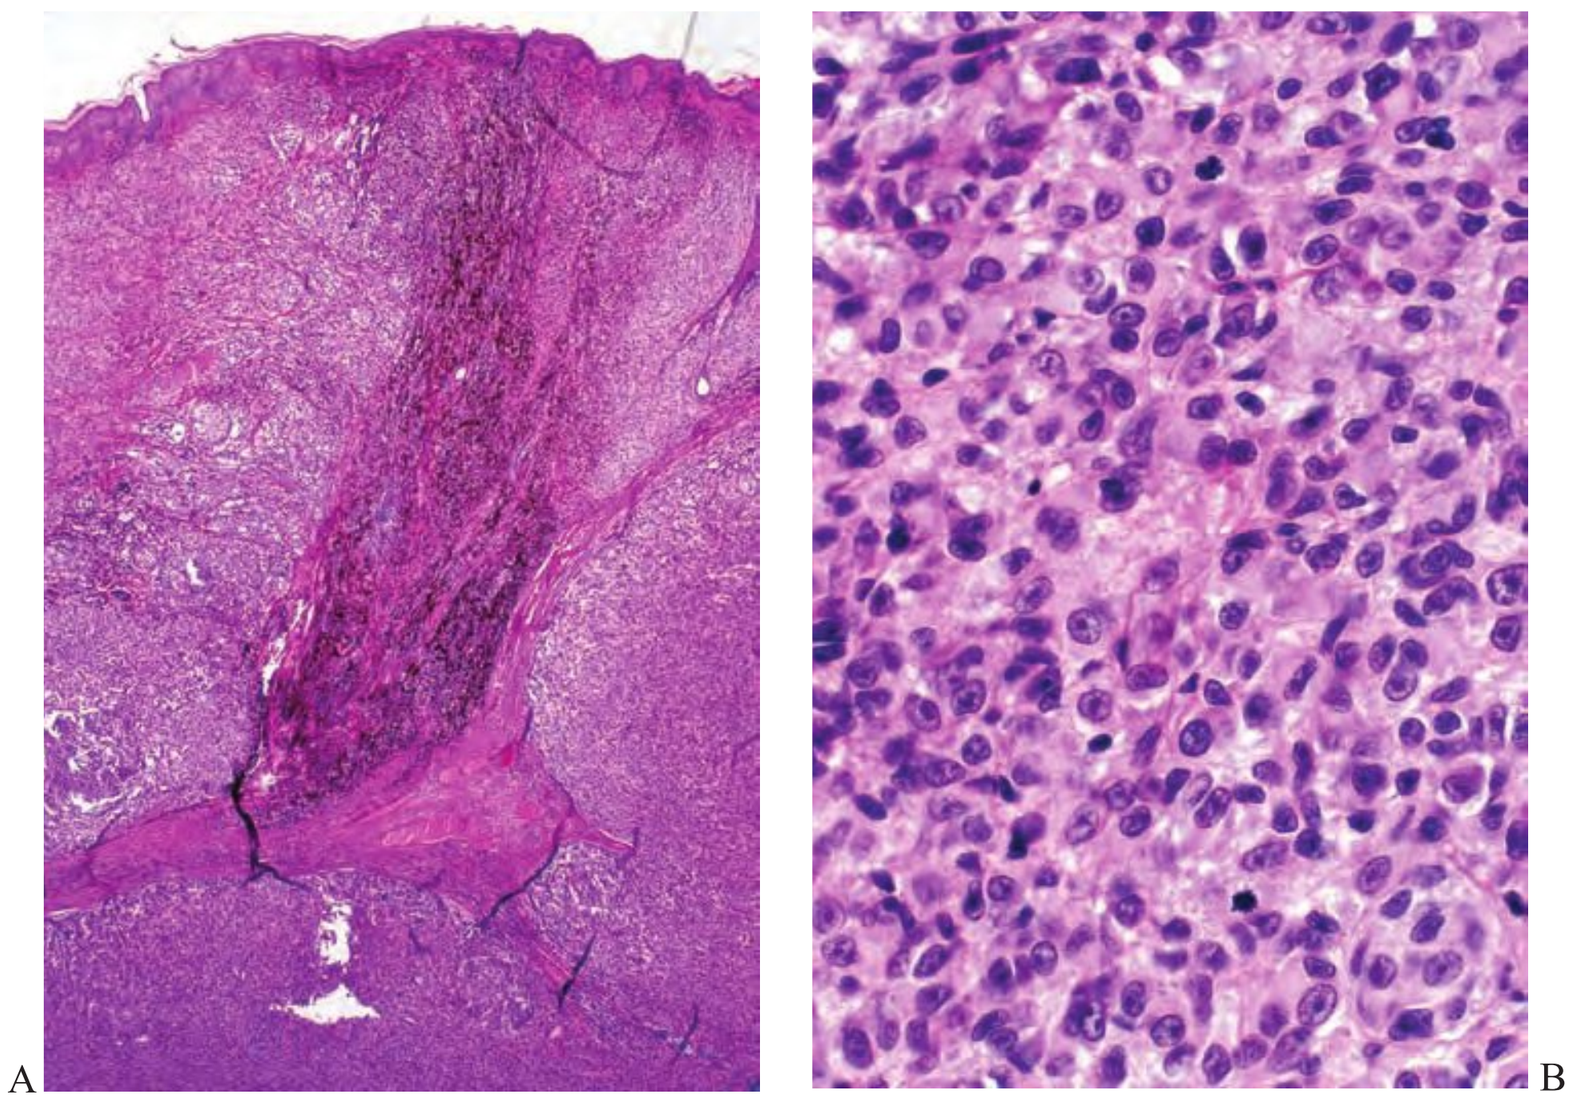
Melanoma patients with palpable lymph nodes are at a high risk of having distant metastases. The number of involved lymph nodes and the depth of the tumor are important prognostic factors. Patients who have metastases in less than 20% of their resected regional lymph nodes and a tumor thickness of less than 3.5 mm have a 5-year disease-free survival rate of 80%, compared with 18% for patients who have a tumor thickness greater than 3.5 mm or metastases in 20% or more of their resected lymph nodes (630). Of interest, the size of involved nodes is not related to survival (750). The presence of brisk TILs in a lymph node metastasis is a favorable prognostic attribute and was associated in one study with a survival rate of 83%, compared to 29% in patients whose metastases lacked TILs. Multivariate analysis confirmed the prognostic value of TILs in predicting disease-free survival in patients with regional node metastases (669).

Selective Lymphadenectomy (Sentinel Lymph Node Dissection)

Selective lymphadenectomy was developed by Morton as a means of sampling regional lymph nodes while avoiding most of the complications of an elective dissection (751). The sentinel lymph node is identified by injections into the region of the melanoma of radioactive colloid and a vegetable dye ("blue dye"). The sentinel node is defined as the first in the regional lymph node basis to contain these markers ("hot and blue"). Studies have demonstrated that if the sentinel node is negative, the probability of metastases being found in the remainder of the lymph node basin is very low. In early studies, the sentinel node was evaluated by frozen sections with rapid S100 staining (752). Currently, the standard procedure is to examine the node with paraffin hematoxylin-eosin sections, with S100 as a sensitive marker, and with HMB-45 or, more recently, Melan-A, as a more specific though less sensitive marker (753). Use of a cocktail of antibodies to MART-1, Melan-A, and tyrosinase has also been proposed (754). In evaluating the S100 stain, reactive dendritic cells, which are present in most sentinel nodes, must be distinguished from metastatic melanoma deposits. Capsular nevic rests must also be distinguished; these are located in capsular or sinusoidal collagen rather than in sinuses, lack significant cytologic atypia, and stain with S100 and sometimes with HMB-45 or Melan-A, although usually less intensely than is seen in authentic melanoma deposits.

True melanoma micrometastases are often present as immunoreactive cells in the subcapsular sinuses and/or the lymph node parenchyma, generally with correlative detection of cytologically malignant cells in corresponding hematoxylin-eosin–stained sections. Such deposits may be measured to provide some indication of tumor bulk, and if extension through the nodal capsule has occurred, this feature should be noted. In situations in which immunohistochemically suspicious cells are present but diligent attempts to confirm them as malignant cells in hematoxylin-eosin sections fails, the findings should be reported descriptively, indicating that the features are suspicious but not conclusive. Often, isolated MART-1– or HMB-45–positive cells may be identified, usually as only one or two cells in the lymphoid parenchyma, and it may be unclear whether these represent true micrometastases. In one recent report, although such cells were regarded as potential authentic single-cell micrometastases, patients with such changes did not exhibit differences in survival from those with negative sentinel nodes over a mean follow-up of 38.1 months (755). Moreover, not all MART-1/Melan A–positive cells in lymph node parenchyma necessarily represent metastatic melanoma, as emphasized in a recent study in which such cells were detected in lymph nodes of some nonmelanoma patients undergoing lymphadenectomy for breast cancer (756).

The clinical rationale for selective lymphadenectomy was recently reviewed by the National Comprehensive Cancer Network (757), citing data from the third interim analysis of the results from a large multicenter trial (758). In patients with primary melanoma 1.2 to 3.5 mm in thickness, there was no significant difference in melanoma-specific survival rates between the two groups (the 5-year disease-free survival was 78% for the biopsy group and 73% for the observation group). However, considering only patients with nodal metastases, those who had



immediate lymph node dissection after a positive sentinel lymph node biopsy (SLNB) had a higher survival rate than patients who had delayed lymphadenectomy for clinical disease (72% vs. 52%). This difference has been attributed to a lower nodal tumor burden in the sentinel node–positive patients than the clinically node-positive patients. It is concluded that "these results confirm that SLNB is of prognostic value and that the procedure can identify patients with low volume nodal metastases whose survival is superior to that of patients whose nodal metastases are detected on clinical examination" (757).

The Association of Directors of Anatomic and Surgical Pathology (ADASP) has published guidelines for the processing of lymph nodes, including sentinel nodes submitted for evaluation of metastatic disease. It is recommended that small nodes be submitted in their entirety or that larger nodes be sectioned at 3- to 4-mm intervals and entirely submitted. Intraoperative examination should be limited to those cases in which the procedure is likely to influence management (e.g., to confirm clinically and grossly positive nodes so that a complete node clearance can proceed). ADASP recommends that more than one section be performed on each sentinel node block. It is considered not clear how many sections and levels are optimal (759). Although the ADASP committee does not provide recommendations for immunostains, or even endorse this procedure unequivocally, in most centers it is the practice to perform S100 (more sensitive, less specific) and either HMB-45 or Melan-A (more specific, less sensitive) staining on one profile from each submitted sentinel node (760).

Malignant Blue Nevus

There exist potentially malignant melanocytic neoplasms that are unusual and do not necessarily qualify for application of the prognostic attributes of conventional vertical-growth-stage melanoma. These include the malignant blue nevus and a conceptual family of neoplasms of uncertain biological/malignant potential discussed in the next section. Malignant blue nevus is a rare tumor. It may arise in a blue or cellular blue nevus (761–764), a giant congenital nevus (289), or in a nevus of Ota (13), or it may be malignant from the start (765) . Malignant blue nevi may involve the dermis and may be ulcerated or may present as a deep-seated expansile mass (765). In some lesions classified as malignant blue nevus, metastases occur that are limited to the regional lymph nodes, and the patient survives after removal of the tumor and the involved lymph nodes (762). There may be overlap in these cases with the phenomenon of cellular blue nevi with regional metastases. In other cases, however, death occurs as the result of widespread metastases (44,761,765,766). Unfortunately, reliable distinction between these two groups of cases is not possible.

Histopathology. Recognition of the lesion as a malignant blue nevus rather than a common melanoma is based on the absence of junctional activity and the presence of at least some bipolar tumor cells with branching dendritic processes typically containing melanin granules, representing a background component of blue nevus or cellular blue nevus (Fig. 28-39A–D) (44,761,765). In some cases, pigment may be scant.

A B

FIGURE 28-39. A: Malignant blue nevus. A bulky melanocytic tumor with variegated patterns of architecture and pigmentation is present in the dermis without an associated in situ component in the epidermis. B: An area of solid growth showing severe uniform atypia and frequent mitoses. (continued)

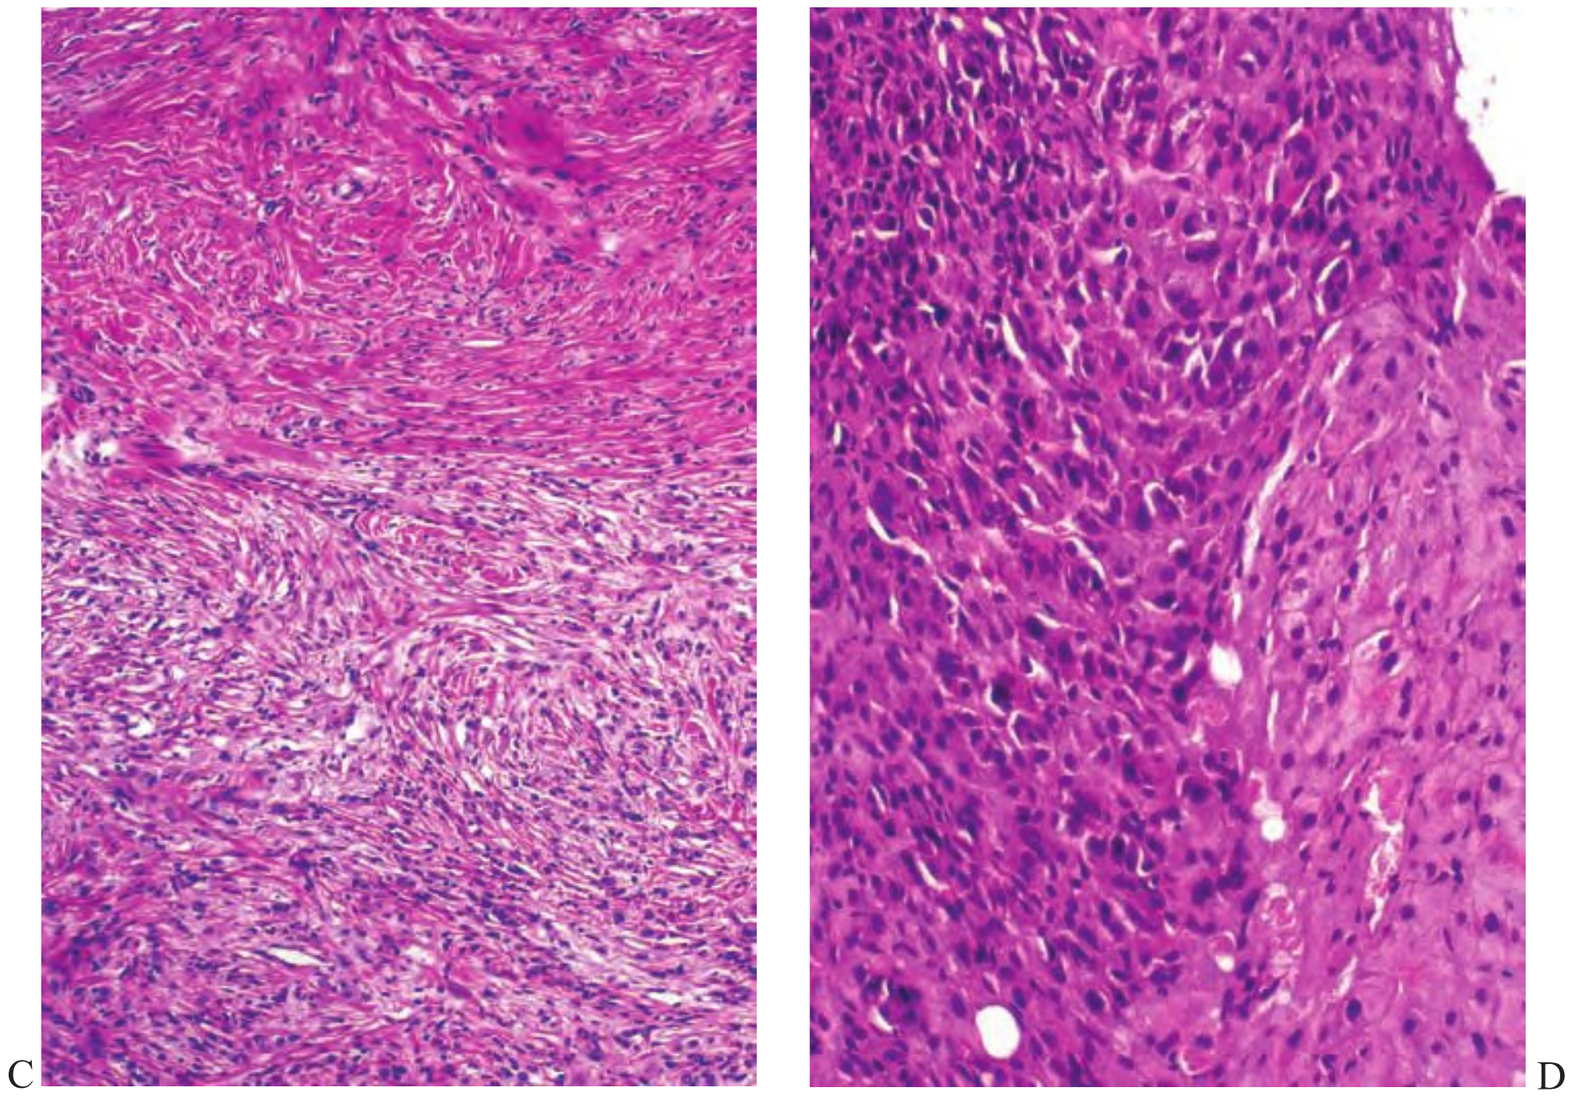


FIGURE 28-39. Continued. C: An area of blue nevus-like pattern at the top, with a more cellular blue nevus–like pattern at the bottom. D: Liver metastasis from a malignant blue nevus. Neoplastic melanocytes (left) in liver tissue (right) from a needle biopsy.

In addition to showing the standard features of malignancy, such as invasiveness of the tumor, atypia with hyperchromatism, pleomorphism and irregularity of the nuclei, and presence of atypical mitoses, malignant blue nevi often show areas of necrosis as evidence of their malignant nature (762,765). The combination of uniform cytologic atypia, high-grade atypia, spontaneous tumor necrosis, and more than a few mitoses may be considered diagnostic of malignant blue nevus in a lesion with a characteristic associated blue nevus pattern. Such cases are easily recognized as fully malignant neoplasms. Some lesions that do not meet all of these criteria; for example, some lesions that have lacked necrosis have metastasized (763). Atypical tumors with the overall appearance of cellular blue nevus that show only some of these features, especially if these are present in minor degree, may be signed out descriptively as melanocytic tumor of uncertain potential (see later section).

Histogenesis. Although some authors have regarded the tumor cells as related to Schwann cells (762), electron microscopic studies have shown the presence of melanosomes in the cells and a lack of cytoplasmic enclosures of unmyelinated axons, which would be seen if the tumor cells were Schwann cells. Although the melanosomes in many cells are devoid of melanin (765), incubation with DOPA has shown that they are strongly DOPA positive (44). Thus, it is evident that the tumor cells are melanocytes. Genetic data regarding the pathogenesis of malignant blue nevi are not available.

Differential Diagnosis. Malignant blue nevus differs from conventional primary melanoma by the absence of junctional activity and the presence of associated common and/or cellular blue nevus. However, distinction of a malignant blue nevus from a metastatic melanoma can be difficult because metastatic melanoma is occasionally found without a demonstrable primary melanoma. The primary melanoma may have involuted or may be located at an obscure internal site. The presence of dendritic cells indicative of an associated blue nevus or cellular blue nevus component is then the most reliable criterion favoring a diagnosis of malignant blue nevus instead of a metastatic melanoma. In doubtful cases, the differential diagnosis of metastatic melanoma should be expressed, and a workup for another primary should be considered clinically.

Melanocytic Tumors of Uncertain Malignant Potential (MELTUMP)

This is a descriptive term for a heterogeneous group of melanocytic tumors that exhibit some features indicative of possible malignancy, such as nuclear atypia, macronucleoli, mitotic activity, necrosis, or ulceration, but in number or

degree insufficient to justify a malignant diagnosis (231,767). Accordingly, they reflect the biological reality that occasional melanocytic lesions that do not meet criteria for fully evolved melanoma cannot be predicted to be benign with 100% accuracy.

Histopathology. Tumors appropriately placed in this descriptive category may be quite bulky neoplasms, of the order of several millimeters in diameter and thickness, composed of pigmented, often spindle-shaped cells. The overall cellularity may be relatively low compared to that of fully malignant melanomas. There may be occasional mitoses, but not more than one or a few per section plane. Abnormal mitoses, if present, are usually indicative of frank malignancy. Focal areas of individual-cell necrosis may be present, but if there are areas of confluent geographic necrosis or if an ulcer is present, a frankly malignant diagnosis is appropriate. There may be a few enlarged melanocytes in the epidermis but, if there is an intraepidermal component that can be identified as a radial growth phase of melanoma of any of the common types, a diagnosis of melanoma should be made.

Other examples include melanocytic tumors that superficially resemble ordinary nevus variants but that also include some (but not all) features associated with a malignant diagnosis. For example, a compound or dermal nevus with significant atypia within the dermal component, a Spitz nevus–like proliferation with some degree of asymmetry and deep mitotic activity, or a deep penetrating nevus with unusual features could all be placed in this category. In general, uncertain malignant potential implies an intradermal architecture with some features of tumorigenic growth (and, hence, some overlap with vertical-growth-phase melanoma), as opposed to a SAMPUS that is devoid of a dermal tumorigenic component, thus having no metastatic potential (albeit with some potential to progress or recur on incomplete excision).

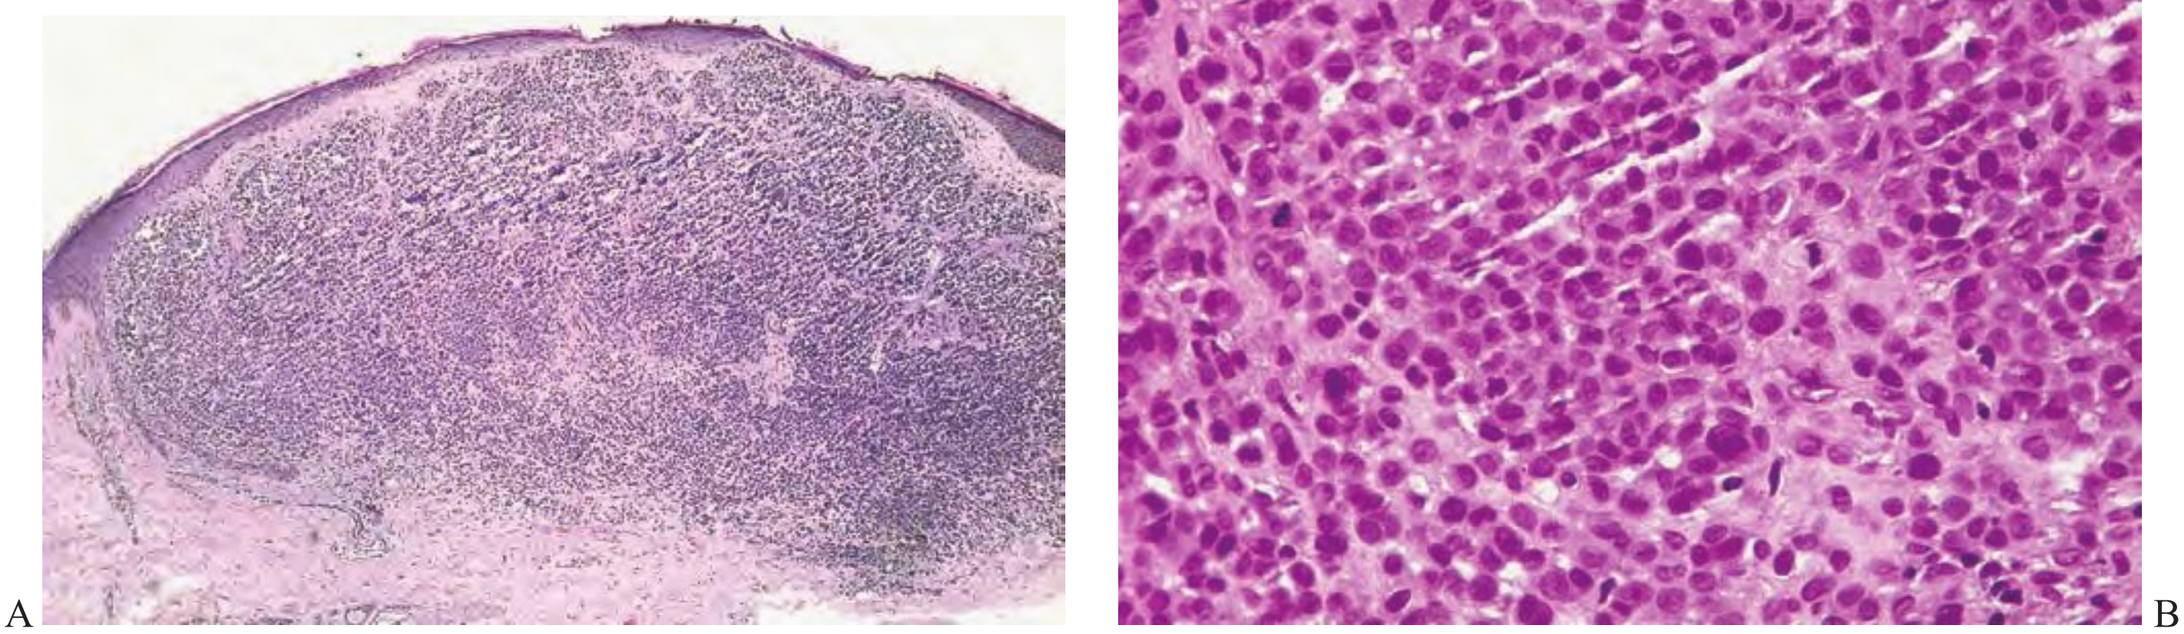
Differential Diagnosis. This descriptive diagnosis is one of exclusion, and the differential diagnosis includes specific neoplasms described elsewhere in this chapter, including atypical and Spitz nevi/tumors, so-called minimal deviation melanomas, some deep penetrating nevi, cellular neurothekeoma (discussed in the chapter on neural tumors), atypical cellular blue nevi, and certain nevoid melanoma variants.

Some lesions that may be placed in this descriptive category (that also have been discussed previously) are composed of tumoral intradermal proliferations of dendritic to epithelioid cells stuffed with abundant and coarsely divided pigment that may obscure the nucleus (554). Sometimes these cells are difficult to distinguish from melanophages. They are also reminiscent of dermal melanophores seen in some vertebrates, which in animals may occasionally give rise to malignant tumor resembling malignant blue nevi. Some of these lesions may have prominent epidermal involvement, with pagetoid spread of the heavily pigmented lesional cells into the epidermis and a dermal component that is broader in the papillary than in the reticular dermis. These lesions, despite their unusual cytology, have architectural features that are relatively characteristic of melanoma. There is overlap between these lesions and the lesions termed pigmented epithelioid melanocytomas, which in turn overlap with epithelioid blue nevi (557) on one hand and with pigment-synthesizing melanomas on the other hand (556). Some related lesions for which criteria for malignancy are not deemed to have been fully met may also be placed in the descriptive category of uncertain malignant potential (231). Still other very rare lesions present as nodular clusters of authentic melanophages (tumoral melanosis) (663). These lesions may be examples of complete regression of a pigmented vertical-growth-phase nodule, a very rare phenomenon that is quite differential from the partial regression frequently observed in the radial-growth-phase compartment of common melanomas.

Management. The existence of these difficult or uncertain cases, in which diagnostic agreement is not likely to be achieved even among experienced observers, suggests a need for a practical means of dealing with these cases in the best interests of the patients. In this regard, two principles apply. First, lesions should be managed by means sufficient to provide adequate therapy for the most clinically significant entity in the differential diagnosis of an uncertain neoplasm, and second, patients and their physicians are entitled to know that their lesion cannot be diagnosed specifically with presently available means. A pathology report in such a case should not provide a false assurance of confidence in any given diagnosis. In these cases, we typically recommend management with the differential diagnosis of melanoma taken into consideration and provide microstaging attributes sufficient at least for AJCC staging of the lesion as melanoma (768). The dimensions of a reexcision procedure could follow guidelines for the AJCC stage of the "melanoma," or at a minimum should be discussed with the patient and include a margin of normal tissue around the scar and any residual lesion.

In addition, a sentinel lymph node sampling procedure may be discussed with the patient. Sentinel lymph node sampling has been offered to patients with atypical or uncertain melanocytic tumors in a number of centers (224,227,769,770). Some of these cases have been found to be associated with lymph node metastases. In such circumstances, there may be a temptation to revise the diagnosis to "malignant melanoma." However, as previously discussed, there have been reports of lesions with characteristics of Spitz nevi that have metastasized to regional lymph nodes, sometimes followed by prolonged, perhaps indefinite survival (223,771,772). Similar situations have been reported in relation to cellular blue nevi (31,773). Therefore, in a situation in which a melanocytic tumor of uncertain malignant potential is found to be associated with regional lymph node metastases, we report the metastasis as "metastatic melanocytic tumor of uncertain malignant potential," where the word "malignant" refers to clinical course as a consequence of persistence and inexorable progression of disease rather than simply the ability of a neoplasm to travel to a draining lymph node. We indicate that the biological potential

of this metastatic tumor remains uncertain. However, the prognosis is clearly more guarded in the presence of such metastases, and, in such circumstances, the possibility of adjuvant therapy including interferon may be taken into consideration (227).



Metastatic Melanoma

Metastatic spread, uncommon in relation to thin melanomas, is quite common in tumors thicker than 2 mm. Regional skin and lymph node metastases usually present earlier than hematogenous metastases. Although metastases tend to occur within 5 years after onset of the disease, their appearance may be delayed, especially in thin melanomas (774). Late metastases, beyond 10 years, do occur, but they are relatively rare (775,776).

Clinically evident cutaneous metastases are arbitrarily called satellites if they are within 5 cm of the primary tumor and in-transit metastases if they are beyond this limit but still regional. The presence of these metastases is compatible with long-term survival but is usually associated with eventual relapse in distant sites (777). The prognosis for patients with distant metastatic disease is very poor. In one study, the median survival overall was 7.5 months; patients with cutaneous, nodal, or gastrointestinal metastases had a median survival of 12.5 months and an estimated 5-year survival rate of 14% (778). In a recent study of patients who had undergone metastasectomy for pulmonary metastatic melanoma, there was an estimated survival advantage of 10 to 12 months (764,779). Resection of a solitary metastasis (e.g., to lung, brain, liver, or gastrointestinal tract) may occasionally be associated with a remarkably good outcome, but such instances are exceedingly rare (780,781).

In about 4% to 10% of the patients who present initially with metastases of melanoma, no primary tumor can be found. The sex ratio, age incidence, family history, survival rates, and patterns of recurrence and further metastases in these patients with unknown primary melanomas are consistent with an unnoticed cutaneous lesion as the site of origin for the metastatic disease (782). Although a primary tumor may in some instances be in an internal organ or perhaps secondary to malignant transformation of extracutaneous nevus cell rests (as in lymph node capsules), it seems likely that in most instances it was located in the skin and regressed spontaneously. In a study of 40 patients with unknown primary melanoma, patients with lymph node metastasis survived significantly longer than patients diagnosed with lymph node metastasis concurrent with a known cutaneous primary melanoma. The prevalence of dysplastic nevi was intermediate between that reported among primary melanoma patients and that reported among population controls, suggesting the likelihood of a primary cutaneous origin for the metastatic melanoma (783). In some instances, there is a history of a spontaneously resolving pigmented lesion, and one may see at that site either a hypopigmented area or an irregular, flat, pigmented lesion, consistent with complete regression of a putative primary melanoma at that site (784).

Histopathology. The histologic appearance of melanoma metastases in the skin resembles the tumorigenic vertical growth phase of a primary melanoma but usually differs from that of a primary melanoma by the absence of an inflammatory infiltrate and of junctional activity (Fig. 28-40). However, primary melanomas may occasionally fail to involve the epidermis and may also not show an inflammatory infiltrate,

A B

FIGURE 28-40. A: Dermal metastatic melanoma. Metastatic melanoma often presents as a fairly symmetric cellular nodule in the reticular dermis or subcutis. The lesions are often quite small at the time they are excised and presented for an initial diagnosis of metastatic spread. B: Cytologically, the cells are uniformly atypical, as in tumorigenic primary melanomas (compare Figs. 28-23B, 28-26B, 28-31A, 28-36, and 28-39B with each other). Sometimes, especially in superficial or epidermotropic cutaneous metastases, atypia is deceptively minimal. The identification of mitotic activity and of lymphatic invasion may be very helpful in making the diagnosis.

particularly when they are deeply invasive. Furthermore, in occasional instances, even metastases exhibit a prominent lymphocytic infiltrate (669) and can contact the overlying epidermis in a way that is suggestive of junctional activity, with nests of atypical melanocytes in the epidermis. Some metastatic melanomas may have a nevoid phenotype, and clinicopathologic correlation (e.g., follow-up) may be required to differentiate them from a primary nevoid melanoma or even from a nevus (785). In the latter situation, careful examination of specimen levels will generally reveal mitotic activity and apoptotic cells in true nevoid metastases.

Microscopic satellites have been defined as deposits of tumor more than 0.05 mm in diameter and separated from the primary mass by normal tissue, such as reticular dermis collagen (707). These should be identified and reported because they are elements of the AJCC staging system (622). In a study of the use of immunohistochemistry to increase sensitivity of detection, small satellite micrometastases were detected in 12.4% of 265 melanoma cases. The presence of these micrometastases has been correlated with sentinel node positivity (709,786).

Epidermotropic metastatic melanoma refers to a metastatic deposit that is initially localized to the papillary dermis and involves the overlying epidermis. Most of these lesions occur in an extremity regional to a distal primary melanoma. Epidermotropic metastasis is characterized by (a) thinning of the epidermis by aggregates of atypical melanocytes within the dermis, (b) inward turning of the rete ridges at the periphery of the lesion, and (c) usually no lateral extension of atypical melanocytes within the epidermis beyond the concentration of the metastasis in the dermis (787). However, this distinction can be very difficult at times, and cases have been reported in which there was lateral extension beyond the dermal component (587,788). In some other cases, the metastatic cells are small and nevoid, with few if any mitoses, and in these instances of differentiated or nevoid epidermotropic metastatic melanoma or epidermotropic metastatic melanomas with maturation the lesions can be mistaken for compound nevi (563).

Generalized Melanosis in Metastatic Melanoma

This is a rare phenomenon that may be associated with widespread melanoma metastases. It is characterized by diffuse, slate-blue discoloration of the entire skin, the conjunctivae, and the oral and pharyngeal mucous membranes, often with melanuria. Melanin granules have been observed also in blood smears within neutrophils and monocytes. Autopsy reveals a similar discoloration in the intima of the large arteries and of many visceral organs (789).

Histologically, numerous melanin granules are seen located within macrophages throughout the dermis, especially around capillaries. They stain with the Fontana-Masson stain and are DOPA positive. In addition, some dermal vessels are focally plugged with dark, amorphous DOPA-positive material. In most instances, only melanophages have been found. It is assumed that the melanin is produced by distant melanoma cells and then carried by the blood to the skin, to be deposited within dermal melanophages (789,790). In a few cases, two types of pigmented cells have been identified in the dermis, particularly in semithin sections: melanophages and individually scattered melanoma cells appearing larger and less pigmented than the melanophages. At autopsy, melanin phagocytosis is seen in many organs, especially in the Kupffer cells of the liver and the cells lining the sinusoids of the lymph nodes, spleen, and adrenal glands (790).

CHAPTER 29

Nigel Kirkham

Tumors and Cysts of the Epidermis

CLASSIFICATION OF TUMORS OF THE EPIDERMIS

Epidermal tumors can be divided into tumors of the surface epidermis and tumors of the epidermal appendages. In each of the two classes, benign and malignant tumors occur.

Benign tumors in general are characterized by (a) a symmetric architecture and a circumscribed profile; (b) a tendency to differentiate along organized tissue lines; (c) uniformity in the appearance of the tumor cell nuclei; (d) architectural order in the arrangement of the tumor cell nuclei; (e) restraint in the rate of growth; and (f) absence of metastases.

Malignant tumors, in contrast, are characterized by (a) a less symmetric architecture and a poorly circumscribed profile; (b) a variable but often poorly differentiated phenotype; (c) atypicality in the appearance of the tumor cell nuclei, which show pleomorphism, that is, great variability in size and shape, and anaplasia, that is, hyperplasia and hyperchromasia; (d) architectural disorder in the arrangement of the tumor cell nuclei with loss of polarity; (e) rapid growth with the presence of mitoses, including atypical mitoses; and (f) potentiality to give rise to metastases.

Of the criteria of malignancy just cited, only the potentiality to give rise to metastases is decisive evidence for the malignancy of a tumor. For metastases to form, the tumor cells must possess a degree of autonomy that nonmalignant cells do not have. This autonomy enables malignant tumor cells to induce foreign tissue to furnish the necessary stroma in which they can multiply.

In addition to malignant tumors, one finds in the surface epidermis so-called premalignant tumors, better regarded as tumors located largely *in situ*. Although cytologically malignant, they are biologically still benign. The World Health Organization has classified tumors of the surface epidermis (1).

LINEAR EPIDERMAL NEVUS

Linear epidermal nevi, or verrucous nevi, may be either localized or systematized.

In the *localized type*, which is present usually but not invariably at birth, only one linear lesion is present. It consists of closely set, papillomatous, hyperkeratotic papules. It may be located anywhere—on the head, trunk, or extremities. Being located on only one side of the patient, it is often referred to as *nevus unius lateris* (Figs. 29-1 and 29-2). In its configuration, the localized type of linear epidermal nevus resembles the inflammatory linear verrucous epidermal nevus (ILVEN), but the latter differs clinically by the presence of erythema and pruritus and histologically by the presence of inflammation and parakeratosis (2,3) (see Chapter 7).

In the *systematized type*, papillomatous hyperkeratotic papules in a linear configuration are present not just as one linear lesion, as in the localized type, but as many linear lesions. These linear lesions often show a parallel arrangement, particularly on the trunk. They may be limited to one side of the patient or may have a bilateral, symmetric distribution. The term *ichthyosis hystrix* is occasionally used, perhaps unnecessarily, for instances of extensive bilateral lesions (4).

Localized and, more commonly, systematized linear epidermal nevi may be associated with skeletal deformities and central nervous system deficiencies, such as mental retardation, epilepsy, and neural deafness (5).

The presence of a basal cell epithelioma within a linear epidermal nevus has been observed occasionally, particularly on the head in cases in which the linear epidermal nevus has been associated with either a nevus sebaceous or a syringocystadenoma papilliferum (see Chapter 30) (6). In areas other than the head, it is very rare (7). Similarly, development of a squamous cell carcinoma has been described only rarely (8,9), but in one instance the squamous cell carcinoma had metastasized to a regional lymph node (10).

Histopathology. Nearly all cases of the localized type of linear epidermal nevus and some cases of the systematized type show the histologic picture of a benign papilloma (4,11). One observes considerable hyperkeratosis, papillomatosis, and acanthosis with elongation of the rete ridges resembling seborrheic keratosis (Fig. 29-3).

Occasionally in cases of the localized type, but quite frequently in cases of the systematized type, particularly those with a widespread distribution, one observes the rather striking histologic picture referred to either as *epidermolytic hyperkeratosis* (12) or as *granular degeneration of the epidermis* (13). It is the same process that was first recognized in all cases of bullous congenital ichthyosiform erythroderma, a disorder that is often referred to as *epidermolytic hyperkeratosis* (see Chapter 6). It has since been

FIGURE 29-1. Epidermal nevus. The nevus lies in a fold of the external ear and has a papillary appearance.

found to occur in several other conditions as well (see Isolated and Disseminated Epidermolytic Acanthoma).

The salient histologic features of epidermolytic hyperkeratosis are (a) perinuclear vacuolization of the cells in the stratum spinosum and in the stratum granulosum; (b) irregular cellular boundaries peripheral to the vacuolization; (c) an increased

FIGURE 29-2. Linear epidermal nevus. This example is pigmented and lies in the midline, on the back of the neck.

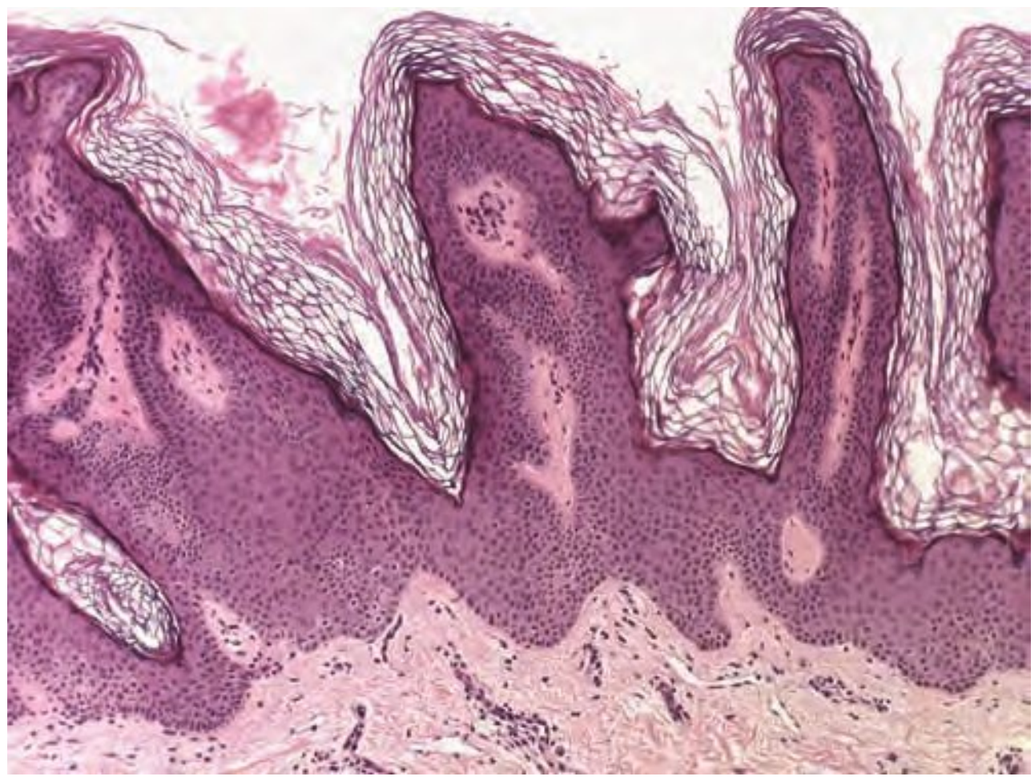

FIGURE 29-3. Epidermal nevus. The nevus shows orthokeratotic hyperkeratosis and flat-topped papillary projections.

number of irregularly shaped, large keratohyaline granules; and (d) compact hyperkeratosis in the stratum corneum (13,14).

In some instances, histologic examination of unilateral linear lesions reveals features of acantholytic dyskeratosis as seen in Darier's disease (see Chapter 6). In some patients, these linear lesions have been present since birth or infancy (15), but in most instances they have arisen in adult life (16). Because acantholytic dyskeratosis is not specific for Darier's disease, the proposal has been made to designate such cases not as Darier's disease, but as acantholytic dyskeratotic epidermal nevus (16).

Differential Diagnosis. The histologic picture of a benign papilloma, as found in most cases of linear epidermal nevus, can also be seen in seborrheic keratosis, verruca vulgaris, and acanthosis nigricans. Even though these four conditions have in common hyperkeratosis and papillomatosis, they can be differentiated easily in typical cases; however, one is occasionally unable to make a diagnosis any more specific than benign papilloma. Thus, in the following three situations, clinical data are required for differentiation from linear epidermal nevus: (a) the hyperkeratotic type of seborrheic keratosis, which is characterized by the absence of basaloid cells and horn cysts and instead shows upward extension of epidermis-lined papillae; (b) old verrucae vulgares, which no longer show vacuolization of epidermal cells or columns of parakeratosis (see Chapter 25); and (c) acanthosis nigricans showing more pronounced acanthosis and greater elongation of the rete ridges than usual (see Chapter 17).

NEVOID HYPERKERATOSIS OF NIPPLE AND AREOLA

Nevoid hyperkeratosis and papillomatosis of nipples and areola presents as sharply demarcated papules and plaques, often appearing at puberty or during pregnancy and persisting unchanged. There are no associated systemic or dermatologic

conditions. The main differential diagnosis is seborrheic keratosis (17).

Histopathology. There are papillomatous elongations of the epidermis with hyperkeratosis and areas of keratotic plugging (18). This condition represents a nevoid form of hyperkeratosis (19).

NEVUS COMEDONICUS

A nevus comedonicus consists of closely set, slightly elevated papules that have in their center a dark, firm, hyperkeratotic plug resembling a comedo. Nevus comedonicus, like linear epidermal nevus, usually has a linear configuration and occurs as a single lesion. In some instances, however, there are multiple bilateral linear lesions (20) or lesions that are randomly distributed rather than linear (21). Lesions may be present on the palms or soles in addition to other areas (22,23). Such cases may represent a combination of nevus comedonicus with a porokeratotic eccrine duct nevus (see text following).

Histopathology. Each comedo is represented by a wide, deep invagination of the epidermis filled with keratin. These invaginations resemble dilated hair follicles; in fact, as evidence that they actually represent rudimentary hair follicles, one occasionally finds in the lower portion of an invagination one or even several hair shafts (20). One or two small sebaceous gland lobules may also be seen opening into the lower pole of invaginations (21).

In several instances, the keratinocytes composing the follicular epithelial wall have shown the typical changes of epidermolytic hyperkeratosis (see text following) (24), indicative of a relationship of nevus comedonicus to systematized nevus verrucosus (see Chapter 30).

POROKERATOTIC ECCRINE OSTIAL AND DERMAL DUCT NEVUS

Porokeratotic eccrine ostial and dermal duct nevus may be limited to a palm (25) or to a sole (26) but may be present on both hands and feet and elsewhere (27,28). It also may involve not only eccrine ducts, but also involve hair follicles on the hairy parts of the body (29).

Histopathology. In the porokeratotic eccrine duct nevus, each invagination consists of a dilated eccrine duct containing a parakeratotic plug. The absence of the granular layer at the base of the plug together with the presence of keratinocytes showing vacuolization of their cytoplasm results in a histologic picture resembling that of porokeratosis (see Chapter 6) (25–27).

ISOLATED AND DISSEMINATED EPIDERMOLYTIC ACANTHOMA

Isolated epidermolytic acanthoma, histologically characterized by the presence of "epidermolytic hyperkeratosis," does not have a characteristic clinical appearance or location. Usually it occurs as a solitary papillomatous lesion less than 1 cm in diameter (30–32). Occasionally, several lesions are seen in a localized area (33,34). One case has been described that was probably secondary to trauma (35).

Disseminated epidermolytic acanthoma occurs as numerous discrete, flat, brownish papules 2 to 6 mm in diameter resembling seborrheic keratoses. The upper trunk, especially the back, is the site of predilection (36,37).

Histopathology. In addition to hyperkeratosis and papillomatosis, one observes pronounced epidermolytic hyperkeratosis, also referred to as *granular degeneration*, throughout the stratum malpighii, sparing only the basal layer, just as seen in linear epidermal nevi with epidermolytic changes. One observes both intracellular and intercellular edema of the epidermal cells and keratohyaline granules that are coarser than normal and extend to a greater depth in the stratum malpighii (30).

Differential Diagnosis. Myrmecia warts, caused by human papilloma virus type 1 (HPV-1), also show perinuclear vacuolization and an abundance of keratohyaline granules, representing a type of "granular degeneration" similar to that seen in epidermolytic hyperkeratosis. However, in myrmecia warts, the keratohyaline granules are eosinophilic and coalesce in the upper layers of the epidermis to form large, homogeneous, eosinophilic "inclusion bodies." In verrucae vulgares, usually caused by HPV-2, foci of vacuolated cells and clumped basophilic keratohyaline granules may be present, but these changes are limited to the upper layers of the epidermis. In addition, both myrmecia warts and verrucae vulgares show focal parakeratosis rather than orthokeratosis as seen in epidermolytic hyperkeratosis (see Chapter 25).

INCIDENTAL EPIDERMOLYTIC HYPERKERATOSIS

Epidermolytic hyperkeratosis is seen not only in isolated and disseminated epidermolytic hyperkeratosis (see text preceding) but also as a *regular* finding in epidermolytic hyperkeratosis, or bullous congenital ichthyosiform erythroderma (see Chapter 6), and in epidermolytic keratosis palmaris et plantaris and as an *occasional* finding in linear epidermal nevus and nevus comedonicus. In addition, epidermolytic hyperkeratosis may represent an *incidental* histologic finding in many different types of lesions, largely but not exclusively tumors. It has also been observed in normal oral mucosa adjacent to lesions of squamous cell carcinoma and basal cell epithelioma (38).

Histopathology. Epidermolytic hyperkeratosis may be seen throughout an entire lesion of solar keratosis (39) and in the entire lining of trichilemmal cyst (40). More commonly, however, the histologic features of epidermolytic hyperkeratosis are seen as a small focus, often limited to a single epidermal rete ridge, in such diverse lesions as sebaceous hyperplasia (41), intradermal nevus, hypertrophic scar (42), superficial basal cell epithelioma (43), seborrheic keratosis, the margin of a squamous cell carcinoma, lichenoid amyloidosis, and granuloma annulare

(12). In some instances, the process is limited to one or two intraepidermal sweat duct units (42). It is more frequently seen in dysplastic nevi than in ordinary melanocytic nevi (43).

ISOLATED AND DISSEMINATED ACANTHOLYTIC ACANTHOMA

This condition usually occurs as a solitary papule or small nodule (45), although there may be multiple lesions (46,47). No characteristic clinical appearance or location exists, although multiple lesions have been seen largely in the genital region (26,50).

Histopathology. Acantholysis is the most prominent feature. The pattern may resemble that of pemphigus vulgaris, pemphigus vegetans, pemphigus foliaceus, or benign familial pemphigus (45). Acantholysis may be combined with dyskeratosis, in which case the histologic picture resembles that of Darier's disease as the result of the presence of corps ronds and grains (12,46,47). Because of this the alternative name of *dyskeratotic acanthoma* has been suggested (48).

INCIDENTAL FOCAL ACANTHOLYTIC DYSKERATOSIS

Analogous to epidermolytic hyperkeratosis, acantholytic dyskeratosis is seen as a *regular* histologic feature in Darier's disease (see Chapter 6), transient acantholytic dermatosis, and warty dyskeratoma. It also is an *occasional* finding in acantholytic dyskeratotic epidermal nevus, a variant of linear epidermal nevus. In addition, again like epidermolytic hyperkeratosis, focal acantholytic dyskeratosis is observed occasionally as an *incidental* histologic finding in a variety of lesions, including vascular nevi (49).

Histopathology. Focal suprabasal clefts with overlying acantholytic and dyskeratotic cells, some of which have the appearance of corps ronds (Fig. 29-4), have been seen as a single focus in the epidermis overlying such diverse lesions as dermatofibroma, basal cell epithelioma, melanocytic nevus, and chondrodermatitis nodularis helicis (40), as well as in pityriasis rosea (51) and acral lentiginous malignant melanoma (Fig. 29-2) (52).

ORAL WHITE SPONGE NEVUS

First described in 1935 (53), oral white sponge nevus is a benign autosomal dominant disorder that affects noncornifying stratified squamous epithelia. It may be present at birth or have its onset in infancy, childhood, or adolescence (54). Extensive areas of the oral mucosa and sometimes the entire oral mucosa have a thickened, folded, creamy white appearance. In some instances, the rectal mucosa (53), vagina (55), nasal mucosa (56), or esophagus (57) is also involved. This distribution of lesions suggests that mutations in the epithelial keratins K4 and/or K13 may be responsible: A three base-pair deletion in the helix initiation peptide of K4 has been reported in affected members of two families (58). Further studies of one large family suggested that a K13 gene was responsible (59).

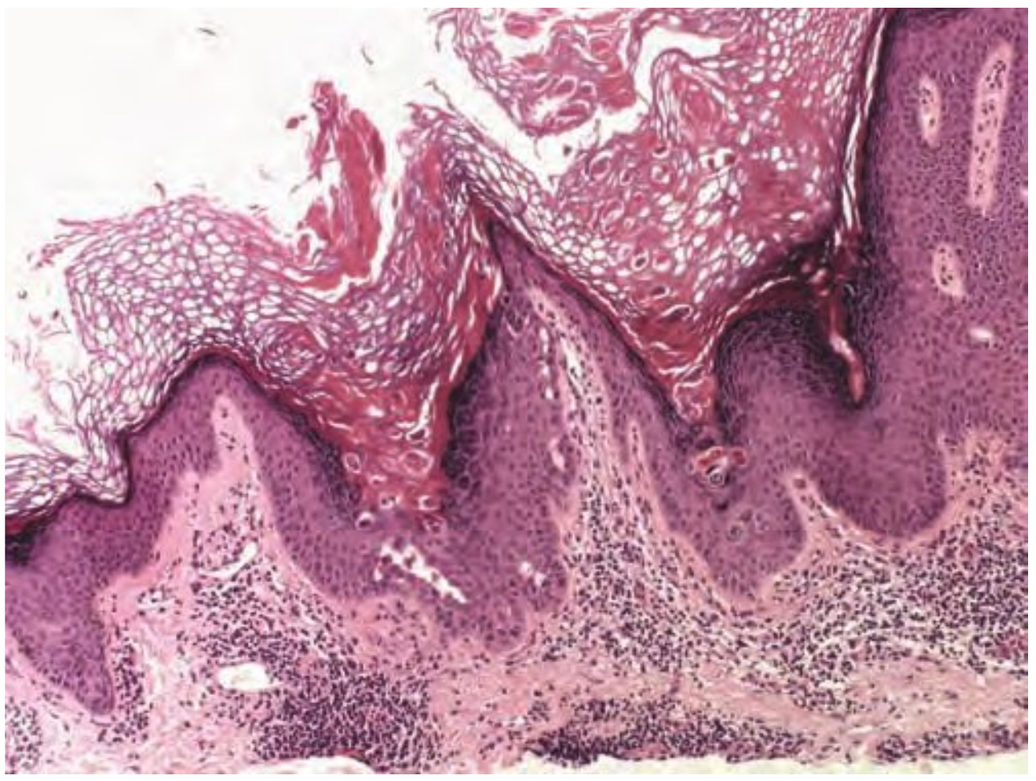

FIGURE 29-4. Incidental focal acantholytic dyskeratosis. Focally, within the biopsy, there is suprabasal cleft formation with overlying dyskeratotic cells.

The oral lesions seen in pachyonychia congenita are both clinically and histologically indistinguishable from a white sponge nevus (see Chapter 6) (56).

Histopathology. The oral epithelium shows hyperplasia with much more pronounced hydropic swelling of the epithelial cells than is normal for the oral mucosa. The swelling, though extensive, is focal (60). It extends into the rete ridges but spares the basal layer (61). The nuclei appear smaller than normal (54). The surface shows parakeratosis, as does the normal oral mucosa, and only rarely are there small accumulations of keratohyaline granules (55).

Pathogenesis. On electron microscopic examination, large cytoplasmic areas of the epithelial cells appear optically empty or contain only faint granular material. Tonofilaments are limited to the perinuclear and peripheral areas. The intercellular areas show irregular dilation, and large, irregularly shaped vacuoles are present within the cytoplasm (62). A possibly fundamental disturbance is the presence of numerous intracellular Odland bodies or membrane-coating granules (see Chapter 3), which are not extruded into the intercellular spaces (63).

Differential Diagnosis. The histologic picture of oral white sponge nevus is identical to that seen in pachyonychia congenita (see text preceding) and to that of oral focal epithelial hyperplasia (62) and of leukoedema of the oral mucosa (see text following).

LEUKOEDEMA OF THE ORAL MUCOSA

Leukoedema of the oral mucosa is a common condition that, when pronounced, shows a clinical and histologic resemblance

to oral white sponge nevus. However, leukoedema differs from white sponge nevus by being patchy rather than diffuse, by having exacerbations and remissions and adult onset, and by not being inherited (64).

Histopathology. In leukoedema of the oral mucosa, as in oral white sponge nevus, the suprabasal epithelial cells show marked intracellular edema. The nuclei appear smaller than normal.

LINGUA GEOGRAPHICA

In geographic tongue, also referred to as superficial migratory glossitis, the dorsum of the tongue shows irregularly shaped red patches surrounded by a whitish, raised border a few millimeters wide (65). It is usually asymptomatic, with local loss of filiform papillae leading to the development of ulcer-like lesions that rapidly change color and size (66).

Histopathology. Whereas the dorsum of the tongue normally shows a granular and a horny layer, these layers are absent in the red patches of lingua geographica. Along the whitish border, the epithelium shows irregular thickening and infiltration of neutrophils. In its upper portion, the epithelium shows collections of neutrophils within the interstices of a spongelike network formed by degenerated and thinned epithelial cells (67,68). The histologic picture thus shows Kogoj's spongiform pustules, which are indistinguishable from those seen in pustular psoriasis.

Pathogenesis. The presence of spongiform pustules generally is regarded as diagnostic of pustular psoriasis and as almost specific for it (see Chapter 7), even though it rarely occurs in other pustules, such as those caused by *Candida albicans* (69). It has therefore been suggested that geographic tongue represents a localized form of pustular psoriasis (70). However, even though pustular psoriasis and lingua geographica may both show annular lesions on the tongue, pustular psoriasis of the mouth generally shows clinical evidence of pustules and is usually seen also in other areas of the mouth. It is therefore best to regard lingua geographica as a separate entity.

SEBORRHEIC KERATOSIS

Seborrheic keratoses are very common: sometimes single but often multiple. They occur mainly on the trunk and face but also on the extremities, excluding palms and soles. They usually do not appear before middle age, but are present in about 20% of the elderly (70). They are sharply demarcated, brownish in color, and slightly raised, often appearing as though stuck on the surface of the skin. Most have a verrucous surface, and a soft, friable consistency. Some have a smooth surface but characteristically show keratotic plugs. Although most lesions measure only a few millimeters in diameter, some occasionally reach a size of several centimeters. Crusting and an inflammatory base are found if the lesion has been subjected to trauma.

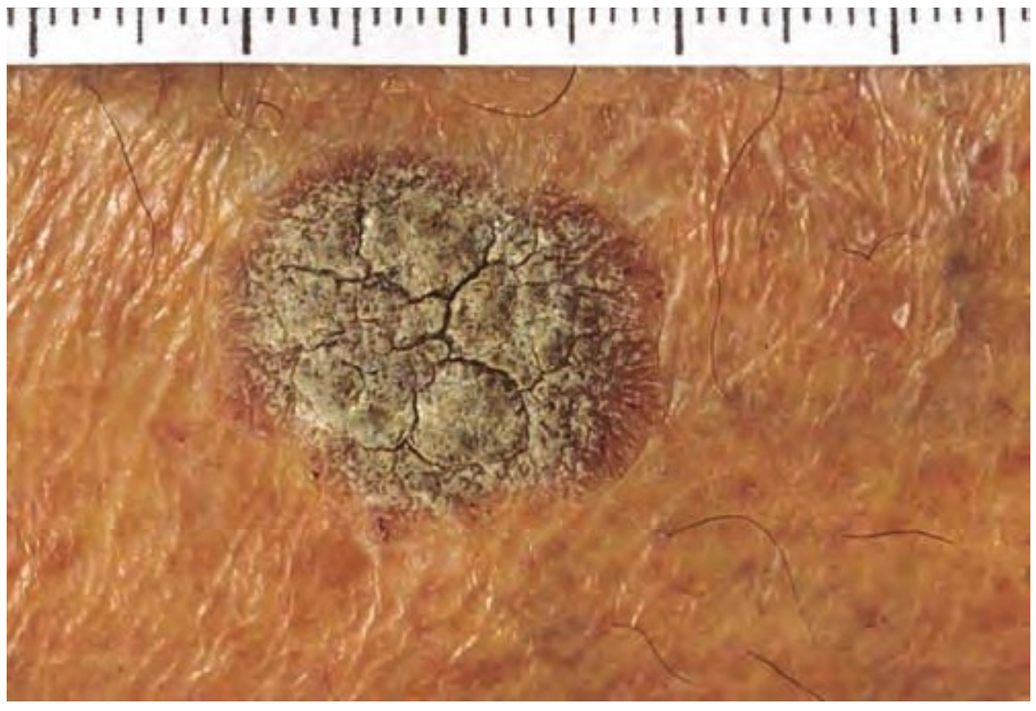

FIGURE 29-5. Seborrheic keratosis. The keratosis has a grayish, waxy appearance.

Occasionally, small examples are pedunculated, especially on the neck and upper chest, where they resemble soft fibromas (see Chapter 32). Malignant change is rare but has been reported in association with unusual clinical appearances to the seborrhoeic keratoses (71).

Histopathology. Seborrheic keratoses show a considerable variety of histologic appearances. Six types are generally recognized: irritated; adenoid or reticulated; plane; clonal; melanoacanthoma; inverted follicular keratosis; and benign squamous keratosis (Figs. 29-5 to 29-13). Often more than one type is found in the same lesion. In addition, two clinical variants of seborrheic keratosis will be described—dermatosis papulosa nigra and stucco keratosis (Fig. 29-14).

All types of seborrheic keratosis have in common hyperkeratosis, acanthosis, and papillomatosis. The acanthosis in most instances is due entirely to upward extension of the tumor. Thus the lower border of the tumor is even and generally lies on a straight line that may be drawn from the normal

FIGURE 29-6. Seborrheic keratosis. Two keratoses lie close together and show variable pigmentation.

FIGURE 29-7. Seborrheic keratosis. Low magnification. The keratosis is radially symmetric, contains several horn cysts, and has a flat base.

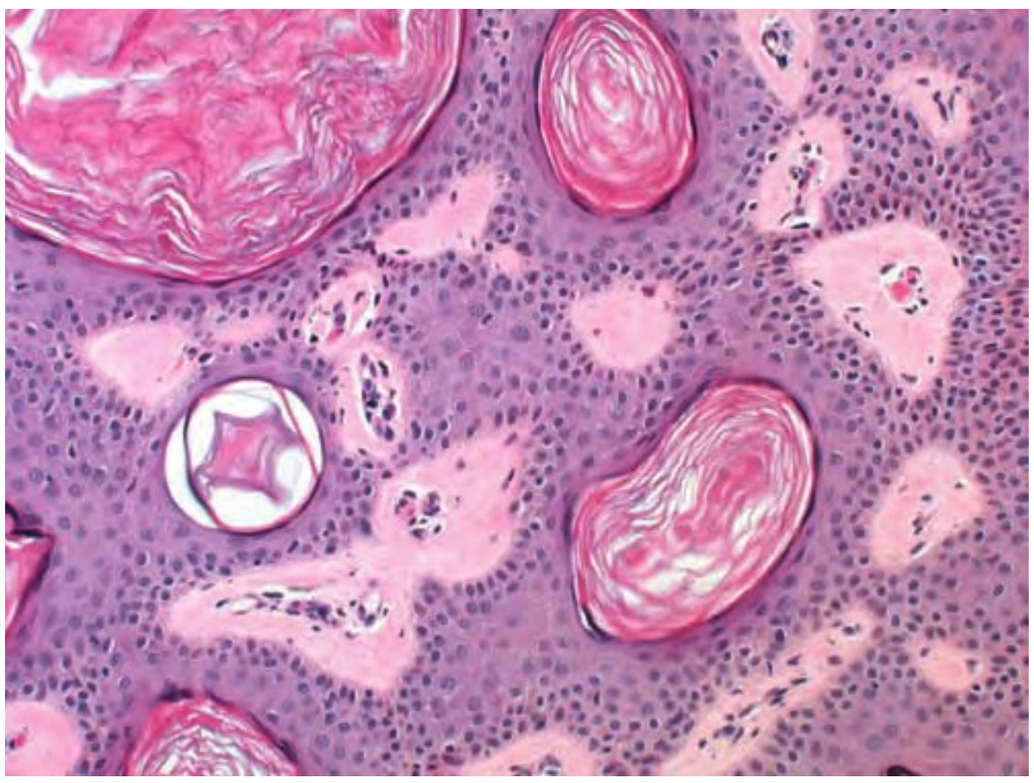

FIGURE 29-8. Seborrheic keratosis. High magnification. Most of the cells have a basaloid appearance, with interspersed horn cysts filled with keratin.

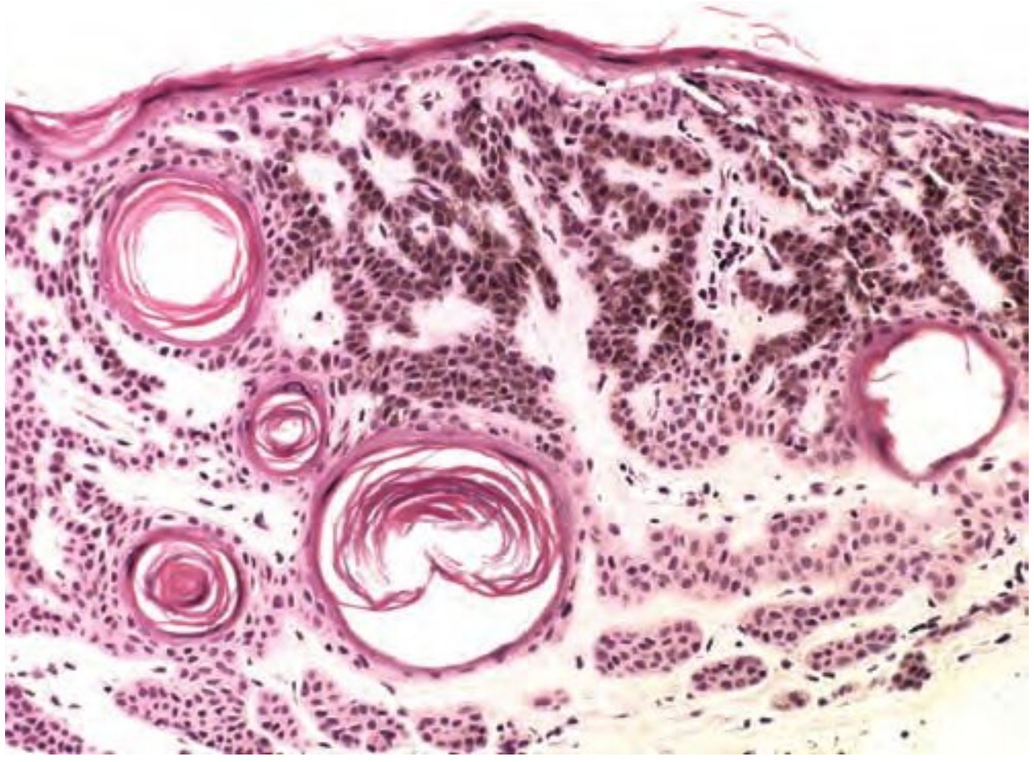

FIGURE 29-9. Pigmented seborrheic keratosis. Thin interwoven cords of basaloid cells show cytoplasmic melanin pigmentation and horn cysts.

FIGURE 29-10. Clonal seborrheic keratosis, showing focal variation in pigmentation.

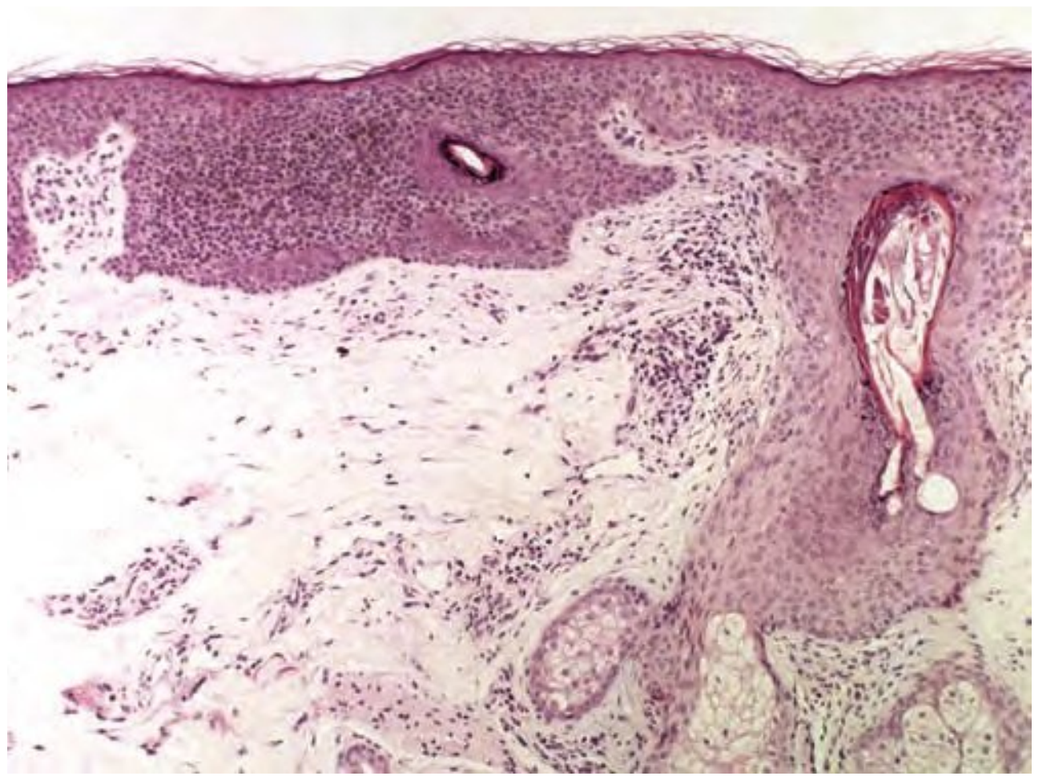

FIGURE 29-11. Clonal seborrheic keratosis showing foci of basaloid cells surrounded by more eosinophilic squamous cells.

FIGURE 29-12. Irritated seborrheic keratosis showing inflammation of the adjacent skin.

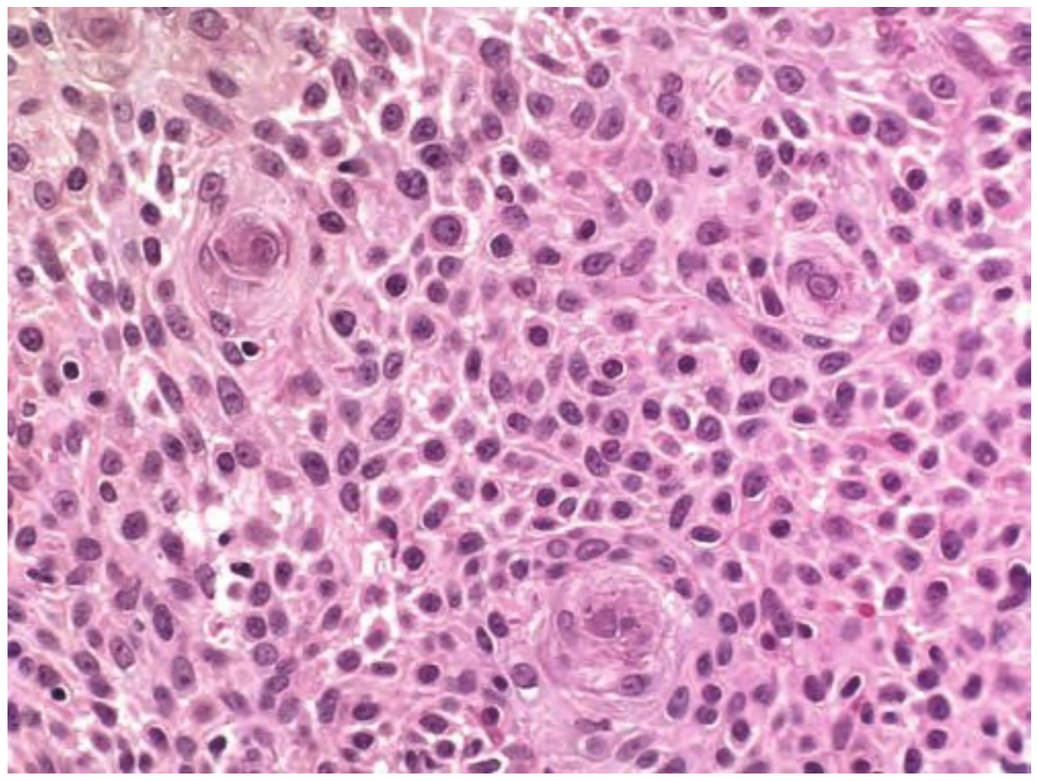

FIGURE 29-13. Inverted follicular keratosis. Squamous eddies are present, composed of whorls of squamous cells. There is no substantial cytologic atypia.

epidermis at one end of the tumor to the normal epidermis at the other end (see Fig. 29-7). Two types of cells are usually seen in the acanthotic epidermis: squamous cells and basaloid cells. The former have the appearance of squamous cells normally found in the epidermis; the basaloid cells are small and uniform in appearance and have a relatively large nucleus. In areas of slight intercellular edema, intercellular bridges can be easily recognized (72). Thus they resemble the basal cells found normally in the basal layer of the epidermis.

Irritated Type and Inverted Follicular Keratosis

In the irritated, or activated, type of seborrheic keratosis, squamous cells outnumber basaloid cells. The characteristic feature is the presence of numerous whorls or eddies composed of eosinophilic, flattened squamous cells arranged in an onion-peel fashion, resembling poorly differentiated horn pearls (Figs. 29-12 and 29-13). These "squamous eddies" are easily differentiated from the horn pearls of squamous cell carcinoma by their large number, small size, and circumscribed configuration. Irritated seborrheic keratoses, in addition, may show areas of downward proliferation breaking through the horizontal demarcation generally present in nonirritated seborrheic keratoses (73,74). Frequently, some of these proliferations are seen to originate from the walls of keratin-filled invaginations. Inflammation beneath irritated seborrheic keratoses usually is mild or absent, indicating that irritated seborrheic keratoses are different from inflamed seborrheic keratoses.

In a few instances, acantholysis has been observed within tumor nests composed of squamous cells (75). These acantholytic changes differ from those occurring in incidental focal acantholytic dyskeratosis by not showing suprabasal location or dyskeratotic cells resembling corps ronds (76).

Pathogenesis. The formation of numerous squamous eddies is the result of the "activation" of resting basaloid cells into squamous cells. This unique and highly diagnostic feature of irritated or activated seborrheic keratoses, as well as their downward proliferation, is the result of irritation. This has been proved experimentally by the excision of seborrheic keratoses either after a previous biopsy (77) or after irritation with croton oil (78).

The identical histologic picture as seen in irritated seborrheic keratosis has been described under the designations of *inverted follicular keratosis* (79,80) and *follicular poroma* (81,82). As these terms indicate, the authors regard the keratin-filled invaginations as follicular infundibula and the proliferations arising from them as composed of cells of the follicular infundibulum. The follicular infundibulum consists of cells with the same type of keratinization as the surface epidermis, and there is evidence that seborrheic keratoses incorporate cells of the infundibular portion of the hair follicle and are partially derived from these cells. Seborrheic keratoses, like inverted follicular keratoses, occur exclusively on hair-bearing skin. Some seborrheic keratoses even contain aggregates of vellus hairs within the keratinous invaginations, an occurrence analogous to trichostasis spinulosa (see Chapter 18) (83). Although some authors merely concede that irritated seborrheic keratoses and inverted follicular keratoses may be histologically indistinguishable (74,84,85), others regard the two disorders as identical (73,83,86). Because of their histologic similarity and particularly because of the highly specific appearance of the squamous eddies that occur in these two conditions, they are best regarded as identical.

FIGURE 29-14. Stucco keratoses: multiple small, white and gray-white seborrheic keratoses.

Adenoid or Reticulated Type

In the adenoid or reticulated type of seborrheic keratosis, numerous thin tracts of epidermal cells extend from the epidermis and show branching and interweaving in the dermis. Many tracts are composed of only a double row of basaloid cells. Horn cysts and pseudo–horn cysts are absent in purely reticulated lesions; however, the reticulated type often also shows areas of the acanthotic type, and horn cysts and

pseudo–horn cysts are commonly seen in these areas. The basaloid cells of the reticulated type of seborrheic keratosis usually show marked hyperpigmentation.

There is both clinical and histologic evidence of a close relationship between solar or senile lentigo senilis and the reticulated type of seborrheic keratosis. A lesion of solar lentigo may even become a reticulated seborrheic keratosis through exaggeration of the process of downward budding of pigmented basaloid cells (see Chapter 28) (87).

Acanthotic Type

In the acanthotic type, the most common type of seborrheic keratosis, hyperkeratosis and papillomatosis often are slight, but the epidermis is greatly thickened. Although only narrow papillae are included in the thickened epidermis in some cases, one can see in other lesions a retiform pattern composed of thick, interwoven tracts of epithelial cells surrounding islands of connective tissue. Horny invaginations that on cross sections appear as pseudo–horn cysts are numerous. In addition, there also are true horn cysts, which, like the pseudo–horn cysts, show sudden and complete keratinization with only a very thin granular layer.

The true horn cysts begin as foci of orthokeratosis within the substance of the lesion (88). In time, they enlarge and are carried by the current of epidermal cells toward the surface of the lesion, where they unite with the invaginations of surface keratin. In the greatly thickened epidermis, basaloid cells usually outnumber squamous cells.

The amount of melanin in seborrheic keratoses of the acanthotic type is often greater than normal. Excess amounts of melanin are seen in about one third of the specimens stained with hematoxylin-eosin (89); staining with silver reveals excess amounts in about two thirds of the cases (90). In dopa-stained sections, melanocytes are limited to the dermal–epidermal junctional layer present at the base of the tumor and at the interfaces between the tumor tracts and the islands of dermal stroma (78). The melanin, largely present in keratinocytes, is in most instances also limited to keratinocytes located at the dermal–epidermal junction. Only deeply pigmented lesions show melanin widely distributed throughout the tumor within basaloid cells (91).

A mononuclear inflammatory infiltrate is seen quite frequently in the dermis underlying a seborrheic keratosis. The inflammation may impinge on the tumor in a lichenoid or eczematous pattern. In the lichenoid pattern, a bandlike infiltrate is seen hugging the basal cell layer of the tumor. In the eczematous pattern, there is exocytosis leading to spongiosis. Squamous eddies, typical of irritated seborrheic keratoses, are only rarely seen in inflamed seborrheic keratoses (92).

Formation of an *in situ* carcinoma within an acanthotic seborrheic keratosis, so-called bowenoid transformation, is seen occasionally (93,94). It seems to occur predominantly in lesions located in sun-exposed areas of the skin, so that sun damage may be a factor (95). In one reported case, a metastasis in a regional lymph node was found (96). On rare occasions, a basal cell epithelioma may form within an acanthotic seborrheic keratosis and may extend from there into the underlying dermis (97,98).

Pathogenesis. Electron microscopic examination has confirmed the light microscopic impression that the small basaloid cells seen in the acanthotic type of seborrheic keratosis are related to cells of the epidermal basal cell layer rather than to the basaloma cells of basal cell epithelioma. They possess a fair number of desmosomes and a moderate number of tonofilaments that differ from those present in cells of the epidermal basal cell layer only by showing less orientation (99).

Hyperkeratotic Type

In the hyperkeratotic type, also referred to as the digitate or serrated type, hyperkeratosis and papillomatosis are pronounced, whereas acanthosis is not very conspicuous. The numerous digitate upward extensions of epidermis-lined papillae often resemble church spires. The histologic picture then resembles that seen in acrokeratosis verruciformis of Hopf (see Chapter 6). The epidermis consists largely of squamous cells, although small aggregates of basaloid cells may be seen here and there. As a rule, no excess amounts of melanin are found.

Clonal Type

In the clonal, or nesting, type of seborrheic keratosis, well-defined nests of cells are located within the epidermis. In some instances, the nests resemble foci of basal cell epithelioma because the nuclei appear small and dark-staining and intercellular bridges are seen in only a few areas (see Figs. 29-10 and 29-11) (100). The histologic picture in such cases has been erroneously interpreted by some authors as representing an intraepidermal epithelioma of Borst-Jadassohn (see Chapter 30) (101). In other instances of clonal seborrheic keratosis, the nests are composed of fairly large cells showing distinct intercellular bridges, with the nests separated from one another by strands of cells exhibiting small, dark nuclei.

Melanoacanthoma

This rather rare variant of pigmented seborrheic keratosis (91) differs from the usual type of pigmented seborrheic keratosis by showing a marked increase in the concentration of melanocytes. Rather than being confined to the basal layer of the tumor lobules, many melanocytes are scattered throughout the tumor lobules (91,102). In some instances, well-defined islands of basaloid cells intermingled with many melanocytes are distributed through the tumor (103). The melanocytes are large and richly dendritic and contain variable amounts of melanin. The block in transfer of melanin from melanocytes to keratinocytes often is only partial (102), although in some instances nearly all the melanin is retained in the melanocytes (104).

Pathogenesis. Melanoacanthoma is a benign mixed tumor of melanocytes and keratinocytes (91).

DERMATOSIS PAPULOSA NIGRA

Dermatosis papulosa nigra is found in about 35% of all adult blacks, often has its onset during adolescence (105), and has been described in a 3-year-old child (106). The lesions are located predominantly on the face, especially in the malar regions, but they also may occur on the neck and upper trunk. They usually consist of small, smooth, pigmented papules, except on the neck and trunk, where some of them may be pedunculated.

Histopathology. The lesions have the histologic appearance of seborrheic keratoses but are smaller. Most lesions are of the acanthotic type and show thick interwoven tracts of epithelial cells. The cells are largely squamous in appearance, with only a few basaloid cells (105). Horn cysts are quite common. An occasional lesion shows a reticulated pattern in which the tracts are composed of a double row of basaloid cells. Melanin pigmentation is pronounced in all lesions.

STUCCO KERATOSIS

Stucco keratoses are small, gray-white seborrheic keratoses 1 to 3 mm in diameter located in symmetric arrangement on the distal portions of the extremities, especially the ankles (Fig. 29-14). They can easily be scraped off without any resultant bleeding.

Histopathology. Stucco keratoses have the appearance of the hyperkeratotic type of seborrheic keratosis, showing the church-spire pattern of upward-extending papillae (96,97). Horn cysts and basaloid cells are usually absent (109).

LESER-TRÉLAT SIGN

The Leser-Trélat sign is characterized by the sudden appearance of numerous seborrheic keratoses in association with a malignant tumor. Although many reports have appeared in recent years concerning this sign and although its existence is accepted, it is not always easy to decide which cases should be included. In some instances, numerous seborrheic keratoses develop on inflamed skin, but this does not represent the Leser-Trélat sign (92). A review of 40 cases that were accepted as representing the Leser-Trélat sign (110) showed that 30% had "malignant" acanthosis nigricans (see Chapter 17) either accompanying (111) or following the sign (112). Thus the Leser-Trélat sign has been interpreted as "an incomplete form of acanthosis nigricans" (113) or as "potentially representing an early stage of acanthosis nigricans" (112).

Although the malignant tumor in 67% of the reported cases consisted of an abdominal adenocarcinoma (110,114), the remaining 33% included many different types of malignancies, including leukemia (115) and mycosis fungoides (116). More controversially, a case–control study failed to demonstrate a specific association between eruptive seborrheic keratoses and internal cancer risk (117).

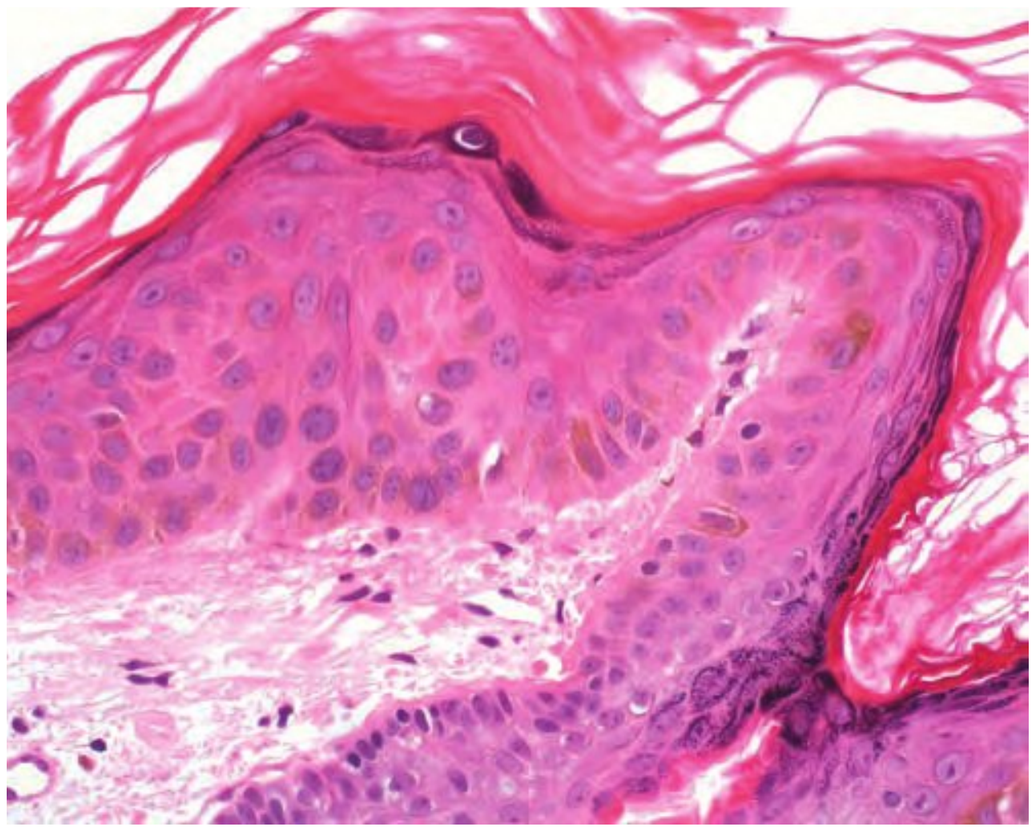

FIGURE 29-15. Large cell acanthoma. Keratinocytes are increased in size and arranged in a disorderly manner.

Histopathology. The seborrheic keratoses in the Leser-Trélat sign are the same as other seborrheic keratoses. The hyperkeratotic form is indistinguishable from malignant acanthosis nigricans (110,118).

LARGE CELL ACANTHOMA

Large cell acanthoma occurs as a slightly hyperkeratotic, sharply demarcated patch, usually on sun-exposed skin of the head or extremities. As a rule, it measures less than 1 cm in size. Generally, it is a solitary lesion; occasionally multiple lesions are observed (119–121).

Histopathology. Within a well-demarcated area of the epidermis, the scattered large keratinocytes are about twice the normal size and have proportionally large nuclei. There may be a disordered arrangement of the keratinocytes (Fig. 29-15).

Pathogenesis. The lesion is aneuploid, with various stages of development, and is probably related to stucco keratosis (119,121).

CLEAR CELL ACANTHOMA

Clear cell acanthoma, a tumor that is clinically and histologically quite distinct, was first described in 1962 (122). It is not rare. Typically the lesions are solitary and occur on the legs. They are slowly growing, sharply delineated, red nodules or plaques 1 to 2 cm in diameter and usually covered with a thin crust and exuding some moisture. A collarette is often seen at the periphery. It has been said that the lesion appears stuck on, like a seborrheic keratosis, and is vascular, like a granuloma pyogenicum (Fig. 29-16) (123,124).

FIGURE 29-16. Clear cell acanthoma. A raised, sharply demarcated patch.

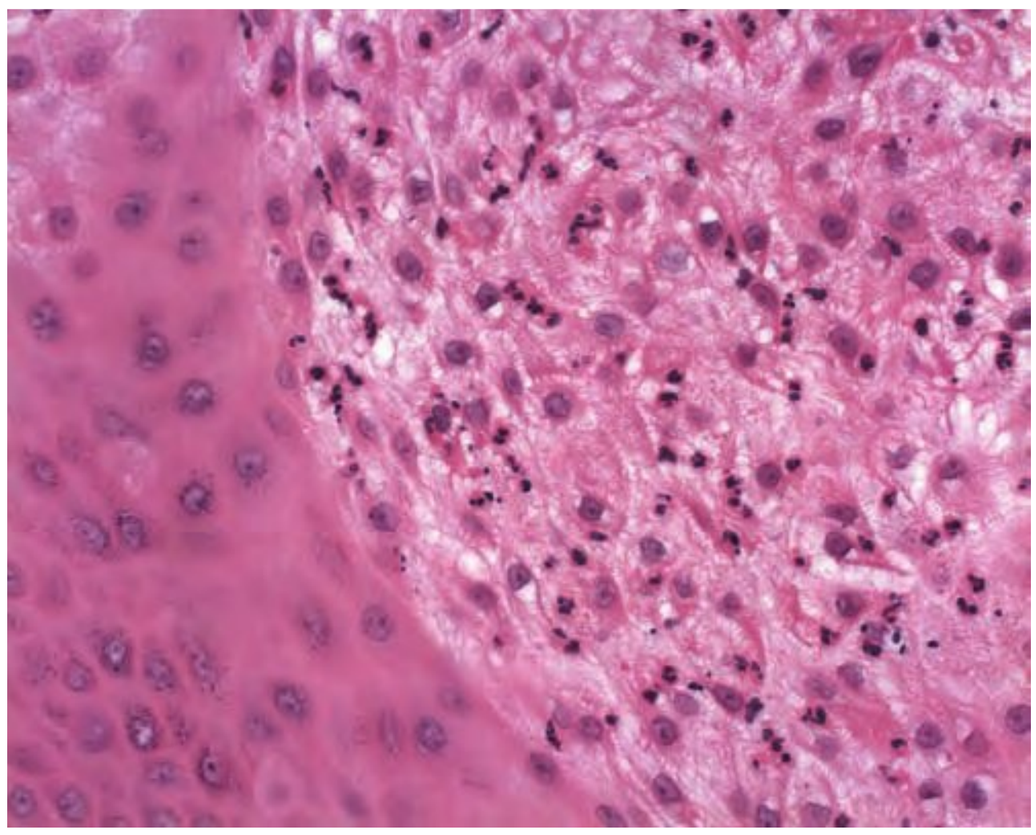

FIGURE 29-18. Clear cell acanthoma. High magnification. Neutrophils and nuclear dust are scattered through the clear cells of the lesion.

Histopathology. Within a sharply demarcated area of the epidermis, all epidermal cells, with the exception of cells of the basal cell layer, appear strikingly clear and slightly enlarged (Figs. 29-17 and 29-18). The nuclei of the clear epidermal cells appear normal. When staining is carried out with the periodic acid-Schiff (PAS) reaction, the presence of large amounts of glycogen is revealed within the cells (122,125).

Slight spongiosis is present between the clear cells. The rete ridges are elongated and may show intertwining (126). The surface shows parakeratosis with few or no granular cells. The acrosyringia and acrotrichia within the tumor retain their normal stainability (125). There is an absence of melanin within the tumor cells, but dendritic melanocytes containing melanin are occasionally seen interspersed between the clear cells (125,128).

A conspicuous feature in most lesions is the presence throughout the epidermis of numerous neutrophils, many of which show fragmentation of their nuclei (Fig. 29-18). The neutrophils often form microabscesses in the parakeratotic horny layer (129,130). Dilated capillaries are seen in the elongated papillae and often also in the dermis underlying the tumor (125). In addition, a mild to moderately severe cellular infiltrate composed largely of lymphoid cells is present in the dermis. Some clear cell acanthomas appear papillomatous, so that they have the configuration of a seborrheic keratosis (131).

Beneath the tumor, some cases have shown hyperplasia of sweat ducts (129) or syringoma-like proliferations (132).

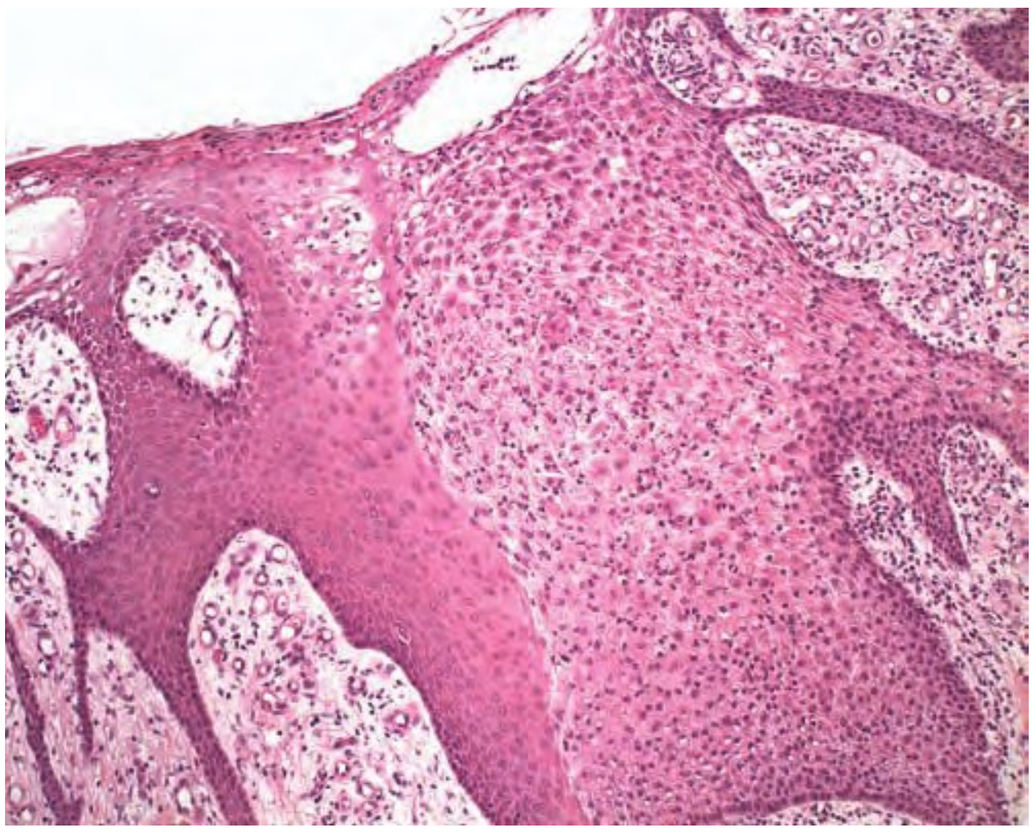

FIGURE 29-17. Clear cell acanthoma. The cells within the lesion appear pale by comparison with the adjacent normal epidermis.

Pathogenesis. On histochemical examination, phosphorylase is absent in clear cell acanthoma except for the basal cell layer. This enzyme normally is present in the epidermis and is necessary for the degradation of glycogen (133).

Electron microscopy reveals glycogen granules in the tumor cells, except in the cells of the basal cell layer. In the lower portion of the tumor, the glycogen granules are seen largely around the nuclei. In the upper portion, however, the amount of glycogen is increased, and the granules are seen to infiltrate between the tonofilaments (133).

Although the melanocytes, including their dendrites, contain melanosomes, hardly any melanosomes are present within the tumor cells, indicating a blockage in the transfer of melanosomes from the melanocytes to the tumor cells (134).

EPIDERMAL OR INFUNDIBULAR CYST

Epidermal cysts are slowly growing, elevated, round, firm, intradermal or subcutaneous tumors that cease growing after

FIGURE 29-19. Epidermal cyst. The cyst distends the overlying skin of the cheek.

having reached 1 to 5 cm in diameter. They occur most commonly on the face, scalp, neck, and trunk (Fig. 29-19). Although most epidermal cysts arise spontaneously in hair-bearing areas, occasionally they occur on the palms or soles (135,136) or form as the result of trauma (137). Usually a patient has only one or a few epidermal cysts, rarely many. In Gardner's syndrome, however, numerous epidermal cysts occur, especially on the scalp and face (see Chapter 32).

Histopathology. Epidermal cysts have a wall composed of true epidermis, as seen on the skin surface and in the infundibulum of hair follicles, the infundibulum being the uppermost part of the hair follicle that extends down to the entry of the sebaceous duct. In young epidermal cysts, several layers of squamous and granular cells can usually be recognized (Fig. 29-20). In older epidermal cysts, the wall often is markedly atrophic, either in some areas or in the entire cyst, and may consist of only one or two

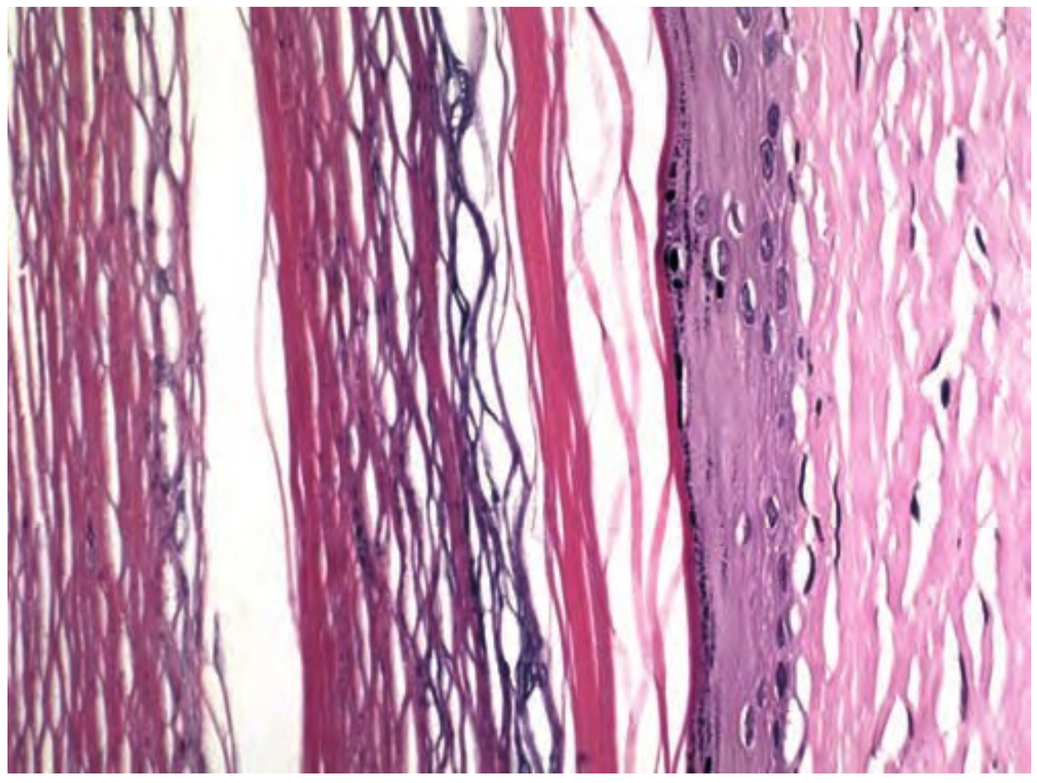

FIGURE 29-20. Epidermal cyst. The cyst is lined by stratified squamous epithelium with a granular layer. The cyst is filled with keratin flakes.

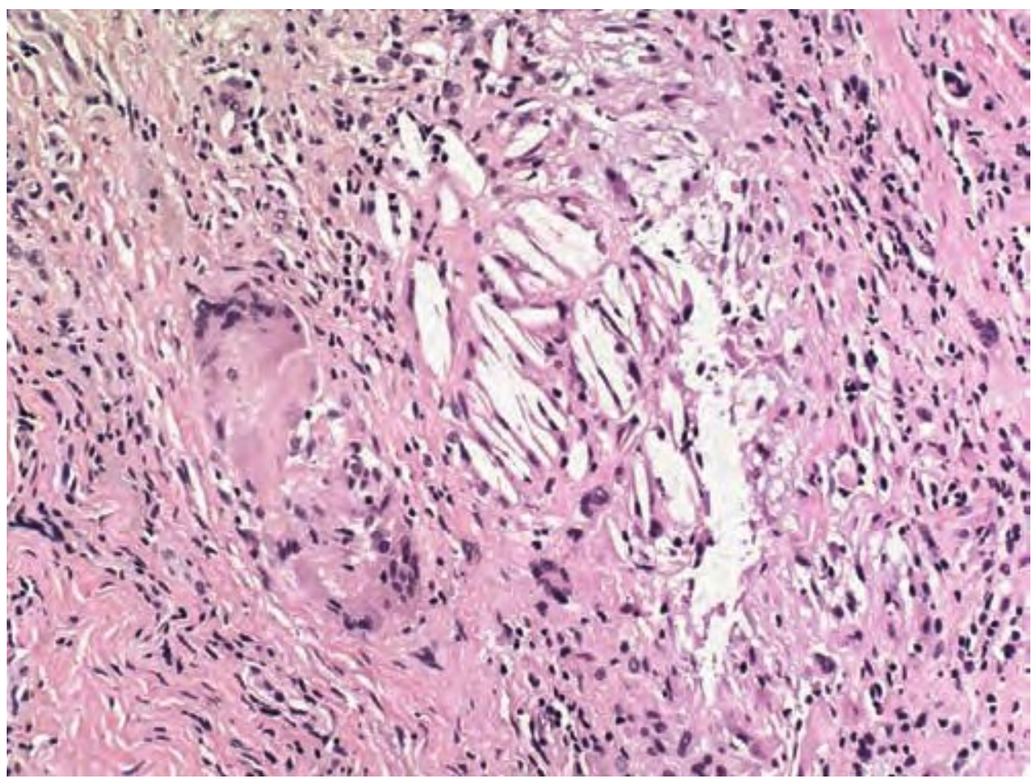

FIGURE 29-21. Keratin granuloma. At the edge of a partially ruptured cyst, cholesterol clefts form part of a keratin granuloma.

rows of greatly flattened cells. The cyst is filled with horny material arranged in laminated layers. In sections stained with hematoxylin-eosin, melanocytes and melanin pigmentation of keratinocytes can be seen only rarely in epidermal cysts of whites but frequently in epidermal cysts of blacks. Silver stains reveal that most of the melanin is located in the basal layer of the cyst lining, but some melanin is seen also in the contents of the cyst (138).

When an epidermal cyst ruptures and the contents of the cyst are released into the dermis, a considerable foreign-body reaction with numerous multinucleated giant cells results, forming a *keratin granuloma* (Figs. 29-21 and 29-22). The foreign-body reaction usually causes disintegration of the cyst wall. However, it may lead to a pseudocarcinomatous proliferation in remnants of the cyst wall, simulating a squamous cell carcinoma (139). Melanocytes, melanin, and melanophages

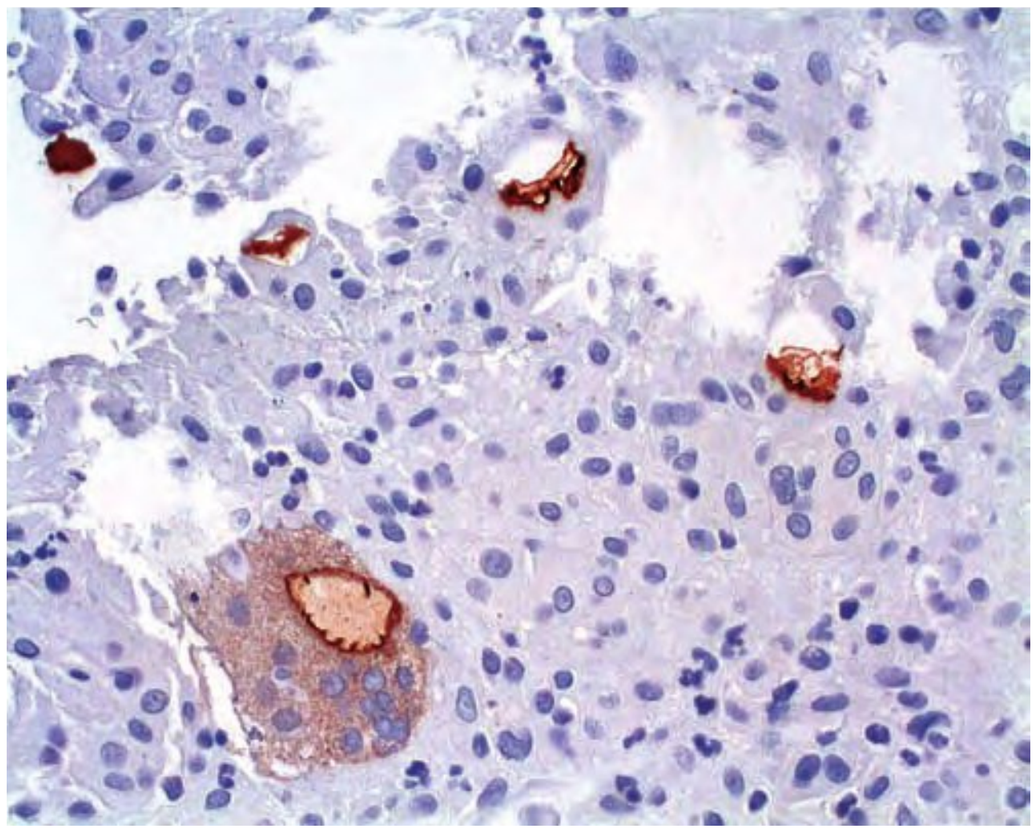

FIGURE 29-22. Keratin granuloma. Cytokeratin staining highlights keratin flakes in giant cells within a keratin granuloma.

have been reported in the walls of epidermal cysts in some Indians (140) and a Japanese patient (141).

Development of a basal cell epithelioma (142), a lesion of Bowen's disease (143), or a squamous cell carcinoma (144) in epidermal cysts is a rare event. In cases of squamous cell carcinoma, the tumor is apt to be of low malignancy and does not metastasize. It is likely that some cases that were regarded in the past as malignant degeneration of epidermal cysts now are interpreted either as pseudocarcinomatous hyperplasia in a ruptured epidermal cyst (139) or as proliferating trichilemmal tumor (see Chapter 30) (145).

Pathogenesis. It is widely assumed that most spontaneously arising epidermal cysts are related to the follicular infundibulum. The occurrence of hybrid cysts with partially epidermal and partially trichilemmal lining favors this assumption (146). Epidermal cysts in nonfollicular regions, such as the palms or soles, probably form as a result of the traumatic implantation of epidermis into the dermis or subcutis (135,136).

As seen by electron microscopy, the keratinization in epidermal cysts is identical to that in the surface epidermis and in the pilosebaceous infundibulum because the keratin located within the keratinized cells consists of relatively electron-lucent tonofilaments embedded in an electron-dense interfilamentous substance derived from keratohyaline granules. The keratinized cells of the cyst content have a markedly flattened, elongated appearance and are surrounded by a thick marginal band rather than by a plasma membrane. Desmosomes are no longer present (147).

MILIA

Milia are multiple, superficially located, white, globoid, firm lesions generally only 1 to 2 mm in diameter. A distinction is made between primary milia, which arise spontaneously on the face in predisposed individuals, and secondary milia, which occur either in diseases associated with subepidermal bullae, such as bullous pemphigoid, dystrophic epidermolysis bullosa (148,149), and porphyria cutanea tarda, or after dermabrasion (150) and other trauma.

Histopathology. *Primary milia* of the face are derived from the lowest portion of the infundibulum of vellus hairs at about the level of the sebaceous duct. The milia often are still connected with the vellus hair follicle by an epithelial pedicle. Primary milia are small cysts differing from epidermal cysts only in size. They are lined by a stratified epithelium a few cell layers thick and contain concentric lamellae of keratin (150).

Secondary milia have the same histologic appearance as primary milia (150). They may develop from any epithelial structure and on serial sections may still show a connection to the parent structure, whether a hair follicle, sweat duct, sebaceous duct, or epidermis (151). Secondary milia that follow blistering arise in most instances from the eccrine sweat duct and very rarely from a hair follicle. In a certain percentage of cases, however, no connection is found with any skin appendage, suggesting that the milia have developed from aberrant epidermis (152). In milia derived from eccrine sweat ducts, the sweat ducts are frequently seen to enter the cyst wall at the bottom of the milium (150,152).

FIGURE 29-23. Pilar cyst. Clinically similar to an epidermal cyst, but more frequently seen on the scalp.

Pathogenesis. Primary milia of the face represent a keratinizing type of benign tumor (150). In contrast, secondary milia represent retention cysts caused by proliferative tendencies of the epithelium after injury (153).

PILAR OR TRICHILEMMAL CYST

Pilar or trichilemmal cysts are clinically indistinguishable from epidermal cysts but differ from them in frequency and distribution. They are less common than epidermal cysts, constituting only about 25% of the combined material; about 90% occur on the scalp (Fig. 29-23). Pilar cysts often show an autosomal dominant inheritance pattern and are solitary in only 30% of the cases, with 10% of patients having more than 10 cysts (154). Furthermore, in contrast to epidermal cysts, pilar cysts are easily enucleated and appear as firm, smooth, white-walled cysts (Fig. 29-24) (155).

FIGURE 29-24. Pilar cyst. The cyst has a well-defined margin, as seen at the time of excision.

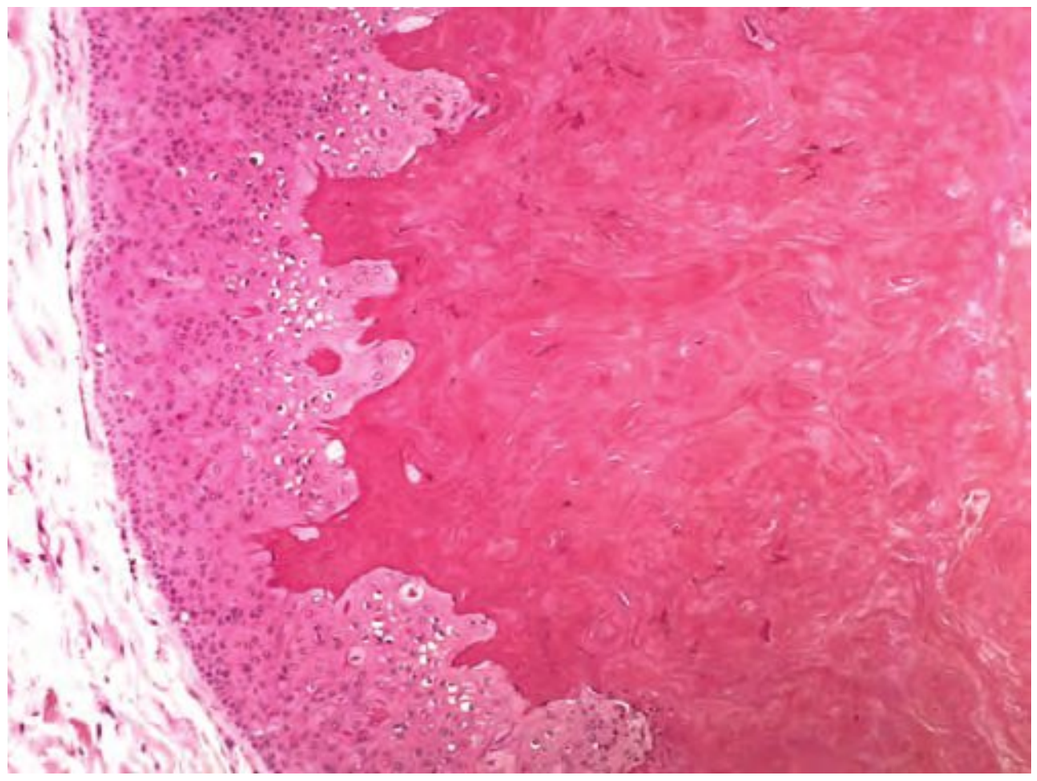

FIGURE 29-25. Pilar cyst. The cyst is lined by a squamous epithelium without a granular layer and with swelling of the cells close to the cyst cavity that is filled with homogeneous keratin.

Histopathology. The wall of trichilemmal cysts is composed of epithelial cells possessing no clearly visible intercellular bridges. The peripheral layer of cells shows a distinct palisade arrangement not seen in epidermal cysts. The epithelial cells close to the cystic cavity appear swollen and are filled with pale cytoplasm (Fig. 29-25). These swollen cells do not produce a granular layer but generally undergo abrupt keratinization, although nuclear remnants are occasionally retained in a few cells. The content of the cysts consists of homogeneous eosinophilic material (147).

Whereas focal calcification of the cyst content does not occur in epidermal cysts, foci of calcification are seen in approximately one fourth of trichilemmal cysts (140). A considerable foreign-body reaction results when the wall of a trichilemmal cyst ruptures, and the cyst may then undergo partial or complete disintegration.

Trichilemmal cysts frequently disclose small, acanthotic foci in their walls that are indistinguishable from solid areas, as seen in a proliferating trichilemmal cyst (156). The association of a trichilemmal cyst with tumor lobules of a proliferating trichilemmal cyst is also seen occasionally (see Chapter 30) (154).

Pathogenesis. Pilar cysts were originally called sebaceous cysts. The name was changed when it became apparent that the keratinization in them is analogous to the keratinization that takes place in the outer root sheath of the hair, or trichilemma (157). The outer root sheath of the hair does not keratinize wherever it covers the inner root sheath. It keratinizes normally in two areas—the follicular isthmus of anagen hairs and the sac surrounding catagen and telogen hairs—because in these two regions the inner root sheath has disappeared. The follicular isthmus of anagen hairs is the short, middle portion of the hair follicle, extending upward from the attachment of the arrector pili muscle to the entrance of the sebaceous duct. At the lower end of the follicular isthmus, the inner root sheath sloughs off, exposing the outer root sheath, which, in its exposed portion, undergoes a specific type of homogeneous keratinization without the interposition of a granular layer. This type of trichilemmal keratinization also takes place in the sac surrounding catagen and telogen hairs because hairs in these stages have lost their inner root sheath. The differentiation toward hair keratin in trichilemmal cysts has been confirmed by immunohistochemical staining because they stain with antikeratin antibodies derived from human hair, in contrast to epidermal cysts, which stain with antikeratin antibodies obtained from human callus (158).

Electron microscopic examination of the epithelial lining of trichilemmal cysts shows that, on their way from the peripheral layer toward the center, the epithelial cells have an increasing number of filaments in their cytoplasm. The transition from nucleate to anucleate cells is abrupt and is associated with the loss of all cytoplasmic organelles. The junction between the keratinizing and keratinized cells shows interdigitations (159). The keratinized cells are filled with tonofilaments and, unlike those in epidermal cysts, retain their desmosomal connections (147).

Differential Diagnosis. Even though both the pilar cyst and the proliferating trichilemmal cyst show trichilemmal types of keratinization and can occur together, one is essentially a cyst and the other essentially a solid, tumorlike proliferation. The latter is therefore discussed under Tumors With Differentiation Toward Hair Follicle Components in Chapter 30.

STEATOCYSTOMA MULTIPLEX

Steatocystoma multiplex is inherited in an autosomal dominant pattern. One observes numerous small, rounded, moderately firm, cystic nodules that are adherent to the overlying skin and usually measure 1 to 3 cm in diameter (Fig. 29-26). When punctured, the cysts discharge an oily or creamy fluid and, in some instances, also small hairs (160–163). They are found most commonly in the axillae, in the sternal region, and

FIGURE 29-26. Steatocystoma multiplex. Multiple small, rounded cysts are present in the axilla.

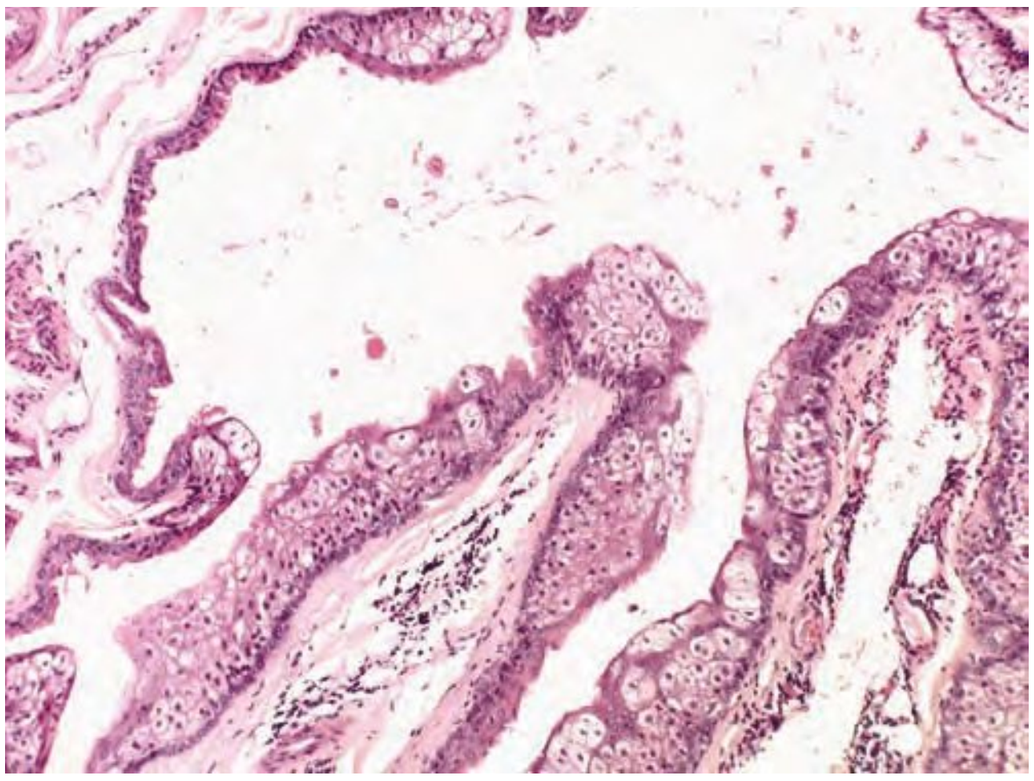

FIGURE 29-27. Steatocystoma multiplex. The cyst wall shows intricate folding. The lining stratified squamous epithelium has sebaceous gland lobules within and close to it.

on the arms. Steatocystoma also occurs occasionally as a solitary, noninherited tumor in adults, where it is referred to as *steatocystoma simplex* (164).

Histopathology. The cysts have walls that are intricately folded with several layers of epithelial cells, although in atrophic areas only two or three layers of flat cells may be present. Elsewhere there is a basal layer in palisade arrangement, above which are two or three layers of swollen cells without recognizable intercellular bridges. Central to these cells there is a thick, homogeneous, eosinophilic horny layer that forms without an intervening granular layer. It protrudes irregularly into the lumen in a fashion simulating the decapitation secretion of apocrine glands (Fig. 29-27) (165).

A characteristic feature seen in most lesions of steatocystoma is the presence of flattened sebaceous gland lobules either within or close to the cyst wall (166). In some cysts, invaginations resembling hair follicles extend from the cyst wall into the surrounding stroma, and in rare instances true hair shafts are seen within them, indicating that the invaginations represent the outer root sheath of hairs. In a few cysts, the lumen contains clusters of hair, mainly of lanugo size but partially of intermediate character (167). When stained with the PAS reaction, the cells of the cyst wall are found to be rich in glycogen.

Pathogenesis. Electron microscopic examination has shown that the cyst wall consists of keratinizing cells. Nearest to the lumen, the cyst wall consists of several layers of flattened, very elongated horny cells interconnected by desmosomes.

It appears likely that differentiation in the cyst wall of steatocystoma multiplex is to a large extent in the direction of the sebaceous duct (168,169). The sebaceous duct and the outer root sheath are composed of similar cells, but undulation and thinning of the horny layer and the existence of sebaceous cells in the cyst wall are characteristic features of the sebaceous gland side of the sebaceous duct (169). Sebaceous duct cells, like outer root sheath cells, contain abundant glycogen and amylophosphorylase, keratinize without the interposition of keratohyaline granules, and, on electron microscopic examination, retain their desmosomes after keratinization (165).

PIGMENTED FOLLICULAR CYST

This is an uncommon pigmented lesion resembling a nevus.

Histopathology. The cyst wall consists of infundibular epidermis. The cyst contains, in addition to laminated keratin, numerous large pigmented hair shafts. One or two growing hair follicles are seen in the wall of the cyst (170).

DERMOID CYST

Dermoid cysts are subcutaneous cysts that usually are present at birth. They occur most commonly on the head, mainly around the eyes, and occasionally on the neck. When located on the head, they often are adherent to the periosteum. Usually they measure between 1 and 4 cm in diameter.

Histopathology. Dermoid cysts, in contrast to epidermal cysts, are lined by an epidermis that possesses various epidermal appendages that are usually fully matured (Figs. 29-28 and 29-29). Hair follicles containing hairs that project into the lumen of the cyst are often present. In addition, the dermis of dermoid cysts usually contains sebaceous glands, often eccrine glands, and, in about 20% of the cases, apocrine glands that have matured (171).

Pathogenesis. Dermoid cysts are a result of the sequestration of skin along lines of embryonic closure.

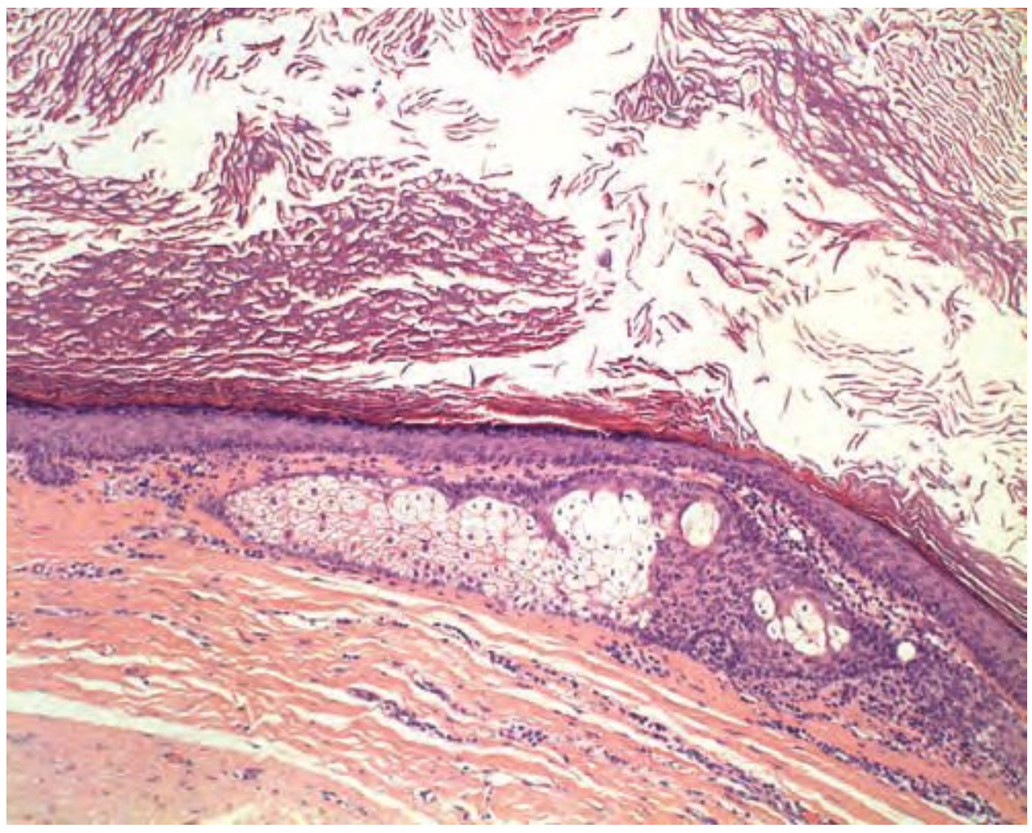

FIGURE 29-28. External angular dermoid cyst. The cyst is lined by stratified squamous epithelium, with adnexal structures in the wall.

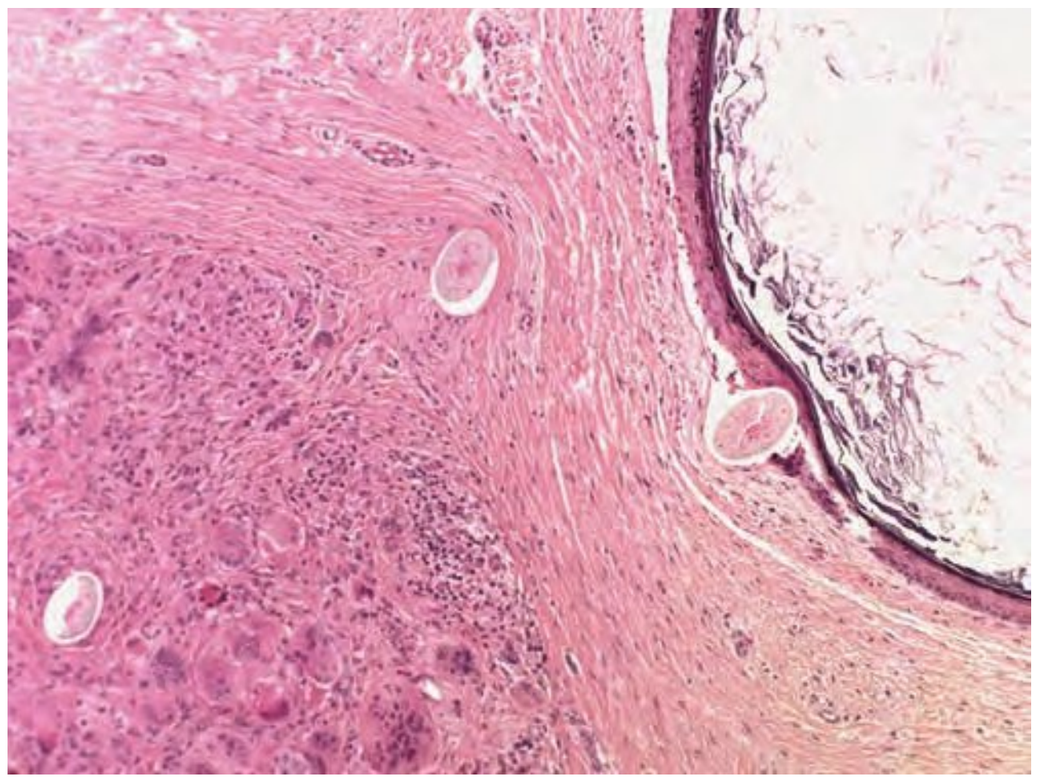

FIGURE 29-29. External angular dermoid cyst. In this example the cyst has ruptured, producing an adjacent granuloma containing hair shafts derived from the cyst.

BRONCHOGENIC AND THYROGLOSSAL DUCT CYSTS

Bronchogenic cysts are rare. They are small, solitary lesions seen most commonly in the skin or subcutaneous tissue just above the sternal notch. Rarely, they are located on the anterior aspect of the neck or on the chin. As a rule, they are discovered shortly after birth. They may show a draining sinus.

Thyroglossal duct cysts are clinically indistinguishable from bronchogenic cysts, except that they are usually located on the anterior aspect of the neck.

Histopathology. *Bronchogenic cysts* are lined by a mucosa consisting of ciliated pseudostratified columnar epithelium (Fig. 29-30). Goblet cells may be interspersed. The wall frequently contains smooth muscle and mucous glands but only rarely contains cartilage (153).

Thyroglossal duct cysts differ from bronchogenic cysts in that they do not contain smooth muscle and they frequently contain thyroid follicles (172).

Pathogenesis. On electron microscopy the cilia show two central microtubules surrounded by nine paired microtubules (173).

CUTANEOUS CILIATED CYST

Cutaneous ciliated cysts are found very rarely in females as a single lesion, largely on the lower extremities, and even more rarely in males and on the back (174–176,178). They usually measure several centimeters in diameter. They are either unilocular or multilocular and are filled with clear or amber fluid. The finding of one on the perineum led the authors to suggest a primitive tailgut origin to this cyst, probably from the embryonic remnants of cloacal membrane (177).

Histopathology. Cutaneous ciliated cysts show numerous papillary projections lined by a simple cuboidal or columnar ciliated epithelium. Mucin-secreting cells are absent (176).

Pathogenesis. The epithelial lining of the cysts resembles that seen in the fallopian tube. On electron microscopy, the cilia show two central filaments encircled by nine pairs of filaments (179).

MEDIAN RAPHE CYST OF THE PENIS

Median raphe cysts of the penis occur usually in young adults. They are located on the ventral aspect of the penis, most commonly on the glans. They are solitary and measure only a few millimeters in diameter (180). However, they may extend over several centimeters in a linear fashion (181). It seems that, in some instances, median raphe cysts have been erroneously reported as apocrine cystadenoma of the penis (Fig. 29-31; see also Chapter 31) (182,183).

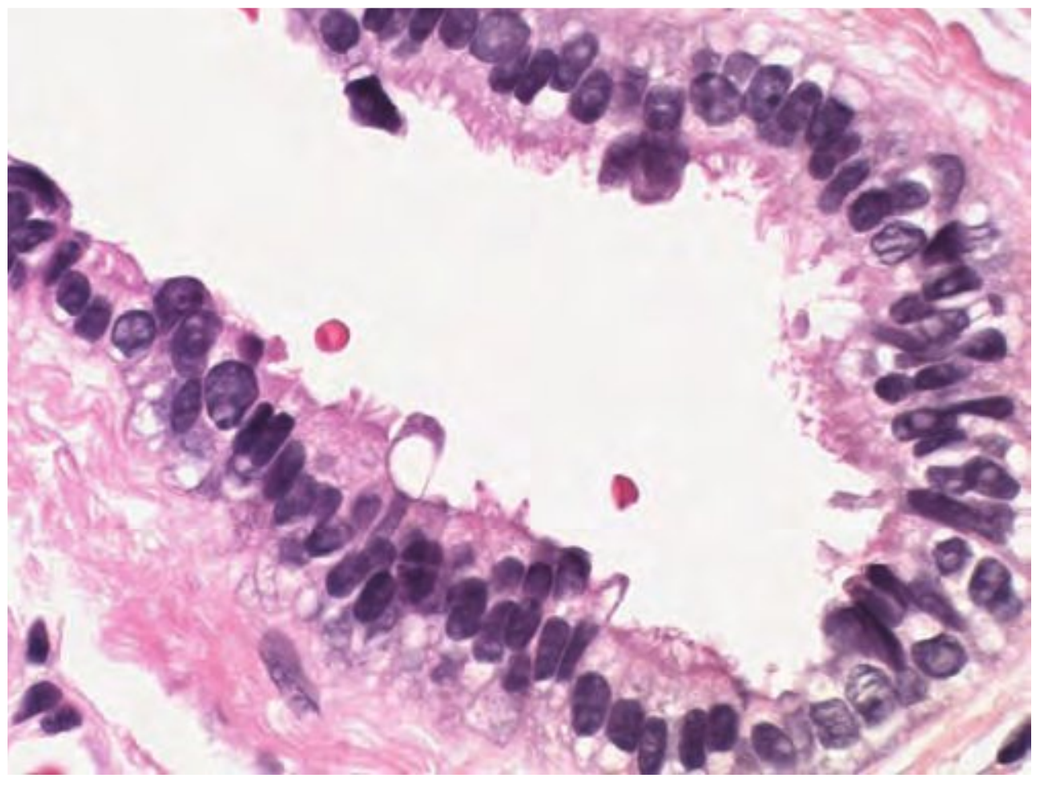

FIGURE 29-30. Bronchogenic cyst. High magnification. The lining epithelium is columnar, with a ciliated surface.

FIGURE 29-31. Apocrine cyst. In this small dermal cyst the lining epithelium forms a single layer with apocrine snouting secretion.

Histopathology. The cysts are lined by pseudostratified columnar epithelium varying from one to four cells in thickness, mimicking the transitional epithelium of the urethra. Some of the epithelial cells have clear cytoplasm, mucin-containing cells are uncommon, and a case lined by ciliated epithelium has been described (184).

Pathogenesis. It is likely that median raphe cysts do not represent a defective closure of the median raphe but rather the anomalous budding and separation of urethral columnar epithelium from the urethra (185).

ERUPTIVE VELLUS HAIR CYSTS

In eruptive vellus hair cysts, a condition first described in 1977 (186), asymptomatic follicular papules 1 to 2 mm in diameter occur, most commonly on the chest but in some instances elsewhere. Some of the papules have a crusted or umbilicated surface. The condition is usually seen in children and young adults but can develop at any age. Spontaneous clearing may take place in a few years. Autosomal dominant inheritance has been described (187,188). Cytokeratin studies have shown that epidermoid cysts expressed cytokeratin 10 and eruptive vellus hair cysts expressed cytokeratin 17, whereas trichilemmal cysts and steatocystoma multiplex showed expression of both cytokeratin 10 and cytokeratin 17, supporting the opinion that eruptive vellus hair cysts, which stained negative for cytokeratin 10, and steatocystoma multiplex are distinct entities and not variants of one disorder (189).

Histopathology. A cystic structure is usually seen in the middermis lined by squamous epithelium. It contains laminated keratinous material and varying numbers of transversely and obliquely cut vellus hairs (186). In some cysts, vellus hairs are seen emerging from follicle-like invaginations of the cyst wall (190). In other cysts, a telogen hair follicle is seen extending from the lower surface toward the subcutis (186). Crusted or umbilicated lesions show either a cyst communicating with the surface and extruding its contents (188,191) or partial destruction of a cyst by a granulomatous infiltrate and elimination of vellus hairs to the surface of the skin (192).

Pathogenesis. Eruptive vellus hair cysts represent a developmental abnormality of vellus hair follicles that predisposes them to occlusion at their infundibular level. This results in retention of hairs, cystic dilation of the proximal part of the follicle, and secondary atrophy of the hair bulbs (186,191). There is a close relationship with steatocystoma multiplex (193). Both processes could be described as multiple pilosebaceous cysts (194).

WARTY DYSKERATOMA

Warty dyskeratoma, first described in 1957 (195), usually occurs as a solitary lesion, most commonly on the scalp, face, or neck, although a case with multiple lesions has been described (196). It has also been reported in non–sun-exposed skin,

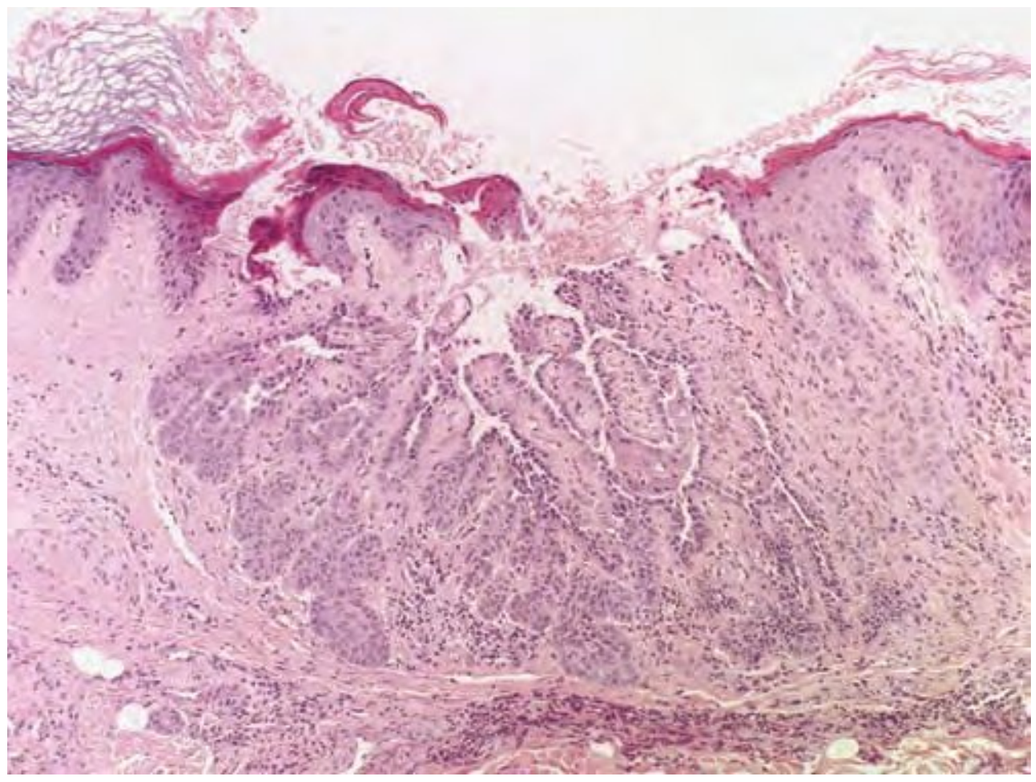

FIGURE 29-32. Warty dyskeratoma. Low magnification. A large invagination is connected to the surface by a channel.

including the oral mucosa, usually on the hard palate or an alveolar ridge (197,198). Although its clinical appearance is not always distinctive, it often occurs as a slightly elevated papule or nodule with a keratotic umbilicated center (199). The lesion, after having reached a certain size, persists indefinitely.

Histopathology. The center of the lesion is occupied by a large, cup-shaped invagination connected with the surface by a channel filled with keratinous material (Figs. 29-32 to 29-34). The large invagination contains numerous acantholytic, dyskeratotic cells in its upper portion. The lower portion of the invagination is occupied by numerous villi, that is, markedly elongated dermal papillae that are often lined with only a single layer of basal cells and project upward from the base of the cup-shaped invagination (Fig. 29-32) (195,200–202). Typical corps ronds can

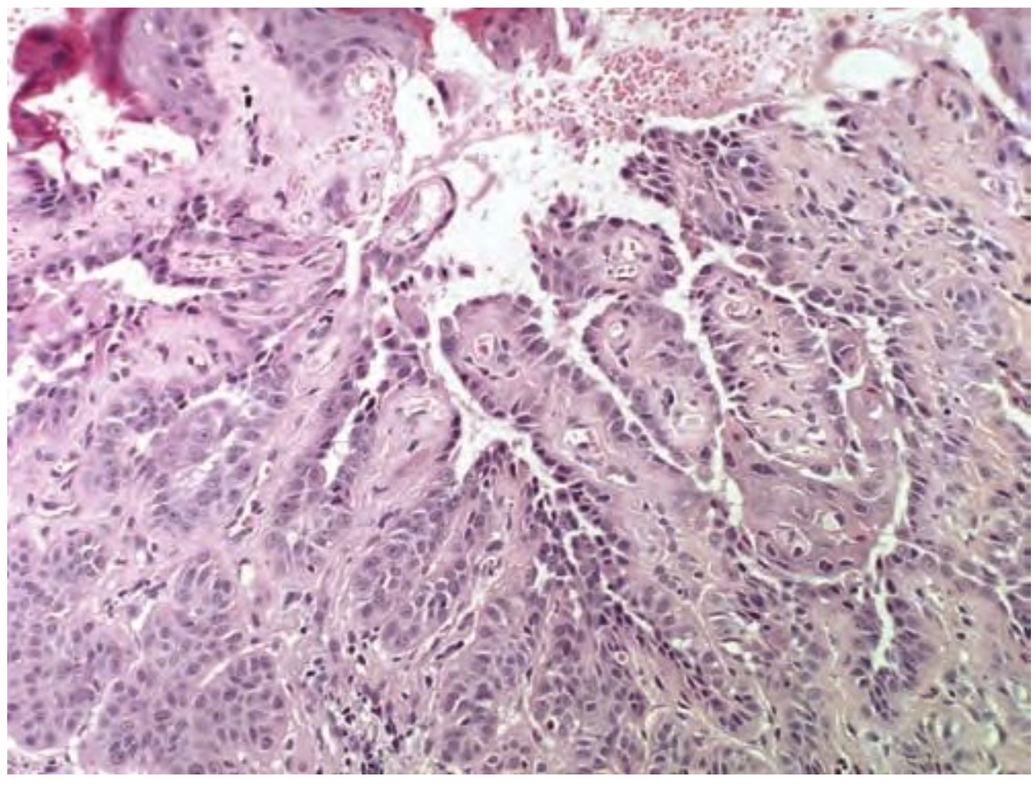

FIGURE 29-33. Warty dyskeratoma. The villi at the base of the invagination are covered with a single layer of cells. Acantholytic, dyskeratotic cells lie above the villi.

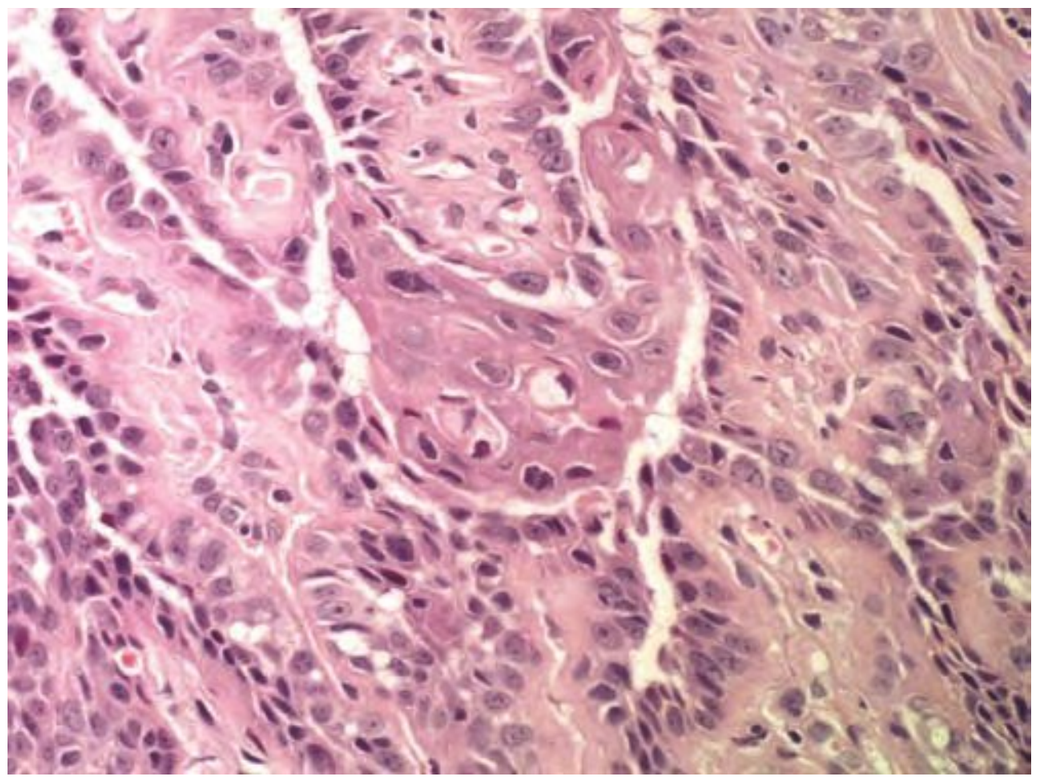

FIGURE 29-34. Warty dyskeratoma. High magnification. Acantholytic and dyskeratotic cells lie above the basal layer of epithelial cells.

usually be seen in the thickened granular layer lining the channel at the entrance to the invagination (Fig. 29-33) (199,203).

Pathogenesis. The central cup-shaped invagination has been interpreted by several observers as a greatly dilated hair follicle because in early lesions a hair follicle or sebaceous gland is often connected with the invagination (200). Occasionally, two or three adjoining follicles seem to be involved (199). The fact, however, that warty dyskeratoma can arise on the oral mucosa indicates that, as in Darier's disease, the dyskeratotic, acantholytic process is not always derived from a pilosebaceous structure.

Although attempts were made at first to correlate warty dyskeratoma with Darier's disease, it is now generally agreed that warty dyskeratoma represents an entity—"a benign cutaneous tumor that resembles Darier's disease microscopically" (195).

ACTINIC KERATOSIS

Solar keratoses are also known as actinic keratoses. The adjective *solar* is more specific because it refers to the sun as the cause, whereas the adjective *actinic* refers to a variety of rays (204). Even among the sun's rays, action spectrum evaluations indicate that the ultraviolet B (UVB) rays (290 to 320 nm) are the most damaging ("carcinogenic") rays, although UVA rays (320 to 400 nm) can augment the damaging effects of UVB rays (205).

Actinic keratoses are usually seen as multiple lesions in sun-exposed areas of the skin in persons in or past middle life who have fair complexions (Figs. 29-35 and 29-36). Excessive exposure to sunlight over many years and inadequate protection against it are the essential predisposing factors. Actinic keratoses are seen most commonly on the face and the dorsa of the hands and in the bald portions of the scalp in men (206).

FIGURE 29-35. Actinic keratosis. The lesion on the forehead is crusted and erythematous.

Usually, the lesions measure less than 1 cm in diameter. They are erythematous, are often covered by adherent scales, and, except in their hypertrophic form, show little or no infiltration. Some actinic keratoses are pigmented and show peripheral spreading, making clinical differentiation from lentigo maligna difficult (207). Occasionally, lesions show marked hyperkeratosis and then have the clinical aspect of cutaneous horns. A lesion analogous to actinic keratosis occurs on the vermilion border of the lower lip as *solar cheilitis* and may show areas of erosion and hyperkeratosis (208–210).

Actinic keratosis and solar cheilitis can develop into squamous cell carcinoma. However, the incidence of this transformation is difficult to determine because the borderline between actinic keratosis and squamous cell carcinoma is not clear-cut (see Histopathology). It has been estimated that in 20% of patients with actinic keratoses squamous cell carcinoma develops in one or more of the lesions (211). Usually, squamous cell carcinomas arising either in actinic keratoses or *de novo* in sun-damaged skin do not metastasize. The incidence of metastasis in different series varies from 0.5% (212) to 3%

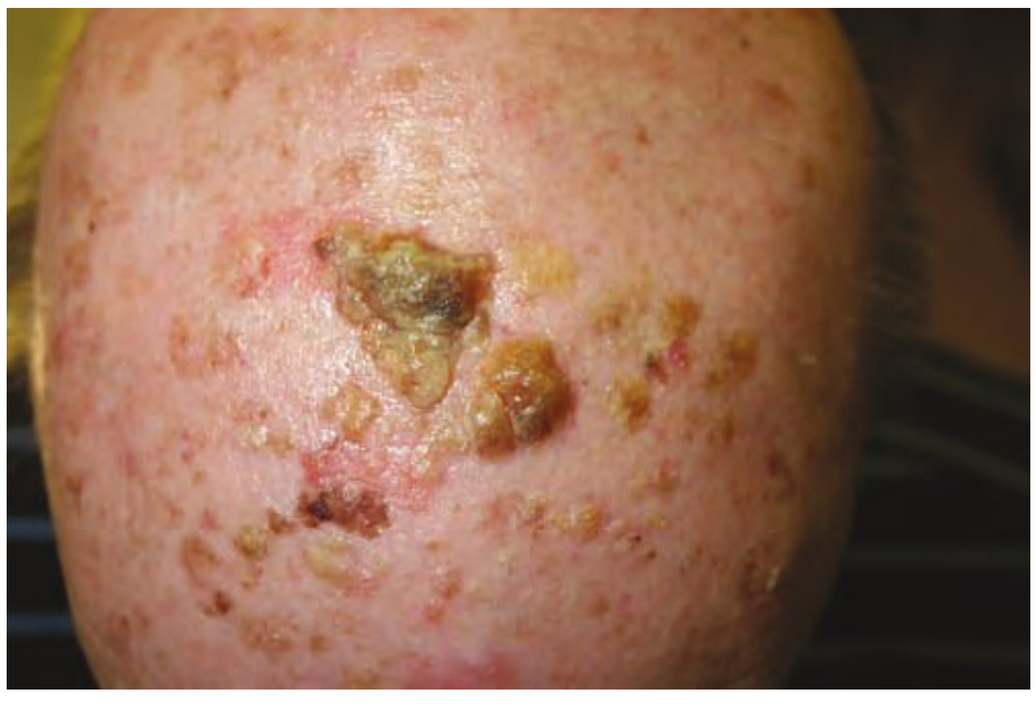

FIGURE 29-36. Actinic keratosis. Multiple lesions on this sun-damaged scalp.

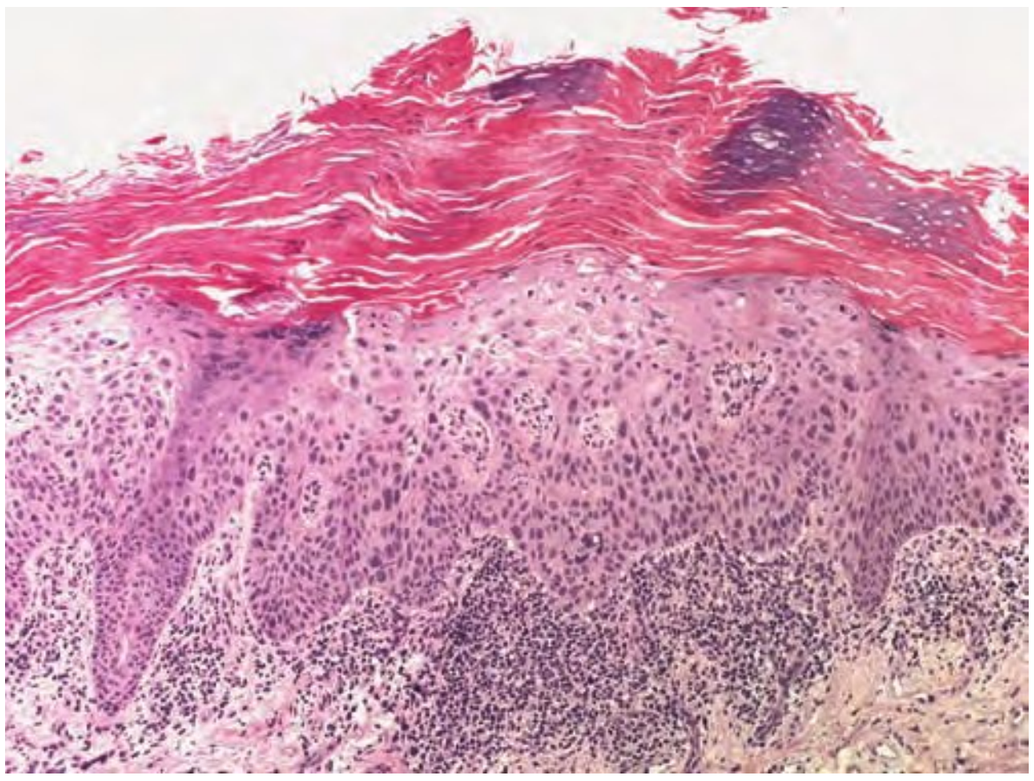

FIGURE 29-37. Actinic keratosis. Tall columns of parakeratotic keratin alternate with bands of orthokeratotic keratin with moderate atypia of the underlying keratinocytes.

(213). In carcinoma of the vermilion border of the lip, however, metastases have been found in 11% of the cases (213).

Histopathology. Actinic keratoses are keratinocytic dysplasias or squamous cell carcinomas *in situ*. This definition is preferable to their designation as precancerous because most of them never progress to cancers. Biologically, the lesions are still benign; invasion into the dermis, if present at all, is limited to the most superficial portion, the papillary dermis (see Differential Diagnosis) (214–227).

Five types of actinic keratosis can be recognized histologically: hypertrophic, atrophic, bowenoid, acantholytic, and pigmented (Figs. 29-37 to 29-46). Transitions and combinations among these five types occur. In addition, many cutaneous horns prove on histologic examination to be actinic keratoses.

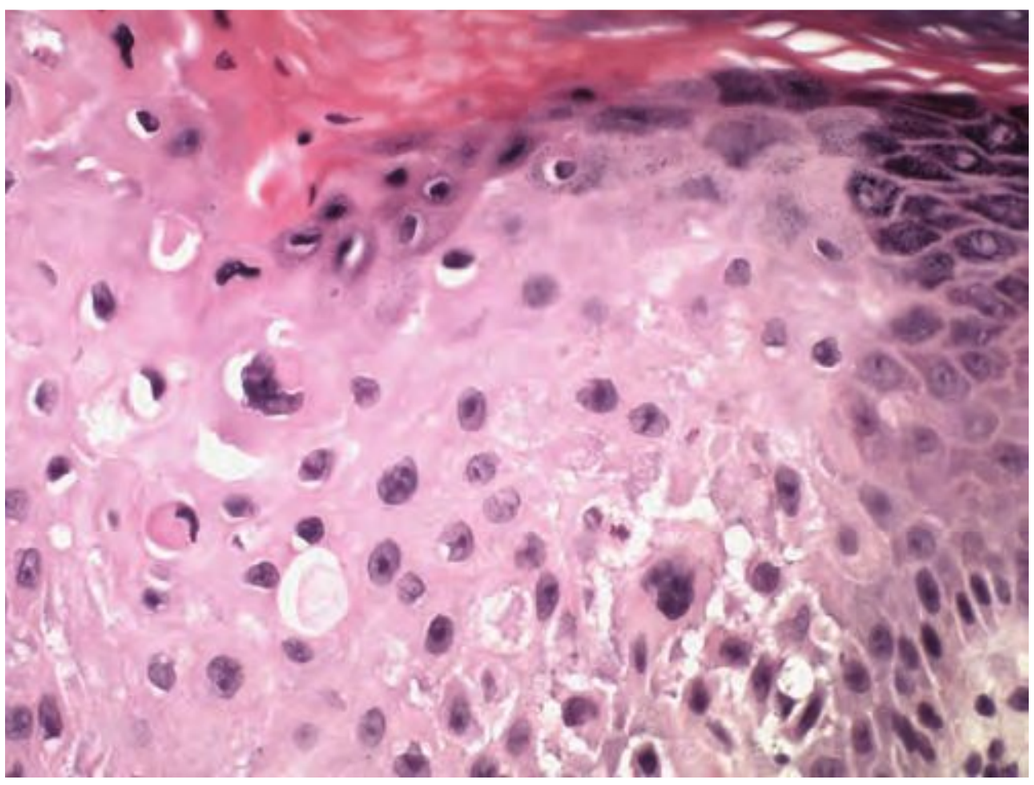

FIGURE 29-38. Actinic keratosis. Beneath a thick layer of parakeratotic keratin the epidermis shows cytologic atypia.

In the *hypertrophic type* of actinic keratosis, hyperkeratosis is pronounced and is usually intermingled with areas of parakeratosis (214). This variety of keratosis, sometimes referred to as *florid keratosis*, may easily be overdiagnosed as invasive squamous cell carcinoma by the unwary. Mild or moderate papillomatosis may be present. The epidermis is thickened in most areas and shows irregular downward proliferation that is limited to the uppermost dermis and does not represent frank invasion (Fig. 29-39). A varying proportion of the keratinocytes in the stratum malpighii show a loss of polarity and thus a disorderly arrangement. Some of these cells show pleomorphism and atypicality ("anaplasia") of their nuclei, which appear large, irregular, and hyperchromatic. Often the nuclei in the basal layer are closely crowded together. Some of the cells in the midportion of the epidermis show premature keratinization, resulting in dyskeratotic cells or apoptotic bodies characterized by homogeneous, eosinophilic cytoplasm with or without a nucleus. In contrast to the epidermal keratinocytes, the cells of the hair follicles and eccrine ducts that penetrate the epidermis within actinic keratoses retain their normal appearance and keratinize normally (215,216). Occasionally, cells of the normal adnexal epithelium extend over the atypical cells of the epidermis in an umbrella-like fashion. In some cases, abnormal keratinocytes extend downward on the outside of the follicular infundibulum to the level of the sebaceous duct and, less commonly, along the eccrine duct (216).

A variant of the hypertrophic type of actinic keratosis is the lichenoid actinic keratosis, which demonstrates nuclear atypia, irregular acanthosis and hyperkeratosis, the presence of basal cell liquefaction, degeneration of the basal cell layer, and a bandlike "lichenoid" infiltrate in close apposition to the epidermis (217). Fairly numerous eosinophilic, homogeneous apoptotic bodies are seen in the upper dermis as so-called Civatte bodies. Aside from the presence of nuclear atypicality,

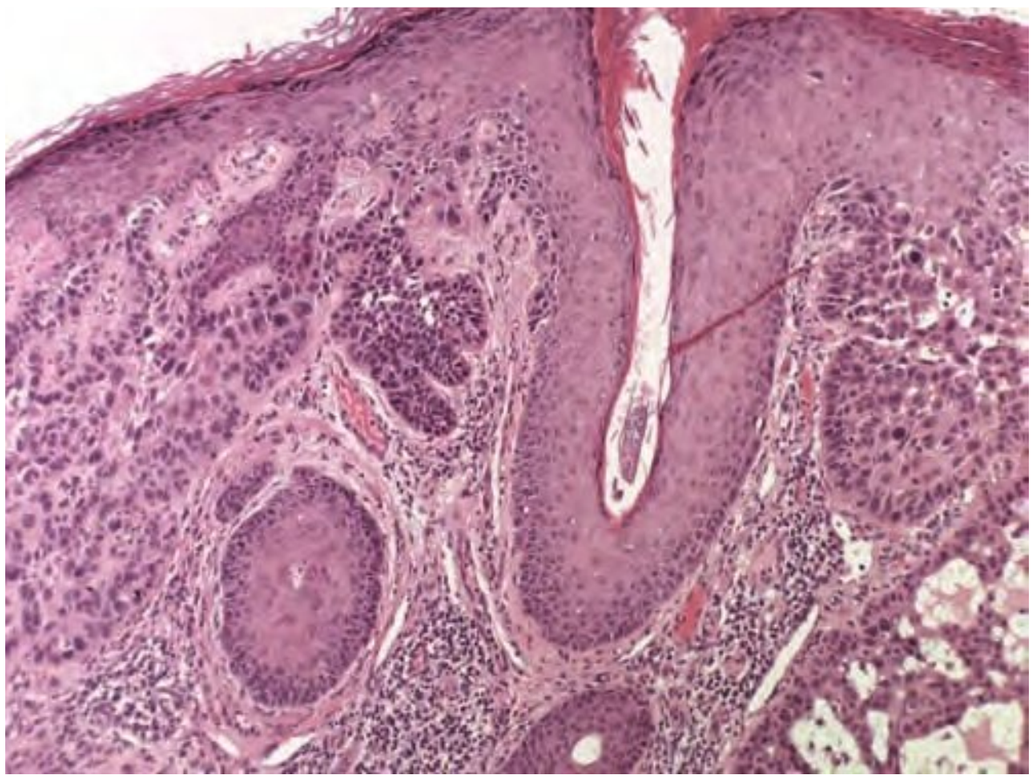

FIGURE 29-39. Actinic keratosis, hypertrophic type. The lesion shows hyperkeratosis and papillomatosis with prominent cytologic atypia. There is a moderate lymphocytic infiltrate in the underlying papillary dermis.

FIGURE 29-40. Bowenoid actinic keratosis. A crusted lesion on the ear helix.

there is considerable resemblance to lichen planus and benign lichenoid keratosis. An additional distinguishing feature may be the presence of plasma cells in the lichenoid infiltrate (see Chapter 7).

In rare instances of actinic keratosis of the hypertrophic type, in addition to finding anaplastic nuclei in the lower epidermis, one finds areas of epidermolytic hyperkeratosis in the upper epidermis. These changes are like those seen in bullous congenital ichthyosiform erythroderma, in linear epidermal nevus, and as incidental epidermolytic hyperkeratosis in a variety of lesions. In areas of epidermolytic hyperkeratosis, one observes in the upper epidermis clear spaces around the nuclei and a thickened granular layer with large, irregularly shaped keratohyaline granules (39). Epidermolytic hyperkeratosis may occur also in lesions of solar cheilitis (218).

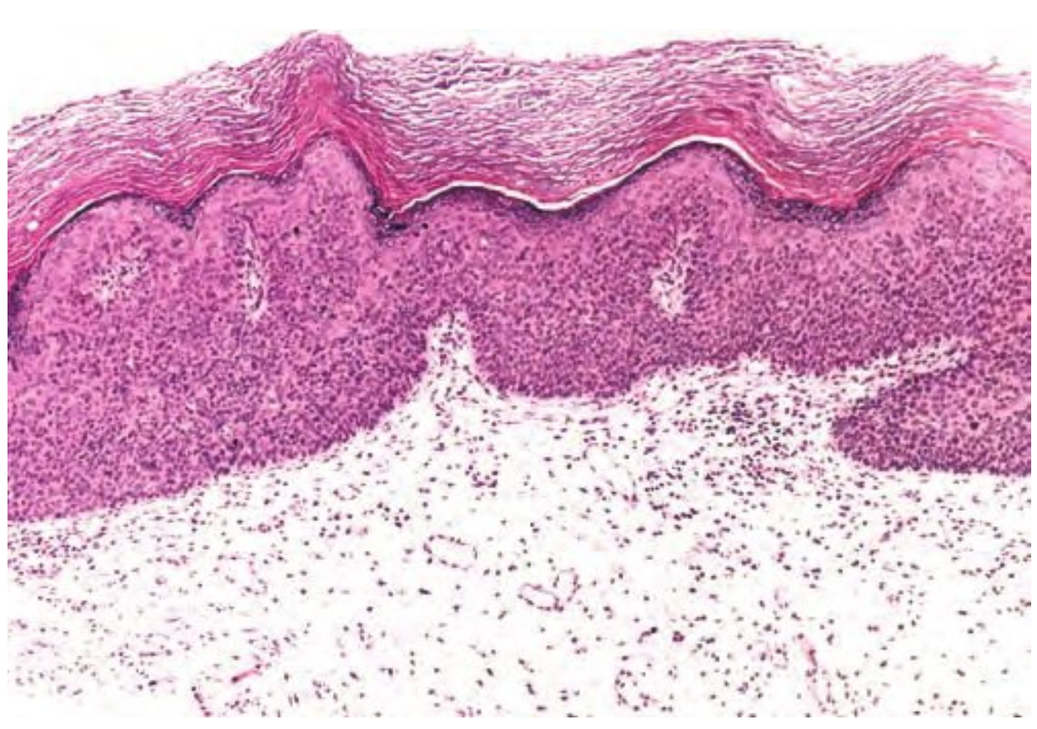

FIGURE 29-41. Bowenoid actinic keratosis. Low magnification. Beneath a thick layer of parakeratotic keratin the epidermis shows cytologic atypia.

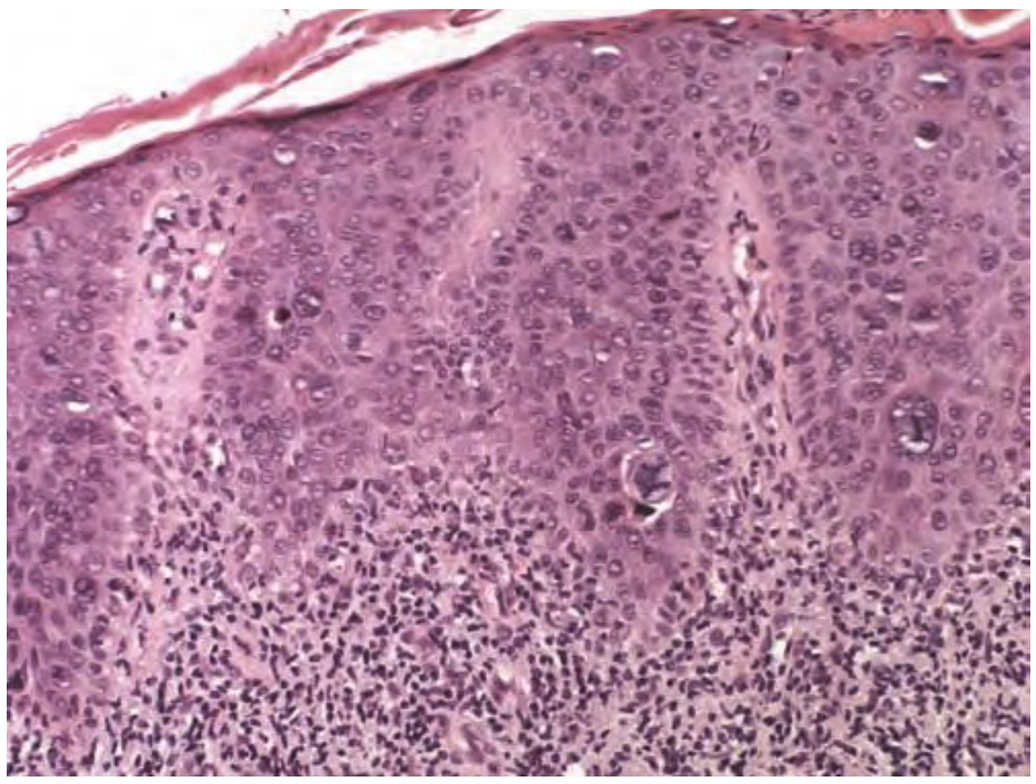

FIGURE 29-42. Bowenoid actinic keratosis. Medium magnification. Marked cellular and nuclear pleomorphisms are present together with frequent and atypical mitoses in a bowenoid actinic keratosis (squamous cell carcinoma in situ).

In the *atrophic type* of actinic keratosis, hyperkeratosis usually is slight. The epidermis is thinned and devoid of rete ridges. Atypicality of the cells is found predominantly in the basal cell layer, which consists of cells with large hyperchromatic nuclei that lie close together. The atypical basal layer may proliferate into the dermis as buds and ductlike structures. It may also surround as cell mantles the upper portion of pilosebaceous follicles and sweat ducts, the epithelium of which otherwise appears normal (196).

The *bowenoid type* of actinic keratosis is histologically indistinguishable from Bowen's disease and may also be referred to as squamous cell carcinoma *in situ*. As in Bowen's disease, within the epidermis there is considerable disorder in the arrangement of the nuclei, as well as clumping of nuclei and dyskeratosis (Figs. 29-40 to 29-43).

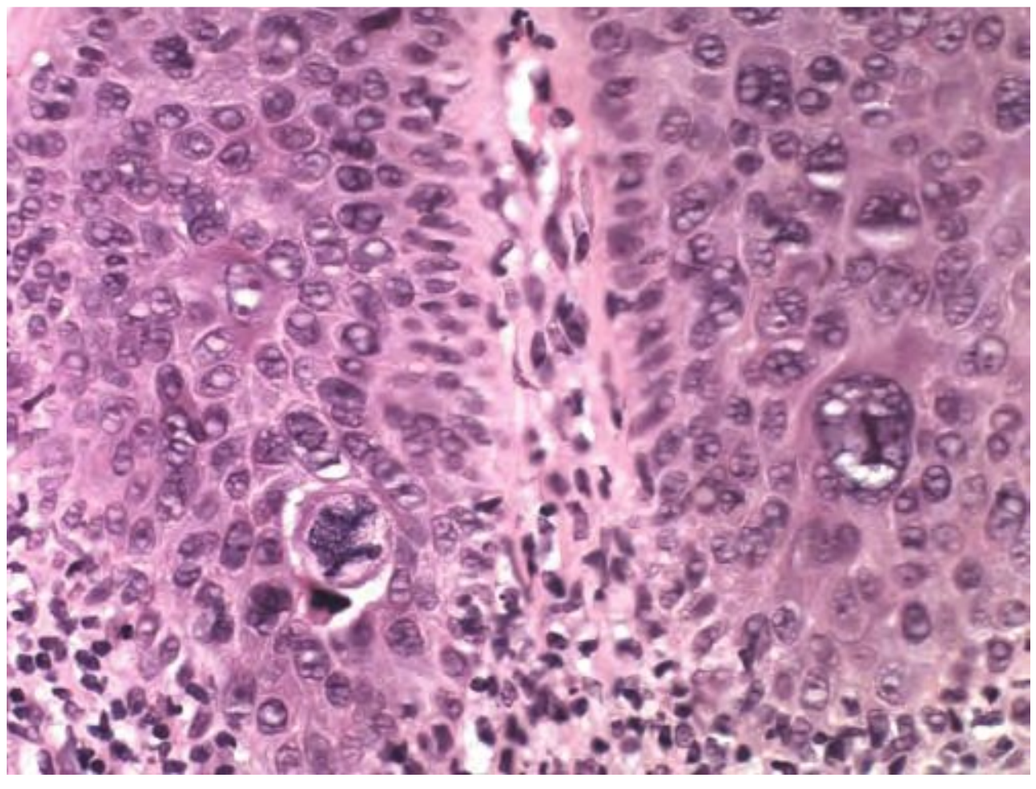

FIGURE 29-43. Bowenoid actinic keratosis. High magnification. Large atypical mitoses are prominent in this bowenoid actinic keratosis.

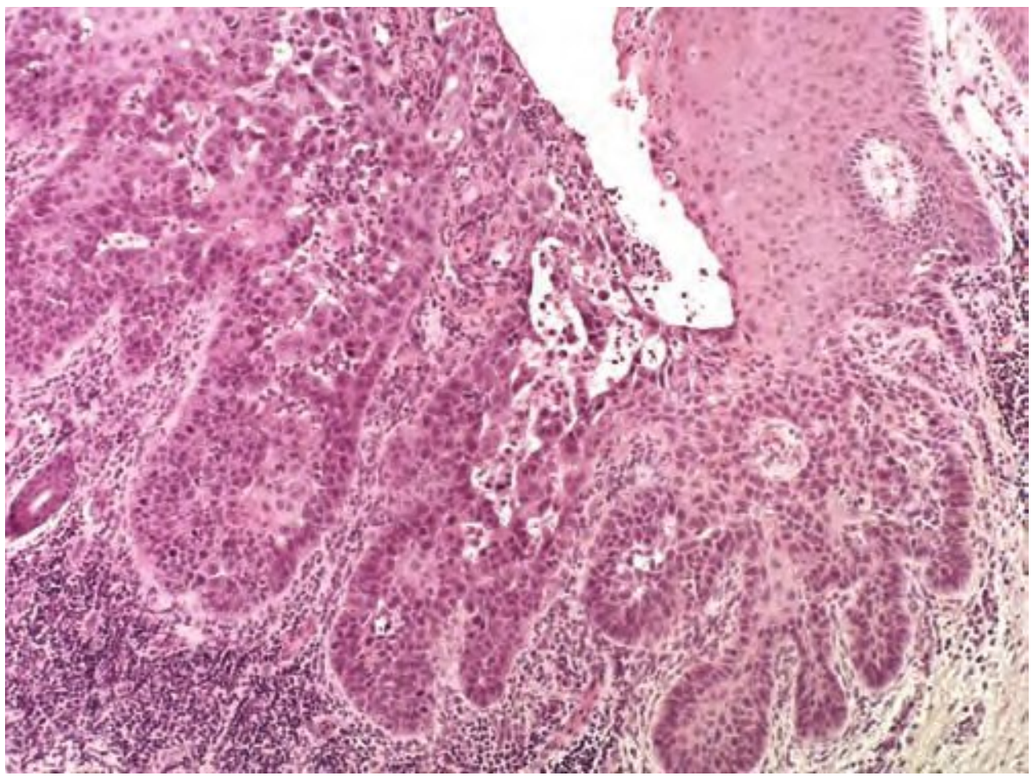

FIGURE 29-44. Actinic keratosis, acantholytic type. Low magnification. The epidermis is markedly hyperkeratotic. In the dermis, there is a dense, lichenoid inflammatory infiltrate. The keratosis shows focal acantholytic change.

In the *acantholytic type* of actinic keratosis, immediately above the atypical cells composing the basal cell layer there are clefts or lacunae similar to those seen in Darier's disease (see Chapter 6) (219). These clefts form as a result of anaplastic changes in the lowermost epidermis, resulting in dyskeratosis and loss of the intercellular bridges (Fig. 29-44). A few acantholytic cells may be present within the clefts (Fig. 29-45). Because the acantholysis is preceded by cellular changes, it is referred to as *secondary acantholysis*, in contrast to the primary acantholysis seen in the "acantholytic" diseases, such as pemphigus vulgaris and Darier's disease. Above the acantholytic clefts, the epidermis shows varying degrees of atypicality but generally less atypicality than is seen in the basal cell layer. The anaplastic cells of the basal cell layer frequently show extensions into the upper dermis as buds or short, ductlike structures. Suprabasal acantholysis may be seen also around hair follicles and sweat ducts in the upper dermis. When atypia is full thickness or high grade, the term *acantholytic squamous cell carcinoma in situ* may be applied.

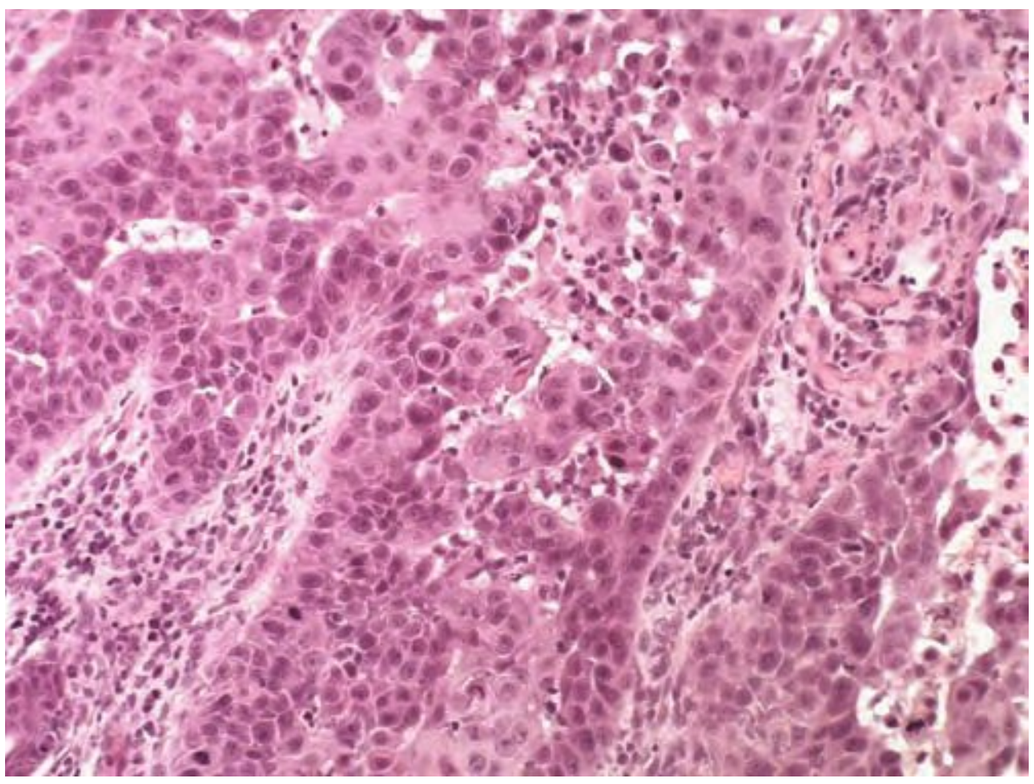

FIGURE 29-45. Actinic keratosis, acantholytic type. High magnification. Keratinocytes in the basal layer are crowded, with an increased nuclear–cytoplasmic ratio. They tend to become separated from one another and adopt a rounded configuration. This process of "secondary acantholysis" may in some instances result in the formation of pseudoglandular spaces that may mimic a glandular pattern of differentiation.

In the *pigmented type* of actinic keratosis, excessive amounts of melanin are present, especially in the basal cell layer. In some cases, the atypical keratinocytes are well melanized (220). In others, almost all of the melanin is retained within the cell bodies and dendrites of the melanocytes, indicating some block in melanin transfer. Numerous melanophages are seen in most cases in the superficial dermis (207).

In all five types of actinic keratosis, the upper dermis usually shows a fairly dense, chronic inflammatory infiltrate composed predominantly of lymphoid cells but often also containing plasma cells. Solar cheilitis, more frequently than actinic keratosis of the skin, shows an inflammatory infiltrate in which plasma cells predominate (208). Although the upper dermis usually shows solar or basophilic degeneration, this may be absent in areas with a pronounced inflammatory reaction, probably because the inflammation has resulted in a regeneration of collagen.

In instances in which the histologic diagnosis is actinic keratosis but the clinical diagnosis is squamous cell carcinoma, it is advisable to section more deeply into the block of tissue because progression into squamous cell carcinoma may have taken place in another area. Because no sharp line of demarcation exists between the two conditions, it is not always possible to decide whether a lesion can still be regarded as actinic keratosis or should be classified as early squamous cell carcinoma. Thus, some authors regard squamous cell carcinoma as a lesion in which irregular aggregates of atypical keratinocytes are found in the papillary dermis, not in continuity with the overlying epidermis (221). Others call a lesion that does not extend downward to the level of the reticular dermis an actinic keratosis without qualification (222). This decision is rarely a vital one because early squamous cell carcinoma arising in an actinic keratosis rarely causes metastases, although it may become deeply invasive and destructive through further growth. Because carcinomas arising in solar cheilitis have a significantly higher tendency to metastasize than carcinomas arising in actinic keratosis, and because invasion of the dermis in solar cheilitis may be focal, lesions of solar cheilitis require thorough examination by means of step sections (209).

Pathogenesis. On electron microscopic examination, only a difference in degree was found to exist between actinic keratosis and squamous cell carcinoma (223). With the use of blood group antigens as indicators of malignancy to sections of actinic keratosis, areas of positive staining alternate with areas showing no staining, the lack of staining being indicative of anaplasia. Areas of irregular downward proliferation or early invasion are consistently negative (224).

Differential Diagnosis. In actinic keratoses showing relatively slight atypicality, or anaplasia, of the tumor cells, diagnosis

may be difficult. Thus a hypertrophic actinic keratosis with a lichenoid inflammatory infiltrate may show a close histologic resemblance to the lesion known as *benign lichenoid keratosis*. In fact, this lesion was at one time believed to be a variant of actinic keratosis (225). Benign lichenoid keratosis differs from actinic keratosis by showing dissolution rather than atypicality of the basal cell layer, analogous to lichen planus (see Chapter 7) (226,227).

An atrophic actinic keratosis may closely resemble lupus erythematosus because both types of lesions show flattening of the epidermis. Although lupus erythematosus shows vacuolization and actinic keratosis shows atypicality of the cells in the basal layer, these two changes are not always easily distinguished from one another. Therefore, other findings, such as follicular plugging and a patchy, periappendageal infiltrate in lupus erythematosus, are necessary for differentiation (see Chapter 10).

A pigmented actinic keratosis may resemble lentigo maligna, particularly if the melanin is seen largely within the melanocytes (227). Usually, however, lentigo maligna shows more flattening of the epidermis than pigmented actinic keratosis and, more important, a great increase in the number of melanocytes, together with atypicality in the melanocytes but not in the basal keratinocytes (see Chapter 28).

CUTANEOUS HORN

Cutaneous horn, or *cornu cutaneum,* is the clinical term for a circumscribed, conical, markedly hyperkeratotic lesion in which the height of the keratotic mass amounts to at least half of its largest diameter (228) (Fig. 29-46). The term refers to a reaction pattern and not to a specific lesion (229).

Histopathology. On histologic examination, different types of lesions can be seen at the base of the conical hyperkeratosis of a cornu cutaneum. Most commonly, an actinic keratosis is

FIGURE 29-46. Cutaneous horn. The horn consists of a column of keratin arising on the sun-exposed skin of the ear.

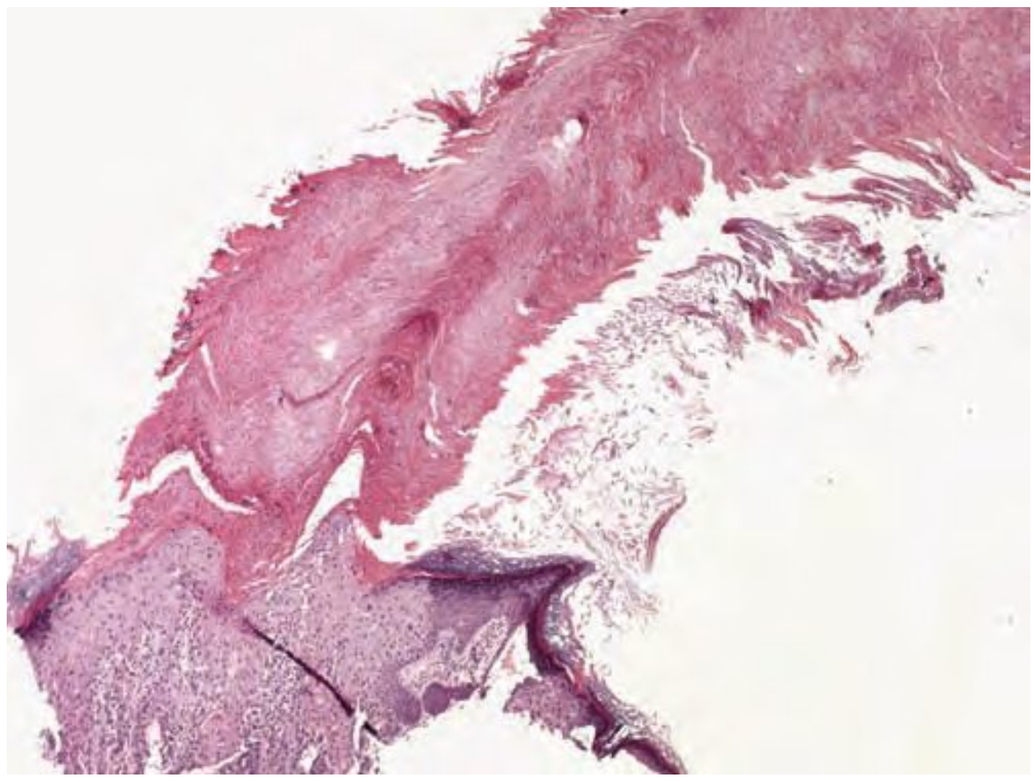

FIGURE 29-47. Cutaneous horn. The horn consists of a column of keratin arising in an actinic keratosis.

encountered (Fig. 29-47) (230). In some instances, a filiform verruca, a seborrheic keratosis, or a squamous cell carcinoma is found (228). On rare occasions, a trichilemmoma (229) or a basal cell epithelioma is seen (231). For a description of trichilemmal horn, see Chapter 30.

ORAL LEUKOPLAKIA

The term *leukoplakia* was used in the past by dermatologists and gynecologists (232) to designate white patches of the oral mucosa or the vulva that showed early, *in situ*, anaplastic changes; the term *leukokeratosis* was used for patches with a histologically benign appearance. However, leukoplakia has been redefined on the basis of the concept proposed by oral pathologists (233), and this concept has been accepted by the World Health Association (234).

According to this concept, the term *leukoplakia* carries no histologic connotation and is used only as a clinical description. It is defined as a white patch or plaque that will not rub off and that cannot be characterized clinically or histologically as any specific disease (e.g., lichen planus, lupus erythematosus, candidiasis, white sponge nevus) (235). The reason for using the term *leukoplakia* as a purely clinical designation is that a distinction between benign leukoplakia and leukoplakia with dysplastic changes cannot be made on clinical grounds. It is therefore essential that all white plaques that either are idiopathic in origin or persist for 3 to 4 weeks after any existing irritation has been eliminated be examined histologically (236). In many cases of oral leukoplakia, either chemical irritation through tobacco use or mechanical irritation through dental stumps or ill-fitting dentures plays a role. Although the leukoplakia clears in some instances after the irritation has been removed, it persists in others. However, the transformation of a benign leukoplakia into a malignant leukoplakia is regarded as rare (237). Still, any leukoplakia that is growing or altering its appearance requires a repeat biopsy (32).

Clinically, lesions of leukoplakia on the oral mucosa consist of one or several white patches that may not be raised and that appear ill defined. However, if they are slightly elevated, they appear sharply demarcated, with an irregular outline.

Erythroplakia of the oral mucosa consists of red, sharply delineated patches that vary greatly in size. Some of these lesions are sprinkled or intermingled with patches of leukoplakia and are then referred to as *speckled erythroplakia* (238).

On examination by histology, scraping, or culture, both leukoplakia and erythroplakia frequently show *Candida albicans* as a secondary invader, a finding that may give rise to an incorrect diagnosis of candidiasis (239). However, infection with *C. albicans* may cause oral lesions that are clinically indistinguishable from leukoplakia (240).

The analysis of oral leukoplakias and oral invasive carcinomas for human papillomavirus–related DNA has shown that a significant percentage of these lesions are reactive with papillomavirus antibodies, allowing the conclusion that they are induced by papillomaviruses, especially by HPV-11 and HPV-16 (see Chapter 25) (241,242).

For a discussion of leukoplakia of the vulva, see page 816, and of oral hairy leukoplakia, see Chapter 25.

Histopathology. The whiteness of leukoplakia is the result of hydration of a thickened horny layer. On histologic examination, about 80% of the lesions of oral leukoplakia are found to be benign (235,239). Such lesions show hyperkeratotic or parakeratotic thickening of the horny layer, acanthosis, and a chronic inflammatory infiltrate (Fig. 29-48). Of the remaining 20% of the cases, 17% show varying degrees of dysplasia or *in situ* carcinoma, and 3% show infiltrating squamous cell carcinoma (235). Ultimate development of carcinoma has been observed in 7% to 13% of all cases of leukoplakia (234). Localization of the leukoplakia seems to play an important role in the presence of malignancy. Leukoplakias on the buccal mucosa were found to be benign in 96% of the cases, whereas on the floor of the mouth, only 32% of the leukoplakias were benign, and 31% showed a carcinoma *in situ* and 37% an invasive carcinoma (243).

In situ carcinoma, also referred to as precancerous leukoplakia, may have a similar histologic appearance to the hypertrophic type of actinic keratosis. Thus the most important features observed within a moderately acanthotic epithelium are, first, pleomorphism and atypicality of the nuclei, which appear large, irregular, and hyperchromatic, and, second, loss of polarity, resulting in a disorderly arrangement of the cells. In some instances, one finds as additional features premature keratinization resulting in dyskeratotic cells in the midportion of the epithelium, crowding of nuclei in the basal cell layer, and irregular downward proliferations of the epithelium. There is considerable histologic, philosophical, and biological overlap among lesions categorized as high-grade dysplasia and carcinoma *in situ* in oral as in other mucous membranes.

Erythroplakia of the oral mucosa, in contrast to leukoplakia, invariably shows nuclear atypicality. One observes *in situ* carcinoma in half of the cases and invasive carcinoma in the other half (238). The red appearance is explained by the absence of the normal surface covering of orthokeratin or parakeratin.

Differential Diagnosis. A decision as to whether *in situ* carcinoma exists in a leukoplakia can be difficult because some pleomorphism of nuclei and some loss of polarity of the cells can be seen occasionally also in various inflammatory conditions, including benign leukoplakia (236). In cases of doubt, step sections throughout the biopsy specimen are required, as well as, possibly, examination of additional biopsy specimens. The decision as to whether a leukoplakia is benign or low grade or is a high-grade dysplasia or a carcinoma *in situ* is of great importance. In comparison with squamous cell carcinoma of the skin developing in an actinic keratosis, squamous cell carcinoma of the oral mucosa developing in a leukoplakia with *in situ* carcinoma has a much greater tendency to metastasize.

Differentiation of leukoplakia from oral lichen planus also may cause difficulties both clinically and histologically. In lichen planus no atypia is seen and there often is partial absence of basal cells. In addition, the prevalence of Langerhans cells in lesions of lichen planus may aid in the differentiation (244).

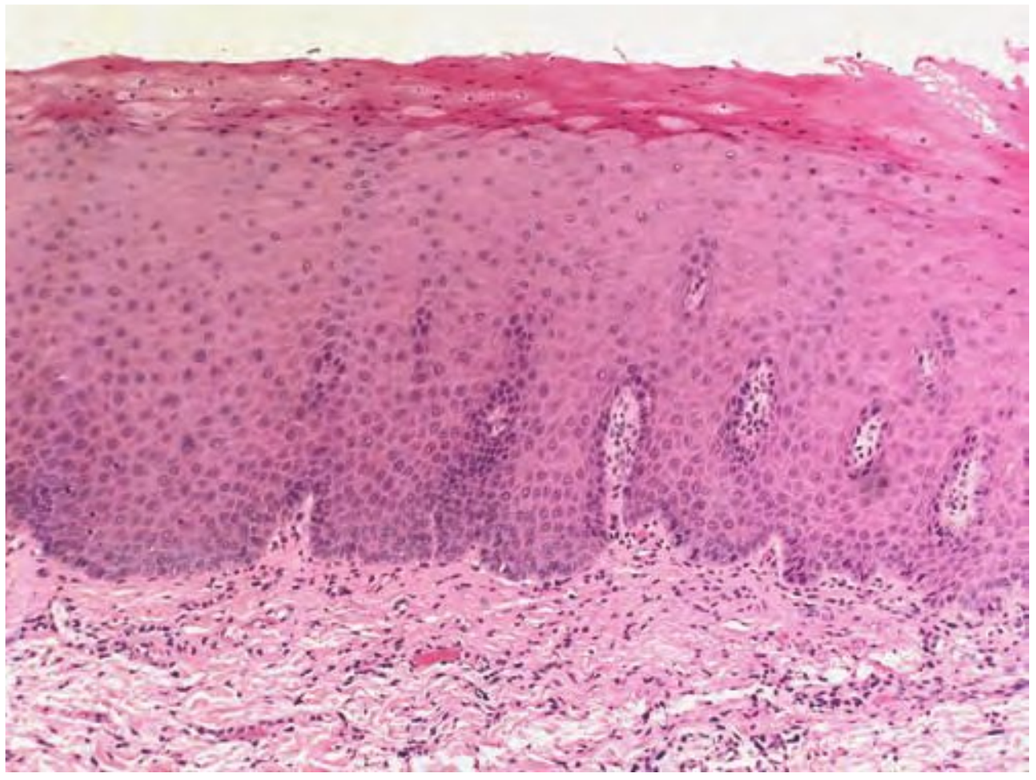

FIGURE 29-48. Oral leukoplakia. In this example the squamous epithelium is hyperkeratotic and acanthotic but shows no evidence of dysplasia.

VERRUCOUS HYPERPLASIA, VERRUCOUS CARCINOMA OF THE ORAL MUCOSA

Verrucous hyperplasia of the oral mucosa consists of extensive verrucous, white patches that may arise as such or develop from lesions of leukoplakia. Verrucous hyperplasia and verrucous carcinoma are indistinguishable clinically. They may coexist, or verrucous carcinoma may develop from verrucous hyperplasia. In some instances, verrucous hyperplasia develops into frank squamous cell carcinoma rather than into verrucous carcinoma (245).

Verrucous carcinoma of the oral mucosa is also known as *oral florid papillomatosis*. Clinically, one observes white, cauliflower-like lesions that may involve large areas of the oral mucosa and that gradually extend and coalesce. Extensive local tissue destruction may occur. However, metastases are rare, and, if they occur, they remain limited to the regional lymph nodes (246–248).

Histopathology. *Verrucous hyperplasia* shows a hyperplastic epithelium with upward extension of verrucous projections located predominantly superficial to the adjacent epithelium (245).

Verrucous carcinoma (oral florid papillomatosis) differs in its early stage from verrucous hyperplasia by showing, in addition to the surface verrucous projections, extension of the lesion into the underlying connective tissue (245). The downward extensions of the epithelium are round and club shaped and appear well demarcated from the surrounding stroma. Nuclear pleomorphism or hyperchromasia and formation of horn pearls are absent.

Some lesions of verrucous carcinoma persist in this stage for many years, although ultimately they show, in the areas of deepest extension, a moderate loss of polarity, increased cytoplasmic basophilia, nuclear hyperchromasia, and frequent mitotic figures. These features, however, do not suffice for a diagnosis of squamous cell carcinoma (249). Other lesions show sufficient nuclear atypicality and loss of polarity in the downward proliferations to indicate the presence of a well-differentiated squamous cell carcinoma (250). In about 10% of the cases of verrucous carcinoma, transformation into a classic squamous cell carcinoma takes place (247,248). (For a more detailed discussion of verrucous carcinoma, see page 822.)

NECROTIZING SIALOMETAPLASIA

One or occasionally two ulcers showing a rolled border and measuring 1 to 2 cm in diameter are found usually on the hard palate and occasionally on the soft palate. If they are located on the hard palate, bone may be exposed at the base of the ulcer. Spontaneous healing takes place within 6 to 12 weeks. The importance of necrotizing sialometaplasia, a rare condition first reported in 1973 (251), lies in its clinical and histologic resemblance to carcinoma (186).

Histopathology. Histologic examination shows coagulative necrosis of salivary gland lobules and squamous metaplasia within adjacent viable lobules. The connective tissue framework of the necrotic glands remains intact, thereby preserving the lobular architecture of the salivary gland. Faintly basophilic material representing sialomucin is seen within the necrotic glands. This is both PAS positive and Alcian blue positive. Adjacent to the necrotic glands, one may see normal-appearing salivary gland acini. Other salivary gland structures show either partial squamous metaplasia, with a peripheral rim of squamous cells, or complete replacement by squamous epithelium. The squamous metaplasia also involves the salivary ducts (252,253).

Pathogenesis. The abrupt clinical onset and rapid spontaneous healing suggest that an acute vascular insult results in infarction and coagulation necrosis of the salivary acini (252).

Differential Diagnosis. To pathologists not familiar with this condition, the apparent irregular proliferation and deep extension of squamous epithelium may suggest a diagnosis of carcinoma. However, the confinement of cytologically benign squamous epithelium to the preexisting lobular pattern of salivary glands should permit the correct diagnosis (254).

EOSINOPHILIC ULCER OF THE TONGUE

One or two asymptomatic ulcers measuring 0.8 to 2.0 cm in diameter arise suddenly on the tongue. Spontaneous healing takes place within a few weeks.

Histopathology. A dense cellular infiltrate is present at the base of the ulcer, extending through the submucosa into the striated muscle bundles of the tongue. Most of the cells are eosinophils, but there are also lymphocytes and histiocytes (255,256). In one case, focal leukocytoclastic vasculitis was present (257).

Differential Diagnosis. This lesion differs from eosinophilic granuloma of histiocytosis X (see Chapter 26) clinically by its tendency to arise and heal rapidly and histologically by the smaller number and smaller size of the histiocytes (255).

BOWEN'S DISEASE

Bowen's disease usually consists of a solitary lesion. It may occur on exposed or on unexposed skin. It may be caused on exposed skin by exposure to the sun and on unexposed skin by the ingestion of arsenic (see Pathogenesis, following, and Arsenical Keratosis and Carcinoma). Lesions of Bowen's disease can form in lesions of epidermodysplasia verruciformis caused by HPV-5 (see Chapter 25). Not infrequently the fingers, including the nail fold or nail bed, are involved (258).

Bowen's disease manifests as a slowly enlarging erythematous patch of sharp but irregular outline showing little or no infiltration. Within the patch are generally areas of scaling and crusting. Although Bowen's disease may resemble a superficial basal cell epithelioma, it differs from it by the absence of a fine, pearly border and lack of a tendency to heal with central atrophy. Lesions of Bowen's disease can occur on the glans penis, where they are referred to also as erythroplasia of Queyrat.

Bowenoid papulosis of the genitalia, because of its probable relationship to genital warts, is discussed in Chapter 25.

Histopathology. Bowen's disease is an intraepidermal squamous cell carcinoma referred to also as squamous cell carcinoma *in situ*. Thus it represents biologically but not morphologically a *precancerous dermatosis*, under which designation it was described originally in 1912 (259).

FIGURE 29-49. Bowen's disease. The lesion is crusted and erythematous, with a poorly defined margin.

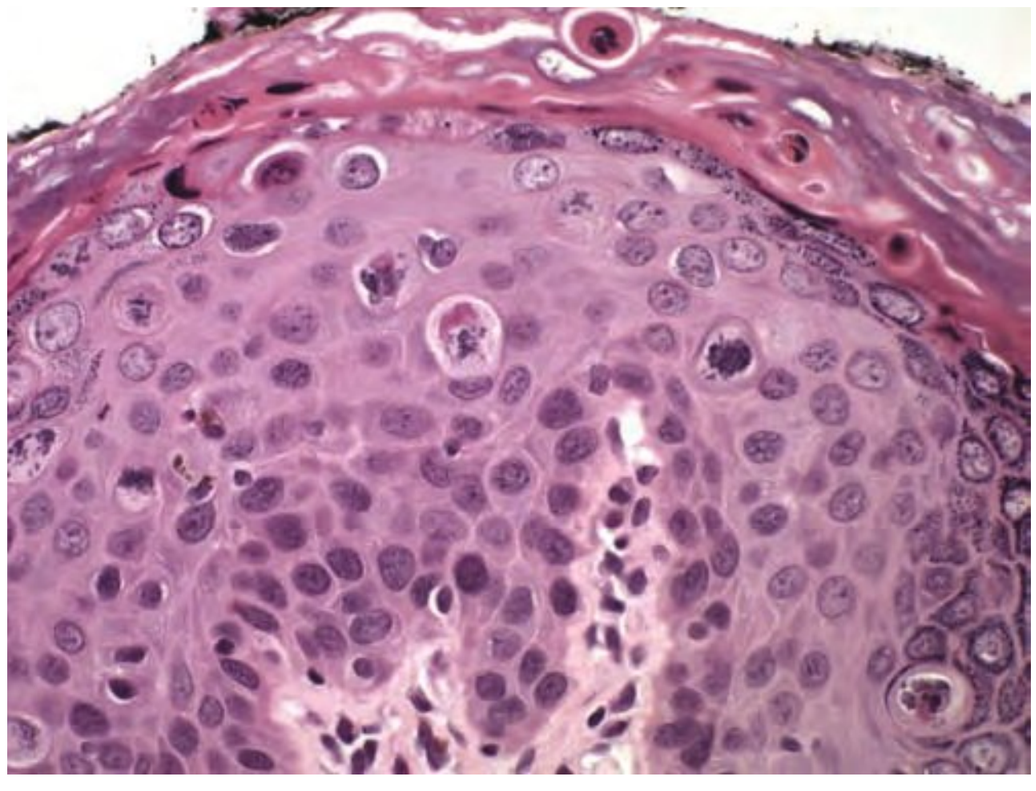

FIGURE 29-51. Bowen's disease. Throughout the epidermis, the cells lie in disarray, with frequent large atypical mitoses.

The epidermis shows acanthosis with elongation and thickening of the rete ridges, often to such a degree that the papillae located between the rete ridges are reduced to thin strands (Fig. 29-49). Throughout the epidermis, the cells lie in complete disorder, resulting in a "windblown" appearance (Figs. 29-50 and 29-51). Many cells appear highly atypical, showing large, hyperchromatic nuclei. Multinucleated epidermal cells containing clusters of nuclei are often present. The horny layer usually is thickened and consists largely of parakeratotic cells with atypical, hyperchromatic nuclei (260).

A common and rather characteristic feature is the presence of cells showing atypical individual cell keratinization. Such dyskeratotic cells are large and round and have a homogeneous, strongly eosinophilic cytoplasm and a hyperchromatic nucleus. The infiltrate of atypical cells in Bowen's disease frequently extends into follicular infundibula and causes replacement of the follicular epithelium by atypical cells down to the entrance of the sebaceous duct (204).

Even though the marked atypicality of the epidermal cells includes the cells of the basal layer, the border between the epidermis and dermis everywhere appears sharp, and the basement membrane remains intact. The upper dermis usually shows a moderate amount of a chronic inflammatory infiltrate.

An occasional finding in Bowen's disease is vacuolization of the cells, especially in the upper portion of the epidermis (261). In addition, in exceptional cases, multiple nests of atypical cells are scattered through a normal epidermis, sometimes with sparing of the basal cell layer. This results in a histologic picture that used to be interpreted as intraepidermal epithelioma of Borst-Jadassohn (see Chapter 31) (204,262).

In a small percentage of cases of Bowen's disease, an invasive squamous cell carcinoma develops. The usual figure quoted is 3% to 5% (263). The highest incidence given is 11% (264). On the opposite end is a statement that, in the vast majority of cases, Bowen's disease remains a carcinoma *in situ* during the lives of those affected (265). If invasion happens, it usually takes place after many years' duration of the disease. The invasive tumor retains the cytologic characteristics of the intraepidermal tumor, and invasion may occur at first in only a limited area. To avoid missing such an area, it is advisable to examine representative sections throughout the entire tissue block. As soon as invasion has taken place, the prognosis changes. So long as Bowen's disease remains in its intraepidermal stage, metastases do not occur. However, once invasion of the dermis has occurred, there exists the possibility of regional and even visceral metastases (264).

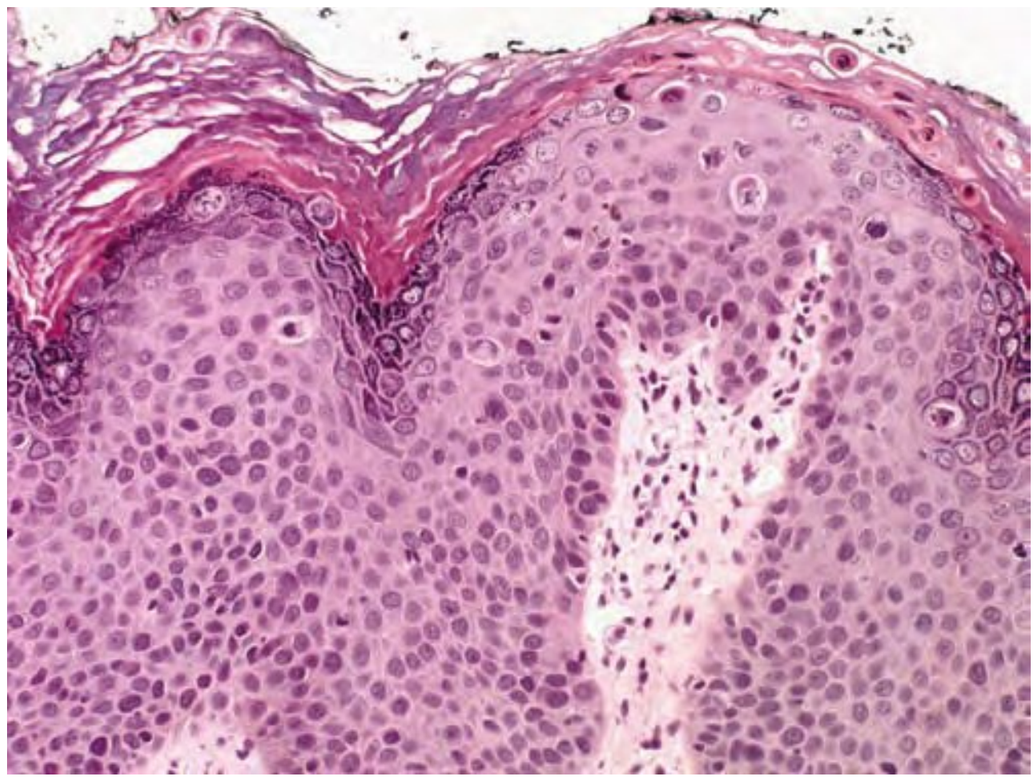

FIGURE 29-50. Bowen's disease. The epidermis is irregularly thickened. The normal maturation pattern is effaced.

Pathogenesis. No agreement exists about the frequency with which visceral carcinoma develops in patients with Bowen's disease. The first authors to point out an association between Bowen's disease and visceral cancer found that, of 35 patients

with Bowen's disease who were known to have died, 20 (57%) had an associated internal cancer (264). In a subsequent series, however, a significant increase in the incidence of associated internal cancer was observed only in patients in whom the lesions of Bowen's disease were located in areas not exposed to the sun (33%); in patients in whom the lesions were in exposed areas, the incidence of visceral cancer was low (5%) (246). Subsequent studies, with one exception (267), have not demonstrated a significantly increased risk of internal malignancy in patients with Bowen's disease (204,268–270).

Electron microscopic examination of lesions of Bowen's disease has demonstrated the presence of many dyskeratotic cells. The perinuclear aggregation and condensation of tonofilaments in these dyskeratotic cells are similar to but more pronounced than in the dyskeratotic cells of Darier's disease (271). Some of the markedly dyskeratotic cells in Bowen's disease disintegrate, and portions of such cells are phagocytized by other epidermal cells, which may contain, in addition to the phagocytized dyskeratotic material, phagocytized desmosomes in their cytoplasm (271,272). In other instances, the intracellularly located desmosomes are not phagocytized but are drawn into the dyskeratotic cells of Bowen's disease together with aggregating tonofilaments (273). The phenomenon of intracytoplasmic desmosomes, however, is not specific for Bowen's disease, although it is found most commonly in this condition. Thus intracytoplasmic desmosomes have been observed within dyskeratotic keratinocytes in Darier's disease (274), squamous cell carcinoma (275), and keratoacanthoma (276); within nondyskeratotic keratinocytes in extramammary Paget's disease (277), and malignant melanoma (278); and even within normal keratinocytes in both the epidermis (279) and the oral mucosa (280). It can be assumed that the occasional occurrence of invaginations of the plasma membrane is a normal event in keratinocytes and that the invaginated plasma membrane can contain desmosomal structures. These structures are more resistant to enzymatic destruction than the plasma membrane and thus may be found free in the cytoplasm (280).

Two types of epidermal giant cells can be recognized in Bowen's disease. In one type, an entire dyskeratotic cell has been "cannibalized" by another keratinocyte and is located within the cytoplasm of the phagocytizing cell (281). In the second type, multiple nuclei lie in the center of the giant cell surrounded by dyskeratotic tonofilaments. It seems that, by becoming entangled with the spindles of the mitotic apparatus, the dyskeratotic tonofilaments interfere with the normal division of the cell so that nuclear division can take place but cellular division cannot (271,272).

Differential Diagnosis. No histologic difference exists between bowenoid actinic keratosis and Bowen's disease. They may differ merely in size, with the bowenoid actinic keratosis usually being smaller than Bowen's disease.

In some cases of Bowen's disease, there are single atypical cells scattered among benign keratinocytes in a pattern of "pagetoid Bowen's disease" or "pagetoid squamous cell carcinoma *in situ*" that must be differentiated from superficial spreading melanoma *in situ*, if necessary with the use of immunostaining for keratin markers and S100 and/or Melan-A/MART1 (see Chapter 28). Paget's disease may similarly share with Bowen's disease the presence of vacuolated cells in a "pagetoid" pattern, but, in contrast with Bowen's disease, it shows no dyskeratosis. In addition, immunostaining for the aforementioned melanoma markers and for carcinoembryonic antigen and keratins may be used to aid in making this distinction, and furthermore the material contained in Paget cells is often PAS positive and diastase resistant, whereas the PAS-positive material that is sometimes present in the vacuolated cells of Bowen's disease is glycogen and therefore diastase labile (282).

ERYTHROPLASIA OF QUEYRAT (BOWEN'S DISEASE OF THE GLANS PENIS, CARCINOMA IN SITU)

Erythroplasia of Queyrat is the term often used for carcinoma *in situ* located on the glans penis. Clinically and histologically, it is identical to Bowen's disease, and this designation would seem preferable for simplicity's sake. The only reason for keeping the term *erythroplasia of Queyrat* alive is that it was introduced in 1911 (283), 1 year before the description of Bowen's disease (259).

Erythroplasia or Bowen's disease of the glans penis is seen almost exclusively in uncircumcised men. It manifests itself as an asymptomatic, sharply demarcated, bright-red, shiny, very slightly infiltrated plaque on the glans penis or, less often, in the coronal sulcus or on the inner surface of the prepuce (284).

Histopathology. Erythroplasia of Queyrat of the glans penis has the same histologic appearance as Bowen's disease. Progression into an invasive squamous cell carcinoma has been observed in up to 30% of the patients (285), with metastases in about 20% of the patients with invasive erythroplasia (286). It thus has a greater tendency toward invasion and metastasis than Bowen's disease of the skin (285).

Differential Diagnosis. A clinical diagnosis of erythroplasia of Queyrat requires histologic examination of an adequate biopsy for confirmation because differentiation from balanitis circumscripta plasmacellularis is not possible on a clinical basis.

BALANITIS CIRCUMSCRIPTA PLASMACELLULARIS

A disorder first described by Zoon in 1952 (287), balanitis circumscripta plasmacellularis has the same clinical appearance as erythroplasia of Queyrat or Bowen's disease of the glans penis. In some instances, erosions with a tendency to bleed are present (288). Like erythroplasia, this disorder is seen almost exclusively in uncircumcised males (289). On rare occasions, an analogous lesion referred to as *vulvitis circumscripta plasmacellularis* is observed on the vulva (290,291).

Histopathology. The epidermis appears thinned and often shows absence of its upper layers (292). It may be partially detached as a result of subepidermal cleavage or even absent (288,293). If present, the epidermis often has a rather distinctive appearance; in addition to being thinned and flattened, it is composed of diamond- or lozenge-shaped, flattened keratinocytes that are separated from each other by uniform intercellular edema (289). Erythrocytes may be seen permeating the epidermis. In some cases, the keratinocytes appear degenerated or necrotic (292).

The upper dermis shows a bandlike infiltrate in which numerous plasma cells are often seen (287,292). In some cases, however, their number is only moderate (289) or even small (293). In addition, the capillaries are dilated, and there may be extravasations of erythrocytes and deposits of hemosiderin (294).

Pathogenesis. It has been pointed out that plasma cells frequently predominate in the inflammatory response at mucocutaneous junctions in a variety of benign and malignant processes. Thus the term *circumorificial plasmacytosis* was introduced for benign plasma cell infiltrates on the glans penis, vulva, and lips (295–297). However, the combination of histologic and clinical features seen in balanitis circumscripta plasmacellularis, and probably also in vulvitis circumscripta plasmacellularis, is unique and deserves recognition as an entity (289,290,292).

SQUAMOUS INTRAEPITHELIAL NEOPLASIA (DYSPLASIA) OF THE VULVA

The term leukoplakia of the vulva is purely a clinical designation requiring histologic examination for clarification of the diagnosis, especially to decide whether atypicality of the epithelial cells exists. The clinical aspect of leukoplakia of the vulva is more variable than that of oral leukoplakia because it does not always consist just of white patches as in the mouth but may have a papular or verrucous appearance. The reason is that on the vulva, HPV infections can occur as flat papular condylomas (298), often in association with similar lesions on the cervix. In addition, the condition previously described as bowenoid papulosis, in the presence of multiple, coalescing papules, may result in a verrucous aspect of the leukoplakia (see Chapter 25) (299). A clear-cut histologic decision often is not possible unless adequate clinical data are available.

The further investigation of dysplastic lesions in the vulva has shown that there are two types of vulvar intraepithelial neoplasia (VIN) (300). The first of these is *undifferentiated VIN*, which is associated with human papillomavirus infection, occurs mainly in younger women, tends to be multicentric, and is of the undifferentiated or bowenoid type. This is probably what has previously been called bowenoid papulosis. The second type is *differentiated VIN*, which is not associated with human papillomavirus infection, typically occurs in older women, and is often unifocal. It is commonly associated with lichen sclerosus or squamous hyperplasia and carries a substantial risk of progression to invasive squamous cell carcinoma.

Histopathology. Flat condylomas that may be associated with VIN show intracellular vacuolization that may result in a somewhat atypical appearance of the epithelium referred to as *koilocytotic atypia*. This may be difficult to differentiate from true atypia (298). In undifferentiated VIN the changes are those of undifferentiated basaloid or bowenoid dysplasia. In differentiated VIN the epithelium is thickened and parakeratotic with elongated and anastomosing rete ridges. The characteristic feature is the presence of large basal or parabasal eosinophilic keratinocytes with abnormal vesicular nuclei and prominent intercellular bridges. Intraepithelial pearls may be present in the rete ridges. There is little or no atypia above the basal layer of the epidermis.

ARSENICAL KERATOSIS AND CARCINOMA

Inorganic arsenic was a frequently used oral medication for a number of dermatoses until evidence accumulated in the 1930s that, besides its long-known tendency to form arsenical keratoses on the palms and soles, inorganic arsenic quite frequently causes carcinoma of the skin (301). In the 1950s, it became apparent that inorganic arsenic could cause visceral carcinoma. The most common form in which inorganic arsenic has been administered was Fowler's solution containing 1% potassium arsenite.

Careless handling of industrial wastes can introduce arsenic into well water used for domestic consumption, resulting in "epidemic" occurrences of arsenical keratoses and cutaneous carcinomas (302,303).

Arsenical keratoses of the palms and soles, consisting of verrucous papules without surrounding inflammation, are a common manifestation of prolonged arsenic ingestion. Thus, in a follow-up study of 262 patients who had been taking Fowler's solution for 6 to 26 years before this study, arsenical keratoses of the palms and soles were observed in 40% and arsenic-induced carcinomas of the skin in 8% (304). In a study from Taiwan, 80% of the 428 patients with arsenical carcinomas of the skin had arsenical keratoses of the palms and soles (305). The minimal latent period between the beginning of arsenic intake and the onset of arsenical keratoses of the palms and soles was 2.5 years, and the average latent period 6 years (304).

Cutaneous carcinomas following arsenic ingestion are usually multiple, and about three fourths of them are located on the trunk (305). They consist of erythematous, scaling, occasionally crusted patches that slowly increase in size. Carcinomas can also arise in arsenical keratoses of the palms and soles (304,305). The average latency between the beginning of arsenic intake and the onset of carcinoma was 18 years, with a range from 3 to 40 years (306).

Visceral carcinoma can be caused by arsenic intake, but the actual incidence is difficult to determine because of the

long latent period, which may vary from 13 to 50 years, with an average of 24 years (307). The most common locations appear to be bronchi and the genitourinary system (304,307). There are on record at least two incidences of prolonged arsenic intake in which lung cancer occurred in a high percentage of the patients: One report concerned vineyard workers exposed to an arsenic insecticide (308), and the other dealt with villagers exposed to arsenic-containing drinking water (309). In the latter series, the onset of pulmonary cancer started 30 years after the arsenic exposure.

Because Bowen's disease is the most common cutaneous carcinoma produced by arsenic, the possibility of a relationship between Bowen's disease and visceral carcinoma is of interest. This association, first pointed out in 1959 (264), appears to be greatest in those cases of Bowen's disease in which the lesions are located in unexposed areas and thus are not caused by sun exposure. In one report, an association with internal carcinoma was found in about one third of the cases (266). It was suggested that arsenic is the common denominator in such cases, causing both Bowen's disease and internal carcinoma. However, subsequent studies showed no significant relationship between Bowen's disease in covered areas and internal malignancy (268), or, if such a relationship was found, no arsenic ingestion was found in most of the patients (267).

Histopathology. In arsenical keratoses of the palms and soles, one may find, in some instances, only hyperkeratosis and acanthosis without evidence of nuclear atypicality (305). However, when one cuts deeper into the tissue block, atypicality may become apparent. Whereas some arsenical keratoses show only mild nuclear atypicality, the findings in others are those of a squamous cell carcinoma *in situ* and are analogous to Bowen's disease or an actinic keratosis. One observes disorder in the arrangement of the squamous cells and nuclear atypicalities, such as hyperchromasia, clumping, or dyskeratosis (310). Atrophy of the epidermis and basophilic degeneration of the upper dermis, as seen in some actinic keratoses, are absent in arsenical keratoses. Evidence of development into an invasive squamous cell carcinoma may be seen in some arsenical keratoses (304,305,310).

The type of cutaneous carcinoma that follows arsenic ingestion can be either squamous cell carcinoma or basal cell carcinoma, usually as multiple lesions. Squamous cell carcinomas usually occur as *in situ* lesions analogous to Bowen's disease, and basal cell carcinomas occur most commonly as superficial basal cell carcinomas, although invasive squamous cell carcinomas and basal cell carcinomas occur occasionally. Invasive tumors may arise *de novo* or may develop within preexisting lesions of Bowen's disease or superficial basal cell carcinoma.

A matter of controversy has been whether arsenical carcinomas occur more commonly as lesions of Bowen's disease or as superficial basal cell carcinomas. For many years, it was accepted that lesions of Bowen's disease were the usual reaction (261). However, whereas two publications stated that superficial basal cell carcinomas are far more prevalent than lesions of Bowen's disease (304,311), in two other publications, Bowen's disease was found to be much more common (305,310). The most likely explanation for this discrepancy appears to be that, in many instances, lesions of Bowen's disease have been misinterpreted as superficial basal cell carcinoma (310). The distinction can indeed be difficult; one author who found mainly superficial basal cell carcinomas conceded that 25% of them showed "squamous metaplasia" (311), and another author proposed the concept of "combined forms" consisting of a "mixture of superficial basal cell carcinoma and intraepidermal carcinoma" (305). It appears likely that lesions designated as superficial basal cell carcinoma with squamous metaplasia or as combined forms represent lesions of Bowen's disease. (For histologic descriptions of Bowen's disease and superficial basal cell carcinoma, see page 813 and page 831 of this chapter respectively.)

Pathogenesis. *In vitro* experiments concerning the effects of inorganic arsenic on human epidermal cells have shown that arsenic depresses premitotic DNA replication. Furthermore, incubation with inorganic arsenic and subsequent exposure of the cell cultures to ultraviolet light causes interruption of the enzymatic "dark repair mechanism" in the epidermal cells. Among other enzymes, arsenic seems to block predominantly DNA polymerase by attaching itself to sulfhydryl groups. The damaging effect of arsenic on DNA may explain its carcinogenic effect (312).

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma may occur anywhere on the skin and on mucous membranes with squamous epithelium. It rarely arises from normal-appearing skin. Most commonly, it arises in sun-damaged skin, either as such or from an actinic keratosis. Next to sun-damaged skin, squamous cell carcinomas arise most commonly in scars from burns and in stasis ulcers, termed *Marjolin's ulcers* (313). In regard to metastases, carcinomas arising in sun-damaged skin have a very low propensity to metastasize, the incidence amounting to only about 0.5% (212). This is in contrast to a metastatic rate of 2% to 3% for all patients with squamous cell carcinoma of the skin, with death resulting in about three fourths of the patients with metastases (213,314). Carcinomas of the lower lip, even though in most cases they also are induced by exposure to the sun, have a much higher incidence of metastasis, about 16%, with death occurring in about half of these patients as the result of metastases (315). In addition, the rate of metastases is higher in adenoid and mucin-producing squamous cell carcinomas of the skin than in the common type.

The diameter and thickness of cutaneous squamous cell carcinoma are related to the likelihood of metastasis, which is most often seen in primary tumors with a diameter of at least 15 mm and a vertical (Breslow) tumor thickness of at least 2 mm. Decreasing degrees of differentiation, desmoplasia, and an inflammatory reaction including eosinophils and plasma cells are also more frequently seen in metastasizing tumors (319).

FIGURE 29-52. Squamous cell carcinoma. This unpigmented tumor has a fleshy surface.

Cutaneous squamous cell carcinomas that arise secondary to inflammatory and degenerative processes have a much higher rate of metastasis than those developing in sun-damaged skin. Thus the rate of metastasis was found to be 31% in squamous cell carcinomas arising in osteomyelitic sinuses (316), 20% in radiation-induced skin cancer (317), and 18% in carcinomas developing in burn scars (318). Furthermore, carcinomas arising from modified skin, such as the glans penis and the vulva, and from the oral mucosa have a rather high rate of metastasis unless recognized and adequately treated at an early stage.

The incidence of squamous cell carcinomas, like that of other malignant neoplasms, is significantly increased in immunosuppressed patients (320). The incidence of cutaneous squamous cell carcinoma has been found to be 18 times greater in patients with a renal transplant and immunosuppression than in the general population (321). Squamous cell carcinomas may also show greater aggressiveness in such patients (322).

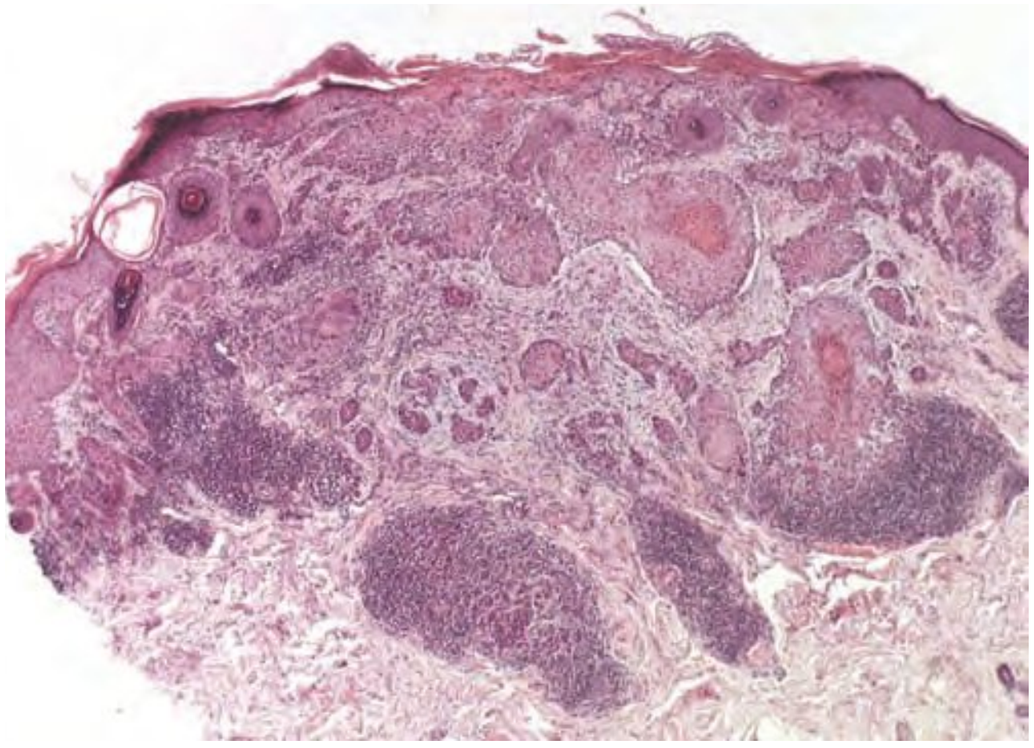

FIGURE 29-53. Squamous cell carcinoma arising in actinic keratosis. Low magnification. The epidermis shows features of an actinic keratosis. There is invasion of the dermis by epidermal masses. The dermis shows a marked inflammatory reaction.

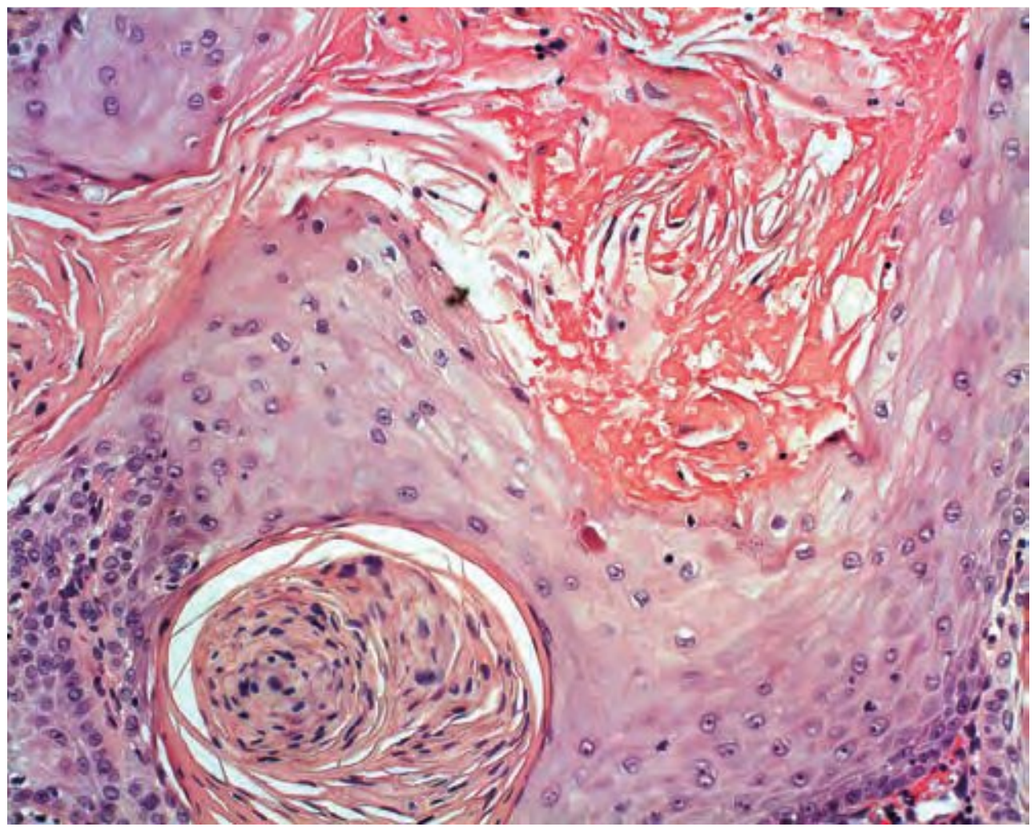

FIGURE 29-54. Squamous cell carcinoma, well differentiated. More than 75% of the tumor is keratinized.

Clinically, squamous cell carcinoma of the skin most commonly consists of a shallow ulcer surrounded by a wide, elevated, indurated border. Often the ulcer is covered by a crust that conceals a red, granular base. Occasionally, raised, fungoid, verrucous lesions without ulceration occur (Fig. 29-52). Multiprofessional guidelines for the management of patients with squamous cell carcinoma have been published (323).

Three variants of squamous cell carcinoma, *adenoid squamous cell carcinoma*, *mucin-producing squamous cell carcinoma*, and *verrucous carcinoma,* are discussed later.

Histopathology. Squamous cell carcinoma of the skin is a true, invasive carcinoma of the surface epidermis. On histologic examination, one finds the tumor to consist of irregular masses of epidermal cells that proliferate downward into the dermis (Figs. 29-53 through 29-61). The invading tumor masses are composed in varying proportions of normal

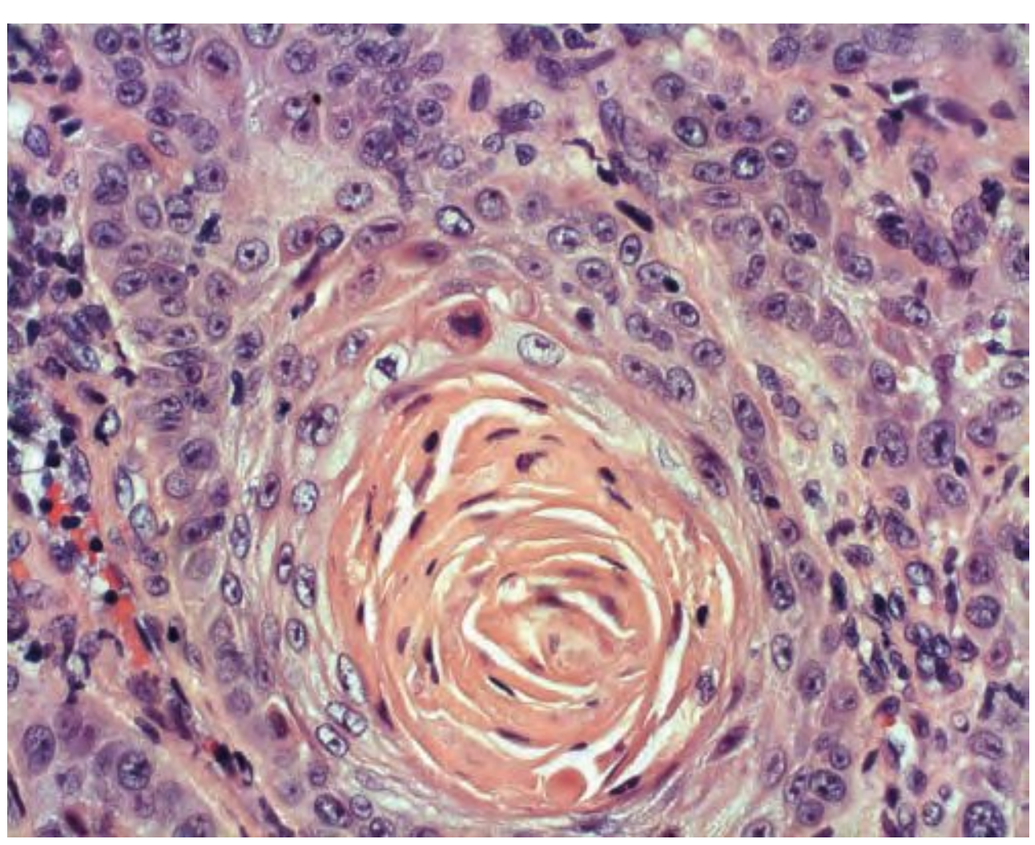

FIGURE 29-55. Squamous cell carcinoma, moderately differentiated. Between 25% and 75% of the tumor is keratinized.

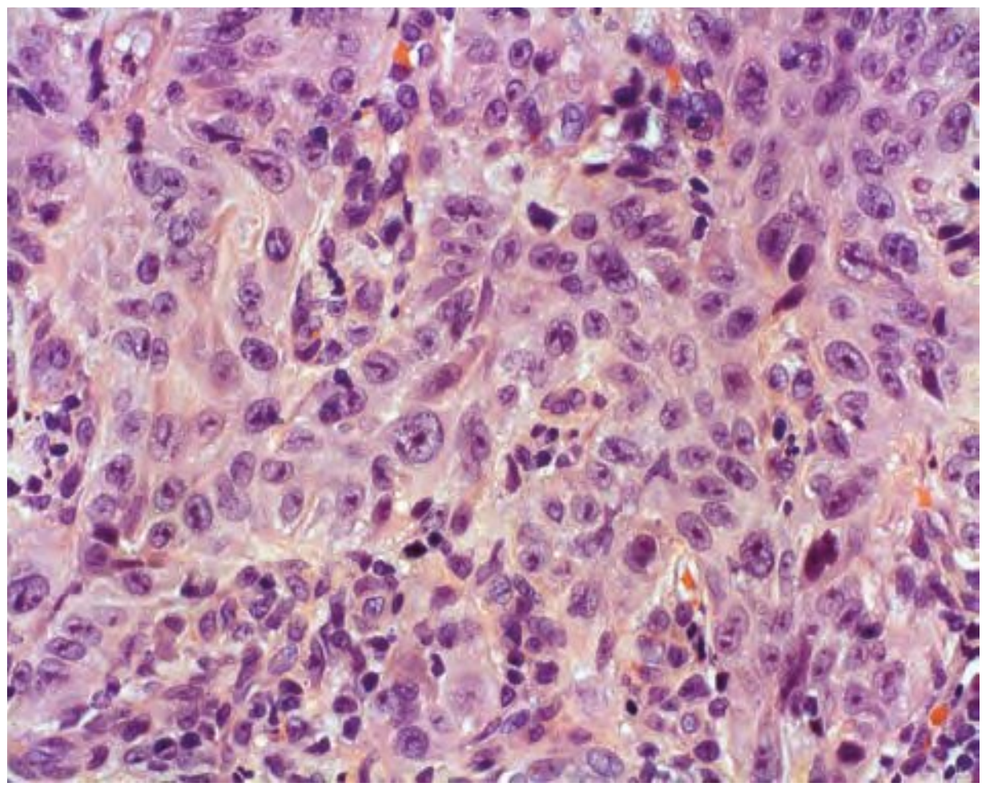

FIGURE 29-56. Squamous cell carcinoma, poorly differentiated. Less than 25% of the tumor is keratinized.

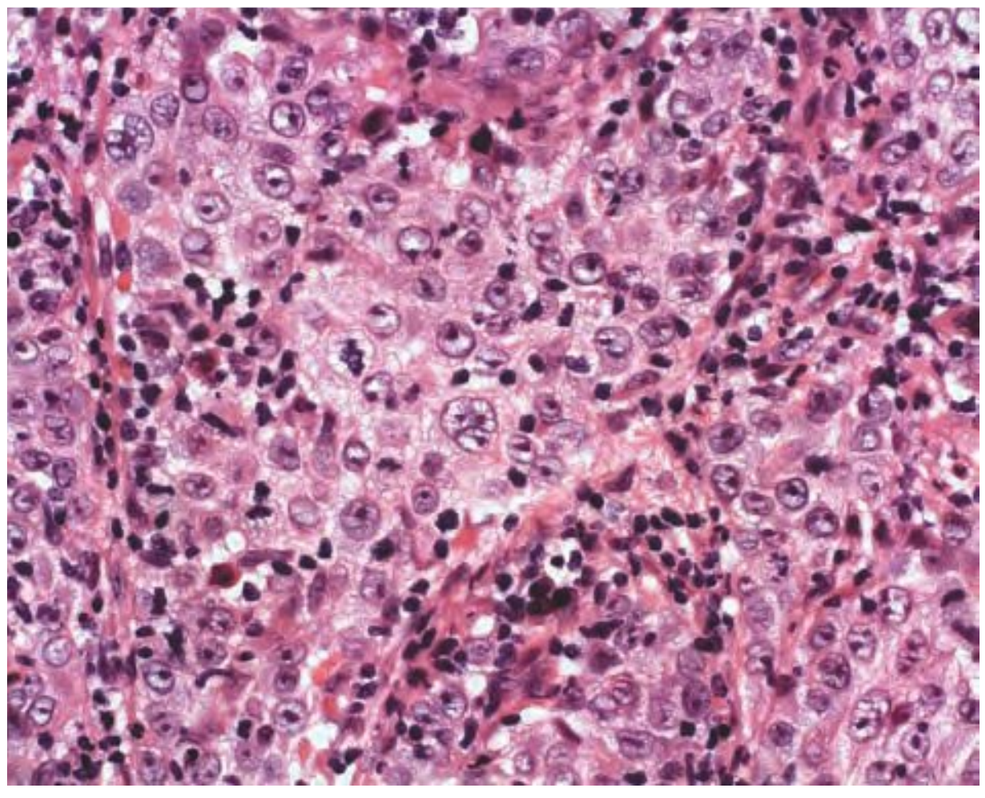

FIGURE 29-57. Lymphoepithelioma-like carcinoma showing similarities to poorly differentiated squamous cell carcinoma but having a more syncytial appearance of tumor epithelial cells and a rich lymphocytic infiltrate.

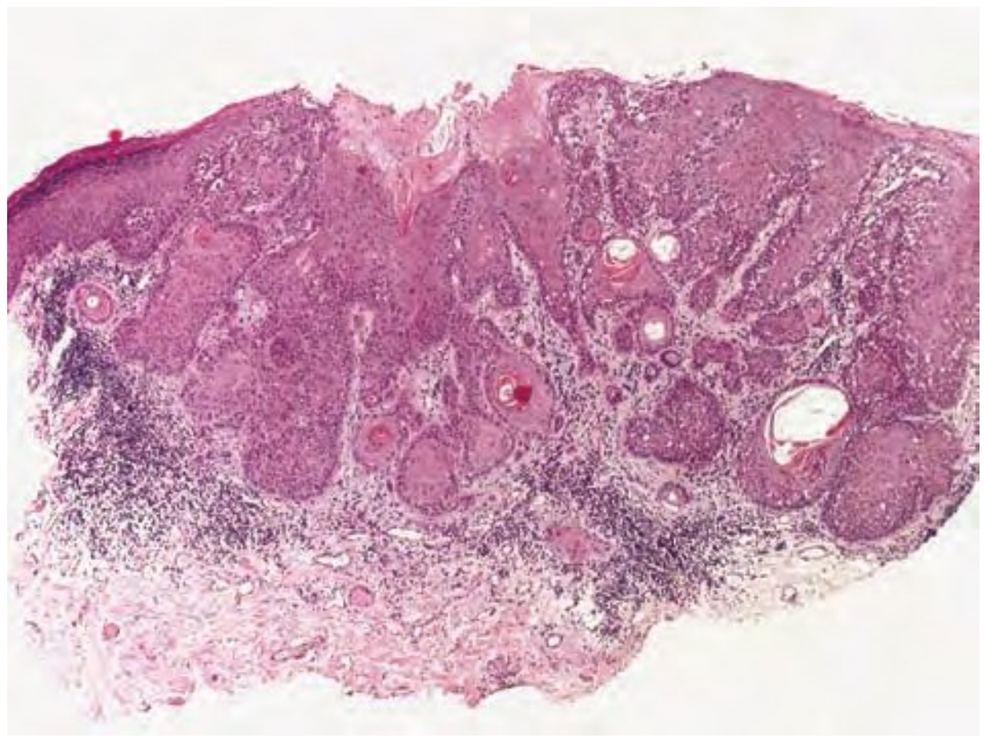

FIGURE 29-58. Squamous cell carcinoma, acantholytic type. In the deep part of the lesion the invasive cell masses show much less keratinization than in a well-differentiated tumor.

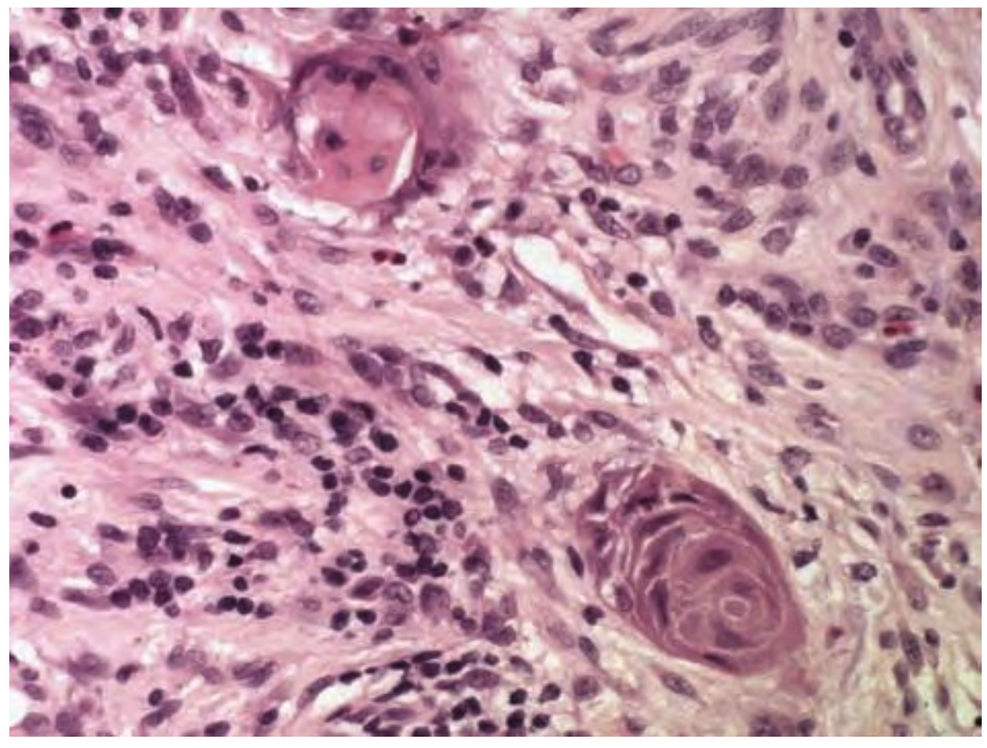

FIGURE 29-59. Squamous cell carcinoma. High magnification. Pleomorphic, hyperchromatic malignant squamous cells infiltrate the dermis.

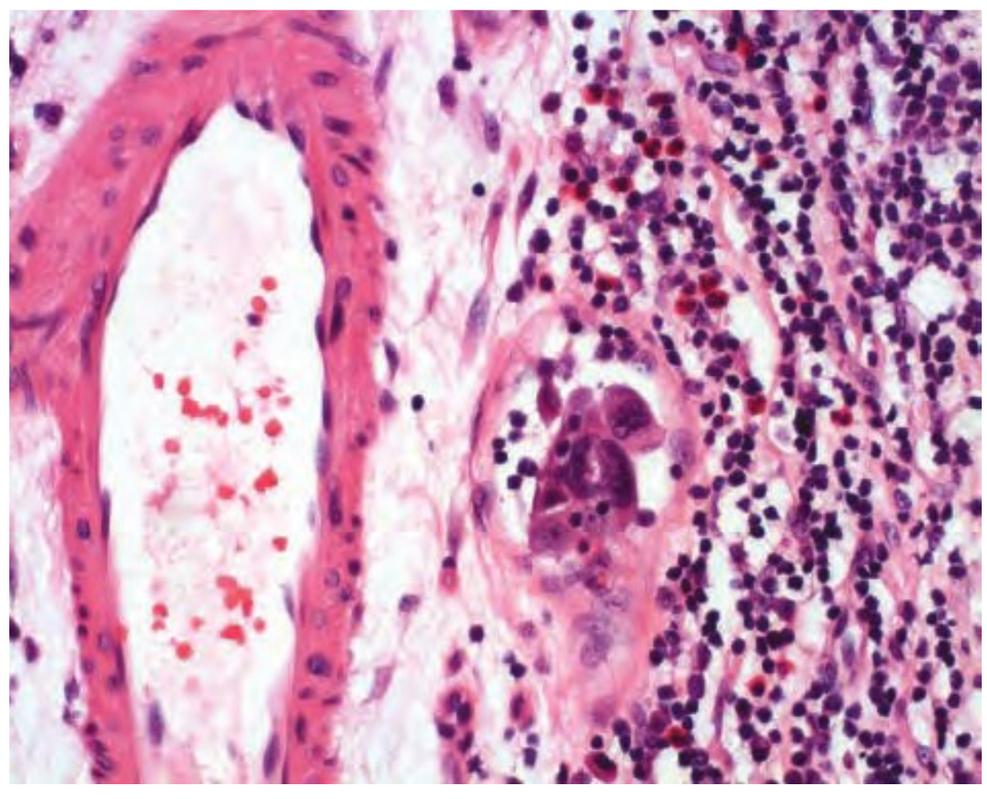

FIGURE 29-60. Squamous cell carcinoma. High magnification. Tumor cells show vascular invasion adjacent to the main tumor mass.

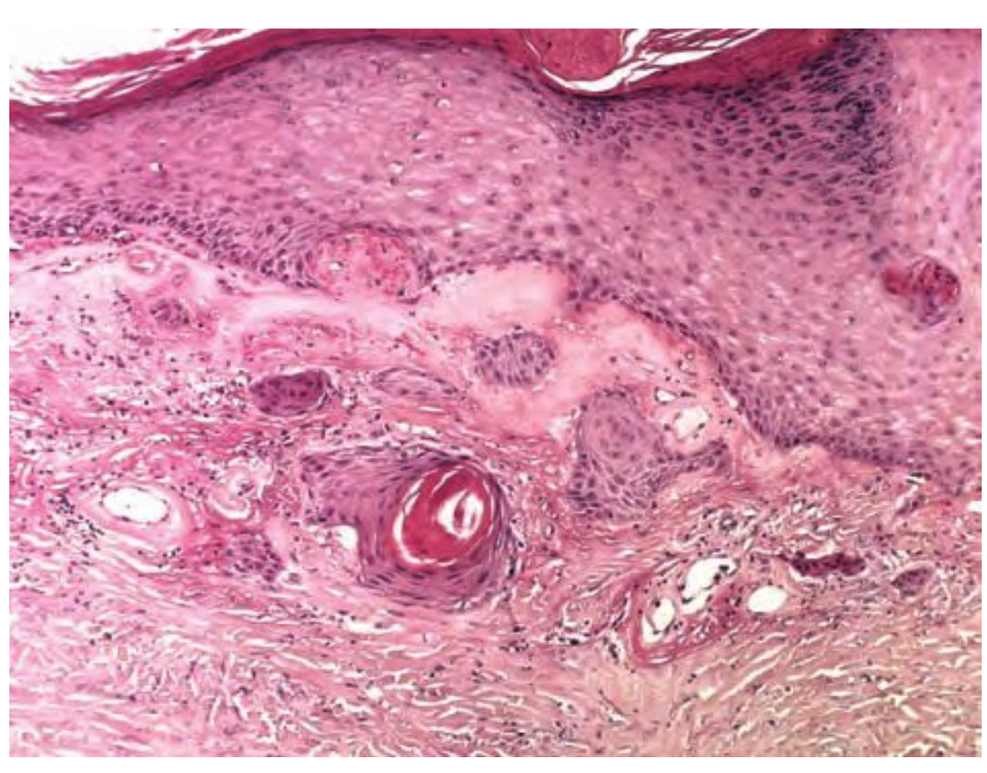

FIGURE 29-61. Postradiotherapy squamous cell carcinoma. This lesion, arising in an area treated many years previously with radiotherapy, shows a combination of invasive keratinizing squamous cell carcinoma and stromal damage secondary to radiotherapy.

squamous cells and of atypical (anaplastic) squamous cells. The number of atypical squamous cells is higher in the more poorly differentiated tumors. Atypicality of squamous cells expresses itself in such changes as great variation in the size and shape of the cells, hyperplasia and hyperchromasia of the nuclei, absence of intercellular bridges, keratinization of individual cells, and the presence of atypical mitotic figures.

Differentiation in squamous cell carcinoma is in the direction of keratinization. Keratinization often takes place in the form of horn pearls, which are very characteristic structures composed of concentric layers of squamous cells showing gradually increasing keratinization toward the center. The center shows usually incomplete and only rarely complete keratinization. Keratohyaline granules within the horn pearls are sparse or absent. There have been attempts to produce grading systems for squamous cell carcinoma, but classification as well-differentiated (Fig. 29-54), moderately differentiated (Fig. 29-55), and poorly differentiated (Fig. 29-56) carcinoma is the most widely adopted and reproducible way of describing the microscopic appearance of the tumors (1).

Marjolin's ulcer is a term applied to tumors that arise at the periphery of a chronic ulcer or a scar (313). The scar may be due to a remote burn or to radiation, or there may be a chronic inflammatory process such as a draining osteomyelitis sinus. The tumors often are well differentiated and may arise in a background of pseudoepitheliomatous (pseudocarcinomatous) hyperplasia, making diagnosis difficult (see discussion on page 822).

Spindle cell squamous cell carcinoma in particular may show a great resemblance to atypical fibroxanthoma (324). In some instances, spindle cell squamous cell carcinomas contain areas in which the cells either show intercellular bridges and beginning keratinization or show evidence of origin from the epidermis. In other cases, however, such areas cannot be detected. The spindle cells are intermingled with collagen and may be arranged in whorls (325). Not infrequently, pleomorphic giant cells are seen (324). In such instances, distinction from atypical fibroxanthoma may be difficult: Differential diagnosis by immunohistochemical examination is required (see Pathogenesis).

Raised, verrucous lesions of squamous cell carcinoma may show a considerable histologic resemblance to keratoacanthoma by having a central keratin-filled crater with peripheral buttresses. Keratoacanthomas typically do not extend into the dermis more deeply than the sweat gland coils, so when a tumor invades into the dermis to a deeper level than this, it can be described with confidence as carcinoma. There has been some reluctance among pathologists to even diagnose keratoacanthoma at all because of the view of some that the entity does not exist. A compromise position is to describe well-circumscribed and well-differentiated tumors as "well-differentiated, keratoacanthoma-like squamous cell carcinomas."

Pathogenesis. Electron microscopy of squamous cell carcinoma, in comparison with normal epidermal squamous cells, shows a reduction in the number of desmosomes on the cell surface. In their place, microvilli extend into the widened intercellular spaces. Desmosomes can be seen within the cytoplasm of some of the tumor cells, either by themselves or attached to bundles of tonofilaments (275). Their intracytoplasmic location may be the result of either phagocytosis or invagination of the plasma membrane. However, it is not a specific finding for squamous cell carcinoma; intracytoplasmic desmosomes also can be found in keratoacanthoma and Bowen's disease, as well as in several unrelated epidermal proliferations and even in normal keratinocytes.

At the dermal–epidermal junction, the basement membrane shows sporadic discontinuities through which long cytoplasmic protrusions penetrate, indicating invasion of the dermis by epidermal keratinocytes (326).

In early squamous cell carcinoma, lymphocytes are often seen in close contact with tumor cells, some of which show degenerative changes such as disruption of the plasma membrane, as well as fragmentation and subsequent release of organelles into the intercellular spaces. This can be interpreted as the cellular expression of an immune reaction against tumor cells (327).

The epithelial nature of the sarcoma-like cells in *spindle cell squamous cell carcinoma* is supported by electron microscopic findings, which have shown that these cells contain tonofilaments and occasional desmosome-like structures (325,328). Electron microscopy has also shown that structures diagnosed by light microscopy as atypical fibroxanthomas represent a heterogeneous group of neoplasms and that some are in actuality spindle cell squamous cell carcinomas (324,329).

Immunohistochemical methods are of considerable value in the differentiation of squamous cell carcinoma from mesodermal tumors, such as atypical fibroxanthoma and malignant fibrous histiocytoma, and from malignant melanoma. For the identification of keratinocytes, primary antibodies directed against high–molecular–weight cytokeratins, such as cytokeratin 13, or a pan-cytokeratin marker may be used. In contrast, atypical fibroxanthoma and malignant fibrous histiocytomas react with vimentin (see Chapter 32) and malignant melanoma with S100 protein and Melan-A/MART-1 (see Chapter 28). At times, even differentiation of a squamous cell carcinoma from a lymphoma may be difficult, in which case a positive reaction with monoclonal antileukocyte antibody (LCA, CD45) would favor lymphoma (330) (see Chapter 31). Immunohistochemistry using keratin markers may also be valuable in identifying tumor cells of a squamous cell carcinoma in the midst of an inflammatory infiltrate and can thus aid in deciding whether the margins of an excised specimen are free of tumor cells (331). The immunohistochemical differential diagnosis of spindle cell neoplasms in the skin is discussed also in Chapters 4, 28, 32, and 34.

Differential Diagnosis. The diagnosis of squamous cell carcinoma, although easily made in typical cases, may sometimes be difficult.

The differences between squamous cell carcinoma *in situ* and actinic keratosis lie in the degree as well as the type of

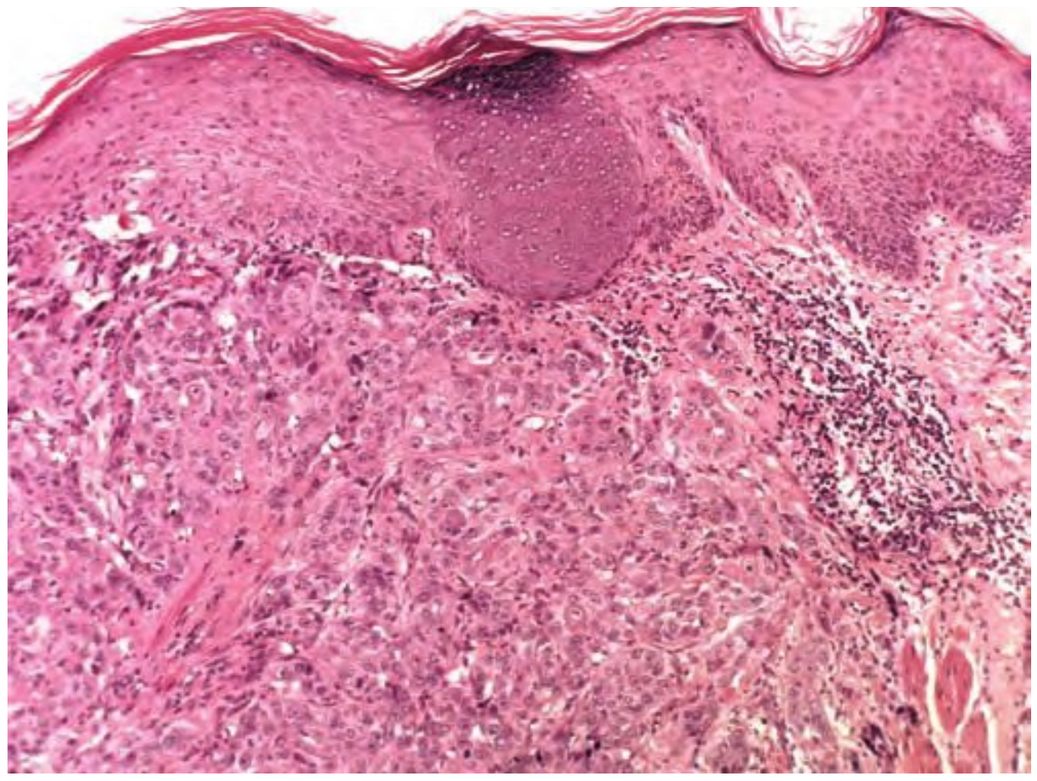

FIGURE 29-62. Metastatic squamous cell. A nodule of squamous cell carcinoma infiltrates the dermis beneath an epidermis devoid of dysplasia. The tumor was metastatic from a bronchial primary.

changes. In both conditions, one finds atypicality of cells, with dyskeratosis of individual cells and downward proliferation of the epidermis. However, only in frank squamous cell carcinoma is there invasion of the reticular dermis. No sharp line of demarcation exists between the two conditions, and not infrequently, on step sectioning for a lesion, the histologic appearance of actinic keratosis reveals one or several areas in which the changes have progressed to squamous cell carcinoma. Metastatic squamous cell carcinoma, for example, from another skin primary or from a mucous membrane or visceral lesion, usually shows a greater degree of cytologic atypia, may be located deeper in the dermis or subcutis, and lacks an overlying *in situ* component (Fig. 29-62).

For discussions of differentiation of squamous cell carcinoma from pseudocarcinomatous hyperplasia, see page 822; from keratoacanthoma, page 837; and from basal cell carcinoma, page 834.

ACANTHOLYTIC (ADENOID) SQUAMOUS CELL CARCINOMA

As a result of dyskeratosis and subsequent acantholysis, squamous cell carcinomas occasionally show what may appear to be tubular and alveolar formations on histologic examination. Such lesions have been termed *adenoid* or *pseudoglandular* squamous cell carcinomas, but they are better termed *acantholytic*. Clinically, they are found almost exclusively in sun-damaged skin of elderly patients, especially on the face and ears (332,333). They have also been seen on the vermilion border of the lower lip (334). Two instances of occurrence on the oral mucosa have been reported, but both were recurrences after radiation therapy (335).

On sun-exposed skin, acantholytic squamous cell carcinomas may arise as such or may develop from an actinic keratosis (333,336). In most instances, they do not differ in clinical appearance from the usual type of squamous cell carcinoma and thus commonly show a central ulceration surrounded by a raised, indurated border. Occasionally, they greatly resemble a keratoacanthoma in clinical appearance (337). The incidence of metastases varies. In one series it was only 2% (333), but in another series 14% of the patients had fatal metastases (338). Tumor size of greater than 15 mm correlates with the risk of an adverse outcome (319).

Histopathology. The adenoid changes may be seen in only a portion of a squamous cell carcinoma or throughout the lesion. Not infrequently, an actinic keratosis of the acantholytic type is seen overlying the lesion. There are tubular and alveolar lumina lined with one or several layers of epithelium (Figs. 29-58 and 29-59). In areas in which the lumina are lined with a single layer of epithelium, the epithelial cells resemble glandular cells, but in areas with several layers of epithelium, squamous and partially keratinized cells usually form the inner layers. The lumina are filled with desquamated acantholytic cells, many of which are partially or fully keratinized (333,337,339). In some cases, the eccrine ducts at the periphery of these tumors show signs of dilatation and proliferation (332,339). These ductal changes probably are induced by the surrounding inflammatory infiltrate.

Pathogenesis. These tumors represent squamous cell carcinomas of lobular growth in which there is considerable dyskeratosis with individual cell keratinization, resulting in acantholysis in the center of the lobular formations. This process is analogous to the suprabasal clefts seen in some actinic keratoses (337). Acantholytic squamous cell carcinomas differ from sweat gland carcinomas (see Chapter 30), in which the single row of cuboidal cells lining the lumina consists of true glandular cells (340,341). In some instances the latter tumors may be highly malignant.

MUCIN-PRODUCING SQUAMOUS CELL CARCINOMA

This rare variant of squamous cell carcinoma is associated with a more aggressive clinical course than are most cutaneous squamous cell carcinomas (342). Eleven cases have been reported under different designations, such as mucoepidermoid carcinoma (343) and adenosquamous carcinoma of the skin (342). The latter designation may lead to confusion with adenoid squamous cell carcinoma.

Histopathology. Varying numbers of mucin-producing cells are found within tumors that have the appearance of a squamous cell carcinoma. These cells generally appear large and pale and stain positively with the PAS method and with mucicarmine (342,344). Treatment of sections with sialidase eliminates the mucicarmine-staining material, whereas treatment with hyaluronidase fails to do so. Thus the material is epithelial mucin (sialomucin) (342). Occasionally, true glandular lumina

are present (342,345). Some of the lumina resemble distorted eccrine ducts and stain positively for carcinoembryonic antigen (345).

VERRUCOUS CARCINOMA

Verrucous carcinoma is a low-grade squamous cell carcinoma first described in 1948 (346) as occurring in the oral cavity. The diagnosis of verrucous carcinoma requires evaluation of the clinical and microscopic appearance and biological behavior of the neoplasm. It is a slowly growing, at first exophytic, verrucous, and fungating tumor that may ultimately penetrate deep into the tissue. However, it causes regional metastases only very late, if at all. Because of its high degree of histologic differentiation, it is often not recognized as a carcinoma for a long time. Three major forms of verrucous carcinoma are recognized, all of them occurring in areas of maceration.

Verrucous carcinoma of the oral cavity, also called oral florid papillomatosis, shows white, cauliflower-like lesions that may involve large areas of the oral mucosa.

Verrucous carcinoma of the genitoanal region, also called giant condyloma acuminatum of Buschke and Loewenstein, most commonly occurs on the glans penis and foreskin of uncircumcised males, where it consists of papillomatous proliferations. Ultimately, it may penetrate into the urethra. It may also occur on the vulva in females and in the anal region (see Chapter 25).

Plantar verrucous carcinoma, also called epithelioma cuniculatum (347), at first shows a striking resemblance to an intractable plantar wart. As the exophytic mass grows, it shows a great tendency toward deep, penetrating growth, resulting in numerous deep crypts filled with horny material and pus. The crypts resemble the burrows of rabbits, hence the name *cuniculatum*. The tumor ultimately penetrates the plantar fascia (348) and may even destroy metatarsal bones and invade the skin of the dorsum of the foot (349).

The occurrence of verrucous carcinoma has been described occasionally in many other areas, such as the face (350) and back (351), as well as in preexisting lesions, such as chronic ulcers and draining sinuses of hidradenitis suppurativa (352).

Histopathology. For the diagnosis of verrucous carcinoma, a large, deep biopsy is essential. The superficial portions generally resemble a verruca by showing hyperkeratosis, parakeratosis, and acanthosis. The keratinocytes appear well differentiated, stain lightly with eosin, and possess a small nucleus. The tumor invades with broad strands that often contain keratin-filled cysts in their center. There are large, bulbous, downward proliferations that compress the collagen bundles and push them aside. Thus the tumor has been said to invade by "bulldozing rather than stabbing" (353). Even in the deep portions of the tumor, nuclear atypia, individual cell keratinization, and horn pearls are absent (354).

However, in some instances, particularly in the oral cavity (247,250), but occasionally also in the genitoanal region (355) and on the plantar surface (356,357), verrucous carcinoma may ultimately show sufficient nuclear atypicality and loss of polarity to indicate the development of a true squamous cell carcinoma. In rare instances, the development of regional lymph node metastases has been observed in verrucous carcinoma of the mouth (248), the genitals (355), and the soles of the feet (357). Radiation therapy has led in some instances of oral verrucous carcinoma to anaplastic transformation and extensive metastases (358).

Pathogenesis. Although a viral cause of verrucous carcinoma has been suspected for a long time, demonstration of viral particles by electron microscopy has been possible in only a few instances. Virus-like particles were demonstrated in 1 case of plantar verrucous carcinoma presumed to be associated with a plantar wart (359), in the superficial epithelium of 5 of 13 cases of plantar verrucous carcinoma (360), and in 1 case of verrucous carcinoma of the vagina. The more sensitive and more specific method of demonstrating various types of human papilloma viruses by means of DNA hybridization has succeeded in proving the presence of HPV-6, and less frequently of HPV-11, in Buschke-Loewenstein tumors of the external genitals in both sexes (361). Similarly, HPV-6 was found in a vulvar tumor of Buschke-Loewenstein through molecular hybridization (362).

PSEUDOCARCINOMATOUS HYPERPLASIA

Pseudocarcinomatous hyperplasia, or *pseudoepitheliomatous hyperplasia,* as it is often called, represents a considerable downward proliferation of the epidermis into the dermis. Clinically and histologically, this downward proliferation may suggest a squamous cell carcinoma. It occurs occasionally (a) in chronic proliferative inflammatory processes, such as bromoderma, blastomycosis, blastomycosis-like pyoderma (pyoderma vegetans) (363), or hidradenitis suppurativa (364), and (b) at the edges of chronic ulcers, as seen in the following conditions: after burns or in stasis dermatitis (365), pyoderma gangrenosum, basal cell epithelioma (366), lupus vulgaris, osteomyelitis, scrofuloderma, gumma, and granuloma inguinale. In addition, granular cell tumor is known to evoke quite frequently a pseudocarcinomatous hyperplasia.

Histopathology. Histologically, pseudocarcinomatous hyperplasia shows an epithelial hyperplasia that often closely resembles moderately or well-differentiated squamous cell carcinoma. Although squamous cell carcinoma may develop at the edges of chronic ulcers, it is likely that some cases that are regarded as such actually represent pseudocarcinomatous hyperplasia. Nevertheless, a lesion starting out as pseudocarcinomatous hyperplasia at the edge of an ulcer may eventually develop into a squamous cell carcinoma and even metastasize (367,368).

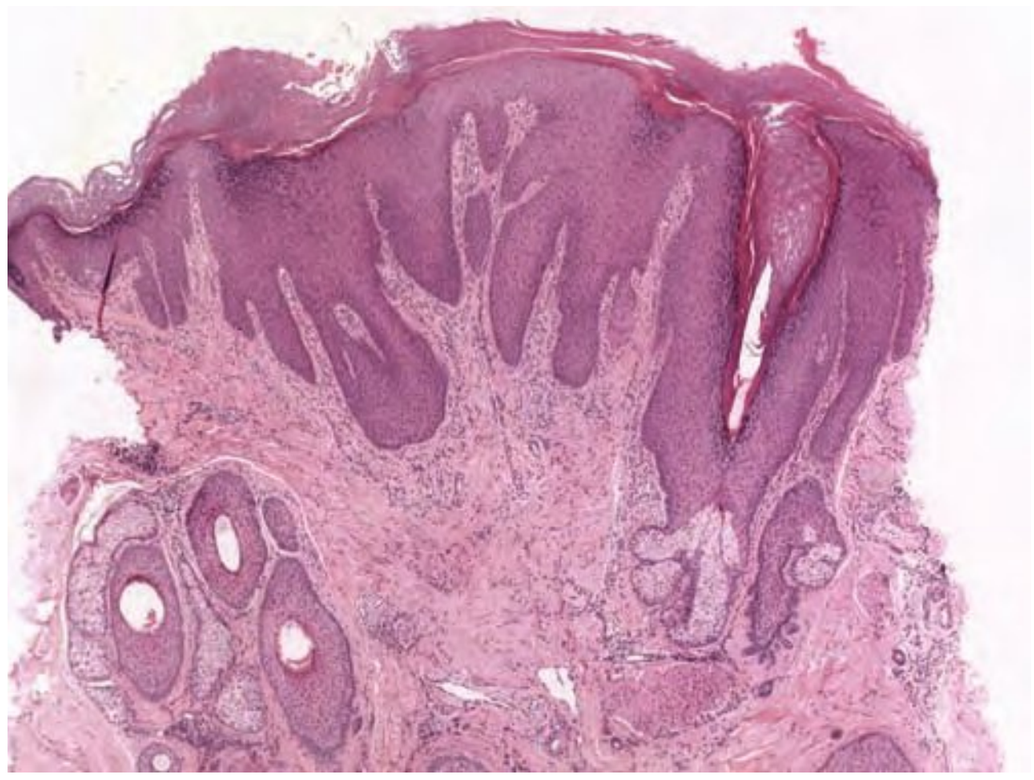

FIGURE 29-63. Lichen simplex chronicus. This punch biopsy specimen shows how epidermal hyperplasia can mainly involve hair follicles to produce a proliferative lesion mimicking an invasive process.

The histologic picture of pseudocarcinomatous hyperplasia shows irregular invasion of the dermis by uneven, jagged, often sharply pointed epidermal cell masses and strands with horn-pearl formation and, often, numerous mitotic figures (Figs. 29-63 and 29-64). These irregular proliferations of the epidermis may extend below the level of the sweat glands, where they appear in sections as isolated islands of epidermal tissue (364). However, the squamous cells usually are well differentiated, and atypicalities, such as individual cell keratinization and nuclear hyperplasia and hyperchromasia, are minimal or absent. Furthermore, one often sees invasion of the epithelial proliferations by leukocytes and disintegration of some of the epidermal cells in pseudocarcinomatous hyperplasia, findings that usually are absent in squamous cell carcinoma (365).

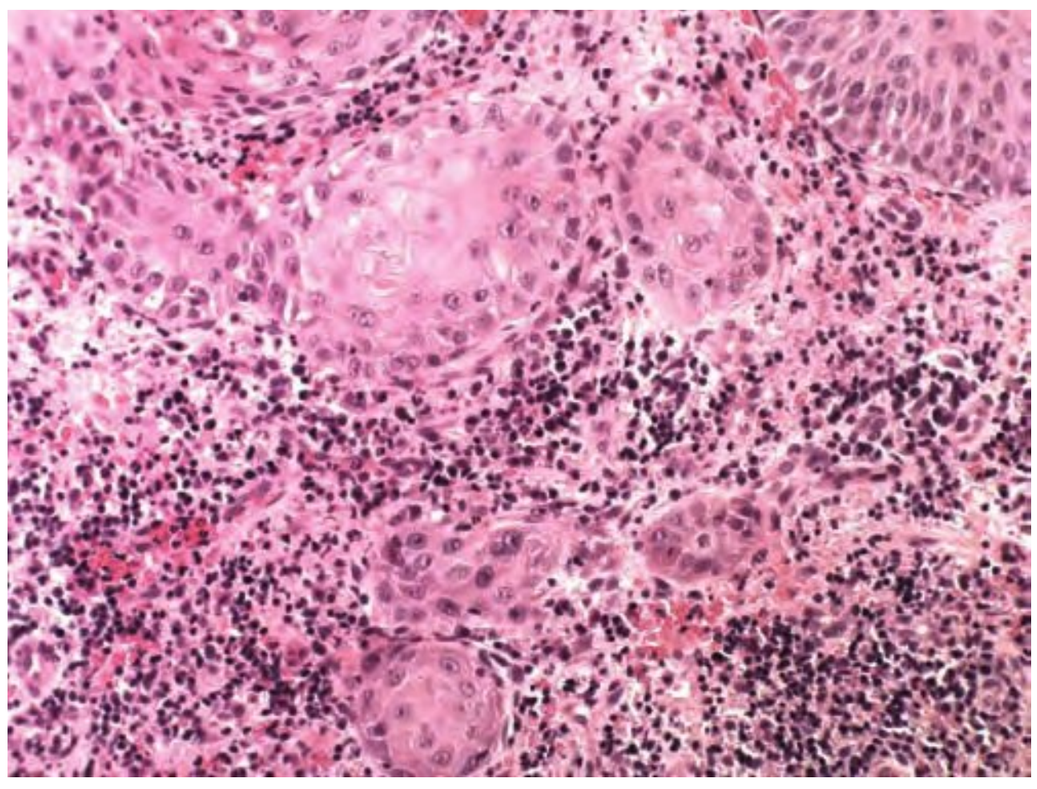

FIGURE 29-64. Pseudocarcinomatous hyperplasia. This curetting specimen shows a proliferative squamous lesion without substantial atypia and mimicking an invasive lesion.

Nevertheless, even when all of these criteria are taken into account, it may still be difficult to differentiate squamous cell carcinoma from pseudocarcinomatous hyperplasia by the study of just one histologic section (364). Multiple biopsies and detailed clinical data may be necessary for differentiation.

In every section in which a diagnosis of squamous cell carcinoma is contemplated, it is worthwhile to study the inflammatory infiltrate for the possible presence of granulomas, as seen in tuberculosis and the deep mycoses, or of intraepidermal abscesses, as seen in bromoderma. If such evidence is found, one may be dealing with pseudocarcinomatous hyperplasia instead of squamous cell carcinoma. In mucous membranes, and especially in the tongue, pseudoepitheliomatous hyperplasia of considerable degree and strongly simulating squamous cell carcinoma may be seen above a granular cell tumor.

Differential Diagnosis. Differentiation of pseudocarcinomatous hyperplasia from verrucous carcinoma rarely causes difficulties because in verrucous carcinoma there is verrucous upward proliferation and downward proliferation. In addition, verrucous carcinoma shows more pronounced keratinization in the downward extensions, which appear bulbous rather than sharply pointed.

BASAL CELL CARCINOMA

Basal cell carcinomas are seen almost exclusively on hair-bearing skin, especially on the face. Except in the nevoid basal cell carcinoma syndrome (see page 825), they rarely occur on the palms (369,370) or on the soles (371,372). Their occurrence on the mucous membrane is doubted; instances of basal cell carcinoma of the oral mucosa reported in the literature (373) probably are ameloblastomas (374).

Basal cell carcinomas usually occur as single lesions, although the occurrence of several lesions, either simultaneously or subsequently, is not infrequent. About 40% of patients who have had a basal cell carcinoma will have one or more basal cell carcinomas within 10 years (375). Basal cell carcinomas generally occur in adults, although they may be seen in children (376–378). However, there are three rare forms of basal cell carcinoma with early onset. In the linear, unilateral basal cell nevus, all lesions are present at birth. In the nevoid basal cell syndrome and the Bazex syndrome, some patients manifest lesions before puberty.

Predisposing Factors. Although basal cell carcinomas may arise without apparent reason, there are several predisposing factors. The most common is a light skin color in association with prolonged exposure to strong sunlight (379). The predisposing effect of sun exposure is particularly evident in patients with xeroderma pigmentosum, in whom both basal cell carcinoma and squamous cell carcinoma are common (see Chapter 6). That prolonged sun exposure alone does not suffice to produce basal cell carcinomas is suggested by their great rarity on the dorsa of hands and fingers (380). Additional factors that

predispose a person to develop both basal cell carcinoma and squamous cell carcinoma are large or numerous doses of roentgen rays (381,382) and, less commonly, burn scars (383,384) and other scars (385). In contrast, most carcinomas of the skin caused by the prolonged intake of inorganic arsenic are squamous cell carcinomas, which often, like Bowen's disease, are located *in situ* (261,310). Occasionally, however, basal cell carcinomas, particularly superficial basal cell carcinomas, can result (304,305) (see Arsenical Keratosis and Carcinoma).

Occurrence of Metastases. As a rule, basal cell carcinomas do not metastasize. However, there are exceptions. The incidence of metastasis ranges from 0.01% in pathologic specimens (386) to 0.028% in dermatologic patients (387) to 0.1% in patients from surgical centers (388). A review published in 1984 described 175 cases with histologically proven metastases (389).

The typical case history of a metastatic basal cell carcinoma is that of a large, ulcerated, locally invasive and destructive primary lesion that has recurred despite repeated surgical procedures or radiotherapy (390–392). However, massive size, ulceration, and history of multiple recurrences are not absolute prerequisites for metastasis (393). Most observers have found no specific histologic type of basal cell carcinoma that is more capable of metastasizing than others (394–396). In addition, as a rule no evidence exists that the hosts' immunologic defenses are severely compromised (389). However, some authors assert that the metatypical or basosquamous type of basal cell carcinoma is the most likely to metastasize (397).

In contrast to metastatic squamous cell carcinoma of the skin, which shows lymphogenic metastases to lymph nodes in 80% to 90% of cases, in metastatic basal cell carcinoma, hematogenic and lymphogenic spread show about an even distribution (389). Although about 50% of the patients with metastatic basal cell carcinoma have metastases to lymph nodes as their first site of spread, lungs and bones also are frequently the first sites of involvement. Metastases to the liver, other viscera, and the skin or subcutaneous tissues have occurred. However, these areas were usually involved only when at least one of the three major sites of metastasis was also affected (398). The average survival time after metastasis to the lungs, bones, or internal organs is about 10 months (399).

Clinical Appearance. Five clinical types of basal cell carcinoma occur: (a) superficial basal cell carcinoma, (b) nodular basal cell carcinoma, (c) micronodular basal cell carcinoma, (d) infiltrating basal cell carcinoma, and (e) fibroepithelioma. In addition, there are three clinical syndromes in which basal cell carcinomas play an important part. They are (a) the nevoid basal cell carcinoma syndrome, (b) the linear unilateral basal cell nevus, and (c) the Bazex syndrome, showing follicular atrophoderma with multiple basal cell carcinomas.

Superficial basal cell carcinoma consists of one or several erythematous, scaling, only slightly infiltrated patches that slowly increase in size by peripheral extension. The patches are often surrounded, at least in part, by a fine, threadlike, pearly border (Fig. 29-65). The patches usually show small areas of

FIGURE 29-65. Superficial basal cell carcinoma. This tumor shows a well-demarcated edge.

superficial ulceration and crusting. In addition, their center may show smooth, atrophic scarring. In contrast to the first three types of basal cell carcinoma, which are commonly situated on the face, superficial basal cell carcinoma occurs predominantly on the trunk.

Nodular basal cell carcinoma begins as a small, waxy nodule that often shows a few small telangiectatic vessels on its surface (Fig. 29-66). The nodule usually increases slowly in size and often undergoes central ulceration. A typical lesion then consists of a slowly enlarging ulcer surrounded by a pearly, rolled border. This represents the so-called rodent ulcer (Fig. 29-67).

Micronodular basal cell carcinoma is diagnosed histologically and may have a diffusely infiltrative growth pattern that extends for some distance beyond the clinically apparent margins of the tumor. This subtype has been associated with a higher rate of

FIGURE 29-66. Nodular basal cell carcinoma. The lesion is well defined.

FIGURE 29-67. Basal cell carcinoma. This example has been neglected, producing a "rodent ulcer."

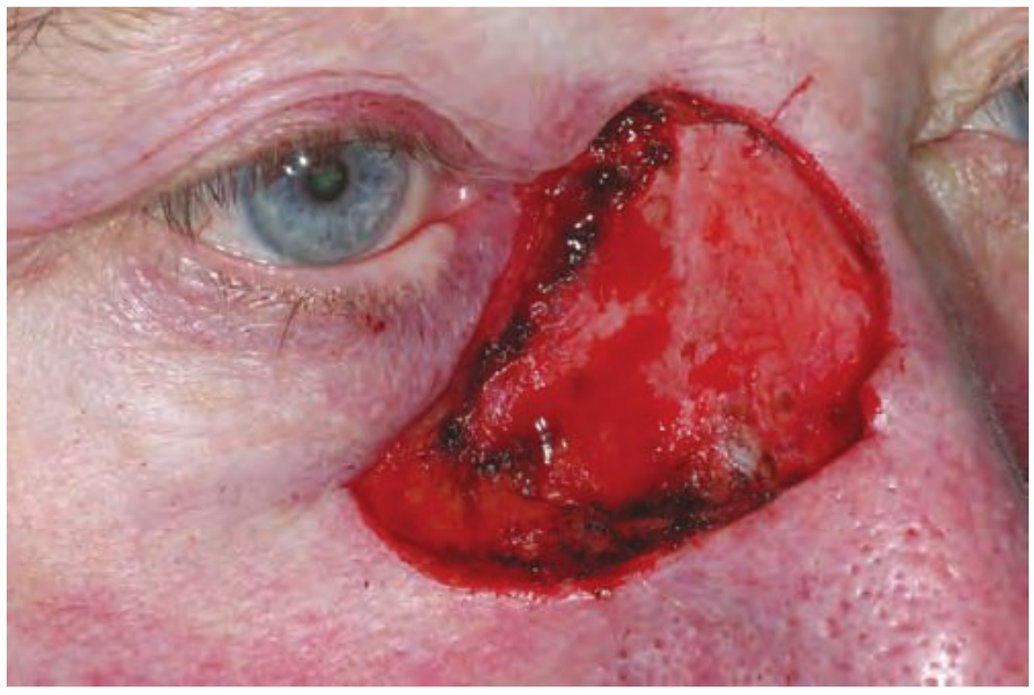

FIGURE 29-69. Micronodular basal cell carcinoma. An extensive resection was required, using Mohs' micrographic surgery, to achieve clear surgical margins.

local recurrence than other subtypes. The use of Mohs' micrographic surgery has been advocated to ensure complete excision of the infiltrating component (Figs. 29-68 and 29-69).

Most rodent ulcers possess a limited potential for growth; however, occasionally they can be infiltrative and aggressive and then can reach considerable size and invade deeply. On the face, they may destroy the eyes and nose (400), or they may penetrate the skull and invade the dura mater (401). Death may then ensue. (Such destructive basal cell carcinomas are seen occasionally also in the nevoid basal cell carcinoma syndrome; see text following.)

Pigmented basal cell carcinoma differs from the nodular type only by the brown pigmentation of the lesion.

Morphea-like or fibrosing basal cell carcinoma manifests as a solitary, flat or slightly depressed, indurated, yellowish plaque. The surface is smooth and shiny. The border is often ill defined (Fig. 29-70). The overlying skin remains intact for a long time before ulceration finally occurs. The term arises from a clinical resemblance to localized scleroderma or morphea. The tumors, despite being deeply infiltrative, may be mistaken clinically for a lesion of morphea or for a scar.

Fibroepithelioma consists of usually only one but occasionally of several raised, moderately firm, slightly pedunculated nodules covered by smooth, slightly reddened skin. Clinically, they resemble fibromas. The most common location is the back.

The *nevoid basal cell carcinoma syndrome* is an autosomal dominant disorder with low penetration. Small nodules appear between puberty and 35 years of age, and there may be hundreds or thousands of them (402). During the "nevoid" stage, the nodules slowly increase in number and size. They are haphazardly distributed over the face and body. During adulthood, many of the basal cell carcinomas undergo ulceration, and later in life, the disease sometimes enters a "neoplastic" stage in which some of the basal cell carcinomas, especially of the face, become invasive, destructive, and mutilating. Occasionally, even death occurs as

FIGURE 29-68. Micronodular basal cell carcinoma, with poorly defined clinical margins. An indication for Mohs' micrographic surgery.

FIGURE 29-70. Basal cell carcinoma, morpheic. The central part of the tumor is clearly seen, but the margins are not well defined.

the result of invasion of an orbit and of the brain (403–405). There also may be metastases to the lung (403).

Half of the adult patients with the nevoid basal cell carcinoma syndrome show numerous palmar and plantar pits 1 to 3 mm in diameter. These pits usually develop during the second decade of life and represent formes frustes of basal cell carcinoma (see Histopathology) (406). In addition, epidermal cysts are quite common (407).

Most patients show multiple skeletal and central nervous system anomalies (404), among which are odontogenic keratocysts of the jaws, anomalies of the ribs, scoliosis, mental retardation, and calcification of the falx cerebri. In several reported cases, there were also cerebellar medulloblastomas (408) or fibrosarcomas of a mandible or maxilla (409). In the jaw cysts, an ameloblastoma may arise (410).

The *linear unilateral basal cell nevus* is very rare. There is an extensive unilateral linear or zosteriform eruption, usually present since birth, consisting of closely set nodules of basal cell carcinoma (411). They may be interspersed with comedones (412,413) and striae-like areas of atrophy (414). The lesions do not increase in size with aging of the patient.

The *Bazex syndrome,* first described in 1966 (415), is dominantly inherited and shows as its main features (a) follicular atrophoderma characterized by widened follicular openings like "ice-pick marks" mainly on the extremities and (b) multiple, small basal cell carcinomas on the face, usually arising first in adolescence or early adulthood (416) but occasionally in late childhood (417). In addition, there may be localized anhidrosis or generalized hypohidrosis, as well as congenital hypotrichosis on the scalp and elsewhere (417).

Histopathology. Basal cell carcinomas tend to share the common features of a predominant basal cell type, peripheral palisading of lesional cell nuclei, a specialized stroma, and clefting artifact between the epithelium and the stroma. In addition, there are variable degrees of cytologic atypia and mitotic activity; some degree of these latter changes is virtually always present (Figs. 29-71 to 29-91). In nodular basal cell carcinoma, nodular masses of basaloid cells are formed that extend into the dermis in relation to a delicate, specialized tumor stroma (Figs. 29-75 to 29-77). Cystic spaces may form as a result of tumor necrosis or cellular dyshesion. The nuclei in basal cell carcinomas as a rule have a rather uniform appearance. They usually show no pronounced variation in size or intensity of staining and no abnormal mitoses, even in the rare instances of basal cell carcinoma with metastases. In the exceptional cases of basal cell carcinoma in which one finds, interspersed among the usual cells of basal cell carcinoma, cells with large hyperchromatic nuclei, multiple nuclei, and bizarre "starburst" mitoses, the clinical course is not different from that of the usual basal cell carcinoma (418,419).

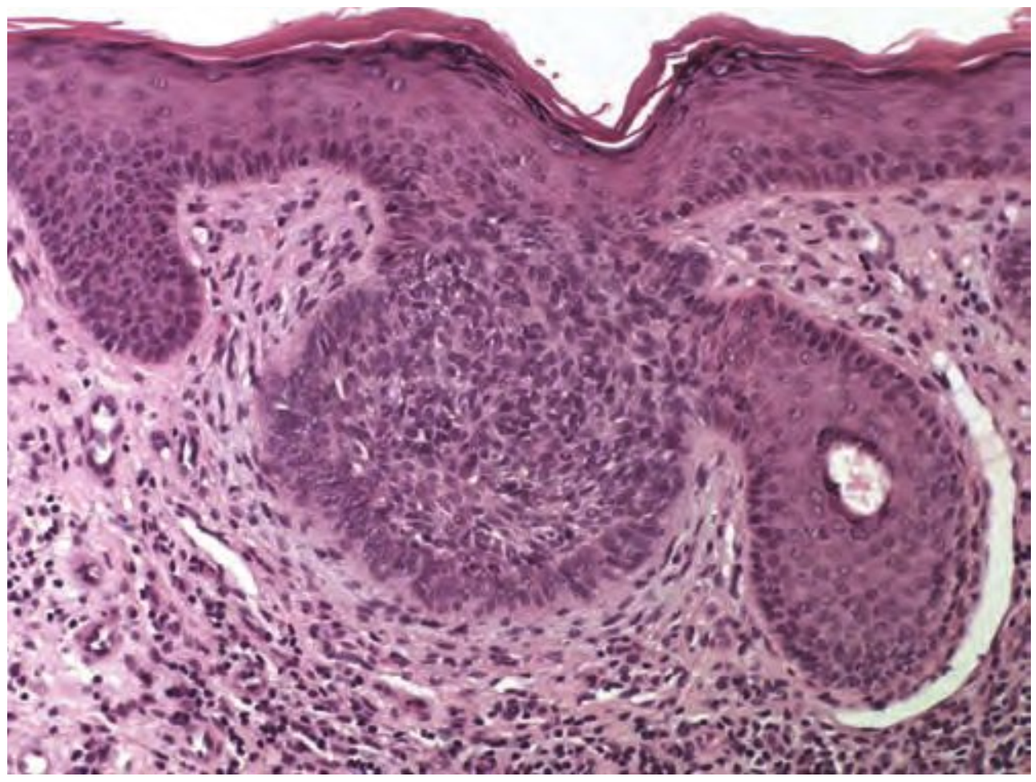

FIGURE 29-72. Superficial basal cell carcinoma. High magnification. The tumor shows a bud of cells in the bulge zone of a hair follicle similar to the primary epithelial germ buds in embryonal skin. A cleft is also present at the interface with the dermis.

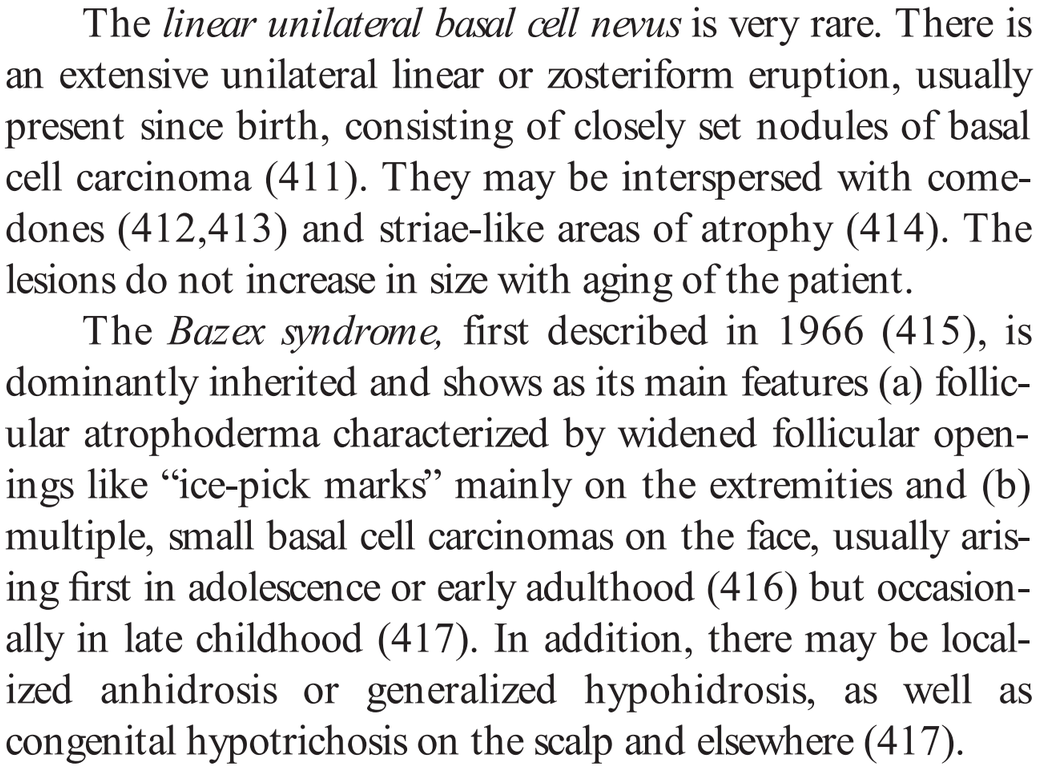

FIGURE 29-71. Superficial basal cell carcinoma. The tumor shows buds and irregular proliferations of tumor tissue attached to the undersurface of the epidermis.

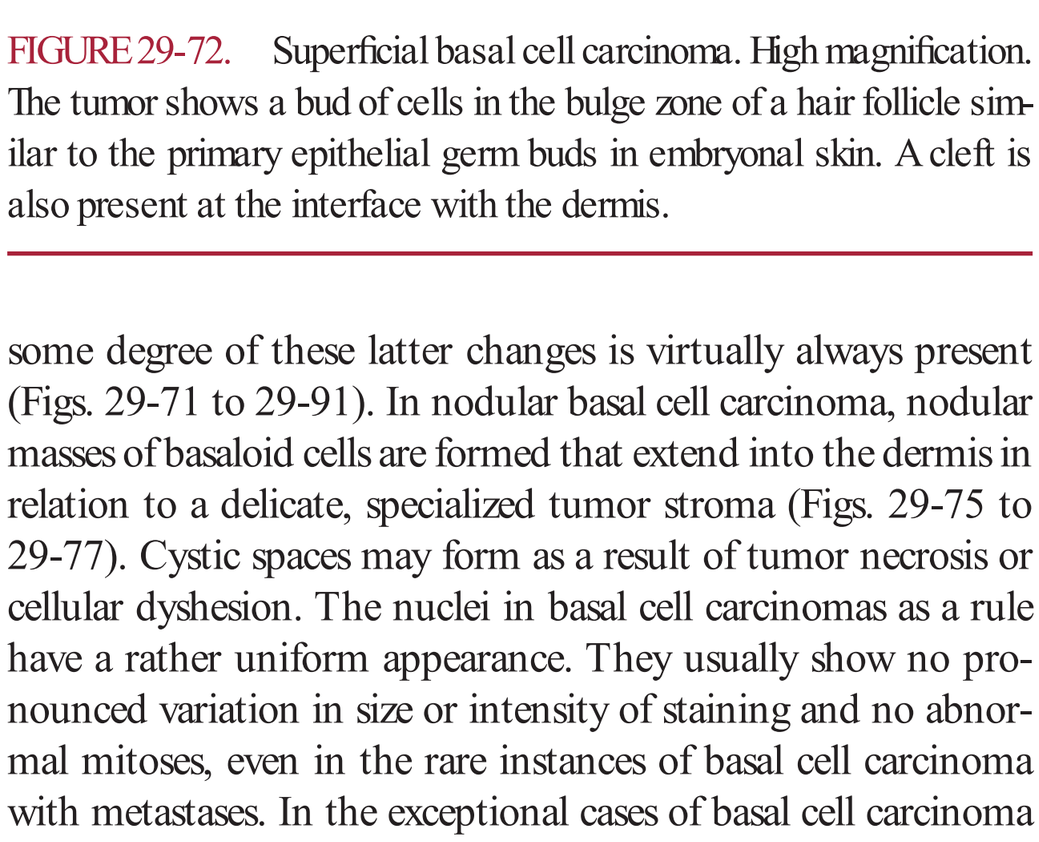

FIGURE 29-73. Superficial basal cell carcinoma. Ber EP4 staining highlights the tumor with normal epidermal structures unstained.

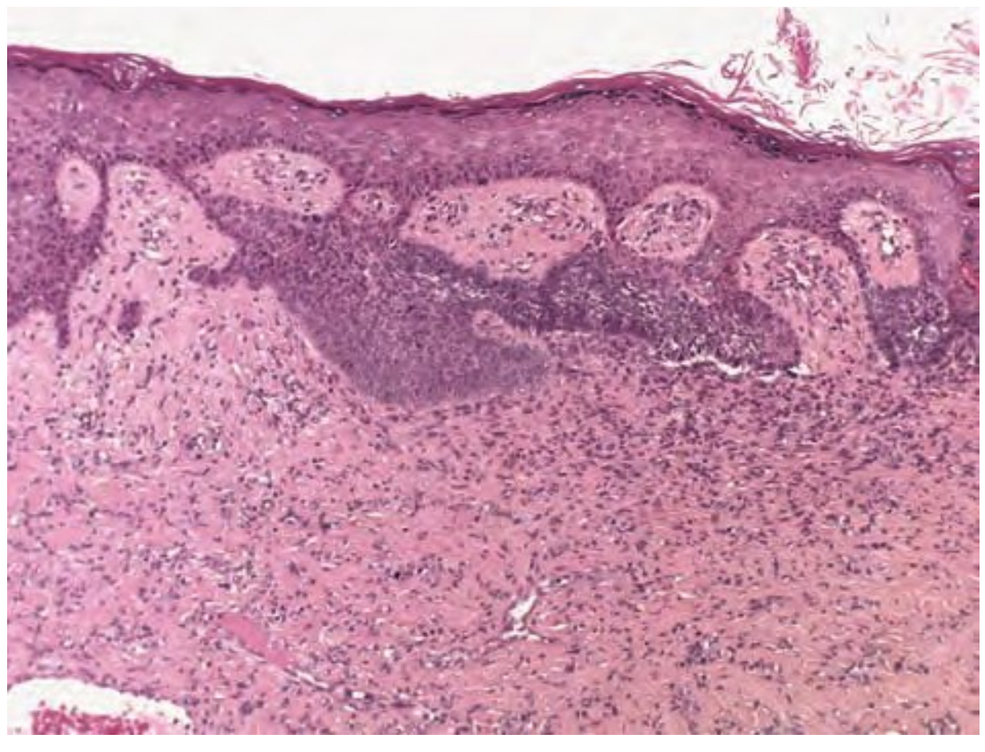

FIGURE 29-74. Dermatofibroma. There is a basal proliferation of basaloid cells mimicking the appearances of a superficial basal cell carcinoma.

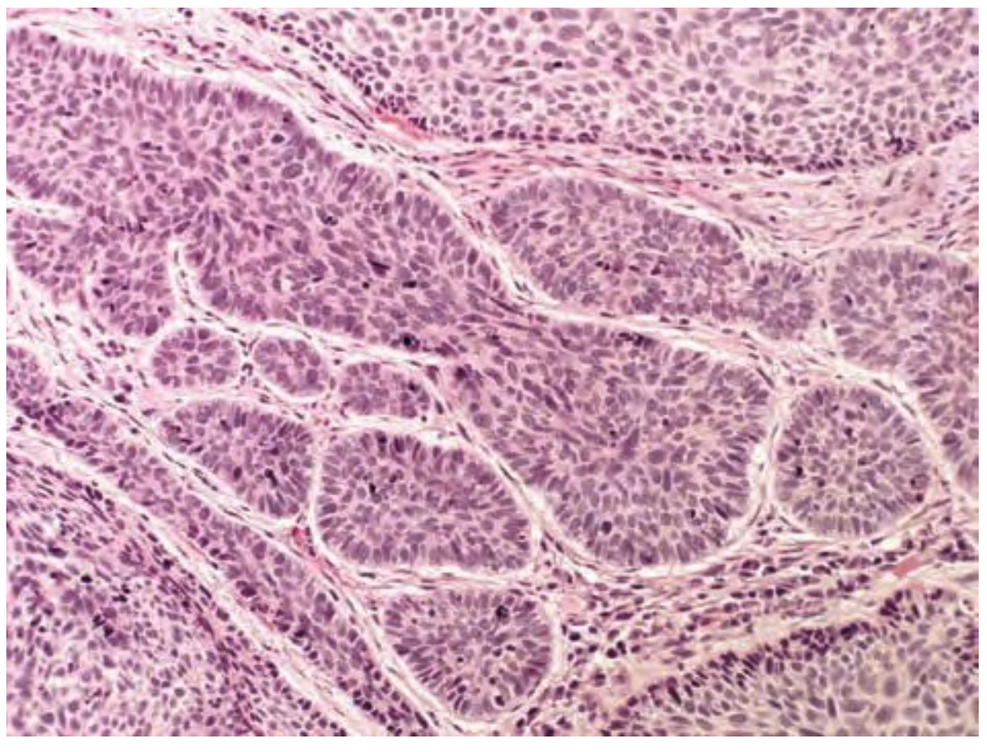

FIGURE 29-77. Nodular basal cell carcinoma. Medium magnification. The islands of tumor cells show peripheral palisading, as well as mitotic and apoptotic figures.

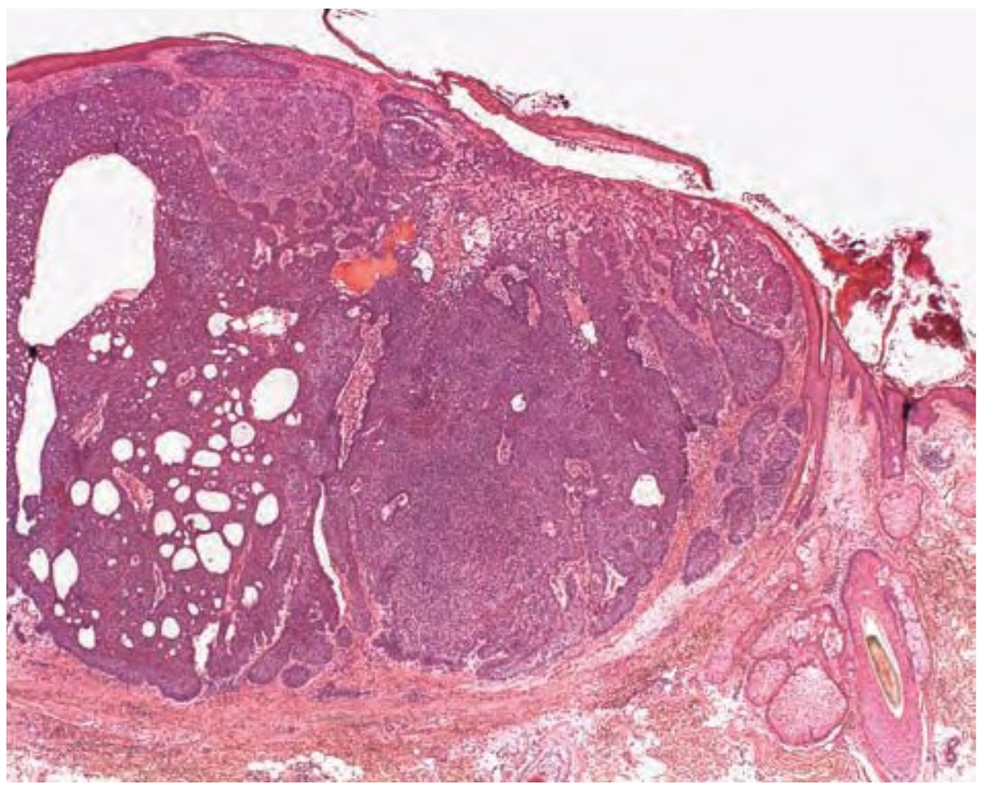

FIGURE 29-75. Basal cell carcinoma, nodular type. This excision specimen shows a nodular tumor with peripheral palisading.

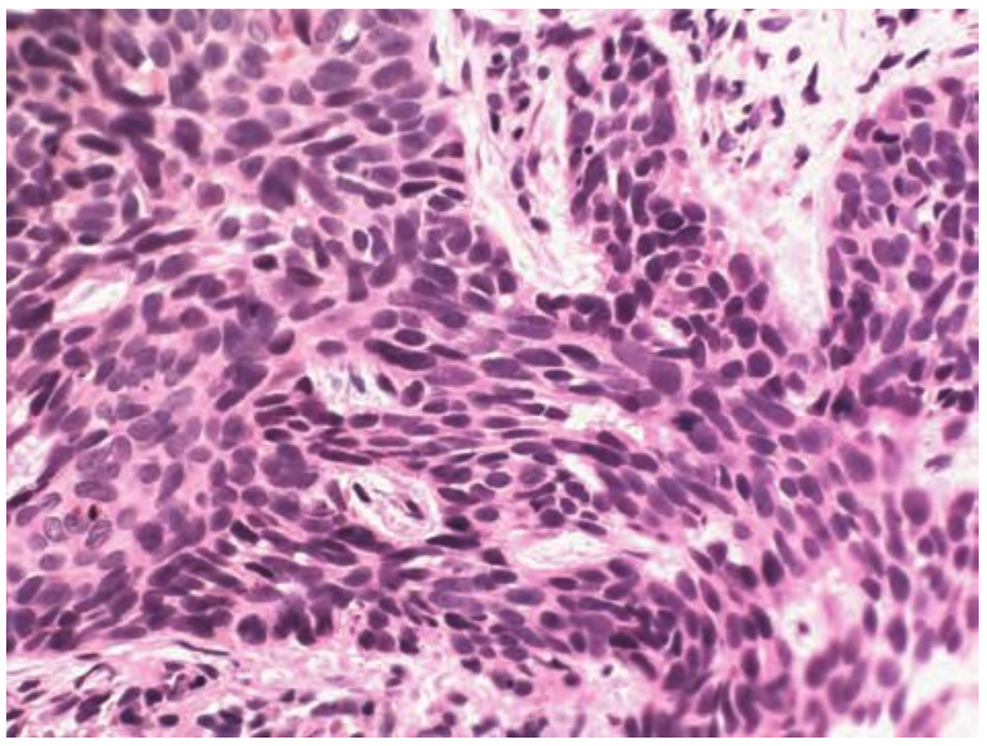

FIGURE 29-78. Basal cell carcinoma, solid type. High magnification. The basaloid tumor cells flow through the dermis with a variable degree of peripheral palisading.

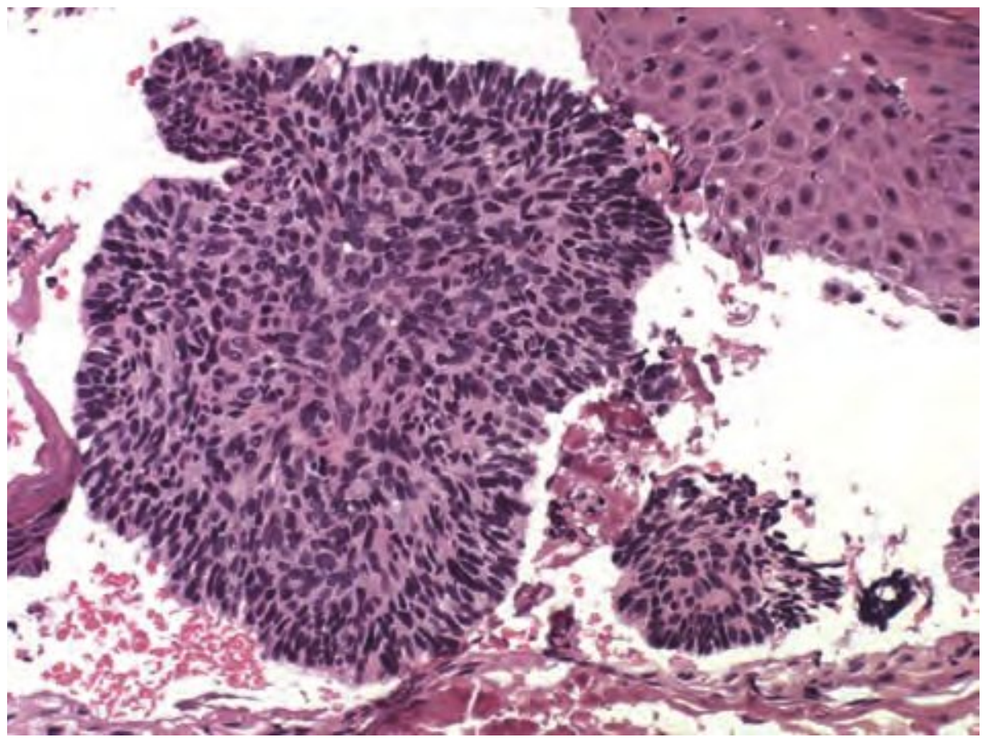

FIGURE 29-76. Basal cell carcinoma, nodular type. In this curetting specimen, nests of cells from a nodular basal cell carcinoma show peripheral palisading.

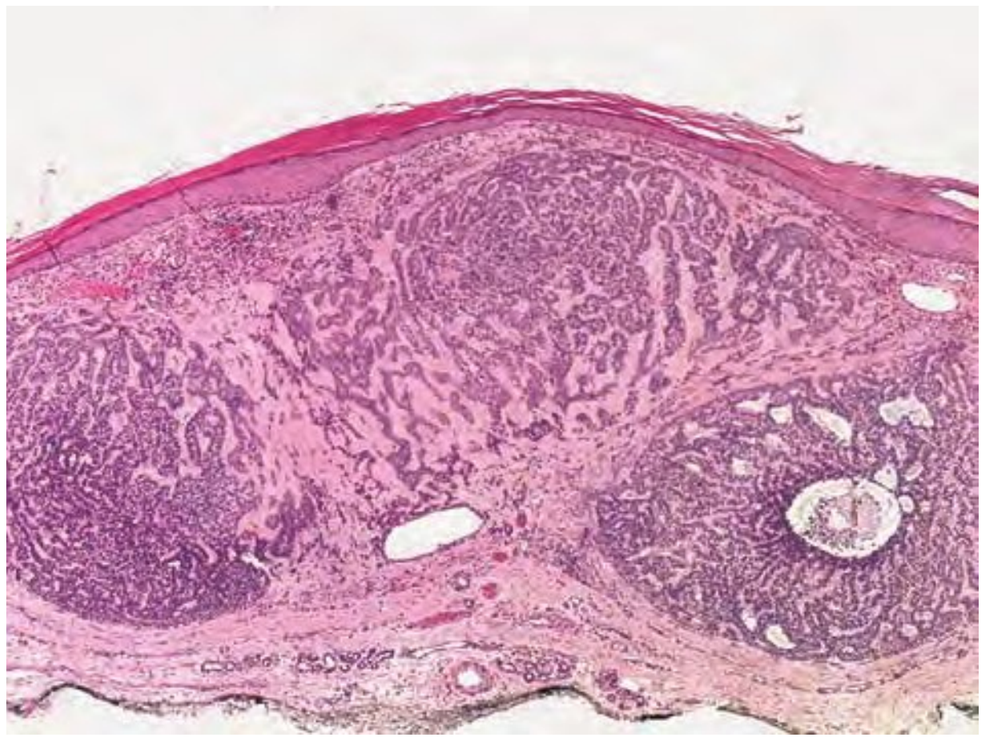

FIGURE 29-79. Adenoid basal cell carcinoma. Scanning magnification. The strands of epithelial cells form nodules, with a lacelike pattern of cells within the nodules.

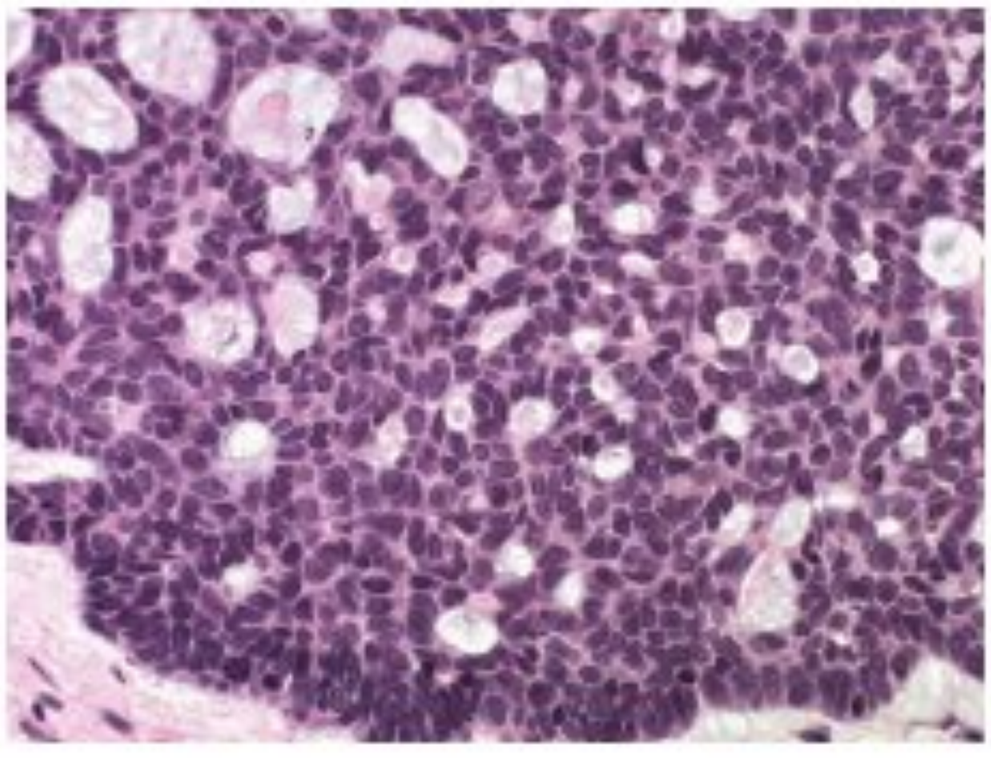

FIGURE 29-80. Adenoid basal cell carcinoma. High magnification. The strands of epithelial cells present a lacelike pattern. The stroma has a mucoid appearance.

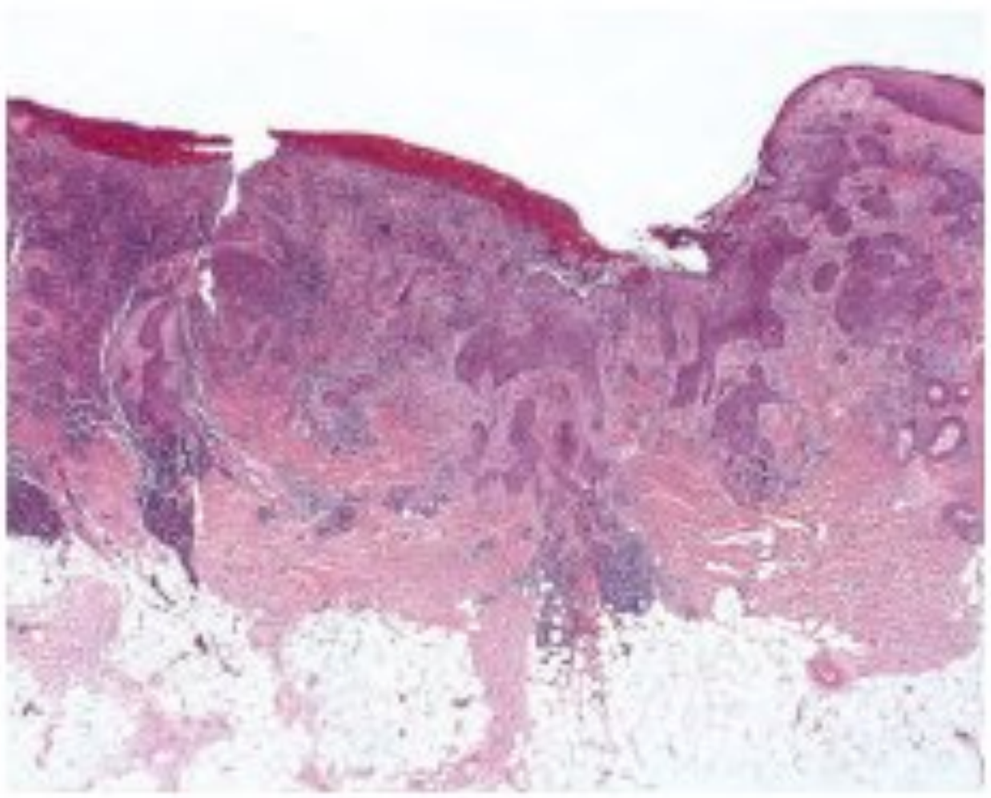

FIGURE 29-81. Micronodular basal cell carcinoma. The tumor is relatively symmetric and circumscribed, but with a more infiltrative element at its base.

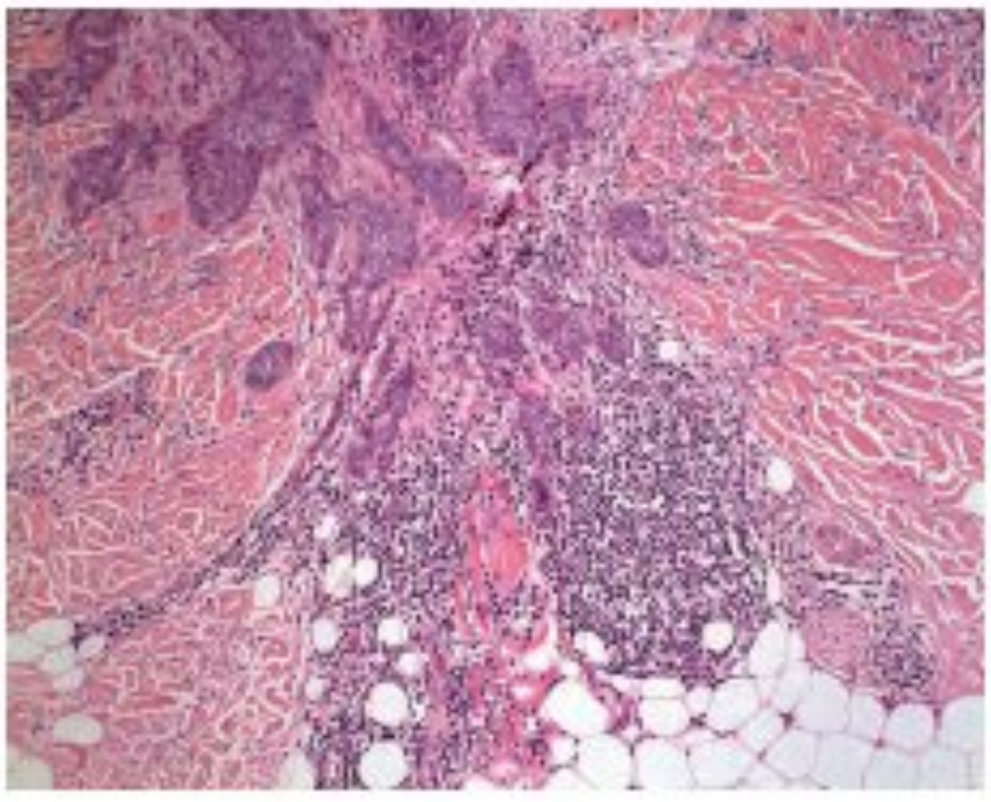

FIGURE 29-82. Micronodular basal cell carcinoma. Medium magnification. The infiltrative element at the base of the tumor extends through the full thickness of the dermis to the subcutis.

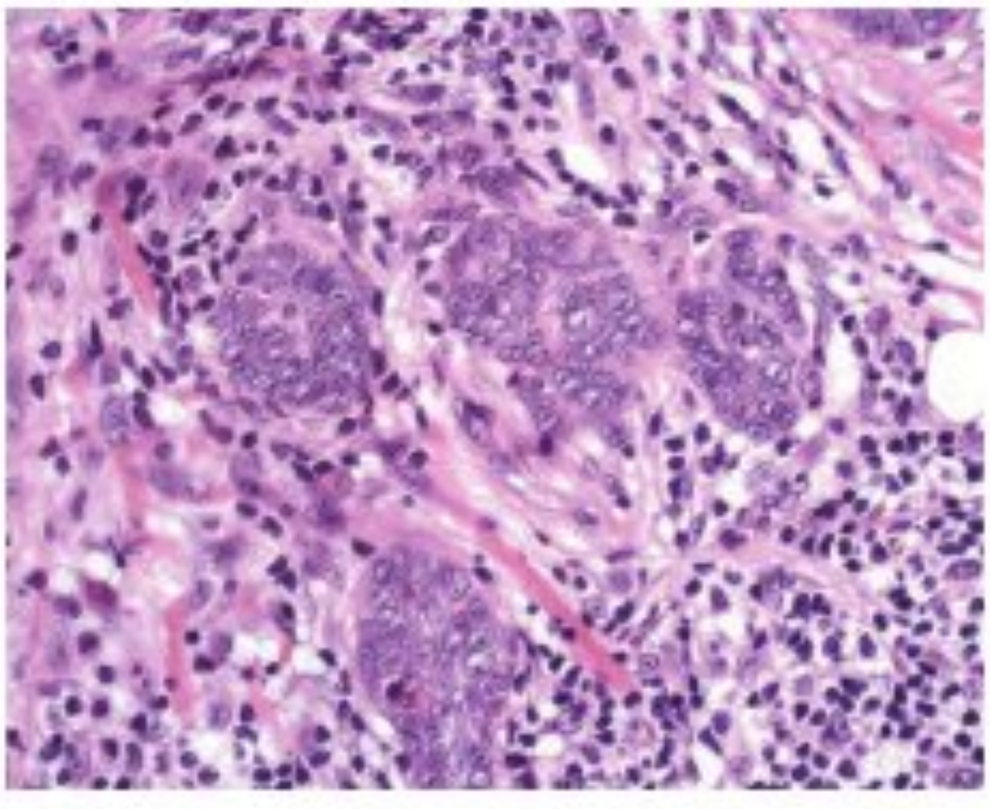

FIGURE 29-83. Micronodular basal cell carcinoma. High magnification. Micronodules of tumor infiltrate the deep dermis.

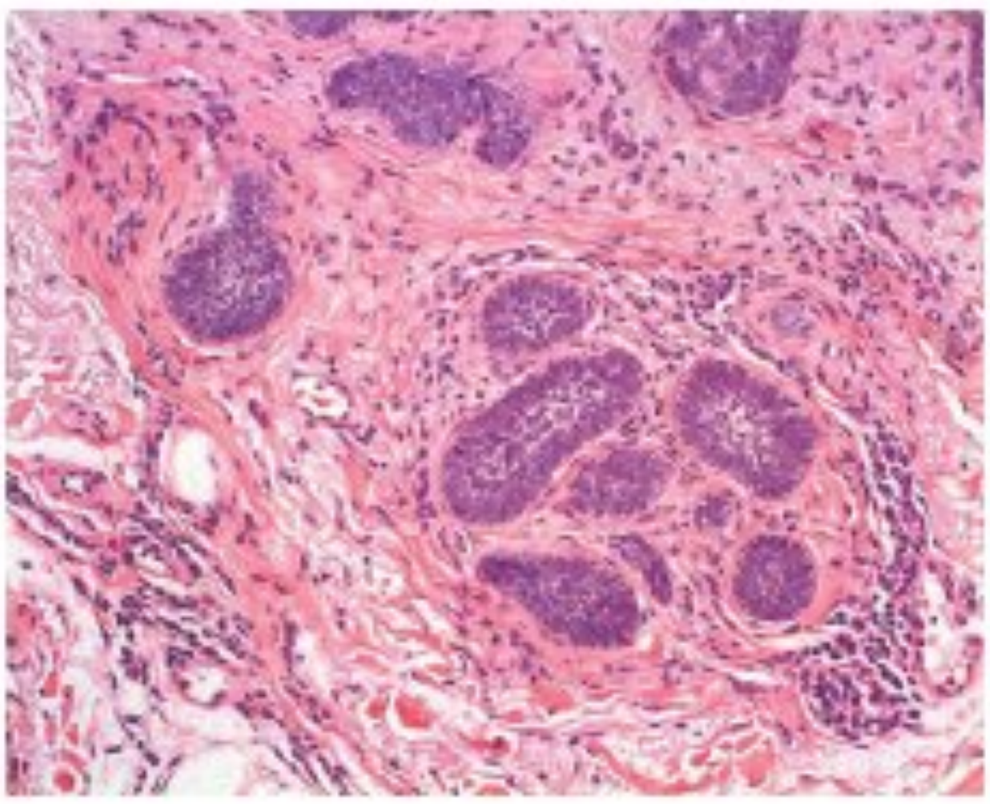

FIGURE 29-84. Micronodular basal cell carcinoma. High magnification. A less-inflamed example showing micronodules of invasive basal cell carcinoma.

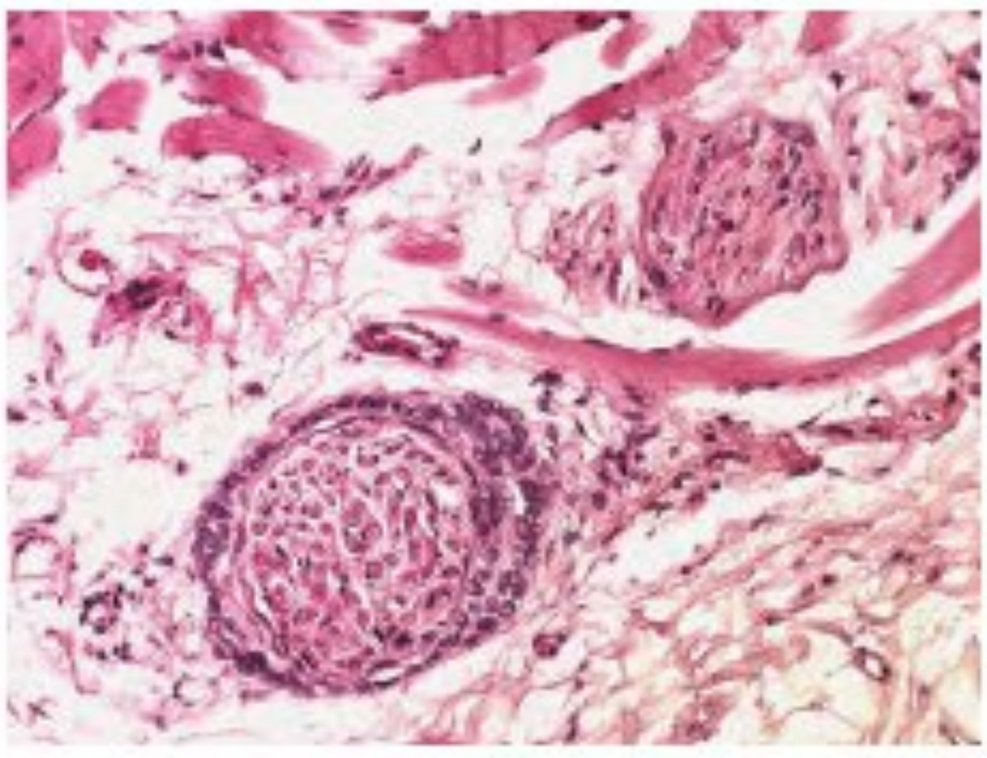

FIGURE 29-85. Micronodular basal cell carcinoma. High magnification. Tumor cells infiltrate around a dermal nerve close to the excision margin.

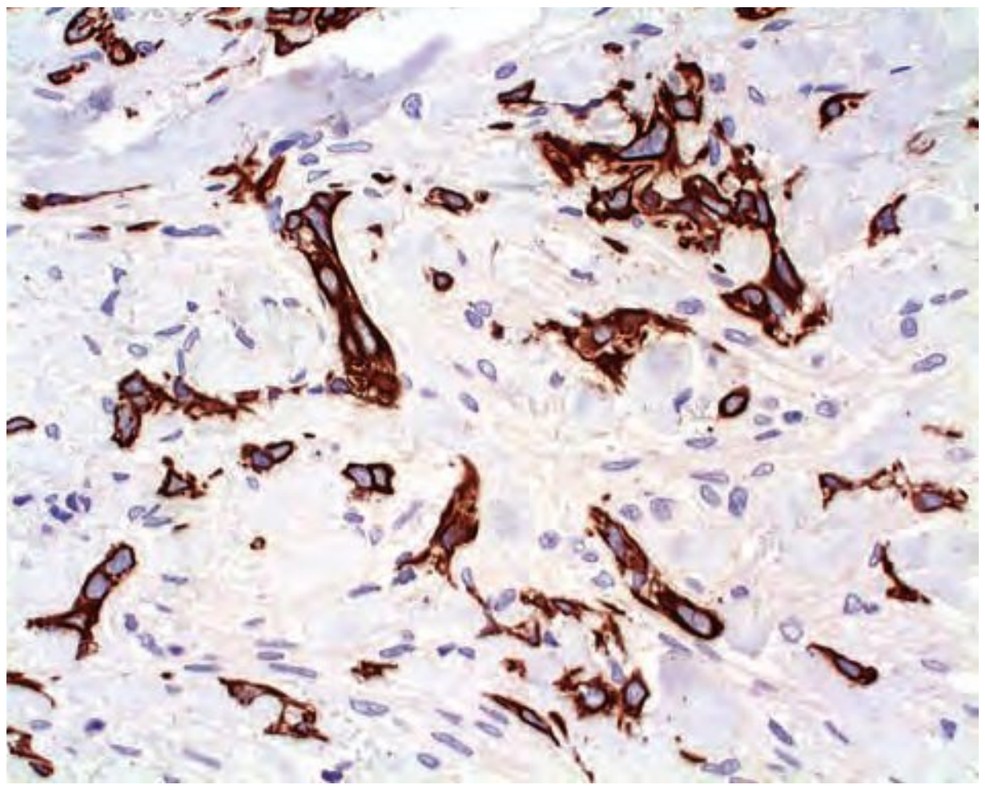

FIGURE 29-86. Basal cell carcinoma, morpheic. Basaloid cells, emphasized by cytokeratin staining, infiltrate the dermis within their specialized stroma.

FIGURE 29-89. Basal cell carcinoma showing follicular differentiation. Epithelium and stroma form structures reminiscent of follicular germs, and there is formation of a horn cyst resembling a follicular structure.

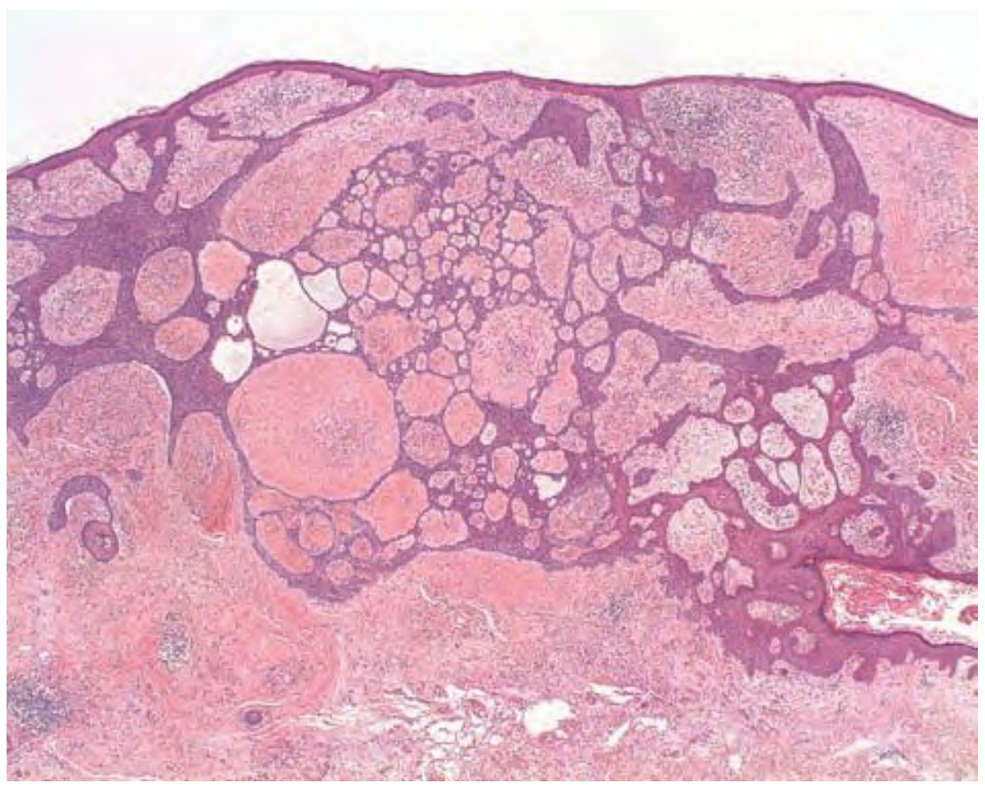

FIGURE 29-87. Fibroepithelioma of Pinkus (fibroepithelial basal cell carcinoma). The tumor has an elevated nodular appearance.

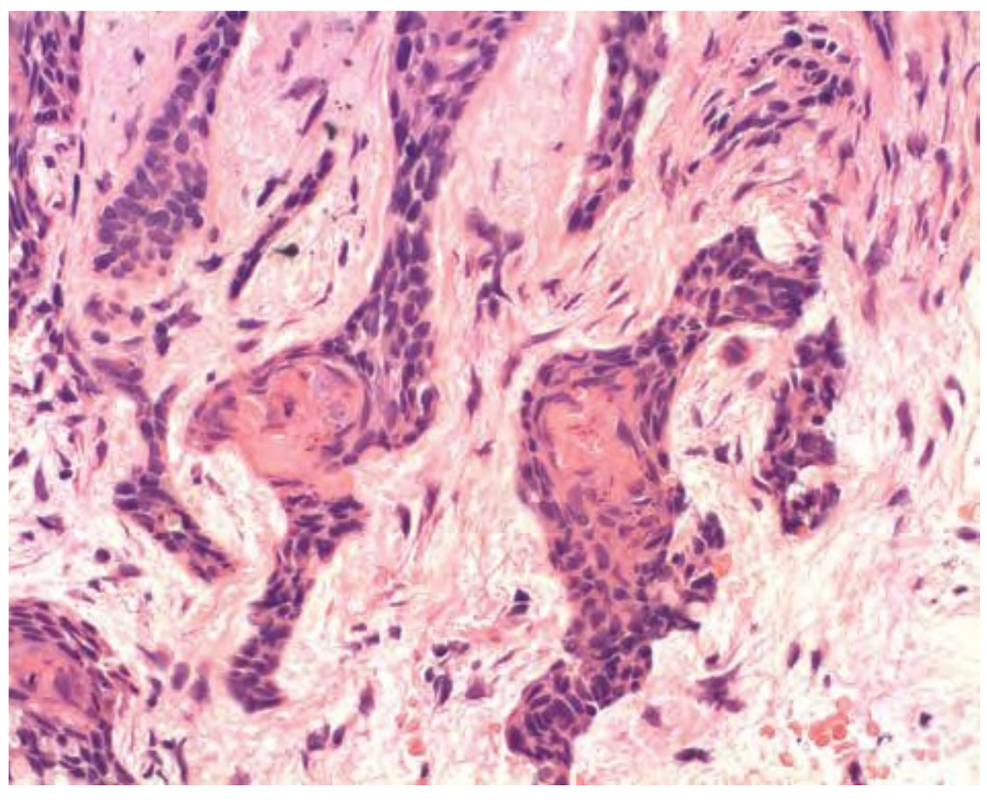

FIGURE 29-90. Basal cell carcinoma, infiltrative, metatypical. There is focal squamous differentiation within the infiltrating cords of basaloid cells.

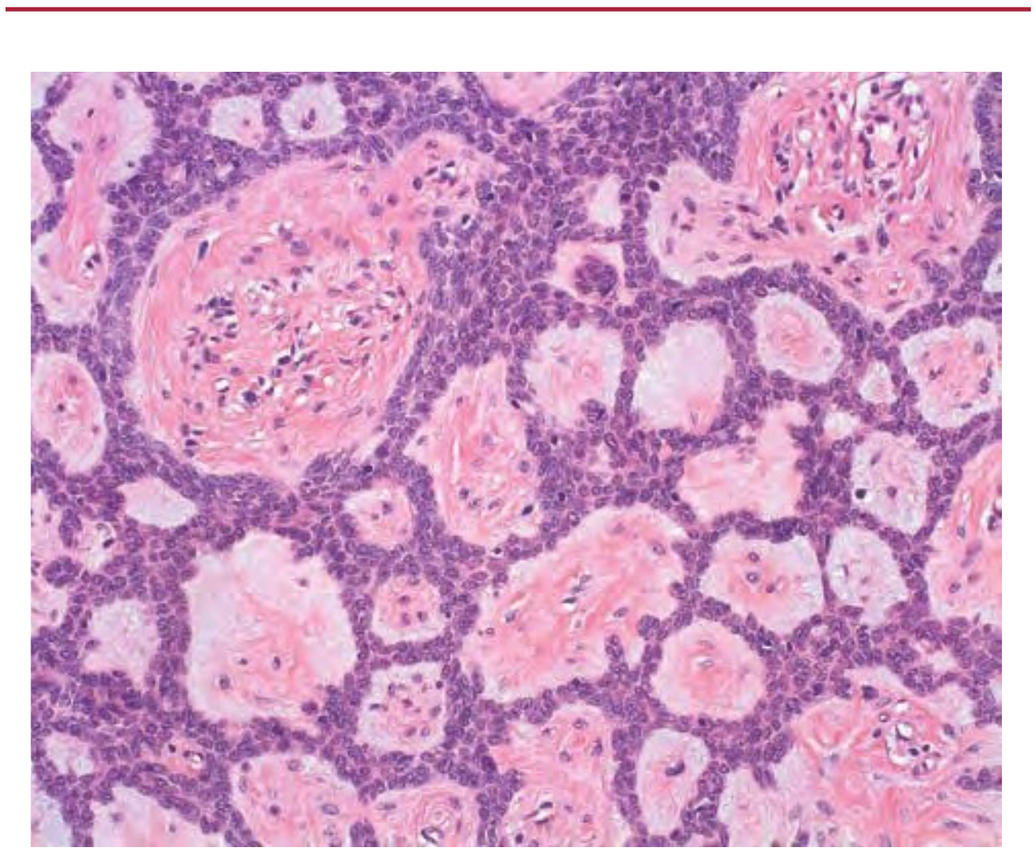

FIGURE 29-88. Fibroepithelioma of Pinkus (fibroepithelial basal cell carcinoma). Long, thin, branching, anastomosing strands of basal cell carcinoma are embedded in a fibrous stroma.

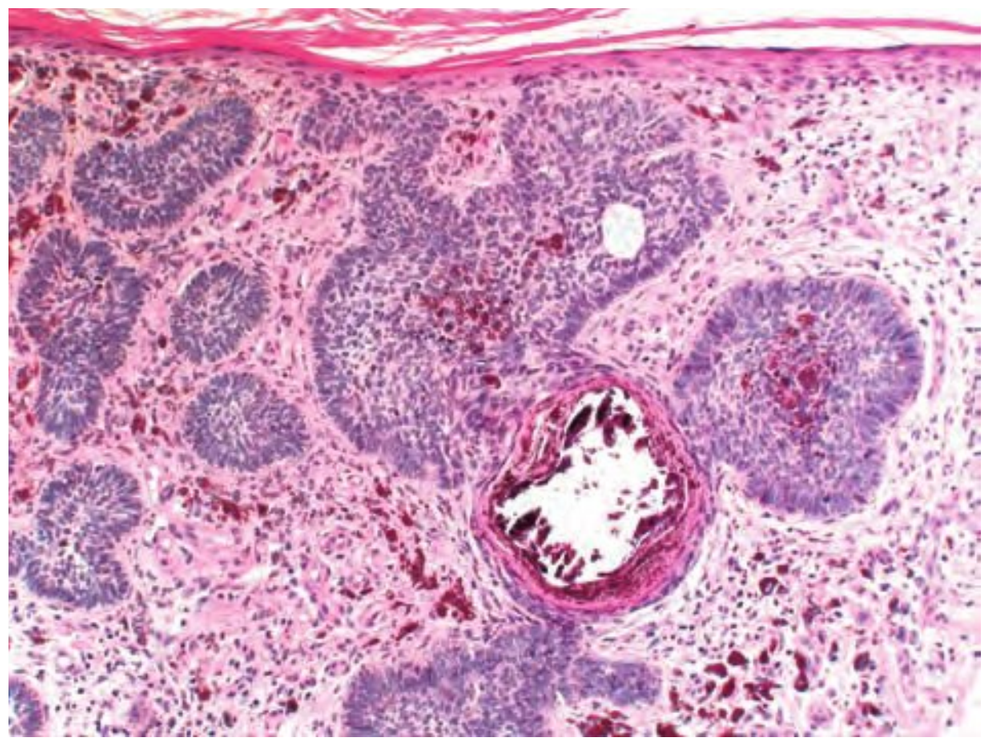

FIGURE 29-91. Pigmented basal cell carcinoma. Melanin pigment is present within solid islands of basal cell carcinoma and in macrophages between the islands of tumor cells.

The connective tissue stroma proliferates with the tumor and is arranged in parallel bundles around the tumor masses, so that a mutual relationship seems to exist between the parenchyma of the tumor and its stroma (420,431). The stroma adjacent to the tumor masses often shows numerous young fibroblasts; in addition, it may appear mucinous (432,433). Frequently there are areas of retraction of the stroma from tumor islands, resulting in peritumoral lacunae (Fig. 29-71). These lacunae once were regarded as a fixation artifact, but peritumoral lacunae can be observed also on cryostat sections. Immunostaining with antibodies to laminin, type IV collagen, and bullous pemphigoid has revealed the presence of laminin and type IV collagen on the stroma side of the lacunae, but bullous pemphigoid antigen is absent at the site of lacunae (434). Even though bullous pemphigoid antigen is diminished in other areas of basal cell carcinoma (435), it is likely that loss of this antigen contributes to the formation of peritumoral lacunae (434). Because these lacunae are quite typical for some basal cell carcinomas, their presence aids in the differentiation of basal cell carcinoma from other tumors, such as squamous cell carcinoma. In addition, stromal or intratumor deposits of amyloid are found quite frequently (see Pathogenesis) (436). A mild inflammatory infiltrate is often seen in the stroma of nonulcerated basal cell carcinomas but may be entirely lacking. If ulceration occurs, there usually is a rather pronounced inflammatory reaction.

From a histologic point of view, basal cell carcinomas can be divided into two groups: undifferentiated and differentiated. Those of the latter group show a slight degree of differentiation toward the cutaneous appendages of hair, sebaceous glands, apocrine glands, or eccrine glands. A sharp dividing line between the two groups cannot be drawn because many undifferentiated basal cell carcinomas show differentiation in some areas, and most differentiated basal cell carcinomas show areas lacking differentiation. By correlating the clinical classification with the histologic classification, it can be stated that nodular basal cell carcinoma, as well as the lesions of the nevoid basal cell carcinoma syndrome, the linear unilateral basal cell nevus, and the Bazex syndrome, may show differentiation or no differentiation, but the other four types of basal cell carcinoma—pigmented basal cell carcinoma, fibrosing basal cell carcinoma, superficial basal cell carcinoma, and fibroepithelioma—usually show little or no differentiation (Figs. 29-87 and 29-88).

From a clinical point of view it is probably more relevant to classify basal cell carcinomas into those with a low risk of recurrence (nodular, nodulocystic and fibroepithelioma of Pinkus) and those with a high risk of local recurrence (superficial, micronodular, infiltrative, morpheic, metatypical). Of these the *micronodular basal cell carcinoma* has received the least recognition but probably carries as high a risk of local recurrence as the others in the high-risk group (Figs. 29-81 to 29-85). They vary between symmetric, circumscribed examples and others that are asymmetric and infiltrate between collagen bundles. The risk of local recurrence may be related to the presence of perineural invasion (which may occur in other types of basal cell carcinoma as well; Fig. 29-85) and to the focal nature, in which the tumor may infiltrate deeply into the dermis to involve the excision margin (Fig. 29-82). Micronodular basal cell carcinoma is rarely seen without other forms of basal cell carcinoma differentiation. More typically, micronodular differentiation is seen toward the base of a tumor. When a basal cell carcinoma is infiltrating deeply into the dermis or reaches the subcutis, micronodular differentiation may frequently be present in the deeper compartment of the tumor. There is an overlap of appearances between morpheic and micronodular basal cell carcinomas. In deciding on the subtype with which one is dealing, the element representing more than 50% of the whole tumor should take precedence.

Basal cell carcinomas showing differentiation toward hair structures (Fig. 29-89) are called *keratotic*; toward sebaceous glands, *basal cell carcinomas with sebaceous differentiation*; and toward tubular glands, *adenoid* basal cell carcinomas (Figs. 29-79 and 29-80). A *signet ring cell* variant has also been described (437). In many differentiated basal cell carcinomas, differentiation is directed toward more than one of these cutaneous appendages. For example, areas of keratinization may be found in a tumor that also shows adenoid structures. No difference exists in the rate of growth between undifferentiated and differentiated basal cell carcinomas.

In more than 90% of basal cell carcinomas, a connection between tumor cell formations and the surface epidermis can be shown to exist (438). Occasionally, a tumor mass is found in contact with an outer root sheath. The peripheral cell layer of the tumor masses often shows a palisade arrangement, whereas the nuclei of the cells inside lie in a haphazard fashion. *Basal cell carcinomas* of the *infiltrative* type, also referred to as *aggressive* basal cell carcinomas, show the basaloid cells predominantly arranged as elongated strands only a few layers thick and with little or no palisading of the peripheral cells. Such strands can invade deeply. The demarcation of the tumor from the stroma is often poor (440). Immunohistochemical staining for cytokeratin may aid to highlight the infiltrating tumor cells (Fig. 29-86). There are cell aggregates that display an irregular, spiky configuration (441). The cells and their nuclei show great variations in size and shape (442). There may be foci of squamous differentiation (Fig. 29-90). The number of inflammatory cells depends to some degree on the extent of ulceration. There often is perineural infiltration (440), and, on the face, there may be invasion of bone (401).

Keratotic basal cell carcinoma shows parakeratotic cells and horn cysts in addition to undifferentiated cells. The parakeratotic cells possess elongated nuclei and a slightly eosinophilic cytoplasm, in contrast to the deeply basophilic cytoplasm of undifferentiated cells. The parakeratotic cells may lie in strands, in concentric whorls, or around the horn cysts. It is likely that they are cells with initial keratinization somewhat similar to the nucleated cells in the keratogenic zone of normal hair shafts. The horn cysts, which are composed of fully keratinized cells, represent attempts at hair shaft formation (443). Just as in the keratinization of the hair shaft, the horn cysts form without the interposition of granular cells. Some keratotic basal cell carcinomas possess horn cysts of considerable size.

Keratotic basal cell carcinoma shares with trichoepithelioma the presence of horn cysts, and it is sometimes difficult to decide whether a lesion represents a keratotic basal cell carcinoma or a trichoepithelioma (see Chapter 30). Clinical data may be necessary for a decision to be reached. The horn cysts must not be confused with the horn pearls that occur in squamous cell carcinoma (see Differential Diagnosis).

Basal cell carcinoma with sebaceous differentiation shows essentially a basal cell carcinoma in which there are interspersed aggregates of sebaceous cells. A clear-cut separation from sebaceoma (sebaceous epithelioma) is at times impossible because transitions exist. Most examples of lesions believed to represent basal cell carcinomas with sebaceous differentiation are probably actually sebaceomas (444).

Adenoid basal cell carcinoma shows formations suggesting tubular, glandlike structures. The cells are arranged in intertwining strands and radially around islands of connective tissue, resulting in a tumor with a lacelike pattern (Figs. 29-79 and 29-80). In rare instances, lumina may be surrounded by cells that have the appearance of secretory cells. The lumina may be filled with a colloidal substance or with an amorphous granular material, but definite evidence of secretory activity of the cells lining the lumina cannot be obtained, even with histochemical methods. Similarly, because of the low degree of differentiation of the cells, histochemical reactions that would indicate either apocrine or eccrine differentiation are negative (445). The tumor originally described as basal cell tumor with eccrine differentiation (446) is now regarded as an eccrine carcinoma and referred to as *syringoid eccrine carcinoma* (see Chapter 30).
