# PROGNOSTIC/PREDICTIVE ROLE OF SEX IN ADVANCED DISEASE

## Insights from Therapeutic Trials: Chemotherapy

Although the potential prognostic influence of sex may be established in surgical series alone or in those patients treated with supportive care alone, in advanced disease, sex may be either prognostic or predictive of a higher effectiveness of chemotherapy. In fact, a prognostic factor mainly reflects the natural history of the disease (i.e., survival after surgery), whereas the predictive factor more precisely reflects the impact of a therapeutic intervention (i.e., predicts response and/or survival from chemotherapy or a biologic agent). For instance, HER-2 positive status in breast cancer is associated with poor prognosis, but this status carries on a positive predictive value for benefit from trastuzumab.

Theoretically, as consequence of the prognostic significance, a hypothetical clinical trial of a new therapy that includes lower stage patients, only PS 0-1, and a high percentage of women will yield favorable results based on these selection factors alone and this independently from the efficacy of therapy.

A large retrospective study reviewed 13 SWOG trials in which 2531 women were enrolled in the period of time between 1974 and 1987. A survival advantage for women was reported. The median survival time was 5.7 and 4.8 months for women and men, respectively and 1-year survival rates were 19% versus 14% ($p < 0.01$). This benefit, however, was not maintained with a multivariate analysis.[127] Similarly, a nonsignificant difference in survival by sex was reported in the setting of multimodality therapy for locally advanced disease (median survival of 21 months for women vs. 12 months for men)[128] (Table 25.3).

The European Lung Cancer Working Party (ELCWP) retrospectively analyzed 1052 patients treated between 1980 and 1991, for locally advanced or metastatic NSCLC. The statistical analysis included 23 pretreatment variables: female sex was one of eight variables significantly associated with improved survival with an RR of death of 0.7 ($p = 0.03$) at the multivariate analysis.[129] Survival advantage according to gender was also reported by O'Connell et al.[130] in a single institution study, in 378 patients with advanced stage NSCLC treated with chemotherapy. Female sex was one of four predictors of improved survival at the multivariate analysis (median survival time for women was 12.4 months vs. 8.8 months for men, $p = 0.001$).

Most of the published randomized trials cannot be pooled because of survival differences between the arms, but in the Eastern Cooperative Oncology Group (ECOG) 1594 study, this evaluation was possible, considering the lack of survival difference among the four arms.[131] In this study, 1207 patients were enrolled (1157 were eligible) with stage IIIB and IV NSCLC and randomized to four different chemotherapy treatment arms.[132] The median survival for all 1207 patients was 8 months, and all the other efficacy outcomes were comparable among four arms in the study. Consequently, it was possible to make a pooled analysis of this trial and to investigate the role of sex in survival. Men were more likely to have weight loss (65% for men vs. 58% for women, $p = 0.02$) and be slightly older (mean age 61.9 vs. 60.5 years for women, $p = 0.02$). Women were more likely to have adenocarcinoma histology (63% of women vs. 53% of men, $p = 0.003$). There was no difference in RR by sex (19% in both cohorts, $p = 0.15$). Median progression-free survival (PFS) and median survival times (MST) were different by sex: median PFS for women was 3.8 versus 3.5 months for men ($p = 0.022$) and MST 9.2 months for women and 7.3 months for men, respectively ($p = 0.004$). Survival was also better at 1, 2, and 3 years being for women, 38%, 14%, and 7%, respectively, versus 31%, 11%, and 5%, respectively, for men. This survival difference remained statistically significant after adjusting for performance status, weight

NR, not reported.

loss >10%, presence of brain metastases and stage (IIIB vs. IV). No difference in survival was found by chemotherapy regimen for both sex cohorts. In terms of toxicity, women tended to have more nausea, vomiting, alopecia, neurosensory deficits, and neuropsychiatric deficits.

Sex-related differences in survival were not identified in a recent study by the North Central Cancer Treatment Group (NCCTG). Nine trials (six phase II and three phase III, five of them platinum-based), conducted from 1985 to 2001, were retrospectively considered. In the multivariate analysis, sex was not an independent prognostic factor for improved overall survival and time to progression. Similar to the previously mentioned study, a difference in toxicity was observed: both grade ≥3 hematologic and nonhematologic toxicities were higher in women than in men with OR of 1.60 ($p = 0.0007$) and 1.71 ($p < 0.001$), respectively.[133]

The TAX 326 trial was a multinational, phase III study of docetaxel plus carboplatin (DCb) or docetaxel plus cisplatin (DC) versus the reference regimen of vinorelbine plus cisplatin (VC). Baseline characteristics were well balanced across treatment groups. Approximately two thirds of the patients in each treatment group had stage IV disease. In the pairwise comparison of DC versus VC, the overall survival times were 11.3 versus 10.1 months, respectively ($p = 0.044$). The 1- and 2-year survival rates were 46% versus 41% and 21% versus 14% for DC versus VC, respectively. The overall response rates were 31.6% for DC and 24.5% for VC ($p = 0.029$). MST and overall response rates were similar in the pairwise comparison of DC versus VC, and within each arm of the study, it has been reported a trend favoring a survival advantage for women.[134,135] Similar to ECOG 1594, sex differences in toxicity were also noted: women were more likely than men to develop grade ≥3 nausea and vomiting and neurotoxicity across all three treatment arms, whereas the other hematological and nonhematological toxicity was similar for both groups.

One potential explanation for this better survival outcome in women is differences in DNA-repair capacities between the sexes, making women more responsive to platinum-based chemotherapies. DNA repair machinery should be, on average, more defective in women, making them more susceptible to respiratory carcinogens but also more sensitive to DNA-interfering agents.

NSCLC is considered a neoplastic disease relatively resistant to chemotherapy, and this resistance has been associated with elevated nucleotide excision repair (NER) in tumor tissue.

In a case-control study, 375 patients with newly diagnosed NSCLC were accrued, and NER activity was estimated by the DNA repair capacity (DRC) measured in the patient's peripheral blood lymphocytes by the host cell reactivation assay. For every unit of increase in DRC, a progressive increase in the RR of death was observed. Of those 86 patients treated with chemotherapy, patients in the top quartile of the DRC distribution were at twice the RR of death as those in the lowest quartile (RR = 2.72; 95% CI, 1.24 to 5.95; $p = 0.01$), whereas effective DRC was not a risk factor for

death in patients who were not treated with chemotherapy. In univariate analysis of the relationship between DRC and clinical and demographic variables, DRC was significantly higher in men than in women (8.37% ± 2.92% vs. 7.13% ± 2.37%, respectively; $p < 0.001$) but was not related stage of disease, histology, differentiation of the tumor, or self-reported weight loss.[136]

Some interesting data regarding differential activity by sex are emerging for paclitaxel poliglumex, a drug that combines paclitaxel with poly-L-glutamic acid, a biodegradable polymer that is broken down to the active form by cathepsin B, which is modulated by estrogens. In two phase III studies, paclitaxel poliglumex did not show any advantage over standard chemotherapy. However, in a subgroup of 198 women from these two studies, it was found that it produced a better survival in younger premenopausal women, especially those with higher circulating levels of estrogens.[137] On the basis of these results, a phase III study comparing paclitaxel poliglumex plus carboplatin versus paclitaxel plus carboplatin was designed, recruiting only female patients with advanced lung cancer patients, who are premenopausal or taking estrogen replacement therapy. Further studies evaluating estrogen levels and outcomes in lung cancer patients are needed to understand the mechanism and significance of these findings. It is possible that estrogens not only influence tumor proliferation, but also alter chemotherapy efficacy and/or carcinogen metabolism to affect patient survival.

## Insights from Therapeutic Trials: Targeted Therapies

Data reported from several phase II and III clinical trials evaluating the role of EGFR TKI, erlotinib, and gefitinib, in the setting of second and third line, NSCLC claim for a higher responsiveness to these agents in women. In the Iressa Dose Evaluation in Advanced Lung Cancer (IDEAL) 1 and 2 studies, gefitinib was tested in patients with advanced NSCLC previously treated with one or two lines of chemotherapy, and female sex was associated with improved outcomes.[138,139] In the IDEAL 2 study, 50% of women had symptom improvements compared to 31% in men and, additionally, 82% of partial responses occurred in women (Table 25.4).

In a randomized double-blind, placebo-controlled phase III trial in second- and third-line advanced NSCLC,[140] patients treated with daily erlotinib had a response rate of 8.9% with a median survival of 6.7 months, resulting in a 42% improvement in median survival compared to patients receiving placebo that had a median survival of 4.7 months. One-year survival rate was 31% in the erlotinib arm and 21% in the placebo arm. Response rate was statistically superior in women (14.4% vs. 6.0% in men) but in the multivariate analysis, sex did not predict increased response to erlotinib. In another large randomized study, a statistically significant higher response rate was observed for gefitinib-treated women compared to men (14.7% vs. 5.1%, respectively). This study included 1692 patients and failed to demonstrate a survival improvement with gefitinib over placebo in either overall population (5.6 vs. 5.1 months) or in adenocarcinomas (6.3 vs. 5.4 months).

| TABLE 25.4 | Gender Differences in NSCLC Patients Treated with EGFR Inhibitors | | | | |
|---|---|---|---|---|---|
| First Author | Therapies | No. of Patients | Sex (M/F) | Response Rate (RR) | Gender Differences |
| Fukuoka[138] | Gefitinib 250 mg | 104 | 78/26 | 18.4% | OR F:M 2.6 ($p = 0.017$) |
| | Gefitinib 500 mg | 106 | 70/36 | 19.0% | |
| Kris[139] | Gefitinib 250 mg | 102 | 60/42 | 12% | RR male 2% — female 10% |
| | Gefitinib 500 mg | 114 | 63/51 | 10% | RR male 2% — female 8% |
| Shepherd[140] | Erlotinib | 488 | 315/173 | 8.9% | Overall RR male 6.0% |
| | Placebo | 243 | 160/83 | <1% | Overall RR female 14.4% |

In a large phase II study, 138 patients with a diagnosis of bronchoalveolar carcinoma were treated with gefitinib as first- or second-line treatment. An exploratory subset analysis found gefitinib more active in women, and a statistically significant difference in survival was observed in the previously untreated women versus men ($p = 0.04$).[141]

The improved survival observed in women treated with these EGFR TKIs may be related to differences in frequency of mutations in tyrosine kinase domain of the EGFR (20% in women vs. 9% in men),[142] an increased percentage of high EGFR copy number by fluorescence in situ hybridization (FISH) or a higher EGFR expression by immunohistochemistry.

In the ECOG 4599 study, the benefit on survival of adding bevacizumab to the doublet of carboplatin/paclitaxel was consistently reported in all subgroups of patients (measurable vs. nonmeasurable disease, prior radiation therapy versus no prior radiation therapy, prior weight loss of less than 5% vs. 5% or more, stage IIIB with pleural effusion vs. stage IV), but not in women and in the elderly patient population. Among men, the median overall survival was 8.7 months in the standard arm and 11.7 months in the experimental arm, whereas in women, 13.1 and 13.3 months, respectively. This unexpected increased survivorship of women may be attributable to imbalances between the two groups related to known or unknown baseline prognostic factors, to the use of second- and third-line therapies may be related to statistical chance or a true sex-based difference[143] (Table 25.5).

| TABLE 25.5 | Bevacizumab in Advanced NSCLC: Efficacy by Gender[143] | | | |
|---|---|---|---|---|
| Parameter | Men | | Women | |
| | PC (n = 230) | PCB (n = 191) | PC (n = 162) | PCB (n = 190) |
| OS, mo | 8.7 | 11.7* | 13.1 | 13.3 |
| PFS, mo | 4.3 | 6.3* | 5.3 | 6.2* |
| RR, % | 16 | 29* | 14 | 41* |

*Statistically significant.

OS, overall survival; PC, paclitaxel carboplatin; PCB, paclitaxel carboplatin bevacizumab; PFS, progression-free survival; RR, response rate.

**Insights from Therapeutic Trials: Small Cell Lung Cancer**    Less extensive information about sex-related differences in survival have been documented in small cell lung cancer: the analysis of four consecutive prospective trials showed a better overall survival favoring women.[144] A total of 2580 patients from 10 SWOG trials with limited (LD) and extensive disease (ED) were analyzed for prognostic factors. Only in LD, female sex ($p = <0.0001$) was a significant favorable independent predictor of survival.[145]

## CONCLUSION

Although lung cancer death rates in recent years have reached a plateau, the number of women who will die from lung cancer remains alarmingly high. A better understating of the genetic, metabolic, and hormonal factors that affect the way women react to carcinogens and lung cancer represents a research priority. This information could affect the way patients who smoke are screened and evaluated, as well as the way smoking cessation and lung cancer prevention programs are directed.

Evidence suggests that the development of lung cancer is different in women compared with men. Female smokers are more likely than men to develop adenocarcinoma of the lung. Women who have never smoked are more likely to develop lung cancer than men who have never smoked. Women with lung cancer also live longer than men with lung cancer, regardless of therapy and stage. These differences are most likely caused by hormonal, genetic, and metabolic differences between the sexes.

The response variations seen with the EGFR inhibitors and antiangiogenesis drugs are intriguing but insufficient to allow the sex of the patient to guide the choice of therapy. All large trials in lung cancer should stratify patients according to gender, and as we enter the era of more personalized medicine, gender will clearly be a critical factor in therapeutic choice in the future.

# Conventional Imaging of Non–Small Cell Lung Cancer

Bronchogenic carcinoma is generally first imaged, and often first detected, by chest radiography. Chest radiography is the preferred initial imaging modality because of its availability, low cost, low-radiation dose, and high sensitivity.[1] Computed tomography (CT) and occasionally magnetic resonance (MR) imaging of the chest and upper abdomen are used to stage a known or suspected lung cancer.

## MORPHOLOGIC APPEARANCES OF LUNG CANCER

Lung cancer morphology depends, to a certain extent, on cell type. Although prediction of cell type from morphology is far from 100% accurate, the following generalizations are often correct[2]:

1. Adenocarcinoma usually presents as a solitary pulmonary nodule (SPN), and most malignant SPNs are adenocarcinomas (Fig. 26.1). Squamous cell is also a common SPN (Fig. 26.2), whereas SPN is the typical manifestation of alveolar cell carcinoma.
2. Large central masses frequently represent squamous cell carcinoma or small cell carcinoma; small cell cancers especially involve mediastinal and hilar lymph nodes, sometimes without a recognizable parenchymal lesion, whereas squamous cell cancer is generally centered at or adjacent to the hilum (Fig. 26.3).
3. A large peripheral mass most commonly represents large cell carcinoma or squamous cell carcinoma; adenocarcinoma occasionally manifests this way. Large cell carcinoma is usually a large peripheral mass, but a large central mass is its next most common manifestation.
4. Multiple nodules generally occur with bronchioloalveolar cell carcinoma (BAC) (Fig. 26.4); adenocarcinoma also occasionally manifests this way.[3] With BAC, multiple nodules are a late manifestation, usually reflecting aerogenous, or less commonly hematogenous, dissemination.

5. Airspace disease is another late manifestation of BAC. It may be focal, lobar, or more diffuse (Fig. 26.5).
6. BAC as well as other types of adenocarcinoma may present as ground glass attenuation nodules, semisolid attenuation, containing solid and ground glass components, or irregular solid nodules.[4,5]

## MISSED LUNG CANCER

Experience teaches that larger lesions are more easily diagnosed than smaller lesions, and peripheral lesions are more readily detected than central lesions. Radiologic diagnosis is facilitated by the presence of typical radiographic features; uncommon manifestations of lung cancer, such as spontaneous regression, may prove misleading.[6,7] In one study of 27 missed lung cancers, the single most frequently identified cause of missed diagnoses was failure of the radiologist to compare the current chest radiographs with previous chest radiographs.[8] Other important factors were upper lobe location of the lesion (81%) and female gender of the patient (67%). A follow-up study from the same institution[9] featured 40 missed non–small cell lung cancers (NSCLC) over an 8-year period. In this series, gender did not play a role, but 72% of missed lesions were again in the upper lobes, and 22% were obscured by a clavicle.

Application of computerized automated lung nodule detection methods (computer-aided diagnosis [CAD]) to digital chest radiographs may improve the detection rate of lung cancers. One preliminary study using a commercial, computerized detection system on radiographs with T1 lesions showed a detectability rate of 74% (37/50) using CAD.[10] However, the CAD system showed a false-positive rate of 2.3 per case in 50 normal chest radiographs. The mean area under the receiver operating characteristic (ROC) curve for all observers increased significantly from 0.896 without CAD to 0.923 with CAD in the lung cancer cases. The primary reason for the improvement in performance was caused by a decrease in the number
**FIGURE 26.1**    T1 adenocarcinoma (*arrow*) surrounded by emphysematous lung.

**FIGURE 26.3**    Middle lobe squamous cell cancer showing broad contact with the mediastinal vascular structures (*arrow*); CT findings are equivocal for mediastinal invasion. The tumor was resected via right upper and middle lobectomies; histological examination showed tumor extending to, but not through, the pericardium.

**FIGURE 26.2**    Small, cavitary squamous cell cancer with soft tissue stranding, extending to the pleural surface (*arrow*). Histopathological examination of the resected specimen revealed tumor invasion of the visceral pleura.

of false negatives and a concomitant increase in the number of true positives.[10]

The novel technique of single-exposure, dual-energy digital chest radiography appears promising for the detection of pulmonary nodules and lung cancers. In a preliminary study assessing the detectability of lung nodules in 77 patients with lung cancer and 77 normal subjects, the combination of standard radiography and single-exposure, dual-energy digital radiography improved nodule detection compared to standard radiography alone.[11]

Some authors have analyzed the detectability of lung cancers based on size and extent of ground-glass opacity at thin-section CT.[12] They reviewed 75 peripheral NSCLC (26 localized BACs and 49 other cell types). The chest radiographs were mixed with 60 normals and blindly reviewed. Sensitivity for detection was 58.5% for BACs and 78.6% for the other cell types. Lesions <15 mm in size and those with ≥70% ground-glass opacity proved to be statistically significantly more difficult to detect. A similar result was obtained in a study analyzing lung cancers missed at low-dose helical CT screening.[13] In this study, 32 of 83 lung cancers found by annual low-dose CT screening had initially been missed. Nodules missed because of detection errors more frequently were ground glass (91%), and also, more frequently were judged to be "subtle" (91%).
**FIGURE 26.4**    Multiple, bilateral solid **(A)** and ground-glass **(B,C)** nodules (*arrows*) in bronchioloalveolar cell carcinoma.

Application of a computerized automated lung nodule detection method to proven lung cancers missed at low-dose CT screening may improve the detection rate significantly.[14] In a series of 38 missed lung cancers, such a method allowed identification of 32 (84%) of the missed lesions.

Similar to its use in chest radiography, CAD is an emerging tool for automatic detection of pulmonary nodules on CT; it may be used as a second reader, drawing the attention of the radiologist to possible abnormalities in order to increase the detection rate of small pulmonary nodules. High-resolution data (thin sections obtained during a single breath hold) acquired with multidetector CT (MDCT) has led to improvements in the sensitivity of various CAD systems and a decrease the false-positive rate. There are diverse methods of CAD, each based on different detection algorithms.[15] One recent study compared two CAD systems in 25 patients with 116 nodules, evaluated by three radiologists with varying levels of expertise[16]; this study showed that sensitivity for pulmonary nodule detection increased with the use of CAD. For example, in nodules smaller than 5 mm, sensitivity increased from 55% to 71% to 68% to 74%. There was no significant difference in the performance of the two CAD systems.
**FIGURE 26.5** Bronchioloalveolar cell carcinoma manifesting as bilateral air space disease (*arrows*).

Other CT evaluation methods have also been shown to decrease perception error and improve detection of pulmonary nodules. These dedicated computer applications involve alternative two- (2D) and three-dimensional (3D) displays of CT data.[17,18] For example, on maximum intensity projection (MIP) images, pulmonary nodules tend to stand out against background structures, such as lung and tubular vessels (Fig. 26.6); several studies have demonstrated the superiority of MIP over standard axial images. In one study, five readers evaluated examinations of 25 patients with 122 nodules (3 to 9 mm in diameter). Readings were performed with and without MIP.[17] MIP enhanced the detection of peripheral nodules for the junior readers, and of central nodules for both the junior and senior readers. Volume rendering (VR) in 3D techniques display the entire volume data, assigning relative opacity values to each voxel (ranging from 0% to 100%). In a study comparing MIP and VR computer applications among three readers, VR was superior to MIP in the detection of pulmonary nodules smaller than 11 mm and was associated with a statistically significant shorter reading time.[18]

Is missed lung cancer automatically evidence of malpractice? In the Mayo Clinic lung cancer screening article

**FIGURE 26.6** Small central lung cancer (*arrow*) is more obvious on MIP **(B)** and VR **(C)** images compared to axial CT image **(A)**.

previously cited,[19] each radiographic study was reviewed by two (and often three), trained and interested observers (chest radiologists or chest physicians) specifically to answer the question: "Is there lung cancer?" Amazingly, 45 of 50 peripheral carcinomas that they diagnosed were visible in retrospect, with 18 visible for more than 1 year and four for more than 2 years; one was visible in retrospect for 53 months. Furthermore, 12 of 16 perihilar carcinomas and 13 of 20 carcinomas presenting as hilar or paratracheal lymph node enlargement were visible in retrospect, although not generally for as long as the peripheral carcinomas. The authors concluded that ". . . failure to detect a small pulmonary nodule on a single examination should not constitute negligence or be the basis for malpractice litigation." In an elegant letter to the editor, Hendrix[20] pointed out the need for an analogy to explain to members of a lay audience (the jury) how a well-qualified, careful radiologist could miss the lesion that they now easily see on a radiograph. He likens the radiologist's analysis of the image to the search for Waldo in the series of *Where's Waldo?* books. As Dr. Hendrix pointed out, everyone understands how hard it can be to locate Waldo in a given illustration. However, once he has been found, Waldo is amazingly obvious when the same illustration is reviewed. As Dr. Hendrix added, it is even harder to look for lung cancer (or any other radiographic finding) because, although Waldo is definitely present on every page of a *Where's Waldo* book, a radiograph may be normal. Even with these potentially helpful legal strategies, defending missed lung cancer is generally an unpleasant experience.[21]

## SOLITARY PULMONARY NODULE

The SPN is a common presentation of lung cancer. However, most SPNs are benign. Summarizing five large series of resected SPNs seen on chest radiographs,[22–26] Siegelman et al.[27] noted that 53.9% were granulomas, 28.3% were bronchogenic carcinomas or other primary malignancies, 6.6% were hamartomas, and 3.5% were metastases. An even higher percentage of all radiographically detected SPNs are presumably benign, because nodules that appear calcified on chest radiographs are rarely resected.

The challenge in evaluating SPNs is to avoid invasive procedures in patients who have benign nodules without allowing potentially curable bronchogenic carcinomas the time to progress to more advanced or even unresectable disease. This is an area of active, ongoing research; however, the many approaches that have been tried attest to the lack of complete success for most modalities to date. A proper SPN evaluation acknowledges the following key points:

1. Imaging at a single point in time relies heavily on morphologic characteristics in distinguishing benign from malignant SPNs.
2. Calcification is the single best morphologic indicator of benignancy.
3. Behavior (i.e., lack of growth) is *far* better than any morphologic criterion at predicting benignancy.

4. Any predictor of benignancy must err on the side of intervention—it is better to resect a benign SPN unnecessarily than erroneously to call a malignant SPN benign.

With these key points in mind and realizing the significant expense (and in some cases radiation dose) of radiologic tests, it is always best to start the evaluation of the SPN by seeking old radiographs for comparison. This saves money, radiation, and often time, and provides the possibility for proving that a lesion is benign, no matter what its morphology is. A lesion that is stable for 2 years or more is considered to be benign, although the exception occurs for ground glass nodules at CT, which may represent very indolent adenocarcinomas. The flip side is that almost no matter what the morphology is, a growing lesion has declared itself to be one that should be resected. The lack of vigor with which old films are pursued is generally disappointing; if the patient were a close relative, we would all try a lot harder to spare him or her unnecessary tests that involve (potentially fatal) injection of intravenous contrast. And consider this—how many adults 40 years of age or older have never had a prior chest radiograph? In the United States, the number must be vanishingly small.

Whereas the concept of stability appears, on the surface, to be fairly straightforward, in practice it can be quite difficult to determine if a nodule has grown, particularly if it is small (e.g., less than 1 cm in diameter). This is true for both conventional radiography and for CT. For instance, a nodule that has increased from 10 to 11 mm in diameter may show no apparent, significant change in size at radiography or on axial CT scans; however, this represents a volume increase of 33%. To maximize the ability to detect such changes in size, it is important to optimize both CT imaging parameters, as well as postprocessing techniques. Particularly for small nodules, the best results may be obtained using thin section (1 to 2.5 mm), overlapping CT sections with 3D volumetric reconstructions (Fig. 26.7).[28,29] In addition, all follow-up scans should be performed using the same techniques. Volumetric measurements may be affected by many factors, including section thickness and spacing, x-ray dose, motion artifact, respiratory or cardiac phase, nodule location, and intraobserver/extraobserver variability; therefore, in general, volume differences less than about 25% should be regarded with skepticism.[28,30–36]

Sometimes, the clinical decision is made to prospectively follow an SPN with imaging, to demonstrate stability; this raises questions about appropriate scanning intervals. One study based on phantom exams and in vivo nodules, using automatic segmentation for lesion boundary definition, found that CT follow-up at 30 days could detect interval growth for all malignant lesions larger than 1 cm, and for lesions as small as 5 mm with a doubling time faster than 150 days.[37] Even for 5-mm lesions with slower doubling times, a second follow-up CT 30 days later rendered growth detectable in all cases. In a subsequent study of 13 patients, all five malignant nodules had doubling times less than 177 days, and all eight benign nodules had doubling times greater than 395 days.[38] However, other authors have found that a significant proportion of
**FIGURE 26.7**    Small, spiculated left lower lobe tumor (*arrow*) on initial axial CT **(A)** shows minimal change in area by visual assessment on 6-month follow-up scan **(B)**. Corresponding 3D-volume reconstructions **(C,D)** show asymmetric growth and approximately 49% interval increase in volume (from 1.23 cm$^3$ to 1.83 cm$^3$).

malignant tumors have much longer doubling times (>465 days), and therefore short-term follow-up may not be helpful in many patients.[5,29,39,40]

For a small indeterminate SPN seen at CT, follow-up guidelines have been published by the Fleischner Society[41] (Table 26.1), as well as others,[42] regarding the suggested time intervals for repeat CT scanning, taking into account nodule size and whether the patient is clinically at low or high risk for developing lung cancer. These guidelines suggest follow-up out to 2 years, unless the nodule is nonsolid (ground glass)

or partly solid; it is probably prudent to follow these nodules out to at least 3 years, because they could represent indolent adenocarcinomas, including BACs.

If a nodule is stable over a substantial period of time (e.g., 2 to 3 years), then it is almost certainly benign. However, it is well-known that not all growing nodules are malignant; various types of benign nodules may increase in size over time, including hamartomas, granulomas, and various other infectious or inflammatory lesions. In general, benign nodules tend to grow either extremely fast or extremely slowly, compared to

| TABLE 26.1 | Fleischner Society Recommendations for Follow-up and Management of an Incidental, Newly Detected, Indeterminate Nodule in Persons Older Than or Equal To Age 35 Years[41] | | |

[d]Nonsolid (ground-glass) or partly solid nodules may require longer follow-up to exclude indolent adenocarcinoma.

malignancies. Therefore, it has been postulated that growth rates of nodules may be helpful in distinguishing benign from malignant nodules. However, a recent study addressing this issue, using data based on serial, thin section CT scans, found extensive overlap among the growth rates of benign and malignant, clinically suspicious, pathologically proven lung nodules.[29]

When comparison studies are not available to establish stability, assessment of morphologic features is the next step in an SPN evaluation. Various morphologic features are suggestive of malignancy, including spiculation; ill-defined, lobulated, or irregular margins, with distortion of adjacent vessels; heterogeneity; central cavity with thick, irregular walls; and air bronchograms (Figs. 26.1 and 26.7). In addition, a ground-glass nodular opacity on CT, particularly with a new solid component (Fig. 26.8), adjacent pleural thickening or retraction (Fig. 26.2), and large lesion size are features associated with malignancy. On the other hand, benign features include calcification, smooth, well-defined margins; concave, linear, branching or polygonal shape; subpleural location; homogeneous and solid opacity; and a cavity with thin, smooth walls. Unfortunately, there is great overlap in these features between benign and malignant lesions.

**FIGURE 26.8**    Small left upper lobe adenocarcinoma manifesting as a ground-glass nodule on the initial CT (*arrow*) **(A)**; follow-up CT 22 months later shows a new solid component (*arrow*) **(B)**.

Helical CT was used in one study to evaluate the surface morphology of lesions, with particular attention to vascular involvement; 29 patients with noncalcified SPNs less than 3 cm in size were examined.[43] Eighteen SPNs were malignant (nine bronchogenic carcinoma, nine metastatic) and eleven were benign (six granulomas, two hamartomas, one mixed granuloma, one arteriovenous malformation, one inflammatory infiltrate). Venous involvement was present in all 18 malignant SPNs, but also in 4 of 11 benign SPNs. Arterial involvement was seen in all nine bronchogenic carcinomas, in five of nine metastatic lesions, and in 2 of 11 benign SPNs. Thus vascular involvement does not distinguish between benign and malignant SPNs.

Of all the morphologic features that can be examined, it appears that demonstration of calcification is the best way to attempt to establish a benign etiology. Unfortunately, analysis of lung nodule calcification on chest radiographs is inaccurate. In a review of 35 nodules seen on posteroanterior (PA) and lateral chest radiographs and thin-section CT, radiologists were asked to predict lesion calcification at radiography with one of six levels of confidence.[44] Among the nodules thought to be "definitely calcified," 7% were not actually calcified. The authors suggested that nodules without documentation of long-term stability may warrant a low threshold for CT correlation. In fact, the demonstration of calcification on chest radiographs has been made more difficult by current widely used techniques that employ high kilovolt (peak). For that reason, chest fluoroscopy with low kilovolt (peak) spot films would be a good next step in looking for calcification. Unfortunately, few centers still perform chest fluoroscopy. Computed chest radiography with selective windowing may be an alternative possibility.[45] In addition, dual energy subtraction radiography is occasionally performed to improve confidence in the detection or exclusion of nodule calcification.[46]

At CT, assessment for calcification is currently performed by visual assessment of thin section images, making sure that the section thickness is less than one half the nodule diameter, to avoid partial volume effects. In addition, such scans should be performed using helical technique, during a single breath hold, in order to avoid scan plane misregistration and motion artifact. It should, however, be remembered that not all calcifications seen at CT indicate benignancy. Benign forms of calcification include diffuse, near complete, laminated or central nidus patterns, and these lesions usually represent old granulomas. Hamartomas may contain coarse, scattered "popcornlike" calcification, either with or without foci of fat. (Depiction of fat within a nodule is essentially diagnostic for a pulmonary hamartoma, regardless of the presence or absence of calcification, and, like calcification, is best detected using thin sections.)[47] On the other hand, malignant forms of calcification include amorphous, stippled, or eccentric patterns (Fig. 26.9). Approximately 10% of lung cancers[48] and up to 30% of carcinoids[49] contain calcification. Malignancies may calcify if dystrophic calcification is formed by the tumor cells, if the neoplasm arises in a preexisting, calcified scar, or if the tumor engulfs a nearby granuloma.

If morphologic features are indeterminate for benignancy, various diagnostic procedures may be attempted. One technique

**FIGURE 26.9**  Right lower lobe carcinoma with amorphous calcifications (*arrow*).

is the assessment of contrast enhancement. Preliminary studies with follow-up of noncalcified SPNs have reported that all or nearly all malignant SPNs enhance by at least 20 Hounsfield units (HU) within 2 to 4 minutes after contrast injection; few benign SPNs enhance to that degree.[50–52] Based on these promising preliminary results, a multicenter study[53] evaluated 356 SPNs that were ≥5 mm, solid, relatively spherical, homogeneous, and without calcification or fat on noncontrast images. Contrast-enhanced, single- or dual-detector helical CT images were obtained at 1, 2, 3, and 4 minutes after onset of injection (3-mm collimation, 420 mgI/kg, 300 mgI/mL administered at 2 mL/sec). Using a threshold increase in attenuation of 15 HU resulted in 98% sensitivity, 58% specificity, and 77% accuracy in diagnosing malignancy. Prevalence of malignancy in this patient group was 48% (171 of 356 nodules). A later study using a four-slice multidetector scanner and a slightly faster contrast injection rate found nearly identical results and also noted that peak attenuation of the nodules correlated with microvessel density.[54] Although uncommon, false-negative exams may occur occasionally in mucin-producing or necrotic tumors. Because of the latter pitfall, it is recommended that the technique not be used in large (>2 cm), potentially necrotic lesions. Given its overall high sensitivity, it is somewhat surprising that this technique has not become a standard tool in the workup of SPNs. However, another study demonstrated overlap in enhancement of malignant lesions and benign, active inflammatory lesions,[55] which may explain the low specificity and the current minor role of this technique.

Some preliminary work has been published on the use of combined contrast wash-in and wash-out, as an attempt to increase the specificity of contrast enhancement techniques. One

study examined 107 nodules (49 malignant, 58 benign) using multidetector helical CT images obtained out to 15 minutes after the onset of contrast injection.[56] Using an increase in attenuation (wash-in threshold) of ≥25 HU resulted in 100% sensitivity, 48% specificity, and 72% accuracy in diagnosing malignancy; however, the addition of a wash-out threshold of 5 to 31 HU led to greatly improved results, showing 94% sensitivity, 90% specificity, and 92% accuracy. False-positive cases were seen in pneumonias and false negatives in adenocarcinomas. Only 57% of malignancies reached peak enhancement within 2 minutes; 92% reached peak within 5 minutes and 98% within 9 minutes. These data suggest that images should be obtained out to at least 9 minutes after administration of the contrast bolus. These results are quite promising; however, a larger, follow-up study by the same group found somewhat less sanguine findings (89% sensitivity, 79% specificity, and 84% accuracy) and suggested that the combination of wash-in plus evaluation of morphologic features gives equivalent results to wash-in plus wash-out.[57]

The degree of lung nodule contrast enhancement has been used not only for diagnostic purposes, but also for regional staging. A recent report has suggested that peak enhancement of a lung nodule ≥110 HU or net enhancement ≥60 HU is indicative of the presence of mediastinal nodal metastases, showing sensitivity, specificity, and accuracy figures of 65%, 89%, and 83%, respectively; these figures were similar to the results of ^{18}F-fluorodeoxyglucose–positron emission tomography (FDG–PET) scanning, performed in the same group of patients.[58]

Magnetic resonance imaging (MRI) is infrequently used for the detection and characterization of pulmonary nodules. The use of 2D half-Fourier single-shot turbo spin echo (HASTE) sequences allows the detection of pulmonary nodules greater than 5 mm in diameter. In a study using this sequence with MDCT as the gold standard, the sensitivity of MRI was 92% for lesions greater than 3 mm and 98% for nodules greater than 5 mm.[59] However, characterization using MRI is more difficult, partly because calcification is hard to identify on MRI. In an early study of 28 patients with SPNs, it was suggested that signal intensity measurements of nodules on dynamic contrast-enhanced MR studies may provide information about the nature of the nodules[60]; in addition, other investigations have suggested that dynamic contrast enhanced MRI, including relative enhancement and rate of enhancement, may be helpful in differentiating benign from malignant nodules.[61] In a study by Schaefer et al.,[62] time–intensity curves showing contrast enhancement profiles were 100% sensitive and 75% specific for malignancy. The absence of enhancement and thin, peripheral rim enhancement are features suggesting a benign lesion.[61–64]

In many centers, nodules that are suspicious for malignancy at CT are percutaneously biopsied using fluoroscopic or CT guidance; this is a relatively safe procedure and high accuracies have been reported, with positive predictive values (PPV) of at least 99%. The key number, however, is the negative predictive value (NPV): How reliable is a negative result? Can a nodule with a negative biopsy be safely watched, or should it be resected regardless of the biopsy result? Reported NPVs for

fine-needle aspiration biopsy (FNAB) of lung nodules range from 59% to 82%.[65–68] There is little data regarding the NPV of core needle biopsies in this setting, and the available results are also somewhat conflicting, ranging from 67% to 92%.[68–71] The NPVs for core biopsies showing nonspecific benign tissue or insufficient tissue for diagnosis were 76% and 50%, respectively, according to one recent study; on the other hand, the NPV for a biopsy revealing a specific, benign diagnosis, such as hamartoma or fungus, approached 100%.[69] Published studies have suggested that the use of core needle biopsy technique increases the frequency of obtaining a specific benign diagnosis, compared to FNAB[72,73]; the proportion of specific benign diagnoses compared to all benign diagnoses ranged from 21% to 83% in recent investigations.[68–71] Given these results, surgeons at many institutions believe that a percutaneous biopsy of an SPN is not indicated: except for the uncommon instance when a specific benign diagnosis is established, they will resect the nodule regardless of the biopsy results. (An exception might occur in the patient with a history of previous extrathoracic primary neoplasm.) At other institutions, where percutaneous biopsy is routinely performed for SPNs, it is advocated that a nonspecific negative biopsy be followed by a repeat biopsy. If the repeat biopsy is also negative for malignancy, then close follow-up is advised.

The various approaches to the SPN described previously have largely been overshadowed by the growing acceptance of PET scanning. PET has the obvious advantage of evaluating the metabolic behavior of the nodule rather than its morphology, and it is of great value in differentiating benign and malignant SPNs. PET is covered in Chapter 27.

Whereas in the general population, the major issue with regard to an SPN is distinguishing the benign nodule from the malignant nodule, the issue is slightly different in the patient with a current or previous extrapulmonary primary cancer. In this type of patient, it can be important to distinguish between a solitary metastasis and a new bronchogenic carcinoma. The relative likelihood that a new SPN seen on a chest radiograph is a solitary metastasis versus a new lung cancer depends on the histology of the previous primary tumor. In some instances, the odds favor a new lung primary, such as for head and neck carcinoma (15.8:1), bladder carcinoma (8.3:1), and cervical carcinoma (6:1).[74] In fact, with some primaries, all malignant SPNs in one series were lung cancers (prostate, 26 patients; stomach, 7 patients; esophagus, 4 patients; pancreas, 3 patients). In other cases, a solitary metastasis is favored, such as in patients with soft tissue sarcoma (17.5:1), osteosarcoma (6.7:1), melanoma (4.1:1), and testicular carcinoma (2:1)[74] With most primaries the answer is in between, but slightly favoring lung cancer; examples include breast carcinoma (1.7:1), colon carcinoma (1.4:1), renal cell carcinoma (1.2:1), and endometrial carcinoma (1.1:1).[74]

Because CT is more sensitive at detecting lung nodules, the CT demonstration of a SPN more reliably indicates that there is really only one nodule. A recent study used CT to readdress the issue of a patient with a previous extrathoracic primary neoplasm and a new SPN.[75] In this study, breast cancer was

grouped with cancers of bladder, cervix, biliary tree, esophagus, ovary, prostate, and stomach, and the overall result was that 26 SPNs were lung cancers, and 8 were solitary metastases (3.3:1). For head and neck cancer, the ratio of lung cancers to solitary metastases was 8.3:1. For patients with carcinoma of the salivary glands, adrenal glands, colon, kidney, thyroid, thymus, or uterus the corresponding ratio was 0.8:1, whereas patients with melanoma, sarcoma, or testicular carcinoma had many more solitary metastases than new lung primaries (3.8:1).[75]

## STAGING OF LUNG CANCER

Initial tumor staging in patients with NSCLC is important in order to identify those patients with locoregional disease who are likely to benefit from surgical resection or other potentially curative therapies, such as definitive radiation therapy or radiofrequency ablation. Staging may be performed using a combination of modalities, although the workhorses are CT and FDG–PET scanning[76]; other techniques, such as MRI, ultrasonography, bone radiography, bone scintigraphy, and endoscopic ultrasound are usually reserved for specific problem solving and/or to enable tissue biopsy. The TNM staging system of the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (Union Internationale Contre le Cancer [UICC]) is the most widely accepted and used classification system for preoperative and postoperative staging,[77–80] although this will be replaced by the new International Association for the Study of Lung Cancer (IASLC) staging system in 2009 (see Chapter 30). In the most current version of TNM staging classification (published in 2002),[77,81] T1 tumors are small (≤3 cm in diameter), are surrounded by lung or visceral pleura, and are without bronchoscopic evidence of invasion more proximal than the lobar bronchus. T2 tumors show one or more of the following features: larger than 3 cm; involvement of a mainstem bronchus 2 cm or more distal to the carina; invasion of visceral pleura; and atelectasis extending to the hilum, without involvement of the entire lung. T3 tumors show invasion of the chest wall, diaphragm, pericardium, mediastinal pleura, or mainstem bronchus (less than 2 cm distal to the carina), or have postobstructive atelectasis or pneumonia of an entire lung. T4 cancers invade the mediastinum, heart, great vessels, trachea, esophagus, or vertebral body, have an associated malignant pleural effusion, or have satellite nodule(s) within the ipsilateral primary-tumor lobe of the lung. Metastatic spread to lymph nodes is classified as N1 for peribronchial or ipsilateral hilar nodes and for intrapulmonary nodes involved by direct extension of the primary tumor. Metastatic disease to ipsilateral mediastinal or subcarinal nodes falls into the N2 category and into the N3 category for involvement of contralateral mediastinal or hilar nodes, and ipsilateral or contralateral scalene or supraclavicular lymph nodes. The M0 category comprises patients with no distant metastases; presence of distant metastases confers M1 status.

In the current TNM system, stage I tumors have no lymph node metastases. Stage II tumors either have no lymph node metastases or spread is confined to hilar lymph nodes. Stage IIIA

includes tumors with spread to ipsilateral mediastinal or subcarinal nodes, whereas stage IIIB includes tumors with involvement of contralateral mediastinal or hilar nodes, or ipsilateral or contralateral scalene or supraclavicular lymph nodes. Tumors with distant metastases are classified as stage IV.[77]

In the summer of 2007, the IASLC published a series of articles outlining recommendations for amendments to the TNM staging system based on data from more than 100,000 patients in its Lung Cancer Staging Project.[82–86] These amendments will likely be reflected in the next official version of the TNM classification system, due to be published in 2009. These changes include the following: the T1 and T2 categories are broken down by tumor diameter (T1a: ≤2 cm; T1b: >2 to 3 cm; T2a: >3 to 5 cm, T2b: >5 to 7 cm). Furthermore, T3 includes tumors >7 cm in diameter. If a patient has a satellite nodule (or nodules) in the same lobe of the lung as the primary tumor, this falls into the T3 category; if the satellite nodule is in a different, ipsilateral lobe, this represents T4 disease; and if it is in a contralateral lobe, this presents M1a disease. There are no changes in the N classification. The M category has been divided into M1a and M1b. M1a includes patients with distant metastatic disease confined to the lung and pleura, for example, malignant pleural nodules, malignant pleural or pericardial effusion, or separate tumor nodule(s) in a contralateral lobe. The M1b category includes distant metastases outside of the lung and pleura. The stage groupings have also shifted somewhat to better align the classifications with prognosis and treatment.[82]

## COMPUTED TOMOGRAPHY

### Evaluation of the Primary Tumor

**Pleural Invasion**　A pleural effusion in a patient with lung cancer may be malignant, caused by pleural metastases, or it may be benign, particularly in a patient with postobstructive pneumonia. The CT hallmark for a malignant effusion is soft tissue nodularity along the pleural surfaces, accompanying the effusion, although this finding is not always present (Fig. 26.10). It has been reported that pleural nodularity and/or fissural thickening are indicative of pleural metastases, even in the absence of pleural effusion.[87] Pleural tumor dissemination is currently classified as T4 disease and is generally considered unresectable.

**Chest Wall Invasion**　CT has shown somewhat disparate results in assessing for chest wall invasion by tumor, with sensitivity ranging from 38% to 87% and specificity from 40% to 90%.[88–94] Signs of invasion may include bone destruction, tumor mass extending into the chest wall, pleural thickening, loss of the extrapleural fat plane, obtuse angle between mass and chest wall, and greater than 3 cm of contact between mass and chest wall (Figs. 26.2 and 26.11 to 26.14). In a series of 112 patients with cancers adjacent to the pleural surface, Ratto et al.[91] found that CT was 83% sensitive and 80% specific for

**FIGURE 26.10** Malignant pleural effusion from adenocarcinoma of the lung. Note pleural tumor nodules (*arrows*).

**FIGURE 26.11** Cavitary non–small cell lung cancer with chest wall invasion. Note abnormal soft tissue in chest wall with accompanying rib destruction (*arrow*).

chest wall invasion using a cutoff of 0.9 for the ratio between the length of tumor–pleura contact and tumor diameter. They also found that obliteration of the extrapleural fat plane was 85% sensitive and 87% specific for invasion. However, they noted that the extrapleural fat plane was not always visible, particularly when the tumor contacted the ribs; on the other hand, this plane was usually visible when the tumor contacted

the pleural surface in between the ribs. Length of tumor–pleura contact, angle between the tumor and the pleura, presence of soft tissue mass involving the chest wall, and rib destruction were less accurate indicators of chest wall invasion in this series. Pennes et al.[90] noted that in their series of 33 patients with peripheral pulmonary malignancies, 5 patients showed encroachment on or increased density of the extrapleural fat; however, only 3 of these 5 had chest wall or pleural invasion at surgery. In the other two patients, lymphoid aggregates were present in the extrapleural fat, suggesting that nonspecific

**FIGURE 26.12** Peripheral right upper lobe adenocarcinoma showing rib invasion (*arrow*) on axial **(A)** and coronal **(B)** CT images.

**FIGURE 26.13**   Right upper lobe adenocarcinoma. CT shows broad contact between the tumor and the chest wall, with mild soft tissue infiltration into the adjacent extrapleural fat (*arrow*). These findings are indeterminate for chest wall invasion.

inflammatory processes involving the pleura may extend into the adjacent extrapleural soft tissues. Pleural thickening was a very sensitive (100%) indicator of chest wall invasion in this study, although very poor specificity (44%) led to poor accuracy (58%). In the 20 patients with peripheral lung malignancies studied by Pearlberg et al.,[94] definite bone destruction at CT showed 100% PPV (11 of 11). Soft tissue extension around ribs into fat or muscle of the chest wall had a PPV of 33% (three of nine). In each of these six false-positive cases, fibrous, inflammatory, and/or hemorrhagic changes were shown in the adjacent pleural or extrapleural tissues, but no tumor extension was seen.

Some investigators have employed artificial (i.e., induced) pneumothorax in order to increase the accuracy of CT in diagnosing chest wall and mediastinal pleural invasion. For example, Watanabe et al.[95] found 100% sensitivity, 80% specificity and 88% accuracy for CT using this technique in 12 patients. In one patient with no separation between the tumor and the mediastinal pleura, only adhesions were found at surgery, with no mediastinal tumor invasion. In a different study of 43 patients with equivocal chest wall invasion on routine CT, artificial pneumothorax yielded 100% accuracy for diagnosing chest wall invasion and 76% accuracy for mediastinal invasion.[96] These authors noted difficulty when the tumor was near the root of the pulmonary arteries and veins, because it was occasionally hard to introduce air into this region of the pleural space.

**FIGURE 26.14**   Right lower lobe adenocarcinoma showing broad contact with pleura and adjacent pleural thickening **(A)** (*arrows*); CT findings are indeterminate for pleural and chest wall invasion. Mildly enlarged right hilar (*white arrow*) and subcarinal (*black arrow*) lymph nodes are seen at CT **(B)**. At surgery, there was a benign pleural plaque adjacent to the tumor, without pleural tumor invasion. Tumor involved hilar lymph nodes (N1), without mediastinal nodal involvement.

Other techniques for diagnosing chest wall invasion rely on the absence of relative movement between the chest wall and the adjacent tumor during respiration. Investigators have used inspiratory or expiratory CT, ultrasonography, and cine MR during deep breathing to evaluate this feature, with moderately successful results.[97–99]

In summary, these studies suggest that the best and the only reliable criterion for diagnosing chest wall invasion with routine CT is definite bone destruction, with or without tumor mass extending into the chest wall. Thin sections are often helpful in making this assessment. It should be noted that chest wall invasion does not preclude surgical resection, because the surgeon can perform en bloc resection and chest wall reconstruction (see Chapter 34). However, this procedure is associated with increased operative morbidity and mortality. In addition, patients with known mediastinal nodal metastases and chest wall invasion are felt to have a very poor prognosis (7% reported 5-year survival following surgical resection), and surgery is usually not advocated in these patients.[100,101] Superior sulcus tumors invading extrapleurally are usually treated with radiation therapy followed by surgical resection.

**Mediastinal Invasion**  Although invasion of the mediastinum falls into the T4 category in the TNM staging classification, minimal invasion of fat only (without invasion of vascular or other structures) is generally considered resectable by many surgeons. Therefore, it is not usually necessary to preoperatively diagnose minimal mediastinal fat invasion (Fig. 26.15); on the other hand, gross invasion is considered

**FIGURE 26.15**  Minimal mediastinal fat invasion (*arrow*) by middle lobe neoplasm, proven at surgery and successfully resected using a middle lobe sleeve lobectomy.

to be unresectable (Fig. 26.16). In addition, a reliable diagnosis of invasion of mediastinal vessels, trachea, esophagus, and/or vertebral body would usually preclude surgical resection. Several studies have investigated the usefulness of CT in detecting mediastinal invasion and in predicting resectability

**FIGURE 26.16**  Two different patients **(A, B)** showing gross, unresectable invasion of mediastinal fat (*arrow*).

of the primary tumor.[88,92,102–109] Accuracy for distinguishing between T0 to T2 and T3 to T4 tumors has been reported to be 56% to 89%.[106–109] However, this information is not particularly helpful, because the clinically important distinction is between resectable (T3) and unresectable (T4) cancers.

In one retrospective study of 80 patients with an indeterminate CT for mediastinal invasion (i.e., mass contiguous with the mediastinum but without definite infiltration into the mediastinal fat or extension around the central vessels or mainstem bronchi), the authors were able to identify a large group of masses that were likely to be technically resectable using one or more of the following criteria: contact of 3 cm or less with mediastinum, less than 90 degrees of contact with aorta, and mediastinal fat between the mass and mediastinal structure.[102] A total of 36 out of 37 masses in this category were resectable; 28 of 36 masses had no mediastinal invasion, and 8 of 36 had focal limited invasion. However, more than 3-cm contact with mediastinum, more than 90 degrees of contact with aorta, obliteration of the fat plane between the mass and mediastinal structures, presence of mass effect on adjacent mediastinal structures, and pleural or pericardial thickening were not reliable signs of either invasion or unresectability. Kameda et al.[104] studied 52 patients with lung cancer, including 21 with central tumors. CT was 100% sensitive although not specific (60% to 67%) in evaluating for
superior vena cava or right pulmonary artery invasion. For the left pulmonary artery and the left atrium or pulmonary vein, CT had high specificity (94% to 100%) but poor sensitivity (56% to 62%). In a CT study of 108 patients, Izbicki et al.[105] reported one false-positive case for aortic invasion and multiple false-negative cases for invasion of an atrium, pulmonary artery, superior vena cava, or mediastinal bronchus. Choe et al.[110] found that obliteration of the superior pulmonary vein at CT was consistent with intrapericardial extension of tumor through the pulmonary vein in 10 of 10 patients. On the other hand, only four of nine patients with obliteration of the inferior pulmonary vein at CT showed intrapericardial tumor extension at surgery.

In summary, CT diagnosis of mediastinal fat or mediastinal structure invasion is generally unreliable (Figs. 26.3, 26.17, and 26.18), and a patient should not be denied of surgery based on unproven CT findings. Gross mediastinal fat invasion may be proved via mediastinoscopy or transtracheal Wang needle biopsy, if the location is accessible using these techniques. Findings suggestive of central tracheobronchial invasion at CT are usually further evaluated using bronchoscopy. CT and bronchoscopy are complementary procedures: bronchoscopy is superior to CT in evaluating the mucosal surface of the airway, whereas CT is superior in visualizing tumor spread extraluminally and occasionally within the wall of the bronchus. Transesophageal echocardiography (TEE) may aid in evaluating for direct aortic invasion by tumor.[111] Occasionally, secondary signs are helpful in diagnosing mediastinal invasion;

**FIGURE 26.17**    Squamous cell cancer of the left upper lobe. Broad, convex margin between the tumor and the mediastinum (*arrow*) is suggestive of mediastinal invasion; the tumor was surgically resected, and there was no mediastinal or pleural invasion.

**FIGURE 26.18**    Obliteration of fat plane between left upper lobe tumor and aorta (*arrow*); CT findings are equivocal for aortic invasion. The tumor was unresectable because of aortic invasion at surgical exploration.
**FIGURE 26.19** Squamous cell cancer (*arrow*) obstructing the right upper lobe bronchus, with minimal extension into the right mainstem bronchus. The tumor was resected using a right upper sleeve lobectomy.

for example, deviation of the left vocal cord and hoarseness in a patient with a left lung cancer is suggestive of mediastinal tumor invasion involving the recurrent laryngeal nerve.

**Prediction of Need for Lobectomy versus Pneumonectomy**    Tumor invasion of central pulmonary arteries and veins, as well as tumor extension across the major fissure (anywhere on the left; above the minor fissure on the right), are findings that would generally require pneumonectomy for resection rather than lobectomy. In many cases, tumor involvement of a mainstem bronchus also necessitates pneumonectomy, although some of these tumors may be resected with lobectomy using a sleeve resection and bronchoplasty (Fig. 26.19). The assessment of the need for lobectomy versus pneumonectomy is important in the patient with poor pulmonary function who cannot tolerate a pneumonectomy. Quint et al.[112] found CT to be inaccurate in making this assessment, although thin sections (1.5 to 3.0 mm) helped in evaluating for tumor spread across a fissure. The recent use of multidetector helical scanning modes enables acquisition of large numbers of thin sections during a single breath hold. These capabilities facilitate optimal evaluation of the central airways and other central structures, particularly by using sagittal, coronal, and off-axis planar reformatted images, as well as 3D reconstructions. Some surgeons find that 3D displays of CT data are helpful in preoperative surgical planning,[113] and 3D reconstructions may improve accuracy in evaluating for central pulmonary vascular invasion.[114]

**Differentiation between Tumor and Adjacent Atelectasis/Pneumonia**    Another use for CT in evaluating local extension of the primary tumor is in distinguishing central tumor from adjacent collapsed lung. After an intravenous bolus of urographic contrast material, the atelectatic lung may enhance much more than the adjacent tumor, thus giving a more accurate assessment of tumor size.[115] However, in many cases, it remains difficult to distinguish tumor from adjacent postobstructive atelectasis or pneumonia.

## CT Evaluation of Hilar and Mediastinal Lymph Nodes

**Significance**    Metastatic disease to hilar lymph nodes (N1 disease) adversely affects patient prognosis, although it does not generally affect resectability. Usually, involved hilar nodes can be easily removed from the hilar vessels at surgery. Thus, although preoperative detection of tumor spread to hilar nodes is useful, it is generally not crucial in directing surgical treatment planning. Moreover, the presence or absence of hilar node metastases is an unreliable indicator of mediastinal node metastases.[116,117]

In the past, the presence of mediastinal node metastases has been considered a contraindication to thoracotomy, and preoperative detection of mediastinal spread of disease has generally precluded surgical resection. However, some investigators have found reasonable 3- and 5-year survival rates for patients with positive ipsilateral mediastinal nodes, and many surgeons now feel that certain groups of patients with limited N2 disease may be surgical candidates.[118–120] Naruke et al.[121] found significantly increased 5-year survival in patients with N2 disease (14%) as compared to patients with N3 disease (0%) following pulmonary resection in 1479 patients with no distant metastatic disease. It has been suggested that resection may be worthwhile in patients with ipsilateral mediastinal nodal disease as long as the nodes are not in the high paratracheal region, are not numerous or bulky, and can be completely resected.[122,123] Some groups have advocated surgical resection in conjunction with postoperative radiation therapy in patients with mediastinal metastases.[116,124,125] Other investigators have suggested that patients with N2 (or even N3) disease may benefit from chemotherapy or combined chemotherapy and radiation, either alone or prior to surgical resection.[126–132] However, most clinicians believe that metastatic disease to contralateral hilar or mediastinal lymph nodes or metastases to any scalene or supraclavicular lymph nodes (N3 disease) precludes surgery. It has been observed that metastases to mediastinal lymph nodes indicates aggressive tumor biology, suggesting the presence of distant metastases and implying poor survival.[126]

## CT Criteria for Detection of Lymph Node Metastases
Given the importance of preoperative nodal staging for treatment planning, a noninvasive imaging modality such as CT is of great potential value for assessment of mediastinal nodes, both ipsilateral and contralateral to the primary lung tumor. Mediastinal lymph nodes are generally identified on axial CT

images as nonenhancing, oval, soft tissue density structures surrounded by mediastinal fat. Nodal size may be estimated by measuring the short and long-axis diameters of a node as seen on the axial images. Glazer et al.[133] stated that the short-axis diameter is a more accurate predictor of nodal size than the long-axis diameter, because long-axis measurements are more dependent on the spatial orientation of the node. The long-axis diameter is accurate on transverse CT images only when the longest axis of the ovoid, 3D lymph node is oriented in the plane of section that is, the transverse plane. If the lymph node is vertically oriented, the long-axis diameter on CT has no relation to the true long-axis measurement of the lymph node. Short-axis diameters are also affected by nodal orientation, although to a lesser extent. In a CT or autopsy correlation study, Quint et al.[134] found that the short-axis diameter of the nodes at CT was the best predictor of actual nodal volume.

CT criteria for lymph node malignancy theoretically include morphological features such as nodal density and margination, as well as nodal size. In practice, however, most of these features are not helpful, and increased nodal size is the only useful criterion for malignancy. One exception to this rule is the occasional finding of central nodal low density, suggesting necrosis; this is a good indicator for malignant nodal disease. Occasionally, the central low density will show the attenuation of fat, and this finding is reliable for benignancy. In addition, another study suggested that rounding of the contour of a hilar lymph node, where it meets the lung margin, is indicative of metastatic disease.[135]

Several groups have investigated the normal size limits for mediastinal lymph nodes, studying normal patients and those with lung cancer. Genereux and Howie[136] studied CT scans of normal patients and compared their findings with dissection of 12 cadaver mediastina. The largest mediastinal nodes at CT were in the precarinal or subcarinal and aortopulmonary regions, and at autopsy, the largest nodes were in the pretracheal and precarinal or subcarinal regions. These authors measured long-axis lymph node diameters at CT and found that 95% were less than 11 mm. In another CT study by Schnyder and Gamsu,[137] the mean diameter of normal lymph nodes in the pretracheal, retrocaval space was 5.5 mm plus or minus 2.8 SD (short vs. long axis not specified), with 91% (116 of 127) being less than or equal to 1 cm. A CT or autopsy study in five cadavers by Quint et al.[134] showed excellent correlation for the number of nodes in right-sided mediastinal regions, with poorer correlation in left-sided regions. Mean short-axis nodal diameters at CT ranged from 3.2 to 7.3 mm, depending on exact nodal location. Kiyono et al.[138] dissected 40 cadaver mediastina from patients without chest malignancy or infection, and recorded the number, size (short and long axes in the transverse plane), and American Thoracic Society (ATS) location of each lymph node identified. Based on their findings, these authors proposed standards for maximum short-axis diameters as follows: 12 mm for ATS region 7 (subcarinal), 10 mm for ATS regions 4 (right lower paratracheal) and 10R (right tracheobronchial angle), and 8 mm for other regions. They found that maximum long-axis diameters showed a wider variation.

Glazer et al.[133] examined normal mediastinal lymph nodes on CT scans from 56 normal patients and tabulated the number and size of lymph nodes in each anatomical region as specified by the ATS lymph node mapping scheme. In this study, 1 cm was the optimal upper limit of normal for the short axis of a mediastinal node at CT, with slight variations according to specific location (range 7 to 11 mm). The largest nodes were in the subcarinal and right tracheobronchial regions, whereas the smallest nodes were in the upper paratracheal and left peribronchial regions. A prior CT study by the same group involving patients with NSCLC similarly found 1 cm as the optimal size threshold for diagnosing metastatic disease in mediastinal nodes.[139] Platt et al.[140] confirmed 11 mm as the upper limit of normal size at CT for subcarinal lymph nodes in 46 patients with NSCLC.

To address the issue of lymph node size versus presence/absence of metastases, Medina Gallardo et al.[141] conducted a pathological study of lymph nodes resected from 67 patients with NSCLC. The authors correlated lymph node size (as measured on the fresh, resected nodes in the pathology department) with presence or absence of tumor at histological examination. Using a size threshold of 10 mm (short vs. long axis not specified), 73 of 167 (44%) patients had enlarged mediastinal nodes and 58 of 167 (35%) had enlarged hilar nodes. There are 18 out of 73 (25%) and 12 out of 58 (21%) patients who had neoplastic involvement of enlarged mediastinal and hilar nodes at pathological examination, respectively (25% mediastinal nodal PPV). The PPV for enlarged mediastinal lymph nodes in squamous cell carcinoma was 23% and in adenocarcinoma was 18%. These low values were reflective of the large number of false-positive cases caused by enlarged, benign lymph nodes.

These results highlight one pitfall in using a nodal size threshold to distinguish benign from malignant lymph nodes at CT. Benign nodes may be enlarged because of reactive hyperplasia, anthracosis, inflammation, or infection (Fig. 26.20). Conversely, malignant nodes may be normal in size if they contain only microscopic metastases. Daly et al.[142] reported that enlarged, benign nodes were a particular problem for central tumors with postobstructive pneumonia. Gross et al.[143] addressed the issue of microscopic metastases to normal-sized nodes in a study of 39 patients with bronchogenic carcinoma. Five of thirty-nine (13%) patients had metastases limited to normal-sized nodes as measured at surgery and pathology; however, two of these five patients showed enlarged nodes at CT owing to inaccurate CT depiction of nodal size in the subcarinal region. In one patient, multiple normal-sized subcarinal nodes containing metastatic tumor were visualized only as a single large mass at CT. In the second patient, a 10 × 9 mm subcarinal node containing metastatic tumor measured 12 × 11 mm at CT, and was therefore identified as abnormal. Thus metastatic disease to normal-sized mediastinal lymph nodes was missed at CT in only 3 of 39 (8%) patients, and the authors concluded that metastatic disease to normal-sized mediastinal lymph nodes was not a major problem in CT staging of lung cancer. Similarly, Daly et al.[142] reported that
**FIGURE 26.20** Squamous cell cancer (*C*) that obstructs the right upper lobe bronchus, with postobstructive pneumonia. Enlarged right hilar (*white arrow*) and tracheobronchial angle (*black arrow*) lymph nodes could be neoplastic or reactive in nature.

those with moderate or gross nodal metastases. These findings are supported by one small CT series which suggested that metastases to enlarged mediastinal nodes were more likely to have extracapsular spread of tumor than microscopic metastases to normal-sized nodes.[143] Because extracapsular spread is thought to be a poor prognostic indicator,[149,150] microscopic metastases to normal-sized nodes may have a less dire prognosis than enlarged malignant nodes.

In summary, although different size threshold values for normal mediastinal lymph nodes have been suggested, the current consensus is that this figure should generally be approximately 1 cm in short-axis diameter.[133,134,136,137,139,146,151–155] Some authors have preferred to use nodal size criteria that vary with the precise mediastinal nodal location, based on the studies described previously.[156,157]

**Evaluation of Hilar Lymph Node Metastases (N1 Disease)** Conventional radiography and tomography have been used extensively in the past to evaluate patients with bronchogenic carcinoma. In one study of 47 lung cancer patients, the reported sensitivity of conventional radiography for hilar disease was 53%, with specificity of 84% and accuracy of 71%[154] (Fig. 26.21). In a subsequent study of 84 patients with suspected intrathoracic neoplasm, sensitivity and accuracy were 64% and specificity was 65%.[158] Conventional tomography has been only slightly better, although it has been replaced by CT at the current time.

of 146 patients studied, only two of eight CT false-negative cases were attributable to microscopic metastases. On the other hand, 10 of 25 (40%) patients with mediastinal metastases in one study[122] and 7 of 11 (64%) patients in another study[144] had no enlarged nodes. There is no obvious explanation for these discrepant results.

Regardless of the actual frequency of microscopic lymph node metastases, it has been suggested that microscopic disease may have a better prognosis than metastases to enlarged nodes, and thus it may not be as crucial to detect microscopic spread of tumor preoperatively.[119,145,146] For instance, Pearson et al.[123] reported that the survival rate in patients whose N2 status was established at mediastinoscopy was significantly worse than in those with a negative mediastinoscopy, in whom the N2 status was established at subsequent thoracotomy. Similarly, Cybulsky et al.[147] found that patients with false-negative CT studies for mediastinal nodal metastases did better than those with true-positive CT studies (5-year survival following resection was 13.5% vs. 6.6%, respectively). These differences may relate to the distinction between normal-sized nodes with microscopic metastases versus enlarged metastatic lymph nodes, because enlarged nodes are more likely to be detected by mediastinoscopy and called abnormal at CT. Moreover, in a study of 115 patients who had undergone resection for NSCLC, Ishida et al.[148] found increased survival for patients with microscopic nodal metastases compared to

**FIGURE 26.21** Frontal chest radiograph shows a small nodule in the right mid lung (*black arrow*) and enlarged lymph nodes in the right hilum (*white arrow*) consistent with T1N1 disease.
**FIGURE 26.22**   Cavitary right upper lobe non–small cell lung cancer **(A)** (*arrow*); adjacent ground-glass (*GG*) opacity may represent local lymphangiectic spread of neoplasm. CT shows enlarged right hilar **(B)** and right paratracheal **(C)** lymph nodes (*arrows*); subsequent FDG–PET scan was consistent with nodal involvement by tumor only in the right paratracheal region.

The accuracy of CT in detecting hilar lymph node metastases is unclear (Figs. 26.14, 26.20, and 26.22). Three lung cancer studies reported low sensitivity (45% to 63%) and PPV (38% to 68%) and moderately high NPV (79% to 85%).[105,159,160] Two of these studies showed high specificity (92% to 93%), whereas the other reported only 58% specificity. Accuracies ranged from 59% to 82%.

**Evaluation of Mediastinal Lymph Node Metastases (N2/N3 Disease)**   The accuracy of conventional radiography in diagnosing mediastinal lymph node metastases has generally been quite low because of poor sensitivity (6% to 81%).[107,142,153,154,161–164] Disparate results have been reported

regarding the accuracy of CT in this setting (Figs. 26.14 and 26.22 to 26.25; Table 26.2). Many studies have found fairly high sensitivity for CT (>85%)[93,108,139,152,154,156,161,165–167] and high NPV (>85%; Table 26.2).[156,157,160,166–170] Others have found high specificity (>85%).[105,142,155–157,162,166,167,169–174] On the other hand, some of the more recent studies have shown low accuracy, resulting from both poor sensitivity and poor specificity.[88,106,159,175–177] Low sensitivity in some studies was attributed to the high frequency of microscopic metastases within normal-sized nodes.[105] Low specificity arose from the frequent occurrence of enlarged, hyperplastic nodes, particularly in patients with postobstructive pneumonitis.[159] Dales et al.[178] performed a metaanalysis of CT accuracy in staging
**FIGURE 26.23**  Right lower lobe non–small cell lung cancer **(A)** (*arrow*). Metastatic disease in subcarinal lymph nodes **(B)** (*arrow*), proven via transtracheal Wang needle biopsy.

**FIGURE 26.24**  Right upper lobe non–small cell lung cancer **(A)** (*arrow*). Enlarged subcarinal lymph **(B)** (*arrow*) showed no tumor upon transtracheal Wang needle biopsy; tumor involvement was proven via subsequent transesophageal endoscopic ultrasound (EUS)-guided biopsy.

mediastinal lymph nodes in NSCLC using data from studies published between 1980 and 1988. Pooled data revealed accuracy, sensitivity, and specificity figures that were approximately 80% each. They found no significant differences between the results from studies performed using fourth-generation versus third-/second-generation CT scanners. Moreover, there is no data to suggest that the helical or spiral scanners (either single or multidetector) improve CT accuracy in this setting.

Results within some of the individual studies quoted previously varied according to the size and morphologic criteria used for diagnosing metastatic disease to mediastinal lymph nodes. For example, Seely et al.[169] found that sensitivity increased and specificity decreased if long-axis diameter measurements were used instead of short-axis measurements or if adjacent nodal stations were considered together instead of considering each nodal station alone. Buy et al.[156] found maximal sensitivity when individual size thresholds were used for each individual nodal station, rather than using a uniform 10-mm size cutoff. In contrast, the data of Ikezoe et al.[157] showed slightly better sensitivity, albeit significantly worse specificity and accuracy, using a uniform 10-mm threshold rather than two separate criteria (13 mm for nodes in the subcarinal, precarinal, and tracheobronchial regions and 10 mm for nodes in other regions). Specificity in the study of Buy et al.[156] was maximized when the criterion for nodal abnormality was defined as follows: the short axis of the largest mediastinal node in the lymphatic drainage territory of the cancer was greater than or equal to 10 mm and the difference between

this node and the largest node in the other territories was greater than 5 mm. According to the investigation of Ratto et al.,[167] specificity increased dramatically if nodes 10 to 15 mm in short-axis diameter were considered indeterminate and excluded from analysis. However, 36% (44 of 123) of patients fell into this category, limiting the usefulness of this criterion. These authors also found increased specificity if the criterion for abnormal nodes was modified to include nodes 10 to 20 mm in short axis diameter with central necrosis and/or a discontinuous capsule.

In some studies, CT accuracy also appeared to depend on the precise anatomic location within the mediastinum being analyzed. In the study of McLoud et al.,[159] sensitivity of CT using a single size criterion (10-mm short-axis diameter) varied for individual nodal stations, ranging from 17% to 83%. Highest sensitivity was found in ATS regions 4R and 5, and lowest in 7, 4L, 10R, 10L. Specificity ranged from 72% to 94%, being highest in 10L and lowest in 10R. Platt et al.[151] compared staging of right and left lung tumors. Although prior reports have shown that CT is more accurate in evaluating right-sided mediastinal lymph nodes,[134,179] Platt et al.[151] found no statistically significant difference in staging accuracy between left and right lung cancers. This is probably a result of involvement of subcarinal and contralateral mediastinal lymph nodes, which are present more often in left lung cancers as compared to right-sided lesions.[180]

There were also some reported differences when the data were broken down according to cell type of the tumor. Ikezoe et al.[157] found that sensitivity for cases of adenocarcinoma (61%) was lower than that for squamous cell carcinoma (86%), but specificity for these two groups was almost the same (93% to 94%). There was an increased number of false-negative cases for adenocarcinomas, as compared to squamous cell carcinomas in both this study and two others[105,147]; the authors postulated that this probably indicated a higher frequency of microscopic metastases in adenocarcinomas. On the other hand, Ratto et al.[167] reported no difference in staging accuracy between squamous cell carcinoma and adenocarcinoma.

When calculated on a nodal station-by-station basis, results in some studies varied according to whether or not adjacent nodal stations were included in the analysis. For instance, inclusion of adjacent nodal stations led to an increase in sensitivity and a decrease in specificity in one investigation.[169] However, it is important to note that the clinical usefulness of a staging modality does not depend on accurate detection of disease in any individual node or nodal group, but rather on accurate detection of mediastinal nodal malignancy in the individual patient, either ipsilateral or contralateral to the neoplasm. Moreover, several authors have reported increased sensitivity in mediastinal lymph node evaluation when calculated on a patient-by-patient basis rather than on a nodal station-by-station basis.[143,159,169]

There are many possible reasons for the different reported CT accuracies among studies in detecting mediastinal metastases. Differences in patient populations and prevalence of mediastinal nodal disease would affect CT accuracy. Some investigations included all patients with known or suspected

**TABLE 26.2  CT Staging of Mediastinal Lymph Node Metastases in Patients with Known or Suspected Lung Cancer**

lung cancer, and some included only those with biopsy proven cancer. Others focused on clinical T1N0M0 cancers, that is, small lesions surrounded by lung parenchyma, with no conventional radiographic signs of mediastinal disease. Seely et al.[169] found higher specificity in their study of T1 cancers as compared to historical controls for all cancers. They postulated that this was partly caused by lack of obstructive pneumonitis with resultant enlarged, hyperplastic nodes.

In addition, there were substantial variations in scanning techniques. Some studies used older CT scanners (second generation) with long scan times (18 to 20 seconds), resulting in image blur from biologic motion; studies done on third- and fourth-generation scanners did not have this problem. CT examinations were performed using different section thicknesses, section spacing, and methods of administration of intravenous urographic contrast material. Gaps between slices[172,173,181] and motion artifact from long scan times[153,171–173] probably contributed to insensitive detection of enlarged lymph nodes. There were no uniform criteria for interpreting the scans, and definitions of nodal enlargement ranged from "any visible node" to 2-cm diameter, with or without morphological nodal changes. Some investigators interpreted their results on a patient-by-patient basis, some on a nodal station-by-station basis, and some on a nodal station-by-station basis including adjacent nodal stations. It can be quite difficult at CT and surgery to precisely determine the boundaries between one nodal station and an adjacent one, and some studies, including the large study of McLoud et al.[159] made no allowances for this pitfall. Many studies appeared to lack precise radiologic/surgical/pathologic correlation, and different methods of proof were employed. This is important because certain mediastinal node groups are accessible only at thoracotomy and would be missed at mediastinoscopy. Moreover, it is plausible that those studies employing thorough mediastinal lymph node dissection rather than nodal palpation and biopsy would show decreased CT sensitivity because of the inability to detect microscopic metastases within normal sized lymph nodes. However, Daly et al.[142] were unable to substantiate this premise. They divided their patients into two surgical groups: in group I (51 cases) mediastinal nodes were removed only if palpably abnormal, if CT showed enlarged nodes, or if hilar nodes were grossly tumorous. In group II (97 cases), the mediastinum was explored in every patient and all nodes were resected. There was no statistically significant difference in CT sensitivity between these two groups (88% and 75%, respectively).

## CT Evaluation of Distant Metastases

Several autopsy series have demonstrated an overall prevalence of distant metastases in patients with end-stage lung cancer as high as 93%. Key sites involved include liver (33% to 40%), adrenal (18% to 38%), brain (15% to 43%), bone (19% to 33%), kidney (16% to 23%), and abdominal lymph nodes (29%).[182–184] Autopsy studies performed in the immediate postoperative period as well as one report of abdominal exploratory surgery prior to thoracotomy for bronchogenic carcinoma have shown lower prevalences of metastatic spread to individual organs (liver 7% to 14%, adrenal 1% to 9%, brain 4%, bone 1% to 5%,

kidney 0% to 4%, abdominal lymph nodes 5% to 8%). Nonetheless, the overall prevalence of occult metastatic disease was fairly high (18% to 36%) in these pre-CT-era studies.[185–188] One of these studies found that extrathoracic metastases were more common among men with adenocarcinoma than among those with squamous cell carcinoma.[185] A more recent autopsy report also found a moderately high frequency (19% of 103 = 18%) of distant metastases in patients dying in the perioperative period after lung cancer resection.[186]

Out of 95 patients with newly diagnosed NSCLC and N0 disease at CT, one report demonstrated CT evidence of extrathoracic tumor spread in 24 of 95 (25%) patients. These included metastases to brain (10), bone (8), liver (6), adrenal (6), and soft tissue (2) (some patients had involvement at more than one site).[189] An additional, prospective study of 146 patients with potentially resectable NSCLC (clinical T3 or less and N2 or less)[190] revealed distant metastatic disease in 30 of 146 (30%) patients. These metastases were detected by chest or abdominal CT, brain CT, abdominal ultrasonography, and/or bone scan, and presumably each finding was proved. The lesions were distributed as follows: 13% bone, 13% brain, 12.3% liver, 7.5% adrenal, 1.4% kidney, and 1.4% subdiaphragmatic nodules. (In 17 patients the metastases were "multiorganic.") The authors indicated that patients with nonsquamous cell carcinomas (adenocarcinoma or large cell carcinoma) were at significantly greater risk for metastases outside the thorax than those with squamous cell cancer ($p$ = less than 0.5). No relationship was detected between the TN stage and the existence of metastases in adenocarcinoma and large cell adenocarcinoma. There was, however, an association between advanced N stage (IIIa) and presence of extrathoracic metastases for squamous cell cancers. None of the stage I intrathoracic squamous cell cancers had metastases. Many patients with metastases to brain, bone, liver, and adrenal were asymptomatic. Thus these authors advocated the routine performance of preoperative upper abdominal CT and/or ultrasonography in all patients except those with asymptomatic stage I squamous cell cancers. Brain CTs were suggested for all patients with adenocarcinoma and large cell carcinoma, as well as for those with squamous cell cancer and neurologic symptoms. Bone scanning was suggested only in those patients with clinical and laboratory indications of possible bone involvement by metastatic disease.

A study by Quint et al.[191] found 21% overall prevalence of distant metastases in 348 patients with newly diagnosed NSCLC. In 56% of patients with distant metastases, the lesions were detected using chest or abdominal CT. Brain, bone, liver, and adrenal glands were the most common sites of disease, in decreasing order (Fig. 26.26). Brain metastases often occurred as an isolated finding. On the other hand, isolated liver metastases were uncommon, and therefore the incremental yield of abdominal CT over chest CT was quite small. Thus these authors concluded that abdominal CT does not appear to be an effective method of screening for metastases if chest CT has been performed. A recent report that examined clinical predictors of metastatic disease to the brain from NSCLC found that

**FIGURE 26.26**   Liver metastases (*black arrows*) and body wall metastasis (*white arrow*) in a patient with metastatic adenocarcinoma of the lung. Also note right pleural thickening and effusion caused by metastatic disease.

the probability of brain metastases correlated with size of the primary tumor, cell type, and intrathoracic lymph node stage, but not with gender, patient age, or central versus peripheral location of the tumor; adenocarcinomas and undifferentiated cell types were more commonly associated with tumor spread to the brain compared to squamous cell carcinoma.[192]

Despite the high prevalence of adrenal metastases from bronchogenic carcinoma, approximately two thirds of adrenal masses in patients with NSCLC actually represent adenomas, rather than metastases.[193] Adrenal adenomas are found in about 3% to 9% of autopsies on adults,[194,195] and approximately 1% of patients undergoing abdominal CT have benign incidental adrenal masses larger than 1 cm.[196] In a study of 546 patients with lung cancer, 22 of 546 (4%) patients had one or more adrenal masses on preoperative CT.[197] Seventeen of twenty-two had proof of adrenal status via either biopsy or follow-up. A total of 5 of these 17 were malignant (29%) and 12 of 17 were benign (71%). These authors reported that adenomas were well defined and low in attenuation and showed a smooth, high attenuation rim and involvement of only part of gland. Features of metastases included a low attenuation, large (larger than 5 cm) mass without a rim and irregular, mixed attenuation.[197] Unfortunately, there is significant overlap in the appearance of adrenal metastases and benign adenomas on routine, contrast-enhanced CT. Therefore detection of an adrenal mass on such a study requires further workup. Unenhanced CT densitometry can be used to distinguish between lipid-rich adenomas and nonadenomatous masses. Using a cutoff of 10 HU, an accuracy of more than 90% can be achieved for the diagnosis

of a lipid-rich adenoma.[198,199] In addition, considerable work has recently been done using dedicated adrenal CT with a combination of noncontrast, postcontrast and delayed enhanced images in evaluating wash-out characteristics in adrenal masses.[200–203] Using these techniques, it is usually possible definitively to diagnose benign adrenal cortical adenomas without biopsy. If these imaging studies suggest the presence of a metastasis, biopsy proof is generally required before altering therapy.

## Usefulness of CT in Clinical T1N0M0 Patients

There has been controversy over the usefulness of CT in the preoperative evaluation of patients with radiographic T1N0M0 cancers. Reports in the surgical and radiologic literature give varying figures for the prevalence of proven mediastinal lymph node or distant metastases in this set of patients, ranging from 3% to 33%.[139,204–211] The lower prevalences may be underestimations, reflecting incomplete mediastinal nodal sampling and/or lack of good-quality preoperative upper abdominal CT scanning. Because distant metastases remain a contraindication to thoracotomy, and known mediastinal metastases will alter treatment at many institutions, CT is potentially useful by detecting such occult disease. In the series of Parker et al.[206] CT evidence for unresectable spread of disease was obtained in 12 of 36 patients with radiographic T1N0M0 disease, including metastases to the liver (four patients), the adrenal (one patient), an axillary lymph node (one patient), and mediastinal lymph nodes (eight patients). Conces et al.[211] reported CT signs of inoperability in 7 of 26 radiographic T1N0M0 cases with surgical correlation (27%). Metastatic disease was confirmed in four of these seven cases, including mediastinal metastases in three (3 of 26, 12% prevalence) and one contralateral lung malignancy. Of 31 radiographic T1N0M0 patients reported by Heavey et al.,[210] eight (26%) had proven spread of disease, including six patients with malignant mediastinal lymph nodes (19% prevalence), one with an adrenal metastasis, and one patient with a metastasis to the contralateral lung. CT detected 5 of these 8 cases, thus preventing thoracotomy in 5 of 31 (16%) patients. As noted by Heavey et al.,[210] preventing thoracotomy in only 16% of patients resulted in significant overall cost savings, even when the cost of CT scans and prethoracotomy biopsies is taken into account. Thus these studies suggest that CT is highly useful in the preoperative workup of such patients.

On the other hand, another study of radiographic T1N0M0 tumors by Pearlberg et al.[209] found only 2 of 23 (8.7%) patients with proven mediastinal metastases; however, these patients did not undergo total mediastinal nodal sampling, and thus the true prevalence may have been somewhat higher. CT findings averted thoracotomy in only one patient, due to mediastinal adenopathy subsequently proven at mediastinotomy to contain metastatic disease. Becker et al.,[207] in a prospective investigation of 38 patients with presumed lung cancer (radiographic T1N0M0), found proven mediastinal nodal metastases in only one patient. Eleven of thirty-eight lesions turned out to be benign. Thus, preliminary data indicate that CT may be helpful and cost-effective in the preoperative assessment of patients with radiographic T1N0M0 lesions when the diagnosis of lung cancer has been proven.

**Predicting Resectability with CT**   Prediction of resectability depends on accurate detection of T4, N3, and/or M1 tumors. One prospective study of 96 patients with lung cancer and preoperative CT found a 12% prevalence of unresectability.[212] CT criteria for unresectability included encasement of the proximal pulmonary arteries or carina, or gross mediastinal involvement by tumor, or widespread lymphadenopathy or distant metastases. Using these criteria, CT was 96% accurate and showed 97% PPV and 50% NPV for resectability. Another, more recent study found that CT erred in predicting resectability in 12 of 50 patients (24%).[213] In three patients, a malignant pleural effusion was missed at CT, and in nine patients, operable patients were deemed inoperable at CT due to incorrect diagnosis of malignant pleural effusion (three patients) or direct mediastinal tumor invasion (six patients). Therefore the usefulness of CT in this setting is uncertain.

**Current Usefulness of Pretreatment CT**   It is important for the radiologist to know what treatment options are available at his or her particular institution and what features of the tumor or its spread would affect treatment decisions. At most institutions, proven T4, N3, or M1 disease is considered unresectable. Patients with N2 disease may be treated with preoperative chemotherapy and radiation therapy. CT findings are used to help define the extent of the primary nodule or mass, look for calcifications that might indicate benignancy, determine its relationships with nearby structures, assess for resectability, and suggest the type of surgery required for resection. If enlarged mediastinal lymph nodes are detected, CT may be used to direct preoperative lymph node sampling via transbronchoscopic Wang needle biopsy, TEE, EBUS, mediastinoscopy, mediastinotomy, or video-assisted thoracoscopic surgery (VATS). Nodes accessible to transbronchoscopic Wang needle biopsy include the paratracheal, tracheobronchial, and subcarinal groups. Transbronchial Wang needle biopsy may be facilitated by ultrasound guidance. Nodes accessible to mediastinoscopy include pretracheal, anterior subcarinal, and anterior tracheobronchial groups. Lymph nodes in the aortopulmonary window are not accessible using these techniques, and tissue sampling requires other approaches such as VATS or anterior thoracotomy. As an alternative to surgical staging procedures, some groups advocate the use of CT-guided hilar and mediastinal lymph node biopsies,[214–216] although this is not common practice unless the nodal masses are large.

In summary, at many institutions, preoperative chest CT, including the adrenal glands, is routinely performed on all patients suspected of having NSCLC. Dedicated abdominal CT is not generally necessary, given the low frequency of isolated liver metastases. Intravenous contrast material is usually administered to help distinguish vessels from lymph nodes and to aid in evaluation of primary tumor extent. However, some investigators believe that intravenous contrast is unnecessary, because the added information obtained from the use of contrast material rarely changes tumor stage and does not substantially influence management decisions.[217]

Many CT studies have reported high NPVs in detecting metastatic disease to mediastinal lymph nodes. In addition, Daly et al.[168] reported that overall projected 2- and 5-year survival rates for 37 CT false-negative patients in their series were 40% and 28%, respectively. Given this information, many investigators believe that a negative CT obviates the need for mediastinoscopy, and these patients should go directly to thoracotomy.[146,160,168] An exception may be made for patients with T3 tumors or central adenocarcinomas, due to the high incidence of positive mediastinal lymph nodes and low NPV of CT in this setting.[168] In addition, patients with suspected chest wall invasion, including Pancoast tumors, should probably have mediastinoscopy regardless of CT findings, because mediastinal nodal metastases and chest wall invasion portend a poor prognosis, and these patients are not usually felt to be surgical candidates.[100,101] In a dissenting opinion, Pearson et al.[218] recommended mediastinoscopy for all T2 and T3 tumors and for T1 adenocarcinomas and large cell carcinomas, even in the setting of a negative CT. A more recent study by Kernstine et al.[176] took this a step further, concluding that CT was not sensitive or specific enough to change their current recommendation to perform surgical evaluation for mediastinal lymph node staging in all patients. On the other hand, it is generally agreed that all patients with abnormal mediastinal lymph nodes at CT need lymph node biopsy (or futher imaging with FDG–PET); therapy should not be planned based on unproven, positive CT findings. Mediastinal and hilar lymph node stations, as delineated by the ATS, have been mapped using axial CT scans in a recently published atlas[219]; reference to such standard locations is essential in directing accurate lymph node sampling.

**CT Imaging in Evaluating Response to Therapy**
Published reports have shown mixed results regarding the usefulness of CT in evaluating for tumor response to therapy. A study of 21 patients who were treated with neoadjuvant concurrent chemoradiotherapy followed by surgery found that CT findings in the primary tumor and mediastinal lymph nodes were not helpful in evaluating tumor response.[220] A more recent study of 57 patients receiving chemotherapy for NSCLC reported that early restaging CT scans (within 1 month after treatment) identified six patients with tumor progression, thereby allowing a change to more appropriate therapy.[221] However, one neoadjuvant chemotherapy study noted that CT findings underestimated the frequency of pathologic complete response.[222] Moreover, another small study concluded that the therapeutic effect on tumors is generally underestimated using CT size criteria after chemotherapy and/or radiation therapy; these authors suggested that CT criteria for response should include change in shape (from round to oval or irregular) and disappearance of contrast enhancement.[223] Other studies have suggested that serial CT scans obtained early during radiation therapy may accurately predict final tumor volume; however, the clinical significance of tumor volume reduction is uncertain, because it does not necessarily indicate histologic tumor clearance.[224,225] The bottom line seems to be that posttherapeutic increase in tumor size at CT indicates lack of tumor response. Decrease in tumor size is consistent with tumor response, but does not necessarily either indicate or exclude complete pathologic response.

## MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging is used infrequently in the staging of lung carcinoma. The development of MDCT (up to 64 detector rows) now allows the rapid acquisition of volumetric data sets that may be reformatted in any plane, giving multiplanar capabilities similar to MRI. The current major advantages of MRI over CT include its superior contrast resolution and ability to image vascular structures without the use of intravascular contrast material. However, MRI is susceptible to motion artifacts, has poorer spatial resolution than CT, calcification is difficult to image, and the relatively low signal from the air containing lung parenchyma limits the evaluation of parenchymal abnormalities. Given these limitations, the role of MRI in the detection and staging of bronchogenic carcinoma has been limited, and MRI tends to be used only to answer very specific questions that CT has been unable to resolve.[226–233]

## Evaluation of the Primary Tumor

**Chest Wall Invasion**    MRI maybe slightly superior to CT for the staging of local tumor extent into the adjacent chest wall, because of its superior contrast resolution[234,235] (Figs. 26.27 and 26.28). Chest wall invasion is best depicted as disruption of the normal high signal intensity extrapleural fat by moderate-intensity soft tissue on spin-echo (SE) T1-weighted images or as abnormal high-signal intensity tissue on T2-weighted images. The use of surface coils may provide high-resolution images depicting these findings. However, unfortunately, inflammatory and malignant tissues may have similar appearances on MRI, making it difficult to distinguish between these two entities.[235–238] Like CT, in the absence of a pleural effusion, MRI cannot differentiate the visceral from the parietal pleura. In most studies that have compared the two modalities, the accuracy rates for assessing chest wall invasion have been similar.

A

B

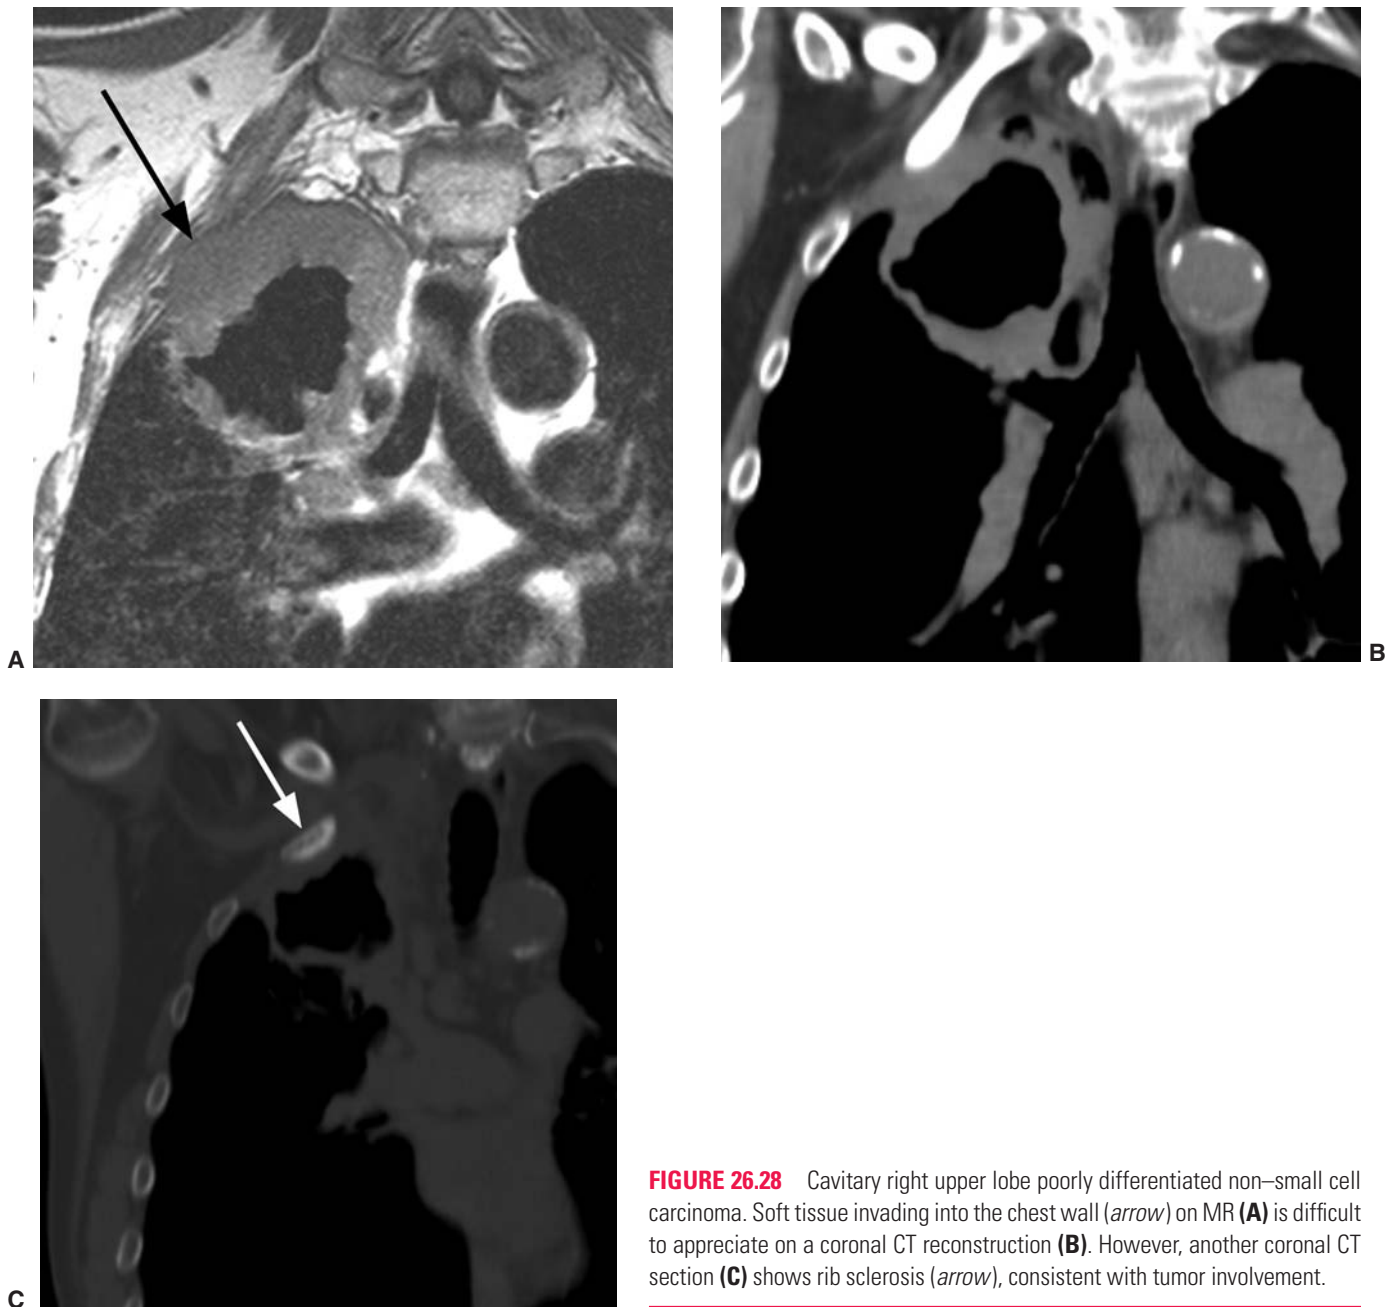
C
**FIGURE 26.27**    Right upper lobe adenocarcinoma with chest wall invasion. Note rib erosion (*arrow*) at CT **(A)** and abnormal soft tissue in the chest wall (*arrow*) on axial **(B)** and coronal **(C)** MR.


**FIGURE 26.28** Cavitary right upper lobe poorly differentiated non–small cell carcinoma. Soft tissue invading into the chest wall (*arrow*) on MR **(A)** is difficult to appreciate on a coronal CT reconstruction **(B)**. However, another coronal CT section **(C)** shows rib sclerosis (*arrow*), consistent with tumor involvement.

The overall reported sensitivity for chest wall invasion by MRI is 63% to 90%, with a specificity of 84% to 86%.[106,239,240] Haggar et al.[241] demonstrated that SE MRI had a NPV of 100% for chest wall invasion. More importantly, in nine cases in which CT was equivocal, MRI accurately resolved the issue. Therefore, MRI may be helpful in cases with equivocal CT findings.[242] There have, however, been no studies comparing MDCT and MRI.

**Superior Sulcus Tumors** MRI is still the modality of choice in evaluating superior sulcus tumors.[243–246] Coronal and sagittal MR images facilitate evaluation for brachial plexus and mediastinal vascular involvement; although contrast enhanced MDCT is good for delineating the vascular anatomy, it will not always identify the brachial plexus (Fig. 26.29).[106,235,242–244,247] In addition, vertebral body invasion, involvement of the neural foramina and marrow infiltration can be readily determined on MRI.[244] Accuracy rates of 94% have been reported with MRI, as compared to 63% with CT, in assessing the true extent of superior sulcus tumors.[234,243,244]

**Mediastinal Invasion** MRI has the same limitations as CT in differentiating a tumor that abuts the mediastinal structures from one invading the mediastinum.[108,248] Both CT and MRI
**FIGURE 26.29**   Superior sulcus tumor. Coronal T1-weighted MRI **(A)** shows involvement of the lower roots of the brachial plexus (*arrow*), and sagittal T1-weighted MRI **(B)** shows encasement of the subclavian artery (*arrow*). Coronal **(C)** and sagittal **(D)** CT reformats reveal the vascular invasion (*arrow*), but not the brachial plexus involvement.

depict mediastinal invasion by lung carcinoma with equal accuracy ranging between 56% to 89% for CT and 50% to 93% for MR.[102,106–108,230,242,249] The Radiology Diagnostic Oncology Group (RDOG) Trials, showed slight superiority for MRI in diagnosing mediastinal invasion in a small group of patients as compared to CT, with areas under the ROC for MRI being 0.924 (SE 0.034) versus 0.832 (SE 0.041) for CT.[106]

Involvement of the cardiac chambers, although rare, and the pericardium can be easily evaluated with MRI. If the normal 2 to 3 mm thick curvilinear low–signal-intensity rim representing the pericardium is disrupted, then tumor extension to the pericardium is to be suspected, although this alone is not a contraindication to tumor resection.[250,251] Using cine MR to identify the sliding motion between the mass and adjacent

structures, cardiovascular invasion can be assessed, showing a reported accuracy of 94%.[252]

### MRI Evaluation of Hilar and Mediastinal Lymph Nodes

Although nodal size is a nonspecific criterion, it is routinely used to help distinguish normal from tumor-containing lymph nodes; generally a size threshold of 1 cm is used.[253] CT and MR are fairly accurate in detecting enlarged lymph nodes in the hilar and mediastinal regions. However, the cause for nodal enlargement maybe reactive hyperplasia or metastases, and these cannot be easily differentiated using either modality.[159] One limitation of MRI for assessing nodal staging is its poor spatial resolution; small adjacent nodes that are discrete on CT may appear as one large, indistinct mass at MRI, leading to an erroneous diagnosis of nodal enlargement.[254] In addition, MRI is poor for detecting calcification, and thus enlarged benign nodes containing calcification may be misclassified as being malignant. CT and MRI have accuracies of 62% to 68% and 68% to 74%, respectively, for detecting metastatic disease to hilar lymph nodes and neither modality will identify micrometastases within normal size lymph nodes.[106,107,251,254–258] Lymph node morphology and signal characteristics on MR have not been useful in predicting the presence or absence of metastatic disease.[106,108,239,253,256,259]

MRI performed after intravenous infusion of ultra small iron-oxide particles that are taken up by the reticuloendothelial system has been used to distinguish between nontumorous lymph nodes and tumor-containing lymph nodes.[260,261] This technique has been shown to be of value in distinguishing between normal and tumor-containing lymph nodes in small series of patients with head and neck and pelvic malignancies,[262–264] but the results in the chest have been disappointing, with a reported specificity of only 37%.[265] The developments of PET/CT and endobronchial ultrasound combined with fine needle cytology hold more promise.[266]

### MRI Evaluation of Distant Metastases

Whole-body MRI, using fast breath-hold T2W sequences with a rolling table top, has been suggested as a screening method for metastatic disease and would appear to be as good as conventional imaging for the detection of cerebral, hepatic and bone metastases.[267] With regard to adrenal masses, like CT, MRI is able to identify lipid-rich adenomas. On lipid-sensitive out-of-phase images, lipid-rich adrenal adenomas show signal loss and appear dark in comparison to a reference organ such as the spleen,[268] whereas most adrenal metastases do not show this change on the out-of-phase images. This technique has an accuracy rate of >90% in the diagnosis of a lipid-rich adenoma.[269–271] Thus either CT or MR can be used to diagnose adrenal lipid-rich adenomas and distinguish them from metastases. However, contrast enhanced CT with delayed imaging can distinguish both lipid-rich and lipid-poor adenomas from nonadenomas,[201,272] and this is an advantage that CT currently has over MR.

The incidence of brain metastases in patients with NSCLC is approximately 12% to 28% over the entire course of the disease. Imaging is usually undertaken when the patient becomes symptomatic, although early screening of asymptomatic patients has been suggested in an attempt to instigate early treatment and improve survival. In a study by Kim et al.,[273] using a modified MR technique, the incidence of asymptomatic brain metastases at the time of initial staging was 21%, with upstaging in 16% of patients who were initially considered suitable for surgery. These authors therefore suggested that a limited MRI, which was both sensitive and cost-effective, should be offered during initial staging for all patients.

# Positron Emission Tomography in Lung Cancer

## BASIC PRINCIPLES AND TECHNICAL ASPECTS

Positron emission tomography (PET) is the most selective and sensitive (picomolar to nanomolar range) imaging technique for measuring molecular pathways and interactions in vivo. Positron-emitting isotopes are radioactive variants of elements naturally occurring in organic molecules and can be incorporated without changing the chemical and biological characteristics of the labeled molecule. They decay by emission of a positron, which is the subatomic, positively charged, antiparticle of the negatively charged electron. The positron will annihilate with an electron and create two 511-keV photons, emitted in opposite directions. The detection of numerous of these annihilations by the detector rings of the PET camera generates high-resolution pictures (5 to 10 mm) indicating the sites of tracer accumulation in the body.

The most frequently used tracer in PET oncology is the glucose analogue $^{18}$F-fluorodeoxyglucose (FDG). Its use is based on the increased glycolysis of cancer cells compared with normal tissues. This increased glycolysis is linked to an increase in glucose membrane transporters and upregulation of the principal enzymes that control the glycolytic pathway.[1] FDG uptake is, however, not specific for cancer cells, and increased FDG uptake is also seen in some inflammatory conditions, the most common cause of false-positive FDG–PET findings.[2] The ability to perform whole-body imaging within one examination makes PET an ideal technique for cancer staging. In clinical oncology, the FDG uptake is often quantified as the standardized uptake value (SUV; i.e., the ratio of the activity in tissue per unit volume to the injected dose per patient body weight). In vitro studies demonstrated that the amount of FDG uptake in tumor tissue is mainly related to the number of viable cancer cells[3] and their proliferation capacity.[4] Therefore, SUV changes on FDG-PET can be used to evaluate treatment efficacy, because tumor cell kill results in a proportional reduction of the FDG signal.[5] Furthermore, the correlation between FDG uptake and proliferation capacity allows in vivo evaluation of tumor aggressiveness.

Interpretation of PET scans is hampered by the lack of anatomical detail, which makes it sometimes difficult to correctly localize hot spots or differentiate tumor tissue from benign structures with physiologically high FDG uptake (e.g., muscle, brown fat, gut). Therefore, PET always has to be interpreted in conjunction with anatomical images such as computed tomography (CT). Attempts to align or coregister CT and PET data sets acquired on separate machines with fusion software are generally only successful in the brain, whereas in the remainder of the body differences in patient setup present a challenge to the software approaches. Recently, integrated PET/CT systems were introduced, which enable acquisition of PET and CT data in the same session without changing the patients' position. Since the installation of the first clinical PET/CT in 2001, the technology has gained widespread use and all new PET scanners installed today are integrated PET/CT machines. Another advantage of PET/CT is the possibility to use the CT component for attenuation correction of the PET images and reduce the scan time substantially (–50%), but specific artifacts can sometimes be a problem.[6] An example are the errors in localization of lesions caused by breathing and the difference in scan time to acquire a PET (minutes) and CT image (seconds). This can result in incorrect anatomical localization of lesions near the diaphragm on the attenuation-corrected images (Fig. 27.1). High-density objects (dental fillings, chemotherapy ports, barium contrast) can lead to an overestimation of tracer uptake, thereby producing false-positive PET findings. Therefore, non–attenuation-corrected PET images, which do not manifest these errors, should always be reviewed in parallel to recognize these artifacts.

Although FDG has made the way for PET in clinical oncology, several other radiopharmaceuticals can be used to study

**403**
**FIGURE 27.1** Ga-68 DOTATOC scan of patient with a typical carcinoid of the left lung (not shown). Existing liver metastasis were rather difficult to discern on the portal phase of CT **(A)**, but Ga-68 DOTATOC PET proved to be a valuable adjunct to establish the liver lesion **(B,C)**. Misalignment of PET and CT caused by breathing introduced attenuation artifacts and caused erroneous projection of the liver metastasis in the base of the right lung on attenuation-corrected (AC) PET images **(B)**. Therefore, non-AC images (which do not harbor these artifacts) should always be reviewed **(C)**.

processes such as blood flow ($H_2{}^{15}O$), hypoxia ($^{18}$F-MISO), DNA synthesis ($^{18}$F-fluorothymidine [FLT]), and somatostatin receptor expression (Ga-68 DOTATOC). Certainly, with the rapid development of molecular-targeted treatments, noninvasive assessment of metabolic processes will become increasingly important to assess efficacy of these drugs. However, in the succeeding text, PET always refers to FDG-PET, unless otherwise specified. It summarizes the standard indications, other applications, and innovative use of this imaging technique (Table 27.1).

**Interpretation of PET Images** If the aim of the PET study is just to stage the patient, visual analysis of non–attenuation-corrected images (i.e., hot spots higher than background activity being regarded positive for tumor) is probably just as good as SUV images, as has been pointed out by different prospective studies, both for the discrimination of nodules as well as for the evaluation of mediastinal involvement.[7]

There is a low degree of physiologic uptake of FDG in thoracic structures, including the lung, the heart, the aorta and large arteries, esophagus, thymus, trachea, thoracic muscles, bone marrow, and joints and soft tissues. This low background tracer activity builds the image contour. The high degree of FDG uptake in the brain and the excretory system impedes sensitive detection in these organs.

False-negative results may be lesion or technique dependent (Table 27.2). A critical mass of metabolically active malignant cells is required for PET detection.[8] Interpretation should be careful in tumors with decreased FDG uptake such as very well-differentiated adenocarcinoma, bronchioloalveolar carcinoma, or carcinoid tumors. FDG-avid lesions smaller than 5 mm may be false negative because of the limitations in spatial resolution of the PET scanner and partial volume effects in small lesions. In the lower lung fields, the detection limit may even go up to 10 mm as a result of additional respiratory motion. Factors inherent to the technique are paravenous FDG injection or high-baseline glucose serum levels. Blood glucose levels should be checked, and it is advised to proceed only if the glucose level is within a normal range prior to tracer injection. Although diabetic patients were often excluded

| TABLE 27.1 | Applications of FDG–PET Scan in Lung Cancer |
|---|---|

**Diagnosis of Pulmonary Nodules and Masses**

Differentiation of malignant vs. benign nodules
    Reduce the need of unwanted invasive procedures
    Aid in decision algorithms
False positives
    Inflammatory respiratory disorders
False negatives
    Small tumors (<8–10 mm)
    Tumors with low glucose metabolism

**Mediastinal LN staging**

High negative predictive value for LN metastasis
    Reduce the number of invasive tests, without loss of accuracy
    Better guidance of invasive procedures
False positives
    Inflammatory LNs
False negatives
    Low FDG uptake in primary tumor
    LNs obscured by centrally located tumors or hilar nodes

**Extrathoracic Staging**

Complement to conventional imaging
    Detection of unexpected metastasis
    Characterization of equivocal lesions
False positives
    Inflammatory lesions
    Second primary tumor
False negatives
    Low FDG uptake in primary tumor
    Small metastatic deposits

**Other Applications**

Prognosis (independent from TNM stage)
Early response evaluation during chemotherapy
Reassessment after induction treatment
Planning of radiotherapy
Diagnosis of recurrence after radical therapy
Selective use in lung cancer screening

**Innovative Indications**

Use of tracers other than FDG
Improvements in PET/CT cameras
Response evaluation in molecular therapy

| TABLE 27.2 | Caveats in the Interpretation of PET in Lung Cancer Patients |
|---|---|

**Causes of False-Negative Findings**

Lesion dependent
    Small tumors (<8–10 mm)
    Ground-glass opacity neoplasms (BAC)
    Carcinoid tumors
Technique dependent
    Hyperglycemia
    Paravenous FDG injection
    Excessive time between injection and scanning

**Causes of False-Positive Findings**

Infectious/Inflammatory lesions
    (Postobstructive) pneumonia/abscess
    Mycobacterial or fungal infection
    Granulomatous disorders (sarcoidosis, Wegener)
    Chronic nonspecific lymphadenitis
    (Rheumatoid) arthritis
    Occupational exposure (anthracosilicosis)
    Bronchiectasis
    Organizing pneumonia
    Reflux esophagitis
Iatrogenic causes
    Invasive procedure (puncture, biopsy)
    Talc pleurodesis
    Radiation esophagitis and pneumonitis
    Bone marrow expansion postchemotherapy
    Colony-stimulating factors
    Thymic hyperplasia postchemotherapy
Benign mass lesions
    Salivary gland adenoma (Whartin)
    Thyroid adenoma
    Adrenal adenoma
    Colorectal dysplastic polyps
Focal physiological FDG uptake
    Gastrointestinal tract
    Muscle activity
    Brown fat
    Unilateral vocal cord activity
    Atherosclerotic plaques

BAC, bronchioloalveolar cell carcinoma.

in prospective studies, FDG uptake is probably not significantly influenced in these patients if the blood glucose levels are reasonably controlled.

False-positive findings are a result of the fact that FDG uptake is not tumor specific, and can be found in all active tissues with high glucose metabolism, in particular inflammation (Table 27.2). Therefore, clinically relevant FDG-positive findings, especially if isolated and decisive for patient management, require confirmation. The differentiation between metastasis, a benign or inflammatory lesion, or even an unrelated second malignancy should be made by other tests or tissue diagnosis. The major causes of false-positive results in lung patients are infectious, inflammatory and granulomatous disorders, and iatrogenic procedures, such as thoracocentesis, placement of a chest tube, percutaneous needle biopsy, mediastinoscopy, and talc pleurodesis.

### Diagnosis of Pulmonary Nodules and Masses

Peripheral solitary pulmonary nodules (SPNs) represent a diagnostic challenge, especially if they are noncalcified. With the increased interest in the use of low-dose spiral CT for early lung cancer detection, the number of coincidental SPNs will only increase.

Multiple studies—often using a threshold maximum SUV ($SUV_{max}$) of >2.5 for the diagnosis of malignancy—have proven the accuracy of PET in the differentiation of malignant from benign lesions (Fig. 27.2). In a metaanalysis, based on series with nearly all nodules larger than 1 cm, an overall sensitivity, specificity, positive and negative predictive value of 96%, 78%, 91%, and 92% was reported.[9]

False-negative findings may occur if a critical mass of metabolic active cells for detection on PET is not in place; therefore, exclusion of malignancy is more hazardous in small lesions.[10] In that respect, the use of the $SUV_{max}$ threshold of >2.5 should better be abandoned, because quite some lesions with $SUV_{max}$ ≤2.5 are malignant.[11] A large prospective series (n = 585) looked at the accuracy of integrated PET/CT scan in SPNs ≤2.5 cm.[12] If the $SUV_{max}$ was between 0 and 2.5, there was a 24% chance of malignancy; if between 2.6 and 4.0, it was 80%; and if >4, it was 96%. Likewise, the accuracy of PET is also challenged in small nodules detected in lung cancer screening studies.[13] Nonetheless, selective use of PET was reported to be useful in some series,[14–16] but with more limitations than in the daily practice population presenting with SPNs.

False-negative images are also common in tumors with low metabolic activity, bronchioloalveolar cell carcinomas in particular,[17,18] because they have significantly lower expression of the glucose transporter Glut-1 compared with other non–small cell lung cancer (NSCLC) subtypes.[19] Carcinoid tumors also have a low FDG uptake,[20,21] but the presence of somatostatin receptors in these neuroendocrine tumors allows PET imaging with radiolabeled somatostatine analogues, such as Ga-68-DOTATOC[22] (Fig. 27.1).

**FIGURE 27.2** Solitary pulmonary nodule in the left upper lobe **(A)**, with clear FDG uptake on PET **(B)**. Surgery revealed pT1N0 adenocarcinoma. Solitary nodule in the right upper lobe **(C)**, no uptake higher than lung background on PET **(D)**. No change during follow-up, probably hamartoma.
**FIGURE 27.3** A 54-year-old woman in follow-up after radical radiotherapy for right vocal cord squamous cell carcinoma. Detection of a nodule in the right upper lobe on chest radiograph **(A)**, confirmed at CT scan **(B)**. PET showed some FDG avidity in the lesion **(C)**, and in addition, a prominent FDG-positive lesion in the right hemicolon **(D)**. Further studies pointed at postradiotherapy inflammation in the right lung and adenocarcinoma of the ascending colon.

False positives occur because of trapping of FDG in activated granulocytes and/or macrophages in several inflammatory conditions[23–25] (Fig. 27.3), and this leads to a variable specificity (50% to 100%) in different series, according to the prevalence of certain inflammatory or infectious diseases, such as tuberculosis or histoplasmosis. A nice pictorial overview of false-positive findings is given in Shim et al.[26] In special situations, specificity can be improved by looking at the FDG uptake kinetics using dual-time–point imaging at 1 and 2 hours (FDG continued uptake in malignant versus rapid uptake followed by washout in benign lesions).[27]

**Lung Cancer Staging** CT, with its excellent anatomic detail, remains the method of choice to assess the *T-factor*, that is, the extent of the primary tumor in relation to lung fissures, mediastinal structures, pleura, or chest wall. PET on its own has little to add to the accuracy of CT because of its lower spatial resolution.[28] For the *N-factor*, one of the main limitations of CT—using only a size criterion—is its low accuracy in differentiating benign from malignant lymph nodes (LNs).[29,30] Since about a decade, PET imaging—with its metabolic information—was proven to be superior,[31,32] a finding confirmed in different meta-analyses based on a multitude of prospective studies.[33–35] PET on its own is more accurate, but is still not perfect in defining the N-status. Lack of anatomical detail is one important reason, for example, PET images often do not allow to distinguish hilar from mediastinal LNs (Fig. 27.4), or to exclude LNs in patients with a large centrally located tumor. Many well-designed prospective studies also demonstrated a gain in accuracy in the *M-factor*, mainly because PET is able to detect additional metastatic lesions in 5% to 25% of the patients.[36–45] There is a substantial variation in the proportion of patients with additional lesions, because authors differ in the definitions of "unexpected" lesions; in most series, an equivocal lesion on conventional imaging, found to be metastatic on PET, was not regarded as unexpected, although this was the case in some series.[37,40] If PET helps to characterize equivocal lesions, this is usually for adrenal lesions, contralateral lung nodules, or bone scintigraphy abnormalities.[36–38,40]

Nowadays, the best combination of morphologic and metabolic information is obtained by integrated PET/CT
**FIGURE 27.4** Transaxial **(A)** and coronal **(B)** PET images with a right lung tumor and accompanying adenopathy, either in the right hilar or mediastinal station. scanners. Comparative results for the *T-factor* are listed in Table 27.3. Comparisons are often made with PET alone or with PET images in visual correlation with CT images. Although the first comparison may be of scientific interest, it is of little clinical relevance. Papers in the late 1990s already pointed out that interpretation of PET images in visual correlation with CT images was the minimum standard.[31,46] Three studies reported better results with PET/CT in comparison with PET alone.[47–49] This superiority can be assigned to the CT compo-

nent of this examination because of poor performance of PET alone in measuring tumor size or assessing potential infiltration of adjacent structures. The integrated images allow more precise evaluation of chest wall and mediastinal infiltration in some patients, and better differentiation between tumor and accompanying inflammation or atelectasis in others. In the Zurich group report, there was a benefit in comparison with side-by-side reading of PET and CT images as well, which was not in the place in the Leuven experience.[50] Results for the *N-factor* display a similar picture (Table 27.4), with PET/CT superior to PET alone. Accurate anatomic correlation allows exact location of involved nodes, and thus better distinction between N1, N2, and N3. Furthermore, the role of PET/CT in identifying supraclavicular N3 nodes and in the distinction between FDG-avid brown fat and a metastatic LN is indisputable[47–49] (Fig. 27.5). Here again, in the study of the Zurich group, PET/CT was superior to visual comparison, but the accuracy of the latter in this study was unexpectedly low at 59%.[47] In the Leuven experience, there was little difference between integrated and visually compared imaging,[50] confirming a similar previous experience with software fusion.[51] Finally, for the *M-factor*, only a few results are available. In a large retrospective study, there was a significant superiority of PET/CT versus PET alone or CT alone, but not versus side-to-side correlation.[28]

There are far less data on the use of PET or PET/CT in small cell lung cancer (SCLC), probably because it is far less frequent, and because the disease is often disseminated at the time of diagnosis.[52] The most relevant question is the distinction between limited disease (LD) and extensive disease (ED).

One prospective study examined how often PET detects ED SCLC in patients considered to have LD based on conventional staging.[53] PET correctly upstaged 2 of 24 patients (8%) to ED. PET also correctly depicted all tumor sites in the primary mass and nodal stations. PET impacted on the radiotherapy planning because of detection of unsuspected locoregional

LN metastasis in 6 of 24 patients. In the largest study to date, a total of 91 SCLC patients underwent conventional staging (including cranial magnetic resonance imaging [MRI] or CT) and PET.[54] In 14 patients, PET caused a stage migration, correctly upstaging 10 patients (11%) to ED and downstaging three patients to LD. PET was significantly superior to CT in the detection of extrathoracic metastases except for the brain. In a recent prospective study with 29 patients, a correct overall change in stage in 10% of the patients was noted with PET/CT, in comparison with staging by means of CT, bone scintigraphy and bone marrow analysis.[55] Interestingly, these authors reported similar results in staging of bone metastases and bone marrow invasion with PET/CT in comparison with bone scintigraphy and bone marrow biopsy. Despite the fact that there is less evidence in SCLC compared with NSCLC, it seems fair to say that about 10% of patients with LD will have their staging upgraded to ED when PET is used, because lesions that may escape standard clinical examination and conventional imaging are detected on whole-body PET/CT imaging (Fig. 27.6).

**Prognostic Value**   Apart from the TNM stage at diagnosis, the classical prognostic factor for NSCLC patient groups, metabolic imaging using the FDG uptake expressed as $SUV_{max}$ was reported to have prognostic value for the individual patient as well. Several retrospective studies—mostly in operable NSCLC patients—demonstrated that survival was significantly better in patients with a tumor of lower metabolic activity (i.e., below the study-specific cutoff value or below the median value),[56–65] and this was confirmed in a recent literature-based metaanalysis.[66] Recently, one retrospective[67] and one prospective study[68] argued that tumor FDG uptake did not provide additional prognostic information apart from

**FIGURE 27.5**   PET/CT in a patient with squamous cell carcinoma of the left upper lobe. FDG uptake is present in the primary tumor and an adjacent hilar LN **(A,B)**. PET also shows a focal hot spot suspected for N2 disease in level 2L (**A,C** *arrow*). PET/CT fusion images project the hot spot in brown fat tissue **(D,E)**. At thoracotomy with LN, dissection confirmed the absence of mediastinal involvement (pT2N1). (See color plate.)

pathologic TNM stage in multivariate analysis. Further studies and individual patient-based metaanalysis are needed to clarify the prognostic role of PET, taking into account methodological issues such as the intercenter reproducibility of the PET acquisition protocol and SUV measurement (such as max or mean). A survival analysis using a stage-specific median $SUV_{max}$ cutoff significantly correlated with long-term overall survival for stage IB, stage II, and stage IIIA (median $SUV_{max}$ of 10, 13, and 14, respectively).[63] Whether PET could be of help in deciding on adjuvant chemotherapy for early stage resected NSCLC is a challenging question that deserves further research.

**Evaluation of Therapy**    Quantitative changes in tumor metabolism on PET during or after completion of chemo-(radio)therapy have been studied in different settings.[69,70]

Two small prospective studies reported on the use of PET to predict clinical outcome of chemotherapy at an early stage of treatment in patients with advanced NSCLC. In one series, a predefined decrease in $SUV_{max}$ of >20% after one cycle of cisplatin-based chemotherapy significantly correlated with prognosis.[71] In the other, a reduction of $SUV_{max}$ by >30% also significantly correlated with survival.[72] The broader application of PET response to clinical practice—as is the case for serial CT in the Response Evaluation Criteria in Solid Tumors (RECIST) system—is hampered by technical and methodological differences between different PET cameras and centers. Although serial FDG-PET on one single camera is valid for treatment monitoring, much more work is still needed to align acquisition and interpretation of SUV data across centers.

More data are available on the use of PET in surgical combined modality treatment for stage III NSCLC.[73–82] Factors associated with good prognosis after induction treatment and surgical resection for stage IIIA-N2 are complete resection, downstaging of mediastinal LNs, and the degree of pathologic response in the primary tumor. These factors are poorly predicted by CT, and classically only available after resection. More than a decade ago, a prospective pilot study reported that the combination of LN downstaging on PET and an $SUV_{max}$ decrease of >50% in the primary tumor after neoadjuvant chemotherapy for stage IIIA-N2 NSCLC significantly predicted a better outcome.[83] Since then, many studies have addressed the value of PET and PET/CT in assessment of LN downstaging, estimation of pathologic response, and relation of these findings with survival outcome.

Results for mediastinal LN restaging are listed in Table 27.5. Again, these studies differ in methodological aspects, such as type of induction (chemotherapy or chemoradiotherapy), timing of imaging (interval 3 to 4 weeks, straight after, or at a variable

interval 4 to 10 weeks after neoadjuvant therapy, respectively), and interpretation of imaging (visual correlation with CT or integrated PET/CT). Nonetheless, it is clear that the sensitivity and specificity are lower than for baseline LN staging, but better if studies with PET/CT are considered.

A unique feature of repeat PET after induction is that it assesses not only mediastinal nodes but response in the primary tumor as well (Fig. 27.7). The earliest studies reported a sensitivity of 81% to 97% and a specificity of 64% to 67% to predict a pathological complete response on PET after neoadjuvant therapy.[74–77] Other studies used the percentage change in the $SUV_{max}$ on PET before and after neoadjuvant therapy, and described a strong but imperfect correlation between this decrease and the residual amount of viable tumor in the resection specimen.[77,80,81]

Several recent studies also confirmed the relevance of changes on PET for survival outcome. In one study, a cutoff value of 60% decrease in $SUV_{max}$ after induction chemotherapy was a significant predictor of 5-year survival (60% vs. 15%; $p = 0.0007$).[84] The picture was less clear for repeat PET after neoadjuvant chemoradiotherapy ($p = 0.02$), mainly because the chemoradiotherapy caused no further decrease in $SUV_{max}$, and because the repeat PET was performed too early (days) after the last dose of radiation therapy. The optimal interval for scanning after induction was recently suggested to be 4 weeks after the last radiotherapy dose.[85] One study even found that the residual glucose metabolic rate after one single cycle of induction chemotherapy provided a statistically significant prediction of outcome.[79]

In a recent paper, a prognostic stratification model, based on the combination of pathologic response in mediastinal nodes and primary tumor response on serial PET was presented, in an attempt to refine the decision regarding which patients are candidate for surgery after induction therapy for stage IIIA-N2 NSCLC.[86]

**Planning of Radiotherapy** Although most of the PET studies on locoregional extension of NSCLC were performed in a preoperative setting—in order to have histological verification of the findings—the use of this technique is of equivalent importance in patients scheduled for radiotherapy. Accurate noninvasive PET staging of the tumor and nodes not only influences the treatment intention (i.e., curative or palliative),[87] but also the volumes to be treated, and therefore may reduce the chances of geographic miss[88] or decrease the risk of toxicity to be expected. Classical radiotherapy planning uses CT to describe the tumor and nodes and to draw the gross tumor volume (GTV). The main limitations are the poor demarcation of some tumors on CT, especially in the presence of atelectasis, and poor accuracy of CT in distinguishing benign and malignant LNs.

A simulation study based on 105 NSCLC patients with surgery verified PET findings looked at the impact on GTV when adding PET information to CT.[89] For 73 of these patients, with positive nodes on CT and/or on PET, the completeness of tumor coverage by the CT-GTV and PET-GTV was calculated, using the available surgical pathology data as gold standard. Tumor coverage improved from 75% with CT to 89% with PET ($p = 0.0005$). In one study, the PET-GTV was actually used for planning radiation fields, and only 1 of 44 patients developed an isolated nodal recurrence.[90]

PET, and especially integrated PET/CT, also alters the GTV by a better discrimination between tumor and peritumoral atelectasis or necrosis (Fig. 27.8),[91,92] thereby reducing the interobserver variability in tumor delineation.[93]

**FIGURE 27.8** Patient with a squamous cell carcinoma in the left hilum (cT3N3) with atelectasis of the left upper lobe resulting in a shift of heart and mediastinum **(A,B)**. For a better discrimination of atelectasis and tumor, PET/CT was performed to optimize radiation treatment planning **(C, D)**. (See color plate.)

A major remaining issue for improvement is the optimal tumor contouring by PET, depending on the size of the tumor and the tumor-to-background ratio,[94,95] and on respiratory motion as PET images—acquired over several minutes during free breathing—result in enlargement of the metabolic lesion in the axis of the respiratory movement. For the latter, respiratory gating techniques should be implemented.[96] Finally, future prospective comparative studies should ascertain that use of PET/CT in radiation treatment planning will actually result in reduced toxicity, better local control, and increased survival.

### Follow-up after Therapy

How to follow patients after a radical primary treatment is a matter of debate, as re-treatment after radical surgery, radiotherapy or combined modality treatment may be rewarding in selected cases. Three prospective studies correlated a repeat PET scan performed "late" after primary treatment at >6 months, at median 8 months, and at 19 months, respectively, to a long-term clinical follow-up of median 19, 34, and 30 months, respectively.[97–99] A significantly better long-term outcome was found for patients with a negative compared with positive late repeat PET scan. In patients with confirmed relapse, the long-term survival rate was significantly better for patients with a cutoff for FDG uptake below the median $SUV_{max}$.[99]

After radical surgery or radiotherapy, it can be difficult to differentiate therapy-induced fibrosis from tumor on conventional imaging. In this situation, PET was able to correctly confirm or exclude disease relapse in an indeterminate lesion on CT scan with a sensitivity of 97% to 100%, a specificity of 62% to 100%, and an accuracy of 78% to 98%.[98,100]

### Impact on Clinical Practice and Recommendations

A large number of different types of accuracy studies—summarized in metaanalyses—have confirmed that assessment of an SPN, mediastinal staging, and detection of extrathoracic metastases are improved by PET in combination with CT compared with CT alone.[9,33] How should this improved test performance be implemented in patient management?

In the evaluation of SPNs, PET should be seen in conjunction with the pretest probability of malignancy, judged according to clinical experience either based on factors such as review of previous radiographs, age, smoking habits, size, and aspect of the lesions on radiological documents or based on a validated calculator model.[101] PET will be most contributive in SPNs with intermediate (5% to 60%) probability of malignancy.[102] For lesions of at least 8 to 10 mm in diameter, the negative predictive value of PET is high. If such a lesion does not show any FDG uptake higher than the surrounding lung parenchyma (thus not using an SUV threshold for interpretation), follow-up with serial CT scans—repeated at months 3, 6, 12, and 24 months—is an acceptable strategy.[10] False negatives can occur in lesions smaller than 1 cm and in ground-glass opacities.

If the SPN is FDG avid, histological exploration by transthoracic needle biopsy, endobronchial ultrasound-guided bronchoscopy, or thoracoscopic wedge excision is recommended, unless there is evidence for a specific benign etiology such as tuberculosis, sarcoidosis, etc.

Patients with NSCLC, considered for treatment with curative intent, benefit from PET scanning for mediastinal and extrathoracic staging.

Patients with a clinical stage I tumor and negative mediastinal PET findings can proceed to direct surgical resection, on the condition that the primary tumor is not centrally located and that there is no major hilar LN involvement (which may obscure mediastinal LN disease on PET), and that the primary tumor is sufficiently FDG avid (thereby avoiding false-negative LN findings).[103] Patients with mediastinal LN enlargement on CT preferably have invasive confirmation of the LN status (by either esophageal or endobronchial ultrasound aspiration or mediastinoscopy, depending on local expertise),[104] as their pretest probability of LN metastases is higher.[105]

Patients with extensive or bulky mediastinal LN infiltration, do not really need PET to assess LNs, but PET is nonetheless useful because it will quite often detect distant metastatic findings undetected at conventional imaging, with a major impact on treatment intent.[44]

Because PET detects additional metastatic lesions and characterizes lesions left equivocal on CT, its use in clinical studies resulted in stage shift from the one determined by conventional imaging in 27% to as high as 62% of the patients with NSCLC and a change in patient management in 25% to even 52% of the patients.[37,39,43,106–108] Multiple intense abnormal foci in different organs usually point at disseminated disease (Fig. 27.9). However, patients should not be excluded from potentially radical treatment based on isolated abnormal finding on PET suggestive for distant metastasis. In these instances, additional confirmation by other imaging procedures or by tissue confirmation should be sought, to rule out a false-positive finding (Fig. 27.10), or a second primary tumor not affecting the stage of the lung cancer[109] (Fig. 27.3).

This clinical trial experience was confirmed in questionnaires and surveys in broader clinical practice.[110–112]

The additive value of PET was also investigated through comparing implementation of PET added to conventional staging compared with the conventional process alone in randomized controlled trials. One trial randomly allocated 188 clinical stage I to III NSCLC patients to either conventional workup

**FIGURE 27.9** Patient with a large cell carcinoma of the right lower lobe with N3 mediastinal LN spread and multifocal metastatic disease (bone, contralateral lung, abdominal LNs, and bilateral adrenal metastases).
**FIGURE 27.10** Patient with left upper lobe adenocarcinoma (not shown) and abnormal left adrenal gland on CT **(A)**, PET **(C)**, and fusion image **(B)**. Needle aspiration biopsy revealed normal cortical adrenal tissue **(D)**. No change in the adrenal gland during follow-up postlobectomy. (See color plate.)

or conventional workup plus PET.[113] A clear reduction in the number of futile surgical procedures in the latter arm was found: five patients needed a PET to prevent one futile surgery. A similar trial in clinical stage I to II patients revealed no difference between a PET-guided or conventional strategy.[114] As with therapeutic interventions, multiple trials should be performed to provide a valid estimation of the effect.

Another prospective randomized study compared staging with upfront PET (i.e., directly after first presentation) versus routine clinical staging in 465 patients.[115] In this study, patients with FDG avid, noncentrally located tumors without signs of mediastinal or distant spread on PET proceeded directly to surgical resection, without conventional staging tests. Quality of staging was measured by comparison of the clinical stage with the final stage, and was similarly good in both arms. Noninvasive tests to reach a clinical TNM were similar in both arms, but invasive tests (i.e., mainly mediastinoscopy) were significantly less needed in the upfront PET group.

**Future Technical Developments** FDG-PET allows excellent discrimination between normal tissues and tissues with enhanced glucose metabolism, but false-positive uptake of FDG in inflammatory tissues is one of the major limitations of this tracer. Therefore, tracers with an equally high sensitivity but a better specificity are in the focus of ongoing research, but none have shown a clear improvement over FDG at this time in clinical lung cancer imaging. Results with ^{11}C-methionine, a marker of protein metabolism,[116,117] and ^{11}C-choline, a component of phospholipids in the cell membrane,[118] were disappointing. The most exciting new tracer is the thymidine analogue FLT, a marker of cell proliferation.[119]

Although FLT itself is not incorporated in DNA, FLT uptake is cycle dependent because trapping occurs only after phosphorylation by cytosolic thymidine kinase-1 activity, an enzyme only functional in the S phase of the cell cycle. In the differentiation of SPNs, FLT proved to be more specific than FDG, although false-positive uptake is also described in acute infections.[120–122] Because the absolute uptake of FLT uptake is usually lower than FDG, especially in slowly proliferating tumors, the sensitivity of FLT-PET is reduced. In one study, the sensitivity on a lesion-by-lesion analysis was only 58%, compared with 79% for FDG-PET.[121] Therefore, FLT-PET will never replace but rather be complementary to FDG-PET in special situations of SPNs. Furthermore, a whole new field using PET is molecular imaging in order to study cellular functions such as receptors, transport proteins, or intracellular enzymes. These results are eagerly awaited, as targeted agents are the emerging new treatments for lung cancer, and targeting these expensive drugs by proper selection of patients by predictive markers is a key question.

With the advent of integrated PET and multislice spiral CT, the hardware for lung cancer imaging has actually come to a high technical standard. Future expectations are a further decrease of the spatial resolution of PET cameras to as low as 2 mm, which will probably be the limit of this technique, as the emitted photons are emitted with some scatter and with a slight deviation from the 180-degree angle of the detectors.

Another feature that could improve the quality of the images, especially in respiratory medicine, is respiratory gating of PET acquisition. Because of respiratory motion, the volume of a lung lesion is smeared out and thus overestimated, whereas the FDG intensity is underestimated, especially in the lower lung fields. Synchronization of the acquisition of the PET emission images with respiratory motion may overcome this problem.

# Bronchoscopy in the Diagnosis and Evaluation of Lung Cancer

Rigid optics to examine the central airways were designed by Gustav Killian in Heidelberg more than a century ago and were revolutionized with the creation of the fiberoptic bronchoscope by Shigeto Ikeda.[1] Recent and continuing advancements in catheter-based tissue imaging and therapeutics have significantly increased the role of bronchoscopy in the management of lung cancer patients because of its minimal invasive nature.[2–6] Bronchoscopy provides us with less morbid and tailored strategies for each individual at risk with regard to extended diagnostics and therapeutics by the application of many techniques currently available.[3–7] Thus, bronchoscopic activities also encompass early detection, staging, and treatment for at-risk individuals with various pulmonary pathologies, and its role for the management of lung cancer has become an integral part in the thoracic oncology discipline as well.[3,4,7]

From the perspectives of interventional pulmonology, target lesions are either centrally located inside or adjacent to the major airways or located in the lung parenchyma beyond the segmental bronchi, in which current fiberoptic bronchoscopes with an average diameter of ≈6 mm have limited access. However, the standard use of fluoroscopy and current advancement of computerized digital four-dimensional (4D) imaging computed tomography (CT), magnetic resonance imaging (MRI), ultrasound, and tissue spectral analysis can be further exploited to refine bronchoscopic applications in studying dynamic disease processes in pulmonary parenchyma beyond our direct vision and toward visualization of subcellular processes.[8–12]

The aim of this chapter is to describe current and future perspectives of various bronchoscopic techniques that are used in the management of lung cancer. Recent advancements in nodal staging and therapeutic strategy for early detected lesion will be more extensively discussed.

## THE CONCEPT OF BRONCHOSCOPIC DIAGNOSIS, STAGING, AND TREATMENT

For most patients with clinically overt lung cancer based on current World Health Organization (WHO) histology classification, the squamous and small cell types are primarily located in the central airways, whereas adeno and large cell neuroendocrine types are mostly located in the lung parenchyma distal to the segmental bronchi. As the majority of patients are still diagnosed at advanced stage, central bulky tumor and nodal disease involvement adjacent to the central airways can be (re-)staged by acquiring specimens for tissue diagnosis with relative ease.[3,6]

Bronchoscopic sampling of specimens for histological evaluation in the central airways can be performed under direct vision, and the use of coagulative techniques (e.g., lasers, electrocautery, and argon plasma) and cryotherapy can better control bleeding that may occur.[3] Extended use of various debulking techniques for obtaining immediate relief in patients with imminent suffocation will not be dealt here (see Chapter 61).

Adjacent to the central airways are the mediastinal lymph nodes (MLN) (Fig. 28.1), which can be staged using transbronchial (and transesophageal) needle aspiration as alternatives for conventional staging (e.g., mediastinoscopy and video-assisted thoracoscopic surgery [VATS]).[6,13,14] These aspiration techniques are a major improvement for reducing morbidity in those with advanced cancers, with improved accuracy and safety caused by the advent of esophageal and endobronchial ultrasound (EUS and EBUS), allowing real-time puncturing of the nodes.[13,14] It is important to know that mediastinal nodes move during respiration, such that in dealing with especially small unforeseen $^{18}$F-fluorodeoxyglucose positron emission tomography (FDG-PET)-positive nodes, one cannot presume the locations to be static during aspiration.[15,16] It is therefore quite obvious that with expertise and real-time puncturing of the nodes, diagnosis can be obtained in >90% accuracy.[13,14] These endoscopic alternatives are straightforward and least morbid in staging procedures, despite the great potential of noninvasive imaging techniques such as PET/CT. Tissue will remain the issue for still a considerable period of time as FDG-PET avidity is showing metabolic function not exclusively for malignancies alone.[17,18]
**FIGURE 28.1** Lymph nodes map for transbronchoscopic (left, anterior view) and transesophageal (right, posterior view) endoscopic punctures. *Ao*, aorta; *inf VC*, inferior vena cava; *I:PA*, left pulmonary artery; *PA*, pulmonary artery; *PV*, pulmonary vein; *r:PA*, right pulmonary artery; *SUP VC*, superior vena cava. (**A:** from Krasnik M, Vilmann P, Herth F. EUS-FNA and EBUS-TBNA: the pulmonologist's and surgeon's perspective. *Endoscopy* 2006;38:S105–S109; **B:** from Herth FJF, Rabe KF, Gasparini S, et al. Transbronchial and transoesophageal [ultrasound-guided] needle aspirations for the analysis of mediastinal lesions. *Eur Resp J* 2006;28:1264–1275.)

Currently, for lesions in the lung parenchyma, tissue sampling under fluoroscopy, CT, or ultrasound guided may prevent the need for more invasive surgical diagnostics.[12,19,20] However, 30% of pulmonary parenchymal lesions do not have proximity to the smaller airways. Therefore, transthoracic approaches may still be required with the inherent risk for causing a pneumothorax—a potential complication often overrated as an interventional specialist should anticipate any procedure-related complication.

The issue of huge numbers of submillimeter parenchymal lesions detected in current CT screening programs cannot be easily addressed with either fluoroscopic or endobronchial techniques. Targeting all these lesions will be a colossal task. The entire strategy regarding CT screening requires thorough understanding of all screening controversies (see Chapter 16).[21–25]

4D navigational techniques based on CT data seem promising. Nevertheless, the requirement for tissue biopsy should be put in the proper perspective of the CT screening controversies.[25–28] The issues of potential overdiagnosis, relatively high number of only bronchioloalveolar cell carcinoma (BAC) lesions found, the lack of any proof that stage shift has been accomplished, together with potential difficulty for proper histological classification if only based on tiny pieces of tissue specimens collected, are among the few aspects to consider.[22,25,26,29,30] The poor negative predictive value (NPV) of CT-detected subcentimeter lesions in lung cancer screening study may encourage bronchoscopists to accomplish tissue diagnosis to exclude malignancy, but is practically unrealistic because of the sheer numbers of these lesions that are found, of which most will be nonmalignant.[22–25] Consideration of theoretical and practical issues should prevent tunnel vision for interventional pulmonologist in dealing with CT screen–detected nodules.[25]

When there is a strong suspicion for lung malignancy, PET/CT may soon be expected to become the standard initial staging procedure.[26–28] Improved spatial resolution of current PET/CT machines can greatly assist the bronchoscopist for optimal selection of techniques, for example, in using ultrathin bronchoscope, steerable catheters (e.g., virtual bronchoscopic navigation).[19,20,31–33] This may ease targeting lesions beyond bronchoscopic reach, thus distal to the segmental bronchi deep in the lung parenchyma, also for first-station nodal disease.

The epidemiological shift of lung cancer cell type to ≈40% adenocarcinoma makes it mandatory for bronchoscopists to be proficient in understanding the potential and limitations of 4D noninvasive spatial data for targeting these lesions.[26,27] Small parenchymal lesions are difficult moving targets because of respiratory cycles and may require adjuncts such as using real-time ultrasound sensor probes.[12,15,16,20] Great promise about the possibility of 4D navigational assistance may improve our ability herein, similar to recent achievements in stereotactic body radiation therapy (see Chapter 43).[34]

For central airway lesions within bronchoscopic reach, minute early preneoplastic lesions at the clonal level located

in the bronchial mucosa of the central airways are difficult to detect.[8] Preneoplastic lesions are aberrant clonal cell groups of several hundred cells with an average thickness of five cells only. The role of autofluorescence bronchoscopy (AF) herein has been established.[4] Tumor infiltration beyond the bronchial wall can be visualized accurately using thin cuts high-resolution CT (HRCT),[5] EBUS,[35] with optical coherence tomography (OCT) as a promising tool (see Chapter 19).[36]

Standard bronchoscopic biopsies may prove sufficient to obtain a diagnosis, and by using tiny biopsy forceps, repeat biopsies can be obtained. Autofluorescence-guided[37,38] sampling can improve accuracy of detection and staging of early squamous cell type lesions, and these can be completely eradicated using intraluminal treatment. Moreover, bronchoscopic approaches are clearly a cost-effective alternative method.[4,5,8,39–41]

Expert opinion as well as international and national guidelines are available on bronchoscopy and interventional pulmonology.[3,4] Optimizing cytological and histological yields requires support from a panel of experienced pathologists based on current WHO classification.[29,30]

## Recent Issues in Mediastinal Nodal Staging

The variable yield (Table 28.1) in puncturing CT-enlarged lymph nodes is understandable, because there is no real-time guidance during bronchoscopic session while these are moving targets if transbronchial needle aspiration (TBNA) is performed under conscious sedation in spontaneously breathing and coughing patient.[13–16]

Currently, many patients with advanced stage cancers have bulky multilevel MLN involvement. Patients' population in each particular medical practice should be put in the proper perspective about the likelihood for obtaining good yields.[42,43] Also, the proper time window for TBNA restaging after induction chemotherapy should be a point for consideration.[44,45] With the advent of ultrasound and 4D PET/CT virtual bronchoscopy previously mentioned, needle aspiration can be executed in real time with utmost accuracy, with excellent yield.[13,14,28]

| TABLE 28.1 | Factors Influencing Diagnostic Yield of Needle Aspiration of Lymph Nodes Adjacent to the Central Airways |
|---|---|

Presence of lymph node enlargement on computed tomography scan
Type of needle employed
Site of the tumor and lymph node
Lymph node size
Number of aspirates performed
Availability of rapid on-site cytopathologic examination
Ability and experience of the operators
Nature of the lesion (malignancy, type of malignancy)

(From Herth FJ, Rabe KF, Gasparini S, et al. Transbronchial and transoesophageal [ultrasound-guided] needle aspirations for the analysis of mediastinal lesions. *Eur Respir J* 2006;28:1264–1275.)

**FIGURE 28.2** EBUS bronchoscope with needle extruded. (Photo courtesy of Felix Herth.)

A major recent advancement in MLN staging is the incorporation of (curvi-)linear ultrasound transducer video/bronchoscope with color flow Doppler that visualized target lymph node and adjacent vessels, allowing accurate needle aspiration with great safety. Endobronchial ultrasound–guided transbronchial needle aspiration (EBUS-TBNA) allows for direct sampling of mediastinal and hilar lymph nodes in real time. The procedure is performed using an ultrasound biopsy bronchoscope, with a 7.5 MHz convex linear array ultrasonic transducer located at the distal tip, encased by a water inflatable balloon. There is also a separate working channel through which the biopsy needle is extended, allowing for real-time biopsy (convex probe EBUS [CP-EBUS], XBF-UC260 F-OL8, Olympus; Figs. 28.2 and 28.3). Once a lymph node is visualized, the balloon is inflated to maintain adequate contact with the bronchial wall and to better visualize the lymph node. The bronchoscope is also supported by Doppler function for the identification of blood vessels. The Doppler is used prior to needle insertion to ensure that a suspected lymph node is not, in fact, a blood vessel. Once the physician is confident that the structure in question is a lymph

**FIGURE 28.3** **A:** Intraluminal view of the carina left upper and lower lobe. **B:** CT image of node station 10 L. **C:** Position of the bronchoscope. **D:** EBUS image of the puncture procedure, the needle is visible. (Photo courtesy of Felix Herth.) (See color plate.)

node, the 22-gauge needle is passed through the bronchial wall and into the lymph node once the outer sheath has been positioned and brought in contact with the airway. The balloon is deflated prior to deployment of the needle to prevent balloon rupture. The needle is passed back and forth through the lymph node once a vacuum syringe has been connected to the needle in order to aspirate lymphatic tissue either in the form of cells or actual tissue cores.

EBUS-TBNA is a promising alternative to mediastinoscopy for the staging of MLN in patients who present with mediastinal lymphadenopathy on CT scan. Compared with mediastinoscopy, EBUS-TBNA is less invasive, can be performed under conscious sedation (as opposed to general anesthesia), and does not require overnight hospitalization (less costly). More importantly, EBUS-TBNA allows access to posterior subcarinal,[7] hilar,[10] and intrapulmonary ($\geq$11) lymph nodes, which are inaccessible by mediastinoscopy. Also, unlike mediastinoscopy, EBUS-TBNA can be performed multiple times on the same patient without deleterious effect, all while preserving the integrity of the mediastinum. This is an important fact if future mediastinal restaging is anticipated, as is often the case with stage IIIA-N2 disease following induction chemotherapy. A recent study by Herth et al.[46] investigated the ability of EBUS-TBNA to accurately restage the mediastinum following induction chemotherapy in patients with stage IIIA-N2 non–small cell lung cancer (NSCLC). Between February 2003 and March 2006, 124 patients who had completed induction chemotherapy, underwent EBUS-TBNA, followed by thoracotomy with resection and systematic lymph node dissection with curative intent. The sensitivity, specificity, positive predictive value (PPV), NPV, and diagnostic accuracy of EBUS-TBNA were 76%, 100%, 100%, 20%, and 77%, respectively. These results compare favorably with those observed in studies that have performed remediastinoscopy[47–50] or EUS-TNA[51,52] in the mediastinal restaging of similar cohorts.

In the largest study published to date on EBUS-TBNA sampling of MLN, Herth et al.[53] biopsied 572 enlarged (>1 cm on CT) lymph nodes from 502 patients, between June 2002 and September 2004. The average lymph node size as measured during EBUS examination was 1.6 cm. (range 0.8 to 3.2). EBUS-TBNA established a diagnosis in 535 of the 572 lymph nodes biopsied, providing a diagnostic yield of 93.5%. On a per patient basis, a diagnosis was obtained in 470 of 502 patients, establishing a diagnostic yield of 93%. Overall, EBUS-TBNA had a sensitivity, specificity, accuracy, PPV, and NPV of 94%, 100%, 94%, 100%, and 11%, respectively. Given the low NPV, which reflects a high number of false negatives, the authors have suggested that a negative EBUS-TBNA be followed by a more definitive diagnostic procedure, presumably, a mediastinoscopy.

Current guidelines for the noninvasive staging of NSCLC recommend that a PET scan be administered to any patient with clinical stage IA to IIIB disease that is being treated with curative intent.[54]

Moreover, it is recommended that any abnormal (positive standardized uptake value [SUV]) lymph nodes on FDG-PET should be further evaluated via tissue sampling. The question then becomes, "What procedure should be performed to obtain tissue samples from PET-positive lymph nodes?" A recent study evaluated the use of real-time EBUS-TBNA for the sampling of PET-positive lymph nodes in 106 patients with proven (29 patients) or suspected (77 patients) lung cancer.[55]

All procedures were done under conscious sedation, and patients were managed on an outpatient basis. Based on the 90 assessable patients, the sensitivity, specificity, PPV, NPV, and accuracy of EBUS-TBNA for PET-positive lymph node staging were 93%, 100%, 100%, 91%, and 97%. Furthermore, surgical intervention was avoided by the use of EBUS-TBNA in 56% (59 of 106) of the patients. In experienced hands, these findings suggest that EBUS-TBNA should be considered as the initial method of sampling in patients with suspected/proven lung cancer and PET-positive lymph nodes. However, subsequent surgical sampling should be performed following a negative EBUS-TBNA, based on a 10% false-negative EBUS-TBNA rate. Lastly, at the time of procedure, EBUS-TBNA also allows the sampling of any PET-normal MLN that are visualized. This provides a simple means to rule out occult N2/N3 disease. EBUS-TBNA found lymph node metastasis in PET-negative nodes in 4 of 58 positive patients, upstaging these patients from suspected N1 and N2 based on PET, to N2 and N3, respectively.

Data exist, which demonstrate that a significant percentage of NSCLC patients with clinical stage I disease do, in fact, harbor lymph node metastases. Anywhere between 15% to 37% of patients with negative lymph nodes on CT scan are found to have nodal involvement upon surgical staging,[56] depending on what data is referenced.[57–60] This is a reflection of the low sensitivity and accuracy of CT scan in staging the mediastinum in lung cancer patients. This percentage drops to 9% to 11% in patients with solely T1 lesions.[61,62]

Even at this lower estimation, MLN staging prior to surgical intervention in clinical stage I NSCLC patients is justified. Between January 2003 and March 2005, Herth et al.[63] evaluated EBUS-TBNA as a means of sampling lymph nodes in NSCLC patients with CT scans showing no enlarged lymph nodes (no node >1 cm) in the mediastinum. In 100 patients, 119 lymph nodes between 5 to 10 mm were sampled, with a mean diameter of 8.1 mm. EBUS-TBNA correctly identified 19 out of 21 lymph node–positive patients and all 79 lymph node–negative patients. Of the 19 positive cases identified by EBUS-TBNA, 3 had N3 disease, 13 had N2 disease, and 3 had N1 disease. Sensitivity, specificity, and NPV of EBUS-TBNA were 92.3%, 100%, and 96.3%, respectively. These findings suggest that EBUS-TBNA can be used as an accurate way to preoperatively stage the mediastinum in NSCLC patients with normal-appearing lymph nodes, a procedure, which in the past was only reserved for mediastinoscopy.

Because of the fact that PET scan is now being incorporated into the standard workup on lung cancer patients, EBUS-TBNA has also been evaluated as a means of staging the mediastinum in NSCLC patients with a CT *and* PET-normal mediastinum.[64]

From January 2004 to May 2007, EBUS-TBNA was used to sample 156 lymph nodes (5 to 10 mm in size) in 97 NSCLC patients. Mean diameter of punctured lymph nodes was 7.9 mm. The sensitivity, specificity, and NPV of EBUS-TBNA in detecting malignancy were 89%, 100%, and 98.9%, respectively. This demonstrates that EBUS-TBNA is an accurate means of staging the mediastinum in NSCLC patients with no evidence of mediastinal involvement on CT and PET scans.

In light of the promising data that have been published on the use of EBUS-TBNA for MLN staging in NSCLC patients, direct comparison with mediastinoscopy (the gold standard) is necessary to establish the appropriate clinical approach to mediastinal staging in patients with NSCLC. Thus far, a study by Ernst et al.[65] is the only one to draw such a comparison. Included in the study were 66 patients with suspected NSCLC and mediastinal adenopathy ($\geq$1 cm) on CT scan that was confined to lymph node stations 2, 4, or 7. Biopsies from 120 lymph nodes (mean size 15 mm, range 10 to 21) in these 66 patients were obtained by both EBUS-TBNA and mediastinoscopy. In a per lymph node analysis, EBUS-TBNA had a higher overall diagnostic yield (91%) than mediastinoscopy (78%). Specifically, EBUS-TBNA had a statistically significant ($p$ <0.05) higher diagnostic yield than mediastinoscopy in subcarinal (98% vs. 78%) and malignant (86% vs. 66%) lymph nodes. There was also a trend toward obtaining a definite histologic diagnosis with EBUS-TBNA (59%) compared with mediastinoscopy (47%), but this did not reach statistical significance. Overall, the sensitivity, specificity, and NPV of EBUS-TBNA were 87%, 100%, and 78%, respectively. The sensitivity, specificity, and NPV of mediastinoscopy were 68%, 100%, and 59%, respectively.

Complementary use of transesophageal MLN sampling further improves staging of aortic window, paraesophageal LN stations and adrenals, still more cumbersome to be tackled using alternative surgical approaches.[13,17] Current screening efforts may increasingly confront clinicians with subcentimeter's lesions in the lung parenchyma, and the potential role for EBUS for obtaining diagnosis have been pusblihsed.[12,20]

For daily practice, the use of bronchial needle aspiration by bronchoscopists is frequently underutilized, resulting from lack of awareness of its potential for accurate and safely sampling nodal stations based on the proximity of many important nodal stations to the central airways. Experts' opinion herein and recent American College of Chest Physicians (ACCP) guidelines have addressed this issue in details.[6,13,66] It is obvious that scalene, aortic, paraesophageal nodes, left adrenal, require EUS and other measures.[17]

## Recent Issues on Bronchoscopic Treatment of Early Lung Cancer

Accurate staging of early central airway cancer is extremely important for the selection of appropriate treatment.[4,5] Although surgery is still the preferred option, many patients harboring early squamous cancer in the central airways have smoking-related comorbidities that place them at high surgical risk, with 20% to 30% multifocal cancers in the event of field cancerization, justifying less morbid early interventional approach.[38–40]

The need for maximal lung preservation strategy has propelled the interest for applying various local treatment alternatives by bronchoscopy, which is a further implementation of its potentials for quick recanalisation in central airway tumor obstruction (see Chapter 61).

Criteria of early central airway cancers suitable for local, thus bronchoscopic treatment are radiographically (currently HRCT) occult without lymph node or distant metastasis, mainly squamous cell cancer–type measuring <1 cm$^2$ in longitudinal axis with visible distal margin confined within the cartilaginous layer of the tracheobronchial tree.[4,5,7,21] It is clear from the point of intraluminal tumor growth that tumor dimensions are the most important determinant for cure, as pathological studies have shown repeatedly the strong correlation between tumor volume in intraluminal growing squamous cell cancer and its nodal status.[4,38,67,68] Hence, excellent local control can be achieved by using local therapy (e.g., bronchoscopic treatment in carefully selected cases), such as has been shown in photodynamic series previously reported. Recent ACCP guidelines have addressed this issue.[4]

The combined use of autofluorescence bronchoscopy, high-resolution CT, FDG-PET, and EBUS can now better select true early stage squamous cancer, which correlated well with excellent cure rate in smaller =1 cm$^2$ flat-type lesions as reported previously in the photodynamic therapy studies.[4,5,35,39]

Whether OCT (Fig. 28.4) and confocal microendoscopy will provide significant clinical benefit in early intervention remains to be seen.[10,36] OCT detects backscattered light instead of sound waves, and because light is 200,000 times faster than sound, low coherence interferometry is required to integrate reflectance properties of tissue scanned for obtaining high-resolution cross-sectional microscopic images of the bronchial wall, with potential in vivo microdynamic imaging without the necessity for biopsy for studying carcinogenesis.[36]

OCT and confocal microendoscopy may facilitate our understanding of dynamic processes in the continuous damage and repair processes of clonal cells over time. Very early carcinogenesis at the clonal level cannot be properly studied, because biopsy in itself may completely eradicate these minute

**FIGURE 28.4** Optical coherence tomography (OCT) of an intraluminal squamous cell cancer in the tracheal wall. **A:** Bronchoscopic image showing nodular tumor (*T*) and normal tracheal wall (*W*). **B:** OCT showing tumor (*T*) infiltrating beyond the cartilage. **C:** Normal OCT. (From Tsuboi M, Hayashi A, Ikeda N, et al. Optical coherence tomography in the diagnosis of bronchial lesions. *Lung Cancer* 2005;49:387–394; courtesy of N. Ikeda, Mita Hospital, Japan.) (See color plate.)

lesions at the initial bronchoscopic study. The relatively high "spontaneous" regression rate for lower-grade dysplasias after bronchoscopic biopsy hampers further study on molecular carcinogenesis,[41] further emphasizing the need for novel optical biopsy techniques.[2,10,36]

## CONCLUSION

The relative inaccessibility of thoracic organs has pushed bronchoscopic techniques to the limit. With the refinements of various catheter techniques and advancements of 4D real-time digital imaging, further exploration is aimed to optimize the use of minimally invasive techniques in thoracic medicine. Activities currently encompass the complete array of diagnostic staging and treatment intervention in patients and individuals at highest risk to develop preneoplastic lesions in their asymptomatic phase. Resolution has allowed us to study tissue at the clonal and subcellular level.

As such, practical exploitation of minimally invasive endoscopy for extended diagnostics in central airway tumor and for accurate staging of MLN suit sell in our common practice, because the majority of patients still have advanced disease.

Early minimally invasive intervention provides great opportunity for true stage shift by significantly reducing morbidity and mortality of early intervention, because quality of life in both patients with advanced cancer and cohort of asymptomatic individuals in lung cancer screening protocols is important.

# Surgical Evaluation of the Mediastinum

At first glance, surgical mediastinal staging may appear to be a mundane and lackluster topic, extensively reviewed with little new information to be added. However, beneath this surface lie many nuances and issues that often lead to confusion, misinterpretation of data, and erroneous conclusions. Furthermore, there are many new developments, both with respect to surgical techniques and in regard to alternative approaches to mediastinal evaluation. Because mediastinal staging remains a key factor in selecting a treatment approach for patients with lung cancer, an understanding of the issues and developments is crucial to achieve optimal clinical outcomes.

Definition of the role of surgical mediastinal staging is complex and depends on many characteristics of the patients being considered. In fact, lack of attention to details of the patients involved is probably the major factor leading to inappropriate application of results from one population to a different cohort. The patients may have undergone minimal imaging (chest x-ray [CXR] or computed tomography [CT]) or more sophisticated imaging (positron emission tomography [PET] or PET/CT). Whether the patient has undergone a careful clinical evaluation for signs and symptoms of distant metastases is often glossed over, and patients may (e.g., those with symptoms of metastases or asymptomatic clinical stage III [cIII]) or may not (e.g., asymptomatic cI) have an indication for extrathoracic imaging for metastases. It is important to note whether the patients have normal-sized or enlarged mediastinal nodes. Finally, results of a procedure done as a staging test are very different from a procedure done merely to make a diagnosis (often including many patients that do not have lung cancer). A lack of awareness of these issues often leads to inappropriate application of the results of a study to a different type of patient.

Even when the focus is limited only to surgical mediastinal staging, there are issues regarding the extent and quality of the procedure. Newer techniques of surgical mediastinal staging can provide a much more accurate assessment,

but the biggest issue is simply whether traditional mediastinoscopy is performed according to accepted standards. It is clear that there are frequent breaches in quality that are likely to have serious consequences for patients,[1] although this has not been studied in detail. Furthermore, there are differences in pathologists' assessment of nodes, and newer techniques can provide more sensitive assessments (i.e., immunohistochemistry of micrometastases). Having said this, the prognostic value of such pathologic investigations is questionable at present.[2–4]

Many alternative techniques have been developed to allow less invasive, "nonsurgical" mediastinal tissue staging. These are discussed in more detail in Chapter 31, but how these techniques can be integrated is discussed here. It is important not to view the various techniques of tissue staging as competitive. To a large extent, the techniques have been used in different patient populations (i.e., anatomic location of particular enlarged or normal-sized nodes), making a simple comparison of test performance characteristics inappropriate. How the different procedures best complement one another depends on patient characteristics, the primary question to be addressed (i.e., to rule in cancer or to rule out cancer), and the level of proficiency available with a particular approach.

Finally, the role of surgical mediastinal staging is a matter of judgment. No test can be expected to yield perfect results, so it becomes a question of how much uncertainty one is willing to accept. This threshold is influenced by the risk and morbidity of the procedures involved. Although mediastinoscopy is done as an outpatient procedure in most centers and is associated with low morbidity (2%) and mortality (0.08%), it is somewhat invasive.[5] It is proposed that in general, invasive staging is justified if there is a >10% chance of error in the mediastinal stage from imaging alone, and noninvasive testing (i.e., PET) for a >5% chance of error. Performing a test for a low prevalence of disease runs the risk of either a test-related complication or an erroneous result without a high chance of benefiting from the test.

## SCOPE

This chapter focuses on surgical methods of mediastinal staging, namely, mediastinoscopy and variation of this technique (videomediastinoscopy, video-assisted mediastinal lymphadenectomy [VAMLA], and transcervical extended mediastinal lymphadenectomy [TEMLA]). The chapter also includes a discussion of thoracoscopic approaches as well as the Chamberlain procedure (anterior mediastinotomy). The focus is on primary staging of patients with non–small cell lung cancer (NSCLC). Restaging of the mediastinum after induction therapy is not covered thoroughly. In addition, mediastinal procedures done only to make a diagnosis (i.e., lymphoma, thymoma) are not discussed.

## DEFINITIONS

It is important to clearly define the major terms used to avoid confusion. *Pathologic staging*, according to the American Joint Committee on Cancer (AJCC), refers to the stage after surgical *resection* and complete pathologic evaluation of the specimen and any other tissues submitted. Clinical stage is the stage as determined by any and all information that is available prior to resection. Thus, clinical stage can involve imaging (radiographic staging) or biopsies such as transbronchial needle aspiration (TBNA) or a mediastinoscopy (tissue staging). Although mediastinoscopy is considered a surgical procedure and involves a pathology report, it is still part of clinical staging.

Various parameters can be used to assess the reliability of a test, including sensitivity, specificity, and false-negative (FN) and false-positive (FP) rates (typically expressed as a percentage). The latter two measures are sometimes expressed in a less intuitive manner as the converse, known as the negative predictive value (NPV = 1 − FN rate) or positive predictive value (PPV = 1 − FP rate). Sensitivity and specificity are derived from patient populations in whom the true disease status is already known, who either all have or do not have the condition in question. These parameters provide data about how often the test will be positive or negative for these respective populations. Thus, these measures provide information about the *test*, because the disease status has already been determined in the patients. In theory, these measures can be used to compare different tests, but *only if* the patient populations in which the tests are used are the same. Unfortunately, particularly with regard to invasive staging tests, the patients selected for different tests are not the same, limiting the value of the measures of sensitivity and specificity.

The FN and FP rates of a test are of much greater practical use to the clinician, who must interpret the reliability of a test result (positive or negative) in an individual patient. The clinician does not know the true disease status of the patient; he/she only knows that the patient has a negative or a positive test result. Interpretation of a test result for an individual patient requires knowledge of the FN or FP rate. It is important to point out that the FN or FP rate of the test *cannot* be estimated from the sensitivity or specificity, because each of these is derived from different formulas. This is a common misconception that frequently creates confusion and inappropriate interpretation of test results. The only exception to this fact is in the case of "perfect" test performance: a sensitivity of 100% does, in fact, imply an FN rate of 0, and a specificity of 100% implies an FP rate of 0.

In general, patients with lung cancer can be separated into four groups (Fig. 29.1) with respect to intrathoracic radiographic characteristics of the primary tumor and the mediastinal nodes.[5,6] Briefly, the groups are patients with extensive mediastinal infiltration (radiographic group A), those with enlargement of discrete mediastinal nodes (radiographic group B), patients with normal mediastinal nodes by CT but a central tumor or suspected N1 disease (radiographic group C), and those with normal nodes, mediastinal nodes, and a peripheral cI tumor (radiographic group D).

A widely accepted definition of normal-sized mediastinal lymph nodes is a short-axis diameter of ≤1 cm on a transverse CT image.[6] Discrete nodal enlargement implies that discrete nodes are seen on the CT scan and are defined well enough to be able to measure their size (and are >1 cm). Mediastinal infiltration is present when there is abnormal tissue in the mediastinum that does not have the appearance and shape of distinct lymph nodes, but instead has an irregular, amorphous shape.[6] In this case, it is difficult to distinguish discrete nodes and impossible to come up with a measurement of the size of nodes. This occurs when multiple nodes are matted together to the point where the boundary between them is obscured and can be assumed to involve extensive extranodal spread of tumor. It may progress to the point where mediastinal vessels and other structures are partially or completely encircled. Finally, the distinction between a central versus a peripheral tumor has also not been codified, but most authors consider any tumor in the outer two thirds of the hemithorax to be peripheral.[6]

## TECHNIQUE AND OUTCOMES OF STANDARD MEDIASTINOSCOPY

Mediastinoscopy has been the mainstay of invasive mediastinal staging for the past 40 years. The procedure is performed in the operating room, usually under general anesthesia. It is currently done as an outpatient in most U.S. centers.[7–9] Mediastinoscopy involves an incision just above the suprasternal notch, insertion of a mediastinoscope alongside the trachea, and biopsy of mediastinal nodes. Rates of morbidity and mortality as a result of this procedure are low (2% and 0.08%).[10] Right and left high and low paratracheal nodes (stations 2R, 2L, 4R, 4L), pretracheal nodes (stations 1, 3), and anterior subcarinal nodes (station 7) are accessible via this approach. Node groups that cannot be biopsied with this technique
**FIGURE 29.1**    Radiographic categories of mediastinal appearance in patients with lung cancer. **A:** Mediastinal infiltration by tumor. **B:** Enlarged discrete N2, N3 nodes. **C:** A central tumor or a tumor with enlarged N1 nodes, but a normal mediastinum. **D:** A peripheral small tumor (lower left corner of image) with normal-sized lymph nodes. (From Silvestri G, Gould MK, Margolis ML, et al. Noninvasive staging of non-small cell lung cancer: ACCP evidenced-based clinical practice guidelines (2nd edition). *Chest* 2007;132:178S–201S.)

include posterior subcarinal (station 7), inferior mediastinal (stations 8, 9), aortopulmonary window (APW) (station 5), and anterior mediastinal (station 6) nodes.

The average sensitivity of mediastinoscopy to detect mediastinal node involvement from cancer is approximately 80%, and the average FN rate is approximately 10% to 15% (Table 29.1), as has been compiled in several systematic reviews.[5,11] Several authors have shown that approximately half (42% to 57%) of the FN cases were caused by nodes that were not accessible by the mediastinoscope.[12–17] The specificity and the FP rates of mediastinoscopy are reported to be 100% and 0, respectively. Strictly speaking, these values cannot really be assessed because patients with a positive biopsy were not subjected to any further procedures (e.g., thoracotomy) to confirm the results. The results of mediastinoscopy are fairly consistent among studies.[5]

**Quality of Surgical Staging**    The results cited in the preceding paragraph outline the experience in dedicated thoracic centers with a specific interest in thoracic surgery. However, there are indications that what is practiced more broadly is not the same.[1,18] In the United States, many patients with lung cancer undergo resection either by general surgeons or cardiothoracic surgeons whose primary scope of practice is cardiac surgery. A fair amount of data suggests that both short- and long-term outcomes of patients with lung cancer are affected by the quality of care as well as the extent of specialization in thoracic surgery.[19–21]

Feas, feasibility; FN, false-negative rate; FP, false-positive rate; Med, mediastinoscopy; Prev, prevalence; Proc., procedure; Sens, sensitivity; Spec, specificity; TCMLA, transcervical mediastinal lymphadenectomy (either TEMLA or VAMLA); TEMLA, transcervical extended mediastinal lymphadenectomy; VAMLA, video-assisted mediastinal lymphadenectomy; VMS, videomediastinoscopy.

With regard to mediastinal staging, it seems obvious that the FN rate depends on the diligence with which nodes are dissected and sampled at mediastinoscopy. Ideally, five nodal stations (stations 2R, 4R, 7, 4L, 2L) should routinely be examined, with at least one node sampled from each station unless none are present after *actual dissection* in the region of a particular node station. The difference between this and what is actually done is underscored in a report by Little et al.[1] Analysis of national data in the United States on 11,688 surgically treated patients disclosed that only about half of the patients underwent either PET or mediastinoscopy to define the status of mediastinal nodes. Even more striking was the fact that in more than half of the mediastinoscopies performed, *not even a single mediastinal node was biopsied*. Finally, in almost half of the patients, no mediastinal nodes were biopsied at the time of thoracotomy.

The survival of patients with intraoperatively discovered "surprise N2" disease discovered at the time of resection varies dramatically according to the extent of preoperative staging that was undertaken.[22] Extrapolation of this data suggests that the differences between good- and poor-quality preoperative staging overshadow any differences that might be realized by integration of newer alternative techniques (esophageal ultrasound-guided needle aspiration [EUS-NA], endobronchial ultrasound-guided needle aspiration [EBUS-NA]). It is probably more important to have expertise in at least one technique of invasive mediastinal staging by a dedicated individual than to quibble about the relative value of one technique versus another. PET alone is clearly not adequate to stage the mediastinum, even in centers with a dedicated interest and expertise in PET for lung cancer.[6,23–25]

The recommendation that five nodal stations (stations 2R, 4R, 7, 4L, 2L) should routinely be examined at mediastinoscopy has been endorsed by the American College of Chest Physicians (ACCP),[5] the American Thoracic Society (ATS), and the European Society of Thoracic Surgeons (ESTS).[26] The ESTS recommends, but does not mandate, that sampling of stations 2R and 2L be done.

# NEWER SURGICAL STAGING TECHNIQUES

**Videomediastinoscopy**   The traditional mediastinoscope consists in principle of a tube with a light. This has been modified to include an optical system that provides a much more detailed view and allows a much more extensive dissection of nodes and other structures. Qualitatively, videomediastinoscopy allows actual dissection of nodal stations and removal of entire nodes. In addition, the fascial plane separating the anterior pretracheal space and the subcarinal space can be opened. Dissection directly adjacent to the carina and bronchi allows the subcarinal nodes to be mobilized, providing access to the posterior subcarinal nodes that are thought to be relatively inaccessible via traditional mediastinoscopy. Data from several series confirms an advantage over traditional mediastinoscopy for staging of the mediastinum: the average reported sensitivity is 90%, FN rate 7% (compared with approximately 80% and 13% for traditional mediastinoscopy).[17,27,28]

## Video-Assisted Mediastinal Lymphadenectomy

The videomediastinoscope has allowed development of techniques to completely remove all mediastinal nodes, which has been called VAMLA. The feasibility of carrying out a complete dissection is reported to be 86% (because of calcified or scarred nodes).[29] Only a few studies of this technique have been published.[29–31] Procedure-related complications have been uncommon (6%) and include recurrent nerve paralysis (five patients), bleeding from the azygous vein (two patients), and infection (one patient).[29,30] At the time of thoracotomy, 19% of patients had residual mediastinal nodes (primarily involving those VAMLA procedures that were deemed not completely feasible).[29] Some mediastinal stations appear to be quite completely dissected (stations 2R, 4R, 4L, and 7), whereas residual nodes were fairly common in others (stations 1, 2L, 3, 5).[30,31] Thus, this procedure results in a partial mediastinal lymphadenectomy, albeit a rather complete lymphadenectomy of the most important nodal stations. Parameters of sensitivity, specificity, and FN and FP rates are reported as 88, 100, 2, and 0, respectively, in a series of 130 patients that included incomplete VAMLA procedures (prevalence of N2, N3 disease of 13%), and 94%, 100, 1, and 0, respectively among only complete VAMLA cases.[29]

## Transcervical Mediastinal Lymphadenectomy   The

technique of TEMLA has been developed by Dr. Zielinski in Zakopane, Poland.[32–34] This involves a collar incision that is wider than for a traditional mediastinoscopy, followed by dissection of the right and left carotid and the innominate arteries and the right and left innominate veins. This mobilization of the vessels allows them to be moved aside and provides excellent exposure to the entire mediastinum. Both of the recurrent nerves are visualized and carefully protected. A complete mediastinal node dissection can be performed, including nodes above the innominate vein (level 1), bilateral paratracheal (2, 4), subcarinal and periesophageal (7, 8), as well as the para-aortic nodes (5, 6). Complications in an experience of 256 cI to III patients were seen in 11% (including transient recurrent nerve palsy in 2.3%, pleural effusion in 4%, pneumothorax in 0.4%).[32] A mean of 39 nodes per patient were removed. At thoracotomy, residual benign nodes were found in 9% and missed malignant nodes in 4%, occurring exclusively early in their experience. The sensitivity of TEMLA for the detection of mediastinal node involvement is 94%, with a specificity of 100%, FN rate of 3%, and FP rate of 0.[32] It is not known at this point whether a small deposit found by such an extensive staging investigation carries the same poor prognosis as a deposit detected by routine mediastinoscopy.

**Thoracoscopy**   Thoracoscopy (video-assisted thoracoscopic surgery [VATS]) for mediastinal staging has been reported in a limited number of studies.[5,35–40] Overall, a sensitivity of 75% and an FN rate of 7% have been reported.[5] However, the sensitivity varies widely (from 37% to 100%) without any obvious explanation. The low results stem primarily from the only prospective multicenter study.[36] Thus, in general, the results of VATS for staging appear to be not as good as that of other techniques, although the degree to which this has been defined is limited. This is coupled with the fact that VATS is associated with more discomfort than all of the other mediastinal staging procedures. VATS for staging is probably best reserved for specific situations, such as in patients with a cervical tracheostomy, or assessment of nodes in stations 5, 6, or 9 if other techniques cannot be used or are not available.

**Nonsurgical Invasive Techniques**   Several newer techniques of invasive staging that are nonsurgical are available, including esophageal ultrasound (EUS) and endobronchial ultrasound (EBUS) coupled with needle aspiration. A full discussion of these is beyond the scope of this chapter, but one cannot discus surgical staging in a vacuum. Details of EBUS are discussed in Chapter 28. A summary of the performance characteristics of these newer tests, taken from a systematic review,[5] is provided in Table 29.2. It must be emphasized that a direct comparison between different techniques is inappropriate because of differences in the patient population, both in terms of the radiographic groups as well as the location of suspicious lymph nodes.

Like mediastinoscopy, these needle techniques generally do not require hospitalization, but in contrast to mediastinoscopy they are generally performed only with sedation (not general anesthesia).[5] Thus, these procedures have an advantage of being less invasive and complex. Unfortunately, the needle-based techniques carry an FN rate of approximately 20% to 25%. The sensitivity of a traditional (non–image guided) TBNA is lower (around 75%) than traditional mediastinoscopy, even though this has been done almost exclusively in patients with markedly enlarged nodes.[5] The sensitivity of EUS (also primarily in enlarged nodes) is similar to traditional mediastinoscopy.[5] On the other hand, EBUS appears to have a higher sensitivity (around 90%) and has been used in both enlarged and normal-sized nodes.[5]

[c]Via transcervical approach.

[d]With needle aspiration.

FN, false-negative rate; FP, false-positive rate; prev, prevalence; sens, sensitivity; spec, specificity.

Data taken from Table 29.1 and Tables in Systematic Review conducted by the American College of Chest Physicians.[5] Transthoracic needle biopsy omitted because it is generally used to establish a diagnosis in patients with mediastinal infiltrative tumors, rather than as a staging test.

The major limitation of needle-based techniques is the FN rate (about 20% to 25%, likely even higher in normal-sized nodes). In general, a negative EUS, EBUS, or TBNA should be followed by a mediastinoscopy.[5] Thus, these techniques are less useful in patients with normal-sized mediastinal nodes. This is both because in general, the sensitivity of the needle techniques is lower in patients with normal-sized nodes (as is also in mediastinoscopy) and a negative result is more likely, but is relatively unreliable (because of the high FN rate).

The various surgical and nonsurgical invasive staging techniques should be viewed as complimentary.[41] Furthermore, all of the techniques depend on the skill of the operator. The results published from the best centers with a dedicated interest in a particular technique cannot often be duplicated more broadly. The presence of a dedicated interest and expertise with a particular test may be a key factor in determining the best way to integrate the various staging techniques in a particular institution. Ideally, the performance characteristics of staging tests at a particular institution should be collected and assessed to have a sound basis for making these decisions.

## WHEN IS TISSUE STAGING NOT NEEDED?

Tissue confirmation of the mediastinal stage is not needed in patients with SCLC, stage IV NSCLC, or malignant pleural effusion.[5] In these patients, the status of the mediastinum is irrelevant to defining the appropriate treatment. In patients with extensive mediastinal infiltration (radiographic group A, Fig. 29.1), the radiographic stage is widely accepted as accurate without tissue confirmation.[5] It must be acknowledged that this is based on general clinical experience, because there is no published data to prove this. These recommendations are summarized in Table 29.3.

Tissue confirmation of the mediastinal stage is unnecessary in patients with cI tumors based on a chest CT and a clinical evaluation (i.e., history and physical examination) (radiographic group D, Fig. 29.1).[5] This is based on extensive data that N2 node involvement (as assessed at thoracotomy) is found in <10% of such patients.[5] The chance of making the diagnosis of N2 involvement by preoperative invasive staging is lower, because the sensitivity of these tests is not perfect. A PET scan to evaluate the mediastinum also appears not to be needed in patients with cI tumors.[6,23,42,43] This is because the chance of finding a PET-positive N2 nodal metastasis is <5%.[23,43] In fact, there is a higher chance of being misled by PET (FP mediastinal uptake or FP distant site of uptake) than the chance of correctly identifying disease spread in patients with cI tumors.[23,43]

## WHEN IS TISSUE STAGING NECESSARY?

Tissue staging of the mediastinum is clearly needed if there is PET activity in mediastinal nodes (unless there is extensive mediastinal infiltration). This is because the FP rate of PET in the mediastinum is approximately 15% to 20%,[5,25] although the largest and most recent metaanalysis found an average FP rate of 27% (on a per patient basis, excluding studies with a prevalence of <10%).[6] These recommendations are summarized in Table 29.3.

Tissue staging is particularly important with increasing wide variability in the quality of PET scans. Furthermore, the accuracy of the scan interpretation is increasingly an issue with the movement to bring PET scanners out into smaller

communities (especially mobile scanners), which hampers communication between the reader of the PET scan and a physician experienced in treating lung cancer. There are data that the interpretation of a CT scan is much more accurate when it is done with input from the treating clinician,[44] and there are multiple reasons that would suggest that this is even more true with PET imaging. Important aspects in this regard include a mechanism for meaningful interaction between a dedicated PET radiologist and a clinician with experience in lung cancer (enabling collective judgment) as well as a mechanism for feedback of final results to the radiologist.[45,46] Little formal study of these issues has been done, but they suggest that one should be cautious about simply accepting PET interpretation without tissue confirmation, especially when the PET is done in a smaller center.

Tissue staging of the mediastinum is also needed in the face of a negative PET in the mediastinum in patients with discrete mediastinal node involvement (radiographic group B) and in patients with central tumors or N1 node enlargement (radiographic group C, Fig. 29.1).[5] The basis for this statement is the finding of an FN rate of PET of approximately 25% in these situations.[5,25,47–49] CT alone is also notoriously inaccurate in these patient cohorts (an FP rate of 40% with discrete mediastinal node involvement and an FN rate of 25% in patients with central tumors of N1 node enlargement).[11] Therefore, tissue staging is necessary in such patients whether or not a PET is performed.

It is worth noting that accurate mediastinal staging is important whenever treatment with curative intent is being planned, not only when the treatment involves surgery. The principles of accurate staging are specific to the disease and not to the modality used. Thus, the same data and, therefore, the same rules about the need for tissue staging of the mediastinum apply if the curative treatment being considered is chemoradiation alone, radiofrequency ablation, or stereotactic radiosurgery.

# LEFT UPPER LOBE TUMORS AND AORTOPULMONARY WINDOW NODES

Cancers in the left upper lobe (LUL) have a predilection for involvement of the nodes in the APW (station 5). These nodes are classified as mediastinal nodes and represent the most important group of N2 nodes that are not accessible by standard cervical mediastinoscopy. It has been suggested that nodes in this region should not be viewed as mediastinal nodes and that resection of patients should be performed regardless of APW node involvement, making assessment of these nodes superfluous.[50] This was based on a selected subgroup of 23 completely resected patients who had APW node involvement as the only site of N2 disease. However, analysis of all of the data in this regard shows that survival of patients with only APW node involvement is not substantially different than that

of patients with involvement of only a single N2 node station in another location.[22,51] Therefore, the issue is more a matter of whether patients with involvement of a single mediastinal node station should undergo surgical resection and not whether APW nodes should be classified as N2 nodes.

The classic way of invasively assessing this area is a Chamberlain procedure (also known as an anterior mediastinotomy), which involves an incision in the second or third intercostal space just to the left of the sternum. Traditionally, an overnight hospital stay was necessary, but in many institutions, this is no longer found to be necessary, especially as surgeons have used visualization between the ribs more frequently as opposed to removal of a costal cartilage. The reliability of this procedure has not been extensively documented, despite its common use. The sensitivity of a Chamberlain procedure in addition to a standard cervical mediastinoscopy in patients with LUL tumors is approximately 87%, and the FN rate is approximately 10%.[5] These patients are primarily from radiographic group B, with probably a few from group C. Two additional studies regarding this procedure have not really addressed the reliability of the procedure for staging of NSCLC. In one study, no actual biopsies were performed in most patients, and the procedure was used to assess resectability (resectable patients included those with bulky APW nodal involvement in this series).[52] The other study used anterior mediastinotomy primarily for diagnosis (not staging), and included pulmonary biopsies and evaluation of patients with mediastinal masses.[53] In fact, only a few patients included in this study had lung cancer.

Extended cervical mediastinoscopy offers an alternative way of invasive assessment of APW nodes, but is used in only a few institutions.[5] With this procedure, a mediastinoscope is inserted through the suprasternal notch and directed lateral to the aortic arch.[54] In 100 consecutive patients with LUL cancers, standard mediastinoscopy and extended mediastinoscopy were found to have a sensitivity of 69% and an FN rate of 11% for detection of N2, N3 disease (prevalence, 29%).[54] Similar results (sensitivity, 81%; FN rate, 9%) were reported in another series of 93 such patients, all of whom had enlarged APW nodes.[55] These patients are primarily from radiographic group B, with probably a few from group C. In approximately 550 patients undergoing extended cervical mediastinoscopy, two major complications (one stroke and one aortic injury) have been reported.[54–58]

Thoracoscopy has been used to assess APW lymph nodes.[5,35] The only study specifically addressing this techniques found complete accuracy in 39 patients.[35] However, the study is limited because it involved only three patients without station 5 or 6 node involvement. EUS-NA also provides an alternative method of sampling APW nodes (see previous discussion). Only one study has specifically addressed EUS-NA for stations 5 and 6, but the data reported do not allow calculation of sensitivity, specificity, and FN or FP rates. However, a high FN rate is suggested.[35]

In conclusion, it appears that the sensitivity of either a Chamberlain or VATS assessment of the APW is high, whereas the results for extended cervical mediastinoscopy, and perhaps also EUS-NA, are somewhat lower. The FN rate appears to be low for all procedures with the exception of EUS-NA. However, these conclusions are somewhat speculative because the amount of data available is limited.

## INTEGRATION OF INVASIVE STAGING TECHNIQUES

The various techniques of tissue staging should be viewed as complementary and not as competitive procedures.[41] There are many reasons for this. First of all, one cannot compare the performance characteristics (sensitivity, specificity, and FN and FP rates) of two tests unless they are being applied to the same patient population.[5] It is quite clear that in most published studies, the patient populations included are *not* the same. They differ relative to whether lymph nodes were enlarged or normal sized, which node stations were most suspicious, and whether the issue at hand was simply to establish a diagnosis or to establish a tissue stage. Furthermore, in assessing the results of a particular technique, it is important to recognize that the performance characteristics will be different in patients with enlarged or normal-sized mediastinal nodes. One should not use data from patients with enlarged nodes to estimate the value of a test for a patient with normal-sized nodes. Therefore, patient characteristics are important determinants in selection of the best method of tissue staging.

The results of staging procedures are also strongly affected by the expertise of the physicians performing the test. It is likely that the difference between the same procedure performed by an expert with a dedicated interest and someone who performs the procedure only occasionally is far greater than differences between different tests. Therefore, appropriate integration of staging procedures is dependent on the local experience. This must be evaluated critically, ideally in a multidisciplinary manner and based on actual local data.

A suggested algorithm (Table 29.3) is to perform mediastinoscopy as the generally preferred tissue staging method in patients with normal-sized mediastinal nodes (e.g., in patients with a central tumor or N1 node enlargement who have a 20% to 25% incidence of N2 involvement). This is because the primary issue is to rule out node involvement, and needle-based techniques carry a high FN rate, especially in normal-sized nodes. Because a negative needle biopsy (EUS-NA, EBUS-NA, or TBNA) should be followed by a mediastinoscopy, most patients would undergo both tests if a needle technique is used as the first step. On the other hand, a needle-based approach may be a good first step in patients with enlarged nodes, because it may spare many patients the need for mediastinoscopy; however, a negative needle test in patients with enlarged nodes should generally still be followed by a mediastinoscopy. Of course, these recommendations are affected by the locations of the nodes that are most in question as well as the local expertise, as previously discussed.

## INTRAOPERATIVE SURGICAL STAGING

Resection of a lung cancer includes a thorough assessment of hilar and mediastinal lymph nodes, and anything less than this constitutes a substandard operation.[59,60] It is important to recognize the differences between a selective node sampling (limited sampling directed by "judgment"), a systematic sampling (at least one representative node from each ipsilateral mediastinal station), a complete mediastinal lymph node dissection (LND, removal of all ipsilateral nodal tissue), and a lobe-specific node dissection (removal of all nodal tissue in the mediastinal node stations most commonly affected for that lobe). Either a systematic sampling or a complete node dissection should be done, although a lobe-specific systematic node dissection may be appropriate in some circumstances.[60]

Several randomized and controlled studies have demonstrated that systematic sampling or node dissection provides more accurate staging information than a selective-node sampling.[61–63] Stage classification is the same after systematic mediastinal node sampling versus a formal lymph node dissection.[61,64–66] There is no increase in morbidity or mortality after LND.[65] Because adjuvant therapy is recommended for patients with nodal involvement, an operation that omits a thorough nodal assessment must be condemned as being of unacceptable quality. This is true whether the procedure is performed via thoracotomy or thoracoscopy, and applies to sublobar resection as well.

Whether there is a therapeutic benefit to a complete lymph node dissection is controversial.[63,67–69] Two randomized studies have found no differences in recurrence rates or survival in patients undergoing LND versus systematic lymph node sampling (in 115 patients with ≤2-cm pathologic stage I [pI] NSCLC and 182 cI to IIIa patients).[68,69] Another randomized study found a benefit to LND as compared with selective sampling, although this was potentially confounded by better staging after LND.[63] Finally, two retrospective studies have found conflicting results.[67,70] The long-term survival results of the completed American College of Surgeons Oncology Group randomized trial of mediastinal node dissection (ACOSOG Z0030) are not yet available.[65]

## CONCLUSION

Surgical evaluation of the mediastinum has evolved, and newer techniques such as videomediastinoscopy or transcervical mediastinal lymphadenectomy are safe and more accurate than traditional mediastinoscopy. At the same time, nonsurgical, needle-based techniques such as EUS-NA and EBUS-NA have been developed. The sensitivity of these techniques is fairly similar, but the needle-based techniques have a higher FN rate that limits their utility, especially in patients with normal-sized mediastinal nodes.

The quality of surgical staging preoperatively is a major issue, and it appears that the difference between high- and poor-quality staging is likely to be much larger than differences between various surgical and nonsurgical techniques. Invasive mediastinal staging remains important in many patients with lung cancer. Careful attention to mediastinal staging is crucial and, ideally, should be addressed in a multidisciplinary fashion.

# The International Staging System for Lung Cancer

Over the last 40 years, the International Staging System (ISS) has become an essential tool for all those involved in the care of patients suffering from cancer or undertaking research in this field. Increasingly, patients are becoming empowered by understanding this system and are making use of this knowledge in their search for information in the literature, on the Internet, and in discussions with their medical advisors. At the heart of the ISS lies an international shorthand that utilizes the TNM-based system to describe the anatomical extent of the disease: the T category describing the size and extent of the primary tumor, the N category describing the extent of involvement of regional lymph nodes, and the M category describing the presence or absence of distant metastatic spread. Each category is defined by ascending numerical descriptors that indicate increasingly advanced disease. All possible combinations of the T, N, and M categories are then used to create TNM subsets. TNM subsets with similar prognoses are then combined into stage groupings. The term *stage*, without further classification, relates to the pretreatment, clinical stage or cTNM. This is derived using the evidence available from clinical history and examination, blood tests, imaging, endoscopic examination, biopsy material, surgical examination, and any other test considered necessary prior to making a decision as to the appropriate treatment in any individual. If this decision leads to surgical treatment, then additional information becomes available at surgery and by pathological examination allowing a more accurate assessment of disease extent, the pathological, postsurgical stage or pTNM. This does not replace the cTNM, which should remain as a record in the patient's notes. If the patient undergoes preoperative, "induction" therapy, usually with chemotherapy and/or radiotherapy, then a reassessment is made after this treatment, prior to a final decision on surgical treatment. The evidence available from this process is used to create the ycTNM, and after surgical treatment in these circumstances, the postsurgical pathological extent of disease is described as ypTNM. At various points in the patient's journey, events may allow or demand a reassessment of disease extent. An rTNM may be established if relapse occurs after a disease-free interval. An aTNM may be formulated if the disease is first discovered at an autopsy. In each case, previous assessments of TNM are retained in the patient records.

The TNM classification is administered by two nongovernmental bodies: the American Joint Committee on Cancer (AJCC) and the Union Internationale Contre le Cancer (UICC) now referred to by the anglicized form of its title, the International Union Against Cancer. Each produces its own publication on cancer staging, denoted as a *Cancer Staging Manual* by the AJCC and the *TNM Classification of Malignant Tumours* by the UICC. In addition, there are several other publications from each organization, such as supplements, atlases, pocket guides, and textbooks on additional prognostic factors. Periodic revisions of *TNM Classification of Malignant Tumours* are undertaken, now on a 7-year cycle. Close collaboration between these organizations in recent years has ensured that for all cancer sites, the definitions of TNM are identical. The 7th edition of both publications was published in 2009.

The anatomical extent of disease, as described by TNM, is not the only prognostic indicator. Many other such indices have been identified.[1] They may be classified as "tumor-related" factors, which include TNM but also other features such as histologic type and grade, "host-related" factors such as gender, age, weight loss, and performance status, and "treatment-related" factors such as the adequacy of resection margins, radiotherapy dose, and chemotherapy response. These can be further categorized as those that are considered "essential," those that provide supplementary guidance by giving "additional" information, and those that are as yet unproven but are "new and promising." These, for lung cancer, are depicted in Tables 30.1 to 30.3.[2] In recent years, advances in molecular biology have taught us much

about the process of carcinogenesis, the genetic basis for predisposition in certain tumor types, the mechanisms by which cancers progress and metastasize, and the reasons for varying responses to treatment and, in some cancers, have provided additional prognostic information. In lung cancer, as yet, there is no consensus as to which molecular markers are of prognostic importance.[3] The anatomical extent of disease, as described by TNM stage, remains the most useful prognostic tool.[4]

The aims of TNM may be summarized as the following:

- To aid the clinician in the planning of treatment
- To give some indication of prognosis
- To assist in evaluation of the results of treatment
- To facilitate the exchange of information between treatment center
- To contribute to the continuing investigation of human cancer

# THE HISTORY OF TNM IN LUNG CANCER[5]

The TNM system for the classification of malignant tumors was developed by Pierre Denoix, a surgeon at the Institute Gustave Roussy in Paris, and published in a series of articles between 1943 and 1952.[6] The following year, 1953, this system was adopted by the recently formed UICC Committee on Tumour Nomenclature and Statistics under the auspices of the League of Nations. The UICC process at this time developed proposals by consensus between experts in the field. These proposals were disseminated in a series of 23 brochures or fascicles published between 1960 and 1967, which covered the TNM classification of cancers in 23 sites, lung being included in the brochure published in 1966. Subsequently, the recommendations were brought together in the 1st edition of the UICC *TNM Classification of Malignant Tumours* published in 1968 in a compact *Livre de Poche* format.[7] The proposals were for "trial" from 1967 to 1971. At that time, there was insufficient information on lung cancer to merit a section of its own, and it was listed under "other sites." The T descriptors included T0 for cases in which there was no evidence of the primary tumor, T1 for tumors confined to a segment or segmental bronchus, T2 where there was lobar involvement, T3 if there was involvement of more than one lobe, and T4 for tumors extending beyond the lung. The N descriptors were NX, N0, or N1, this last category being applied if *intrathoracic* nodes were involved. Intrathoracic nodes were described as *hilar* or *peripheral* with no mention of nodes in the mediastinum. The M1 descriptor was subdivided into M1a in which there was a pleural effusion with malignant cells present, M1b cases with palpable cervical nodes, and M1c for cases in which other distant sites were involved. Stage groupings were not proposed at that time.

The AJCC, formed in 1959 as the American Joint Committee (AJC) for Cancer Staging and End Results Reporting, developed a separate and distinctive process in which "Task Forces" were set up to gather data, which were used to inform its proposals. There was clearly a possibility that these two organizations would make different, and possibly conflicting, recommendations to the cancer community. Therefore, at a series of meetings between the UICC and the AJC, a rapprochement was reached, which ensured that these two organizations would not produce further recommendations without consultation between themselves and other National TNM Committees and International nongovernmental professional organizations.

In 1973, the Task Force on Lung Cancer of the AJC accepted proposals from Dr. Mountain, Dr. Carr, and Dr. Anderson for "A Clinical Staging System for Lung Cancer."[8] This was based on data from 2155 cases of lung cancer, of which 1712 were cases of non–small cell lung cancer (NSCLC), diagnosed at least 4 years before analysis. The majority of the T, N, and M descriptors in use today were introduced at that time, including the impact on T category of such features as the 3-cm cutoff between T1 and T2 tumors, the bronchoscopic extent of disease, the extent of atelectasis/consolidation of the lung parenchyma, and the invasion of chest wall, diaphragm, or mediastinum. The T categories 0 to 3 were retained but T4 was dropped, N categories 0 to 1 were retained but N2 was added to address the issue of mediastinal node involvement, and M categories 0 to 1 were retained. Pleural effusions were removed from the M1 category and became a T3 descriptor.

The resultant TNM subsets were grouped into stages I to III. Four of the possible eighteen TNM subsets had too few cases for analysis and seven others contained less than 100 cases. Survival curves showed distinct differences between prognosis in overall T, N, and M categories and the three-stage groupings to 5 years and beyond. A table showed the differing survival at 12 and 18 months for those TNM subsets for which data was available. No assessment of statistical significance was presented, and there was no validation of the individual descriptors. These proposals were incorporated in the 2nd edition of the UICC *TNM Classification of Malignant Tumours* published in 1975[9] and the 1st edition of the *Manual for Staging of Cancer* published by the AJC in 1977.[10]

The 3rd edition of the UICC manual, published in 1978[11] and revised in 1982, further divided stage I into Ia and Ib (note that at that time, stage subgroups were lowercase) and established stage IV for cases with M1 disease. The "x" descriptor, erratically applied to some categories in earlier editions, was, for the first time, introduced as an option in all three categories of T, N, and M.

The American committee, now the AJCC, did not make these changes in its 2nd edition, which was published in 1983.[12]

By 1986, Dr. Mountain had assembled a new database containing 3753 cases of lung cancer with a minimum follow-up of 2 years. The proposals from this source were accepted by the AJCC, and subsequently by the UICC and cancer committees in Germany and Japan, creating "A new International Staging System for Lung Cancer."[13] The recommendations were published in the 4th edition of the UICC *TNM Classification of Malignant Tumours* in 1987[14] and in the 3rd edition of the American manual in 1988.[15] Changes proposed in this edition include the addition of "visceral pleural invasion" as a T2 descriptor, the designation of superficial tumors limited to the bronchial wall as T1 irrespective of location, a recommendation that the occasional pleural effusion that was cytologically negative could be ignored in defining the T category, the reemergence of the T4 category, and the creation of an N3 category. The existing T3 descriptors were split between T3 and the new T4 category on the basis that the former would retain those descriptors that indicated that such tumors were "candidates for complete resection," whereas the latter would be "inoperable." The previous descriptor of mediastinal invasion was split into its component parts, with invasion of the mediastinal pleura or pericardium remaining T3, whereas invasion of the great vessels, heart, trachea, esophagus, carina, and vertebral bodies became T4 descriptors, along with the presence of a pleural effusion. The situation was confused by additional definitions of T3 and T4 given in the text. Those tumors with "limited, circumscribed extrapulmonary extension" were to be retained within the T3 category, whereas those with "extensive extrapulmonary extension" became T4. These conflicting definitions resulted in a lack of clarity as to whether tumors invading such structures as the pericardium remained T3 if there was extensive invasion and were considered inoperable or became T4, or if invasion limited to a circumscribed area of the esophagus and resected completely at surgery should be considered to be T3 or T4. Metastases to the ipsilateral mediastinal nodes and subcarinal nodes remained within the N2 category, and the new N3 category was added to accommodate metastases to the contralateral mediastinal nodes, contralateral hilum or ipsilateral, and contralateral supraclavicular or scalene lymph nodes. Additional changes in that edition include the moving of T1N1M0 cases from stage I to stage II and the division of stage III into IIIA (containing T3 and N2 cases) and IIIB (containing T4 and N3 cases). Once again, a table showed the differing survival prospects for TNM subsets, and a graph showed statistically significant survival differences between stage groupings. No validation was presented for the individual descriptors or to substantiate the movement of some into T3 and others T4.

The AJCC made no changes in the classification for lung cancer in its 4th edition published in 1992.[16]

At the time of the next revision in 1997, the database of Dr. Mountain has increased to include 5319 cases, all but 66 being NSCLC, 4351 cases treated at the MD Anderson Cancer Center between 1975 and 1988, and 968 cases referred there from the National Cancer Institute Cooperative Lung Cancer Study Group for confirmation of stage and histology.[17] Tables showed statistically significant differences in survival as far as 5 years between clinical/evaluative cTNM categories and pathological/postsurgical pTNM categories T1N0M0 and T2N0M0 and these were divided into a new stage IA and stage IB, respectively. Similarly, T1N1M0 cases were placed in a new stage IIA, and T2N1M0 and T3N0M0 cases became stage IIB. The remaining TNM categories in stages IIIA, IIIB, and IV remained unchanged although statistically significant differences were found between some TNM categories. An additional paragraph determined that "the presence of *satellite* tumor(s), not lymph nodes, within the primary-tumor lobe of the lung should be classified as T4. Intrapulmonary ispilateral [sic] *metastasis* in a distant, that is, nonprimary lobe(s) of the lung, should be classified M1."[17] No data was presented to support these suggestions and the wording used to describe such additional pulmonary nodules was loaded to underline the apparent logic of considering some to be "satellite" lesions and, therefore, a T descriptor, whereas those in other lobes were a "metastasis" and, therefore, an M descriptor.

These recommendations were accepted by the AJCC and the UICC-TNM Prognostic Factors Project Committee and appeared in the 5th edition of their publications in 1997.[18,19]

There were no changes in the lung cancer classification in the 6th edition of *TNM Classification of Malignant Tumours* published in 2002.[20,21]

## THE NEED FOR CHANGE

Undoubtedly, the lung cancer community owes an enormous debt of gratitude to the pioneers of TNM, especially to Dr. Clifton Mountain. However, over the last decade, there has grown a feeling among lung cancer clinicians and scientists that changes were needed to the process for revision of the *TNM Classification for Lung Cancer*. The Mountain database, which

had been the major source of data to inform revisions of the TNM system up to and including the 6th edition had, by 1996, enlarged to include 5319 cases. Thus, it was a relatively small database, accumulated over 20 years, during which period many advances had been made in the techniques available for pretreatment staging, most noticeably the routine application of computed tomography (CT) scanning. The great majority of cases in this database had been referred for surgical treatment and had been recruited from a single center. There were understandable concerns as to whether the recommendations emanating from such a database were historically valid, globally relevant, and appropriate for evaluating treatment by nonsurgical or combined modality care. Oncologists treating small cell lung cancer (SCLC) had abandoned TNM for all, except those very limited cases in which surgery was considered and instead were using a simpler classification based on the single distinction between "limited" or "extensive" disease.[22] Even when used in a surgical setting and for NSLC, the lack of validation in previous editions of the *TNM Classification of Malignant Tumours* had led to many of the descriptors being increasingly challenged. Data had been published supporting size cutoffs other than the 3-cm limit separating T1 and T2 tumors, ranging from less than 1 cm to more than 9 cm. "Irresectable" T4 tumors had been resected with good results in selected cases. The descriptors applied to cases in which there were additional tumor nodules in the lobe of the primary and other ipsilateral lobes were generally regarded as harsh. Oncologists had long treated cases with pleural effusion, the "wet" IIIB cases, with the therapeutic strategies used for patients with metastatic, stage IV disease. Clearly, if the TNM classification was to retain its central role in the day-to-day care of patients with lung cancer in an evidence-based era, its recommendations had to be intensively validated and the process for change had to be modernized to make the staging system fit for purpose. These concerns crystallized at an International Association for the Study of Lung Cancer (IASLC) workshop on "Intrathoracic Staging" held at the Brompton Hospital in London in October 1996.[23] One of the published recommendations of this meeting was "the establishment by the IASLC of a staging committee."

## THE IASLC STAGING PROJECT[24]

At the 8th World Conference on Lung Cancer in Dublin in 1997, the board of the IASLC considered a submission from the late Dr. RJ Ginsberg and Dr. P Goldstraw to create an international staging committee. The board agreed that the IASLC, as the only global organization dedicated to the study of lung cancer, representing all clinical and research aspects of lung cancer care, had a responsibility to become involved in the revision process and to develop a new database to inform future revisions. At its next meeting in December 1998, the board agreed to provide pump-priming funds for such a project. Meetings were held in London in 1999 and 2000, during which the composition of the committee was developed to ensure speciality and geographical representation and the involvement of stakeholders such as

the UICC, the AJCC, and the joint Japanese societies involved in the study of lung cancer. At the next World Conference in 2000, collaboration was established with colleagues from Cancer Research and Biostatistics (CRAB), a not-for-profit medical statistics and data management organization based in Seattle with extensive experience with multicenter data collection and analysis. At that meeting, sufficient funds were guaranteed from the pharmaceutical industry to allow a major meeting in London in 2001, to which database proprietors were invited to present an outline of the data they held. Over the 2-day workshop, data on 80,000 cases were presented from 20 databases across the globe. In was decided to estimate the budget based on the assumption that 30,000 suitable cases could be recruited and that the length of the project would be the 5-year cycle used by the UICC and AJCC at that time. Cases would be solicited from databases worldwide, treated by all modalities of care, between 1990 and 2000, a period during which there had been relative stability in staging methods. This would ensure a 5-year follow-up by the time of analysis. In collaboration with CRAB, the data fields and data dictionary were finalized. Later that year, full funding was obtained by the IASLC via a partnership agreement with the pharmaceutical industry.

Meetings continued to be held on an annual basis utilizing the world conferences, now held biennially, wherever possible.

The UICC was well aware of the need to update the revision process and, around this time, established a "TNM Process Subcommittee. Criteria were established for instituting changes to the TNM classification and for the evaluation of proposals for such changes."[25] A system for continuous monitoring of the proposals in the literature, a "literature watch," was set up. For each cancer type, a "TNM expert panel" was established to review the sifted literature and help in the evaluation of proposals for change. In May 2003, the UICC and AJCC extended the revision cycle to 7 years, which resulted in publication of the 7th edition of the *TNM Classification of Malignant Tumours* being deferred until 2009. The internal review processes within these organizations required that the IASLC submitted its proposals to the UICC in January 2007 and the AJCC in June 2008.

Data collection was discontinued in April 2005, by which time, over 100,000 cases had been submitted to the data center at CRAB. After an initial sift, which excluded cases with insufficient data on stage, treatment, or follow-up, cases outside the designated study period and cases in which the cell type was unsuited or unknown 81,015 were available for analysis, 67,725 cases of NSCLC, and 13,290 cases of SCLC. The proposals for the 7th edition of *TNM Classification of Malignant Tumours* were formulated on the NSCLC cases alone. The geographical distribution of the data sources in this cell type is illustrated in Figure 30.1 and the spread of treatment modalities is shown in Figure 30.2. This enormous task was divided among subcommittees, each charged with collaborating with CRAB to analyze the data and develop proposals for given aspects of the study. These covered the T, N, and M descriptors, the relevance of TNM in SCLC and in carcinoid tumors, the development of an internationally agreed nodal chart, and a thorough review of the value of additional prognostic factors
**FIGURE 30.1** The geographical spread, by continent, for the 67,725 cases of NSCLC that informed the IASLC recommendations for the 7th edition of *TNM Classification of Malignant Tumours.*

and biological markers. As validation had been an issue with previous revisions, a separate subcommittee was created to undertake a comprehensive validation process and to ensure that revisions were compatible with the methodology of the UICC and AJCC. This committee was closely involved with the work of the other groups as their proposals evolved.

**a) Validation and methodology subcommittee[26]**

All exploratory analyses were examined for their relevance in the clinical/evaluative, cTNM population and the postsurgical/pathological pTNM population. There was cTNM data on 53,640 cases, pTNM on 33,933 cases, and both c and p TNM in 20,006 cases. The recommendations of the T descriptors subcommittee were assessed in M0 cases with all combinations of N category and completeness of resection, R, category. Internal validation of the recommendations was checked for consistency across all geographical areas and between differing types of data source. Where the volume of data permitted, in the T descriptors and the TNM stage grouping analysis, the recommendations were created using a "training set" of a randomly selected subgroup comprising two thirds of all cases and then validated against the other one third of cases in the

**FIGURE 30.2** The treatment modalities utilized in the 67,725 cases of NSCLC that informed the IASLC recommendations for the 7th edition of *TNM Classification of Malignant Tumours.* RT, radiotherapy.

"validation set." External validation was mainly established by studying the appropriateness of all recommendations against the Surveillance, Epidemiology, and End Results (SEER) database for 1998 to 2000. Consistency with suggestions raised in the literature was undertaken in collaboration with the UICC Literature Watch program.

**b) T descriptors subcommittee[27]**

There was a paucity of data on many T descriptors. However, data on tumor size was well represented within the database. A running log-rank analysis of size as a continuous variable in T1 tumors revealed a significant cut point at 2 cm. When tested in the validation subset, there was a statistically significant difference in survival between T1 tumors up to 2 cm in size compared with those more than 2 cm but not more than 3 cm.

**Recommendation:** T1 tumors should be subclassified as T1a for tumors up to 2 cm in size and T1b tumors for those that are more than 2 cm in size but not greater than 3 cm in size.

A similar analysis of size in larger tumors showed two additional cut points, one at 5 cm and another at 7.3 cm. For clinical utility, the latter was taken as 7 cm. Using these cut points, three additional size groupings were identified in the training set; those patients whose tumors were larger than 3 cm but not more than 5 cm in size, those with tumors more than 5 cm in size but not more than 7 cm in size, and those whose tumors were more than 7 cm in size. When the survival of these groups was assessed in the validation subset, there were distinctly different survival curves for each group. Furthermore, survival of those with the largest tumors, larger than 7 cm in size, was similar to cases classified as T3 by other criteria.

**Recommendation:** T2 tumors should be subclassified into T2a tumors, more than 3 cm in size but not more than 5 cm, and T2b tumors, more than 5 cm but not more than 7 cm in size. Tumors more than 7 cm in size should be reclassified as T3 tumors.

When the survival of cases classified by the 6th edition of *TNM Classification of Malignant Tumours* as T4 on the basis of additional tumor nodules in the lobe of the primary was compared with that of cases classified as T3 or T4 by other criteria, the survival of the former was found to be different to that of T4 tumors but similar to that of T3 tumors.

**Recommendation:** Reclassify T4 tumors by additional nodules in the lobe of the primary tumor as T3.

Similarly, the survival of cases with additional tumor nodules in ipsilateral lobes other than that of the primary tumor, classified as M1 in the 6th edition of *TNM Classification of Malignant Tumours*, compared with T4 and M1 cases by other criteria, was in line with T4 cases and much better than other M1 cases.

**Recommendation:** Reclassify M1 tumors by additional nodules in other ipsilateral lobes (other than the lobe of the primary tumor) as T4.

Cases classified by the 6th edition of *TNM Classification of Malignant Tumours* as T4 by the presence of a malignant pleural effusion had a survival that was much worse than T4 tumors and similar to that of M1 cases.

**Recommendation:** Reclassify tumors by malignant pleural or pericardial effusion as M1 disease.

### c) N descriptors subcommittee[28]

This subcommittee studied the prognostic significance of the nodal categories in the 6th edition and found that the current N0 to N3 descriptors defined distinct prognostic groups for both clinical and pathologic staging. They undertook exploratory analyses on the prognostic impact of individual nodal stations in the hilum and mediastinum, and combinations and permutations of cell type, lobe of the primary, patterns of nodal involvement in N1 and N2 locations, and the impact of "skip" metastases to the mediastinal nodes without hilar node disease. Although these analyses showed some interesting results, the groups were small and compromised geographically and by treatment modality. They concluded that further prospective studies were necessary before taking these suggestions forward. Such studies would be facilitated by an agreed set of international definitions for nodal stations, and a new "IASLC" international nodal chart, which, for the first time, could reconcile the differences between the Japanese nodal chart and the Mountain/Dressler chart. The concept of "nodal zones" was suggested, amalgamating nodal stations into larger units within the anatomical region. It was hoped that this would ensure that nodal mapping was relevant to oncologists and radiologists used to dealing with bulky disease that often transgressed the boundaries of adjacent nodal stations.

**Recommendation:** The existing categories of N0 to N3 should be retained for the 7th edition. An IASLC nodal chart was created, incorporating the concept of nodal zones.[29]

### d) M descriptors subcommittee[30]

An analysis of those cases suggested for reclassification as M1 caused by malignant pleural effusion showed a similar survival to those classified as M1 in the 6th edition because of additional tumor nodules in the contralateral lung. These two groups had a better survival than that of cases classified in the 6th edition as M1 by the presence of distant metastases, by a small but significant difference.

**Recommendation:** Reclassify M1 because of additional tumor nodules in the contralateral lung as M1a. Reclassify T4 tumors caused by malignant pleural or pericardial effusions as M1a. Reclassify M1 caused by distant metastatic disease as M1b.

### e) Changes to the TNM stage groupings in the 7th edition[31]

This aspect of the project raised issues that affected the way that the recommendations derived from the T, N, and M descriptor subcommittees were presented in the final documents. Where analysis suggested that new descriptors were necessary to accommodate patients whose prognosis differed from the other cases within any particular T or M category, two alternative strategies were considered: (a) Retain that descriptor in the existing category, identified by alphabetical subsets. For example, additional pulmonary nodules in the lobe of the primary, considered to be T4 in the 6th edition, would remain T4 but identified as T4a, whereas additional pulmonary nodules in other ipsilateral lobes, designated as M1 in

the 6th edition, would become M1a. (b) Allow descriptors to move between categories, to a category containing other descriptors with a similar prognosis, for example, additional pulmonary nodules in the lobe of the primary would move from T4 to T3, and additional pulmonary nodules in other ipsilateral lobes would move from M1 to T4. The first strategy had the advantage of allowing, to a large extent, retrograde compatibility with existing databases. Unfortunately, this strategy generated a large number of descriptors (approximately 20) and an impractically large number of TNM subsets (>180). For this reason, backward compatibility was compromised and strategy *b* was preferred for its clinical utility. The recommendations were therefore formatted as previously described. These changes to T and M descriptors were then incorporated into the resultant TNM subsets. A small number of candidate stage grouping schemes were developed initially, based on a "training" set, using a recursive partitioning and amalgamation (RPA) algorithm.[32] This generated a tree-based model for the survival data using log-rank test statistics for recursive partitioning and, for selection of the important groupings, bootstrap resampling to correct for the adaptive nature of the splitting algorithm. An ordered list of groupings from the terminal nodes of the "survival tree" was created, and with this as a guide, several proposed stage groupings were created by combining adjacent groups. Selection of a final stage grouping proposal from among the candidate schemes was based on its statistical properties in the training set and its relevance to clinical practice, and was arrived at by consensus.

The survival of cases within our database stratified by the 6th edition of *TNM Classification of Malignant Tumours* and by the IASLC proposals for the 7th edition are shown for cases staged clinically in Figure 30.3 and for pathologically staged cases in Figure 30.4. The proposed system better delineated the early stage cases, where problems with overlap between IB and IIA have been noted with the 6th edition of *TNM Classification of Malignant Tumours*.[33] Improvement was also seen in the distinction between clinical IIA and IIB, as well as the proportion of cases assigned to stage IIA, another weakness of the 6th edition of *TNM Classification of Malignant Tumours*. For both the clinical and pathological stage models, there was an increase in the value for $R^2$, an estimate of the percent variance explained (PVE) by the model.[34] The proposals for the 7th edition made use of well-justified changes to T and M, and served to identify subsets of patients with tumors of different sizes with differing prognoses. Both the proposed new system and the 6th edition of *TNM Classification of Malignant Tumours* showed a reversal on pathological staging from the expected survival for advanced stage disease (IIIB and IV). This result, although anomalous, could be explained by the selective nature of advanced cases undergoing surgery, many of which were taken to surgery on the assessment that their disease was limited only to be discovered to have advanced disease at thoracotomy.

**Recommendation:** The new descriptors and the recommended stage groupings, now enacted in the 7th edition, are shown in Tables 30.4 and 30.5.

| | IA | IB | IIA | IIB | IIIA | IIIB | IV |

### f) SCLC subcommittee[35,36]

There were 13,290 cases of SCLC in the IASLC database, of which details on clinical TNM stage were available in 8088. Survival was found to be reliably related to both T and N categories. Differences were more pronounced in patients without mediastinal or supraclavicular nodal involvement. Stage grouping, using the 6th edition of *TNM Classification of Malignant Tumours*, also differentiated survival except between IA and IB. Patients with pleural effusion regardless of the cytology were found to have an intermediate prognosis between those with limited and extensive disease. The IASLC proposals for the 7th edition of the TNM classification were found to be applicable to this series of SCLC and to the SEER database.

**Recommendation:** TNM staging is recommended in the staging of SCLC, and stratification by stage I to III should be incorporated in clinical trials of early stage disease. Further studies are needed to clarify the impact of pleural effusion and the extent of N3 disease.

**g) Carcinoid tumors subcommittee[37]**

Previously, carcinoid tumors had been excluded from the TNM classification, although TNM was frequently used in the literature to describe the anatomical extent of disease in surgical and pathology reviews of carcinoid tumors. Data on carcinoid tumors were not specifically requested for our database, but nevertheless, we received details on 520 cases. The SEER data for the corresponding period (1990 to 2002) also contained TNM data on 1998 cases of carcinoid tumors. Unfortunately, the distinction between "typical" and "atypical" tumors was infrequently and unreliably recorded. Our analysis of these cases found that the TNM classification, by the 6th edition and using our proposals for the 7th edition of *TNM Classification of Malignant Tumours*, was a useful predictor of survival and a strong predictor when assessing N and M descriptors. The analysis of T descriptors was confounded by the lack of clarity on several aspects of the pathology reports such as

| TABLE 30.4 | The T, N, and M Descriptors in the 7th Edition of *TNM Classification of Malignant Tumours** |
|---|---|

**T: Primary Tumor**

TX  Primary tumor cannot be assessed, *or* tumor proven by the presence of malignant cells in sputum or bronchial washings but not visualized by imaging or bronchoscopy

T0  No evidence of primary tumor

Tis  Carcinoma in situ

T1  Tumor 3 cm or less in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than the lobar bronchus (i.e., not in the main bronchus)[1]

 T1a  Tumor 2 cm or less in greatest dimension

 T1b  Tumor more than 2 cm but not more than 3 cm in greatest dimension

T2  Tumor more than 3 cm but not more than 7 cm;

 or tumor with *any* of the following features*:

 • Involves main bronchus, 2 cm or more distal to the carina

 • Invades visceral pleura

 • Associated with atelectasis or obstructive pneumonitis that extends to the hilar region but does not involve the entire lung

 T2a  Tumor more than 3 cm but not more than 5 cm in greatest dimension

 T2b  Tumor more than 5 cm but not more than 7 cm in greatest dimension

*T2 tumors with these features are classified T2a if 5 cm or less

T3  Tumors more than 7 cm or one that directly invades any of the following: chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; *or* tumor in the main bronchus less than 2 cm distal to the carina[1] but without involvement of the carina; *or* associated atelectasis or obstructive pneumonitis of the entire lung or separate tumor nodule(s) in the same lobe

T4  Tumor of any size that invades any of the following: mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; separate tumor nodule(s) in a different ipsilateral lobe

**N: Regional Lymph Nodes**

NX  Regional lymph nodes cannot be assessed

N0  No regional lymph node metastasis

N1  Metastasis in ipsilateral peribronchial and/or ipsilateral hilar lymph nodes and intrapulmonary nodes, including involvement by direct extension

N2  Metastasis in ipsilateral mediastinal and/or subcarinal lymph node(s)

N3  Metastasis in contralateral mediastinal, contralateral hilar, ipsilateral or contralateral scalene, or supraclavicular lymph node(s)

**M: Distant Metastasis**

MX  Distant metastasis cannot be assessed

M0  No distant metastasis

M1  Distant metastasis

 M1a Separate tumor nodule(s) in a contralateral lobe; tumor with pleural nodules or malignant pleural (or pericardial) effusion[2]

 M1b Distant metastasis

**Notes:** 1. The uncommon superficial spreading tumor of any size with its invasive component limited to the bronchial wall, which may extend proximal to the main bronchus, is also classified as T1a.

2. Most pleural (and pericardial) effusions with lung cancer are due to tumor. In a few patients, however, multiple cytopathological examinations of pleural (pericardial) fluid are negative for tumor, and the fluid is nonbloody and is not an exudate. Where these elements and clinical judgment dictate that the effusion is not related to the tumor, the effusion should be excluded as a staging element and the patient should be classified as T1, T2, T3, or T4.

*From UICC. *TNM Classification of Malignant Tumours.* 7th Ed. New York: Wiley-Liss, 2009. Reproduced with kind permission by the UICC.

size, atelectasis, the presence of multiple nodules, pleural invasion, and bronchoscopic extent.

 **Recommendation:** Carcinoid tumors will be included under the 7th edition. A registry of such tumors will form part of the next phase of the IASLC Staging Project.

**h) Visceral pleural invasion subcommittee[38]**

 Visceral pleural invasion was identified as a T2 descriptor in the 4th edition of *TNM Classification of Malignant Tumours* published in 1987.[14] It has persisted into the 6th edition of *TNM Classification of Malignant Tumours* and will remain so according

| TABLE 30.5 | The TNM Stage Groupings in the 7th Edition of *TNM Classification of Malignant Tumours** | | |
|---|---|---|---|
| Occult carcinoma | TX | N0 | M0 |
| Stage 0 | Tis | N0 | M0 |
| Stage IA | T1a,b | N0 | M0 |
| Stage IB | T2a | N0 | M0 |
| Stage IIA | T1a,b | N1 | M0 |

| Stage IV | Any T | Any N | M1a,b |

*From UICC. *TNM Classification of Malignant Tumours.* 7th Ed. New York: Wiley-Liss, 2009. Reproduced by kind permission of the UICC.

to our recommendations for the 7th edition. However, pathologists have struggled to arrive at an internationally agreed definition of such invasion. The UICC states in the *TNM Supplement*: *A Commentary on Uniform Use*[39] that "invasion of visceral pleura (T2) includes not only perforation of the mesothelium but also invasion of the lamina propria serosae" although the Japan Lung Cancer Society only considers that "p2," defined as "tumor that is exposed on the pleural surface but does not invade adjacent anatomic structures" is by itself a T2 descriptor.[40] The IASLC Staging Project has undertaken a literature review of this subject and has proposed a standardized definition.

**Recommendation:** Invasion of the visceral pleura should be defined as "invasion beyond the elastic layer including invasion to the visceral pleural surface." The use of elastic stains is recommended when this feature is not clear on routine histology.

**i) Additional prognostic factors subcommittee[3]**

There is a growing debate as to how additional prognostic factors should be integrated with the TNM classification. As suggested earlier, some of these will have prognostic importance and others are predictive of response to treatment. Ultimately, the UICC and AJCC must decide whether such factors are incorporated within TNM or, as seems more probable, are added to TNM in a composite prognostic model. The IASLC database contained limited information of patient-related factors such as age, gender, and performance status; tumor-related factors such as cell type and degree of differentiation; and laboratory variables such as serum albumen, hemoglobin, white blood cell count, and sodium. An analysis of the value and interaction of these variables with TNM stage in clinically and pathologically staged cases on NSCLC was undertaken and the results were published.[3,4]

We did not collect data on positron emission tomography (PET) studies but a metaanalysis, based on a literature review,

was undertaken by the European Lung Cancer Study Party in collaboration with the IASLC Staging Project. This showed the prognostic significance of the PET maximum standardized uptake value ($SUV_{max}$) in the primary tumor at diagnosis[41] to be an independent prognostic factor in lung cancer.

## THE 7TH EDITION OF TNM IN LUNG TUMORS

The recommendations from the IASLC Staging Project were submitted to the UICC and AJCC on time, underwent internal review, and were accepted without change as the 7th edition of *TNM in Lung and Pleural Tumours*. Because of the central role of the IASLC Staging Project in the creation of the 7th edition and delays in the publishing schedules of the UICC and the AJCC, the IASLC was accorded the privilege of being the first to publish this new classification, at the 13th World Conference on Lung Cancer in August 2009.[42,43] The 7th editions of this classification were subsequently published later in 2009 by the UICC and AJCC.[44,45] The T, N, and M descriptors are listed in Table 30.4 and the resultant stage groupings in Table 30.5.

**Additional Changes in the 7th Edition of *TNM Classification of Malignant Tumours*** The additional proposals, suggested by analyses within the IASLC Staging Project, have all been incorporated into the 7th edition of *TNM Classification of Malignant Tumours*, along with clarification on other aspects of the classification. These include the following:

1. The "IASLC" nodal chart and the accompanying table of definitions has been accepted as the recommended means of describing the regional lymph node involvement for lung cancers. It is also recommended that at least six lymph nodes/stations be removed/sampled and confirmed on histology to be free of disease to confer pN0 status. Three of these nodes/stations should be mediastinal, including the subcarinal nodes (#7) and three from N1 nodes/stations.
2. There is greater emphasis on the use of the TNM classification in SCLC.
3. Bronchopulmonary carcinoid tumors are, for the first time, covered by the TNM classification.
4. The definition of visceral pleural invasion is included within the TNM classification.
5. In cases in which there is more than one tumor in the lung(s), the distinction between metastases and multiple synchronous primary tumors has traditionally been based on the Martini and Melamed[46] paper. In the 7th edition, these definitions are retained but supplemented by a new emphasis on the role of the pathologist, utilizing where necessary special studies such as immunohistochemistry and molecular markers. In this distinction, lung differs from other organ sites as additional tumor nodules that are microscopic or otherwise only discovered on pathological examination are also covered in the classification.

6. In the application of the "V" classification, lung also differs from other organ sites as, in lung, invasion of arterioles is not uncommon. The V classification in lung therefore covers vascular invasion, whether venous or arteriolar.

**Proposals for Testing** The *TNM Classification of Malignant Tumours* allows for the formulation of "proposals for testing." This section is largely aspirational allowing additional classifications to be trialed for some years. Often, these have been suggested by inquiries to the UICC TNM Helpdesk or in published studies scrutinized by their systematic annual literature search. For some, there is already supportive data, but for all, additional data and validation are required before considering their inclusion into future revisions. In the 7th edition, these proposals include the following:

1. Where the pN0 category has been based on less than the recommended number of lymph nodes (six lymph nodes/stations, three mediastinal, including the subcarinal nodes [#7], and three N1) or where the highest node removed contains metastases, it is proposed that the resection be categorized as an "**Uncertain Resection**," and designated "**R0(un)**."[47]

2. The concept of nodal zones has been suggested as a simpler, more utilitarian system for clinical staging where surgical exploration of lymph nodes has not been performed.[28] An exploratory analysis suggested that nodal extent could be grouped into three categories with differing prognoses: (a) involvement of a single N1 zone, designated as N1a, (b) involvement of more than one N1 zone, designated as N1b, or a single N2 zone, designated N2a, and (c) involvement of more than one N2 zone, designated as N2b. It is suggested that radiologists, clinicians, and oncologists use the classification prospectively, where more detailed data on nodal stations is not available, to assess the utility of such a classification for future revision.

3. A recent metaanalysis[48] has confirmed that pleural lavage cytology (PLC), undertaken immediately on thoracotomy and shown to be positive for cancer cells, has an adverse and independent prognostic impact following complete resection. Such patients may be candidates for adjuvant chemotherapy. Surgeons and pathologists are encouraged to undertake this simple addition to intraoperative staging and collect data on PLC+ve and PLC–ve cases. Where the resection fulfils all of the requirements for classification as a "Complete Resection," R0 but PLC has been performed and is positive the resection should be classified as "**R1(cy+)**."

4. A standardized definition of visceral pleural invasion (VPI) has been incorporated into the 7th edition of *TNM Classification of Malignant Tumours*.[38] A subclassification has been proposed using a "PL" category be used to describe the pathological extent of pleural invasion:

> PL0 tumor within the subpleural lung parenchyma or invades superficially into the pleural connective tissue beneath the elastic layer

> PL1 tumor invades beyond the elastic layer
> PL2 tumor invades to the pleural surface
> PL3 tumor invades into any component of the parietal pleura

5. There are suggestions that the depth of chest wall invasion may influence prognosis following resection of lung cancer. A subclassification has been proposed, based on the histopathologic findings of the resection specimen, dividing such pT3 tumors into pT3a if invasion is limited to the parietal pleura (PL 3), pT3b if invasion involves the endothoracic fascia, and pT3c if invasion involves the rib or soft tissue.

6. Imaging evidence of lymphangitis carcinomatosa is usually a contraindication to surgical treatment. The "L" category, which is used to assess pathological evidence of "lymphatic invasion," is therefore not applicable. The radiological extent of lymphangitis is thought to be of prognostic importance. An exploratory analysis of this feature is proposed using a "cLy" category in which cLy0 indicates that radiological evidence of lymphangitis is absent, cLy1 indicates lymphangitis is present and confined to the area around the primary tumor, cLy2 indicated lymphangitis at a distance from the primary tumor but confined to the lobe of the primary, cLy3 indicates lymphangitis in other ipsilateral lobes, and cLy4 indicates lymphangitis affecting the contralateral lung.

7. All cases in which there is metastatic spread to distant organs are classified as M1b disease. However, there are clear differences in prognosis based on tumor burden and the critical nature of some organ sites. Such differences will influence the choice of treatment and the intent of treatment by all modalities of care. Selected patients with isolated metastases to a single organ may benefit from surgical treatment. Data on M1b cases should record the number of metastases and the number of metastatic sites as far as is practicable. It should prove feasible in all cases to record if metastases are single or multiple.

8. The categories assigned to cases in which there are additional tumor nodules of similar histological appearance in the lung(s) has been reclassified in the 7th edition of *TNM Classification of Malignant Tumours*. We cannot determine that this is valid for cases in which multiple deposits are encountered and prospective data collection is necessary to fully validate this reclassification. It is recommended that the number of nodules in the lobe of the primary, other ipsilateral lobes and the contralateral lung, and the diameter of the largest deposit in each location be documented as far as is practicable.

9. Bronchopulmonary carcinoid tumors are included within the 7th edition of *TNM Classification of Malignant Tumours*. However, further data are needed to assess the prognostic impact of certain features in carcinoid tumors; typical versus atypical features, T size cut points, the prognostic impact of multiple deposits, and whether these are associated with the syndrome of diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH). In addition, in carcinoid tumors, long-term survival can be expected even when associated with multiple tumor nodules or nodal disease. It is therefore important to collect data on disease-specific survival

10. PET scanning using $^{18}$F-fluorodeoxyglucose (FDG) is now widely utilized and has had an impact of the accuracy of clinical staging and referrals for surgical treatment. In addition, a metaanalysis has shown that PET features, such as the maximum value of the $SUV_{max}$ in the primary tumor prior to treatment is an independent prognostic factor.[41] Where PET scans are performed, it is suggested that data is collected on features such as $SUV_{max}$ in the primary and any nodal and/or metastatic sites.

We encourage clinicians, radiologist, nuclear medicine specialists, and pathologists to collect data on these aspects of lung cancer staging for subsequent analysis.

## Clinical Implications of the 7th Edition

Intensive validation formed a central feature of the IASLC Staging Project resulting in robust changes for the 7th edition of *TNM Classification of Malignant Tumours*. However, it is recognized that some of these changes will create problems for colleagues in this field. The necessity to sacrifice backward compatibility with existing databases in the search for a staging system, which is manageable in clinical practice, has already been mentioned. It is also recognized that moving some descriptors within stage categories and recommending the proposed changes to the stage groupings will cut across established treatment algorithms. The moving of the larger, node-negative T2 tumors (T2b cases more than 5 cm in greatest dimension) and tumors more than 7 cm in greatest dimension (which would become T3) from stage IB into stage IIA and stage IIB, respectively, will clearly raise the question as to whether such cases should have adjuvant chemotherapy after complete resection. Although there is still doubt as to the value of adjuvant chemotherapy after complete resection for node-negative cases in stage IB,[49,50] at least two large trials have shown a benefit for node-positive cases in stages II and IIIA.[51,52] The question as to whether these larger, node-negative tumors benefit from adjuvant therapy after complete resection will only be resolved by large, prospective randomized trials. The reassignment of cases with additional nodules in an ipsilateral, nonprimary bearing lobe into a T4 descriptor rather than an M1 descriptor and the relocation of T4 N0 M0 and T4 N1 M0 cases into stage IIIA will also lead to questions as to the appropriate treatment algorithm. One limitation of our database was that it does not allow us to be certain whether this reassignment is appropriate for cases with multiple additional tumor nodules or for all T4 cases. Multimodality treatment models, some including surgery, will no doubt evolve, informed by appropriate trials. In other situations, the changes included in the 7th edition of the *TNM Classification of Malignant Tumours* better reflect current practice as with the move of cases with malignant pleural effusions into an M category from a T category. Within the IASLC database, there was a clear difference in prognosis between patients with metastases to the contralateral lung or associated with a pleural effusion and those with metastases at distant sites outside the thorax. In general, the latter have the worst prognosis and have been historically considered as stage IV, and candidates for primarily systemic treatment. It therefore seems relevant to subclassify, within an expanded stage IV, those cases with spread within the thorax as M1a and those with metastases to distant sites as M1b.

## The Future for TNM

The 7th edition was based on the IASLC international database, the largest databases ever accumulated for this purpose. The number of cases recruited was 15 to 20 times larger than that which informed any previous revision. Data were donated by 46 sources in over 19 countries. The IASLC is grateful for the support offered by colleagues around the world, which has ensured the success of the staging project. Although the treatment of these cases included surgery in 53% of the patients, there were 30% in which chemotherapy was used and 29% in which radiotherapy was utilized. The data were collected from cases treated over a relatively short period during which the techniques used in clinical staging were reasonably standardized worldwide. The recommendations have been, for the first time, intensively validated. Internal validation has ensured that the recommendations are supported by data from all geographical areas and across all types of database. External validation has been established against the SEER database.

There are, however, limitations to this project. The volume of data and the international nature of the data sources has made data audit extremely difficult and, as a result, only limited checks for consistency have been possible. There are glaring deficiencies in the global distribution of the data with no data at all being included from Africa, South America, or the Indian subcontinent. Other vast countries such as Russia, China, and Indonesia are not represented or only poorly represented. Although less surgically dominated than previous databases, the spread of treatment modalities does not reflect the practice in most institutions. The period under study predates the widespread and routine use of PET scanning, which has had an enormous impact on clinical staging algorithms. In any retrospective database, one has to collect the data that were considered important by each source and this reflects the use for which the data were collected. Although we have an enormous amount of data on some descriptors, such as tumor dimension, we have too little on many to prove or disprove the validity of some descriptors.

It is hoped that our colleagues in clinical practice will recognize that the changes suggested by this project are driven by the data available to us from a database of over 68,000 cases. Even with the acknowledged limitations of the database, its breadth has allowed the application of evidence-based standards in terms of statistical power, reliability, and scientific validity that were not possible in previous revisions. Inevitably, existing treatment algorithms will be challenged but it is hoped that by the rigorous analysis of large volumes of data, the utility of the TNM classification for lung cancer will be strengthened. The IASLC Staging Project is now entering its next phase. This will see the scope of the project expand to include neuroendocrine tumors, including carcinoid tumors, mesothelioma, and possibly other thoracic malignancies. A prospective

data set has been established and web-based data collection has been trialed.[53] We hope that these features will ensure further, carefully validated proposals concerning thoracic malignancies for the 8th edition of the *TNM Classification of Malignant Tumours* and beyond. Any institution that wishes to contribute can receive additional information by sending an email to information@crab.org with the phrase "IASLC Staging Project" in the subject line. The success of the next cycle of revision, as in this cycle, totally depends on the support we receive from the global lung cancer community.

## CONCLUSION

The *TNM Classification of Malignant Tumours* has stood the test of time and remains the most powerful prognostic tool in lung cancer.[4] The IASLC Staging Project created robust proposals for the 7th edition and the resultant 7th edition of *TNM Classification of Malignant Tumours*, which more accurately correlates the anatomical extent of disease and prognosis. In the future, the challenge will be to integrate TNM with other prognostic factors as they are identified and validated.

# Surgical Management of Lung Cancer

# Minimally Invasive Techniques for the Management of Lung Cancer

The hope for video-assisted thoracic surgery (VATS) treatment of lung cancer is that it would reduce morbidity, mortality, and hospital stay and allow quicker return to regular activities for patients after procedures that formerly required major incisions. However, since the first VATS lobectomy (VL) with anatomic hilar dissection was performed in 1992, some have questioned the safety and benefits reported for a VATS approach.[1–3] Although there is no large, randomized prospective study from around the world, the experience is now sufficiently large enough to compare VATS with open thoracotomy for pulmonary resection. Large series of VATS lobectomies show impressive results. More and more, thoracic surgeons offer their patients minimally invasive pulmonary resections. This chapter will provide the current data regarding minimally invasive procedures for the management of lung cancer.

## QUESTIONS ABOUT VATS LOBECTOMY

The following are the current questions about VATS for lobectomy:

- What is the definition of a VATS lobectomy?
- How is it done?
- Is it safe?
- Is it an adequate cancer operation?
- Are there advantages over a thoracotomy?

## DEFINITION

There are some controversies about the exact definition of a VL, and these issues include rib spreading, instrumentation, and anatomic dissection. However, most agree that a VL should include an anatomic dissection of pulmonary vessels, a nodal sampling or dissection, an incision ≤10 cm long, and, most importantly, no rib spreading. Visualization should be on a monitor, not through the incision. A retractor to hold open the soft tissue may be helpful to prevent expansion of the lung during intrapleural suctioning. The use of standard, open instruments or disposable, minimally invasive instruments does not matter and should not be part of the definition. Simultaneous ligation of the hilar structures[1] should be discouraged. A "hybrid" operation that involves rib spreading through a small incision has only recently been addressed in the literature, and surely is used by many surgeons as a compromise between complete VATS and open thoracotomy. There are few reports comparing these techniques[4] and patients undergoing lobectomy and lymph node dissection with a complete VATS had less blood loss, faster recovery, shorter hospitalization, and longer operating times than did patients undergoing the lobectomy with the open approaches. At a mean follow-up of 38.8 months, Kaplan-Meier probabilities of survival at 5 years were complete VATS, 96.7%; hybrid VATS, 95.2%; and open techniques, 97.2%. There was no significant difference in the rate of recurrence among the three different procedures. It was concluded that VATS lobectomy is an acceptable cancer operation for patients with peripheral non–small cell lung cancer less than or equal to 2 cm in diameter (clinical stage IA) with the same long-term survivals as open surgery.

## GENERAL APPROACH FOR A VATS LOBECTOMY

Philosophically, a lobectomy should be the same operation, whether it is performed through a thoracotomy or by VATS. The arteries, veins, and bronchi should all be individually ligated and a lymph node dissection or sampling should be performed.[5]

With current technology, most lobectomies can be performed by VATS. In 2005, although 94% of the 239 lobectomies performed by our group were VATS, only 18% of lobectomies in the 2005 Society of Thoracic Surgeons General Thoracic Surgery Database were performed by VATS (personal communication). The adoption for VATS lobectomy was slow after the first VATS lobectomy in 1992, but the momentum is currently growing rapidly, because patients demand the procedure and thoracic surgeons gain an understanding of the techniques to perform the procedure.

| TABLE 31.1 | Indications and Contraindications for VATS Lobectomy |
|---|---|
| **Indications** | |
| Clinical stage I lung cancer | |
| Tumor size <6 cm | |
| Physiologic operability | |
| **Possible Contraindications** | |
| Nodal disease (benign or malignant) | |
| Pancoast tumors | |
| Chest wall or mediastinal invasion (T3 or T4 tumor) | |
| Need for sleeve lobectomy | |
| Neoadjuvant chemotherapy | |
| Neoadjuvant radiation therapy | |
| **Contraindications** | |
| Nodal disease densely adherent to vessels | |
| Chest wall or mediastinal invasion (T3 or T4 tumor) | |
| Neoadjuvant chemotherapy and radiation therapy | |

**FIGURE 31.1**   The incisions for our approach to video-assisted thoracic surgical lobectomy include the following: (*1*) incision 1 in the auscultatory triangle for an assistant's instrument, (*2*) an incision 2 for the trocar and the thoracoscope, (*3*) the utility thoracotomy incision 3, and (*4*) incision 4 in the midclavicular line for the stapler.

## INDICATIONS AND CONTRAINDICATIONS

The indications for a lobectomy (Table 31.1) are similar whether the procedure is performed by VATS or via a thoracotomy. For VATS, the ideal case is a T1N0 peripheral tumor; however, we have removed an 8-cm tumor through a 5-cm incision by cutting one rib. Centrally located tumors that require a bronchial sleeve resection are generally performed via a thoracotomy, although VATS sleeve resections have been performed with good results.[6] VATS may expand the indications to include patients with marginal performance status and who are not candidates for a thoracotomy.

The contraindication and possible contraindications to a VATS lobectomy are also shown in Table 31.1. Safe dissection around the vessels and in the mediastinum after neoadjuvant chemotherapy and/or radiation is challenging and may require a thoracotomy. Reports do show that VATS lobectomies after neoadjuvant chemotherapy, and sometimes after chemotherapy and radiation treatment, can be performed safely.[7]

## TECHNIQUE FOR VATS LOBECTOMY

**Procedure**   Typical placement of incisions for a VATS lobectomy is seen in Figure 31.1. The utility incision is 4 to 6 cm, and the ribs are not spread. The fissure, bronchus, and pulmonary vessels larger than 5 mm are individually transected with the endoscopic stapler. Smaller vessels may be tied or clipped. The completeness of the fissure is not a factor in determining the feasibility of performing a VATS lobectomy, because the vessels are stapled anteriorly and then the fissure is completed. Vessels are dissected anteriorly, not through the fissure; the fissure is usually completed after the vessels and bronchus are transected. To minimize the risk of contaminating the incision with the tumor, the lung specimen is placed in a bag for removal through the utility incision.

**Lymph Node Dissection**   Mediastinal node sampling or complete lymph node dissection should be part of all lobectomies for cancer; and they can properly be performed by VATS. In a prospective study, after one surgeon performed a VATS nodal dissection, another thoracic surgeon then performed a thoracotomy to remove any additional lymphatic tissue that could be found.[8] For the right-sided procedures, the mean numbers of lymph nodes resected by VATS was 40.3 (weight = 10 g), and mean number of additional nodes found at thoracotomy was 1.2 (weight = 0.2 g). Therefore, a good node dissection can be performed by VATS.

## IS A VATS LOBECTOMY SAFE?

Table 31.2 shows the result of several large series. The morbidity and mortality are low in these series, and the length of stay is short. These statistics are comparable or better than those for lobectomy by thoracotomy. The mortality, morbidity, and length of stay for the VATS approach are comparable or better than the results with current series utilizing a thoracotomy.[9] A small randomized study showed fewer complications for the VATS approach (18% vs. 50%).[10]

**Conversion to Thoracotomy**   Conversion from VATS to thoracotomy is not a failure for a VATS lobectomy. Conversion to thoracotomy was necessary in 0% to 19.5% of patients in large series of VATS lobectomy referenced in this chapter. This was most often required for oncologic reasons, such as a centrally located tumor requiring vascular control,

| TABLE 31.2 | Results after VATS Lobectomy for Several Large Series | | | |
|---|---|---|---|---|
| Reference | No. of Patients | Mortality | Morbidity | Length of Stay* |
| McKenna Jr. et al.[1] | 1100 | 0.8 | 15% | 4.8/4 |
| Onaitis et al.[24] | 500 | 1% | 15% | /3 |
| Yim et al.[25] | 214 | 0.5% | 22% | 6.8/NR |
| Kaseda et al.[27] | 204 | 0.8% | 2.3% | NR |
| Swanson et al.[9] | 180 | 0.6% | 21% | NR/4 |
| Roviaro[28] | 171 | 0.6% | 8.7% | NR |
| Walker et al.[3] | 159 | 1.8% | NR | NR/6 |
| Iwasaki[29] | 140 | 0% | NR | NR |

*mean/median days
NR, not reported.

a sleeve resection, or an unsuspected T3 tumor, attached to the chest wall, diaphragm, or superior vena cava, prompted the conversion. Abnormal hilar nodes with granulomatous or metastatic disease adherent to the superior pulmonary vein may be better evaluated and more safely resected with thoracotomy. Approximately 30% of the conversions to thoracotomy are for nononcologic reasons, such as pleural symphysis.

**Intraoperative Hemorrhage**    Although bleeding during a VATS procedure can be dangerous because access is limited, this occurs rarely when an experienced surgeon performs VATS resections. The scrub nurse should always keep a sponge stick available to immediately apply pressure for controlling hemorrhage in the event that bleeding occurs. After the bleeding is controlled, the surgeon can then deal with the bleeding by VATS or thoracotomy. Significant bleeding occurs in <1% of cases and can usually be managed with low risk.[11]

**Tumor Seeding of the Incision**    Although tumor recurrence in a VATS incision with a poor prognosis, the incidence appears to be very low (<0.5%). The risk of tumor seeding in an incision can be minimized with the use of proper bags to protect the incisions during removal of specimens.

**Immunologic Effect of VATS versus Thoracotomy**
There appears to be less impact after a VATS procedure than after a thoracotomy. VATS is associated with a reduced stress response, reduced postoperative C-reactive protein, reduced IL-6 levels, and better cellular immune function.[12–14] However, the clinical significance of this is unclear.

## ADEQUACY OF VATS AS A CANCER OPERATION

The ultimate measure of any cancer treatment is long-term disease-free survival. Although, in general, the 5-year survival for stage I lung cancer after resection is about 60%, the 5-year survival after a VATS lobectomy for stage I lung cancer has been reported to be 72% to 94%. This may be related to patient selection, rather than any true benefit from the VATS approach.

## BENEFITS OF VATS OVER THORACOTOMY FOR LOBECTOMY

Nonrandomized studies suggest that there are benefits for VATS compared with a thoracotomy for lobectomy (Table 31.3). Patients generally appear to have less pain after a VATS than after a lobectomy by thoracotomy ($p < 0.02$).[15–17] VATS patients averaged less morphine, less breakthrough narcotic, less sleep disturbance, and a better pain analogue score than the thoracotomy patients. The incidence of postthoracotomy pain syndrome after VATS lobectomy (2.2%) is lower than expected after thoracotomy.[1] The VATS patients also experienced less pain and greater shoulder strength in the first 6 months postoperatively, but there was no difference after 1 year.

In single-institution series, other benefits to VATS appear to be the following: reduced blood loss and need for transfusion,[18] atrial fibrillation,[1] incidence of pneumonia.[19] VATS appears to be easier for elderly patients and allows surgeons to offer a lobectomy to older patients than can tolerate a thoracotomy.[20]

Cost analysis favors a VATS approach, with fewer lab charges, anesthesia charges, less disposable charges, and fewer hospital charges.[21]

| TABLE 31.3 | Studies Showing Benefits of VATS |
|---|---|
| Benefit | Author |
| Fewer complications | Hoksch et al.[10] |
| Less pain | Walker et al.,[3] Li et al.[22] |
| Better shoulder ROM | Li et al.[22] |
| Better PFT | Nakata et al.[26] |
| Better quality of life, earlier recovery | Sugiura et al.,[23] Demmy and Curtis[18] |
| Less pneumonia | Whitson et al.[19] |
| Easier for octogenarians | McVay et al.,[20] Demmy and Curtis[18] |
| Less cost | Nakajima et al.[21] |
| Receive more adjuvant chemotherapy | Peterson et al.[2] |
| Less impact on immunotherapy | Walker et al.,[3] Ng et al.[14] |

PFT, pulmonary function test; ROM, range of motion.

There are also benefits after discharge from the hospital. These include reduced need for pain medicine,[22] an earlier recovery,[18] reduced need for skilled nursing unit,[18] and better quality of life.[23] Acutely, pulmonary function[23] and shoulder strength and range of motion[16,22] are better after VATS than after thoracotomy; although at 1 year, the results are the same.

Furthermore, VATS benefits patients who need postoperative adjuvant chemotherapy. Adjuvant treatment for other cancers show that the benefit from adjuvant treatment only occurs if patients receive a high percentage of their chemotherapy, so presumably that is also important for lung cancer patients. More patients receive at least 75% of their planned chemotherapy after VATS lobectomy than after a thoracotomy (61% vs. 40%).[2]

## CONCLUSION

The experience and techniques for minimally invasive thoracic procedures have progressed. With VATS, thoracic surgeons can perform the same major lung resections with the same long-term survival as with thoracotomy; whereas VATS appears to offer patients lower complication rates and earlier recovery.

# Extent of Resection for Stage I Lung Cancer

## HISTORICAL BACKGROUND

The surgical management of lung cancer has undergone tremendous evolution since the first case series of pulmonary resection for lung cancer was reported by Oschner and DeBakey in 1939.[1] Since that time, the extent of surgical resection for lung cancer has been a point of heated debate among thoracic surgeons. In the early 20th century, most surgeons considered pneumonectomy the treatment of choice for lung cancer despite its associated high operative mortality.[1] Later, noncomparative retrospective case series showed that lobar resection can result in equivalent survival to that achieved by pneumonectomy with lower morbidity and mortality.[2] Anatomic segmentectomy was first described by Churchill and Belsey[3] in 1939 for resection of bronchiectasis and tuberculosis. Anatomic segmentectomy for resection of lung cancer was performed by some thoracic surgeons.[4–7] However, the relative complexity of the operation and the perceived higher risk of local recurrence dampened the enthusiasm of most surgeons.[8] In 1995, the Lung Cancer Study Group (LCSG) reported a randomized trial of 247 patients with clinical T1N0 (cT1N0) peripheral non–small cell lung cancer (NSCLC) who were randomly assigned to either limited resection (anatomical segmentectomy or wedge resection) or lobectomy.[9] Absence of nodal metastases to the draining segmental, lobar, hilar, and mediastinal lymph nodes was confirmed by frozen section examination prior to randomization. The study showed that locoregional recurrence was significantly higher in patients treated by sublobar resections. Locoregional recurrence rates per person-year were 0.022 following lobectomy, 0.044 following segmental resection, and 0.086 after wedge resection. Although patients treated by lobectomy had a higher 5-year survival compared with those treated by limited resection, the difference in survival did not achieve statistical significance (73% vs. 56%, $p = 0.06$).[9] This trial established lobectomy as the surgical standard of care for early stage disease. Limited resection (segmentectomy or wedge) has since been largely reserved for patients with compromised cardiopulmonary function who could not tolerate a lobectomy.

Recently, there has been renewed enthusiasm for the use of limited resection as a result of increased detection of smaller tumors by more widespread use of computed tomography (CT). Evidence derived mostly from retrospective case series and a few prospective studies suggested that sublobar resection was feasible and possibly associated with 5-year survival comparable to that attained by lobectomy in patients with stage I peripheral NSCLC measuring 2 cm or less in size. Ongoing prospective randomized clinical trials are currently underway to determine the relative merits of sublobar resection compared with lobectomy in this subset of patients. In this chapter, we will review the results reported after limited resection done either as a compromise procedure in patients with suboptimal cardiopulmonary reserve or intentionally in patients considered suitable candidates for lobar resection. We will also discuss some of the factors one needs to consider in selecting patients for limited resection including tumor size, location, intralobar satellites, cell type, nodal metastases, and surgical margins. Methods such as brachytherapy to extend the effective surgical margin will also be discussed.

## LIMITED RESECTION AS A COMPROMISE PROCEDURE

Several studies have examined the outcome of limited resection as a compromise procedure in patients with limited cardiopulmonary reserve. For example, Landreneau et al.[10] analyzed the results of 219 consecutive patients with pathologic T1N0 NSCLC who underwent wedge resection or lobectomy. The wedge resection group of patients was significantly older and had reduced pulmonary function. At 5 years, overall survival (OS) was 58% following treatment by open wedge resection, 65% for patients treated by video-assisted wedge resection, and 70% for those treated by lobectomy. The difference in survival between the lobectomy group and the entire wedge resection group approached but did not attain statistical significance ($p = 0.56$). The difference in survival at 5 years was a result of

a significantly greater frequency of non–cancer-related deaths among patients treated by open wedge resection (38% vs. 18% for the lobectomy group; $p = 0.014$). Furthermore, there was no significant difference in the local/systemic recurrence rates between patients treated by wedge resection and those treated by lobectomy. The authors concluded that wedge resection was a viable surgical option for patients with stage I NSCLC who have impaired cardiopulmonary function.

Keenan et al.[11] retrospectively reviewed patients with stage I NSCLC who had either lobectomy (n = 147) or anatomical segmentectomy (n = 54). The segmentectomy group of patients had a significantly greater degree of preoperative pulmonary impairment compared with the lobectomy group. The authors reported no statistically significant difference in overall and disease-free survival (DFS) between the two groups of patients. The 4-year OS was 67% for lobectomy and 62% for segmentectomy ($p = 0.86$). The authors also compared pulmonary function between the two groups 1 year postoperatively. Patients treated by segmentectomy had preservation of forced vital capacity, forced expiratory volume in 1 second, and maximum voluntary ventilation postoperatively. In contrast, patients treated by lobectomy experienced a significant decline in all pulmonary function parameters.

In 2006, El-Sherif et al.[12] reported the results of sublobar resection for stage I NSCLC in 207 patients with cardiopulmonary impairment and compared them with the results following lobectomy in 577 patients with similar stage disease. For stage IA patients, both sublobar resection and lobectomy resulted in identical DFS of 65% at 7 years ($p = 0.308$). For stage IB patients, there was a significantly worse DFS after sublobar resection compared with lobectomy, 50% versus 58%

($p = 0.009$). The authors concluded that sublobar resection seemed appropriate for stage IA patients.

## INTENTIONAL LIMITED RESECTION

Most, if not all, of the evidence supporting the use of limited resection in early stage NSCLC is derived from case series reported by Japanese surgeons (Table 32.1). For example, Kodama et al.[13] reported a case-control series of 46 patients with cT1N0 NSCLC treated by intentional limited resection with curative intent. All patients had peripheral tumors less than 2 cm in size, and all were treated by segmentectomy with regional lymph node dissection. The comparator or control group comprised 77 patients with stage I treated by lobectomy. The segmentectomy group had a 5-year survival of 93%, which was similar to survival in the control group. Locoregional recurrence was 2.2% in the segmentectomy group and 1.3% in the lobectomy group.

Similarly, Okada et al.[14] reviewed their prospective experience with 70 patients who had T1N0 NSCLC 2 cm or less treated by intentional limited resection. The authors performed what they termed an *extended segmentectomy*, which is essentially a segmental resection where parenchymal division extends slightly beyond the anatomical segmental boundary. In this study, segmentectomy was performed only after frozen section examination of the segmental, hilar, and mediastinal nodes confirmed the absence of metastatic disease. Patients with nodal disease were treated by lobar resection. Five-year survival of pathologic T1N0 patients was 87.1% in the extended segmentectomy group compared with 87.7% in the lobectomy group ($p = 0.8$). There were no local recurrences after limited resection. The local recurrence rate

| **TABLE 32.1** | | **Studies of Intentional Limited Resection for Stage I NSCLC** | | | |
|---|---|---|---|---|---|
| **Study** | **n** | **Type of Resection** | **Tumor Sizes** | **Recurrence (%)** | **5-Yr Survival (%)** |
| Kodama et al.[13] | 46 | Segmentectomy with frozen nodal analysis | Avg 16.7 mm | Local 2.2 | 93 |

| | | | | Distant 2.9 | 84 |
| | 57 | Lobectomy | | N/A | |

Avg, average; N/A, not applicable.

for the lobectomy group was not reported in that study. The authors concluded that extended segmentectomy is an acceptable alternative to lobectomy for T1N0 NSCLC 2 cm or less.

Yoshikawa et al.[15] published their multi-institutional prospective Japanese trial of limited resection for peripheral NSCLC less than 2 cm. A total of 55 patients were enrolled. Intraoperatively, an extended segmentectomy with frozen section of hilar and mediastinal lymph node was performed. The authors reported a 5-year OS of 81.8% and lung cancer–specific survival of 91.8%.

Koike et al.[16] reported their results of intentional limited resection for peripheral T1N0 NSCLC 2 cm or less. The limited resection group consisted of 60 segmentectomies and 14 wedge resections, which was compared with 159 patients treated by lobectomy. Intraoperative frozen analysis of hilar and mediastinal lymph nodes was performed, and a standard lobectomy was done when lymph node metastasis were detected. The 3- and 5-year OS was 94.0% and 89.1% in the limited resection group compared with 97.0% and 90.1% in the lobectomy group. Tumor recurrence was noted in five patients after limited resection and in nine patients after lobectomy. Both the OS and the local recurrence rate were not significantly different between the two groups.

Watanabe et al.[17] reported their results of intentional limited resection for T1N0 peripheral NSCLC 2 cm or less in size. Limited resection was done in 34 patients, wedge resection in 14 patients, and extended segmentectomy in 20 patients. Again, intraoperative examination of hilar and mediastinal lymph nodes showed no evidence of nodal metastases. Impressively, the 5-year survival after extended segmentectomy was 93% with no local recurrences. This compared favorably with 5-year survival after lobectomy patients, which was 84%.

Collectively, these studies suggest equivalence between anatomical segmentectomy (the data are less robust for wedge resection) and lobectomy in a select group of patients with peripheral small (≤2 cm) NSCLC who are meticulously staged to rule out the presence of segmental, hilar, and mediastinal nodal metastases. Nonetheless, the data are largely derived from retrospective or prospective noncomparative studies that are inherently limited by unavoidable selection biases. Furthermore, one cannot reasonably exclude the possibility of a significant impact of ethnicity on biological tumor characteristics and survival.

## CONSIDERATIONS IN LIMITED RESECTION

**Tumor Size** Tumor size is a critical factor in determining the feasibility and safety of limited resection. It is well established that tumor size is an important prognostic factor for survival in NSCLC.[18–23] The current staging system recognizes a difference in survival between tumors >3 cm and those ≤3 cm. This is supported by several retrospective studies that showed a survival advantage for T1 tumors compared with T2.[24–28] Even within T1 tumors, several retrospective studies have shown that survival is better with smaller tumor size. Gajra et al.[29] reported their experience with 246 patients

surgically resected for stage IA NSCLC. Patients with tumors ≤1.5 cm had a significantly improved DFS and OS compared with those patients with tumors 1.6 to 3.0 cm. Tumor size was an independent prognostic factor for survival in their multivariate analysis. Similarly, Port et al.[18] reviewed 244 patients with resected stage IA NSCLC. The 5-year OS for patients with tumors ≤2 cm was 77.2% compared with 60.3% in patients with tumor >2 cm in size, again supporting the relationship between tumor size and survival. For subcentimeter stage IA tumors, Lee et al.[19] reported 5- and 10-year OS of 94% and 75%, respectively, with the disease-specific survival was 100% at both time points without any recurrences. Other investigators have also reported excellent survival following resection of subcentimeter tumors.[30,31] The aforementioned studies along with many others have led to the new proposed staging system, which divides T1 tumors into T1a and T2b at the 2-cm cutoff.[32–36] Given the preceding evidence of tumor sizes, sublobar resection may be more appropriate for the T1a tumors ≤2 cm in size.

**Tumor Location** Tumors for which wedge resections are planned *must* be peripherally located at or close to the costal or diaphragmatic pleural surface. Tumors considered for limited resection by a segmentectomy must be confined within the anatomical segmental boundaries without crossing intersegmental planes. Although segmentectomy may be performed for central tumors, the bulk of the evidence supporting segmentectomy with curative intent is accumulated from series with peripheral tumors located within the outer third of the lung. The traditional TNM classification does not consider tumor location as a prognostic factor. However, some studies suggested that central tumors are more likely to harbor lymph node metastases and have a poorer prognosis. For example, Ketchedjian et al.[37] reported that central T1 tumors had a 50% incidence of lymph node involvement.[37] Similarly, Lee et al.[38] reported that for centrally located tumors, the incidence of occult N2 disease was 21.6% and was as high as 26.7% for tumor greater than 2 cm in size. In that same study, the incidence of occult N2 disease was 2.9% for peripherally located tumors. The high prevalence of nodal metastasis in central tumors suggests that these tumors may be best treated by a lobar rather than a sublobar resection.

**Intralobar Satellite Tumors** One of the theoretical criticisms of a limited resection is the risk of intralobar satellite lesions that were not recognized by preoperative radiographic studies or intraoperative palpation. The incidence of intralobar satellite lesions in small peripheral tumors is actually quite small in published series. Koike et al.[21] have examined 496 patients with cT1N0 peripheral NSCLC, and found that the incidence of intrapulmonary satellite lesions was only 1% to 2%. In a study by Lee et al.[19] of 84 patients with resected subcentimeter NSCLC, 5 patients (6%) had intralobar satellite lesions in the resected specimen that were unrecognized in preoperative CT or positron emission tomography (PET) scanning. Even though the incidence of intralobar satellites may be low, great

care must be taken at the time of a sublobar resection to carefully palpate the entire lobe. Clearly, if suspicious lesions are found, a lobectomy rather than a limited resection may be more appropriate once the malignant nature of the satellite is histologically confirmed. Current evidence from our group and others suggests that patients with resected T4 NSCLC have a reasonable survival, with the 5-year OS as high as 58% for properly selected T4N0 patients.[39–41]

**Cell Type** The traditional TNM classification does not consider cell type as a prognostic factor. Several studies have suggested that there is a difference in the incidence of lymph node metastases between squamous cell carcinoma and adenocarcinoma. Asamura et al.[42] have shown that in squamous cell carcinoma ≤2 cm, lymph node involvements are rare. They examined 337 patients with peripheral resected NSCLC in regard to lymph node involvement. The authors have found that lymph node involvement was very rare among squamous cell carcinoma of 2 cm or less in diameter, and concluded that the rarity of lymphatic spread might justify not performing a lymphadenectomy in this subset of patients. Lee et al.[38] made similar observations in a study of occult mediastinal metastases in clinical stage I NSCLC. In that report, all 16 patients with occult N2 disease had adenocarcinoma as the primary tumor cell type. None of the 34 patients with squamous cell carcinomas harbored any occult N2 metastases. Although this was not statistically significant ($p = 0.082$), the trend certainly suggests that adenocarcinoma cell type as compared with squamous cell carcinoma is a relative risk factor for occult N2 metastases. Suzuki et al.[42a] have investigated predictors of lymph node and intrapulmonary metastases in clinical stage IA NSCLC. Multivariate analyses showed that the grade of tumor differentiation was a significant predictor of regional lymph node metastases.

The only possible relevance of these findings to limited resection is the extent of lymphadenectomy that may be required in the event a sublobar resection is performed for a peripheral squamous cell cancer. Until the results of prospective randomized trials offer further insight into this subject, the standard of care during a sublobar resection, regardless of the histology of the cancer, remains a complete hilar and mediastinal nodal examination to confirm N0 status.

**Nodal Metastases** The prevalence of mediastinal metastases increases with tumor size. Asamura et al.[42] have found that among patients with resected peripheral NSCLC, the prevalence of lymph node metastases increased from 19.5% in tumor 2 cm or smaller to 32.5% in tumors 2 to 3 cm in diameter. Even for subcentimeter tumors, it appears that a subset of tumors may have aggressive biologic behavior. In a report by Lee et al.[19] on 83 patients with NSCLC 1 cm or less, six patients (7.2%) had nodal metastases, with N1 nodal metastases in four patients and N2 metastases in two patients. The survival in this non-IA group was significantly diminished compared with node-negative patients with deaths associated exclusively with tumor recurrence.

Additionally, occult nodal micrometastasis may occur in NSCLC patients who have histologically negative nodes. Wu et al.[43] studied a total of 103 N0 patients with peripheral lung adenocarcinomas 2 cm or less. A total of 1438 regional lymph nodes were examined for occult micrometastasis by immunohistochemically staining for cytokeratins. Micrometastases were detected in 49 lymph nodes (3.4%) of 21 patients (20.4%). The 5-year survival of patients with micrometastasis was significantly lower (61.9%) compared with those patients free of micrometastases (86.3%). Similarly, Ohta et al.[33] reported that nodal micrometastases were found in 20% of patients with adenocarcinoma 1.1 to 2.0 cm in size, and in 4 of 11 patients with tumor 1 cm or less in size. Interestingly, nodal micrometastases were not found in patients with squamous cell carcinoma of 2 cm or less.

When lymphatic vessel invasion was examined, Ichinose et al.[25] have found a direct correlation between tumor size and incidence of lymphatic vessels invasion in completely resected pathologic stage I peripheral NSCLC. The incidence of lymphatic invasion was 25% for tumors size 1 cm or less, 40% for those 1.1 to 2.0 cm in size, 49% for tumors 2.1 to 3.0 cm in size, and up to 57% for tumor size greater than 3.1 cm. In light of these findings, whenever a limited resection is entertained for a curative resection for NSCLC, it is imperative that a thorough intraoperative examination of hilar and mediastinal lymph nodes be performed. If nodal metastases were found, a lobectomy should be performed.

**Surgical Margins** The greatest concern after limited resection is a possible increase in the rate of local recurrence. Studies examining the minimal margin necessary in limited resection are sparse. Generally, the margin is considered adequate if it is equal to or greater than the maximal tumor diameter as measured in the deflated lung.[44–46] Adequacy of the resection margin should, whenever possible, be confirmed by frozen section examination. Despite a negative surgical margin, local relapse is not uncommon. New techniques have been recently described to further examine the surgical lung margin and confirm complete tumor resection. Higashiyama et al.[47] developed a novel intraoperative lavage technique to assess surgical margin status at the time of limited resection. Both wide wedge resections and segmentectomies were done. Wide wedge resection was defined by the authors as a macroscopically assessed margin that was greater than the maximal tumor diameter. The margins of the resected specimen were lavaged and the fluid was centrifuged. An on-site cytologist then examined the sediment after proper fixation. In a total of 112 resections, they observed that 11 lesions (10%) had cytological evidence of tumor at the margin. This was significantly higher for patients with more advanced stage, those in whom a compromise limited resection was performed and those with large tumor size. In four cases with positive cytology at the margins, a wider resection by lobectomy or segmentectomy was done in three patients and laser ablation in one patient who later developed recurrence at the surgical margin. Interestingly, all four patients were originally treated by wedge resections. During follow-up, local

recurrence at the surgical margin occurred in four patients, all of whom were treated by a wedge resection because of impaired cardiopulmonary function. Remarkably, there were no local recurrences at the surgical margins among lesions with negative cytology at the margin. The main limitation of this technique is the risk of tumor cell contamination from the visceral pleural surface. The success of this technique also depends very much on the expertise and availability of an on-site cytologist.

Sawabata et al.[48] reported a different test of surgical margins using another cytologic technique (run-across method) in which a glass slide is run across the stapled site. They examined 15 NSCLC excised by limited resection. The rate of positive cytology was 47% compared with the rate of positive histology of 20%. Of the seven patients with positive cytology margins, four patients had margin relapse, with no margin relapse in the negative cytology group ($p = 0.03$). The authors concluded that despite a negative histology margin, a positive cytology margin could lead to margin relapse. In contrast to the lavage technique described by Higashiyama et al.,[47] Sawabata reported a much higher sensitivity rate of 47%, possibly because of a direct extraction of cells or tissues from the surgical margin by the glass slides.

The presence of occult tumor cells at the time of limited resection might very well account for an increase in local relapse rate especially following wedge resection. The incidence of occult tumors at the surgical margins appears to increase with larger tumor size and advanced stage. This is an important consideration during a limited resection for NSCLC, and may account for the increase in local recurrence in earlier studies of limited resection such as the trial conducted by the LCSG. In general, when performing a limited resection (especially wedge resection), one should attempt to achieve a wide resection margin equivalent at least to the longest diameter of the tumor.

In addition to achieving a wide resection margin, techniques have been described to effectively increase the local resection margin. Yoshikawa et al.[15] published their results of extended segmentectomy as an alternative method of resection for small <2-cm peripheral tumors. The essential point of the technique is to divide the lung beyond the tumorous segment. After the segmental bronchus is isolated, the tumorous segment is inflated and the affiliated segmental bronchus is tied. The rest of the surrounding segments are left deflated. Using stapling or electrocautery, the resection line is placed on the adjacent collapsed segment so that the margin is beyond the affected segment. A hilar and mediastinal lymph nodes dissection is done concomitantly.

## BRACHYTHERAPY

Because of the concerns regarding higher local recurrences following sublobar resection, adjuvant radiotherapy has been used in an attempt to sterilize any residual microscopic tumor cells adjacent to the primary tumor. Miller and Hatcher Jr.[49] has reported a small group of sublobar resection patients in whom postoperative focal radiotherapy significantly decreased local recurrence. However, difficulties in three-dimensional radiation planning of resection site as well as the risk of radiation-induced lung injury in patients who often have compromised pulmonary function has dampened the enthusiasm for adjuvant external beam radiotherapy.

Other investigators have used intraoperative brachytherapy with [125]Iodine (^{125}I) as a means to achieve further local control in cases where the resection margins were close or positive. The theoretical advantage of this approach is that surgeons can place the brachytherapy seeds directly at the margins of concern without delay. D'Amato et al.[50] described their experience of intraoperative brachytherapy following thoracoscopic wedge of stage I lung cancer with clear surgical margins. [125]I pellets were embedded along a polyglycolate suture at 1-cm interval, with the sutures sewn onto a polyglocolate hernia mesh template. The mesh template was then sutured onto the stapled line. The technique was calculated to deliver very high intensity radiation of 10,000 cGy to a 1-cm depth, thereby extending resection margin by another centimeter. Various studies have demonstrated that risk of local recurrence can be diminished with this technique.[51,52] Fernando et al.[52] conducted a retrospective multicenter study of 291 patients with surgical resected T1N0 disease, where 124 patients had sublobar resection and 167 patients had lobar resection. Brachytherapy with ^{125}I seeds were used in conjunction with sublobar resection in 60 patients. Brachytherapy decreased the local recurrence rate significantly to 3.3%, compared with 17.7% in the sublobar resection group without brachytherapy. Interestingly, for tumors smaller than 2 cm, there was no difference in survival between the sublobar and lobar resection groups. However, for larger tumors 2 to 3 cm in size, the median survival was significantly better in the lobar resection group, 70 versus 44.7 months ($p = 0.003$). More recently, Birdas et al.[53] have extended the use of ^{125}I brachytherapy to larger T2 tumors chosen for sublobar resection. They compared the results of 41 patients treated by sublobar resection and ^{125}I brachytherapy with 126 lobectomy patients, and found similar local recurrence rates of 4.8% and 3.2%, respectively. There was no difference in DFS and OS between the two groups. Although these preliminary results regarding the use of ^{125}I brachytherapy as an adjunctive therapy for sublobar resection are promising, they should be validated in a prospective randomized manner prior to adoption as the standard of care. Currently, an American College of Surgeons Oncology Group prospective randomized trial (Z04042) of sublobar resection (segmentectomy or wedge) with and without intraoperative ^{125}I brachytherapy in stage IA NSCLC is underway.

## CURRENT CLINICAL TRIALS

Cancer and Leukemia Group B (CALGB) has recently activated a phase III randomized trial (CALGB 140503) of lobectomy versus sublobar resection for ≤2-cm peripheral node-negative NSCLC. Eligibility criteria consist of peripheral lung nodule ≤2 cm on preoperative CT scan, with the

**TABLE 32.2**    **Comparison of CALGB 140503 and JCOG0802 Trials**

|  | CALGB 140503 | JCOG0802 |
|---|---|---|
| Design | Randomized phase III | Randomized phase III |
| Preregistration eligibility criteria | Peripheral ≤2-cm NSCLC | Peripheral ≤2-cm NSCLC part-solid to solid on chest CT |
| Intraoperative randomization criteria | N0 status confirmed by frozen exam: right (level 4,7,10), left (level 5–7,10) | Free of noncurative factor (i.e., malignant pleural effusion and dissemination) |
| | | Frozen exam of lymph nodes not required |
| Exclusion criteria | Pure ground-glass lesions | Carcinoid tumors |
| | Carcinoid tumor | |
| Control arm | Lobectomy | Lobectomy |
| Study arm | Segmentectomy or wedge resection | Segmentectomy |
| Primary end point | Disease-free survival | Overall survival |
| Secondary end points | Overall survival, local and systemic recurrence rates, pulmonary function at 6 months | Pulmonary function at 3 months and 1 year, disease-free survival, local recurrence rate, adverse events, hospitalization, chest drainage amount, operative time, bleeding amount, number of autostaplers |
| Target number/entry period/follow-up | 1297 cases, 908 eligible cases after randomization/5 years/3.25 years | 1100 cases/3 years/5 years |
| Postoperative follow-up | CT chest at 6 months, 1 year then yearly for 4 years | CT chest every 6 months |

center of the tumor located in the outer third of the lung field. Patients are randomized intraoperatively into lobectomy versus sublobar resection (segmentectomy or wedge). Confirmation of N0 status by frozen section of mediastinal and major hilar nodal stations is required prior to randomization. The primary end point of the trial is DFS. Secondary end points include OS, rate of locoregional and systemic recurrence, and pulmonary function as measured by pulmonary expiratory flow rate 6 months after the surgery. The target accrual is 908 randomized patients over 5 years with 3 years of follow-up. The trial is supported by most American cooperative groups as well as National Cancer Institute of Canada (NCI-Canada).

Concurrently, a multi-institutional trial is in the planning phase by the Japan Clinical Oncology Group (JCOG0802). The trial will randomize patients with ≤2-cm peripheral NSCLC to lobectomy or segmentectomy. Target accrual is 1100 cases over 3 years with 5 years of follow-up. Table 32.2 highlights the similarities and differences between the CALGB 140503 and the JCOG0802 trials.

## CONCLUSION

Since the report of the LCSG, lobectomy has been regarded by most thoracic surgeons as the gold standard for resection of early stage NSCLC. Limited resection has been largely reserved for those patients with compromised cardiopulmonary status. However, recent evidence supports the use of intentional limited resection (segmentectomy or wedge) for small peripheral stage I NSCLC 2 cm or less in size. Careful intraoperative analysis of hilar and mediastinal lymph node must

be performed to exclude occult lymph node metastases and ensure accurate staging in determining the need of adjuvant chemotherapy. Future results from the randomized phase III limited resection trials CALGB 140503 and JCOG0802 for peripheral ≤2-cm NSCLC will hopefully elucidate the role of sublobar resection as a viable alternative to lobectomy.

# Management of Ground-Glass Opacity Lesions

Recently, smaller and fainter nodules are being found on computed tomography (CT) imaging.[1,2] This is partly a result of the markedly improved quality of CT images and the increased likelihood of CT examinations in screening programs. On CT images, all noncalcified nodules should be carefully checked because of the possibility of lung cancer. A nodule might manifest as a focal nonlinear opacity regardless of its characteristics (i.e., solid or subsolid, parenchymal or endobronchial). The term *ground-glass opacity* (GGO) is used to describe noncalcified, subsolid nodules. The pathobiological nature, natural history, and proper management of GGOs have become of greater concern in the thoracic community.

According to recent studies on the relationship between appearance on CT and the histopathology of GGOs, a considerable portion of these lesions, although not all, correspond to preinvasive, noninvasive, or early forms of neoplastic growth, especially those of adenocarcinoma lineage.[3–11] The clinicopathological entity of these tumors has been established only recently, and has never been the subject of clinical studies. Interestingly, some of these tumors show obvious progression to more advanced, invasive tumors, and some show a constant shape for more than 10 years. The rate of growth, if any, is generally slow. A diagnostic workup for these tumors has not yet been developed. Therefore, these tumors are outside the scope of the standard management of lung cancer. Surgical intervention is difficult with regard to the indication and proper mode of surgical resection. The present surgical management of lung cancer, in which at least lobectomy is performed in conjunction with systematic lymph node dissection/sampling, cannot be applied to these GGOs.[12] A standard care for these lesions is currently being established. Clear-cut indications and the rationale for limited resection have not been demonstrated. Some of the treatment strategies for GGO lesions will require future clinical trials.

## DEFINITION OF GROUND-GLASS OPACITY

The term GGO is currently being used more often to describe the CT appearance of a focal, noncalcified lesion with a slight/moderate increase in CT density. Routine CT images with 1-cm thick slices are not suitable for the diagnosis of GGO, and usually the GGO is characterized on high-resolution CT scan images with a slice thickness of 1 to 3 mm. The CT appearance of GGO is characterized as a "focal, transparent" lesion. GGO refers to a localized or focal lesion regardless of multicentricity, and the diffuse ground-glass appearance seen for interstitial pneumonitis should be excluded from this category. GGO lesions are well characterized by a slight/mild increase in CT density, which does not obscure preexisting lung structures such as blood vessels and bronchi. This appearance refers to CT transparency (Fig. 33.1). When the shape of the pulmonary vessels in the nodules is not recognized in the nodule, the lesion is no longer considered GGO, and instead is called a "solid" lesion. GGO lesions, therefore, can be either homogeneous or heterogeneous.

GGO lesions are classified according to the absence or presence of a solid part. If GGO lesions are homogeneous and do not contain a solid part, they are called *nonsolid GGO* or *pure GGO* (Fig. 33.2). If GGO lesions contain a solid, cystic, or linear part inside the nodule, they are called nonsolid GGO or complex GGO (Fig. 33.3). The solid part is more likely to be located in the center of the nodule and surrounded by the GGO part, which shows a so-called fried egg appearance. The solid part might be scant or prominent, with various proportions of solid to GGO parts. In the classic solid tumor, the GGO part no longer exists within the nodule (Fig. 33.4). The relationships between the subtype of CT appearance and histopathologic findings are discussed later.

## HISTOPATHOLOGIC FEATURES OF GROUND-GLASS OPACITY LESIONS

With regard to histopathology (see Chapter 22), GGO lesions are either neoplastic or inflammatory. A focal inflammation of the lung parenchyma sometimes presents with a GGO on
**FIGURE 33.1**   Schematic drawing of CT appearance of ground-glass opacity (GGO). In the GGO lesion, preexisting anatomical structures such as bronchus and blood vessels are apparent.

the CT image, and pathologically this pattern is described as *organizing pneumonia*. These changes are more likely to be temporary. In contrast, persistent GGOs are more likely to be neoplastic. According to the World Health Organization (WHO) histological classification of lung and pleural tumors, GGO lesions are associated with three pathological entities.[5] Atypical adenomatous hyperplasia (AAH) is described as a pre-invasive lesion, in which slightly atypical tumor cells line the involved alveoli and respiratory bronchioles. Nonmucinous bronchioloalveolar carcinoma (BAC) is an adenocarcinoma with Clara cells and/or type II pneumocytes growing along alveolar walls, and without stromal invasion. The important feature of BAC is "noninvasive" growth of the tumor, and therefore, this lesion could be considered in situ carcinoma. The third category is adenocarcinoma with mixed subtypes, which shows a mixture of histologic subtypes as well as obvious invasive growth.

**FIGURE 33.3**   CT appearance of part-solid GGO. There is a region of increased density in the center of the lesion.

The relationship between CT appearance and histology has been studied.[6–8] Most nonsolid GGOs are AAH or BAC. Invasive growth is rarely seen in the pathology of nonsolid GGO. On the other hand, most part-solid GGOs are BAC and adeno-carcinoma with mixed subtypes. A solid lesion usually exhibits invasive growth and is diagnosed as adenocarcinoma with mixed

**FIGURE 33.2**   CT appearance of nonsolid GGO. There is no solid or linear part in the lesion.

**FIGURE 33.4**   CT appearance of a solid lesion. The CT density of the whole area is increased, and intrinsic structures are no longer obvious.

Feb 5, 1998                                     Aug 4, 2006
**FIGURE 33.5**    Indolent GGO (nonsolid GGO). The appearance of GGO remained unchanged for 8 years.

subtypes. Although the image findings on high-resolution CT cannot precisely reveal the pathology with special reference to invasive growth of the tumor, the value of high-resolution CT should be addressed.

The pathobiological background of GGO–BAC tumors has been studied by several investigators.[9,10] GGO–BAC tumors are more likely to arise in nonsmoking women in their 50s and 60s. They also tend to be multicentric, both synchronously and heterochronously. Interestingly, among nonsolid GGOs, some are followed up for more than 10 years without any intervention, and there has been no overt growth (Fig. 33.5). In contrast, some show overt growth with consolidation (Fig. 33.6). These observations indicate that GGOs do not always grow or they only grow slowly, and as a result, they are indolent for considerably long periods. These observations have also shown that GGOs with a smaller size or with a scarce solid component tend to be stable in size, and GGOs in patients with a history of lung cancer tend to grow faster. Other factors that may affect the growth of GGO tumors need to be defined in future studies. In case series from many institutions, noninvasive BAC has been shown to have a superb prognosis, which supports the notion that BAC is carcinoma in situ. According to the degree of invasive growth of adenocarcinoma, the prognosis is determined in a step-ladder fashion.[11]

## INTERVENTION FOR GGO–BAC TUMORS

The intervention strategy for GGO lesions has been established only very recently, and future clinical trials to validate the

suggested approaches are still needed. Several factors are related to the management strategy: the size of lesions, image characteristics (nonsolid vs. part solid), and a history of previous lung cancer. The indolent nature of small-sized, nonsolid GGOs needs to be stressed. For these tumors, immediate surgical intervention should be avoided. Furthermore, the physical condition of the patient, such as age and coexisting medical conditions, must also be taken into consideration. When we consider surgical intervention, the location of the lesion (outer vs. inner) is also an important issue from a technical point of view. For tumors that are located deep within the lung parenchyma, sublobar resection is generally amenable because of the lack of sufficient surgical margin.

The intraoperative localization of a GGO can be challenging, even if the procedure is performed via an open rather than videothoracoscopic method. GGOs tend to be soft lesions that are painfully difficult to feel, and palpating these lesions are like feeling a sponge within a sponge. If they are located at the very periphery of the lung, one can see a faint change in the color of the visceral pleura, which is greyer than usual and circumscribed. Usually, however, for pure GGOs or those with a minimal solid component, it is best to employ methods for the marking of the lesion using interventional radiologic techniques using methylene blue or isotopic localization. Although all of the methods are effective in locating the target lesion, their limitations are obvious. The needle-wire technique is associated with several complications, such as lung hemorrhage, pleuritic pain, and pneumothorax.[13] A hookwire dislodgement rate of 7.5% has been reported.[14] A failure rate
**FIGURE 33.6** Obvious growth of GGO in a 54-year-old woman (part-solid GGO).

of approximately 13% for preoperative methylene blue injection under the CT fluoroscopic guidance has been reported because of either an excess of liquid injection or an error in nodule localization. Moreover, the dye frequently dissipates over a large area by the time the surgical procedure is done, making its localization features inadequate.[15] The localization of pulmonary nodules by radio-guided technique[16] also has drawbacks including fast diffusion of contrast medium in the pulmonary parenchyma surrounding the nodule. Moreover, special radiation protection precautions in the operating room or in handling the surgical specimens are required. Injection of coils[17] or agar[18] under CT guidance into the lesion will also assist the surgeon in palpating the lesion intraoperatively.

### Nonsolid Ground-Glass Opacities Less than 15 mm in Diameter
These small lesions without any solid part in the nodule (nonsolid GGO) are watched carefully with repeated high-resolution CT. The appropriate interval between repeated CTs has not been clearly demonstrated but may range from 3 to 6 months. If overt growth or a newly developing solid component is seen, surgical intervention should be considered.

### Part-Solid Ground-Glass Opacities Less than 15 mm in Diameter
The solid component in part-solid GGOs represents a fibrotic scar and/or collapse of the lung in which the proliferation of collagen fibers and active fibroblast is generally seen, and these findings reflect invasive growth. Therefore, tumors in this category should be resected. Careful observation should be indicated only for patients with poor physical condition, which would compromise surgical resection. However, if we consider their minimally invasive nature and small size, sublobar resection should be a reasonable option. For these tumors, segmentectomy should be preferable to wedge resection. The location of the tumor should be carefully evaluated. When the tumor is located in the outer two thirds of the lung parenchyma, segmental resection should be acceptable. When the tumor is located in the inner third of the lung, segmentectomy may not be able to ensure a safe surgical margin. Thus, lobectomy, instead of segmentectomy, must be chosen. Furthermore, the lymph nodes at the hilum and, preferably, mediastinum should also be evaluated during surgery. If any of the nodes is positive, the surgery should be converted to traditional lobectomy.

### Nonsolid Ground-Glass Opacities Larger than 15 mm in Diameter
As with smaller nonsolid GGOs, these lesions should not be resected immediately. However, larger GGOs are more likely to grow faster even if they do not contain a solid part. Therefore, if the lesion stays the same in size (i.e., does not decrease in size as an inflammatory lesion would) after an appropriate follow-up period of 3 to 6 months,

these GGOs should be resected. Similarly, resection should be performed with a sublobar resection, such as segmentectomy, rather than lobectomy. The location of the lesion is also considered when choosing the surgical mode.

**Part-Solid Ground-Glass Opacities Larger than 15 mm in Diameter** Part-solid GGOs of this size are more likely to be invasive adenocarcinomas. When the solid part exceeds 50% of the whole area of the lesion, invasive features become more common. Therefore, the standard of care for such a lesion would, at present, be a lobectomy. The hilar/mediastinal lymph nodes should also be evaluated during surgery.

**Lobectomy versus Segmentectomy in the Surgical Management of Small-Sized Lung Cancer Including Ground-Glass Opacity** Whether limited resection such as segmentectomy or wedge resection can replace lobectomy or not in the surgical management of smaller (less than 2 cm) lung cancer including both GGO and solid appearance is a great concern. The definitive answer to this crucial question is only given by the controlled randomized, phase III trial (see Chapter 32). Although more than 1000 patients need to be enrolled in such studies for enough statistical power, the results might revise the standard surgical care for tumors without nodal involvement. Such studies are already open in North America or will be launched very soon in Japan.

# Management of Stage II Non–Small Cell Lung Cancer and Pancoast Tumors

## STAGE II TUMORS

Lung cancer remains the single most deadly cancer in the United States with an incidence of 170,000 per year and a 5-year overall mortality of 84%. This poor prognosis is secondary to the fact that most patients are diagnosed at higher stage (III and IV) on presentation.[1,2] The best chance for cure is provided by surgical resection of early stage (stage I and II) non–small cell lung cancer (NSCLC). This chapter focuses on surgical management of stage II NSCLC. The treatment, and even the definition, of stage II lung cancer have undergone significant changes over the last decade. Data examining the role of chemotherapy have expanded treatment options for patients with stage II NSCLC through adjuvant and neoadjuvant regimens. Although surgical therapy still remains the mainstay of therapy, a complete understanding of the role of multimodality therapy is crucial in the management of stage II NSCLC.

This chapter will first review the definition of stage II NSCLC along with the proposed modifications to the staging system. The presentation, diagnosis, and staging of stage II lung cancers will be reviewed followed by a discussion of the surgical treatment. Pancoast tumors without nodal involvement, a distinct subgroup of stage II NSCLC, will be discussed separately secondary to their unique presentation and treatment approach.

## TNM CLASSIFICATION

The TNM classification for lung cancer, developed by Dr. Clifford Mountain in 1972, has been revised once in 1997. More recently, an international effort organized through the International Association for the Study of Lung Cancer (IASLC) has led to a further revision outlined in greater detail earlier in this book.

Stage II NSCLC is currently defined as tumors confined to the lung or obstructing a bronchus >2 cm distal from the carina (T1 to T2) with involvement of nodes within the ipsilateral visceral pleura (N1). Stage II also includes tumors adherent to surrounding structures such as chest wall, mediastinal pleura, diaphragm, or pericardium (T3) without nodal involvement (N0).[1,3] Stage II, therefore, includes T1N1, T2N1, and T3N0 tumors.

The new proposed system for stage II NSCLC will include T1a, T1b, and T2a lesions with N1 disease or T2b or T3 lesions without nodal involvement (N0). T1a are tumors <2 cm, T1b are tumors 2 to 3 cm in size, T2a lesions are 3 to 5 cm in size, and T2b lesions are tumors 5 to 7 cm in size. The term T3 will not only refer to tumors causing postobstructive lung collapse and/or tumors invading the surrounding structures, but will also involve intraparenchymal lesions greater than 7 cm in size or tumors with satellite nodules in the same lobe of the lung (prior T4). N1 definition will remain as nodes within the ipsilateral visceral pleura (stations 10 to 14.)[1–3] Thus, large tumors (>7 cm) with negative nodes, previously stage I, will now be considered stage II. Tumors with satellite nodules, which were previously considered T4N0 and therefore stage IIIB, will now be considered T3N0 stage IIB.

These changes to the stage groupings and the T descriptors will clearly have an impact on which patients are now considered resectable. In a recent validation, Kassis et al.[3] studied the impact of the new staging system on 1154 pathologically staged patients. Stage assignments changed in a total of 202 patients (17.5%) using the new proposed system, (79 patients [6.3%] upstaged and 129 [11.2%] downstaged). However, it is important to note that no patient was upstaged into a nonsurgical stage (i.e., stage IIIB or IV). Downstaging from a traditionally nonsurgical stage to a surgical stage occurred in 59 patients previously staged IIIB and in 2 patients who had been staged IV. What remains to be determined, however, is what the impact of this redistribution of patients will be on recent adjuvant chemotherapy data. The recent studies demonstrating adjuvant chemotherapies' effectiveness was performed on stage I to IIIA patients staged using the prior systems. Whether this new system alters those results is yet to be seen.

# EVALUATION AND STAGING

**Clinical Presentation**   Risk factors for lung cancer include age, history of smoking, and history of lung cancer. Of the 170,000 new patients with lung cancer diagnosed each year in the United States, 90% are older than age 45, and 85% have a history of smoking.[1] When present, clinical symptoms of lung cancer include cough, weight loss, dyspnea, hemoptysis, chest pain, and hoarseness in decreasing order.[1,2,4] There is limited data regarding symptoms at presentation of a clinical stage II lung cancer. Therefore, we reviewed our prospective database at the MD Anderson Cancer Center, and found 280 clinical stage II patients over the last 7 years. Symptoms were reported in 69.6% of patients at presentation. The most common symptom for the entire group was cough. For those with T3N0 caused by chest wall invasion, chest wall pain was a very common symptom. The remaining patients presented with an incidental finding of a lung lesion on chest radiograph or a computed tomography (CT) scan.

**Imaging**   Earlier chapters have addressed imaging in lung cancer (see Chapters 26 and 27), but some specific aspects of imaging related to stage II lung cancer are discussed here.

Chest radiograph has traditionally been the modality of choice for screening and evaluating lung cancer. The advantages of chest radiographs include widespread availability, low-radiation dose, and low cost. The disadvantages include low sensitivity and specificity, especially for small tumors. The role of chest radiographs in stage II lung cancer is confined to excluding more advanced stage through identification of a pleural effusion or an extrathoracic bony metastasis.

During the past 20 years, development of the CT technology has made CT scans of the chest a standard of care in the evaluation of lung cancer. Patients with suspected lung cancer should receive CT scan of the chest with inclusion of the liver and adrenals. The latest versions of high-resolution CT scanners provide 1.2-mm thick slice capabilities, and this resolution improves almost yearly. These scans carry a sensitivity of 98%, a specificity of 58%, and an accuracy of 77% in the diagnosis of lung cancer.[1] Specifically with regard to stage II lung cancer, CT scans can assess both the nodal and tumor status of a lesion. The T status including size, ipsilateral/ipsilobar satellite lesions (now considered T3 based on the IASLC staging recommendations), involvement of central lobar structures, and proximity to the carina are easily assessed by CT imaging. However, for the latter two, bronchoscopy remains the gold standard to confirm the lobar involvement and the distance from the carina to the tumor. Pleural and chest wall involvement, distinguishing characteristics of T2 and T3 tumors, respectively, are also addressed by CT scanning. CT scans have an 80% sensitivity and specificity at predicting chest wall involvement using established criteria such as obliteration of the extrapleural fat plane, length of tumor–pleura contact, high ratio of contact length to tumor diameter, and obviously, rib destruction. However, when these criteria are absent and the patient has no symptoms consistent with chest wall involvement (constant or episodic pleuritic chest pain), surgery remains the gold standard approach for elucidating chest wall involvement. If the presence of chest wall involvement is a significant factor to determine respectability (e.g., a patient with marginal performance status and limited cardiopulmonary reserve), a thoracoscopy may be necessary to establish chest wall involvement.

Hilar nodal involvement (N1 disease), a hallmark of most stage II patients, is also assessed by CT scanning although its accuracy is limited. In the absence of significant N1 nodal enlargement, many stage II lung cancers will be difficult to distinguish from stage I lung cancer based on CT alone. Several studies have evaluated CT criteria for predicting lymph node involvement. These studies have focused on the predictive ability of CT for N2 disease (mediastinal nodal involvement) and have a pooled positive predictive value of 0.56.[4] Extrapolating from this data, one can estimate that a solitary peripheral lung cancer can carry 26% to 44% risk of lymph node involvement (hilar or mediastinal), despite a negative CT scan for nodal enlargement.[1] Data specifically assessing the diagnosis of N1 (hilar) disease is limited, because preoperative determination of N1 disease has limited clinical relevance. Currently, both stage I and II patients are offered surgical resection, and it is only the preoperative identification of N2 (mediastinal) disease that alters treatment. For this reason, most investigators have not addressed the diagnosis of N1 disease specifically. However, if appropriate application of lung sparing techniques, such as stereotactic radiotherapy, radiofrequency ablation, and cryoknife are to be made, then accurate information on the presence or absence of N1 disease will be mandatory to prevent early recurrence within the hilum.

Positron emission tomography (PET) and PET/CT scans have been the latest addition in the armamentarium for the evaluation and staging of lung cancer. PET scans are excellent at discerning metastatic disease; however, their poor spatial resolution makes evaluation of nodal disease less than optimal. Similarly, this poor spatial resolution limits PET's contribution to the evaluation of the T status. PET/CT has greatly improved the spatial resolution of the PET scan and thus improved the nodal evaluation of the test, although T status is still best evaluated by CT scanning. Where PET/CT scanning excels is in its negative predictive value. A negative CT and PET scan of the mediastinum has a high sensitivity. A recent study by Cerfolio et al.[5] addressed this issue, where 129 consecutive patients with NSCLC underwent PET and integrated PET/CT. Patients then underwent mediastinal node biopsy, and if negative, went on to pulmonary resection. Their study reported a negative predictive value of 99% for N2 nodal disease. Their positive predictive value was only 49%; however, the positive predictive value is hampered by endemic chronic inflammatory conditions (i.e., histoplasmosis) and acute inflammatory processes (i.e., postobstructive pneumonia secondary to a central lobar tumor). For this reason, PET or PET/CT positive N1 or N2 lymph nodes that are accessible should be biopsied to confirm their involvement, especially when the node is normal or only slightly enlarged on CT imaging.

**Bronchoscopy** Bronchoscopy, as indicated previously, has a prominent role in stage II disease. As mentioned earlier, it remains the gold standard for evaluation of lobar involvement and proximity to the carina. The treating surgeon should perform the bronchoscopy or be present when it is performed. This is especially true of central lobar T2 lesions that may require a sleeve resection. In this case, accurate assessment of the airway anatomy by the operating surgeon is required to assist with surgical planning.

**Mediastinoscopy** Evaluation of the mediastinum in stage II lung cancer is paramount. Although imaging has provided significant advances in noninvasive staging, there still remains a significant role for direct biopsy. Mediastinoscopy and its ability to assess mediastinal nodes are discussed in detail in Chapter 29. It remains a vital component in the evaluation of stage II disease. The obvious benefits of assessing ipsilateral and contralateral mediastinal nodes are well established. Many stage II tumors already involve hilar nodes and microscopic nodal involvement in the mediastinum can easily escape detection by imaging. However, an additional benefit of mediastinoscopy is its ability to assess the degree of mediastinal involvement. Mediastinal invasion by central tumors abutting the trachea or the proximal pulmonary artery can be difficult to assess by radiographic imaging. Mediastinoscopy is perfectly suited to evaluate this aspect of a tumor distinguishing a T4 tumor from a T3 or lesser tumor. However, mediastinoscopy, performed in this setting, can lead to scarring and distortion of normal-tissue planes. Although this degree of scarring is limited, it can increase the difficulty of subsequent planned complex resections such as a sleeve resection. If a sleeve resection or central dissection is anticipated, then the mediastinoscopy should be performed concurrently or within 2 to 3 days of the resection.

**Endobronchial Ultrasound and Esophageal Ultrasound** Similar to mediastinoscopy, endobronchial ultrasound (EBUS) allows sampling of mediastinal nodes for pathologic evaluation. Unlike mediastinoscopy, EBUS is less invasive and allows some hilar (level 10) nodes to be assessed. Esophageal ultrasound (EUS) coupled with transesophageal fine-needle aspiration (FNA) has the capability of reaching paraesophageal and inferior pulmonary ligament nodes (levels 8 and 9) as well as some of the nodes reached by EBUS (levels 7 and less frequently level 4). When combined, these two complimentary procedures have the capability of sampling seven nodal stations[2,4,6–10] versus only four stations with mediastinoscopy.[2,4,6,11] Discussed in Chapter 29, EBUS is quickly becoming a powerful tool in the evaluation of patients with lung cancer. Its high specificity has been consistently reported, but its sensitivity, especially compared with mediastinoscopy, is still debated. The high resolution of some EBUS and EUS probes can even supplant the evaluation of mediastinal invasion performed by mediastinoscopy.

The complete evaluation of mediastinal nodal involvement and assessment of mediastinal invasion has a clear impact on the subsequent treatment of a lung cancer. Until recently, the preoperative identification of hilar nodal involvement had fewer treatment-related consequences. When the treatment of stage I or II lung cancers were confined to lobectomy or conventional radiation, the preoperative determination of N1 nodal disease was of prognostic value only. However, the use of lobectomy as the sole treatment of subcentimeter node negative peripheral tumors is no longer the sole modality offered. Lung sparing techniques including stereotactic radiotherapy, percutaneous treatments such as radiofrequency ablation, or techniques such as wedge resections or segmentectomies (see also Chapters 32, 37, and 43), may be appropriate options. In these cases, preoperative identification of N1 involvement will play a significant role in treatment decisions. Similarly, the use of neoadjuvant chemotherapy, although currently not extensively utilized for early stage lung cancer, may be an option in the future. Again, pretreatment identification of N1 disease may be paramount in making these treatment-related decisions. The role of EBUS and EUS will undoubtedly increase in the evaluation and confirmation of stage II lung cancer.

All patients with stage II NSCLC without signs of metastatic disease should be evaluated for surgery. Exercise testing and preoperative evaluation of the patient with lung cancer is applicable to patients with stage II disease. Considerations that are specific for stage II disease stem from the frequently central location of some of these tumors. The involvement of a lobar bronchus by either the primary tumor (T2) or a hilar lymph node (N1) is encountered in stage II disease. These tumors can be approached by a sleeve resection rather than a pneumonectomy, and this should be considered when calculating the postoperative pulmonary reserve. In addition, the distal collapse caused by large >7-cm tumors (T3) or the lobar obstruction requires a split perfusion scan to be performed when calculating the postoperative pulmonary reserve. Additional considerations applicable to Pancoast tumors are discussed later in this chapter.

## SURGICAL TREATMENT

**Surgical Approach** Possible approaches include an open thoracotomy or a minimally invasive approach. The open thoracotomy remains the dominant approach for stage II disease, and it can include various methods. These include the posterolateral thoracotomy with division of the latissimus muscle and ± the serratus muscle. Muscle-sparing techniques are also quite common and include a posterior, anterior, or axillary approach. In rare cases a sternotomy, a hemiclamshell incision can also be utilized. These incisions are useful for centrally placed tumors that abut the anterior mediastinum.

The minimally invasive approaches have included several approaches that are nothing more than an open thoracotomy with an additional port for the thoracoscope to a completely thoracoscopic procedure. The definition most widely accepted for minimally invasive pulmonary resection was outlined in the feasibility trial of video-assisted thoracic surgery (VATS) lobectomy (Cancer and Leukemia Group B [CALGB] 39802).[12] The study mandated no rib spreading; a maximum length of

8 cm of the access incision for removal of the lobectomy specimen; individual dissection of the vein, arteries, and airway for the lobe in question; and standard node sampling or dissection (identical to an open thoracotomy). All specimens were placed in an impermeable bag and removed through the access incision. Although other approaches and techniques that have been reported included minimal rib spreading and hilar ligation, the authors agree with the intergroup investigators in maintaining a rigorous adherence to the principles utilized in an open thoracotomy.

The use of a VATS lobectomy in stage II disease may be limited by the tumor size. To effectively remove a tumor without rib spreading, most authors feel that the primary must be less than 5 to 6 cm in greatest diameter. Of course, flat tumors larger than 6 cm can be removed if the specimen is appropriately oriented in the impermeable bag. Additional concerns about a VATS approach in stage II disease center on the dissection of enlarged hilar nodes. Although lymph node dissection via a VATS approach has been shown to be very effective,[13] the intergroup investigators did comment on factors that required conversion to an open procedure. In 25% of the case (4 of 12), conversion was secondary to the difficulty dissecting lymph nodes from the vascular structures. Although this is not an absolute contraindication for a VATS approach, the surgeon should consider the size of the hilar nodes, the presence of calcifications or scarring from prior induction therapy, and the technical experience with a VATS approach.

**Open Thoracotomy**    Although there are several types of open thoracotomy, the most commonly employed versions include a posterolateral thoracotomy, a posterior muscle-sparing thoracotomy, and perhaps an axillary thoracotomy. All are performed with the patient in a lateral decubitus position. Attention to the method of pain control should also be given with the most common approach being a thoracic epidural. Local delivery of analgesics with a self-contained pump and catheter positioned in the extrapleural space are also gaining acceptance.

Although each has slight advantages and disadvantages when compared with one another, they are all appropriate for resection of most stage II lung cancers. The posterolateral thoracotomy is the most commonly employed incision and is the gold standard with regard to hemithoracic exposure. Its primary drawback remains the pain associated with this large incision and the division of the latissimus dorsi muscle, which has implications in postoperative function and the muscle's availability as a rotational flap. The posterior muscle–sparing thoracotomy uses the posterior two thirds of the posterolateral thoracotomy incision and mobilizes the latissimus dorsi and serratus anterior muscle anteriorly. Although the incision is slightly smaller, almost all procedures performed via a posterolateral thoracotomy can be safely approached through this incision. Exceptions, although not absolute, include complex sleeve resections and chest wall resections. The preservation of the latissimus dorsi muscle (and perhaps the speed of closure) is its primary advantage. The axillary thoracotomy utilizes either a vertical incision in the low axilla aligned with the anterior border of the latissimus dorsi muscle or a transverse incision centered on the anterior border of the latissimus dorsi muscle. The fibers of the serratus anterior muscle are separated exposing the third or fourth intercostal space through which the thorax is entered. The entry through the lateral aspect of the chest wall, where the ribs are most mobile, allows for distraction of the ribs with the least force being applied to the costovertebral junction. The main disadvantage is the limited exposure of lower lobe lesions.

For stage II tumors, each of these approaches can be used at the discretion and comfort of the surgeon. Patients with significant hilar disease or central lesions requiring sleeve resections may be best approached through a larger posterolateral thoracotomy. The limitations of an axillary thoracotomy make this approach the least utilized incision.

**Video-Assisted Thoracic Surgery**    In the past, the definition of a VATS resection has been variable in the literature. The range of definitions has included everything from a limited posterior muscle–sparing thoracotomy with thoracoscopic visualization, to a completely thoracoscopic approach without any rib spreading. Most thoracic surgeons today will agree that a true VATS resection should include absolutely no rib spreading, although the conduct of the resection should duplicate an open resection. The technical considerations for this approach have been discussed in detail previously in this text.

Although the effectiveness of this technique for early stage malignancies seems apparent, there are some concerns when applying the technique to stage II malignancies. Enlarged hilar N1 nodes, especially where there is concern of arterial or bronchial invasion, can magnify the technical complexity of a VATS resection. Although reports of VATS sleeve resections and pneumonectomies exist, these require advanced skills and will be adopted more slowly. A more practical limitation of the VATS technique in stage II malignancies is the size of the tumor that can be physically removed. Tumors larger than 5 to 6 cm cannot be removed through the utility thoracotomy without rib spreading. Correspondingly, these large tumors may limit visualization of and accessibility to the hilar structures increasing the technical complexity of the resection. Finally, the utility of combining a chest wall resection with VATS lobectomy may be questionable. Reports of chest wall resections accomplished by VATS do exist. However, the main advantage of a VATS resection, which is of rapid recovery of function, may be lost when coupled with a chest wall resection.

**Extent of Resection**    Although some debate exists regarding the extent of resection for stage I tumors, the options are less contentious for stage II disease. The frequent involvement of hilar lymph nodes in stage II disease mandates a resection that encompasses the nodal basin of the tumor. Although the new staging system includes some tumors that are without nodal involvement (T2bN0 and T3N0), the large size of these tumors (greater than 5 cm) and their aggressive features (chest wall invasion and interlobar satellite lesions) would make lung-sparing techniques difficult or less advantageous. For these reasons, there

is relatively uniform agreement that an anatomical lobectomy with complete hilar nodal dissection should be performed.

For the same reasons mentioned previously, most surgeons would also advocate a systematic mediastinal nodal dissection rather than a nodal sampling. However, definitive data demonstrating an advantage from complete nodal dissection on survival has yet to be established. The ACOSOG Z0030 trial randomizing clinical stage I patients to systematic node dissection versus node sampling have not yet reported long-term results. The early results exhibited no difference in morbidity associated with the performance of a systematic node dissection.[14] Mediastinal nodal involvement was identified in 3.8% of clinical stage I patients. Considering the higher likelihood of occult N2 disease in clinical stage II patients and the lack of evidence for increased morbidity associated with complete lymph node dissection, we would endorse complete lymph node dissection in all stage II patients.

**Pneumonectomy**    Pneumonectomy, or the complete removal of an entire lung, entails the division of the ipsilateral main pulmonary artery, both pulmonary veins and the mainstem bronchus. Ipsilateral hilar nodes are removed en bloc with the lung, and the mediastinal lymph nodes are removed as part of a systematic nodal sampling or dissection. A conventional pneumonectomy implies division of the vessels within the thoracic cavity. An intrapericardial pneumonectomy entails entry into the pericardium for division of any of the pulmonary vessels.

The definition of stage II disease includes several features that can require a pneumonectomy for complete resection. The most common is hilar nodal disease with concomitant invasion of the mainstem bronchus or the proximal pulmonary artery. This is especially true when the primary tumor resides in the lower lobes and the nodal disease involves the upper lobe bronchi or vasculature. Other reasons are large tumors (>7-cm tumors now classified as T3) that cross the fissure and involve the upper and lower lobes or tumors that obstruct the mainstem bronchus not amenable to a sleeve resection.

**Bilobectomy**    As the name implies, a bilobectomy is the removal of two lobes and can only be performed on the right lung. The indication for such a procedure is a large tumor that extends across the fissure to involve a substantial portion of an adjacent lobe. Additionally, hilar nodal disease that invades the central bronchi of two lobes can also necessitate bilobectomy. The later indication is not uncommonly seen in stage II disease.

**Lobectomy**    The definition of a lobectomy is, as expected, the removal of the entire lobe of a lung. The vascular and bronchial branches are individually identified and ligated along with the resection of any hilar lymph nodes surrounding these branches. Intraparenchymal lymph nodes associated with the lobe are removed en bloc with the specimen. Similar to a pneumonectomy, the mediastinal lymph nodes are removed as part of a systematic nodal sampling or dissection.

Lobectomy is the most common procedure for stage II lung cancer. The frequent central location of the tumor or the associated hilar nodal disease necessitates resection of the entire lobe. Even if the hilar nodal disease can be resected without sacrificing the lobar structures, most thoracic surgeons would not advocate a wedge or segmental resection of the primary tumor. A lobectomy should be performed to remove the entire nodal draining basin.

**Wedges or Segmental Resection**    These techniques resect a portion of lung surrounding the lesion or a segment of the lung. Segments are anatomically distinct with 10 named segments in the right lung and 8 in the left lung. These segments have a discrete arterial, venous, and bronchial anatomy, and a true segmentectomy would involve their isolation and division similar to a lobectomy.

As discussed earlier, these lung-sparing techniques are not frequently an option in stage II disease. The need to resect the hilar lymph nodes and their parenchymal nodal basin usually necessitates a lobectomy at the least. However, in some cases, such as a chest wall lesion without nodal disease (T3N0), one of these lung-sparing techniques can be used especially in patients with marginal pulmonary function.

**Sleeve Resections**    Sleeve resection, also referred to as bronchoplastic procedures, are techniques that preserve normal lung tissue when the lesions are small but located at or near the main bronchi. The technique involves resection of a portion of the main bronchus followed by an end-to-end anastomosis to preserve the lung tissue distal to the resection. Examples are shown in Figure 34.1.[15] In stage II disease, common indications for sleeve resection are involved hilar nodes that invades the origin of the lobar bronchus or small central tumors within 2 cm of the carina without lymph node involvement (T3N0). Although these tumors can also be resected with a pneumonectomy, there is clear data that the morbidity and mortality following a sleeve resection is less than a pneumonectomy. The added oncologic benefit of a pneumonectomy has not been clearly demonstrated.

**Chest Wall Resections**    Isolated chest wall involvement outside of the superior sulcus is also encountered in lung cancer. In the current staging system, a chest wall lesion without lymph node involvement is considered stage II disease, in the proposed changes to the staging system a T3 tumor with hilar nodal disease (N1) will also be considered stage II. Both of these tumors could be offered surgical resection. The goal of resection is an en bloc anatomical resection. Most investigators have identified completeness of resection as a prognostic factor in long-term survival.[16–18] The depth of invasion seems to be less predictive of survival.

There are areas of controversy that exist regarding the treatment of lung cancer invading the chest wall. The first is the use of an extrapleural dissection for tumors limited to parietal pleural involvement. Several publications have decried the use of this technique reporting worse outcomes.[19,20] Although the series from Memorial Sloan Kettering[21] failed to demonstrate a difference, the authors stated that patients with any suspicion of parietal pleural involvement were addressed with

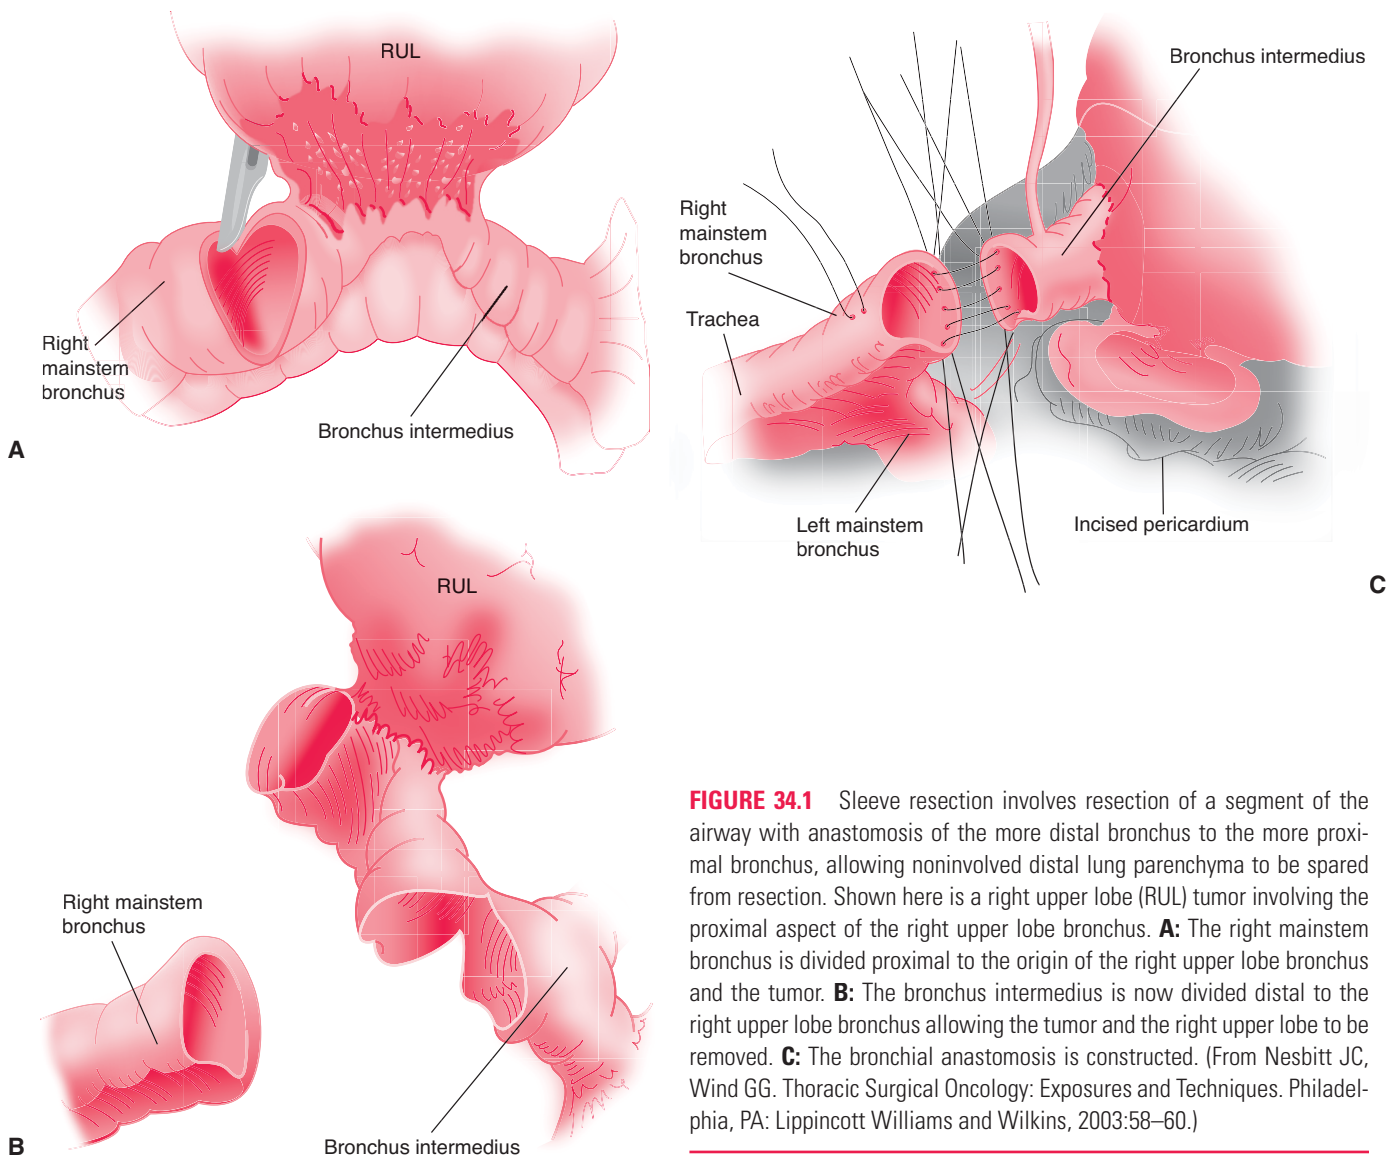

**FIGURE 34.1**    Sleeve resection involves resection of a segment of the airway with anastomosis of the more distal bronchus to the more proximal bronchus, allowing noninvolved distal lung parenchyma to be spared from resection. Shown here is a right upper lobe (RUL) tumor involving the proximal aspect of the right upper lobe bronchus. **A:** The right mainstem bronchus is divided proximal to the origin of the right upper lobe bronchus and the tumor. **B:** The bronchus intermedius is now divided distal to the right upper lobe bronchus allowing the tumor and the right upper lobe to be removed. **C:** The bronchial anastomosis is constructed. (From Nesbitt JC, Wind GG. Thoracic Surgical Oncology: Exposures and Techniques. Philadelphia, PA: Lippincott Williams and Wilkins, 2003:58–60.)

a chest wall resection. Extrapleural resection was reserved only for those with filmy inflammatory adhesions to the chest.

A second area of controversy surrounds the impact of nodal disease. Most series have shown a significant decrease in survival with increasing nodal involvement.[22–25] Evidence of N2 disease should be aggressively sought during evaluation of these patients. Identification of N2 or N1 disease may prompt the use of induction chemotherapy followed by resection for patients with a favorable response. However, data regarding the advantage of this approach, outside Pancoast tumors, do not exist.

Other controversies center on the use of radiation therapy after a complete resection and the extent of the pulmonary resection. Neither of these issues has been addressed with a randomized study, and an attempt at addressing the former question by the North American Lung Cancer Study group during the 1980s was closed for poor accrual. Our approach

has been to not offer adjuvant radiation therapy for completely resected chest wall lesions. Positive margins are offered radiation therapy if the area of positivity is clearly delineated. Wedge or segmental resections are avoided with a preference for a lobectomy unless comorbidities or pulmonary function dictates a lesser resection.

**Mediastinal Lymph Node Dissection**    Mediastinal lymph node dissection in the right chest includes dissecting and removing all visible nodes at level 2R, 4R, 7, and 9R position. Left chest mediastinal lymph node dissection involves removing all nodes at level 5, 6, 7, and 9L position. Levels 10 to 14 nodes of the corresponding lobe should have been removed with the specimen. Care should be taken to avoid injury to the right phrenic and right recurrent laryngeal nerves during dissection of levels 2R and 4R and the left phrenic and left recurrent nerve during dissection of levels 5 and 6.

The preference of a complete dissection in stage II disease was discussed earlier. Data comparing a complete node dissection versus a systematic nodal sampling has been evaluated in a randomized setting, but these studies have had mixed results with regard to long-term oncologic benefit.[26,27] These trials were limited by small numbers of patients, but a recent trial sponsored by the American College of Surgeons Oncology Group is hoped to address this issue definitively. Early results demonstrate no additional morbidity, but long-term survival data are still pending.[28]

**Adjuvant Therapy**  The role of adjuvant chemotherapy in the treatment of NSCLC is discussed in Chapter 45. For many decades, adjuvant chemotherapy, radiotherapy, or a combination was not offered for completely resected stage II lung cancer. Recent results generated from large multi-institutional and multinational trails have begun to identify early stage patients who do benefit from adjuvant chemotherapy. Stage II disease, specifically, has been identified in many of these studies as a favorable stage to receive therapy.

**Follow-up**  Stage II NSCLC patients should be followed postoperatively for two reasons. First, long-term survival is only 30% to 40% even with the best available treatment. Majority of patients (90%) present with metastatic disease, whereas a few (10%) develop local recurrence. Those who develop local recurrence can be treated with additional radiation therapy for symptomatic control. Those who develop systemic disease can be helped with palliative treatment. Secondly, lung cancer is a risk factor for a second cancer. Thirty percent of patients with lung cancer develop a new malignancy. Patients with history of lung cancer also have 1% to 4% per year risk of developing a new primary lung cancer.[1] Thus, patients followed aggressively may benefit from detection of early new primary lung cancers.

The recommendations for follow-up include at least 6 months with the specialist providing care and then a systematic follow-up every 6 to 12 months. The focus should be on detecting metastatic disease within the first 2 years and then detecting any new malignancies subsequently.

## PANCOAST TUMORS

In 1932, Henry Pancoast,[29] a radiologist from Philadelphia, addressed the American Medical Association describing for the first time what he termed a *superior pulmonary sulcus tumor* that was associated with Horner syndrome, rib destruction, and atrophy of the hand muscles. Although Hare[30] had first described this tumor in 1838, it was Pancoast's classic clinical presentation of pain of the eighth cervical or the first and second thoracic trunk distribution that has become known as Pancoast syndrome.

A Pancoast tumor is defined as a tumor arising in or near the apex of the lung, at or above the level of the second rib, with involvement of extrathoracic structures of the apical chest wall. The tumor originates peripherally and extends over the apex of the lung to involve the apical chest wall. This involvement can be seen by clinical and radiological evidence and can include the parietal pleura, lymphatics, endothoracic fascia, intercostal nerves, ribs, vertebral bodies, lower roots of the brachial plexus, the sympathetic chain (stellate ganglion), and subclavian vessels. The clinical triad of shoulder or arm pain, atrophy of the hand muscles, and Horner syndrome is the sine qua non of a Pancoast tumor. Lack of rib involvement accompanied by these symptoms is frequently included in the definition of a Pancoast tumor.[31]

An apical lung tumor with invasion of similar structures but without the symptom triad that defines a Pancoast tumor has been developed as a broader group termed a *superior sulcus tumor*. The anatomic definition of the superior sulcus of the chest has been debated with various definitions offered. Most seem to agree that the sulcus is the costovertebral gutter, and the superior sulcus is the uppermost extent of this.[32] These tumors may have some of the symptoms seen in a Pancoast tumor but are defined as an apical tumor with extension into the chest wall (the upper two or three ribs), the vertebral body, or the subclavian vessels.[31,33] Because the treatment of superior sulcus tumors and their narrower subgroup of Pancoast tumors are similar, most studies have evaluated all superior pulmonary sulcus tumors.

## EVALUATION AND STAGING

**Clinical Presentation and Diagnosis**  The incidence of superior sulcus tumors is uncommon, and it is estimated that only 5% of NSCLC will present in this manner. By definition, a Pancoast tumor includes shoulder or arm pain or paresthesias, Horner syndrome, and atrophy of the intrinsic muscles of the arm. However, as described previously, not all superior pulmonary sulcus tumors will present with a complete Pancoast syndrome. Therefore, patients with risk factors for lung cancer who present with any combination of these symptoms should be evaluated for an apical tumor. Although the history and physical exam can be suggestive, the diagnosis is commonly made after radiographic examination.

The chest radiograph is regrettably very uninformative in many cases with only a small homogenous apical cap or pleural thickening visible (see Fig. 34.2). With advanced tumors, chest radiographs can visualize bony destruction of ribs and vertebral bodies. Unfortunately, the low sensitivity of chest radiographs can lead to a delay in diagnosis. A high level of clinical suspicion on the part of the treating physician is necessary for diagnosis of these lesions. This is especially true for early and hence more treatable tumors.

CT scans are highly accurate at detecting apical abnormalities. An apical mass apparent on a CT scan in a patient with symptoms of a Pancoast tumor can be diagnostic but nonmalignant, and metastasis presenting with similar findings have been

**FIGURE 34.2** Posteroanterior (PA) chest radiograph of a patient with a right-sided Pancoast tumor with the apical cap on the right. This tumor invaded the subclavian artery and vein, as well as the T1 nerve root. This patient had classic symptoms consistent with Pancoast syndrome.

reported.[34–36] Therefore, the diagnosis should be confirmed by a biopsy. Transthoracic biopsies can be obtained without significant complications. The biopsy can also assist in staging. In patients without symptoms or radiographic evidence of chest wall invasion a transthoracic biopsy complicated by a small pneumothorax can differentiate an apical tumor without chest wall invasion from a true superior pulmonary sulcus tumor.

**Staging** Pancoast tumors are lung malignancies, and therefore, staged with the same TNM classification system. Because of the involvement of the chest wall, all Pancoast tumors are by definition at least stage IIB. If the proposed changes to the staging system take effect, there will be some shifting of stages

IIIA and IIIB Pancoast tumors into the stage IIB category. These changes are primarily a result of changes in the TNM groupings (Table 34.1).

**T Descriptors** Inherent in the definition of a Pancoast tumor is chest wall involvement. Identification of any extension into nearby structures is paramount to establishing the T status of the tumor and, more importantly, determining its resectability. Although the new definitions of the T descriptors proposed by the IASLC may alter the staging of Pancoast tumors, most of these changes occur in the T1 and T2 descriptors. Their effect on Pancoast staging is negligible. The majority of the changes will express themselves as a shift of previously stage IIIA and IIIB tumors into earlier stages. Although these changes were established based on considerable data, there is some concern that applying these definitions to a Pancoast tumor will not yield similar results. Pancoast tumors with extension into the vertebral body (T4 extension) and any nodal disease have historically done very poorly.[37]

Although CT imaging is adequate for the initial evaluation of these tumors, determination of resectability requires greater resolution. Magnetic resonance imaging (MRI) has been the modality of choice for this anatomic region. Sagittal imaging allows better visualization of the brachial plexus and the subclavian vessels but additionally, evaluation for invasion of the vertebral body and the neural foramina is improved with MRI.[38,39] An MRI can help characterize C8 and T1 roots. Although the T1 nerve root can be sacrificed distal to its contribution to the brachial plexus with little impact on arm and hand function, preservation of the C8 nerve root is required for adequate hand function. Establishing their involvement is a key to the determination of resectability. In a study comparing CT with MRI, Heelan et al.[39] found CT scan to have a sensitivity of 60%, a specificity of 65%, and an accuracy of 63% in determining resectability. MRI was 88% sensitive, 100% specific, and 94% accurate. Thus, most centers today will obtain a CT and an MRI to best assess the local extension of the tumor (see Fig. 34.3). Improvements in CT resolution continue and CT coronal and sagittal reconstructions combined with refinements in CT imaging may eventually supersede MRI's role in the evaluation of these tumors.

| TABLE 34.1 | **Proposed Stage Grouping Changes that Would Effect Pancoast Tumor Staging by the IASLC Staging System** | | | |
|---|---|---|---|---|
| | **Existing UICC Stage** | | | **Proposed** |
| **Stage** | **T** | **N** | **M** | **IASLC Stage** |
| IIIB | T4 (same lobe nodule) | N0 | M0 | IIB |
| IIIB | T4 (same lobe nodule) | N1–N2 | M0 | IIIA |
| IIIB | T4 (extension) | N0–N1 | M0 | IIIA |
| IV | Any T | N0–N1 | M1 (ipsilateral lung) | IIIA |
| IV | Any T | N2–N3 | M1 (ipsilateral lung) | IIIB |

IASLC, International Association for the Study of Lung Cancer; UICC, Union Internationale Contre le Cancer.
**FIGURE 34.3**   Pancoast tumor with direct extension to apical chest wall, abutting brachial plexus and involving subclavian vessels. **A,B:** The CT scans clearly show the abutment of the tumor and the subclavian vessels. MRI allows greater resolution of this region, however, and the multiplanar reconstructions are useful for preoperative assessment and evaluation of vascular structures as well as involvement of the brachial plexus. **C,D:** MRI images of a different patient whose tumor can be seen involving the T2 vertebral body on the coronal images. The sagittal image **(D)** demonstrates a clear plane between the tumor and the left subclavian artery.

**N Descriptors**   Pancoast tumors with positive mediastinal nodes (N2 or N3) have a uniformly poor prognosis. Mediastinoscopy is required in all clinical trials and should be strongly considered when evaluating patients for surgery. The use of endoscopic bronchial ultrasound can also be considered in centers with sufficient experience in its use. An added advantage of EBUS is its ability to biopsy some hilar nodes, allowing tissue confirmation of N1 disease. In patients with suspicious scalene nodes, an ultrasound-guided FNA or a scalene node dissection is also strongly recommended.

**M Descriptors**   PET/CT scanning is a powerful tool to assess for metastatic disease and should be performed during the evaluation of these patients. Any suspicious lesions should

be confirmed with a biopsy of the region before finalizing the patient's stage. The brain and long bones, areas poorly visualized by conventional PET/CT should also be evaluated with a CT or MRI of the brain and a bone scan. Although the new IASLC staging system has downstaged ipsilateral lung lesions as T4 rather than M1, most would continue to approach Pancoast tumors and an ipsilateral lung lesion with trepidation.

**Histology**   The origin of Pancoast tumor was uncertain in the early years. Pancoast believed these tumors originated from a brachial pouch, and it was not until 1932 that the pulmonary origin of these tumors was identified. Despite its peripheral position in the lung, many of these tumors were squamous

cell histology; however, recent series have demonstrated an increase in the number of adenocarcinomas. The most recent published series from France reported nearly identical rates of each of these histologies and a large number of large cell histology as well. Only 3% to 5% of total Pancoast tumors are small cell carcinomas. Other rare etiologies include adenoid cystic carcinoma, hemangiopericytoma, and localized mesothelioma. Rarely, Pancoast syndrome has been reported in patients without pulmonary etiologies because of apical chest involvement by hematologic malignancies and infectious agents such as tuberculosis.[40]

## MULTIMODALITY TREATMENT

There is no definitive or agreed-upon treatment strategy for Pancoast tumors. The treatment regimens have varied from radiotherapy, chemoradiotherapy, induction radiotherapy followed by surgical resection, induction chemotherapy with or without radiotherapy followed by resection, and surgical resection followed by adjuvant chemoradiotherapy.

Historically speaking, Pancoast tumors were considered universally fatal until the 1950s because of technical limitations of resection and lack of effective multimodality therapy. Chardack and MacCallum[41] reported the first successful resection of a Pancoast tumor in 1953. An en bloc lobectomy and chest wall resection was employed followed by adjuvant radiation therapy (65 Gy over 54 days). The patient died almost 6 years later and a postmortem revealed no evidence of malignancy.[42] In 1961, Shaw and colleagues [42a] treated their first in a series of 18 patients with superior sulcus tumors employing preoperative radiation therapy (30 to 35 Gy over 2 weeks) followed by en bloc surgery 4 to 6 weeks later. Although retrospective and a small series, the data demonstrated that high resectability with minimal morbidity could be achieved. The reported survival rate was also greater than expected leading to wide spread acceptance of this treatment approach. For the next 30 years, numerous investigators confirmed Shaw's findings and few alterations were made.[43]

This began to change approximately 2 decades ago as researchers around the globe began not only to expand the definition of resectability but also to address the systemic nature of the disease through multimodality therapy. The definition of resectability was initially confined to chest wall lesions with limited involvement of the spine (i.e., the transverse process). Improvements in surgical techniques and a multidisciplinary approach to surgical resection allowed resection of tumors involving the vascular structures of the thoracic inlet and the vertebral bodies. Dartevelle et al.[44] anterior transcervical approach was one such advance. This approach allowed safe access to the subclavian vessels and demonstrated that their resection could achieve comparable survival rates. Rapid acceptance of the anterior approach followed throughout the world. A similar extension of the definition of resectability occurred with the multidisciplinary approach to vertebral involvement. Advances

in spine stabilization developed by neurosurgeons and orthopedic surgeons were applied to Pancoast tumors with surprisingly effective rates of local control.[45]

The addition of systemic therapy to the treatment regimen of Pancoast tumors was the next appropriate step considering the survival advantages seen with induction chemotherapy for stage IIIA NSCLC. The Southwest Oncology Group (SWOG 9416, INT 0160) was a phase II trial that addressed this in a prospective multi-institutional fashion. The induction regimen was similar to previous trials in stage IIIA disease and was known to be well tolerated and effective.[46] The initial results were reported in 2001[31] and updated in 2003.[47] Over 4 years, 111 patients were eligible for this trial with surgery performed by 26 surgeons throughout five cooperative groups. Seven patients did not complete their induction therapy as planned with three deaths (2.7%). A total of 87 patients were eventually registered for the surgical arm of the trial although four were not resected at the discretion of the individual investigators. The final number taken to surgery, 83, represented 75% of the 111 enrolled patients.

The next major development was the North American Southwest Oncology Group trial (9416) of induction chemoradiotherapy followed by resection, which has now become the most widely used approach for Pancoast tumors with survival ranging as high as 53%. One hundred ten patients with T3N0 to T4N0 disease received induction chemoradiotherapy with etoposide and cisplatin and 45 Gy radiation. Patients with resectable disease postinduction underwent thoracotomy. The 5-year survival was 41% for all patients and 53% for complete resection.

The morbidity of the induction regimen was well tolerated with only 18 patients suffering a reduction in their performance status. At restaging, there were 0%, 36%, and 41% complete, partial, and stable responses, respectively. Resection was performed with various anatomic resection, the most common being lobectomy and en bloc chest wall (67.5%). Interestingly, 12 patients (14%) had lung resection without chest wall resection. Although this may represent effective induction therapy, another consideration must be that these patients were clinically overstaged and were not true pathologic T3 tumors at the time of their registration. The morbidity and mortality of surgery was not substantially different from other series with two deaths (2.4%) and 10 pneumonias (12%), and a median hospital stay of 7 days.

The pathologic response was encouraging with 65% of patients demonstrating a complete pathologic response or only minimal microscopic disease. The individual frequencies of these two groups were evenly distributed between the two groups. Also apparent was the striking inaccuracy of the preoperative radiographic assessment of the response.

The overall survival in this initial report with a median follow up of 21 months was 55% at 2 years. In the group who enjoyed a complete pathologic response, the 2-year survival was 70% (Fig. 34.4).[48] At the time of the initial report, there was no statistically significant prognostic factor evident, the

|  | No. | Deaths | Median (months) |
|---|---|---|---|
| Pathologic CR | 32 | 12 | NR |
| Residual disease | 56 | 35 | 30 |
| $P = .02$ | | | |
**FIGURE 34.4** Results of the SWOG trial 9416 comparing patients with pathologic complete response and patients with residual disease at final pathology. *CR*, complete response; *NR*, no record. (From Rusch VW, Giroux DJ, Kraut MJ, et al. Induction chemoradiation and surgical resection for superior sulcus non-small-cell lung carcinomas: long-term results of Southwest Oncology Group trial 9416 [Intergroup trial 0160]. *J Clin Oncol* 2007;25:313–318.)

updated results in 2003 demonstrated that the pathological response, but not tumor stage, predicted the overall survival. Updated survival data demonstrated 5-year survivals of 41% overall and 53% in the complete pathologic response group.

Since its publication, two additional small studies have supported the findings of this trial.[49] Clearly, their results demonstrate the feasibility of induction chemoradiotherapy for this challenging group of patients. These data will also serve as a benchmark for future studies. It is clear that multimodality must play an integral part in the treatment of these tumors. Although the overall survival has been enhanced and the size of the patient population offered treatment with curative intent, expanded surgery remains the basis of any meaningful approach to Pancoast tumors.

## SURGICAL TREATMENT

### Surgical Approach

**Posterior Approach** This approach was utilized in the initial reports of successful resection of Pancoast tumors and has remained the mainstay in exposing most Pancoast tumors. The patient is positioned in a lateral decubitus position with careful attention to expose the base of the cervical spine and support the head. A posterolateral thoracotomy incision is performed and based on the position of the tumor, a safe interspace is chosen to enter the thorax. Exploration is performed to confirm resectability. The incision is then extended posteriorly and superiorly between the medial border of the scapula and the spine up to the seventh cervical vertebra (Fig. 34.5). After division of the trapezius and rhomboid muscles, the scapula can be elevated away from the chest wall allowing visualization up to the first rib. Retraction can be achieved with one arm of the rib spreader, an internal mammary retractor, or a customizable frame mechanical retractor such as the Thompson retractor (Fig. 34.6).

The scalene muscles can now be divided exposing the upper border of the first rib and the subclavian vessels. Involvement of these vessels can be assessed as well as the superior extent of

**FIGURE 34.5** The posterior approach to Pancoast tumors is an extension of the standard posterolateral thoracotomy incision with division of the latissimus, trapezius, and rhomboid muscles, permitting access to the apex of the chest. The planned incision begins the base of the neck posteriorly, extends between the scapula and the spine, and curves beneath the scapula to extend across the lateral chest wall similar to a standard posterolateral thoracotomy. (From Nesbitt JC, Wind GG. Thoracic Surgical Oncology: Exposures and Techniques. Philadelphia, PA: Lippincott Williams and Wilkins, 2003:164.)

the tumor. If the lesion appears resectable, then the chest wall resection can begin with the anterior division of the ribs. It is sometimes useful to resect a small portion (<1 cm) of each rib to allow easier manipulation of the chest wall segment during the subsequent disarticulation of the ribs from the spine. Every effort is made to achieve a 4-cm margin at the anterior division of the ribs.

The posterior disarticulation of the chest wall is begun at the inferior most rib and then progresses superiorly. Each rib has two synovial plane joints: the medial costovertebral joint that articulates the vertebral column with the heads of the ribs and the more lateral costotransverse joint. Between these two facets lies the neural foramen. A surgeon operating in this area should become very familiar with the bony anatomy and the position of the neural vascular structures. If there is any concern over vertebral involvement or unfamiliarity with operating in this region, a spine surgeon should be engaged to assist with this portion of the dissection.

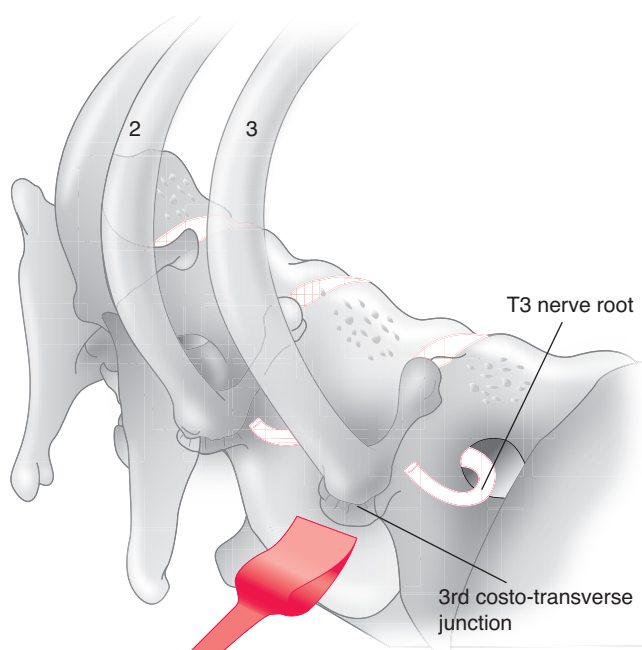
The transverse processes should be exposed posteriorly by elevating the erector spinae muscle. If involved, these can then be divided at their base with either an osteotome or rongeurs with care not to injure the nerve roots. More commonly, the transverse process can be preserved, and the dissection begins with anterior and medial distraction of the chest wall segment. The costotransverse ligaments are then carefully divided with cautery or sharp dissection. If accomplished correctly, the costotransverse joint is exposed and disarticulated. (Fig. 34.7) This joint has a superior (larger) and inferior (smaller) facet resulting from its intervertebral location and both facets will need to be exposed. If compression of the chest wall segment is insufficient to achieve disarticulation (common during the dissection of the initial lowest rib), disarticulation can be assisted with a Cobb retractor placed in the joint and used to apply forceful anterior retraction. Medial force or leveraging with these instruments should be avoided because the instrument may slip into the neural foramen.


**FIGURE 34.7** Tumors abutting or invading the proximal rib near the vertebral body may require disarticulation of the costovertebral junction. (From Nesbitt JC, Wind GG. Thoracic Surgical Oncology: Exposures and Techniques. Philadelphia, PA: Lippincott Williams and Wilkins, 2003:171.)

With the more lateral costotransverse joint disarticulated, the nerve root must now be identified and ligated. The neural foramen, an oval opening located at the base of the transverse process, can be exposed by continuing the division of the costotransverse ligaments, the levator costorum muscles, and distracting the chest wall segment. As the chest wall segment begins to loosen, care should be taken to not distract the segment aggressively and risk avulsing the nerve root before they can be identified, ligated, and divided. Ligation can be accomplished with surgical clips or a silk ligature and is advocated, because the dura may be incompletely fused with the nerve root resulting in a postoperative cerebrospinal fluid leak. After division of the nerve root, the vascular structures can also be identified and ligated with clips, ties, or even bipolar cautery and attention can be turned to the costovertebral joint.

This medial joint can be disarticulated by continuing to apply anterior and medial compression on the chest wall. Use of a Cobb retractor can also be employed although involvement of the rib with tumor can sometimes weaken the bone leading to fracture. If this occurs, the remaining fragments of the rib will need to be removed. Sometimes, if the tumor is situated laterally, the costovertebral joint can be approached intrapleurally. This helps define the location of mediastinal vascular structures and define the medial extent of the dissection.

Although these techniques are useful, they must be used with caution at the level of the first rib. Two aspects of the first rib require greater attention to the dissection. The first is the close approximation of the C8 nerve root to the superior border of the first rib head. If the costotransverse joint of the first rib

is aggressively distracted, inadvertent avulsion of this root can occur with resulting hand weakness. Even more attention must be paid when approaching the more medial costovertebral joint. One technique is to grasp the first rib with a Kocher forceps and apply purely lateral retraction during dissection of the joint.

The second aspect of the first rib is that the T1 nerve root, after leaving the foramen, provides a branch to the brachial plexus that joins the C8 nerve root. If the tumor is positioned lateral to this branch, the T1 nerve can be divided distal to this branch preserving this sensory nerve contribution to the arm. In addition, the costovertebral joint can be left undisturbed lessening the risk of injury to the C8 root.

There are a few additional structures that need to be recognized and, in some cases preserved, during the medial–superior mobilization of the chest wall. A structure that can be sacrificed if involved is the superior stellate ganglion of the sympathetic chain. Frequently, these patients already have a Horner syndrome, but infrequently the Horner is new, and appropriate patient education will need to be provided. Other structures that rarely can be involved are the vertebral arteries and, on the left side, the esophagus and the thoracic duct. The proximity to the vertebral artery and esophagus should be established by preoperative imaging, but the thoracic duct may be encountered intraoperatively. In tumors that approach these structures, even greater care should be taken when completing the medial portion of the dissection after division of the costovertebral joint.

**Anterior Approach**    Superior sulcus tumors include the classic Pancoast tumors that invade posteriorly leading to the classic Pancoast syndrome but can also invade anteriorly toward the subclavian vessels. The posterior approach, although sufficient to assess vessel involvement, does not provide adequate distal control of the artery or vein to allow resection. The anterior approach popularized by Dartevelle et al.[44] has become the ideal approach for these presentations of superior sulcus tumors. Alterations to this approach have allowed even greater exposure of posterior elements and the hilum of the lung allowing access to more posteriorly placed tumors and performance of greater lung resections.

The patient is positioned supine with the neck rotated toward the contralateral side and extended. The actual incision has varied with modifications both in the position of the incision and the method of exposing the subclavian vessels. Dartevelle utilized a transclavicular approach with the incision following the anterior border of the sternocleidomastoid muscle then extending laterally along the clavicle. Masaoka et al.[50] utilized a median sternotomy with extension into the fourth intercostal space and an incision along the superior border of the clavicle (similar to a hemiclamshell incision). Grunenwald and Spaggiari[51] addressed the limitations of a clavicular resection by developing a transmanubrial approach with sparing of the clavicle and the sternoclavicular joint. (Fig. 34.8)

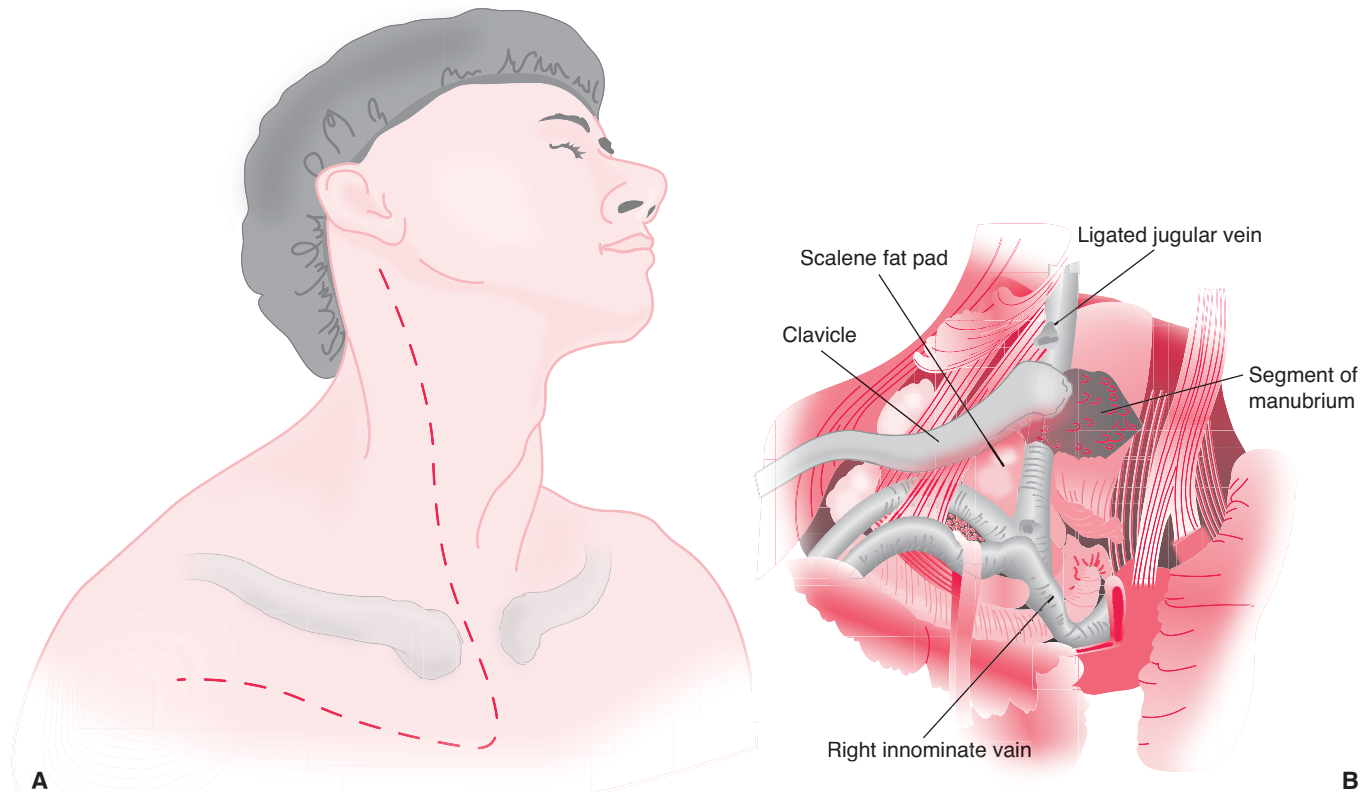
The transclavicular approach proceeds with elevation of the pectoralis major as a myocutaneous flap, allowing exposure of the chest wall. The scalene nodes are completely dissected, and


**FIGURE 34.8** **A:** The anterior approach involves an incision along the sternocleidomastoid, extending inferiorly across the manubrium then turning laterally below the clavicle across the superior anterior chest wall. **B:** This permits safe access to vascular structures. (From Nesbitt JC, Wind GG. Thoracic Surgical Oncology: Exposures and Techniques. Philadelphia, PA: Lippincott Williams and Wilkins, 2003:182,184.)

the chest is entered through a safe intercostal space below the tumor. If deemed resectable, the clavicular head of the sterno-cleidomastoid muscle is divided and the medial third of the clavicle resected. The subclavian vein can be dissected free or, if involved, resected. On the left side, care should be taken to preserve or ligate the thoracic duct, if involved. The an-terior scalene is now exposed, and the phrenic nerve should be sought and mobilized medially. Division of the anterior scalene muscle above the level of the tumor will expose the subclavian artery and the brachial plexus. If the artery can be preserved, it is carefully dissected, and every attempt is made to preserve the vertebral artery if possible. If preoperative imaging suggested involvement of the vertebral artery, then a cranial ultrasound or MR cerebral angiogram should be performed to confirm an intact circle of Willis, which would allow safe divi-sion of this vessel. If the subclavian artery cannot be dissected free, the excellent proximal and distal exposure of the artery allows resection if so indicated. The final dissection addresses the brachial plexus and allows complete release of the superior aspect of the tumor.

Attention is now turned to the chest wall resection. The first rib can be disarticulated from the manubrium followed by division of any additional ribs as indicated. With increas-ing experience, the posterior attachments of the ribs can also

be approached and disarticulated using posterior and medial compression of the chest wall segment to distract the costo-transverse and costovertebral joints. Although this exposure is sufficient for limited posterior extension, tumors that involve anterior structures as well as the vertebral body should be mo-bilized anteriorly then approached with a posterior approach to achieve an en bloc resection. Finally, the resulting chest wall defect is usually sufficient to perform a lobectomy and an ad-equate lymph node dissection.

The transmanubrial approach preserves the sternoclavicu-lar joint by creating an L-shaped incision in the manubrium. The first rib is disarticulated from the manubrium and with gradual elevation of the manubrial–clavicular segment, the in-ternal mammary vessels are identified and ligated. The remain-der of the anterior dissection then proceeds in a manner similar to that described by Dartevelle. Grunenwald then proceeded to perform a posterolateral thoracotomy for the remainder of the dissection, whereas others have used an anterolateral tho-racotomy.[52] The combination of a pure anterior transcervical approach, or a modified anterior approach with various other methods to gain access to the chest (sternotomy, posterolat-eral, or anterolateral thoracotomy) can be confusing. Each ap-proach has subtle advantages and disadvantages and the reader is recommended a recent concise review by Macchiarini.[15]

## Extent of Resection and Reconstruction

**Anatomic versus Limited Resection**    Early series sometimes utilized a limited aggressive wedge resection when performing the pulmonary resection of a Pancoast tumor. This was logical because early series had such high rates of local recurrence in the thoracic inlet (around 40% in most series) that the advantage of a lobectomy versus a limited resection would not be apparent. However, later larger series began to identify an advantage associated with lobectomy rather than limited resections.[53] Currently, most investigators agree that a lobectomy should be offered if the patient is an appropriate candidate physiologically.

The role of a pneumonectomy in the resection of a Pancoast tumor, although rare, is not unheard of. In the SWOG trial, 3.6% of patients required a pneumonectomy, whereas the French trial, reported by Martinod et al.,[10] performed a pneumonectomy in 5% of patients. Although both series reported acceptable morbidity and mortality rates, the ubiquitous application of these data to all patients must be done cautiously. If the work by the SWOG investigators is correct and induction chemoradiotherapy becomes the standard approach to these tumors, then further data on the risks of induction chemoradiotherapy coupled with a pneumonectomy will be needed. Cause for this concern is evident in reports of significant increase in mortality following induction therapy and a right pneumonectomy.[54]

**Chest Wall Reconstruction**    Chest wall reconstruction after a Pancoast resection is rarely performed, because most of the resection is subsequently covered by the scapula. The scapula provides adequate structural rigidity, allowing adequate ventilation to continue. However, if the chest wall resection extends to or below the fourth rib, postoperative trapping of the scapula inside the chest can occur. This occurs when the arm is elevated, drawing the scapula superiorly. As the arm is brought down, the tip of the scapula can herniate into the chest restricting the patient's ability to lower his/her arm. Two solutions are available. At the time of resection, a limited chest wall reconstruction can be performed using nonabsorbable material. The lower ribs should be covered and the material secured to the inferior rib, so that the scapula can ride over the material and not herniate into the chest. Alternatively, the lower 3 cm of the scapula can be exposed with a periosteal elevator and then resected using a sternal or oscillating saw. Either method is appropriate at the time of the tumor resection, although the latter is ideal when this complication is first identified postoperatively.

**Vertebrectomy**    Originally, vertebral involvement was thought to be a contraindication to resection in these difficult patients because of poor long-term survival. Advances in spine technology combined with multispecialty approaches have led investigators to look at the feasibility of vertebral body resection in conjunction with superior sulcus tumor resection. Gandhi et al.[55] found a 2-year survival of 54% in patients with a superior sulcus tumor and vertebral body resection. The survival was 80% for negative margins and 0% for patients with positive margins. A recent update confirmed the earlier findings and also demonstrated the very poor results in these patients with any nodal disease. A more complete discussion of vertebral involvement and the techniques of resection is found in Chapter 35.

**Subclavian Vessel Involvement**    Subclavian vessel involvement, once considered unresectable, is now addressed through an anterior approach popularized by Dartevelle. The vein can be resected without reconstruction, because there is frequently extensive collateralization already in place to provide adequate drainage of the arm. Arterial resection requires reconstruction. Although a direct reconstruction from the two divided ends of the vessel using a ringed polytetrafluoroethylene (PTFE) material is the most common method of reconstruction, a reversed venous graft can also be used. An alternative method for reconstruction to consider is a carotid–subclavian bypass. This method is especially useful for extensive tumors that cannot be completely mobilized from the anterior approach. These tumors will need to remain in place after completion of the anterior dissection until they can be released posteriorly. Rather than performing a direct end-to-end reconstruction, which will take a circuitous route around the tumor, a carotid subclavian bypass can be constructed very close to its final length with the tumor still in place or with limited proximal subclavian artery exposure.

The impact of subclavian arterial resection on long-term survival appears to be negligible in these highly selected patients. Dartevelle et al.[44] reported 12 patients in 1993 who underwent subclavian artery resection and reconstruction with 5-year 30% survival. Martinod et al. have reported 25 patients with subclavian artery involvement with 40% 5-year survival.[10]

**Postoperative Morbidity and Mortality**    The most current data on the morbidity and mortality of Pancoast resection comes from the data obtained in the SWOG trial. Although this trial did use induction chemoradiation therapy, the modern nature of the series gives the best reflection of the current status in the United States. The surgical mortality rate in that series was very low at 2.4%. There was an additional three treatment-related deaths for a final mortality rate of 4.5%. Earlier series have reported similar rates of mortality and are summarized in Table 34.2. The morbidity in all the series was similar to what was seen in the SWOG trial. The dominant complications were pulmonary with pneumonia rates around 12%.

Local recurrences also varied considerably between series ranging from 9% in the recently updated SWOG data[47] to as high as 72% in a series of 124 patients treated with surgery and brachytherapy.[56] Although this variation is very multifactorial, including tumor-specific and treatment-related factors, more modern series appear to be able to achieve local recurrence rates below 30%.

| TABLE 34.2 | Mortality and Local Recurrence Rates Reported in Major Series on Pancoast Tumor Resections | | |
|---|---|---|---|
| **Preoperative Treatment** | **N** | **Mortality** | **Local Recurrence** |
| Chemo/XRT[48] | 110 | 4.5% | 9% |
| Chemo, XRT or Chemo/XRT[53] | 225 | 4% | 40% |
| XRT or Chemo/XRT[49] | 35 | NR | 30% |
| Chemo, XRT, Chemo/XRT or Surgery alone[10] | 139 | 7.2% | 35% |

Chemo, chemotherapy; NR, not reported; XRT, x-ray therapy.

## FUTURE ADVANCES

There are several areas where future advances can be directed in the treatment of these malignancies. One area is common to both stage II disease, and the subset of Pancoast tumors is the integration of targeted therapies either preoperatively or as adjuvant therapy.

Many of the trials of adjuvant chemotherapy have demonstrated the challenges of administering postoperative platinum-based systemic therapy.[57] Induction therapy is better tolerated, but even in the SWOG trial it was clear that, when combined with radiotherapy, platinum-based therapy administration is still challenging.[31] The use of targeted therapies initiated preoperatively or postoperatively may have a role in this disease. Certainly, minimally invasive approaches may improve patient's tolerance of adjuvant therapy, but in the case of Pancoast tumors, there is little that can be done presently to reduce the physiologic stress of surgery. Agents targeting angiogenesis (e.g., bevacizumab) or epithelial growth factor receptor antagonists (e.g., erlotinib) are just a few examples of these agents. As improvements develop in genetic and proteomic analysis of lung cancers, even more intelligent choices on chemotherapeutics can be applied to these malignancies limiting the toxicities that already accompany the treatment of these advanced malignancies. To this end, the SWOG has initiated a trial (0220) to examine the effect of a less toxic regimen, docetaxel, in an adjuvant setting for Pancoast tumors.

Novel radiotherapy techniques are becoming available as well. It is clear that a multidisciplinary approach to Pancoast tumors is necessary to achieve the lowest local recurrence rates. The development of proton radiation techniques with their decreased collateral radiation damage may have a significant effect in these tumors. Additionally, the high rate of brain metastases seen in these patients may lead to prophylactic cranial irradiation in high-risk patients after resection.

## CONCLUSION

Stage II NSCLC and their subset of Pancoast tumors, although considered surgically resectable, still suffer from relatively poor survival statistics. Overall, this group, when clinically staged, has a survival at 5 years of less than 30% to 40%. Although disappointing, this also provides the greatest opportunity for significant improvement. As we have shown, the local therapy for stage II lesions and even the technically challenging Pancoast patients have improved considerably. The majority of failures in these patients are a result of systemic failures. As investigators now concentrate their efforts on improving cytotoxic and biologic therapies, we have an opportunity to diminish these failures and greatly impact on their overall outcome.

# Vertebral Body Resection

Non–small cell lung cancer (NSCLC) that extends to the vertebrae is classified in the TNM system as T4 disease. The T4 description is historically used for locally advanced tumors involving a structure that is considered "unresectable" for cure. Incomplete resection offers no survival advantage, and until recently, surgical techniques provided few options for removing and reconstructing the vertebral body. Nonsurgical therapy for T4 tumors leads to dismal survival rates (5% to 10% 5-year survival for superior sulcus tumors treated without surgery[1,2]), which has prompted thoracic surgeons to attempt resection of supposedly unresectable structures in the last 2 decades. Complete resection of T4N0 NSCLC invading the vertebrae can achieve 5-year survival of approximately 45% to 50% in some series.[1,3–5]

Lung cancer with spinal involvement usually occurs in the upper thoracic spine, most frequently seen as a superior sulcus tumor (see Chapter 34). Approximately 2% to 3% of all NSCLC presents as a superior sulcus, or *Pancoast* tumor. Pancoast syndrome is defined as the triad of (a) shoulder and arm pain, (b) wasting of the hand muscles, and (c) ipsilateral Horner syndrome (ptosis, miosis, and anhidrosis caused by invasion of the stellate ganglion); not every case of superior sulcus tumors will present with the Pancoast syndrome, but it is more commonly seen with vertebral invasion because of the posterior location of the tumor within the thoracic inlet. The remainder of this chapter will refer to the entity of superior sulcus tumor with vertebral invasion unless otherwise specified.

Collaborative efforts between thoracic and spine surgeons for spinal resection for metastatic disease has greatly increased knowledge and surgical skills that can be applied to this small subset of patients with T4 Pancoast tumors who may now be considered for cure. Furthermore, improved outcomes with multidisciplinary treatment approaches for superior sulcus tumors has engendered optimism for achieving complete resection and even cure for these difficult tumors. Not surprisingly, careful patient selection, meticulous attention to detail both in the clinic and the operating room, and diligent postoperative care are necessary elements for success with vertebral resection for Pancoast tumors.

## PATIENT SELECTION

As always, a complete history and physical exam should be performed. The usual imaging and cardiopulmonary evaluation are required (Table 35.1). Tissue diagnosis is important to obtain preoperatively; there are reports of lymphoma, metastatic tumors, or mycobacterial infections masquerading as superior sulcus NSCLC.[6] Percutaneous image-guided biopsy is usually very high yield with these peripherally located tumors, whereas bronchoscopy is rarely helpful for obtaining tissue.

For a multimodality treatment strategy that includes major pulmonary resection with concomitant rib and vertebral resection, patients need to be in optimal condition. Performance status must be satisfactory, and patients must have adequate cardiac, pulmonary, and renal function. Pulmonary complications are the most frequent source of postoperative morbidity; thus, patients with marginal respiratory status preoperatively are unlikely to have a good result. Smoking cessation is also critical to minimize perioperative respiratory events.

Other important factors in patient selection include a thorough assessment of any neurologic deficits. Brachial plexus involvement above the lower trunk of the plexus is likely to lead to significant limb dysfunction with resection, so most surgeons consider this a contraindication to resection. Lower extremity weakness may indicate direct extension of tumor into the spinal cord, or perhaps unstable bony elements of the vertebrae because of tumor destruction. Spinal cord impingement typically causes pain, followed by weakness, and less frequently sensory deficits and bowel or bladder dysfunction.[7,8] Although spinal canal involvement portends a worse prognosis, it is not strictly a contraindication. It is important to query the patient about subtle symptoms, and involve a spine surgeon early on in case impending neurologic damage may ensue. In some instances, these patients may be well palliated by undergoing resection to prevent or limit lower extremity neurologic deficits, even when an R0 resection is not possible.

Neurosurgical or orthopedic spine consultation should be obtained whenever there is suspicion of vertebral involvement.

Spine surgeon consultation

Electromyography in select cases

*Mediastinoscopy, thoracoscopy, or transbronchial needle aspiration to confirm absence of N2 or contralateral N3 disease, may be performed after induction therapy.

FDG, ^{18}F-fluorodeoxyglucose; MRI, magnetic resonance imaging; NSCLC, non–small cell lung carcinoma; PET/CT, positron emission tomography and computed tomography scan.

In some cases, electromyography or nerve conduction studies may be helpful to delineate the extent and reversibility of neurologic dysfunction. Magnetic resonance imaging (MRI) of the chest and spine with contrast usually accurately demonstrates the extent of vertebral body involvement, nerve impingement, vascular invasion, and juxtaposition of the tumor with the thecal sac. Vertebral artery and anterior spinal artery invasion can also be determined with MR angiography, or in some cases, computed tomography (CT) arteriography can be helpful. Brain MRI is highly recommended given the frequency of brain metastases in this population (7% at presentation, up to 25% within 10 months of diagnosis).[9] For the same reason, fused imaging with positron emission tomography (PET) and CT is also critical to evaluate for metastatic disease.

Brachial plexus involvement should be evaluated clinically and by MRI and CT imaging. It is useful to review the sensory and motor findings expected with invasion of the brachial plexus and lower nerve roots to assist in the preoperative assessment; in addition, these potential neurologic changes should be discussed with patients before resection and possible nerve ligation. The C8 and T1 nerve roots make up the lower trunk of the plexus as it crosses the first rib. The T1 dermatome extends across the upper chest onto the anteromedial aspect of the forearm. The C8 dermatome follows the ulnar nerve distribution along the medial aspect of the arm and the fourth and fifth digits. C7 innervates sensation for the index and middle fingers, C6 for the thumb. A C7 nerve motor function abnormality is manifested by weakness of forearm extension (triceps). C8 motor nerve impingement leads to weakness of finger flexors and wasting of interosseous muscles of the hand.[10] T1 weakness leads to inability to abduct the little finger. If the clinical exam is equivocal, MRI of the brachial plexus as well as nerve conduction studies can be helpful.

Most agree that division of T1 is acceptable with minimal hand and arm morbidity, whereas the ligation of C8 will be associated with hand deformity that is excessive. Uniformly, C7 ligation is not acceptable. The rationale is that it makes little sense to perform an aggressive surgical resection to preserve a functionless upper extremity that is a source of severe pain or is completely insensate. Although it sounds extreme, sometimes forequarter amputation may provide better palliation than preservation of a useless limb.[11] Having an experienced neurosurgeon perform plexus neurolysis may allow for resection with nerve preservation in cases of significant brachial plexus displacement or invasion.

Many authors have recognized poor outcomes with N2 or N3 metastases particularly in the setting of T4 primary tumor.[12–14] Thus, invasive mediastinal staging is a necessary step in the preoperative workup, and if mediastinal nodal disease is identified, radical resection should not be offered. The possibility of downstaging these nodes to N0 or N1 with induction chemoradiation with a reasonable long-term result is a subject of debate. N3 status on the basis of ipsilateral supraclavicular nodal metastases (rather than contralateral mediastinal N3) is considered local spread by some authors, analogous to N1 disease with a typical lung primary[15,16] and not a contraindication to resection, whereas others exclude any N2 or N3 disease from surgical consideration.[5] Recent series have reinforced the importance of nodal disease as it pertains to curative resection, as outcomes have been uniformly poor with N1, N2, or N3 diseases.[4]

To summarize, contraindications to resection (Table 35.2) include involvement of the anterior spinal artery,[17,18] brachial plexus compromise at or above C7, poor cardiopulmonary reserve, distant metastases, N3 disease, and persistent N2 disease after preoperative therapy. Relative contraindications are involvement of more than three vertebral bodies, N2 disease prior to induction therapy, and invasion of the C8 nerve root.

| TABLE 35.2 | Contraindications to Resection of Lung Cancer with Vertebral Invasion |
|---|---|

**Absolute**

Inadequate cardiopulmonary reserve

Metastatic disease

Brachial plexus invasion at or above C7 level

Invasion of the anterior spinal artery

N3 disease: contralateral mediastinal or ipsilateral supraclavicular lymph node metastases

Persistent N2 disease after induction therapy

**Relative**

Presence of N2 disease at diagnosis

Functionless upper extremity

Spinal cord invasion

Invasion of C8 nerve root

## THERAPEUTIC APPROACH

For most stage IIIB NSCLC, chemoradiation alone is offered, either concurrently or sequentially, depending on performance status.[19] However, local control rates are only about 17% at 1 year,[20] and distant failure more than 50% at 2 years,[21] prompting interest in trimodality therapy. Several series of locally advanced T4, N0 or N1, NSCLC cases with adjacent structure invasion have been treated aggressively with resection alone, resulting in 5-year survival rates in the 20% to 35% range.[21] Distant failure is still a problem even after complete resection. Clearly, multidisciplinary care is necessary; questions remain about which chemotherapeutic agents are best, optimal dose of radiation, and the order in which chemotherapy, radiation, and surgery are used. Regardless of these questions, the lessons learned from this aggressive treatment for locally advanced lung cancers are that not all T4 designations are created equal, and most structures deemed unresectable in the last iteration of the lung cancer staging system have indeed been successfully resected with reasonable oncologic and functional outcomes. Surgery alone is almost never going to be adequate treatment, and it must be combined with other therapy. These lessons have been learned over the last 4 to 5 decades for superior sulcus tumors with or without vertebral body invasion.

Since 1961, the standard treatment for superior sulcus tumors has been radiation followed by surgery. This is based on the Shaw et al.[22] publication where 30 Gy radiation was given followed by successful resection for a subset of patients who had previously been offered no treatment. The treatment scheme and radiation dose delivered was empiric, and not challenged for many years. Rates of complete resection (around 50%) and overall 5-year survival (average 30%)[22,23] remained suboptimal, prompting the introduction of concurrent chemoradiation prior to surgery. The recently published phase II Intergroup 0160 study[5] of 110 patients resulted in a 76% rate of complete resection, partial or complete pathologic response in 56%, and overall 5-year survival of 44% after induction with cisplatin, etoposide, and 45 Gy radiation to the primary tumor bed, resection, then consolidation chemotherapy. A total of 32 of the 110 patients had T4 disease based on vertebral or subclavian vessel involvement; outcomes for these patients were surprisingly equivalent to T3 patients. Another phase II trial involving 76 patients conducted by the Japan Clinical Oncology Group (9806) using mitomycin, vindesine, and 45 Gy radiation as induction therapy yielded a 68% complete resection rate and 5-year survival of 56%.[15] Many consider induction chemotherapy with 45 Gy external beam radiation followed by surgery to be the new standard of care. Questions remain as to the optimal dose of radiation. Kwong et al.[24] used high-dose radiation in conjunction with induction chemotherapy in 36 patients, 15 of which had either N2 or N3 disease pretreatment or solitary brain metastases. Pathologic complete response occurred in 40.5%. Median survival was 2.6 years, and perioperative complications were similar to lower-dose radiation schemes. These excellent results will need to be repeated in a multicenter setting before becoming accepted practice.

Some institutions favor reserving chemotherapy and radiation for the adjuvant setting.[16] The rationale is to allow for treatment of the anticipated positive microscopic margin, to allow for an uninterrupted course of radiotherapy postoperatively, and to preserve tissue planes without the added adhesions and treatment effect of neoadjuvant radiation. Finally, immediate resection offers perhaps better, more rapid palliation of what is often debilitating pain from chest wall and brachial plexus invasion.[4] The argument for this strategy is that outcomes and patterns of failure are no different for preoperative versus postoperative therapy. In a French series, 67 patients were treated without induction therapy; 53 of 61 patients who survived the operative period had postoperative treatment, most commonly, concurrent chemoradiotherapy. After complete resection, 5-year survival was 44.9% (0% with incomplete resection).[25] It is unlikely that the two main strategies outlined previously will ever be compared head to head in a randomized trial; surgeon and institutional preference will likely drive the therapeutic plan.

## TECHNIQUES OF RESECTION

There are several particular considerations for the operative planning of these complex cases. Beginning with anesthesia monitoring and positioning, standard practice includes use of a double lumen endotracheal tube, preoperative antibiotics, and deep vein thrombosis prophylaxis. A central line is not mandatory but highly recommended for reliable intravenous access, and to monitor central venous pressure during and after surgery. It is best placed in the contralateral neck, as it may be in the way of the dissection that frequently goes up to the neck or requires anterior exposure. Similarly, the arterial line should be placed in the contralateral extremity in case subclavian artery resection is necessary on the surgical side. An esophageal bougie may be helpful for large tumors to help identify the course of the esophagus during the dissection; with a large, invasive tumor, it can be easy to inadvertently enter the esophagus when working close to the vertebral bodies.[26] This has been a source of postoperative complications in some centers and a bougie, in our experience, has helped to avoid this problem. Patients are positioned in the lateral decubitus position; we favor use of a beanbag for stabilization. Cervical tongs are very helpful to enhance access to the upper thoracic spine, and they help with the critical step of attaining perfect horizontal alignment of the spine to allow for proper spinal hardware placement. Evoked potential monitoring of spinal cord function intraoperatively is recommended.

There are two main schools of thought on resectional technique for vertebrectomy. The technique championed by Grunenwald et al.[27] involves an en bloc total vertebrectomy, whereas the MD Anderson Cancer Center (MDACC) approach involves intralesional resection. There are several advantages and disadvantages to each choice, which will be discussed later.

**The MD Anderson Cancer Center Technique**   In most superior sulcus tumors invading the spine, the tumor is centered posteriorly within the thoracic inlet; satisfactory exposure

is achieved through a posterolateral thoracotomy with extension to the upper chest parallel to the spine. A second vertical incision is made directly over the spinous processes when extensive vertebral body involvement is present and posterior stabilization will be required. More recently, posterior stabilization has been accomplished first, then the patient returns to the operating room 2 or 3 days later for the anterior approach and tumor resection. It is also a critical step to carefully plan the intersection of the two incisions so that it is perpendicular (Fig. 35.1). Otherwise, if the angles between the incisions are acute, there is an island of skin that is at high risk of necrosis directly overlying spinal hardware—a set up for disaster. When the tumor extends more anteriorly, medially, or extensively involves the brachial plexus, an anterior L-shaped incision along the sternocleidomastoid and clavicle is added.

The chest is entered one interspace below the tumor. The involved ribs are divided several centimeters anterior to the tumor. For smaller tumors, dissection is greatly facilitated by dividing the lung between the tumor and the hilum with a linear cutting stapler; a completion lobectomy is performed with hilar dissection and individual vessel ligation in the standard fashion after the chest wall has been removed (Fig. 35.2A). In some cases, only a wedge resection is performed when pulmonary function is limited; several series have shown no difference in long-term results with wedge resection compared with lobectomy in this circumstance.[4,28] The portion of the lung attached to the chest wall is removed en bloc with the specimen after complete mobilization of the bony elements (Fig. 35.2B).

If necessary, a laminectomy for the involved vertebral levels is performed. The involved ribs are then disarticulated at the costotransverse and costovertebral ligaments unless the tumor transgresses these joints, in which case en bloc resection may be done with an osteotome through the vertebral body. The anterior spinal ligament and parietal pleura are mobilized off the vertebral bodies toward the lung and the entire specimen, short of the vertebral bodies, are removed. With better

**FIGURE 35.1** Mapping of thoracotomy incision for a posterior approach to a combination lung and vertebral resection. The patient had laminectomy and posterior instrumentation 2 days previously. The patient's head is to the right; drains exit caudal to the stapled incision. Note the perpendicular intersection of the thoracotomy incision with the posterior midline incision.

**B**

**FIGURE 35.2**  **A:** View through a left posterolateral thoracotomy for resection of a left upper lobe tumor invading the T1 and T2 vertebral bodies. Ligated hilar vessels are visible on the left side of the photograph. The lung tumor is still attached to the chest wall (right side of photograph); a linear staple line marks where the lobe was bisected to allow for en bloc chest wall resection after the proximal lobe is removed. **B:** Specimen from resection. Peripheral portion of lung is removed en bloc with chest wall and vertebral bodies.

exposure, the vertebral bodies can now be carefully assessed for extent of involvement. If only the foramen or pedicle is invaded, these bony elements can be removed with the high-speed drill, preserving the vertebral body. When the cancellous bone of the vertebral body is invaded, at least a partial corpectomy is carried out with an intralesional resection technique using a high-speed drill. Once the lateral and posterior elements are removed, the dural sac is well exposed and any intracanal component of tumor can be safely removed. Nerve roots are directly ligated as they exit the dural sac (Fig. 35.3).

Spinal reconstruction techniques have evolved with the experience of over 2000 resections for metastatic lesions to the spine at MDACC. Initially, anterior stabilization was accomplished
**FIGURE 35.3**  Operative view of chest wall and left pleural cavity after resection. The top of the photograph is anterior; the bottom is posterior chest wall. The dural sac with intact nerve root is nicely exposed; in this case, nerve root ligation was not necessary. Posterior hardware is already in place from laminectomy 2 days prior. The vertebral body defect (T1 and T2) is anterior to the dural sac.

with methyl methacrylate injected through a 32 French chest tube strut as described by Errico, Cooper, and Miller,[29,30] with additional anterior plate fixation and posterior instrumentation. More recently, expandable titanium cages have been used that will lock into the adjacent vertebral body end plates (Fig. 35.4A,B), and can facilitate fusion when packed with bone chips. Drilling

adjacent vertebral bodies is avoided. When needed, the posterior elements are stabilized with wires, screws, rods, hooks, and cervical lateral mass plates (Fig. 35.4C). Care should be taken to preserve paraspinous muscles and soft tissues to cover the hardware. In addition, avoidance of a dural tear is optimal but should one occur, efforts should be made to recognize it intraoperatively, as it can be repaired with monofilament suture and buttressed with a tissue flap such as intercostal muscle.

In most cases, chest wall reconstruction is not required as the scapula covers the area of resection. If the tip of the scapula is close to the chest wall edge, there is a risk of scapular entrapment that presents similarly to shoulder dislocation. To avoid this, the chest wall can be reconstructed with taut, 2-mm thick polytetrafluoroethylene, or the tip of the scapula may be resected. Two chest tubes should be placed intrapleurally in the standard fashion. Soft tissue closure is performed in layers, again taking great care to provide adequate coverage for spinal hardware. Most patients are extubated in the operating room, and early ambulation commences as soon as possible postoperatively. Radiographic confirmation of hardware alignment is usually done prior to discharge (Fig. 35.5).

**European Approach**  Vertebral resection for direct extension from Pancoast tumor was first described by Grunenwald et al.[27] in 1996. The technique was initially described as a three-step procedure—first an anterior cervical incision, then a standard thoracotomy to divide the ribs, wedge resection of the lung leaving the tumor-bearing portion attached to the chest wall, followed by a posterior midline incision for the vertebrectomy. Currently, a transmanubrial approach is used followed by a posterior midline incision, with the patient positioned prone with a head holder.

**A**

**B**

**C**
**FIGURE 35.4**  **A:** Titanium cage (Synthes, West Chester, PA) used for anterior spinal stabilization. **B:** Insertion of titanium cage into vertebral body defect. Great care must be taken to properly align the device. **C:** Completed spinal reconstruction. The inflated lung is present at the top of the photograph. The titanium cage is replacing the resected vertebral body, and posterior instrumentation is affixed to transverse processes of the vertebral bodies above and below the area of resection. Note the proximity of the lung to the dural sac, which illustrates how a pulmonary parenchymal air leak might communicate with an opening in the dural sac, leading to postoperative pneumocephalus.

**FIGURE 35.5**  Postoperative radiograph confirming proper hardware position.

A laminectomy is performed one level above and below the tumor; facets and pedicles are removed bilaterally including a portion of contralateral rib, just beyond the costotransverse juncture. The posterior longitudinal ligament is divided, then the vertebral body is rotated into the chest toward the tumor and subsequently removed en bloc with the lung and chest wall.[18,31]

Reconstruction is performed with a clavicular or fibular bone graft for anterior fusion, and posterior fixation with transpedicular screws. For further stability, patients are required to wear a plastic jacket for 6 months until bone engraftment occurs. When only the foramina or costovertebral junction is invaded, a partial vertebrectomy can be performed using an osteotome in an oblique pathway, after contralateral transpedicular screws have been placed to maintain spinal stability.[18,31] This concept of partial vertebrectomy has also been embraced by other groups when less than 30% of the vertebral body is involved.[32,33]

The advantages of the MD Anderson technique are relative ease of exposure through one incision, and decreased morbidity and complexity using intralesional resection rather than en bloc vertebrectomy. The need for a plastic vest in the European series for 6 months is far from ideal, not only for patient comfort, but also the mechanical failure rate is notably higher than when anterior and posterior internal fixation is used. Although the MDACC approach does not strictly follow principles of "no touch" en bloc cancer surgery, local and distant failure rates are quite similar.

## POSTOPERATIVE COMPLICATIONS

Patients undergoing resection of Pancoast tumors with vertebral involvement are subject to all the usual risks seen with any lung resection. It is noteworthy that even with these more complex operations, the most common postoperative event is respiratory in nature[25]—pneumonia, reintubation, or atelectasis requiring bronchoscopy occur in about 20% to 40%[4,25,31] of patients. The usual risk of respiratory complications following any lung resection is compounded by the added chest wall resection, disruption of accessory muscles, and risk of phrenic nerve injury with thoracic inlet dissection. The best way to avoid these problems is to carefully select good-risk patients preoperatively. Neoadjuvant radiation may increase the risk of pulmonary complications especially when pneumonectomy is required. Smoking cessation for at least 2 weeks, and preferably 4 weeks preoperatively is mandatory for active smokers. Aggressive pulmonary toilet and early mobilization are always helpful as well. When a corset is required (European approach) or if a cerebrospinal fluid (CSF) leak occurs mandating bed rest and lumber drainage, the propensity for respiratory complications is increased in this already high-risk population. Other complications, such as atrial fibrillation, stroke, myocardial infection, pulmonary embolism, and prolonged air leak occur at similar frequency to any lung resection. Bleeding risk seems to be slightly higher because of extensive chest wall resection, but most series have not reported significant numbers of reoperations for bleeding. Intraoperative blood loss tends to be much higher than expected for a standard lobectomy, with several authors reporting average blood loss in the range of 2 L or more.[31,32]

There are unique concerns related to this complex operation including hardware infection, neurologic complications, CSF leak, pneumocephalus, and esophageal injury (Table 35.3). Providing adequate, well-vascularized soft tissue coverage for hardware, as outlined previously, will avoid hardware infection in most cases. Prevention of esophageal injury and prolonged air leak, both of which will eventually lead to empyema, are obviously beneficial also. Neurologic complications caused by spinal instability have not occurred in the MD Anderson series[4] where anterior and posterior fixation are used, but were reported in 3 of 36 cases with an additional two long-term mechanical problems with spinal hardware in the French series.[31]

CSF leak usually results from inadequate ligation of nerve roots, or sometimes from dural tear. Intraoperative recognition allows for repair with fine monofilament suture buttressed with an intercostal muscle flap, but when it occurs in the

postoperative period, it can manifest in one of two ways: CSF coming out of the chest drains or wound, or pneumocephalus caused by pulmonary air leak entry into the subarachnoid space (see Fig. 35.4C). When chest tube output is thin and profuse, a few drops of fluid can be placed on filter paper to check for the "double-ring sign"—an inner ring of blood with an outer ring of clear fluid. More definitively, it can be sent for beta-2 transferrin or beta-trace protein to confirm the presence of CSF. There is almost always a CSF collection locally when a leak occurs, and this can be demonstrated by MRI if suspected postoperatively. Lumbar drain placement and bed rest will usually heal the leak. Subarachnoid pleural fistula may be demonstrated by the development of altered mental status or seizure, frequently presumed to be because of brain metastases, but brain imaging will show air within the ventricles. This phenomenon seems to happen several months postoperatively[16,31] for unclear reasons. The mechanism is communication between pulmonary parenchyma and the subarachnoid space. Treatment is reoperation to close the dural leak and patch it with vascularized autogenous tissue. Esophageal injury is briefly mentioned earlier and can often be avoided by using a bougie intraoperatively to facilitate identification of the esophagus in the thoracic inlet and upper chest.

## CONCLUSION

Surgical treatment for Pancoast tumors has been increasingly aggressive over the last few decades, and what was previously considered inoperable can now be successfully resected with good oncologic and functional results. Vertebral body resection and reconstruction with lung resection is a complex procedure, but can be accomplished in experienced centers. When combined with chemotherapy and radiation, T4 superior sulcus tumors have similar outcomes to T3 tumors and long-term survival up to 50% has been documented. Careful pretreatment evaluation with extensive imaging allows for optimal patient selection. Neurosurgical or orthopedic spine specialist collaboration is a must. There are several unique complications, such as hardware infection or failure, CSF leak, or subarachnoid–pleural fistula that require increased vigilance and awareness if they are to be properly managed. Ongoing areas of controversy include the sequence and dose of trimodality care, technique of vertebral resection (intralesional vs. en bloc), and whether or not patients with N2 or N3 disease should be offered curative resection. Overall, successful resection of superior sulcus tumors with vertebral body invasion represents a significant advancement in the treatment of a subset of lung cancer that previously was considered uniformly fatal.

# Surgical Management of Second Primary and Metastatic Lung Cancer

More than half of the approximately 160,000 patients diagnosed with lung cancer annually in the United States have metastatic disease at the time of presentation.[1] In the past, a selected few patients with metastases to other lung segments or the brain have been treated surgically; otherwise, there has not been a defined role for surgery in the treatment of advanced lung cancer. Recently, however, there have been increasing reports of surgical management of adrenal, liver, bone, and pleural metastases from primary lung cancer. Surgical resection is also indicated for a heterogeneous group of patients with multiple primary lung cancers (MPLCs). This chapter presents a guideline for addressing these special considerations in lung cancer.

## MULTIPLE PRIMARY LUNG CANCERS

Patients with a history of current or previously treated lung cancer are at high risk for additional primary lung cancers because of a high prevalence of tobacco exposure. Although Bilroth and von Winiwarter[2] first described MPLCs over 100 years ago, it is Beyreuther who is credited with directing attention to this subgroup of cancer patients with his 1924 report of two primary lung cancers in a tuberculosis patient. A review of the English literature from 1983 to 2002 identified MPLCs occurring in only 2.7% of more than 36,000 patients (Table 36.1). The true incidence of MPLCs has been difficult to estimate because diagnostic criteria have not been agreed upon and the staging system for lung cancer has changed multiple times in the last decade. Despite their rarity, the incidence and reports of such lesions seem to be increasing (Table 36.2). Martini and Melamed[3] described diagnostic criteria for MPLC (Table 36.3).

## EVALUATION AND MANAGEMENT OF SYNCHRONOUS PULMONARY TUMORS

**Synchronous Primary Carcinomas of Lung** Originally defined by Bilroth and von Winiwarter[2] to (a) have different histologic characteristics, (b) originate from different locations, and (c) produce individual metastases, synchronous primary lung cancers are now frequently distinguished by different histologic patterns and locations—the same or different lobes. Controversy remains among investigators about the involvement of mediastinal lymph nodes as a factor in the classification of synchronous primary lung carcinomas. Many would, however, agree with Antakli et al.,[4] who have suggested that tumors of the same histologic subtype only be categorized as synchronous in the absence of mediastinal nodal disease (Tables 36.4 and 36.5).

**Primary Lung Carcinoma with Intrapulmonary Metastasis** These tumors are similar in histology, but differ in anatomic location. Satellite nodules are metastatic lesions that occur within the same lobe as the index tumor. The American Joint Commission on Cancer (AJCC) has long defined satellite nodules as T4 (stage IIIb) disease, and ipsilateral intrapulmonary metastases as M1 disease (stage IV). However, in the absence of nodal involvement, several centers have reported that with lobar resection, patients with satellite nodules have 5-year survival of close to 60% comparable to patients with Ib or IIa disease.[5,6] Meanwhile, Deslauriers et al.[7] reported only a 22% 5-year survival among the 84 patients with satellite nodules. Zell et al.[8] analyzed Surveillance, Epidemiology, and End Results (SEER) data and reported improved survival outcomes among patients with ipsilateral pulmonary metastases compared with other stage IV patients. The recent International Association for the Study of Lung Cancer (IASLC) proposed staging system downgrades satellite nodules to T3 disease and ipsilateral intrapulmonary metastases to T4 disease (see Chapter 30).[9] This change is supported by validation studies carried out using population-based data.[8,10] The role of chemotherapy either in a neoadjuvant or adjuvant setting for these patients has not been carefully studied. It is the bias of the authors of this chapter to treat patients with presumed or questionable T4 satellites with up-front chemotherapy, resection, and adjuvant therapy based on intraoperative findings.

There are little data to support surgical resection of intrapulmonary metastases from lung cancer, although some patients

MPLCs, multiple primary lung cancers.

anecdotally are cured after complete resection. Patients with multifocal bronchioloalveolar carcinoma (BAC) are exceptions to the poor prognosis of multifocal lung cancer. Patients with multifocal BAC who undergo complete resection can achieve 5-year survivals of upward of 60%.[11,12] These patients have a high rate of intrapulmonary recurrence. Epidermal growth factor tyrosine kinase inhibitors (EGFR TKIs) have been a useful adjuvant treatment in such patients, although the optimal time course of treatment has not been well studied. Lung transplantation has been used at selected centers in patients with unresectable multifocal BAC, who have no evidence of nodal or distant metastases with promising long-term results. The largest

reported series (29 patients) reported a 5-year survival of 51%, although there was tumor recurrence in 13 patients (45%).[13]

**One Primary Carcinoma and One Benign Lesion** A significant proportion of the second pulmonary nodules discovered preoperatively by Kunitoh et al.[14] were found to be benign. Pathologic diagnoses included infarction, granuloma, fibrosis, and hamartoma. A thorough metastatic evaluation is indicated in patients with a known lung carcinoma and a second indeterminate parenchymal mass. Positron emission tomography (PET) and fusion computed tomography (CT)/ PET scanning are useful both for staging and to estimate the probability that a lesion is benign or malignant. Once there is no proof of metastatic disease, one could either observe the second lesion or opt to obtain a tissue sample for a histologic diagnosis. In the case of an ipsilateral nodule, the assessment can be performed at the time of thoracotomy. For contralateral

lesions, CT-guided fine-needle aspiration biopsy (FNAB), video-assisted thoracoscopic surgery (VATS) wedge resection, or Wang biopsy as well as mediastinoscopy at the time of surgery may be required.

**Evaluation** Specific questions must be addressed in the evaluation of two distinct lung cancers.

1. Does the lesion(s) represent an extrathoracic primary carcinoma with pulmonary metastases?
2. Are mediastinal lymph nodes involved?
3. In the case of a primary lung cancer, is there evidence of distant metastatic disease?
4. What is the histologic diagnosis of the nodule(s)?

The accuracy of a cytologic diagnosis from an FNAB ranges from 60% to 80%.[15–17] Treatment of two lung nodules should be based on a histologic diagnosis from either a core needle or a wedge biopsy. Disseminated neoplastic disease should be assessed with CT, PET, and brain magnetic resonance imaging (MRI).

Bronchoscopy allows for evaluation of the bronchial lumen, assessing for tumor involvement, communication with the esophagus, and obstruction. McElvaney et al.[18] discovered synchronous endobronchial foci of adenocarcinoma in nearly 20% of surgical patients evaluated with bronchoscopy before surgical resection—only two of which were identified preoperatively. These data support the universal requirement for bronchoscopic examination prior to proceeding with any planned surgical resection.

Mediastinoscopy has been established as an important component in the evaluation of patients with lung cancer. The use of endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS) to perform fine-needle aspiration (FNA) of mediastinal lymph nodes for staging have been increasing. EUS and EBUS offer less invasive staging of the mediastinum, but are operator dependent and result in far less tissue for analysis. Tournoy et al.[19] recently reported similar diagnostic yields for EUS and mediastinoscopy, whereas Wallace et al.[20] reported excellent yields when combining both EUS and EBUS. We cur-

rently employ EUS and EBUS in patients who have previously undergone mediastinoscopy, or who have other contraindications to mediastinoscopy or general anesthesia.

**Treatment** Surgical resection is indicated when there are two primary lung carcinomas without evidence of mediastinal lymph nodes or distant metastases—clinical stage I or II.[21] Those patients with N1 disease (stage II) should be offered surgery and referred for adjuvant chemotherapy. The clinical stage of the tumors should be used to determine which lesion should be pursued initially.[22–26] Other factors to consider before surgical resection of the second tumor are pathologic stage of the first tumor, extent of the second tumor, extent of resection required for the second tumor, and the patient's pulmonary reserve. Also, possible benefit of systemic therapy prior to either initial resection or second resection should be considered.

In such cases where a second cancer is discovered intraoperatively in a different lobe, N2 disease should be ruled out and pulmonary function should be reviewed. In all cases, a mediastinal and hilar lymph node dissection should be performed initially with intraoperative frozen section analysis for accurate pathologic staging. Presence of N1 disease and certainly N2 would preclude pneumonectomy. Regardless of the surgical procedure chosen, the goal should always be complete resection of the tumors, as this has an evident impact on survival. If the patient has adequate respiratory reserve and no evidence of N2 disease, an anatomical resection should be pursued. If pulmonary function is insufficient, wedge resection should be considered. On the other hand, there are proponents of nonsurgical treatment in patients found to have positive hilar or mediastinal lymph nodes intraoperatively, based on a median survival of 11 months compared to 26 months in those with negative lymph nodes.[24,27] Patients who do not undergo surgical resection are referred for definitive chemoradiation. In addition, ablative procedures such as radiofrequency ablation and CyberKnife should be considered.

**Prognosis** Stage for stage comparison, survival after resection of synchronous primary lung cancers is worse than for a solitary bronchogenic neoplasm.[28] These data have led some to believe that synchronous lesions should be classified as stage IV disease.[29] The lower survival rates may be explained by an overall greater probability of recurrent disease given two independent cancers, more aggressive biologic behavior, an inherent increased risk of developing a neoplastic process.[25,27] The fact that the second lesion is usually treated with wedge or segmental resection—procedures associated with increased incidence of locoregional recurrence and lower survival—may also explain these poor survival results.[30] Compared to other treatment methods (i.e., radiation therapy, ablative procedures, chemotherapy), surgery has still been shown to significantly prolong survival.

**Metachronous Tumors** The minimum duration of time, between treatment of a first primary tumor and the appearance second primary tumor, that defines metachronous tumor is considered to be 2 years.[3,23,27,30–35] Multiple series

have cited a median of 48 months or longer between the treatment of the first lung tumor and the presentation of a second,[23,31,32,36] whereas others report shorter time periods, between 24 and 48 months.[27,33,34] Most recently, Aziz et al. reported an average tumor-free interval of $46 \pm 14$ months in patients with metachronous lesions; however, the 3-, 5-, and 10-year survival rates of 39%, 15%, and 2%, respectively, were no different than those in studies with a median interval of 24 months.[37,38] Additionally, there is no consistent evidence relating the tumor-free interval to either the type of surgical resection or histologic cell type of the tumors.

The incidence of metachronous second primary lung cancers is estimated to be 0.5% overall, including 2.5% of the surgical patients and 10% to 32% of long-term survivors. The risk of developing a metachronous primary lung cancer after curative resection of an initial early stage NSCLC is 0.65% to 5% annually (Table 36.6).[26,27,35,39–40] Pairolero et al.[29] reviewed 346 surgically treated stage I patients from the Mayo Clinic and discovered a metachronous second lung primary in 10% of their NSCLC patients. A more aggressive approach to surveillance and the increasing sensitivity of surveillance modalities (i.e., CT, PET, PET/CT) may contribute to what appears to be an increased incidence of these tumors. As far as location, there appears to be a prevalence for metachronous lesions to develop on the same side as the initial primary lung cancer. Feld et al.[41] reported the metachronous second primary lung cancers in 390 stage I and II NSCLC patients to occur twice as often on the ipsilateral side compared to the contralateral side; 26% and 13%, respectively.

**Evaluation** The majority of patients (80%) are asymptomatic, with lesions revealed on surveillance chest roengenograph.[8,23,25,26,31] This statistic supports the need for close follow-up and surveillance of all patients with lung cancer. Smoking cessation should be encouraged, as there is certainly an increased risk of developing a second primary lung cancer in patients who continue to smoke after treatment of the index tumor.[14] Evaluation of the second tumor should mimic the initial workup and should certainly include close assessment for locoregional and distant metastatic disease.

**Treatment** Most of these lesions—approximately 75%—are stage I, and it is estimated that 65% are amenable to surgical resection.[42] Complete resection is indicated to treat these lesions, of which two thirds of the patients will require extended surgical resection. The surgical decision must be based on the site of neoplasm, previous surgical procedures, and the extent of disease.

**Residual/Contralateral Lung** The gold standard for an early stage NSCLC is lobectomy, based on Lung Cancer Study Group (LCSG) data and on the Memorial Sloan Kettering data, demonstrating a significantly higher rate of recurrence and decreased 5-year survival with limited resection.[43] Despite this, there were very few patients with cancers smaller than 2 cm in the LCSG trial, and clinical trials comparing wedge resection to lobectomy in patients with very small tumors are currently underway. Limited surgical resection should only be considered in patients with inadequate pulmonary reserve or in patients who are high operative risk, in which case either a segmentectomy or wedge resection with lymph node sampling is appropriate. In those patients who experience a metachronous pulmonary cancer after limited resection, a completion lobectomy should be considered. When a metachronous tumor is ipsilateral, and in a different lobe than the index tumor, a completion pneumonectomy may be considered but usually lobectomy of the index tumor and generous wedge resection of the synchronous lesion is also reasonable.[44,45] Emerging experience with high energy, focal radiotherapy (CyberKnife radiation, etc.) may provide comparable local control to surgery in small (less than 3 cm) lesions in patients with limited pulmonary reserve or postpneumonectomy.

**Endobronchial Lesions** Recurrences can be limited to the mucosa/submucosa of the bronchial stump, sparing the peribronchial lymphatics. This small subset of patients experiences a better prognosis than those with lymphatic involvement. Although these endobronchial recurrences can be addressed with local treatment (i.e., photodynamic therapy, brachytherapy), surgery does play a role in selected patients. Either a sleeve lobectomy or completion pneumonectomy should be considered worthwhile given the potentially curative intent. Compared to an initial pneumonectomy, there is a higher morbidity and mortality rate (MR = 0% to 15%). The postoperative mortality rate and 5-year survival (25%) are the same whether the completion pneumonectomy is performed for a local recurrence or second primary lung cancer. Increasing evidence supports the use of sleeve resections wherever possible over pneumonectomy. Long-term survival and disease-free recurrence are comparable, and sleeve resection preserves parenchyma and lung function.

**Nodal Recurrence**    Metastatic disease involving the lymph nodes can occur in the mediastinal, hilar, or intraparenchymal nodes. Rarely is metastatic disease limited to the intraparenchymal or hilar nodes; however, these patients are potentially curable with surgery. In the absence of mediastinal lymph node involvement, one should consider a surgical resection using a similar treatment approach as that used for the index tumor. A positive mediastinoscopy revealing mediastinal (N2) lymph node involvement should preclude thoracotomy in most cases. Select patients may benefit from induction chemotherapy and subsequent restaging. Those with sterilization of their N2 disease (verified by repeat mediastinoscopy, etc.) can do well, long term, with resection (see Chapter 55).

**Pleura/Chest Wall**    Involvement of the pleura or chest wall with malignancy is usually indicative of a diffuse process involving the entire pleural space. There are, however, some rare true solitary recurrences involving either the pleura or chest wall. These lesions should be approached with complete surgical resection (i.e., chest wall resection), with the curative intent. The majority of these cases are better treated with local external beam radiation therapy.

**Prognosis**    The best chance for cure and long-term survival for all of these patients is surgical resection. Undoubtedly, the morbidity and mortality rates are higher with re-resection; up to 39%[35] and 4.5% to 9.3%,[27,31,34] respectively. Overall, the 5-year survival in patients treated surgically is 20% to 30%, and 20% at 10 years.[10,25,46,47] Multiple studies cite improved 5-year survival (36%) with complete resection of the metachronous lesion. Complete surgical resection increases survival to 36%.[10,25,27,37,48,49]

## BRAIN METASTASIS

The brain is the most common site of metastasis for bronchogenic carcinoma,[50] and is found in approximately 25% of patients with stage IV NSCLC[51] (see also Chapter 63). The discovery of brain metastases is usually a manifestation of widely disseminated disease. Occasionally, however, the brain is the only site of distant disease as Arbit and Wronski[52] reported to be the case in 18.9% of their patients. Unfortunately, it is estimated that 40% of patients with NSCLC will develop brain metastases during the course of their disease.[53–57]

A correlation has been found between the treatment of brain metastases and median survival. Patients not receiving directed therapy can expect a less than 3-month median survival.[58,59] In addition to symptomatic relief gained with treatment, patients experience prolonged survival of up to 6 months when treated with whole-brain radiotherapy (WBRT).[51,60,61] Arbit and Wronski[52] demonstrated improved median survival to 9.4 months by using stereotactic radiosurgery to treat brain metastases. The availability of steroids and modern advances in neurologic imaging (i.e., MRI) with gadolinium, neurosurgical

technique, and postoperative care has led to an increase in surgery in the treatment of these patients.[62–64] In addition to prolonged survival, the associated operative mortality is reported to be approximately 5% on average.[51]

**Evaluation**    Upon discovering a brain lesion in a patient with a history of NSCLC, efforts should be directed at determining if it represents metastasis. Patients considered to be candidates for surgical resection should undergo extensive metastatic evaluation to assess for other sites of distant disease, as only 3% of patients with NSCLC develop an isolated and single operable brain metastasis. The use of highly sensitive brain MRI with contrast has significantly increased the rate at which occult, small asymptomatic brain lesions are identified. Nearly 10% to 15% of patients with advanced stage cancer (IIIb or IV) harbor occult brain metastasis. As imaging modalities continue to improve, a greater focus on the treatment of prevalent brain metastases will be required.

Symptomatic brain lesions are common, nearly half of all patients with brain metastasis experience, at the minimum, headaches.[65] Neurologic signs such as focal weakness or hemiparesis are almost as common, occurring in roughly 40% of patients. Other symptoms, such as dysphasia, seizures, and visual changes occur less frequently.[54,55,65] Interestingly, Pladdet et al.[65] found patients with metastatic adenocarcinoma tended, on the whole, to be less symptomatic than other non–small cell histologic types. Thus, we recommend that these patients be considered for further evaluation (i.e., brain MRI) if one has sufficient suspicion even in the absence of symptoms. Most patients with bulky hilar tumors (greater than T3) or suspicious or proven N2 (stage IIIa) disease should undergo brain MRI. CT scanning is much less sensitive.

CT and MRI scans are the primary radiologic studies used to evaluate brain lesions. CT scanning is occasionally better for smaller lesions as well as assessing the effect of steroid therapy, whereas MRI is better to evaluate the brainstem.[65,66] Considering that the majority of patients with brain metastases have up to three lesions at presentation, less than 50% can be offered surgical resection for local control. Unfortunately, only 30% to 50% of these patients are surgical candidates.[50,52,56,65,67–71] The presence of any of the criteria listed in Table 36.7 render a patient inoperable for brain metastasis.

---

**TABLE 36.7**   **Criteria for Inoperable Brain Metastases**

Surgically inaccessible location

Detection of other distant sites of metastatic non–small cell lung cancer

Poor medical condition

Anticipated life expectancy is less than 3 months

From Patchell RA, Cirrineione C, Thales HT, et al. Single brain metastases: surgery plus radiation or radiation alone. *Neurology* 1988;36:447–453.

A thorough search for other sites of recurrent NSCLC should be conducted prior to deciding if a patient is a candidate for curative treatment. Given the short survival of patients with brain metastases, aggressive treatment with surgical resection or radiosurgery should be considered as a palliative attempt to increase survival. In those patients with a solitary focus of metastasis, however, these approaches may offer potential chance of cure.

**Treatment** Treatment of brain metastases involves chemotherapy, external beam radiation (EBRT), brachytherapy, surgery, stereotactic radiosurgery, or a combination thereof. Selection of appropriate treatment modality is based on the patient's symptoms, medical condition, extent of cerebral disease, and the presence of extracranial disease. Unfortunately, there are no randomized trials comparing surgical resection and radiosurgery. A comparison of palliative treatment approaches, however, has yielded similar survival, disease control, morbidity, and mortality rates between the two modalities.[50,72] Chemotherapy should be considered as an adjunct to surgery or radiotherapy in the management of brain metastases after they have been controlled. Surgical resection and radiosurgery are considered to be comparable at this time, and the decision of which modality to use is individualized (Table 36.8), based on the characteristics of the metastatic bronchogenic lesions.

**Prognosis** The data reported by Detterbeck et al.[42] suggest better outcome for patients who are younger, of female gender, have metachronous lesions or supratentorial lesions, and tumors under 3 cm in diameter. These relative considerations, however, should not exclude other patients from complete resection. Regardless of whether the goal is cure or palliation, patients universally report an improvement in their symptoms with treatment,[69,73,74] and surgery combined with WBRT has been demonstrated to result in a survival benefit over WBRT alone. In fact, Magilligan Jr. et al.[70] experienced an average 2.3-year survival in their patients with a solitary brain metastasis treated with surgical

resection. Average 5-year survival in completely resected patients has been reported to be approximately 20%,[50,70] with patients experiencing a only 2% operative mortality. Such survival data combined with low operative mortality support a more aggressive approach to such patients.

## ADRENAL METASTASIS

Although enlarged adrenal glands have been demonstrated in an appreciable proportion (4.1% to 15%)[2,75–77] of patients with operable bronchogenic carcinoma, only half of these lesions are proven to be metastatic lung cancer.[2,75] The majority of patients with adrenal metastases are asymptomatic, because more than 90% of the gland must be replaced before dysfunction is clinically evident. The solitary adrenal metastasis is extremely rare, occurring in 1.6% to 3.5% of patients.[78]

**Evaluation** CT is the primary modality used to evaluate the adrenal glands, and it is common practice to extend chest imaging to the level of the adrenals in patients with lung cancer. The rate of "incidentalomas" is 21%, with two thirds being benign adenomas. The sensitivity of CT scan is reported to be only 40% for adrenal metastasis[79]; however, Silverman et al.[28] cited a 96% accuracy when CT scanning is combined with FNAB. Percutaneous fine-needle biopsies may be nondiagnostic, and we consider a history of recent lung cancer and corroborating PET scan as sufficient for diagnosis of metastasis. We do not recommend routine needle biopsy of suspected adrenal metastases, unless biopsy findings will alter the treatment plan. If fine-needle biopsy is to be performed, the diagnosis of pheochromocytoma should be excluded first by measuring urine metanephrines.

According to Shea and Lillington,[80] MRI appears to be comparable to CT by detecting adrenal abnormalities in 10% to 20% of patients with lung cancer, with one third of the abnormalities representing metastatic lung cancer. Schwartz et al.[81] actually found the powerful technique of chemical shift MRI to be valuable in evaluating adrenal masses in patients with lung cancer. Its ability to detect fat within an adrenal mass with better specificity than CT scan yields a 96% sensitivity and 100% specificity for adenomas obviates the need for percutaneous biopsy in over one half of the patients.

PET or PET/CT has become a routine part of lung cancer staging. The sensitivity and specificity for adrenal metastasis were 100% and 80%, respectively, in 33 patients with bronchogenic carcinomas and adrenal masses.[82]

**Treatment** Neither laterality, histologic type, nor timing of the adrenal mass has been determined as prognostic factors in patients with lung cancer. Only nodal disease and the resectability of the primary lung tumor are important.[83–85] The literature suggests potential long-term survival benefit after adrenalectomy for metastatic NSCLC, with small series and isolated case reports. The treatment of isolated

From Patchell RA, Cirrinicione C, Thaler HT, et al. Single brain metastases: surgery plus radiation or radiation alone. *Neurology* 1986;36:447–453.

adrenal metastasis is surgical resection, preferably with a laparoscopic approach. Expedient resection of isolated adrenal mass as a laparoscopic approach may not be possible because of large tumor size or regional invasion of tumor. Most surgeons would initially address the lung tumor; however, there have been reports of combined resection with improved survival.[83,85]

**Prognosis**    A recent systematic review by Tanvetyanon et al.[86] showed a 5-year survival of 25% for patients with surgically resected isolated adrenal metastases. Metachronous metastases have a somewhat better median survival compared with synchronous metastases that are surgically resected, but long-term survival is similar among the two groups. Long-term survival is rare without surgical resection.

## OTHER METASTASIS

Surgery has sporadically been suggested to have a role in the management of metastatic bronchogenic carcinoma to other sites,[2,83,87] but it is mostly performed at the adrenal gland. Excluding the brain and adrenal gland, surgery should be considered for palliation in the management of metastatic NSCLC. Most skeletal metastatic lesions involve the axial skeleton, and only 5% of patients have an isolated bony lesion.[88] These patients are treated with palliative radiation therapy with the goal of restoring function.

Small bowel metastases have been described as an epiphenomenon of NSCLC, consisting of yet unidentified biologic characteristics that portend a higher metastatic potential of the bronchogenic carcinoma. Stenbygaard and Sørenson[89] reported a 4.6% incidence of small bowel involvement in 218 autopsy cases, with concurrent metastatic lesions in additional sites in all patients with small bowel metastases. Further investigation of small bowel involvement may lead to suggestions for neoadjuvant or adjunctive chemotherapy that may have an impact on long-term survival of patients with NSCLC.

Unfortunately, surgical extirpation has been reported in only a small group of advanced-stage patients, but has not been found to have a significant impact on cure or survival. Hasse[87] investigated the benefit of pleurectomy in five patients, and noted only one patient to be disease free postoperatively. Certainly, the presence of pleural metastases or malignant pleural effusion suggests surgery for palliation only.[90]

# Percutaneous Therapeutic Technologies for Medically Inoperable Lung Cancer

Lung cancer is the number one cause of cancer death in the United States, accounting annually for approximately 160,000 deaths per year.[1] If diagnosed at an early stage, surgical resection of non–small cell lung cancer (NSCLC) offers the best opportunity for local control and survival. However, it is estimated that more than 15% of all patients and 30% of those aged 75 years or older diagnosed with stage I or II NSCLC will be considered medically inoperable.[2] The majority of these patients are not surgical candidates because of their poor cardiopulmonary function.

For many years since the first pulmonary resections described by Churchill et al.[3] in the early 20th century, pneumonectomy and, subsequently, lobectomy were considered the standard operations for lung cancer. Sublobar resection for stage I NSCLC then emerged as an attractive option, but was subsequently demonstrated to be associated with a threefold increase in local recurrence in the randomized trial conducted by the Lung Cancer Study Group[4] during the late 1980s and early 1990s (see Chapters 32 and 33).

Since the publication of that study, most surgeons consider sublobar resections (such as a wedge or segmentectomy) a compromise operation that should be reserved for patients who are felt to be at increased risk for lobectomy, but can still tolerate a smaller pulmonary resection.[5,6] With the increasing identification of smaller cancers, particularly with implementation of computed tomography (CT) screening programs, this approach is being challenged, particularly for small stage I cancers. Further discussion of sublobar resection for small-diameter cancers is found in Chapters 32 and 33.

One approach that has been described to minimize local recurrence when sublobar resection is performed is the use of adjuvant intraoperative brachytherapy.[7] Initial results have been encouraging, with a multicenter trial of this technique currently underway. For patients that are considered too high risk for any resection, the standard therapy has been external beam radiation. An alternative to radiotherapy (XRT) is percutaneous image-guided tumor ablation, which has been used for various solid tumors, including liver, kidney, breast, bone, adrenal, and is now proving to be an important tool in the treatment of primary and secondary lung neoplasms. Radiofrequency ablation (RFA) is the current ablative method of choice, although other techniques including microwave ablation (MWA) and cryoablation are also available. In this chapter, we review these alternative therapies that can be used for the high-risk patient with NSCLC.

## SUBLOBAR RESECTION AND BRACHYTHERAPY

Higher local recurrence remains the primary problem of sublobar resection for NSCLC. In an effort to improve local control, postoperative external beam XRT following sublobar resection can be used. Miller and Hatcher[8] used this approach on a small group of patients who were treated with sublobar resection followed by "postage stamp" external beam radiation. The authors reported a significant decrease in local recurrence compared with an earlier group of patients they had managed with sublobar resection alone.

Unfortunately, this approach is not easy to apply to most of the high-risk patients with NSCLC where sublobar resection is selected. Many of these elderly patients are unwilling to travel for several radiation treatments. Additionally, radiation treatment planning is challenging, because it can be difficult to target small areas around the staple line, particularly if this is in a region of lung that moves with respiration. Radiation pneumonitis is also a potentially life-threatening problem, particularly for patients with impaired pulmonary function, who are the typical candidates referred for these compromise therapies.

An alternative option is the intraoperative placement of $^{125}$Iodine ($^{125}$I) brachytherapy seeds along the staple line after sublobar resection.[7,9] This brachytherapy technique utilizes a commercially available vicryl suture that contains 10 $^{125}$I pellets incorporated at 1-cm intervals along the length of the suture (Oncura, Arlington Heights, IL). In the first report describing this technique, these vicryl sutures were placed on a

vicryl mesh. Usually 40 to 60 $^{125}$I pellets with four to five lines of suture material are used with each brachytherapy implant. The total delivered radiation dose to the local tissues (staple line) is usually around 10,000 cGY at a 1-cm distance from the staple line. In essence, this technique effectively extended the margin of resection by another centimeter. The advantage of using intraoperative brachytherapy compared with external beam radiation therapy is that this is a one-time treatment, with 100% patient compliance. There is no burden placed on the patient to return for several radiation therapies after recovering from their operation. Additionally, the radiation is delivered directly at the staple line with minimal injury to surrounding lung parenchyma.

An alternative technique to that described previously is to place the $^{125}$I sutures directly adjacent to the staple line without the use of mesh. This technique of "paired" $^{125}$I suture lines was described by Lee et al.[10] The authors reported the use of brachytherapy "paired-suture line" technique in 33 high-risk patients, primarily after wedge resection. The local recurrence rate was 6.1%, which was similar to the 6.4% reported after lobectomy in the Lung Cancer Study Group study.

A larger study from Pittsburgh utilizing the mesh technique compared the results of sublobar resection with adjuvant $^{125}$I brachytherapy in 101 patients with a historical control group of 102 patients who underwent sublobar resection alone; both groups had poor cardiopulmonary function.[9] A significant reduction in local recurrence was noticed with the use of brachytherapy (18% vs. 2%). There was no evidence of radiation fibrosis or implant migration among patients receiving $^{125}$I brachytherapy (Fig. 37.1). Another multicenter study of stage

**FIGURE 37.1**    Chest radiograph demonstrating the $^{125}$Iodine implant following sublobar resection.

IA patients undergoing lobar and sublobar resection was also reported.[11] Included in the study cohort were 124 patients who underwent sublobar resection. Brachytherapy was used in 60 of 124 patients. A decrease in local recurrence from 17.2% to 3.3% was demonstrated in the patients treated with adjuvant brachytherapy. More recently, Birdas et al.[12] analyzed the local recurrence, disease-free survival, and overall survival for patients with stage IB cancer who underwent lobectomy (n = 126) versus sublobar resection with brachytherapy (n = 41). Local recurrence was similar between the groups (3% to 5%), with no statistical difference in survival or disease-free interval.

One concern with the technique of brachytherapy is the radiation risk posed to the staff caring for the patient, as well as to the patient's family. Smith et al.[13] have addressed this risk in a prospective study of 22 patients who underwent $^{125}$I vicryl mesh implantations. Diodes to measure radiation exposure were placed on the back of each hand of the primary radiation oncologist and primary surgeon during the creation and implantation of the mesh. A control reading was obtained by placing diodes on the posterior shoulder of the patient. The authors concluded that there is very little radiation exposure: 1 and 2 mrem/h for the radiation oncologist and surgeon, respectively. Median dose to the control diode on the patient was 5.4 mrem/h. Although the ALARA (as low as reasonably achievable) principle should still be followed, this is a safe method of lung cancer treatment for healthcare professionals. As a precaution beyond state and national radiation guidelines, general recommendations postoperatively for the patients include avoiding close contact with small children or pregnant women for the first 3 months following surgery.

The results of these single-center studies of sublobar resection and brachytherapy have been encouraging. A phase III study of this technique in stage IA NSCLC patients who are at high risk for lobectomy is currently underway by the American College of Surgeons Oncology Group (Z4032). This study will better define the role of adjuvant brachytherapy when sublobar resection is selected for NSCLC.

## PERCUTANEOUS IMAGE-GUIDED ABLATION FOR NSCLC

**Mechanism**    Percutaneous image-guided ablation is performed using various thermal energy sources, including radiofrequency (RF), microwave (MW), high-intensity focused ultrasound, laser, and cryoablation to kill tumor cells. These techniques are being applied with increasing frequency for several cancers. The most commonly used ablative modality for NSCLC has been RFA, although some centers are using MWA and cryoablation.

Heat-based ablative methods are effective means of depositing energy into a discrete focus via percutaneously placed electrodes. The volume of heat ablation is dependent on the temperature distribution within the tissue, which often has heterogeneous composition and perfusion. The heat distribution in a target lesion was described by Pennes' "bioheat"

equation[14] in 1948. This equation can be simplified to a first approximation as "necrosis = energy deposited × local tissue interactions − heat loss."[15]

Cellular homeostasis can be achieved with mild temperature elevation of approximately 40°C. Hyperthermic states (42°C to 45°C) cause cellular susceptibility to chemotherapy and radiation therapy.[16,17] Cellular death does not occur at these elevated temperatures, however, and continued cellular proliferation has been observed even after prolonged exposure to these temperatures. Long-term exposure to temperatures above 46°C can cause irreversible cellular damage. Increasing the temperature by a few degrees to 50°C to 52°C markedly shortens the time necessary to induce cytotoxicity (down to 4 to 6 minutes).

Between 60°C and 100°C, there is near instantaneous induction of protein coagulation that results in irreversible damage to critical cytosolic and mitochondrial proteins and nucleic acid–histone complexes. Cells experiencing this degree of thermal damage immediately die and undergo coagulative necrosis over the course of several days. *Coagulative necrosis* denotes irreversible thermal damage and cellular death regardless of the ultimate microscopic findings, which may not meet histologic criteria for coagulation necrosis. Temperatures greater than 105°C to 115°C result in tissue boiling, vaporization, and carbonization.[18] These processes limit optimal ablation as a result of the insulating effects of the produced gas, which decreases the amount of energy deposited, and reduces thermal conduction into the lesion. The goal of ablative therapies is to achieve stable temperatures ranging between 60°C and 100°C throughout the entire volume of the lesion.

## Technique

**Radiofrequency Ablation**    RFA is currently the most robust technique for the treatment of solid malignancies. RFA has become the ablative method of choice because of its relatively low cost, its capability of creating large regions of coagulative necrosis in a controlled fashion, and its relatively low toxicity. RFA applies to all electromagnetic energy sources with frequencies less than 30 MHz, although most clinically available devices function in the 375- to 500-kHz range. The technique for thermal ablation utilizing RFA was first described in animal lung tumor models in 1995,[19] and reported in human lungs in 2000.[20]

Percutaneous RFA deposits energy into the local tissue environment by converting RF waves into heat via ionic vibrations, elevating cellular temperatures, and causing necrosis. RF electrodes are available in various lengths and have an insulated shaft and an uninsulated conductive "active tip" that emits the RF current (Fig. 37.2). When possible, the electrode is positioned along the long axis of the lesion, and advanced into deepest margin of the lesion for the first treatment. The more proximal margins of the tumor can then be treated by retracting the electrode and administering an additional treatment. Larger tumors can be treated by repositioning the electrode into a new portion of the tumor 1.5 to 2 cm away from the initial longitudinal axis of the previous treatment.

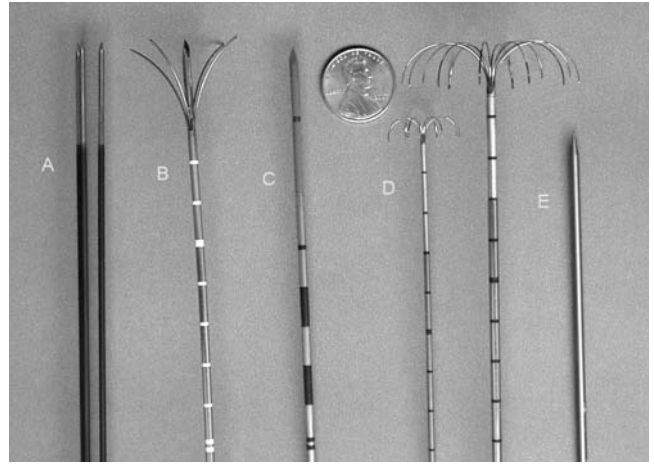

**FIGURE 37.2**    Commercially available radiofrequency, microwave, and cryoablation probes. (*A*) Valleylab Cool-tip Cluster RF electrode. (*B*) RITA Talon infusion RF electrode. (*C*) Valleylab Vivawave MW antenna. (*D*) Boston Scientific small and large Levine RF electrode. (*E*) Endocare PERC-24 cryoapplicator.

The RF electrode is coupled to the RF generator and grounded by means of a grounding pad applied to the opposite side of the chest wall or the thigh. The generator produces a voltage between the two electrodes, establishing lines of electrical field that oscillate with the alternating current. This oscillating electrical field causes ionic vibrations in proportion to the field intensity. Tissue heating occurs by frictional or resistive energy loss caused by ionic motion from the current.[21] Tissue heating more than temperatures of 60°C for varying amounts of time leads to coagulation necrosis and, ultimately, cell death.[22]

The volume of ablation is based on the energy balance between heat conduction of the local RF energy and the heat convection from the circulating blood and extracellular fluid. In the lung, RF energy is efficiently deposited because the surrounding air acts as an insulator (concentrating the energy within the lesion), and the high pulmonary vascular flow acts as a "heat sink" that dissipates heat from normal parenchyma. Although this will have a protective effect on the surrounding normal parenchyma and pulmonary vasculature, this peripheral heat sink will also limit the therapeutic ablation margins surrounding the lesion, which is important to prevent local recurrence.

Currently in the United States, there are three commercially available RFA systems. Two of the systems (Radiotherapeutics, Boston Scientific, Watertown, MA and RITA Medical Systems Inc., Mountain View, CA) utilize a deployable array RF electrode that consists of 4 to 16 small wires (tines) deployed through a 14- to 17-gauge needle. Because the tines curve backward toward the handle, the Boston Scientific device (Leveen electrode) is initially deployed at the deep aspect of the tumor. In contrast, the RITA electrode tines course forward and lateral so the probe is deployed on the near surface of the tumor. The Leveen electrode measures only impedance, and

treatment time depends on repeated rises in impedance during active heating to achieve adequate thermocoagulation. With the RITA system electrodes, temperature readings are obtained throughout the ablation cycle through multiple peripheral thermocouples. The third RF system (Radionics CC-1, Valleylab, Boulder, CO) utilizes a single or triple "cluster" (three single electrodes spaced 5 mm apart) perfused electrode; the tip is positioned at the deepest aspect of the tumor. The single or cluster RF electrode contains a thermocouple embedded in its tip, used to measure intratumoral temperature. A switching controller can be used with the Valleylab system, allowing for the placement of up to three separate single electrodes spaced 2 to 2.5 cm apart, increasing the duty cycle of the generator and allowing for the creation of a greater volume of tissue thermocoagulation compared with three separate ablations with a single electrode.

The effective local control and safety profile of percutaneous RFA has been firmly established in the treatment of numerous solid malignancies, including those in liver, bone, lung, breast, kidney, and adrenals. As of this writing, there have been no head-to-head comparisons of safety and efficacy between these devices in the lung.

**Microwave Ablation**  Like RFA, MWA utilizes electromagnetic waves to produce tissue heating effects. Unlike RFA, however, the microwave energy spectrum lies in a much higher frequency range, extending from 300 MHz to 300 GHz; microwave probes available for clinical use generally operate in the 900- to 2450-MHz range.[23] Microwave tissue heating occurs as a result of the induction of kinetic energy in surrounding water molecules. Because of their electron configuration, water molecules are highly polar and function as small electrical dipoles with the negative charges preferentially localized around the oxygen nucleus. The rapidly alternating electric field of the microwave probe causes water molecules to rapidly spin in an attempt to align with electromagnetic charges of opposite polarity. These spinning water molecules interact with neighboring tissues, transferring a portion of their kinetic energy. Because temperature is merely a proxy measurement of molecular kinetic energy, this energy transfer results in local tissue hyperthermia. Currently, in the United States, there is one commercially available microwave system (VivawWave, Valleylab, Boulder, CO) that utilizes a 915-MHz generator and straight antennae with active tips of 3.7 cm (Fig. 37.2). Cooling of the antennae shaft with infused room temperature saline reduces conductive heating of the nonactive portion of the applicator, thus preventing damage to the skin and tissues proximal to the active tip.

**Cryoablation**  Cryoablation, with the local application of liquid nitrogen directly or within sealed metal cryoprobes, has been used to treat tumors in the operating room setting for more than 3 decades. With the development of the argon-based cryoablation systems, which are now widely available, cryotherapy applicator diameters have decreased significantly, making the percutaneous utilization of this technique to other sites of disease more feasible than ever before.[24]

Cryoablation involves the insertion of one or more hollow needles (cryoprobes) directly into a tumor, under image guidance. The probes are filled with pressurized argon gas and cooled to temperatures as low as −140°C via the Joule-Thomson effect (in which the expansion of compressed gas through a small gap causes a temperature drop). The extreme cold at the tip of the probe creates an expanding ice ball that freezes the surrounding tissue as it progresses. At temperatures of below −40°C, cryogenic destruction of living tissue occurs via several mechanisms, including protein denaturation, osmotic shifts in intracellular and extracellular water, membrane destabilization, cell rupture, and tissue ischemia. Currently, there are two commercially available percutaneous argon-based cryoablation devices available (CryoHit, Galil Medical, Plymouth Meeting, PA and Cryocare, Endocare Inc., Irvine, CA; Fig. 37.2). These systems allow the placement of between 1 and 15 individual 1.5- to 2.4-mm diameter cryoprobes. Typically, a freeze-thaw-freeze cycle in a single probe position is used to achieve local tumor necrosis. Ice ball visualization under CT or MR imaging allows for direct comparison of kill zone with respect to tumor margins, and allows for accounting of a cytotoxic ice margin of 3 to 5 mm within the most peripheral aspect of the ice ball.

## Clinical Results of Thermal Ablative Therapies

The current standard therapy for patients considered high risk for surgical resection is external beam XRT. A previous study[25] of 71 node-negative patients who received at least 60 Gy showed 3- and 5-year survival rates of 19% and 12%, respectively. In another report of 60 patients treated with XRT for stage I/II cancers, local progression occurred in 53% of patients, with a median progression-free survival of 18.5 months and overall median survival of 20 months.[26] A metaanalysis[27] evaluating the efficacy of radical XRT alone for stage I/II medically inoperable NSCLC patients found an overall 5-year survival rate of 0% to 42%, with local failure rates ranging from 6% to 70%. These studies demonstrate marginal efficacy of XRT in eradicating pulmonary tumors and argue for the development of minimally invasive therapies such as RFA to treat these high-risk NSCLC patients.

**Radiofrequency Ablation**  RFA has been used in the treatment of lung tumors for several years. In 2000, Dupuy et al.[28] published the first report of the use of RFA for the treatment of lung malignancies. As previously mentioned, many factors affect the efficacy of complete tumor ablation, including tumor histology, size, and location. Studies have demonstrated that complete tumor ablation is more likely in lesions less than 3 to 5 cm. The majority of these studies are retrospective reviews of institutional experience.

In a series of 27 patients with NSCLC and 4 patients with lung metastases by Lee et al.,[29] complete tumor necrosis (as confirmed by a mean follow-up imaging of 12.5 months) was demonstrated in all 6 patients with lesions less than 3 cm, but only 23% complete ablation (in 6 of 26 patients) in lesions greater than 3 cm. There was at least 50% tumor necrosis

among the 20 lesions (62%) with incomplete necrosis. They also noted at least a 5-mm well-demarcated nonenhancing zone of ground-glass opacity surrounding the ablated lesion in 8 of the 12 cases of complete necrosis. None of these patients demonstrated any local tumor recurrence on follow-up imaging (mean 22.2 months).

Akeboshi et al.[30] similarly demonstrated higher rates of complete tumor necrosis in a series of 54 ablated lung neoplasms. There was a 69% rate of complete tumor necrosis in 36 lesions less than 3 cm, and 39% complete necrosis in 18 tumors larger than 3 cm; tumor type did not influence the rate of necrosis. Yasui et al.[31] achieved a 91% rate of complete tumor necrosis among 99 neoplasms with a mean diameter of 1.9 cm (based on stable CT size and follow-up biopsy of one third of the lesions). All of the studies mentioned used the Valleylab RFA system, and most used a single electrode rather than a cluster probe. The expandable RFA electrodes such as the Boston Scientific or RITA probes theoretically allow a larger diameter of ablation.

In another study,[32] using the Boston Scientific system, 33 tumors were ablated in 18 patients. Results were superior in patients with tumors 5 cm or less. Response (as defined by a composite score comprising of tumor mass, tumor quality, and, when indicated, [positron emission tomography] PET) was seen in 66% of the patients with tumors 5 cm or less compared with only 33% in those patients with tumors >5 cm. Additionally, 33% of the patients with small tumors were not alive at follow-up, compared with 66% in those patients with larger tumors. This experience demonstrates that that recurrence rates are directly related to completeness of tumor necrosis, which not surprisingly is dependent on tumor diameter.

Another series of 18 NSCLC patients with RFA has also been previously reported.[33] The median tumor diameter was 2.8 cm. Nine patients had stage I cancers. Fifteen (83.3%) of the patients were alive at a median follow-up of 14 months. For the stage I cancers, the mean progression–free interval in this study was 17.6 months. The median progression–free interval was not reached, with only three (33%) of these patients demonstrating local progression. More recently, these results have been updated in a group of 19 stage I NSCLC patients,[34] who had a median forced expiratory volume (FEV) 1% of 29%, making them high-risk surgical candidates. During follow-up, local progression occurred in eight (42%) patients, with a median time to progression of 27 months. There were no procedure-related mortalities, and six deaths occurred during follow-up. The probability of survival at 1 year was estimated to be 95%.

A large multicenter study known as the RAPTURE (Radiofrequency Ablation of Pulmonary Tumors Response Evaluation) trial[35] included 106 patients. In this study, there were 33 NSCLC patients. The 2-year overall survival was 48%. However, most of these high-risk patients died from noncancer-related causes, as indicated by their cancer-specific survival, which was much higher at 92%.

The long-term outcomes in a cohort of 153 patients were also recently reported.[36] This study included 75 stage I NSCLC patients. Median survival for the NSCLC group was 29 months. Overall survival at 1, 2, 3, 4, and 5 years was 78%, 57%, 36%, 27%, and 27%, respectively. Local tumor progression was reported for all tumors rather than by tumor type. The key finding was that there were differences in local control between tumors 3 cm or less in size compared with tumors larger than 3 cm. In patients with smaller tumors, median time to progression was 45 months, and 1-, 2-, 3-, 4-, and 5-year progression-free rates were 83%, 64%, 57%, 47%, and 47%, respectively. In the patients with larger tumors, median time to progression was 12 months and the progression-free rates at 1, 2, 3, 4, and 5 years were 45%, 25%, 25%, 25%, and 25%, respectively. It should be noted that all ablations were performed using the single-electrode or cluster-tip Valleylab probes, which may not as effective for tumors larger than 3 cm. However, this study supports the earlier argument that therapeutic outcomes will be better with smaller cancers.

**Microwave Ablation**    To date, there have been two reports regarding MWA[37,38] of pulmonary tumors. The largest study is by Wolf et al., using a 914-MHz VivaWave microwave system in 50 patients who underwent 66 percutaneous MWAs for 82 intraparenchymal pulmonary masses without chest wall involvement. Patients were followed for a mean period of $10 \pm 6.8$ months, and during this time, 22% of patients (11 of 50) were found to have recurrent disease distant from the ablation site. Progressive disease within the treated lobe, but not at the ablation site, was found in 9 of 11 patients, and new metastatic foci in untreated lobes or organs were found in 2 of 11 patients as evidenced by enhancement on routine contrast-enhanced CT or $^{18}$F-fluorodeoxyglucose (FDG) avidity on PET scan. This resulted in a 1-year local control rate of 67% $\pm$ 10% with a mean of $16.2 \pm 1.3$ months to first recurrence distant from the ablation site. Presence of residual enhancing tumor was more commonly found in follow-up of treated tumors greater than 3 cm. Thus, index tumor size greater than 3 cm was predictive of residual disease in these patients ($p = 0.01$). The Kaplan-Meier median time to death for all patients (n = 50) resulting from any cause, including the pulmonary malignancy being treated, was $19 \pm 1$ months. The 1-, 2-, and 3-year actuarial survival rates were 65% $\pm$ 7%, 55% $\pm$ 9%, and 45% $\pm$ 11%, respectively. Analysis of cancer-specific mortality yielded a median time to death of $22 \pm 1$ months, and 1-, 2-, and 3-year survival rates of 83% $\pm$ 6%, 73% $\pm$ 9%, and 61% $\pm$ 13%, respectively.

Wolf et al. also discussed the radiographic evolution of an ablated tumor, noting that the ablated index tumor changed in appearance, demonstrating the effects of thermally induced coagulation necrosis. A hazy, "ground-glass" opacification was most commonly observed within and extending from the zone of ablation penetrated by well-defined antennae tracts. At 1-, 3-, and 6-month intervals, ablated tumors (zones of ablation) were measured, and mean maximum postablation diameters were compared with index dimensions. Preliminary data revealed an initial increase in size (t[158] = 2.4 cm; $p = 0.02$), with a mean increase in maximum diameter of $0.65 \pm 0.27$ cm, caused by thermal changes in adjacent lung tissue, followed by a persistent

reduction in diameter consistent with consolidation. Cavitary changes were identified in 35 of 82 (43%) treated tumors (26 of 50 patients, 52%), and had a statistically significant relation to cancer-specific mortality ($p = 0.02$). No intraprocedural deaths occurred; pneumothoraces occurred in 39% of the ablations, 69% of which did not require chest tube placement. Of the 26 pneumothoraces, 8 required chest tube placement. Two patients experienced intraprocedural skin burns, one of which required surgical debridement and plastic surgery reconstruction.

**Cryoablation**    To date, there is only one report of percutaneous lung cryoablation. Wang et al.[39] reported the technique, feasibility, and safety profile of the procedure for thoracic malignancy in 187 patients (89% of patients had advanced cancer and had failed conventional therapy). Complete ice ball coverage for peripheral lesions less than 4 cm was 100%, with 80% success rate for complete ice ball coverage in lesions greater than 4 cm. Tumor size and location were highly predictive of tumor ice coverage even when controlled for tumor stage and type. By 6 months, 86% of the CT scans available were stable or smaller than the original tumor. A short follow-up period precluded any accurate survival estimates, but palliative benefits of cryoablation were noted in terms of the Karnofsky Performance Status scale and general health status (e.g., increased dietary intake and weight gain).

**Combination Ablation and Radiotherapy**    As discussed earlier, local tissue factors and vital adjacent structures can limit the volume of coagulation necrosis, leaving incomplete tumor margins with potential for residual disease. This provides ample argument for the combining thermal therapy with other treatments, including chemotherapy, chemoembolization, and XRT. Multimodality insult to tumor cells can only serve to increase the potential for cell death. Synergy between chemotherapeutic agents and hyperthermic temperatures (42°C to 45°C) has already been established.[40,41] Combining RFA with additional therapies is one of the many topics of ablation currently under research, intended to mirror the current literature supporting the multidisciplinary approach that includes surgery, chemotherapy, and XRT. Preliminary results are already suggesting that combination therapy of RFA and XRT has improved local control and survival rates as compared with XRT alone, without any additional major side effects.[42,43] The combination of RFA and radiation is intriguing. The center of a tumor tends to be more hypoxic and, therefore, more resistant to radiation. RFA is more effective in the central dense portion of a tumor that conducts heat easily, but has gradually decreasing potential for coagulation necrosis as the radius from the electrode tip increases, which creates a potential for incomplete tumor margin ablation. Radiation can complement RFA in treating tumor margins, particularly if the there is a good inflammatory response with resultant neovascularity post-RFA.

Dupuy et al.[44] published the first series of 24 RFA stage I NSCLC tumors (mean size of 3.4 cm) that were subsequently treated with XRT (average of 66 Gy), demonstrating survival rates of 50% and 39% at 2 and 5 years, respectively. Grieco et

al. reported a series of 41 patients who underwent RFA and MWA of inoperable stage I/II NSCLC tumors coupled with external beam XRT or brachytherapy. Local tumor recurrence was 11.8% for tumors less than 3 cm (after an average of 45.6 months), and 33.3% in tumors larger than 3 cm (occurring after an average of 34.0 months). There was no difference between the XRT and brachytherapy groups.

**Imaging Features Post-RFA**    An understanding of the radiographic evolution of ablated tumors is important to accurately assess the efficacy of this therapy and to differentiate normal post-RFA changes from incomplete tumor necrosis and local recurrence. Given the multiple factors that create a potential for incomplete tumor ablation, long-term follow-up surveillance imaging is mandated. The goal of surveillance is to detect recurrent malignant disease at its earliest stages, and offer re-treatment with RFA or other types of therapy. Blood-pool contrast agents are typically used to differentiate between nonenhancing coagulated tissue and enhancing viable incompletely treated residual tumor. Nonionic iodinated contrast enhanced CT and gadolinium-chelate contrast enhanced MRI are being used. The choice of modality depends on the target organ of interest, user experience, and clinical factors including contrast allergies and renal function.

Immediate post-RFA CT imaging demonstrates vaporization and wrinkling surrounding the margins of the lesion. The ablated lesion is typically surrounded by concentric rings of varying densities, referred to as a "cockade phenomenon,"[45] which is thought to represent the thermal gradient between the tumor and the surrounding parenchyma. This has also been described as a rim of ground-glass parenchymal opacity surrounding the lesion, which typically resolves within 1 to 3 months. Lee et al.[46] noted at least a 5-mm well-demarcated nonenhancing zone of ground-glass opacity surrounding ablated lesion in 8 of the 12 cases of complete necrosis. None of these patients demonstrated any local tumor recurrence on follow-up imaging (mean of 22.2 months), suggesting better treatment of tumor margins. Similar findings were noted in rabbit animal models and were found to correlate with coagulation necrosis on histology.[47]

Tumor size is variable within the first 6 months following RFA. Short-term follow-up imaging within the first 3 months has shown that lesions may increase in size. Bojarski et al.[48] report of a series of 32 RF-ablated pulmonary neoplasms: 64% of lesions increased in size, 32% remained unchanged, and 4% decreased in size at 1-month post-RFA. It is believed that the peripheral rim of ground-glass opacity contributes to the apparent increase in the size of treated tumors in the short term. Tumors that demonstrate continued growth beyond 6 months are highly suspicious for residual malignant disease, however. Cavitation was also noted within the first 3 months post-RFA in 31% of lesions in this series by Bojarski et al., typically occurring in larger lesions (with a mean of 3.8 cm in diameter). The majority of these cavitations decreased or completely collapsed on long-term follow-up (Fig. 37.3). Subcentimeter bubble-like lucencies are also noted in treated neoplasms, and also resolve within the first year. Pleural changes are occasionally noted

within the first 3 months, consisting primarily of pleural thickening (usually in the area of pleura traversed by the electrode). Reactive pleural effusions are relatively uncommon after RFA.

The use of nodule CT densitometry for solitary pulmonary nodule has received considerable attention[49] for ablation surveillance. This involves measuring the enhancement of the lesion after the administration of intravenous contrast, and is based on the hypervascular nature of most malignancies. Suh et al.[50] demonstrated that RFA-treated malignancies have marked diminution of mean contrast enhancement at 1- to 2-month follow-up. Only one lesion demonstrated enhancement greater than baseline on initial follow-up, and this patient went on to develop a malignant effusion and expired during the course of the study. These lesions demonstrated mildly increased enhancement at 3-month follow-up, which remained below the pretreatment baseline levels. The marked decrease of mean contrast enhancement at follow-up is secondary to local vascular damage caused by RFA. The mild delayed increase in contrast enhancement is likely a result of local angiogenesis in the setting of granulation tissue formation. Peripheral nodular enhancement that increases in size on follow-up imaging would, therefore, be most suggestive of residual malignant disease.

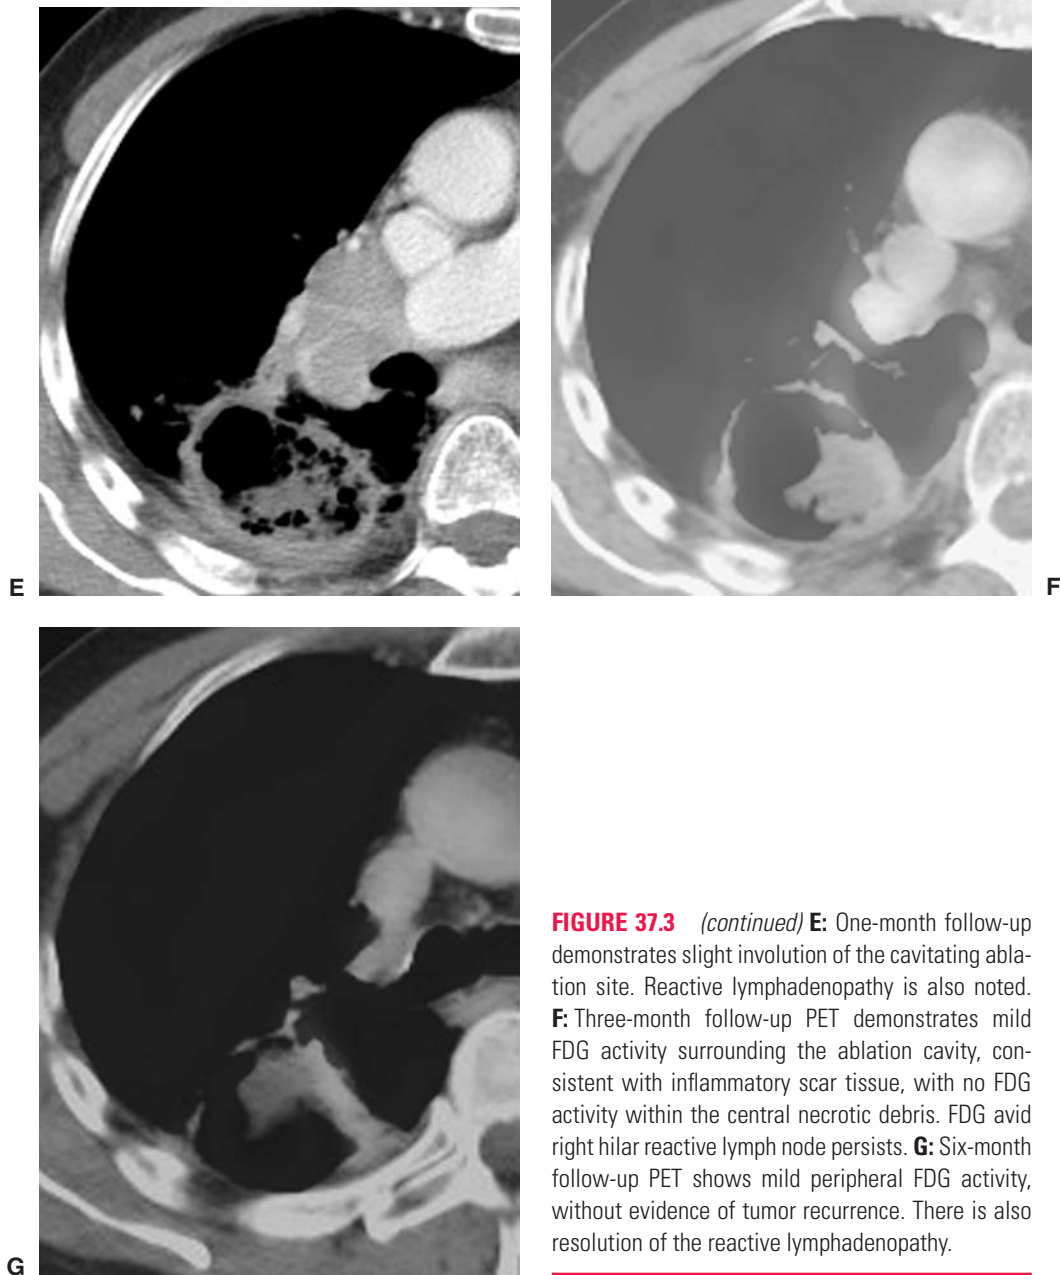
**FIGURE 37.3    A:** Initial study showing a stage IA squamous cell carcinoma. **B:** Radiofrequency ablation of the lesion. **C,D:** Two-week follow-up imaging shows a large cavitary mass with reactive rim enhancement and bubble-like lucencies, containing nonenhancing central necrotic debris. *(continues)*


**FIGURE 37.3**   *(continued)* **E:** One-month follow-up demonstrates slight involution of the cavitating ablation site. Reactive lymphadenopathy is also noted. **F:** Three-month follow-up PET demonstrates mild FDG activity surrounding the ablation cavity, consistent with inflammatory scar tissue, with no FDG activity within the central necrotic debris. FDG avid right hilar reactive lymph node persists. **G:** Six-month follow-up PET shows mild peripheral FDG activity, without evidence of tumor recurrence. There is also resolution of the reactive lymphadenopathy.

Functional imaging with FDG-PET also holds great potential. Akeboshi et al. have shown that preablation high FDG uptake in malignant lesions on PET is eliminated on post-RFA scans. Other studies have demonstrated that complete disappearance of FDG activity within a malignant pulmonary lesion after any treatment (surgery, XRT, or chemotherapy) is a good prognostic indicator,[51,52] and this principle is similarly applied to RFA. Limitations of PET imaging include its low resolution and the prominent FDG avidity of the inflammatory reaction surrounding an ablated lesion on short-term follow-up imaging, which has a uniform circumferential appearance. Residual or recurrent malignant disease typically appears as increased asymmetric focus of FDG uptake, often at the periphery of the lesion.

Lesion size and enhancement pattern may therefore be used to evaluate ablated lesions for recurrent or residual malignant disease. Figure 37.4 illustrates this multimodality approach to follow-up imaging of tumor ablation and recurrence. CT densitometry and FDG–PET imaging will likely become the preferred methods of surveillance for ablated pulmonary lesions.

## Complications after Lung Ablation

Patients undergo screening for bleeding diathesis, and anticoagulants and antiplatelet drugs are discontinued prior to ablation. When using

conscious sedation, many patients experience mild-to-moderate pain during the procedure, which is controlled with intravenous fentanyl. Mild fevers can occur up to 1 week following the therapy. Productive cough producing brown sputum may last 1 to 2 weeks in a minority of patients after ablation. Postprocedural pleurisy or small pleural effusions have also occurred in patients with pleural-based or peripheral lesions, although symptoms have rarely warranted thoracocentesis. Although there is a

case report of massive pulmonary hemorrhage in a patient on clopidogrel,[53] significant pulmonary hemorrhage and hemoptysis are extremely rare complications.

Pneumothoraces occur in approximately 20% to 35% of patients after RFA[31,46,54] with approximately 6% to 16% requiring placement of a chest catheter.[45] This higher rate of pneumothorax and chest tube placement, as compared with pulmonary needle biopsy rate, is likely attributed to the larger

**FIGURE 37.4** **A:** Initial PET showing a stage IB NSCLC. **B:** Radiofrequency ablation of the lesion. **C:** One-week postcontrast image shows thermal scar without any enhancement within the lesion, consistent with tumor necrosis. The punctuate high attenuation density in the periphery of the lesion was present on noncontrast images and is consistent with calcification. **D,E:** Six-month follow-up PET shows mild peripheral FDG activity surrounding the lesion, typical of surrounding inflammatory changes. There is a more focal focus of intense uptake at the periphery of the lesion (*arrow*), suspicious for residual tumor. This is also supported by CT imaging, which shows a similar enhancing soft tissue density along the ablation margin (*arrow*). *(continues)*
**FIGURE 37.4** *(continued)* **F,G:** Ten-month follow-up PET demonstrates more intense focal FDG uptake along the tumor margin (*arrow*), which correlates with a growing enhancing soft tissue mass (*arrow*), consistent with tumor recurrence. **H:** Patient undergoing microwave ablation of recurrent malignant disease at the tumor margin. **I:** Follow-up imaging demonstrating lack of enhancement along ablated lesion (*arrow*).

electrode size (often a 14- to 17-gauge electrode as compared with a 20-gauge needle biopsy), and a selection bias toward patients with severe emphysema who are nonsurgical candidates. Preventative measures include planning the electrode access route to avoid bullae and interlobular fissures when possible. Most chest tubes are typically removed within 24 hours, and patients may be followed in the outpatient setting with the addition of a Heimlich valve.

Pulmonary complications include pneumonia, exacerbation of existing chronic obstructive pulmonary disease, abscess, and bronchopleural fistula. Pulmonary abscess and bronchopleural fistulae are felt to be more common following ablation of larger tumors; however, as seen in Table 37.1, the incidence of these specific complications is extremely low.

One unique risk of RFA within the lung is systemic embolization, including potential risk for stroke. Experience with liver ablation had previously demonstrated the generation of microbubbles that are thought to occur from vapor formation from blood and intracellular and extracellular water. This raises the possibility of microbubbles flowing into the pulmonary veins, and resulting in cerebral microemboli. Yamamoto et al.[55] prospectively monitored 17 patients who underwent RFA of lung tumors with carotid sonography, noting echogenic microbubbles ascending the carotid arteries of three patients (who all had larger tumor diameters ranging from 2.5 to 6.5 cm). None of their patients demonstrated any evidence of acute infarct on MRI imaging that was performed within 24 hours. Microbubbles are used as a sonographic contrast agent, and the incidence of acute infarction is very low with the 35.5-$\mu$m microbubbles commonly used for this technique. Microbubbles generated by RFA are reported to be 3 to 8 $\mu$m, and are therefore of unlikely clinical significance. Jin et al.[56] have reported a case of an acute cerebral infarction following the ablation of a 4-cm atypical carcinoid tumor that resulted in left hemifacial palsy and grade 3 left upper and lower extremity weakness that improved following course of anticoagulation.

There is no definitive evidence of RFA interfering with pacemaker devices. Hayes et al.[57] reported no adverse events with pacemaker function in the ablation of liver tumors. Tong et al.[58]

| TABLE 37.1 | Types and Frequency of Lung Ablation–Related Complications |
| --- | --- |
| **Type** | **Frequency** |
| Pneumothorax requiring chest tube or aspiration | 0%–54% (most <20%) |
| Pneumonia | 0%–22% |
| COPD exacerbation | 0%–6% |
| ARDS | 0%–3% |
| Pulmonary abscess | 0%–6% |
| Hemoptysis | 0%–12% |
| Hemothorax | 0%–2% |
| Pleural effusion requiring drainage | 0%–4% |
| Parenchymal hemorrhage | 0%–1% |
| Death | 4 case reports[36,61] |
| Bronchopleural fistula | 1 case report |
| Acute renal failure | 1 case report |
| Vocal cord paralysis | 1 case report |
| Atrial fibrillation | 1 case report |
| Pulmonary embolus | 1 case report |
| Third-degree skin burn | 1 case report |
| Stroke | 1 case report |
| Tumor tract seeding | 1 case report |

Adapted from Rose SC, Thistlethwaite PA, Sewell PE, et al. Lung cancer and radiofrequency ablation. *J Vasc Interv Radiol* 2006;17:927–951.

ARDS, acute respiratory distress syndrome; COPD, chronic obstructive pulmonary disease.

report of a single case of irregular pacing rhythm in the ablation of an adrenal lesion, with resumption of normal paced rhythm posttreatment, with no evidence of malfunction or damage on interrogation.

Finally, skin burns associated with improper ground pad placement can occur, but this is rare if the pads are placed appropriately. Rare cases of pulmonary emboli and periprocedural atrial fibrillation are likely secondary to associated comorbid conditions in this patient population, including advanced age and debilitation and tumor-related coagulopathy. A single case of tumor tract seeding has also been reported.[59]

Equally important, RFA does not appear to affect the overall pulmonary function. In a series of 97 ablated lesions by de Baère et al.,[60] 47 patients in the 60-patient study underwent spirometry between 3 and 5 weeks after RFA. There was no significant change in their forced expiratory volume in 1 second ($FEV_1$) or their vital capacity as compared to pretreatment spirometry.

## CONCLUSION

Sublobar resection in combination with adjuvant brachytherapy appears to be a reasonable option for the patient considered high risk for lobectomy. Preliminary results are encouraging,

and a current randomized trial will better define the role of this approach. Thermal ablation is an alternative for patients who are high risk for any resection or those patients with tumors in anatomic locations that preclude a sublobar resection. Thermal ablation is more successful with smaller tumors and results may be improved if used in combination with radiation therapy. MWA may also be preferable to RFA, although studies to confirm this are still needed.

# Surgical Management of Small Cell Lung Cancer

Small cell lung cancer (SCLC) is a virulent, rapidly growing, early metastasizing, invasive cancer. SCLC represents approximately 15% of all lung cancers and up to 25% of lung cancer deaths each year in the United States.[1] At diagnosis, approximately 90% of patients will have regional or distant spread. Although the incidence of SCLC in the United States is decreasing, there have been only modest improvements in survival noted over the past 30 years.[2]

Although several decades ago, surgery for SCLC was the treatment of choice, this was abandoned following the 1973 report of the British Medical Research Council, which randomized patients with limited disease SCLC to either surgery or radiotherapy alone.[3–5] It was concluded from this study that radiotherapy was preferable to surgery. Subsequently, it has been shown that SCLC can exhibit an initial dramatic response rate to chemotherapy and radiation therapy.[2] Numerous clinical trials have reported response rates of 80% to 90%. Nevertheless, despite this initial response to therapy, most patients ultimately die from this disease. For patients with limited-stage disease, the most frequent site of chemoradiotherapy treatment failure is localized recurrence.[6,7] It is this sobering fact that has led many to reconsider surgery as part of the treatment armamentarium of SCLC. This chapter will review four clinical circumstances in which surgery may be beneficial in the treatment of SCLC: (a) SCLC presenting as a solitary pulmonary nodule (SPN) and diagnosed at the time of surgery, (b) mixed histology (i.e., SCLC and non-SCLC combined) lung cancers, (c) salvage therapy for local failure of chemoradiotherapy, and (d) planned multimodality therapy consisting of induction chemotherapy followed by surgery for limited-stage SCLC.

## HISTORICAL BACKGROUND

Mountain[8] reported the MD Anderson Hospital and Tumor Institute's surgical experience for 368 patients with pathologically proven SCLC and found only one patient surviving greater than 5 years as compared to 15% to 25% 5-year survival for non–small cell lung cancer (NSCLC). Mountain[8] did not identify any prognostic factors positively influencing survival and concluded that SCLC was a nonsurgical disease warranting systemic treatment.

To try and determine if it was ever appropriate to utilize surgery as primary treatment for SCLC, a prospective randomized trial was undertaken by the Medical Research Council of Great Britain.[3–5] In this study, 144 patients were diagnosed with SCLC by bronchoscopy, and then randomized with 71 having surgical resection and 73 radiotherapy (>30 Gy over 20 to 40 days). Median survival for the surgical patients was 199 days compared to 300 days for the radiotherapy patients. At 5 years, one and three patients were alive in the surgical and radiotherapy arms, respectively ($p = 0.04$), and at 10 years, only the three radiotherapy patients remained. This study discredited surgery for SCLC for years to come. Retrospectively, the British Medical Research Council study has been criticized in several areas: (a) initial staging was crude compared with today's preoperative staging modalities, and many of the patients likely would have been deemed inoperable, (b) only patients with central tumors were included since all required bronchoscopy for diagnosis, peripheral tumors, which might have received the most benefit were excluded, (c) only 48% of the surgical patients had complete surgical resection, all of which entailed pneumonectomy, and (d) no intraoperative staging was performed.[9–12] Subsequently, the addition of preoperative radiotherapy was examined; however, no survival advantage was achieved.[13–15] Considering these facts, some surgeons still believed in the role for surgery in select patients with SCLC; therefore, further investigations were continued. Table 38.1 outlines the results of surgery alone for SCLC.

It became evident to the 1960s and 1970s investigators that most patients with SCLC were dying from systemic metastatic disease, and that effective systemic treatment was needed. Bergsagel et al.[25] showed an improved overall survival with the addition of low-dose cyclophosphamide to radiation therapy. Similarly, the British Medical Research Council Lung Cancer Working Party[26] showed improved disease-free survival with multiagent chemotherapy and radiation. Concurrently, other investigators were applying the same adjuvant chemotherapy

principles to surgical SCLC patients. The Veterans Administration Surgical Adjuvant Group (VASOG) in the United States showed no survival benefit in 417 lung cancer patients (both SCLC and NSCLC) treated by either surgery alone, surgery plus single-agent chemotherapy, or surgery plus multiagent chemotherapy.[27] When considering those patients specifically diagnosed with SCLC, 4 out of 18 total patients were alive at 3 years, none being in the surgery alone arm. This was the first study demonstrating a possible increased survival for patients with SCLC who underwent adjuvant chemotherapy following complete surgical resection.[27]

In 1982, Shields et al.[28] evaluated four of the VASOG adjuvant chemotherapy trials, which resulted in the reawakening of surgical interest in the treatment of limited disease SCLC. This study analyzed 148 patients diagnosed with SCLC who had undergone potentially curative resection. There were 16 operative deaths, and in the remaining 132 patients, the overall 5-year survival was 23%. Although in this study, there was no benefit shown with adjuvant chemotherapy, the importance of the TNM (tumor, node, metastasis) staging SCLC was demonstrated. SCLC patients with T1N0M0 tumors had a 60% 5-year survival, T1N1M0 31%, T2N0M0 28%, T2N1M0 9%, and any T3 or N2 3.6%.[28] (Fig. 38.1) SCLC may occasionally present as an SPN. In 1975, Higgins et al.[29] reported on a VASOG trial involving 1134 patients with asymptomatic SPN. The 392 patients underwent resection for lung cancer, and 15 (4%) were found to have SCLC. The 1-, 5-, and 10-year survivals were 64%, 36%, and 18%, respectively.[29] In a retrospective review of 40 patients who underwent potentially curative resection for SCLC between 1959 and 1972, overall 5-year survival was 25%, and long-term survival was 40% in patients without

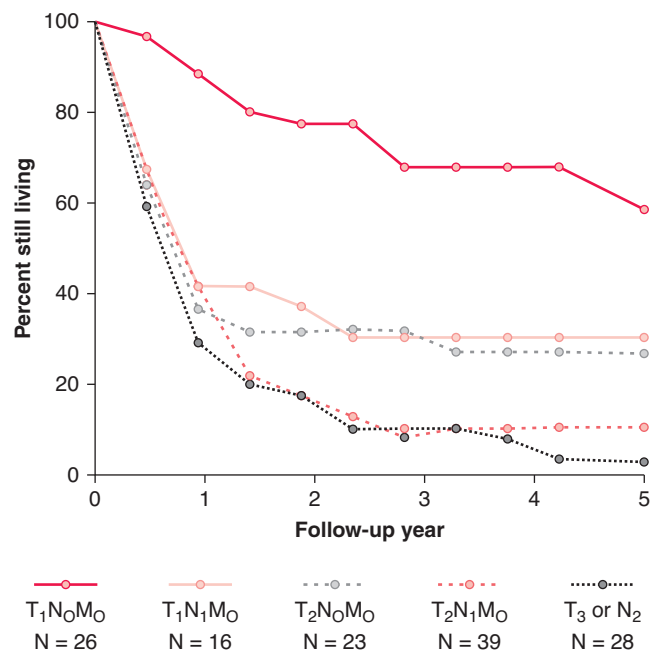

**FIGURE 38.1** Survival, computed by the life-table method, from postoperative day 30 (early trials) or from randomization (recent trials) by TNM classification for patients with undifferentiated small cell carcinoma who had undergone a "curative" resection in the VASOG lung trials. (From Shields TW, Higgins GA, Matthews MG, et al. Surgical resection in the management of small cell carcinoma of the lung. *J Thorac Cardiovasc Surg* 1982;84:481–488, with permission.)

metastatically involved lymph nodes.[18] Similarly, Angeletti et al.[30] suggested that survival was statistically influenced by the N stage rather than T stage. Their results demonstrated that patients with T1, T2, and T3 SCLC tumors, without evidence of lymph node involvement, might benefit from surgical resection and adjuvant chemotherapy. SCLC typically presents as a central mass. Lennox et al.[19] observed that patients with more proximal tumors requiring pneumonectomy had worse survival than patients requiring lobectomy. The 2- and 5-year survival rates for patients undergoing lobectomy were 32% and 18%, respectively, compared with 14% and 7% for patients having pneumonectomy.[19]

Although some authors may consider the combination of chemoradiotherapy to be the standard of care for limited disease SCLC,[31] from this historical review, it is suggested that various subpopulations of patients with SCLC might benefit from surgery. Whether surgery can offer any substantial advantage over radiotherapy in terms of local control is still an unanswered question. However, we concede that if surgery is to have any meaningful role in the treatment of SCLC, it must be in the context of a combined modality treatment regimen, which includes systemic chemotherapy and possibly radiotherapy.

## SURGICAL INDICATIONS IN THE MANAGEMENT OF SMALL CELL LUNG CANCER

**Solitary Pulmonary Nodule**    The SCLC that presents as an SPN is often diagnosed at the time of therapeutic resection.

This represents a small percentage of patients that carry the diagnosis of SCLC ranging from 4% to 12%.[29,32,33] These patients usually have solitary peripheral nodules on chest radiograph and computerized tomography (CT). Bronchoscopy tends to be nondiagnostic, and the definitive diagnosis often is not made until the time of surgical resection. Some investigators have hypothesized that SCLC presenting as an SPN has an inherently different biology and, in turn, natural history than the more typical SCLC.[32,34]

The VASOG trial reported by Higgins et al.[29] is one of the earliest studies confirming an improved outcome (5-year survival 36%) for patients with resected SCLC presenting as an SPN. Several series of peripheral SCLC treated by surgery alone have been previously discussed and show survivals similar to resected NSCLC (Table 38.1). A 5-year survival of approximately 50% can be seen with pathologic stage I SCLC patients treated with surgery and adjuvant chemotherapy.[27] Randomized trials have not been carried out in this subset of patients with resected peripheral SCLC, and it is therefore impossible to know if this more favorable outcome is caused by the surgical resection, the adjuvant chemotherapy that many receive, or the natural history of this subset of SCLC. The accuracy of the pathologic diagnosis must always come to mind in any of the older series of resected peripheral SCLC. Some of these SCLCs may, in fact, be atypical carcinoids or other well-differentiated neuroendocrine carcinomas.[35] Some surgeons have questioned the necessity for adjuvant chemotherapy following resection of peripheral SCLC.[16] Many clinical series of surgery and chemotherapy have shown improved survival when compared to historical groups of patients treated by surgery alone (Table 38.2).

[a]All survivors were T1, T2, or T3 with N0 disease. No patients with N1 or N2 disease survived.

Chandra et al.[36] from the Mayo Clinic recently reviewed 77 patients who, from January 1985 to July 2002, underwent thoracotomy for SCLC. Many of the SCLC were solitary nodules or masses. The median tumor diameter was 4 cm (range: 1 to 10 cm) Surgical procedures included wedge resection in 30 patients (6 with concomitant talc pleurodesis), lobectomy in 28, segmentectomy in 4, bilobectomy in 3, pneumonectomy in 2, and thoracotomy with biopsy of the hilar mass in 10. Mediastinal lymphadenectomy was performed in 50 patients, mediastinal lymph node sampling in 19, and no mediastinal lymph nodes were biopsied in 8. Patients were classified using the TNM staging system according to the criteria established by the American Joint Committee for Cancer and End Results Reporting for NSCLC. Postsurgical stage was IA in 7 patients, IB in 11, IIA in 8, IIB in 7, IIIA in 30, IIIB in 10, and IV in 4. Five patients had combined chemoradiotherapy prior to thoracotomy. Adjuvant therapy included chemotherapy in 20 patients, radiation therapy in 3, and both in 40. Figure 38.2 shows the 5-year survival for these patients according to stage. Five-year survival for patients with stage I disease was 36%, stage II 40%, stage III 17%, and stage IV 0% ($p = 0.06$). Five-year survival for patients with stages I and II combined was 38% compared with 16% for patients with stages III and IV combined. After multivariable analysis, surgical stage I/II versus III/IV was the only significant predictor identified.

In patients whose performance status is acceptable for surgical resection, we do not routinely perform transthoracic needle aspirations (TTNA) of peripheral lung nodules. In patients who, for some reason, have had a TTNA and a diagnosis

**FIGURE 38.2** Survival of patients following resection of SCLC. Probability of survival (death from any cause) in patients who underwent resection of SCLC. Zero time on the abscissa represents the date of lung resection. Patients who had surgical biopsy only are excluded. Numbers under the graph represent the number of patients at risk. (From Chandra V, Allen MS, Nichols FC III, et al. The role of pulmonary resection in small cell lung cancer. *Mayo Clin Proc* 2006;81:619–624, with permission.)

of SCLC is obtained, consideration for surgical resection is still given. This is because the cytologic diagnosis may be in error as mentioned previously. Additionally, some SCLC are mixed tumors with NSCLC being present as well.[48,49] Surgical resection clarifies the pathology and eliminates the NSCLC portion of the tumor.

Preoperative staging for patients with peripheral SCLC is more thorough than that for NSCLC. Noninvasive staging includes a CT scan of the chest and abdomen, whole body positron emission tomography (PET), and head magnetic resonance imaging (MRI). Depending on the results of the noninvasive staging, invasive preoperative staging may include endoscopic bronchoscopic ultrasound (EBUS), esophageal endoscopic ultrasound (EUS) both with fine-needle aspirations as appropriate, and finally mediastinoscopy. The intraoperative management of peripheral SCLC is similar to that of NSCLC. Complete resection of the tumor most commonly includes lobectomy and mediastinal lymphadenectomy. For those patients where the diagnosis of SCLC is made at the time of surgical resection, missing parts of the noninvasive metastatic workup are completed postoperatively. This allows for accurate cancer staging and appropriate adjuvant therapy.

**Mixed Histology Tumors** Approximately 5% to 10% of patients diagnosed with SCLC will have "mixed tumors," meaning other pathologies such as adenocarcinoma or squamous cell carcinoma can be found within the pathologic specimen.[48,49] The University of Toronto Lung Oncology Group reported a mixed histology in 17.7% of surgical patients with adjuvant chemotherapy and in 7.5% of surgical patients with neoadjuvant chemotherapy.[49] There appears to be a higher percentage of surgical patients with mixed histology. This, in part, is thought to be a result of the more peripheral location of most mixed SCLC.[48] Other factors may also contribute to the increased incidence of mixed histology in resected SCLC including: (a) the surgical cases have more pathologic tissue available for analysis increasing the likelihood of finding other histopathology, and (b) the NSCLC component is much less sensitive to chemoradiation therapy and is often the major histology found in residual tumors undergoing resection.[50] This latter fact should be remembered when limited disease SCLC fails to respond as expected to chemotherapy. In such a situation, repeat biopsy should be considered, and if NSCLC is identified and there is no evidence for metastatic disease, then the operative criteria for NSCLC should be followed. Based on these facts, it is reasonable to consider surgical resection for patients with mixed SCLC, as the standard chemoradiation therapy will manage the small cell component, and surgery will eliminate the non–small cell component potentially curing this small subset of patients.[2,10]

**Salvage Surgery for Initial Treatment Failure or Relapse** When treatment in limited disease SCLC is unsuccessful with either persistence of disease or localized recurrence, second-line chemoradiotherapy is usually ineffective.[50] This sparked interest in the concept of salvage surgery. Shepherd et al.[51]

reported on 28 patients who underwent salvage surgery after neoadjuvant chemotherapy ± radiation therapy. The patients considered had either relapse following complete remission, no response to neoadjuvant therapy, a partial response followed by local progression while on chemotherapy, or a residual tumor mass >3 cm.[51] Histopathology revealed SCLC alone in 18 patients, mixed in 4, and NSCLC alone in 6. Postsurgical stage was stage I in 4 patients, stage II in 10, and stage III in 14. Overall 5-year survival was 25%, and all patients with pathologic stage I were still alive at the time of publication.[51] Yamada et al.[52] reported on salvage surgery following chemotherapy for SCLC in 9 patients. Four patients experienced long-term disease-free survival ranging from 3 to 11 years. Three of the long-term survivors had stage I tumors. Although the outcome data is limited, surgical resection in carefully selected patients with persistent or recurrent localized SCLC offers the best chance for local control and may improve long-term survival in a group of patients whose prognosis is otherwise dismal.

In long-term survivors of successfully treated SCLC, there is an increased frequency of second primary tumors, most commonly NSCLC. This was demonstrated by Heyne et al.[53] at the MD Anderson Cancer Center when they reviewed 47 patients with more than 2-year survival following successful treatment of SCLC and identified 14 patients with second malignancies. The risk of developing these secondary cancers increases with time from 2% at 2 to 4 years, 12.6% to 14.4% after 10 years, to a 70% actuarial cumulative risk after 15 years.[53–55] The University of Toronto reported on eight patients who developed apparent relapse after long-term survival from successful treatment of SCLC. Two patients had NSCLC and achieved successful long-term survival after surgical treatment of their second malignancy.[49,56] Any patient who develops a second lung lesion, after long-term survival following successful SCLC treatment, should not be assumed to have recurrent SCLC. Many times, the histopathology is NSCLC, which can potentially be cured with surgical resection. Needless to say, the patients with these new lung lesions should be evaluated in the same manner as any other patient with a newly diagnosed pulmonary lesion. In these cases, we would consider biopsy of the new lesion if possible. Pending the pathology, clinical stage, and performance status of the patient, surgery may be warranted with the potential of long-term cure.[10,56]

## Prospective Trials of Induction Chemotherapy Followed by Surgical Resection

As some of the promising results from adjuvant chemotherapy for SCLC were reported, an interest in neoadjuvant chemotherapy was begun. Several institutions developed phase II prospective trials to further evaluate the benefit. The results of 15 such studies can be found summarized in Table 38.3.

[a]Stage reported only for surgical patients.

[b]Includes patients who had surgery before chemotherapy.

From Darling GE, Shepherd FA. Surgical management of small cell lung cancer. In: Pass HI, Carbone DP, Johnson DH, Minna JD, Turrisi AT, eds. Lung Cancer Principles and Practice. 3rd Ed. Philadelphia: Lippincott Williams & Wilkins, 2005;475–490, with permission.

A, doxorubicin; C, cyclophosphamide; Car, carboplatin; CR, complete response; CSR, complete surgical resection; E, etoposide; Ep, epirubicin; O, vincristine; ORR, overall response rate; P, cisplatin; V, vincristine.

Each of the studies administered multiple courses of combination chemotherapy. Approximately 60% of patients were rendered resectable after neoadjuvant therapy with more than 80% of those being completely resected.[71] Although there is mention of a more difficult surgical dissection after neoadjuvant therapy, the overall morbidity/mortality did not appear to be significantly increased or different from that seen in patients without neoadjuvant therapy. The complete pathologic response rate ranged from 4% to 37%, with an average of about 10%, not dissimilar to the results found in patients with NSCLC treated with surgery and neoadjuvant chemotherapy. Patients with no viable tumor identified within the surgical specimen had the best survival with some patients cured.[71] The importance of pathologic TNM staging was verified, with stage I tumors having a 5-year survival of approximately 70% when complete resection was performed. The results were not as good for stages II and III, but all series report at least few patients with N2 disease that achieved long-term survival and appeared cured by the multimodality therapy.[71]

The objective of these trials was to look at the combination of induction chemotherapy followed by surgical resection in terms of long-term survival and cure by reducing the rate of local recurrence. The local failure rate of most studies ranged from 10% to 20% in patients with complete resection (Table 38.4). Of the patients who responded to chemotherapy and proceeded to surgery, approximately 15% had unresectable tumors. If the unresectable patients are combined with those patients who locally relapsed, the local failure rate is approximately 25% of the surgical patients.

In 2007, Veronesi et al.[72] reported a single-center prospective trial to evaluate the utility of surgical resection after neoadjuvant chemotherapy (cisplatin/carboplatin and etoposide ± ifosfamide) in patients with limited disease SCLC. Data from

1998 to 2004 on 23 consecutive patients was accumulated. Nineteen patients underwent curative surgery. Four patients had a complete pathologic response, with 7 being stage I, 7 stage II, and 5 stage III. Overall 3-year survival was 25%, but in the 11 with pathologic stage 0 or I, it was 90% at 2 years versus 20% in those with pathologic stage II or III. Local recurrence rate was 17%, and the brain was the most common site of distant metastases occurring in 39% of the patients. They concluded that patients with limited clinical disease (N0), or those pathologically downstaged to pN0 following neoadjuvant therapy would benefit from surgery with the result being good local control. They also recommend prophylactic brain irradiation for all responders, because this was the most common site of distant metastatic recurrence.

Although these phase II trials would suggest a benefit to including surgery with neoadjuvant chemotherapy for limited small cell carcinoma, there has still been question as to whether patient selection was the reason for the outcomes seen in these trials. The Toronto Group has emphasized the importance of selection bias.[73] A significant survival advantage was found for patients who had no clinical involvement of mediastinal lymph nodes.

**Randomized Trials**   To further determine the role of surgery combined with chemoradiotherapy in the treatment of SCLC, Lad et al.,[74] as part of the Lung Cancer Study Group, organized a prospective randomized trial of induction chemotherapy and surgery in 1983. The patients received five courses of induction chemotherapy, which included cyclophosphamide, doxorubicin, vincristine, and etoposide in the early phase, and cyclophosphamide, doxorubicin, and vincristine in the later phase. Afterward, patients were evaluated for response to chemotherapy. Induction therapy had to be received by all patients, the tumor had to be

[a]Excluding patients who did not have complete surgical resection at time of thoracotomy.

From Darling GE, Shepherd FA. Surgical management of small cell lung cancer. In: Pass HI, Carbone DP, Johnson DH, Minna JD, Turrisi AT, eds. *Lung Cancer Principles and Practice*. 3rd Ed. Philadelphia: Lippincott Williams & Wilkins, 2005;475–490, with permission.

judged resectable, and there had to be no evidence of spread of disease. They were then randomized to receive surgery followed by thoracic radiation and prophylactic cranial radiation versus the same without surgery. There were 340 patients entered into the trial with a 68% clinical response rate, 28% complete, and 37% partial. Sixty-eight patients were randomized to surgery, 76 patients to no surgery, 6 patients refused surgery, and 8 had off-protocol surgery, totalling 70 patients that underwent surgery. Fifty-four patients (77%) were thought to have complete resection with an 18% complete pathologic response. The median survival for all patients was 14 months, with a 15.4-month median survival for the surgical arm and 18.6 for the no surgery arm. The 2-year survival rate was only 20%, with a local failure rate of approximately 38% in both arms.

Several groups are currently in the process of randomized trials to further define the specific role of surgery in limited disease SCLC. Eberhardt and Korfee,[75,76] of the Essen Thoracic Oncology Group, have a randomized phase II trial where patients will receive neoadjuvant chemotherapy with etoposide and cisplatin for three cycles, followed by twice-daily radiation (45 Gy) with concurrent chemotherapy, followed by randomization. The first arm will be definitive surgery and the second arm will be small-volume chemoradiation boost (20/26 Gy daily). The primary end point will be a comparison of locoregional relapse-free survival in 4 years.[75] Fukuoka and Tada, of the West Japan Lung Cancer Group, are performing a prospective randomized trial to evaluate trimodality therapy in patients with mainly stage IIIA disease.[75,76] One arm includes neoadjuvant chemotherapy with etoposide and cisplatin for three cycles, followed by twice-daily radiation (45 Gy) with concurrent chemotherapy, followed by surgery. The second arm includes one cycle of chemotherapy, followed by two cycles of hyperfractionated accelerated twice-daily radiation therapy (45 Gy), followed by two more cycles of chemotherapy. Thomas and Passlick are part of a German multicenter randomized trial, where patients are randomized to five cycles of chemotherapy with paclitaxel, etoposide, and carboplatin, followed by surgery with or without once-daily radiation therapy (50 Gy) versus the same neoadjuvant chemotherapy, followed by once daily-radiation therapy (50 Gy) only.[75,76] Hopefully, these trials will yield insight into improved treatment options for limited disease SCLC.

## CONCLUSION

It is clear that surgery plays a less definitive role in the treatment of SCLC than in NSCLC. Moreover, the exact role of surgery in treating SCLC remains elusive because of the paucity of up-to-date information. For the patient where SCLC is diagnosed intraoperatively at the time of SPN or presumed NSCLC resection, surgical staging followed by appropriate surgical resection is the preferred treatment. This should be followed postoperatively by noninvasive staging, which might not have been preoperatively obtained and adjuvant chemotherapy.

Based on several historical series, clinical T1 and T2 SCLC without evidence of lymph node involvement (N0) can be considered for surgical resection. Careful patient selection is of paramount importance. When making decisions about the best treatment for SCLC, it must be remembered that a substantial percentage of patients have a higher pathologic stage than clinical stage. Therefore, prior to any surgery, an extensive mediastinal and distant metastatic disease evaluation, both noninvasive and, if necessary, invasive, should be performed. There is unanimous emphasis on the importance of TNM staging which has been shown to correlate with long-term survival and possible cure.

With regard to stage II disease, it is not possible to make generalized recommendations regarding surgery, and treatment decisions must be individualized. If surgery is part of the treatment approach, it is likely best offered as adjuvant therapy to patients with a demonstrated response to chemotherapy.

The poor prognosis for stage III SCLC clearly does not justify surgical therapy outside of the setting of a prospective randomized trial. For stage IV SCLC, surgery is reserved for palliation of symptoms such as treatment of symptomatic pleural effusion or central airway obstruction.

The final group of SCLC patients that might benefit from surgical resection is those patients with mixed histopathology. For such patients, the treatment might be up-front resection for early stage disease, followed by adjuvant chemotherapy or neoadjuvant chemotherapy to control the small cell component followed by surgery for the NSCLC remnant. For patients who experience an unexpectedly poor chemotherapeutic response or develop a localized relapse, repeat biopsy should be performed, and if NSCLC is found, surgical resection should be considered therapy.

# Complications of Surgery for Lung Cancer

## BACKGROUND

Surgery remains the primary therapy for patient with early stage non–small cell lung cancer. Nonsurgical modalities of local therapy such as focused stereotactic radiation and radiofrequency ablation have been used recently, particularly in patients thought to be of high operative risk. In an era of multimodality therapy, with the availability of several emerging treatment options for local therapy, it is imperative that we understand the potential complications of surgery for lung cancer as well as treatment strategies for these complications to select the best treatment options for individual patients.

The risks for pulmonary resection depend primarily on the preoperative status of the patient with regard to factors such as comorbidities, overall functional status, and preoperative pulmonary function. Complications of pulmonary resection that are well described and will be discussed in this chapter include pneumonia, respiratory failure, empyema, bronchopleural fistulae, prolonged air leaks, chylothorax, postpneumonectomy pulmonary edema, postpneumonectomy syndrome, and death.

## OPERATIVE RISKS ASSESSMENT

Several contemporary studies have demonstrated improved outcomes in patients undergoing pulmonary resection for malignancies compared to resections performed in an earlier era. Recent improvements in patient survival and reduction in complications have been attributed to better patient selection for surgery as well as improved postoperative care, although these perceptions are not well supported by objective data.

Recently, the American College of Surgeons Oncology Group (ACOSOG) Z0030 trial randomized patients with non–small cell lung cancer undergoing an anatomic resection for clinical T1 to T2, N0 to N1 tumors to mediastinal lymph node sampling or mediastinal lymph node dissection.[1] This study included 1023 patients from 63 different institutions and 102 different surgeons. There were 42 pneumonectomies,

42 bilobectomies, 766 lobectomies, 70 segmentectomies, and 101 patients with a combination of resections. The overall mortality rate in this patient group was 1.4%, and the overall morbidity rate was 38%. The most frequent morbidities were atrial arrhythmias (14%) followed by chest tube drainage >7 days (11%), air leak >7 days (8%), respiratory (7%), hemorrhage (3%), chylothorax (1%), and recurrent laryngeal nerve injury (1%). Table 39.1 outlines the incidence of significant complications occurring in both historical and contemporary series of lung cancer resections for comparison. The ACOSOG Z0030 multi-institutional study provides a contemporary benchmark of morbidity and mortality for patients undergoing major pulmonary resections for stage I and II lung cancers when performed by surgeons specializing in thoracic surgery.

In published series of major pulmonary resections for lung cancer, the reported mortality rates have ranged from 1.3% to 5.5% (Table 39.2).[2–8] Wada et al.[8] reported a series of 7099 thoracic procedures with significant differences in mortality noted depending on the extent of lung resection. The mortality rates were 3.2% for pneumonectomy, 1.2% for lobectomy, and 0.8% for sublobar resections. There were also significantly more deaths in patients with increasing age where the mortality rates were 0.4% for patients younger than 60 years, 1.3% for patients aged 60 to 69, 2.0% for patients 70 to 79, and 2.2% for patients 80 years or older. In the Z030 trial, there were no trends toward increased mortality or complications with larger pulmonary resections although the trial was not designed to examine differences in resection strategy.[1] Romano and Mark[5] reported a direct correlation between the extent of pulmonary resection and mortality. In this retrospective study, the mortality rates were 3.8% for wedge resections, 3.7% for segmentectomy, 4.2% for lobectomy, and 11.6% for pneumonectomy. Factors that significantly correlated with patient mortality were patients older than 60 years, extent of resection, male gender, chronic lung or heart disease, diabetes, and volume of pulmonary cases performed at each participating institution. The finding that mortality rates are higher when cases are performed by general surgeons rather than surgeons

specializing in thoracic surgery has been suggested in other studies but remains controversial.[6,7]

## RISK STRATIFICATION

Clinical stage of disease plays an important role in identifying the high-risk surgical patient for two reasons. The first is the perceived likelihood of achieving the goal of cure of cancer. Patients with early stage disease have improved survival over patients with advanced stage disease. As a rule, only patients with stage I to IIIA disease are even considered for surgical therapy. Within this group, patients with stage I disease have improved survival over those with stage IIIA disease. The surgical team may favor a more aggressive approach in a patient

with earlier stage disease because of an increased likelihood of cure. The second reason clinical stage is important is because of the extent of resection needed to obtain tumor free margins. Tumors requiring chest wall resection, sleeve resection, vascular reconstruction, and pneumonectomy have higher rates of complications. At times, the risk of complications is high enough to avoid recommending surgery to less surgically fit candidates with more advanced tumors.

Although a basic understanding of the expected morbidity and mortality rates is important for discussions with patients before and after major lung resections, further risk stratification based on patient comorbidities and the extent of the planned operation are also necessary. Strand et al.[7] reviewed the Norwegian experience of patients undergoing pulmonary resections between 1993 and 2005. During this period, there

**TABLE 39.2    Operative Mortality following Lung Cancer Resection**

*All patients ≥80 years old.

were 4395 procedures with an overall mortality rate of 4.4%. Multivariate analysis identified several procedure-related factors associated with an increased risk of mortality including male gender (odds ratio [OR] = 1.76), age 70 to 79 or $\geq$80 (OR = 3.38 and 9.94 compared to patients $\leq$50), right-sided tumors (OR = 1.73), and bilobectomy or pneumonectomy (OR = 3.06 and 4.54, respectively). In this study, neither the extent of local–regional advancement nor tumor size had any impact on 30-day mortality. The presence of metastatic disease was the only tumor-related factor that had a negative impact on survival. The largest observational study evaluating the impact of patient's age found a direct correlation between the patient's age and mortality with the most significant increased risk occurring after the age of 70.[7] The 30-day mortality OR for patients aged 70 to 79 and 80 to 89 were 4.91 and 19.71, respectively, when compared to patients $\leq$50 years. Most studies have shown that advanced age is a predictor of morbidity and mortality after pulmonary resection,[7–10] although studies in carefully selected patients older than 80 years of age undergoing pulmonary resection have shown similar morbidity and mortality rates to younger patient cohorts.[11]

In addition to factors associated with the extent of resection required, scoring systems exist to further stratify patients according to medical comorbidities.[3] Algorithms for identifying higher risk patients include the Cardiopulmonary Risk Index (CPRI),[12] the Physiological and Operative Severity Score for Enumeration of Mortality and Morbidity (POSSUM),[13] and the EVAD scoring system. The EVAD scoring system is primarily based on the patient's forced expiratory volume in 1 second (FEV$_1$), age, and diffusing capacity of lung for carbon monoxide (DLCO).[3] In a comparison of these three systems in a cohort of 400 patients, POSSUM scores that were retrospectively calculated did not correlate with either fatal or nonfatal complications of surgery.[3] The CPRI scoring system did not correlate with patient mortality but did correlate with nonfatal complications when analyzed together. More specifically, the CPRI calculations correlated significantly with pulmonary and cardiopulmonary complications but did not correlate with cardiovascular, infectious, or other complications. The EVAD scoring system showed trends toward prediction of mortality and did correlate significantly with all types of morbidity evaluated with the exception of infectious complications. Unfortunately, the statistical predictive power of this scoring system is, at this point, not sufficient for application to individual patients and has not been further evaluated in other institutions. In addition, scoring systems specifically developed for lung resection, such as the Predictive Respiratory Quotient (PRQ)[14] and the Predicted Postoperative Product (PPP),[15] have not gained widespread use. Although the surgical team may not rely completely on a particular scoring system to determine the surgical fitness of a patient, many of the factors that make up these scoring systems along with surgical judgment are used to make the ultimate decision. Some of these factors may include clinical stage of disease, patient age, spirometry, and presence of comorbidities.

## PREOPERATIVE SPIROMETRY

An important component of risk assessment is to determine whether there is sufficient pulmonary reserve to sustain the patient postoperatively. Pulmonary function testing is used to assess airflow, lung volume, lung mechanics, and gas exchange. The two most commonly used parameters for determining surgical resectability are FEV$_1$ and DLCO. Surgical risk has little or no correlation with preoperative FEV$_1$ when lung function is relatively preserved. An observational study of patients categorized into either normal lung function (FEV$_1$ >80% predicted, mean = 92.2%) or reduced lung function (FEV$_1$ $\leq$80% predicted, mean = 64.2%) found no differences in the rates of air leaks >7 days, atelectasis, bleeding, contralateral pneumothorax, or atrial fibrillation.[16] However, the value of preoperative FEV$_1$ evaluation is more important with a greater reduction in pulmonary function. The risk of pulmonary resection increases substantially if the preoperative FEV$_1$ is less than 60% predicted.[17] In general, patients who fall below this mark need further testing with ventilation/perfusion scanning, which is used to determine preoperative split lung function and predicted postoperative FEV$_1$. DLCO is used to evaluate the integrity of the alveolar capillary membrane for gas exchange. Ferguson et al.[18] found in a retrospective study of 237 patients that preoperative DLCO predicted postoperative pulmonary complications in patients with acceptable FEV$_1$. They subsequently confirmed the importance of DLCO by showing that predicted postoperative DLCO is a predictor of morbidity and mortality independent of FEV$_1$.[19] In addition, patients with DLCO less than 60% for pneumonectomy and less than 50% for lobectomy have an increased risk of postoperative complications.[20] Although these factors are frequently utilized in the preoperative risk assessment, it should be noted that others have not found spirometric parameters such as FEV$_1$ or DLCO to be significant predictors of postoperative complications.[21,22] Others have successfully utilized spirometry in combination with exercise tolerance as a means of predicting pulmonary complications following resection.[23] Vital capacity, exercise induced hypoxemia ($\Delta$ PaO$_2$), low oxygen uptake/body weight (VO$_2$ max/BW), and $\Delta$ PaO$_2$/$\Delta$ VO$_2$ max/BW may be associated with an increased risk for complications.

After poor pulmonary reserve, the next most important factor contributing to risk of pulmonary resection is the presence of concomitant organ system dysfunction. In general, preoperative dysfunction of each of a particular organ system makes the risk of postoperative complications involving that organ system more likely. It is therefore essential to assess these organ systems preoperatively by history, physical exam, and special studies as needed.

## INTRAOPERATIVE COMPLICATIONS

The most common, immediately life-threatening intraoperative complications of pulmonary resection not related to anesthesia

management are massive hemorrhage, cardiac ischemia, arrhythmias, and contralateral pneumothorax. Common intraoperative complications that cause significant morbidity and mortality postoperatively are nerve injuries and injuries to the esophagus and thoracic duct.

## Hemorrhage

Massive intraoperative hemorrhage is usually the result of an injury to a pulmonary artery or vein branch sustained during dissection. The pulmonary artery and its branches are especially thin walled and easily injured during manipulation or traction employed to increase exposure. In contrast, the walls of the pulmonary vein are more resilient and withstand surgical manipulation much better. The risk of a difficult dissection and pulmonary artery injury can be anticipated in patients who have had induction chemotherapy or prior irradiation. In addition, patients with mediastinal granulomatosis or prior silica exposure will have regional bronchopulmonary lymph nodes densely adherent to branch pulmonary arteries. In such cases, it is prudent to begin the surgical dissection by encircling the ipsilateral main pulmonary artery and both pulmonary veins to obtain proximal and distal control in the event of vessel injury.

Because the pulmonary circulation is under low pressure, arterial and venous injury can usually be immediately controlled with local pressure at the injury site. It is necessary, when massive hemorrhage occurs, that the surgeon make an immediate analysis, knowing the site and magnitude of the injury, of what will be required to control the bleeding. This often requires calling for additional assistance in the operating room. With additional help and a good plan of attack, it is usually possible to readily obtain control, and perform a fine nonabsorbable suture. Rarely, injury to the main pulmonary artery, left atrium medial to the pulmonary vein, or superior or inferior vena cava will require cardiopulmonary bypass to control the situation for adequate repair.

In addition, injuries to bronchial arteries, parenchymal surfaces, pleural adhesions, as well as intercostal and internal mammary vessels can also lead to significant intraoperative blood loss if they go unnoticed. It is important to use careful dissection techniques at all times during the conduct of the operation to avoid injury to these structures and to control them quickly when they occur.

## Ventilatory Complications

A host of problems can occur and put the gas exchange of the patient at risk. If ventilation is established through a double-lumen endobronchial tube or a single-lumen tube with a bronchial blocking balloon, it is essential that the surgeon as well as the anesthesiologist be confident that it is in the correct position before starting the resection. The surgeon must also be aware of the presentation of tube displacement. High airway pressure and absent $CO_2$ in the ventilator circuit indicates that the bronchial cuff has herniated into the trachea producing an effective tracheal obstruction. Deflation of the cuff solves the problem and advancement of the tube prevents the problem from reoccurring. While conducting a right-sided resection with ventilation only on the left, persistent hypoxemia suggests that the left limb off the double-lumen

tube has advanced too far and is occluding the left upper lobe orifice. This problem is sometimes first detected by the attentive surgeon, who recognizes that the usual ventilatory movement of the mediastinum is absent because of the progressively atelectatic left upper lobe. Withdrawal of the tube solves the problem.

Occasionally, it is necessary to change the endotracheal tube during resection. During resection of central T2 or T3 lesions, the endobronchial cuff may be injured or the tube may interfere with the bronchial resection or repair. The surgeon can assist with tube change by fixing a heavy suture to the distal end of the tube to be changed. After it is withdrawn, the anesthesiologist affixes the new tube to the suture. Traction on the suture by the surgeon helps guide the tube into position.

Patients undergoing thoracotomy for lung cancer resection as a rule are more susceptible to barotrauma pneumothorax because of preexisting bullous emphysema. Pneumothorax can occur at the time of induction and onset of positive pressure ventilation or, at any point, during the actual operation on the contralateral side. The surgeon should be aware of this development because airway pressures will increase, and the rhythmic movement of the mediastinum will be absent. Indeed, the mediastinum will sometimes balloon out toward the operative side. The problem is easily remedied by opening the mediastinal pleura.

## Nerve Injury

Nerve injuries occur in 1% to 2% of patients undergoing surgery for lung cancer. The recurrent laryngeal nerve as well as the phrenic nerve are generally considered the most important nerves encountered during lung cancer surgery. However, musculocutaneous nerves, such as the long thoracic nerve, can also be injured directly during dissection or by traction injuries during exposure. Injury to the phrenic nerve most often occurs when tumors are adherent or directly adjacent to the nerve with injury resulting in hemidiaphragm paralysis. Diaphragm plication may improve symptoms of dyspnea and breathlessness following phrenic nerve injury although the relative benefit remains controversial.[24]

The recurrent laryngeal nerve provides ipsilateral motor innervation to the intrinsic laryngeal muscles for vocalization. Injury to the nerve unilaterally may result in hoarseness or a weak voice, whereas bilateral nerve injury frequently results in a compromised airway with associated respiratory distress in the immediate postoperative period. The right recurrent laryngeal nerve can be injured during resection of apical tumors on the right as it originates from the vagus nerve at the level of the right subclavian artery medially. The left recurrent laryngeal nerve can be injured during mediastinoscopy as well as during dissection of level 5 and 6 lymph nodes or during dissection of tumors adjacent to the preaortic and subaortic region on the left side. Unilateral nerve injury significantly increases the risk of aspiration and pneumonia following lung resection. Direct laryngoscopy is diagnostic, and strict precautions should be undertaken to avoid aspiration when the diagnosis is made. Several surgical techniques are available to improve vocal cord function after injury if symptoms are debilitating or if they do not improve with speech therapy.

# POSTOPERATIVE COMPLICATIONS

**General Considerations**    There are many complications that can arise after pulmonary resection, and some can be fatal if not recognized and managed early and aggressively. Attention to patient symptoms, clinical exam, and routine chest x-rays (CXR), in addition to a high level of suspicion during the postoperative period, will help the clinician identify complications and manage them effectively.

## Airway Complications

**Sputum Retention**    Poor airway hygiene is a significant life-threatening problem in the postthoracotomy patient. Factors such as postoperative pain and compromised mental status lead to inability to deep breathe and cough with subsequent retention of airway secretions. These airway secretions can go on to plug the airways causing atelectasis, lobar collapse, pneumonia, and respiratory failure. Specific patients at risk for postoperative sputum retention are current smokers and patients with a history of chronic obstructive pulmonary disease (COPD), cerebrovascular accident (CVA), or ischemic heart disease, and those without regional analgesia.[25] Prophylactic measures should be considered in these patients to reduce the incidence of sputum retention. An important maneuver to reduce this risk preoperatively is smoking cessation prior to elective thoracotomy. Vaporciyan et al.[26] demonstrated that patients undergoing pneumonectomy who continued to smoke within 1 month of operation were at increased risk for developing pneumonia and acute respiratory distress syndrome (ARDS). Chest physiotherapy, including coughing, early ambulation, incentive spirometry, and percussion with postural drainage, is the standard for postoperative prophylaxis and therapy for sputum retention. However, patients with recalcitrant sputum retention may require intermittent bronchoscopy to aspirate secretions and stimulate a more vigorous cough. Some surgeons recommend liberal use of minitracheostomy tubes in high-risk patients as a form of prophylaxis and treatment. The minitracheostomy tube allows immediate and repeated aspiration of the tracheobronchial tree. It is placed percutaneously through the cricothyroid membrane either at the time of surgery or at the bedside postoperatively. In a prospective randomized trial of 102 high-risk patients, Bonde et al.[27] found that prophylactic use of minitracheostomy tubes significantly lowered the incidence of sputum retention. Similarly, Au et al.[28] reported decreased need for suction bronchoscopy in patients who had undergone minitracheostomy tube placement.

**Lobar Torsion**    Lobar torsion is a rotation of the remaining lobar bronchovascular pedicle with resultant airway obstruction, vascular compromise, and gangrene. This is a rare but life-threatening complication with an associated mortality of 12% to 16%.[29] The incidence of lobar torsion after pulmonary resection is 0.09% to 0.3%.[30–32] Lobar torsion after right upper lobe resections accounted for 70% of the cases in the literature, whereas 15% involved the left lower lobe following resection of the left upper lobe. The majority of lobar torsions involve the right middle lobe. As with most complications, prevention is the key. The surgeon should visualize the remaining lung fully inflated to ensure proper orientation after every pulmonary resection.

The presentation of lobar torsion may be dramatic, especially in the early postoperative period. Physical findings may include fever, tachycardia, sudden cessation of a previous air leak, and loss of breath sounds over the affected lung field. Computed tomography (CT) is more sensitive than CXR in the evaluation of these patients. Radiologic findings include rapid opacification or serial positional change of the affected lobe, complete opacification of the involved lung or inversion of the vascular pattern. However, immediate bronchoscopy is the most expedient diagnostic modality to confirm suspected lobar torsion. Bronchoscopy reveals a compressed bronchus with a fishmouth appearance.

Exploratory thoracotomy must be performed without delay. The involved lobe or lung is untwisted to assess its viability. If the diagnosis is made early, the involved lobe may be viable and fixation may be all that is necessary. However, when a gangrenous lobe or lung is rotated back into normal position, the airways may be flooded with serosanguineous fluid. It is, therefore, prudent to use a double-lumen endotracheal tube to prevent soilage of the remaining lung. Many times, the involved lobe or lung must be resected. The concern for lobar torsion has lead to the common practice of prophylactic fixation of the middle lobe to the lower lobe after right upper lobectomy if the oblique fissure is complete to prevent middle lobe torsion.

**Bronchopleural Fistula**    After pulmonary resection, a communication between the airway and the pleural space can establish itself in the form of a bronchopleural fistula. This is a serious and potentially life-threatening complication that can occur after pulmonary resection. The incidence of bronchopleural fistula after pulmonary resection ranges from 1.6% to 6.2%.[33] A multivariate analysis of 1360 pulmonary resections demonstrated that risk factors for bronchopleural fistula include wider resection such as pneumonectomy, residual cancer at the bronchial stump, preoperative radiation therapy, and diabetes mellitus.[34] Subsequent mortality after bronchopleural fistula was 71%. It has also been noted that postpneumonectomy bronchopleural fistula is more likely to occur on the right side. Postlobectomy bronchopleural fistula is exceedingly uncommon except following bilobectomy involving the right middle and lower lobes. Other situations have been shown to predispose to the development of bronchopleural fistula (e.g., radical mediastinal lymphadenectomy, and resections for infectious or inflammatory disease).

Whether to staple or suture the bronchus at the time of resection is a continuing source of controversy in thoracic surgery. In experimental conditions, El-Gamel et al.[35] found that hand sutured bronchi tolerate higher inflation pressures compared with stapled ones before leaking air but at supraphysiologic pressures (200 vs. 105 mm Hg, respectively). Clinically, both manual suture[36] and stapled closure[37] have been found to be

safe and reliable methods of bronchial stump closure. There has been no definitive study to show that one method is superior to the other. However, in cases in which close bronchial margins are likely, it is better to cut the bronchus with a scalpel and close the bronchial stump by suturing to avoid the possibility of residual cancer at the bronchial stump. In addition, patients with any of the previously described risk factors should have preventive pedicled flap coverage at the time initial resection.

During the early postoperative period (1 to 2 days), the most likely cause of bronchopleural fistula is technical failure. This usually manifests as a massive air leak from the chest tube and progressive increase in subcutaneous emphysema. These early fistulae should be repaired surgically and the bronchial stump securely covered with a viable pedicled flap. Bronchopleural fistula sustained later in the postoperative course are usually caused by bronchial stump ischemia secondary to extensive dissection, or the presence of infected pleural fluid with resulting rupture of the empyema through the bronchial stump closure. At this point, the patient will typically develop a cough with expectoration of serosanguineous, frothy fluid. Efforts to protect the contralateral lung should be instituted such as placing the operated side down and prompt drainage of the infected pleural space. The bronchopleural fistula, which occurs later

than 2 weeks, is also likely secondary to an infected pleural space. However, the patient is more likely to present with sepsis, and the sputum is more likely to be purulent. In addition, these patients may have a more indolent presentation. In fact, patients may present with minimal symptoms yet demonstrate a fall in the air fluid level on radiographs, suggesting a fluid leak into the airway (Fig. 39.1). The diagnosis of bronchopleural fistula can be confirmed by bronchoscopy, bronchography, or radionuclide inhalation imaging.

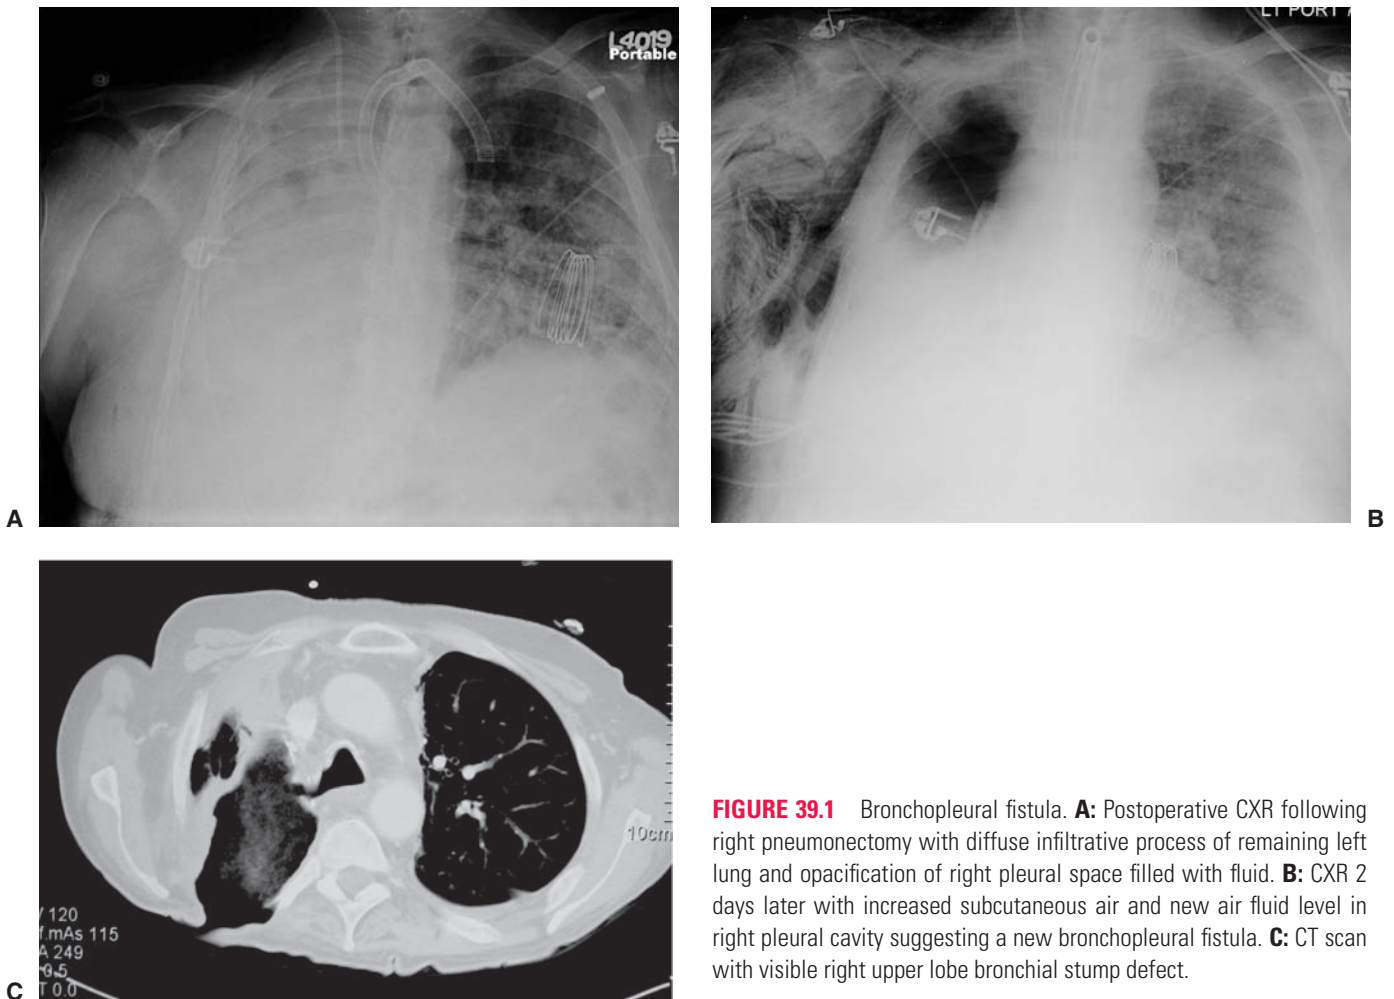
Initial management of bronchopleural fistula involves drainage of the involved pleural space and dependent drainage of the operative side to prevent soiling of the uninvolved lung. Subsequent management is based on timing after surgery and the presence or absence of sepsis. An early bronchopleural fistula (first 7 days) is unlikely to have significant pleural space infection and is usually caused by a technical problem. These should be reexplored with bronchial stump closure and covered with a flap of muscle, pericardium, or omentum. A bronchopleural fistula, which develops later than the first week is less likely to be the result of a technical problem and should not be treated with immediate stump reclosure. A delayed bronchopleural fistula is usually associated with some degree of empyema and requires immediate chest tube drainage of the infected


**FIGURE 39.1** Bronchopleural fistula. **A:** Postoperative CXR following right pneumonectomy with diffuse infiltrative process of remaining left lung and opacification of right pleural space filled with fluid. **B:** CXR 2 days later with increased subcutaneous air and new air fluid level in right pleural cavity suggesting a new bronchopleural fistula. **C:** CT scan with visible right upper lobe bronchial stump defect.

space and appropriate antibiotic therapy. If the fistula is not large and there is remaining lung in the pleural space, spontaneous closure will often occur with this management alone.

A detailed discussion of the management of postpneumonectomy bronchopleural fistula is beyond the scope of this chapter. The traditional management approach involves three separate procedures; early open drainage, closure of the fistula, and subsequent closure of the cavity. Open window thoracoplasty such as Eloesser flap or Clagett window provides excellent drainage, prevents soilage of the contralateral lung, and creates a large opening for insertion of sterile packing. Ordinarily, a period of several weeks or months of intensive dressing changes are required to get the pleural cavity clean and covered with healthy granulation tissue. Indeed, depending on the overall status of the patient and the anticipated technical challenges of possible closure, the best option for the patient may be a permanent open-window thoracostomy.

The strategy for fistula repair depends on the location of the fistula. Direct dissection and primary repair of the bronchopleural fistula is usually impossible. Lobar fistulae can usually be successfully covered with a pedicled muscle flap or omentum. Depending on the bulk of the flap and the size of the pleural space, this coverage procedure may also serve to fill the cavity and achieve simultaneous closure of the cavity. For postpneumonectomy bronchopleural fistulae, there are several options for fistula closure. If there is some length of main bronchus proximal to the fistula, the main bronchus can be sealed and divided proximal to the fistula. A transsternal, transpericardial approach provides access to either main bronchus by retracting the superior vena cava and ascending aorta laterally. If there is inadequate bronchial length, closure of the fistula by muscle flap or omentum is the best option. In this circumstance, depending on bulk of flap and size of pleural space, the flap may completely fill the cavity. If not a subsequent rotation or free-flap procedure may be necessary to fill the cavity.

**Postpneumonectomy Syndrome**   Tracheobronchial obstruction may occur after pneumonectomy associated with severe mediastinal shift. This is a rare complication most commonly seen after right pneumonectomy in which the left mainstem bronchus is displaced toward the side of the pneumonectomy resulting in its compression between the thoracic spine and the aorta or pulmonary artery (Fig. 39.2). It can also be seen after left pneumonectomy in patients with a right aortic arch. It has a late clinical presentation with findings of dyspnea on exertion, ineffective cough, expiratory stridor, difficulty clearing secretions, and recurrent pulmonary infections. Complete shift of the heart and mediastinum into a hemithorax devoid of fluid is usually seen on chest radiograph. Chest CT clearly demonstrates the mediastinal shift and cardiac rotation as well as compression of the mainstem bronchus between the vertebral body and the aorta or pulmonary artery.

Management of postpneumonectomy syndrome involves repositioning the mediastinum back toward the midline, thereby relieving the bronchial obstruction. This can be done with cardiopexy and placement of autologous tissue or an expandable prosthesis placed in the pneumonectomy space (Fig. 39.2).[38,39] Aortic division and bypass has been utilized for this problem with less favorable results. In some patients with longstanding airway compression, bronchomalacia can develop which significantly lowers the efficacy of mediastinal repositioning. Placement of bronchial stents has also been described for relief of postpneumonectomy airway obstruction.[40] This may prove useful for patients with associated bronchomalacia.

## Parenchymal Complications

**Postresection Pulmonary Edema**   Noncardiogenic pulmonary edema is a rare but lethal complication of major lung resection. The incidence is 2% to 5% after pneumonectomy (right more common than left) and 1% after lobectomy.[41,42] This complication is often fatal with mortality rates of 30% to 100%. Consistent findings include onset 24 to 72 hours after surgery, diffuse interstitial infiltration to frank alveolar edema on chest radiograph (Fig. 39.3) and CT scan, progressive hypoxia, and overall rapid clinical decline. These patients have no evidence of heart failure, pneumonia, pulmonary emboli, or fluid overload.

It has been thought that the edema is caused by intraoperative or postoperative fluid overload. In a retrospective study by Parquin et al.,[43] multivariate analysis identified prior radiotherapy, perfusion of the remaining lung of 55% or less and high intraoperative fluid load as independent risk factors for postpneumonectomy pulmonary edema. Zeldin et al.[44] as well as Verheijen-Breemhaar et al.[45] found overhydration to be a common precipitating factor in these cases. However, Turnage and Lunn[46] found no association between fluid balance and the development of edema. Other factors such as increased permeability and filtration pressure[12] and decreased lymphatic drainage from the affected lung are thought to play a more important role.

Given the rapid progression of this syndrome, therapy must be early and aggressive including early intubation and mechanical ventilation, aggressive diuresis to improve fluid balance, broad-spectrum antibiotic coverage, and aggressive pulmonary toilet such as bronchoscopy and frequent position changes of the patient (to include prone and lateral positioning during mechanical ventilation). Steroid therapy has been recommended by some but has no proven benefit. Mathisen et al.[47] found early use of inhaled nitric oxide to be a useful strategy in these patients.

As this condition most commonly occurs following right pneumonectomy, there is a distinct risk of bronchopleural fistula, if mechanical ventilation is required. This risk can be minimized by immediate tracheostomy and insertion of an endotracheal tube, which can be advanced into the left main bronchus to accomplish positive pressure ventilation without exposing the bronchial stump to positive pressure. Using this ventilatory strategy and the other techniques described previously, we have had success in salvaging some patients with this devastating problem.

**Postoperative Pneumonia**   Postoperative pneumonia continues to be a significant cause of morbidity and mortality after major thoracic procedures. The incidence of pneumonia after
**FIGURE 39.2**  Postpneumonectomy syndrome. Chest radiograph showing mediastinal shift into pneumonectomy space **(A)**. Chest CT scan showing complete displacement of mediastinal structures with compression of the left mainstem bronchus against the vertebral column **(B)**. Chest CT scan showing expandable saline implants used to reposition the mediastinum back to midline **(C)**.

**FIGURE 39.3**  Postpneumonectomy pulmonary edema after right pneumonectomy. CXR on postoperative day 1 **(A)**. Several hours later, the patient was intubated for acute hypoxia. The endotracheal tube was advanced over a bronchoscope into the left main bronchus to protect the right pneumonectomy stump. The chest radiograph shows severe diffuse interstitial infiltrates of the remaining left lung **(B)**.

pulmonary resection is 5.3% to 11.7%.[9,31,48] In a retrospective study, Kutlu et al.[49] found pneumonia to be the cause of 5% of all deaths after pulmonary resection. Risk factors for the development of postoperative pneumonia include preoperative pneumonia, postoperative sputum retention, current smoking status, poor mental status, poor pain control, COPD, bronchitis, immunodeficiency, and prolonged ventilator support.

Prophylactic measures to avoid postoperative pneumonia include preoperative smoking cessation, good postoperative airway hygiene, and good postoperative pain control with routine epidural catheter use. The use of prophylactic antibiotics is controversial. Older reports have shown that prophylactic antibiotics do not protect against the development of pneumonia after pulmonary resection.[50,51] However, these studies assessed the efficacy of first-generation cephalosporins and penicillin, which may lack effectiveness against the common causes of pneumonia such as Gram-negative bacteria or *Staphylococcus aureus*. Other studies have shown the benefits of cephalosporins for wound infection.[52,53] Today, it is common practice to use first-generation cephalosporins for pulmonary resections, although the benefit for prevention of postoperative pneumonia is still lacking. In a randomized study of 212 patients, cephalothin was effective in reducing wound infections, although there was no statistically significant change in the rate of pulmonary infections.[53] In a prospective randomized study using broader coverage, sulbactam plus ampicillin was more effective than cefazolin in preventing postoperative pulmonary infections.[54] The initial dose should be administered such that levels are highest at the time of incision.

It is often difficult to determine the etiology of postoperative pneumonia as many patients may have some degree of postobstructive process preoperatively from the tumor. It can also be difficult to determine the difference between true infection and airway colonization associated with a chronic condition such as COPD and bronchitis. In general, postoperative patients with persistent fever, elevated white blood cell count, purulent sputum, pathogenic bacteria from endotracheal aspirate, and persistent infiltrate on CXR should be aggressively treated for pneumonia with appropriate antibiotic coverage, chest physiotherapy, and dependent drainage. The most common responsible organisms are Gram-negative rods and *S. aureus*. Although most pneumonias are bacterial in nature, the possibility of other causes such as viral, fungal, *Legionella* and *Mycoplasma* should be entertained in patients that do not respond to antibiotic therapy. The index of suspicion should be higher in patients who are immunocompromised. Antibiotic therapy should be adjusted on the basis of tracheobronchial culture results.

## Pleural Space Problems

**Residual Air Space and Prolonged Air Leaks**    During the normal conduct of partial lung resection for lung cancer, there can be small injuries to the visceral pleura resulting in air leaks. These small visceral pleural injuries can be minimized with meticulous technique. Normally, these small air leaks are impeded by apposition of pleural surfaces once the lung is reexpanded, resulting in termination of the leak. A residual air space exists when there is failure to fill the chest cavity after reexpansion of the lung. Greater amounts of parenchymal resection increase the risk of residual air space such that bilobectomies and lobectomies have a higher rate of residual air space than segmentectomies and wedge resections. Usually, the space is noted at the apex after upper lobectomy but can also be found at the base near the diaphragm after other types of resections. Although persistent residual air space is a common cause of persistent air leak, many patients will not suffer any other morbidity from this problem. The space gradually disappears over several weeks, secondary to reabsorption of gases within the space, further reexpansion of the lung, and pleural peel formation. When a residual air space is associated with symptoms such as pain, dyspnea, hemoptysis, or fever, a bronchopleural fistula should be suspected and requires appropriate intervention with thoracostomy tube placement.

Prolonged air leak is generally defined as an air leak that persists more than 7 days after surgery. It is the most common complication seen after pulmonary resection and the most common reason for prolonged hospital stay. Prolonged air leak occurs in 4% to 15% after partial lung resection.[51,55] It is responsible for approximately 25% of all morbidity after lung resection. It also increases patient discomfort, cost of care, and utilization of resources. The most consistent risk factor for prolonged air leak is severe obstructive pulmonary disease.[56,57] Other potential risk factors for prolonged air leak include advanced age, pleural adhesions, preoperative steroid use, and induction chemotherapy or radiation therapy.

Preoperative awareness of increased risk for prolonged air leaks should engender extra measures in addition to meticulous technique during the operation to help prevent them. The use of bovine pericardial strips as a buttress along the lung staple line to decrease air leaks was first described for lung volume reduction surgery.[58] However, their efficacy for completing fissures during lobectomy and segmentectomy is unclear. Previously, Venuta et al.[59] found that the use of pericardial strips to complete interlobar fissures for pulmonary lobectomy significantly reduced the duration of postoperative air leaks and hospital stay. More recently, in a randomized controlled group of 80 patients, Miller et al.[60] found a trend but no statistically significant improvement in prolonged air leak rate after lobectomy and segmentectomy when utilizing buttressed staple lines. The use of synthetic (polytetrafluoroethylene or vicryl) sleeves has also been described, but more data is needed to examine efficacy.

Other measures to reduce the incidence of prolonged air leak in the high-risk patient are maneuvers, which displace the potential residual space to an extrapleural position, thereby making apposition of pleural surfaces more likely. One common practice is the creation of a pleural tent. In a prospective randomized study of 200 patients undergoing upper lobectomy, Brunelli et al.[61] found that pleural tenting reduced the duration of air leaks and the hospital costs. Similarly, a randomized study by Okur et al.[62] and a retrospective study by Robinson and Preksto[63] showed that pleural tenting following

lobectomy shortens the duration of chest tube drainage and hospital costs. A second way to limit the potential residual pleural air space is to elevate the diaphragm by insufflating air into the peritoneal cavity. Pneumoperitoneum has been described to treat air leaks and residual spaces after lung volume reduction surgery.[64] Subsequently, De Giacomo et al.[65] described its use after pulmonary resection. In a prospective randomized study of 16 patients undergoing bilobectomy, Cerfolio et al.[66] showed that intraoperative creation of pneumoperitoneum decreased the incidence of air leaks and shortened hospital stay without increasing morbidity.

A third measure, which has been used to lower the incidence of prolonged air leak, is the use of biologic sealants. Their effectiveness is controversial. Previously, it was shown that fibrin glue is not effective in reducing the duration of air leaks after lobectomy.[67,68] More recently, Fabian et al.[69] showed in a randomized study that fibrin glue reduced the rate of postoperative air leak from 15% to 2% after lung resection. Similarly, Wain et al.[70] found that the use of fibrin glue treated patients had a mean air leak time of 31 hours, whereas untreated patients had a mean air leak time of 52 hours. Although this difference was significant, there was no reduced time to chest tube removal and earlier hospital discharge. Further study is needed to determine patient selection and cost-effectiveness for the use of fibrin sealants to prevent prolonged air leak.

Despite preventive measures, many patients go on to develop prolonged air leak. Although this is the most common problem thoracic surgeons deal with in the postoperative period, there is no consensus on the management. Most surgeons believe that conversion from suction to water seal is an effective way of encouraging an air leak to seal. Development of a pneumothorax in the setting of an expiratory air leak is uncommon. This is supported by a study by Cerfolio et al.[71] in which 33 patients with postoperative air leak were randomized to continued suction versus water seal on postoperative day 2. In this study, 67% of the patients treated with water seal versus 7% of the patients that remained on suction had air leak resolution by postoperative day 3. Air leaks that do not resolve on water seal should be placed on a Heimlich valve once the fluid drainage is minimal. The patient can be discharged to home with the chest tube and Heimlich valve in place as long as there is no new or enlarging pneumothorax on chest radiograph. Outpatient chest tube management is well tolerated and desirable for the patient as it avoids prolonged hospitalization. Most air leaks stop after several days, and the chest tube can be removed at that time. The chest tube can usually be removed at 2 to 3 weeks even if the air leak is still present because the formation of pleural adhesions prevent further lung collapse and tension pneumothorax.

**Postresection Empyema**    Although less common than in the early years of thoracic surgery, empyema still occurs in 2% to 12% of patients after pneumonectomy and 1% to 3% after lobectomy. This complication is often associated with a bronchopleural fistula, leading to a further increase in morbidity and mortality. In addition to the presence of bronchopleural fistula, other factors such as poor pulmonary function, lower preoperative serum hemoglobin, right pneumonectomy, completion pneumonectomy, and lack of bronchial stump reinforcement have been shown to be associated with the development of postresection empyema.[72] It is also believed that the use of neoadjuvant and adjuvant therapy also contribute to the development of postresection empyema. For postpneumonectomy empyema, the perioperative mortality rate is 12% to 40%.

The diagnosis of empyema is suspected in any patient with signs and symptoms of infection after lung resection. Development of serosanguinous sputum, purulent chest tube or wound drainage are also highly suspicious findings. Imaging studies consistent with empyema are pleural opacity with or without an air-fluid level after partial lung resection or a new or falling air fluid level after pneumonectomy (Fig. 39.1).

Once the diagnosis of postresectional empyema is made or strongly suspected, immediate management includes closed chest tube thoracostomy as well as appropriate antibiotic therapy. Once adequate drainage has been established and the patient is stabilized, the appropriate definitive management can be decided. Factors determining definitive management include presence or absence of bronchopleural fistula, partial lung resection versus pneumonectomy, stability of the patient and need for positive pressure ventilation. The traditional management approach involves three separate procedures as previously outlined for bronchopleural fistula management; early open drainage, closure of a fistula if present, and subsequent closure of the cavity as previously outlined. Several weeks of dressing changes are usually required to get the pleural cavity clean and covered with healthy granulation tissue. Patients deemed unsuitable for definitive closure can be managed with open window thoracostomy and dressing changes indefinitely. A more aggressive approach for management of postpneumonectomy empyema utilizes VATS techniques for debridement in conjunction with antibiotic irrigation. In a small series of patients with postpneumonectomy empyema with no evidence of bronchopleural fistula, this technique, using antibiotic irrigation for 10 days, was successful in the treatment of empyema with prevention of the need for open drainage in 89% (16/18) of patients.[73] Further data is needed to assess the efficacy of this technique in a larger group of patients.

**Chylothorax**    The incidence of chylothorax after thoracotomy is less than 1%.[74,75] When untreated, the mortality from this complication can be as high as 50%. The additional morbidity is caused by the metabolic and mechanical insults of nutritional deficiency, dehydration from volume loss, immunosuppression from lymphocyte depletion, and pulmonary dysfunction.

The etiology of chylothorax involves injury to the thoracic duct or one of its tributaries. The thoracic duct carries intestinal lymph from the cisterna chyli to the venous system at the junction of the left internal subclavian veins. The fat contained in chyle is what gives it its characteristic appearance. The main cellular components of chyle are lymphocytes. Injury to the thoracic duct or one of its tributaries may occur while dividing the pulmonary ligament, mediastinal lymph

node dissection, or pleural flap creation along the thoracic aorta. It can occur after upper or lower lobectomy and pneumonectomy on either side.

The diagnosis is suspected by the findings of high volume (500 to 1200 cc/day), milky chest drain output, or thoracentesis fluid postoperatively. Occasionally, a patient may have high-volume output but the fluid is not milky in character. In these cases, the diagnosis can be confirmed by giving the patient a fat challenge with cream by mouth. This will turn the chest drain output milky if chylothorax exists. Microscopic examination of the chest drainage will show the presence of fat globules that stain positive with Sudan-3. In addition, the chest drainage can be tested for triglyceride levels, which will be elevated in the case of chylothorax.

The initial management of postoperative chylothorax is maintenance of effective chest drainage, cessation of enteral feeds and implementation of central total parenteral nutrition. In approximately 50% of patients, the leak will stop with this therapy alone. There is no standard recommendation for the period of time to wait for spontaneous leak closure. However, most would agree that if the drainage remains greater than 500 cc per day for several days, then operative intervention is mandatory unless there is a contraindication to thoracotomy. Many groups recommend early reoperation and thoracic duct ligation in patients with higher chest tube outputs that increase or fail to respond to conservative management within 1 to 7 days.[76–78] Our technique of thoracic duct ligation involves a mass ligature technique, encircling all tissue between the azygos vein, esophagus, and aorta immediately above the diaphragm, and not at the fistula site. Other techniques described in the management of postoperative chylothorax include pleuroperitoneal shunting[79] and percutaneous catheterization with thoracic duct embolization.[80] In addition, somatostatin has proved useful for the conservative management of chylothorax of other causes and may be used as an adjunct but is rarely useful in a large volume chylothorax.[81] More data is needed to determine the benefit of these techniques over traditional reoperation and thoracic duct ligation.

## Complications of Bronchoplastic Procedures

A worthwhile alternative to pneumonectomy for proximal lung tumors is sleeve lobectomy. In addition to preserving pulmonary function, these bronchoplastic procedures are associated with lower morbidity and mortality. However, bronchoplastic procedure complication rates exceed those of lesser resections. In a review of 1915 bronchoplastic procedures for malignancy, Tedder et al.[82] found the mortality rate to be 7.5%.

Patients tend to be particularly susceptible to sputum retention caused by edema at the bronchial anatomists in the early postoperative period after sleeve resection. Good postoperative airway hygiene is crucial in these patients. Liberal use of bronchoscopy or minitracheostomy can be very helpful. In addition, there are complications that are specific to bronchoplastic procedures such as bronchial anastomotic dehiscence (3.5%), bronchial stenosis (5.0%), bronchopleural fistula (3.5%), and bronchovascular fistula (2.6%). Similar to traditional pulmo-

nary resections, comorbidities such as preexisting poor pulmonary function and cardiovascular disease significantly influence the postoperative complication rate. Bronchial anastomotic dehiscence is caused by impaired healing with resulting necrosis of the bronchial mucosa and subsequent bronchopleural fistula formation. These small areas of bronchopleural fistulae at the anastomosis usually heal over time. However, occasionally, these small defects can progress to complete dehiscence, especially in patients who require mechanical ventilation. Bronchoscopy can be used to assess the extent of bronchial wall necrosis in these patients. Hemoptysis after sleeve resection is concerning for erosion of the bronchial anastomosis into a nearby blood vessel, usually a branch of the pulmonary artery. The mortality of this complication is high and mandates immediate reexploration. Anastomotic stenosis is a late complication with an incidence between 2% and 5%. It can be caused by granulation tissue or an interrupted blood supply or anastomotic dehiscence with secondary healing and stricture formation. Management consists of bronchoscopic removal of the granulation tissue and repeated dilatation. Stents may be useful. In recalcitrant cases, re-resection with redo anastomosis or completion pneumonectomy may be necessary.

## Cardiovascular Complications

**General Considerations** Given the high degree of associated mortality, cardiovascular complications are among the most concerning. Overall, noncardiac thoracic surgery is considered intermediate risk as a category of procedures by the American College of Cardiology and the American Heart Association with an overall risk of less than 5% for perioperative myocardial infarction (MI) and related mortality.[83] A comprehensive review of the recommendations for preoperative cardiac risk assessment has recently been updated by Eagle et al.[84] In general, the presence of preexisting heart disease is the greatest risk factor for the development of postoperative cardiovascular complications.

**Cardiac Ischemia and Arrhythmias** Patients with preexisting cardiac disease are at greatest risk for perioperative cardiac ischemia and infarction. It is important to identify these patients based on history, physical exam, and preoperative testing to determine the need for prophylactic measures to avoid cardiac ischemia. For MI the importance of preexisting heart disease is characterized in a review of the literature by Herrington and Shumway[73,85] with a reported incidence of postoperative MI of 0.13% in patients with no prior history and between 2.8% and 17% for patients with a prior history of heart disease. Postoperative MI is associated with mortality as high as 32%.[86] Recently, the American College of Cardiology and the American Heart Association published recommendations for patients who should undergo preoperative evaluation with a cardiac stress test.[84] Under these guidelines, patients are categorized into one of three risk strata based on their medical history, cardiac symptoms, and exercise tolerance. Clinical factors that characterize the highest risk group that should not have an elective noncardiac operation are unstable angina,

decompensated congestive heart failure (CHF), severe valvular disease, and significant arrhythmias. Intermediate risk factors that indicate the need for a preoperative stress test, depending on the planned operation and exercise tolerance are a history of prior MI, mild angina, compensated CHF, diabetes, renal insufficiency. Factors that place patients in the low-risk strata are old age, uncontrolled hypertension, history of stroke, low functional capacity, and an abnormal electrocardiogram (EKG). Patients in this group do not necessarily require preoperative testing under the current guidelines, unless they are unable to exercise at the level of four METs (metabolic equivalents). These guidelines help the clinician council patients about the risk of perioperative MIs and identify patients that will benefit from perioperative prophylactic measures or perhaps should have their planned operation delayed until coronary intervention is undertaken.

Perioperative MIs are thought to occur by one of two pathways that occur with an equal incidence. Patients with fixed high-grade coronary stenosis may have perioperative MI during times of cardiac stress associated with tachycardia. Other patients have perioperative MI as the result of relatively low-grade plaques that rupture and cause coronary thrombosis.[87] MIs that result from high-grade lesions tend to occur in the first 24 hours, following surgery and are tightly associated with episodes of tachycardia.[88] Patients having MIs as the result of plaque rupture occur with no particular peak incidence in the first 30 postoperative days.[87]

Perioperative heart rate control is critical for the prevention of MI occurring from high-grade coronary lesions. Several prospective randomized studies have shown a significant reduction in perioperative MI and death when $\beta$-blockers are used in patients with significant coronary risk factors.[89–91]

Indications for cardiac catheterization are similar to those in patients not being evaluated for surgery. They include evidence of ischemia on noninvasive testing, angina unresponsive to medical therapy, unstable angina, and equivocal noninvasive test results in patients at high-clinical risk. In general, patients found to have significant coronary artery disease amenable to vascular reconstruction should have an intervention; either at the time of the cardiac catheterization via percutaneous technique or coronary artery bypass grafting (CABG). The Coronary Artery Surgery Study (CASS) database evaluated almost 25,000 patients with known or suspected coronary disease and looked at outcomes after CABG versus medical therapy. Eagle et al.[92] looked at 1961 patients in this study who underwent major noncardiac surgery, including thoracic procedures. They found significantly lower rates of MI and perioperative death in the group that had known coronary artery disease managed with CABG rather than medical treatment. This data implies that percutaneous coronary interventions would also offer a benefit to these patients. Whether the benefit is greater than CABG because of lower morbidity and shorter recovery, time is unclear as patients who undergo percutaneous intervention are routinely placed on antiplatelet agents for at least 2 to 6 weeks, making lung resection unsafe immediately after percutaneous coronary interventions as well.

**Cardiac Arrhythmias** By far, the most common cardiac complication after thoracic surgery is supraventricular tachycardia (SVT). Ninety-five percent of SVT is atrial fibrillation with the rest being atrial flutter and multifocal atrial tachycardia. The incidence of SVT after thoracic surgical procedures ranges from 9% to 33%. Clinically significant ventricular arrhythmias are rare. Advanced age and the presence of COPD are the most common factors that predispose patients to develop SVT after lung resection for cancer. Other risk factors for the development of SVT include coronary artery disease, CHF, and valvular disease. Surgical risk factors for the development of SVT are increasing extent of resection (Table 39.3) and need for intrapericardial dissection. VATS procedures may be associated with a decrease in the incidence of postoperative SVT although others have suggested that the VATS approach does not alter the incidence compared to open resections.[93] Patients without preexisting cardiac dysfunction can also be exposed to intraoperative physiologic alterations that can cause intraoperative arrhythmias such as hypothermia, hypoxemia, hypokalemia,

| TABLE 39.3 | Incidence of Supraventricular Tachychardia according to Extent of Resection for Malignancy at Barnes-Jewish Hospital, 2003–2006 | | |
|---|---|---|---|
| **Lung (n = 695)** | **N** | **Dysrhythmia** | **%** |
| Wedge | 74 | 6 | 8.1% |

| **TOTAL** | **695** | **136** | **19.6%** |

hyperkalemia, hypovolemia, and acidosis. These problems must be corrected as soon as possible when they occur.

Most patients who develop SVT after pulmonary resection do so by postoperative day 3. The consequences of SVT depend on the duration and frequency of the events. Patients who have a single episode of SVT, which is short in duration, may have very little or no consequences. Patients at the other end of the spectrum with prolonged or recurrent SVT have been shown to have a prolonged hospital stay.[94] In addition, it has been shown that patients who experience SVT have poorer survival after thoracic surgical procedures independent of advanced age, stage of disease, and extent of resection.[95]

Given its ubiquity and adverse effect upon the management and outcomes, there has been a great deal of interest in prophylaxis against the development of SVT. Agents that have been shown to have a prophylactic effect against the development of SVT after pulmonary resection include $\beta$-blockers,[96] calcium channel blockers,[97,98] magnesium sulfate,[99] and class I antiarrhythmics.[100] Unfortunately, adverse effects were also seen with the use of these agents such as hypotension and bradycardia for $\beta$-blockers and calcium channel blockers. Class I antiarrhythmics have significant proarrhythmic potential. Amiodarone, a class III antiarrhythmic agent, has been shown significant reduction in the incidence of SVT[101] in cardiac surgical patients. There has been apprehension for the use of amiodarone after pulmonary resection for lung cancer given the risk of lung toxicity in a patient population with smoking and surgically reduced pulmonary function. Randomized data are needed to determine clinical efficacy and toxicity after pulmonary resection.

When SVT occurs, its management depends on the acute clinical consequences, including symptoms, heart rate, and blood pressure. Occasionally, patients will develop chest discomfort or hypotension. These patients should undergo urgent electrical cardioversion. More commonly, patients will have a sensation of malaise and palpitations without chest discomfort or hypotension. This situation is less urgent and can be managed by rate control with $\beta$-blockers, calcium channel blockers, or digoxin. The use of amiodarone to chemically cardiovert these patients has become more widespread recently. In general, patients with persistent or recurrent SVT despite rate control or the use of amiodarone should undergo elective electrical cardioversion or anticoagulation to minimize the risk of thromboembolic sequelae. Although SVT is a common event after otherwise uncomplicated pulmonary resection, the clinician should keep in mind that SVT can also be a marker of the presence of other postoperative complications such as MI and pulmonary embolism. These complications should be investigated depending on clinical circumstances.

**Cardiac Herniation**   Cardiac herniation is a rare complication of intrapericardial pneumonectomy. However, when it occurs, it is associated with 50% mortality. The herniation occurs through the pericardial defect (right more commonly than left). This complication usually occurs within the first 24 hours after surgery. The diagnosis is based on clinical suspicion and findings on chest radiograph. It is associated with sudden onset of hypotension, tachycardia, and cyanosis. Chest radiograph after right-sided herniation will show obvious mediastinal displacement (Fig. 39.4), whereas left herniation will have more subtle radiographic findings of subtle cardiac shift with a rounded opacity in left chest.

Factors thought to contribute to the development of cardiac herniation include placing the chest tube to suction and positive pressure ventilation. The pathophysiology of right and left cardiac herniation differs. Right herniation is associated with torsion of venous inflow at the superior and inferior vena cavae as well as distorted and compromised left ventricular outflow. Left herniation involves constriction of the left ventricle by the sharp edges of the pericardial defect with potential laceration of epicardial vessels resulting in myocardial ischemia, edema, and dysfunction.

**FIGURE 39.4**   Cardiac herniation. Chest radiograph immediately following right pneumonectomy **(A)**. Chest radiograph repeated shortly thereafter for hemodynamic instability showing cardiac displacement into the right chest **(B)**.

Once cardiac herniation is recognized, the patient should be taken emergently back to the operating room or undergo bedside thoracotomy if severely unstable. Management of right cardiac herniation consists of reducing the heart and closure of the pericardium primarily or with a Dacron or polytetrafluoroethylene patch. Management of left herniation consists of opening the pericardium down to the diaphragm to eliminate cardiac strangulation.

# Radiation Therapy and Lung Cancer

Paul Keall
José Belderbos
Feng-Ming (Spring) Kong

# Physical Basis of Modern Radiotherapy: Dose and Volume

About 60% of cancer patients receive radiation therapy (RT),[1] making radiation the most common "drug" (or more appropriately termed, *prodrug*) in cancer treatment. Radiation affects cell function by either directly ionizing intracellular targets or creating free radicals near the intracellular targets, which can then react with and disrupt normal cell processes. The most important and understood intracellular target is deoxyribonucleic acid (DNA), where single- and double-strand breaks can occur resulting in cell damage and cell death.

Radiotherapy is an example of individualized therapy. The delivery of the cytotoxic agent—radiation—varies from patient to patient as a result of the changing tumor and normal anatomy. Determining the appropriate dose and tumor volume to treat, choosing the appropriate beam shapes and energy for the treatment plan, and executing the treatment plan during radiation delivery involves a dedicated and coordinated effort by the treatment team, including the radiation oncologist, medical physicist, dosimetrist, and radiation therapist. Lung cancer is a particular challenge for radiotherapy given the number of radiation-sensitive tissues that ideally should be avoided—the lungs, esophagus, heart, spinal cord, mainstem bronchii, pulmonary vessels, brachial plexus and ribs, as well as the large changes in tissue density that challenge accurate calculation of dose to these structures.

This chapter describes the physical basis of dose and volume in radiotherapy and is divided into four main parts: imaging for volume delineation in RT, treatment planning, dose and fractionation, and treatment delivery. Although imaging, planning, and delivery have previously been three distinct processes in radiotherapy, with the emergence of image-guided therapy and adaptive therapy, the imaging–planning–delivery processes are merging.

## IMAGING FOR VOLUME DELINEATION IN RADIATION THERAPY

**Preparation**    In radiotherapy for lung cancer, it is important to keep geometrical uncertainties such as patient tumor delineation, organ motion, and setup variation to a minimum. The requirements on accuracy, dependent on the dose prescribed, are dictated by the purpose of the irradiation. In case a palliative treatment for lung cancer is prescribed, the requirements of the radiotherapy treatment preparation (traditional two dimensional [2D] using x-ray simulator) and delivery are relatively uncomplicated compared with three- or four-dimensional radiotherapy techniques used in radical or curative settings. Three-dimensional (3D) conformal radiotherapy is based on computed tomography (CT) scan treatment preparation and individualized treatment fields. Four-dimensional (4D) CT scans provide information on respiratory-induced tumor motion, which can be used for patient-specific treatment preparation.

**Immobilization**    To reassure stable and reproducible patient positioning during treatment preparation and execution, the patient is placed (as comfortably as possible) on a flat couch with both hands stable above the head using immobilization devices (e.g., T-bar device, forearm support, alpha cradle, Wing Board, or vacuum mattress). These immobilization devices, sometimes personalized, will decrease the setup errors and reduce the daily setup uncertainty.[2] Available data support the use of an immobilization device to achieve stable and reproducible patient positioning during treatment planning and delivery.[3–5] The delivery of hypofractionated treatment fractions (stereotactic body irradiation; see Chapter 43) or gated treatments (irradiation to a restricted portion of the respiratory cycle) takes more beam-on and total machine time. For these treatments with prolonged treatment time, additional immobilization devices such as a stereotactic body frame and/or abdominal compression might be used to increase intrafraction stability or decrease respiratory tumor motion. Other devices such as head and knee cushions are frequently used to ensure maximum comfort and thus improve the position reproducibility. However, results of studies reveal that the setup accuracy (with respect to the bony anatomy) using a stereotactic body frame is of the same order (2 to 4 mm [1 standard deviation]) as without using such immobilization devices.[6,7]

The training and attention to detail of the treatment team is important in maintaining anatomic reproducibility throughout the treatment course.

**Simulation**    For radiotherapy treatment preparation of a palliative schedule, an x-ray simulation session using a diagnostic x-ray generator (that has the same geometrical features of the linear accelerator) can be sufficient, although a growing number of centers are performing CT simulation for all patients, including those treated for palliation. During simulation the patient is in treatment position, and the radiation oncologist will determine the treatment field borders. Tumor motion information gathered during fluoroscopy in the cranial–caudal direction may be used. The anterior and lateral laser lines and/or the treatment field borders will be marked on the patient (sometimes using tattoos) to be used during daily patient setup.

For 3D conformal radiotherapy, a CT scan of the thorax in treatment position using a CT simulator is necessary. A CT simulator is a CT scanner with a laser system to align the patient and specific software. Laser lines will be marked on the patient, and the isocenter of the laser lines will be made visible on the planning CT scan. This so-called planning (or simulation) CT scan provides information on the 3D tumor extensions (and the normal tissues surrounding the tumor) and will be used to determine the optimal beam arrangements and calculate the dose distribution. An axial planning CT slice is shown in Figure 40.1. This planning CT is normally performed from middle/upper neck (the level of C2–C3) to middle abdomen (L2–L3), so that the whole lung is included for dosimetric estimation. Intravenous contrast is recommended for patients with tumors near the mediastinum and/or pathological lymph nodes. This is helpful for differentiating centrally located tumors and enlarged lymph nodes in the hilum and mediastinum from adjacent vessels.[8,9] The use of intravenous contrast may not be that critical if a recent contrast-enhanced diagnostic CT scan or positron emission tomography (PET)-CT simulation is available,[10,11] or for a peripherally located tumor without positive lymph nodes. CT scans with a slice thickness of 2 to 3 mm are recommended to enable accurate gross tumor volume (GTV) delineation, better recognition of nodal structures, and high-resolution digitally reconstructed radiographs (DRR) to be generated, which in turn may allow for the omission of a separate simulation step.[12] Study of a small patient series indicated that the impact of contrast on dose estimation is less than 2% to 3% of the prescription dose.[13]

Multiple laser setup points are placed on the patient to ensure that the patient is approximately in the same position each day for treatment. The distributions of treatment setup errors measured against DRRs obtained in the CT simulation are similar to previously obtained distributions measured against simulator films, and DRRs are well suited for setup verification. A verification simulation under conventional fluoroscopic simulator may be omitted.[12] However, the tumor motion should be checked for estimation of planning target volume (PTV) margin and adequate target coverage if the simulation and treatment were performed under free breathing (see section on "Motion Considerations" later in this chapter).

**FIGURE 40.1**    Views from a planning CT scan. Note the flat tabletop used for radiation therapy imaging, the absence of the patient's arms as they are above their head to avoid being radiated during treatment, and the foam mold surrounding the patient to assist with immobilization. The gross tumor volume (*red*) and planning target volume (*pink*) are shown. (See color plate.)

To minimize simulator setup errors, a treatment isocenter (preferably located within the treatment target) should be defined at the time of treatment planning. Volumetric information from spiral CT scans is superior for defining target volumes rather than data derived using axial CT scans.[14] However, it should be recognized that movement-induced artifacts for mobile organs or targets can arise during most CT scan techniques.[15] The possibility of time-related displacements and treatment-related changes of target volumes that had been defined prior to a 4- to 7-week course of radiotherapy has not been adequately studied,[16] and is an import topic of future research.

## Determination of Treatment Volumes

The modern 3D conformal radiation technique (CRT) requires precise definition of the treatment target and organs at risk. This is different from the traditional 2D practice. Definitions: the GTV includes the primary tumor (GTV-P) and the nodal GTV (GTV-N). The clinical target volume (CTV) accounts for microscopic (subclinical) disease. The PTV incorporates tumor delineation uncertainty, organ motion, setup variation, and intrafraction stability.

Lymphatic spread is an important pathway of progression of non–small cell lung cancer (NSCLC), along with local spread and distant metastasis. The probability of lymph node invasion is dependent on the site of the primary lung tumor, tumor stage, and histology. Before radiotherapy treatment starts, the extent of lymph node spread needs to be determined as correctly as possible. In the past, it was impossible to stage lymphatic spread accurately, and large radiation fields were used to encompass lymph node areas that were clinically and radiologically uninvolved. These large fields, called elective nodal irradiation (ENI), were covering, for example, the homolateral supraclavicular fossa, the hilar region, or the mediastinal lymph nodes. The use of these large irradiation fields increased the volume of normal tissues irradiated considerably, which led to more toxicity and prevented successful dose escalation. The influence of these large elective fields on treatment outcome was never established in randomized trials. Obviously, the extent and quality of the staging examinations performed pretreatment influences the need for ENI.

## Delineation of Gross Tumor Volume

Target delineation of GTV is essential for 3D CRT. The target volume definition should follow the guidelines of the International Commission of Radiation Units and Measurements (ICRU). The GTV includes the GTV-P, and the GTV-N; GTV-N includes any abnormally enlarged regional lymph node (hilar and/or mediastinal), as well as mediastinal and/or supraclavicular nodes enlarged 1 cm or more in the short axis,[12] unless metastases have been excluded by other means such as mediastinoscopy or ^{18}F-fluorodeoxyglucose (FDG)-PET scanning. GTV-N should also include lymph nodes that are not enlarged but have been documented by mediastinoscopy/endoscopic ultrasound (EUS)/endobronchial ultrasound (EBUS) as being pathologically involved or have higher FDG activity than the mediastinal blood pool. The measured diameter of tumors in lung parenchyma or mediastinum is highly dependent on the window width and level chosen during the delineating process.[17] Lung primary tumors should be outlined under the standard lung window, whereas the nodal disease and centrally located tumors are better contoured under mediastinum window/levels. The specific window widths and levels may vary with the CT scanner, software used, and the technique, with lung settings at $W = 400$ to $1600$, $L = -400$ to $-600$, and mediastinum settings ranges $W = 400$ to $1000$, $L = 0$ to $50$.[17–19] One study found that the best concordance between measured and actual diameters and volumes was obtained with the following settings: $W = 1600$ and $L = -600$ for parenchyma, and $W = 400$ and $L = 20$ for mediastinum.[19] It is preferable that such parameters be specified in each center with the help of a radiologist, and be preset in treatment planning workstations, to improve consistency in contouring.

Depending on the tumor location, the adequate window and level setting should be viewed to delineate the GTV. For example, when the tumor is surrounded by lung tissue only, the lung level and window CT settings should be used. For lymph nodes and lung tumors invading the mediastinum or chest wall, only the window with mediastinum level and window settings should be viewed. The use of 4D CT scanning may reduce delineation uncertainties because of an improved visualization of the tumor shape (see section on "Motion Considerations").

## Determination of Clinical Target Volume

The CTV accounts for microscopic (subclinical) disease. This subclinical area may involve a region around the GTV as well as regional lymph node areas that were not documented to have adenopathy or proved by mediastinoscopy to be involved. It is controversial what this volume should include. It is extremely challenging to estimate the extent of CTV. Generally, the size of margin added to the GTV to account for microscopic extent has been arbitrary, ranging from 5 to 8 mm. Giraud et al.[19] examined NSCLC surgical specimens with adenocarcinoma (ADC) and squamous cell carcinoma (SCC) histology. The mean value of microscopic extension was 2.7 mm for ADC and 1.5 mm for SCC. A 5-mm margin covers 80% of the microscopic disease extension for ADC and 91% for SCC. To have 95% confidence that all tumor is included in the clinical target volume, a margin of 8 and 6 mm must be chosen for ADC and SCC, respectively. Grill et al.[20] analyzed microscopic disease extension in 35 cases and reported that in a GTV contoured using CT lung windows, the margin required to cover microscopic extension for 90% of the cases was 9 mm (9, 7, and 4 mm for grade 1 to 3, respectively).

The concept of nodal CTV includes CTV around the GTV-N and the microscopic disease within clinically normal nodes. Yuan et al.[21] studied extracapular extension (ECE) in 243 cases and concluded that ECE extent was related to lymph node size, stage, and differentiation. The extent of ECE was 3 mm in 95% of the nodes. It may be reasonable to recommend 3-mm CTV margins for pathologic lymph nodes (GTV-N) <20 mm and more generous margins for lymph nodes ≥20 mm. The

microscopic disease extension to the clinically uninvolved nodal regions has been a topic of debate and has been evolving over the last several years. During the 1980s, this volume routinely included mediastinum, bilateral hilum, and the supraclavicular areas. Emami et al.[22] reported that inclusion of the contralateral hilum, the mediastinum, and supraclavicular lymph nodes in the field did not affect local control or survival. In the 1990s, most had eliminated the contralateral hilum and/or the supraclavicular areas. However, whether or not the ipsilateral hilum lymph node group was included per protocol did appear to affect local control and survival.[23] Recent results with 3D CRT without intentionally including these elective nodal regions showed a low incidence (0% to 7%) of isolated nodal failure in several dose escalation studies.[16,24–26]

There is lack of solid evidence currently existing for either pro or con ENI.[27] Although most of the published results from the cooperative groups used the elective radiation to most of the mediastinum regions, the newly activated protocols for NSCLC have a tendency to omit such radiation (Radiation Therapy Oncology Group [RTOG] 0617 and European Organisation for Research and Treatment of Cancer [EORTC] trials). If the treating physician believes an elective nodal area (primarily of the mediastinum or ipsilateral hilum) is indicated, it should be contoured and identified on CT scans. The atlas of nodal regions from University of Michigan is an important tool to determine the anatomic area of the lymph nodes involved.[28]

**Determination of Planning Target Volume**   A range of geometrical uncertainties are associated with radiotherapy of lung cancer patients, such as target definition uncertainties, setup errors, organ motion, and anatomical changes. Errors (uncertainties) made during treatment preparation (e.g., target definition errors, or a nonrepresentative planning CT scan) will be made only once. In the absence of correction protocols, these errors will then be present during every treatment fraction. Errors made during treatment delivery of fractionated radiotherapy (e.g., misalignment of the patient), on the other hand, will be made several times and are likely to be different every day. Errors that are identical for every fraction are called *systematic errors*, whereas errors that vary day-by-day are called *random errors*. The dosimetric effect of systematic and random errors is different; random errors blur the cumulative dose distribution, whereas systematic errors shift the cumulative dose distribution.

To account for geometrical uncertainties, safety margins are applied around the CTV, thereby defining the PTV and thus irradiating a larger volume (Fig. 40.2). Often, separate margins are used for patient positioning uncertainty and for organ motion, called the *setup margin* (SM) and the *internal margin* (IM), respectively. As external error sources and internal error sources are generally not correlated, a linear addition of these margins, however, is not correct. Alternatively, the CTV is directly expanded to the PTV. Several margin recipes have been proposed in the literature with different objectives. For example, van Herk et al.[29] showed that the margin around the CTV for conventional fractionation should be 2.5 times the standard deviation of all the systematic error plus 0.7 times the standard deviation of all the

**FIGURE 40.2**   Schematic of the relationship of planning target volumes (PTVs) for various planning concepts: conventional free breathing, internal target volume, gating (at exhale), and midposition. *Ave.*, average; *CTV*, clinical target volume; *Geo.*, geometrical; *GTV*, gross tumor volume; *ITV*, internal target volume; *pos.*, position; *TW*, time-weighted.

random error to make sure that 90% of the patient's GTV will receive at least 95% of the dose. Note that the distribution of systematic and random uncertainties is institution dependent and, thus, need to be carefully evaluated for each department.

Traditionally, a uniform 7- to 10-mm margin was used to extend the CTV in all directions to form the PTV. However, because the respiratory induced tumor motion is nonuniform and patient dependent, the PTV should also be nonuniform and patient dependent. Moreover, detailed analysis of several sources of geometrical uncertainties[30–33] has revealed that such margins are too small in the absence of image guidance and associated correction strategies.

The use of 4D CT scanning technique allows for accurate estimation of tumor motion, although over a short time interval, and generates individualized margins. Various approaches for the incorporation of 4D CT scanning in treatment planning have been published recently.[34–37] In general, the use of 4D scanning in combination with gating, or the reconstruction of a time-averaged tumor position (midventilation CT scan), allows an important reduction of the PTV (Fig. 40.2) compared with the PTV for conventional free breathing CT scanning or the internal target volume (ITV). The ITV concept (note that the ITV is defined differently from the original ICRU definition) covers the entire tumor motion, in one breathing cycle, and therefore, may overestimate the influence of the motion on the tumor dose.[38] Additionally, critical normal tissues where knowledge of the radiation dose is important and/or dose should be minimized need to be carefully and consistently defined. An example of normal structure definition is shown in Figure 40.3.

**The Role of the Positron Emission Tomography Scan on Target Delineation**   FDG-PET has had a significant impact on the delineation of the GTV for NSCLC, because it images metabolically active tumor cells, and identifies pathological lymph nodes more accurately than CT scanning.[39,40,54] A metaanalysis of 39 FDG–PET studies examined
**FIGURE 40.3**   Dose-limiting normal tissues to avoid and/or limit radiation dose. Target volume delineation is performed on the entire 3D (or 4D) data set. Right lung: *blue*; left lung: *green*; heart: *pink*; esophagus: *green*; spinal cord: *brown*; main airways: *yellow*. The target volumes can be seen in Figure 40.1. (See color plate.)

the diagnostic accuracy of FDG–PET scanning in patients with NSCLC using stratification for mediastinal lymph node size on CT scan.[41] Based on this analysis, the sensitivity of the FDG–PET scan for enlarged mediastinal lymph nodes was 91% and 75% for not-enlarged lymph nodes. FDG-PET also improved the staging of solitary pulmonary lesions[42] and extrathoracic spread of the disease. Another advantage of FDG–PET scanning is the possibility to distinguish tumor from collapsed lung or mediastinal structures. In addition, evidence is accumulating that the standardized uptake value (SUV) of FDG–PET tracer in the primary tumor is an important prognostic factor for radiotherapy treatment outcome.[43–46]

The introduction of FDG-PET has a large influence on selecting patients for radical radiotherapy treatment. Several studies have demonstrated that FDG–PET scan implementation in radiotherapy treatment planning influenced the delineation of the GTV.[47–61] The most common findings of the studies have been changes of GTV and PTV based on the PET image, which subsequently might improve the estimated tumor control probability and normal-tissue complication probability.[55,56] PET imaging can provide a more accurate representation of the 3D volume-encompassing motion of model tumors and has the potential to provide patient-specific motion volumes for an individualized ITV.[57] For patients, the PET-delineated target volume seemed to be consistent with the ITV determined from all sets of gated-CT and regular spiral CT images. PET use in estimating the individual ITV is further addressed by Fernando et al.[58] Additionally, implementing matched CT-FDG-PET reduced interobserver and intraobserver variation in target delineation significantly with respect to CT only.[52,59]

Steenbakkers et al.[33] observed a reduction in the interobserver variability of more than 50% in the standard deviation of the GTV delineations if FDG–PET information coregistered with CT was used. Preferably, the tumor delineation should be based on a matched CT-FDG-PET scan (with both examinations in treatment position) and performed by a radiation oncologist experienced in lung cancer treatment in the presence of a detailed delineation protocol and adequate delineation software.[33]

It is clear that PET has significantly changed the treatment planning of NSCLC patients, and is considered to be a state-of-the-art technique. Images from a planning FDG-PET-CT scan are shown in Figure 40.4.

Issues remain, however, with the use of PET in target delineation, some of which were discussed in a recent journal editorial.[60] For example, the determination of the edges of the tumor in the metabolically active area on PET is not straightforward. Most of the studies that were mentioned used an arbitrary threshold value of the maximum intensity (30% to 50%) in the PET-avid area or a standardized uptake value (range: 2 to 5). This threshold, however, was generated from phantom studies of limited target size,[61] and is not correct for most patients with NSCLC.[62] Several phantom studies have attempted to determine optimal threshold values, with differing results. Researchers from Beaumont Hospital[63] performed a series of sphere phantom studies to determine an accurate and uniformly applicable method for defining a GTV with
**FIGURE 40.4** PET images overlaid on the CT scan from a treatment planning PET-CT simulation session. For radiation oncology, a critical step is the delineation of the tumor boundaries that are necessary for determining the shape of the radiation treatment beams. (See color plate.)

FDG-PET. They found a strong linear relationship between the threshold SUV and the mean target SUV. Recent studies from patients further confirmed that the threshold for the best match of CT-GTV averaged 20% to 25% (range: 10% to 50%) ITV 15% to 20% (range: 10% to 50%), depending on the tumor size, activity, and location.[58]

Unfortunately, FDG-PET has its limitations. Firstly, the spatial resolution of FDG–PET images is poor (4 to 6 mm) compared with CT scan images.[57,64] Therefore, the increased FDG uptake should be used for localization of the tumor, not for defining boundaries, except for the tumor-atelectasis region. In a study by Steenbakkers et al.[33] 10% of the lymph nodes with increased FDG uptake were missed by the radiation oncologists. One explanation might be that the FDG–PET report was not read accurately enough by the radiation oncologists. Furthermore, for some lymph nodes, the level and window settings of the FDG-PET had to be changed before they were visible.

Another challenging issue of using PET for treatment planning is to register the PET image accurately when a PET-CT simulator or hybrid PET-CT is not available. An ideal registration method, which uses the entire volume of image data (i.e., intensities of the image voxels) for matching of "mutual information" and displays the two modalities simultaneously, would significantly improve the accuracy of PET in target delineation.

**Motion Considerations** Tumor motion caused by breathing and heartbeat is a topic of many investigations. Tumor motion could be rather substantial and heterogeneous, ranging from a few millimeters to 25 mm based on tumor location, size, and patient condition.[65–69] The greatest tumor motion is seen in the cranial–caudal direction. Information on the individual patient's lung tumor motion is necessary to determine individual margins.[66] It is critical to accurately estimate the motion for each tumor, so that the treatment planning is optimized for target coverage and normal-tissue sparing. With the advancement of imaging techniques, several strategies are now available to approach this goal. These include, but are not limited to, visualization under fluoroscopy, respiratory-gated CT simulation, and 4D CT simulation.

Tumor motion can be visualized under a conventional simulator with fluoroscopy, and the extent of motion can be estimated for each tumor.[70,71] With quiet respiration, the maximum tumor movement in the craniocaudal direction was 12 mm, and the mediolateral and dorsoventral direction was 5 mm in a study by Ekberg et al.[70] Other reported movements ranged from 0 to 12.8 mm in the superior–inferior direction, 0 to 3.2 mm in the lateral direction, and 0 to 4.4 mm in the anterior–posterior direction.[71] Large variation in GTV motion from patient to patient was observed, especially in the superior–inferior direction, for which interpatient variability was >10 mm.

Tumor motion seemed to be unique for each patient and in each dimension. A standard uniform PTV margin of 10 or 15 mm is inappropriate. Motion check under fluoroscopy can provide an estimation of the internal motion in each patient. This method is simple; however, it is limited by the facts that (a) some tumors can be difficult to visualize with fluoroscopy x-rays; (b) diaphragm motion may not correlate with tumor movement; and (c) the shape change of the tumor cannot be measured clearly. Additionally, fluoroscopy generally overestimates the mobility of visible lung tumors and may result in irradiation of unnecessarily large target volumes.[72] Even if an individualized margin is obtained from the fluoroscopy, an

ideal PTV cannot be guaranteed from GTV because the free-breathing CT images can be taken in any phase of the breathing cycle when the target volume is scanned. For example, assume the target is scanned at the end of exhale (the target in the most superior position), a uniform expansion would include unnecessary normal tissue superiorly and would not cover the inferior part of the target adequately.

With the wide availability of CT simulation, techniques with modifications to the CT simulation procedure have been proposed to better define the treatment target. The most common of these is respiratory correlated 4D CT.[73–76] A multislice CT scanner is typically used for 4D CT. In the cine mode, the CT scanner scans the same table position for one or more whole respiratory cycles, and then moves to another table position. Computer programs then sort out the images according to the respiratory phases and reconstruct the 3D CT images at each phase. Usually, 10 sets of images of 10 different phases are obtained for one simulation.

An ITV can then be generated by combining the GTVs of different phases with a CTV margin. Theoretically, using 4D CT images should be the best way to approach ITV accurately. The challenge of this technique is the burden for the treatment planning computer to handle the large amount of data and for the radiation oncologists to delineate/check the target in each image set. Also, there are several artifacts found using current generation 4D CT scan technology[77–79] that could be improved through breathing training, improved acquisition techniques, and/or better post-acquisition reconstruction methods.

Another technique referred to as the mid-ventilation (MidV) CT scan generates a single 3D CT frame from 4D CT images representing the tumor closest to its mean tumor motion position.[37] Using this MidVCT scan, the systematic contribution caused by breathing motion can be reduced to nearly zero, permitting a reduction of the treatment margin. The expected dose-blurring effect of the respiration can be accounted for in the CTV to PTV margin. Because of the presence of the wide beam penumbra in lung, Engelsman et al.[80] and Witte et al.[81] reported that if a treatment plan is designed for the tumor in its (time-weighted) average position during the respiration cycle, a good dose coverage is still obtained even if the tumor is not fully within the PTV during a small part of the breathing cycle.

One or more phases of the 4D CT scan (e.g., the end exhale, or scans near and including end exhale) can be used for respiratory-gated treatment planning/delivery. Alternatively, a gated CT scan can be acquired by triggering the CT scanner to acquire imaging data when the patient's respiratory signal crosses a predetermined threshold (e.g., near end exhale).

To reduce tumor motion, several strategies have been developed and tested. These fall within two classes: abdominal compression and breath-hold techniques. Abdominal compression was originally developed for stereotactic irradiation of small lung and liver lesions by Lax and Blomgren[82–84] and has been used elsewhere.[6,85–91] The technique employs a frame with an attached plate that is pressed against the abdomen. The applied pressure to the abdomen reduces diaphragmatic excursions, while still permitting limited normal respiration. The accuracy and reproducibility of both the body frame and the pressure plate have been evaluated by several groups, with a comprehensive assessment reported by Negoro et al.[86] Abdominal compression has predominantly been applied to early stage lung and liver tumors without mediastinal involvement or nodal disease, although the technology is also applicable to conventional lung treatments.

The most widely used breath-hold methods are active breathing control (ABC) described by Wong et al.[92,93] and deep inspiration breath hold.[94–96] Using breath-hold devices, CT simulation and treatment delivery can be performed at the same fixed level of controlled breathing; thus, the target is considerably reduced during treatment planning and delivery. In addition to motion reduction, breath-hold techniques have the advantage that the lung volume is expanded by 30% to 50%, thus for a given beam aperture, the fraction of lung being irradiated is smaller. However, implementation of breath-hold techniques requires patient selection for compliance and increases the time of the imaging and treatment procedures.

Other motion management techniques, such as using gated treatment at a specifically defined phase window when the patient breathes freely, or tumor tracking (in which the radiation beam follows a measurement or estimate of the tumor motion) are clinically available and, with improved integration of image guidance with treatment delivery, are likely to become more widespread.

## TREATMENT PLANNING

Aiming to maximize the radiation dose to the target volume while minimizing dose to surrounding normal tissues, the 3D CRT is now the standard technique of RT in lung cancer. Planning and delivery of RT is a multistep process that is individualized for each patient. Literature-based EORTC guidelines on each of these steps for 3D CRT in the setting of clinical practice and clinical trial have been published.[97] The process of RT planning includes dose/fractionation, immobilization/localization, target and normal-tissue delineation (including tumor and important normal structures), radiation beam design, and treatment delivery.

**Beam Arrangements/Aids and 3D CRT** The design of the radiation beam field or aperture depends on the treatment volume, with or without inclusion of ENI. With ENI, the beam selections are limited by the extensive volume of the target—often large fields aimed from the anterior and posterior (AP/PA) direction of the patient in parallel-opposed fashion. The AP/PA beam arrangement is limited by the tolerance dose of the cord, thus, one or more "off-cord" fields are always needed for radical treatment when a dose of 60 Gy or higher is needed. Although the nodal volume was traditionally determined by anatomical landmarks located on simulator radiographs or reconstructed coronal CT planes (as it was for 2D planning), the nodal regions should be contoured consistently,

so the PTV can be defined and the plan of 3D CRT can be generated. This technique offers the potential advantage of improved dose delivery to a target volume (as opposed to a point dose calculation in 2D planning, historically).

Using 3D CRT with selective ENI or without ENI, the PTV is to be treated with any combination of coplanar or noncoplanar 3D conformal fields shaped to deliver the specified dose while restricting the dose to the normal tissues. Field arrangements are determined by 3D planning to produce the optimal conformal plan in accordance with volume definitions. Multiple coplanar or noncoplanar field arrangements are preferred, but AP/PA fields are still used, if appropriate, on an individual basis. The beam directions are selected by the use of the beam's eye view (BEV) tool. Target and normal structures are viewed from different directions in planes perpendicular to the beam's central axis using BEV. The beam shape is then modified by designing a block or a block substitute called a *multileaf collimator* (MLC) shaper, which will allow full dose to the PTV but minimize the dose to surrounding normal tissue. To cover the entire PTV with the prescription dose, an additional margin (block margin) should be added to each aperture. The block margin is to compensate the penumbra at each beam edge; and often 5 to 10 mm is needed for an adequate coverage at the peripheral part of PTV. It should be kept in mind that this margin width is dependent on the number and arrangement of fields and the specific technique used. For coplanar arrangement of multiple beams, smaller lateral margins are needed for adequate PTV coverage (i.e., relatively larger superior–inferior margins for each beam).

Once beam angles and shapes are designed, beam energy and beam aids need to be chosen for each individual beam. To select the appropriate energy for each beam, one should keep in mind the nature of low intensity of lung tissue. Photon energy of 6 megaelectron volts (MV) is preferred for beams passing through large volume of lower–density lung parenchyma to provide better PTV coverage; 15 to 18 MV may decrease the monitor unit (MU) and provide better dose homogeneity for AP/PA mediastinal beams. In the case of a large sloping contour, such as usually encountered

when treating upper lobe tumors in large patients, beam aids such as wedge or compensating filters are recommended to improve the dose distribution. Dose calculations incorporate basic data that characterize the radiation beam energy and geometry, such as depth dose curves and isodose information for standard field sizes. Computerized algorithms have been developed to combine the dose distributions generated by combinations of beams, using individual patient information such as depth of the point of calculation, external body contour, and various densities of anatomical structures. Dose distributions are displayed with concentric curves for chosen dose levels (isodoses), which are displayed as overlays on anatomic structures. These curves are normalized to a reference dose, either at isocenter (ICRU point) or to the lowest isodose curve that encompasses the PTV.

The treatment plan can be evaluated whether it meets the objectives of PTV coverage and normal-tissue avoidance. The idealized, perfect plan would be 100% coverage of a tumor target with a minimal amount of dose heterogeneity or overdose to achieve that 100% minimum dose coverage. This is very often a quite difficult goal, as lung tumors are often surrounded by low density of the lungs or other critical structures. In practice, a 95% PTV coverage is acceptable for 3D RT. A set of criteria for normal-tissue tolerances (discussed in the next section) must be given to guide the treatment planning. Dose distributions for 3D volumes can be displayed and analyzed graphically with dose–volume histograms (DVH), which are generated for each structure. The cumulative form of the DVH is a plot of the volume of a given structure receiving a certain dose or higher as a function of dose. The DVH for normal lung is the addition of the dose distributions of both lungs but minus the dose distribution in the GTV. The GTV is selected instead of the PTV, because the PTV contains normal lung receiving a high dose, which influences the normal-tissue toxicity rate. A 3D conformal radiotherapy treatment plan is shown in Figure 40.5.

If the treatment plan does not meet the given dose–volume objectives, beam arrangements or other parameters are adjusted. This can include a change of beam energy, beam angle, or

**FIGURE 40.5** The beam arrangement for an intensity-modulated radiotherapy (IMRT) treatment of lung cancer. (See color plate.)

adjustment of the beam intensity. For conformal therapy, beam arrangements and adjustments are carried out manually, with changes made in an iterative fashion by the treatment planner.

Once the final beams are designed, radiographs in the form of DRRs are generated from the treatment planning CT to enhance the bony anatomy with high contrast, and are in the BEV plane. DRRs are used to compare with portal images taken before treatment, which are either films placed in the beam exiting the patient or with an electronic portal device. Verification of the radiation beam placement should be carried out pretreatment and at least weekly during the course of treatment so that patient position can be adjusted accordingly.

**Intensity-Modulated Radiation Therapy**    Although radiation intensity is uniform across the beam/field for conventional 3D CRT, intensity-modulated radiation therapy (IMRT) adjusts the beam intensity across the beam width and length. The simplest modification of the intensity is a wedge-shaped filter or a physical compensator placed in the machine head. Modern machines can also use MLC movement to achieve the same goal. A slightly more complex method is to break the field aperture into segments with varying beam-on times. Currently, the most intricate form of intensity modulation achieves a checkerboard pattern with each square of a varying intensity. The modern concept of IMRT involves delivery of this type of pattern with a device called an MLC, which can be moved under computer control to shape segments of the field to deliver the intensity pattern. Because the intensity pattern is so complex, a different type of computerized treatment planning is used, called *inverse planning*. The treatment planner defines the dose to be delivered to a target volume and the limiting dose to the surrounding normal tissues, and beam angles. The computer determines the corresponding intensity profiles to achieve the desired dose distribution. There have been several theoretical treatment planning studies published, with findings that higher levels of tumor dose can be achieved while maintaining the same normal lung dose–volume indices.[98–102] Compared with 3D CRT, IMRT reduced the percentage of lung volume that received >20 Gy and the mean lung dose, with a median reduction of 8% and 2 Gy, respectively.[103] Treatment planning with IMRT under deep breath-hold results in lower $V_{20}$ and lower-modeled pneumonitis rates,[104] allowing delivery of a higher dose to the target. IMRT can be used to reduce the irradiation of, for example, the esophagus (whose damage causes dysphagia) without deterioration of the target coverage. This might be particularly important for patients treated with concomitant chemoradiation regimes. Therefore, IMRT is of significant value (compared with 3D CRT) in node-positive cases with target volumes close to the esophagus.[98,105] For such patients, IMRT can deliver RT doses 125% to 130% greater than an optimized 3D CRT plan and 130% to 140% greater than a plan including ENI.[100] In a planning study by Schwarz et al.,[102] the increase in deliverable dose was 135% compared with the 3D CRT plan if IMRT and dose heterogeneity within the PTV was allowed. IMRT is of limited additional value (compared with 3D CRT) in node-negative patients.[100,102] IMRT is associated with increased lung volume exposed to low doses (<10 Gy) in some studies,[98] but Schwarz reported no increase of lung volume receiving (very) low doses, even down to 5 Gy. Additionally, IMRT delivers radiation through multiple small segments that do not cover the whole target, and may thus underdose parts of the target or overdose the adjacent normal tissue if the motion is not appropriately controlled. IMRT is in an early stage of clinical practice in the treatment of lung cancer and the clinical impact on lung toxicity is not yet completely known. An IMRT treatment plan is shown in Figure 40.6.

**FIGURE 40.6** The dose distribution for an intensity-modulated radiotherapy (IMRT) treatment of lung cancer. (See color plate.)
**Dose Calculation and Tissue Heterogeneity Correction** With the availability of either superposition/convolution (SC) or Monte Carlo (MC) dose calculation algorithms on all major treatment planning systems, tissue heterogeneities (particularly those found for lung cancer radiotherapy treatment plans) can be accurately accounted for. Accurate dose calculation algorithms give the treatment team confidence that the planned dose is a valid estimate of the delivered dose, keeping in mind that there are several other uncertainties, such as target delineation, interfraction and intrafraction motion, and tumor response to radiation treatment. The challenge of dose calculation in the lung is that the reduced lung density (from 0.1 to 0.5 times that of surrounding muscle and tissue) means that photons and electrons will travel 2 to 10 times further in the lung tissue relative to the surrounding material. This increased particle range means that the beam edges become less sharply defined, and larger beam apertures may be necessary to ensure adequate coverage of the edge of the target volume. Secondary build up at the tumor-lung interface can also occur.

For lung cancer cases, SC and MC method–calculated dose distributions are characterized by reduced penetration and increased penumbra caused by larger secondary electron range in the low-density media compared with previously used correction methods (e.g., equivalent path length [EPL] methods). Based on the MC method, target dose was overestimated (though less than 10%), and the dose of adjacent lung was underestimated in the plans calculated by the EPL method.[106–108] This effect is more prominent around the tumor-lung boundary, less at the PTV-mediastinal boundary. The mean lung dose as determined by the CS and EPL algorithms differed on average by 17%, and the $V_{20}$ differed on average by 12%.[106]

In general, tissue heterogeneity effects depend on the lung density, the lung length traversed, beam energy, and beam field size. In addition to altering PTV coverage, heterogeneity correction changes the ICRU prescription dose. Correction factors for 6 MV photon AP/PA beams in lung range from 1.05 to 1.13, which varies with dose calculation algorithms. The CS and MC methods provide very close estimation. When dose was measured in a benchmark test phantom to a point in between two lungs, there was increased dose ranging from 5% to 14% relative to a phantom of unit density. The effect decreases as the photon energy increases. The use of high-energy beams could be used to minimize the dose correction discrepancies. However, higher energy beams tend to "spare" the surface of the tumor when traversing through the lung. Higher energies will have an increased range of secondary electrons in lung tissue, which further spreads out the low isodoses relative to a water-equivalent tissue.[109] When a clinically relevant phantom study was performed,[110] the dose delivered to the PTV with 6 MV was within 5% of prediction, but low by 11% with the use of 18 MV. MC calculations showed that all target coverage indicators were significantly worse for 15 MV than for 6 MV, particularly the portion of the PTV receiving at least 95% of the prescription dose.[107]

Between SC and MC, MC is considered the most accurate algorithm as photons and electrons are individually transported through the patient using our best understanding of the laws of physics, although careful commissioning and implementation is required.[111] It is now the consensus of RTOG and the American Association of Physicists in Medicine (AAPM)[111,112] that tissue heterogeneity needs to be corrected for treatment planning of lung cancer and the most accurate dose calculation algorithm used for treatment.

# DOSE AND FRACTIONATION

## Dose and Fractionation in Non–Small Cell Lung Cancer

### Dose and Fractionation for Definitive Radiation

**DOSE FOR ADJUVANT RADIATION FOR PATIENTS WITH RESECTED NSCLC.** A dose of 45 to 50 Gy in 1.8 to 2 Gy daily fractions is generally recommended for preoperative radiation. When postoperative RT is indicated, the mediastinum is commonly treated to 50 Gy in 25 fractions, and regions of extracapsular extension and/or bulky nodal disease boosted by an additional 10 Gy. Areas of gross residual disease may be treated to 66 to 70 Gy if the volume to the normal structure is limited. When T3N0 chest tumors with chest wall invasion are given postoperative RT, the regional nodal area does not require postoperative RT if it was adequately staged during surgery. However, the chest wall should receive up to 60 Gy postoperatively. (See also Chapter 41.)

**DOSE AND DOSE ESCALATION FOR PATIENTS WITH INOPERABLE OR UNRESECTABLE NSCLC.** The prescription dose for definitive RT depends on the presence of chemotherapy and the volume of the organ at risk. It is generally felt, and supported by a few studies, that if high doses of radiation could be delivered safely, treatment outcomes might improve. For definitive RT alone, the mediastinum or elective nodal area (if given) was traditionally treated to 45 to 50 Gy in conventional fractions (once-daily doses of 1.8 to 2.0 Gy), and the primary or gross tumor boosted to a total dose of 60 Gy or more. The tumor dose of 60 Gy was established as the standard of care in RTOG 73-01, the only randomized trial that reported intrathoracic failure rates of 52%, 42%, and 33% for 40, 50, and 60 Gy, respectively, at 3-year follow-up.[113,114] Although the study did not show an improved overall survival, review of the results from other RTOG trials led to the conclusion that local tumor control was significantly correlated with improved survival.[114] A dose of 60 Gy or slightly higher has since become a frequently employed prescription dose, but long-term tumor control and survival are generally poor. Evaluation by means of bronchoscopy and biopsy at 1 year after treatment completion revealed local control rates of only 15% to 17%,[115] with 5-year overall survival reported to be less than 10%.[116,117] For stage I NSCLC, retrospective studies from Duke University and Washington University reported that patients who received a dose of ≥70 Gy had local tumor control compared with those who had <70 Gy.[118,119] More

than 64 Gy was associated with superior survival in patients with stage III NSCLC disease based on a recent retrospective review from the Memorial Sloan-Kettering Cancer Center.[120] Using 3D CT-based conformal RT techniques, several radiation dose escalation studies have shown much higher than 60 to 70 Gy to be feasible,[26,118,121–128] and higher doses appear to be associated with better local tumor control and survival in medically inoperable or unresectable NSCLC.[16,120]

Several phase I/II dose escalation trials were performed and the safety of radiotherapy doses above 100 Gy for patients with small tumor volumes was reported by researchers from the University of Michigan.[124] Most dose escalation trials entered patients into different risk groups to develop pulmonary toxicity based on the relative mean lung dose or the percentage of lung receiving more than a certain threshold dose. The RTOG 9311 trial escalated the dose to 83.8 Gy for patients with $V_{20}$ <37.5% (the lung volume received >20 Gy), using daily fractions of 2.15 Gy.[121] Investigators from the Netherlands Cancer Institute reported that doses up to 94.5 Gy in 42 fractions within 6 weeks could be safely delivered in case the mean lung dose was less than 11.3 Gy (corresponding to 13.6 Gy in case a simple planning algorithm is used).[129] Investigators from Memorial Sloan-Kettering Cancer Center safely escalated to a dose of 84 Gy for normal-tissue complication probability (NTCP) of less than 25%.[122] The maximum tumor dose delivered in these dose escalation trials (using different fractionation schedules and overall treatment times) can be compared by the calculation of the time-corrected biologically effective dose (tBED)[130] (with $\alpha/\beta = 10$ Gy and proliferation starting at 28 days). Compared with the dose escalation trial of the University of Michigan (UM 9204) and the RTOG 93-11 trial, the tBED in the trial of the Netherlands Cancer Institute was the highest (108 Gy) because of the reduced overall treatment time of 6 weeks.

Higher doses significantly increased the failure-free interval for the total group of patients in multivariable analysis in this dose escalation trial.[129] Kong et al.[16] reported improved local control and survival in patients irradiated with doses above 74 Gy in the dose escalation trial from the University of Michigan. For patients with newly diagnosed or recurrent stage I to III disease, multivariate analysis of this dose escalation trial found the radiation dose to be the only significant factor for local tumor control and overall survival. This demonstrated a positive relationship between dose and local/regional control, as well as overall survival, when doses ranging from 63 to 103 Gy were used. An increase of 1 Gy was associated with a more than 1% improvement in the 5-year tumor control, and a 3% decrease in the risk of death. Higher radiation doses may, therefore, be beneficial to patients with inoperable/unresectable NSCLC. A recent secondary analysis from RTOG trials has demonstrated a 2% reduction of risk from death with each increase of 1 Gy biological equivalent dose.[131] Bogart et al.[126] used >2.25 Gy daily fractions to a total nominal dose up to 84 Gy (range: 60 to 84) and reported a promising overall tumor response rate of 88% (35% complete response and 53% partial response), actuarial median survival of 38 months, and

3-year overall survival of 60% in early stage medical inoperable NSCLC.

In the setting of concurrent chemoradiation therapy (ChemoRT), the group from the University of North Carolina reported safe dose escalation up to 90 Gy with 2 Gy daily fractions, and with concurrent cyclophosphamide (CP) chemotherapy.[132] Clinical trials are ongoing to confirm the efficacy of such high-dose radiation in patients receiving concurrent ChemoRT, an example of which is RTOG 0617/North Central Cancer Treatment Group [NCCTG] N0628/Cancer and Leukemia Group B [CALGB] 30609, a randomized phase III comparison of standard dose (60 Gy) versus high-dose (74 Gy) conformal radiotherapy with concurrent ChemoRT in patients with stage IIA/IIIB NSCLC.[133]

In summary, the dose of radiation should be individualized based on normal-tissue tolerance, particularly normal lung, and the use of concurrent chemotherapy. A dose of more than 70 Gy may be given with RT, or sequential ChemoRT, and when the lung volume to be irradiated is limited (see succeeding section for lung dose tolerance). For large tumors when normal lung irradiation is extensive, or concurrent chemotherapy is given, most patients are unable to tolerate higher radiation doses due to severe toxicity; the safe prescription dose may still be around 60 to 70 Gy.

## Treatment Duration and Altered Fractionation

**TREATMENT DURATION.** Extension of treatment duration may allow tumor repopulation and decrease the probability of local tumor control and survival. In RTOG 83-11, the highest survival was found in patients who received 69.6 Gy. These patients often had extended treatment duration and delays caused by acute esophagitis. Indeed, survival at 2 and 5 years was significantly better in patients who completed treatment in the planned time, compared with those who had treatment interruptions (24% vs. 13% at 2 years and 10% vs. 3% at 5 years).[134] In a large phase III trial reported by Saunders et al.,[135] 563 patients were randomized into two groups treated with radiation alone: standard RT (60 Gy in 2 Gy fractions, Monday through Friday in 6 weeks), or continuous hyperfractionated accelerated RT (CHART)—54 Gy delivered over 12 consecutive days. Two-year survival was noted to be superior in the CHART arm (29% vs. 20%; $p = 0.008$), which could be caused by a reduction in the overall treatment time with CHART, as the biological equivalent dose (BED) was 72 and 62 Gy for the conventional arm and CHART regimen, respectively. The ECOG 2597 trial compared 64 Gy/32fx/6.5 weeks with hyperfractionated accelerated radiation therapy (HART) (57.6 Gy/36 fx/3 weeks) after induction chemotherapy in locally advanced stage III NSCLC, and reported a trend of improved survival with the accelerated arm.[136] An early analysis estimated that the tumor control probability of NSCLC decreases 1.6% per day after a 6-week duration of RT.[137] In a recent secondary analysis of three RTOG trials in patients with stage III NSCLC who were treated with immediate concurrent ChemoRT, prolonged treatment time was significantly associated with poorer survival.[131]

The latter translated into a 2% increase in the risk of death for each day of prolongation in therapy. It was estimated that the tumor control probability of NSCLC decreases 1.6% per day after a 6-week duration of RT.[137] Thus, every effort should be made to limit treatment duration and avoid treatment delays. Currently, there are investigative efforts to increase daily fraction size to escalate total radiation dose without extending the treatment duration. One approach involves dose escalation using 2.25 Gy daily fractions (once or twice daily) but limiting treatment duration to 6 weeks.[126] This approach was used to escalate radiation doses to 94.5 Gy in patients with limited lung volume.[129] Another approach is to use a higher fraction dose every day while limiting the treatment duration to 5 weeks.[130] The University of Michigan has an ongoing trial to limit the radiation to 6 weeks by escalating daily dose at the later part of the week (Thursday and Friday).

**ALTERED FRACTIONATION.** Hyperfractionated RT delivers multiple smaller fractions each day, and used to be an area of interest for clinical trials to prevent excessive late tissue toxicities such as radiation pneumonitis that result from large daily fractions. However, randomized clinical trials have not unequivocally shown an advantage for hyperfractionated RT.[134,138,139] With radiation alone, the RTOG 8311 trial tested multiple total tumor doses (60, 64.8, 69.6, 74.5, and 79.2 Gy) and showed superior results with 69.6 Gy in 1.2 Gy twice daily fractions, compared with 60 Gy in 2 Gy daily fractions with a similar BED and treatment duration.[134] Although there is no reduction of radiation pneumonitis, the apparent survival benefit in these phase I/II trials was used to justify the inclusion of a hyperfractionated arm in subsequent trials, such as RTOG 8808 and RTOG 9410.[138,139] In the setting of neoadjuvant chemotherapy, RTOG 8808 failed to show a significant advantage to using hyperfractionated radiation. Using concurrent ChemoRT, RTOG 9410 compared induction chemotherapy with vinblastine and cisplatin followed by standard, single daily fraction RT (day 50) versus either identical chemotherapy and radiation given concurrently on day 1, or a third arm incorporating hyperfractionated RT and concurrent cisplatin and oral etoposide. The hyperfractionated arm was associated with an increased incidence of esophagitis and inferior survival compared to the daily fractionated concurrent arm.[139] Using hyperfractionated and accelerated radiation, the aforementioned CHART and HART delivered 1.5 Gy in three fractions a day with or without continuous radiation during the weekend, was associated with increased mortality when it was delivered with concurrent chemotherapy, or resulted in a higher esophagitis rate (25% for HART vs. 16% for the conventional arm) with sequential ChemoRT. In summary, hyperfractionated schemes are not recommended because of the lack of significant survival benefit in phase III trials, increased acute esophagitis, especially with concurrent chemotherapy, and the burden to the patients and radiation departments. Although hyperfractionated accelerated RT may be an option for radiation alone, the "safe" fractionation prescription is still 1.8 to 2.0 Gy conventional fractionations, particularly when concurrent chemotherapy is given.

## Dose and Fractionation in Small Cell Lung Cancer

Thoracic radiation for limited stage small cell lung cancer (LS-SCLC) should be delivered early and concurrently with cisplatin-based chemotherapy, with 45 Gy in 1.5 Gy twice-daily fractions. If hyperfractionation is not possible, a dose of at least 54 to 60 Gy in 2 Gy daily fractions should be given. If the chemotherapy has been given prior to the thoracic RT, 50 to 54 Gy in 1.8 to 2.0 Gy should be given to the complete responders and 60 Gy to partial responders. Current investigations within cooperative groups include dose escalation to 70 Gy using standard fractionation (such as CALGB) and 61.2 Gy using a concomitant boost scheme (such as RTOG). Accelerated hyperfractionated RT (45 Gy in 1.5 Gy twice-daily fractions) was based on a randomized phase III clinical trial, intergroup trial (INT) 0096.[140] This trial compared once daily (45 Gy in 1.8 Gy daily fractions) versus twice-daily RT (45 Gy given in twice daily 1.5-Gy fractions) in combination with concurrent cisplatin and etoposide therapy. An improved median survival time and 5-year survival rate was observed in the accelerated arm compared with the once-daily group, 23 months versus 19 months and 26% versus 16%, respectively ($p = 0.04$). One must note that the accelerated hyperfractionated RT was associated with increased toxicities. A dose of 45 Gy in 1.8 Gy daily fractions is not biologically equivalent to 45 Gy in 1.5 Gy twice daily. Treatment duration may also impact the outcome of SCLC treatment. Using a similar regimen of hyperfractionated RT with a treatment break of 2.5 weeks, the NCCTG failed to show a benefit of using hyperfractionated RT compared with conventional RT.[141,142] Nevertheless, 45 Gy in 30 fractions over 3 weeks concurrent with etoposide and cisplatin therapy generated superior results to other published reports and is the recommended regimen for the treatment of LS-SCLC. When twice-daily radiation is impossible, daily fractionation with higher dose (54 to 60 Gy in 2 Gy fractions) is an acceptable alternative.

## Palliative Thoracic Radiation

Symptoms such as chest pain, hemoptysis, dysphagia, and dyspnea in NSCLC as well as in SCLC can be effectively palliated using different treatment regimes. The optimal dose for palliation remains controversial.[143] Several randomized trials were performed with sometimes controversial results. Comparing the trials reported next is difficult, because frequency and duration of measurements vary substantially. Another aspect is the need to analyze the sum of the palliative effect: the symptom reduction and symptoms induced by the treatment.

In the first Medical Research Council (MRC) trial reported in 1991,[144] no differences in palliative effect or in survival were seen between 10 × 3 Gy and 2 × 8.5 Gy. In a second MRC trial (1992),[145] no differences in survival were seen between 10 Gy single fraction and 2 × 8.5 Gy. In a study by Bezjak et al.,[146] however, 5 × 4 Gy and a single 10-Gy dose was favorable for the multifractionated treatment only in patients with good performance. For patients in poor general condition and/or exhibiting significant weight loss, the 10 × 3 Gy treatment was significantly better than the 2 × 8 Gy in a large Dutch randomized trial reference.[147] The palliative effect differed significantly over time between the treatment arms. In the 10 × 3 Gy arm, the onset of the palliative

effect occurred later and persisted longer with less worsening symptoms than in $2 \times 8$ Gy. Furthermore, the 1-year survival in this trial was better in patients treated with $10 \times 3$ Gy. Based on a recent informal survey performed among RTOG lung committee members, a wide range of regimens are currently in use: once 10 Gy, 5 times 4 Gy, twice 8.5 Gy (with a week interval), 13 or 15 times 3 Gy daily, 2.5 Gy daily times 20, or even 2 Gy daily.[30]

A short treatment regimen such as 30 Gy in 10 daily fractions is frequently used in this patient population to achieve a quick palliation without the patient and family spending significant time traveling back and forth to the treatment center.[147–150] Although using this dose regimen does initially relieve symptoms, it may not have a sustained effect. Thus, in an effort to keep the amount of therapy to a minimum, but tailor the therapy to the needs of the patients, another short course of radiation may be considered after a 2-week break. Under such circumstances, the patients are reevaluated for overall status and tumor response. If they have improvement in their symptoms, and have continuing good performance status, an additional 20 Gy in 4 fractions to 30 Gy in 10 fractions with oblique fields may be given to these patients for a sustained palliative benefit while reducing the time commitment and minimizing the side effects during the course of treatment. If patients show evidence of disease progression, either locally or systemically, and their general condition is continuing to decline, no additional RT is given after the initial treatment. There is limited evidence showing that higher palliative dose thoracic irradiation is associated with improved survival (in patients with good performance status).[147,148]

Selection of regimen should be based on comprehensive consideration of age, performance status, tumor burden, and symptoms of each individual patient. Patients with poor performance status, and patients with large distant tumor burden (regardless of their performance status) should be treated by a short course of relatively low-dose radiotherapy. For patients with good performance status, the choice of the optimal radiation schedule could be between 30 and 45 Gy in 2.5 to 3.0 Gy fractions. A definitive dose of radiation with combined chemotherapy may be preferred for patients with good performance and limited distant disease (such as solitary brain metastasis).

**Cranial Irradiation**    The standard dose prescription for prophylactic cranial irradiation (PCI; see also Chapters 57, 60, and 63) for LS-SCLC is 25 to 30 Gy in 2 to 2.5 Gy daily fractions over 12 to 14 days for patients in complete remission.[140,151] However, a review including 42 PCI trials with 4749 patients revealed the optimal total RT dose to be 30 to 35 Gy given as 2 Gy fractions.[152] A dose of 24 Gy in 3 Gy fractions also appeared safe based on data from a large randomized study. According to a comparison of four dose regimens: 8 Gy, 24 to 25 Gy, 30 Gy, and 36 to 40 Gy, higher doses of radiation appeared to be correlated with incremental decreases in the risk of brain metastasis ($p$ for trend = 0.02), without significant impact on survival.[153] Meanwhile, high-dose radiation may be associated with impaired neurocognitive function. Thus, more efficacious and less toxic treatment regimens are being sought. A recent randomized phase III INT (RTOG 0212) compared different doses of PCI in LS-SCLC (25 Gy in 2.5 Gy

daily vs. 36 Gy in 2.0 Gy daily vs. 36 Gy in 1.5 Gy twice-daily fractions). Initial results from this large trial revealed no significant change in quality of life caused by PCI compared with baseline, although longer follow-up is necessary.[154] For patients with extensive stage (ES) SCLC, PCI significantly reduced the incidence of symptomatic brain metastases and prolonged both disease-free and overall survival and should be part of standard care in SCLC patients who respond to chemotherapy.[155]

**Normal-Tissue Dose Constraints**    The other important consideration in treatment planning is to limit the radiation to the normal tissue to avoid excess treatment toxicity. The critical structures for radiation of lung cancer are lung, esophagus, spinal cord, and heart. A set of criteria for normal-tissue tolerances should be established from published studies and adapted for local clinical use. A good starting point is the report by a National Cancer Institute–sponsored task force, which carried out an extensive literature search and presented updated information on tolerance of normal tissues, with emphasis on partial volume effects.[156] For uniform irradiation of normal lung, tolerance doses for a 5% chance of pneumonitis occurring within 5 years for uniform irradiation of one third of the lung was 45 Gy, two thirds was 30 Gy, and whole lung was 17.5 Gy. For the esophagus, the corresponding doses are 60 Gy (one third), 58 Gy (two third), and 55 Gy (whole) for an end point of clinical stricture/perforation. For the heart: 60 Gy (one third), 45 Gy (two third), and 40 Gy (whole) for the end point of pericarditis. The above Emami tolerance data summary was one of the early efforts toward the use of objective criteria in evaluating treatment plans. However, the tolerance doses given were based on limited volumetric dose data publications and are "guesstimates" based on clinical experience.

As 3D dose distributions became available, dosimetric parameters have been correlated with complication data. Although there is not sufficient toxicity data in spinal cord and heart tolerance to change the above criteria, toxicity data for esophagus and lungs are available and should be taken into consideration in the treatment planning. For example, of the lung, many dosimetric factors are associated with the occurrence of grade 2 to 3 radiation pneumonitis. As it was recently reviewed,[16] lung volumes receiving a certain dose ($V_d$), such as $V_5$, $V_{13}$, $V_{20}$, $V_{25}$, and $V_{30}$, are highly correlated with each other and associated with the incidence of pneumonitis in multiple series; similarly, the doses to a specific percentage of the lung volume ($D_v$ such as $D_{20}$) are also associated with the incidence of pneumonitis. The problem with those point dosimetric factors is its dependency on the shape of the DVH, which vary with the beam arranging pattern of each individual practicing physician. Lung effective volume ($V_{eff}$, a "toxicity normalized" volume to a reference dose), mean lung dose, and model estimations of NTCP include the contributions of all parts of the dose distribution and may thus provide the most consistent prediction. Indeed, Seppenwoolde et al.[157] suggested that the mean lung dose model was significantly better than $V_d$ models. Although it rarely occurs, radiation pneumonitis increases remarkably after mean lung dose reaching 15 to 20 Gy, and the curve is in agreement with the traditional sigmoid-shaped dose–response relationship, with increasing steepness in

the slope after passing a threshold dose. Using a 20-Gy cutoff for mean lung dose, the probability of freedom from pneumonitis in patients treated with radiation alone or sequential ChemoRT is given in Kong et al.[16]; for concurrent ChemoRT, refer to Liao et al.[158] Despite the very attractive feature of NTCP models, it is generally observed that for these mostly conformal irradiation techniques, the NTCP correlates mean lung dose or $V_{20}$, and fails to show significant superiority in predicting either moderate pneumonitis or clinical fibrosis.[16] However, these NTCP models, because of their averaging (or weighting) of doses across the organ, have better potential for describing a wider realm of irradiation conditions, and may provide better prediction when the functional status of the organ are taken into consideration.

Although the lungs and the spinal cord are the primary organs of concern in limiting the dose and field of radiation, toxicities to other structures within the mediastinum, such as esophagitis and resultant dysphagia and odynophagia, are often the dose-limiting side effects of combined chemotherapy and radiotherapy to the chest. In practice, severe esophagitis ranges from 5% to 37%. Many dosimetric parameters are significantly associated with the occurrence of grade 2 and above esophageal toxicity. Such factors include, but are not limited to, the length of the irradiated esophagus, the surface area of receiving 55 Gy, the volume receiving more than 60 Gy, maximal dose, or volume of the organ treated beyond a threshold dose (40 to 70 Gy), NTCP of esophagus, and the use of concurrent chemotherapy. Bradley et al.[159] correlated the rate of ≥grade 2 acute esophagitis to radiation dose–volume parameters for patients treated with or without concurrent chemotherapy. The data suggests that the use of concurrent chemotherapy increases the risk of clinically relevant esophagitis significantly.[155,160] Hyperfractionation also significantly increases the esophageal toxicity.[161] The heart does not, except under rare circumstances, contribute to the acute toxicity. However, cardiac toxicity in the form of pericardial disease or pericardial effusions and later myocardial and coronary artery disease has been reported in long-term survivors, making it desirable to reduce the dose to the entire heart as much as possible. However, one must note that radiation heart toxicity in general is poorly studied in patients with lung cancer.

The University of Michigan's current ongoing trial sets constraints for dose to normal tissue for patients receiving concurrent ChemoRT as the following: the maximum dose to the spinal cord is a dose biologically equivalent to 50 Gy in 2 Gy fractions. The $V_{eff}$ computed for the esophagus with a normalization dose biologically equivalent to 72 Gy in 2 Gy fractions must be less than one third. The $V_{eff}$ for the heart with a normalization dose of 40 and 65 Gy must be less than 100% and 33%, respectively. The $V_{eff}$ computed for both lungs minus the composite volume of inhale and exhale GTVs for the prescription dose must be generating less than 15% of NTCP, approximating a mean lung dose of 20 Gy. Current ongoing RTOG trials use $V_{20}$ of 30% for lungs.[105,159–170]

## TREATMENT DELIVERY

### The Linear Accelerator

The delivery of thoracic radiation treatment is almost exclusively delivered using a linear accelerator, although radioactive cobalt therapy units are still in use. Linear accelerators deliver x-ray beams with peak energies between 4 and 23 MeV. The x-ray beams have an energy spectrum with the mean energy typically one third of the maximum energy. Hence, the energy of these beams is often referred to as *MV* rather than MeV to recognize the beam spectrum. Typically, 6 MV is the most common energy used for lung cancer radiotherapy. Higher energy beams offer increased depth penetration at the cost of broader lateral radiation spread and underdosage of tumor target at the side of beam entry. Higher energy beams also require more shielding for radiation protection, and energies above 10 MV produce neutrons that are a dose concern. An IMRT planning study by Weiss et al.[171] found, on average, no clinically or statistically significant differences between treatment plans generated for low (6 MV) and high (18 MV) photon energies.

An example of a modern linear accelerator is shown in Figure 40.7. Modern linear accelerators have variable collimators, typically MLCs, to automatically create treatment fields for conformal radiotherapy and IMRT. Another feature of modern accelerators is the in-room imaging options provided by either the linear accelerator vendor or independent companies. These imaging systems may include the following:

- Electronic portal imaging devices (EPIDs) that image the radiation emitted from the treatment machine that has passed through the patient (shown in Fig. 40.7). The EPID

**FIGURE 40.7** An example of a treatment setup in a modern linear accelerator for the radiotherapy treatment of lung cancer. Note the two x-ray imaging (kilovoltage and megavoltage) and optical device that can be used to monitor internal and external motion. *DMLC*, dynamic multileaf collimation; *kV*, kilovoltage; *MV*, megavoltage.

can be used to reduce setup errors, to acquire megavoltage CT scans,[172] monitor target position during radiation delivery,[173,174] and potentially be used to adjust the treatment delivery in real time.[175]

- Kilovoltage (kV) x-ray tubes and detectors that image the patient (shown in Fig. 40.7), provide superior soft-tissue visualization compared with megavolt imaging. For real-time tracking images, radiopaque markers are particularly useful. These radiopaque markers should be implanted into or near the tumor using either percutaneous or bronchoscopic techniques. These kV images can be used for pretreatment cone–beam CT acquisition,[176] fluoroscopic verification of motion at the time of treatment,[176] and respiratory-correlated (4D) cone beam CT.[177]

- Optical monitoring of a point (shown in Fig. 40.7) or points on the patient surface or the actual surface itself, which gives real-time information without giving extraradiation dose. The optical signals can be used to monitor respiration and patient motion for respiratory-gated radiotherapy,[178] and can also be combined with kV or MV imaging data to estimate internal target positions.[179,180]

MRI is a modality for in-room imaging currently under development by several groups and is promising because of its exquisite soft-tissue contrast that is very attractive for image-guided radiotherapy. Electromagnetic transponders, currently used for prostate radiotherapy, are another promising area under investigation for lung treatments.

These imaging systems facilitate image-guided radiotherapy (IGRT). There are strong similarities between image-guided surgery and IGRT, where in IGRT images of the patient acquired during a treatment fraction are used to measure or estimate the position of the patient's anatomy at a given time to drive the therapeutic instrument—the radiation treatment beam.

IGRT has the potential to considerably increase the precision of radiotherapy as lung tumors change between treatments because of changes in the functional reserve capacity, tumor shrinkage, and radiation-induced pulmonary changes. Lung tumors move during treatment because of respiration, cardiac, musculoskeletal, and gastrointestinal motion. Several authors (Borst, Erridge, van Sornsen, de Boer)[3,28,29,181] have studied interfraction patient setup error and reported systematic and random errors up to 4 and 3 mm (1 SD), respectively, in the absence of setup correction protocols. Using simple offline correction protocols (imaging approximately one third of the fractions), the systematic error can be reduced by a factor of 2 to 3. More recently, considerable day-to-day variation of the tumor relative to the bony anatomy (baseline shifts) were observed (Wulf,[6] Purdie,[6a] Sonke[30]), with systematic and random baseline variations up to 4 and 2 mm (1 SD), respectively. Soft-tissue visualization or accurate surrogates are required to correct for such baseline shifts. In the absence of such corrections, the application of gated treatment delivery is not recommended. Note that when an ITV is constructed to account for internal organ motion, baseline shifts need to be taken into account next to respiration. The type of correction strategy applied to reduce geometrical uncertainties is a balance between work load and precision, and depends on the fractionation scheme. For conventional fractionation using a large number of fractions, an offline correction strategy is generally considered adequate. Stereotactic body radiation therapy (SBRT), using a limited number of high-dose fractions, requires daily imaging and corrections based on soft-tissue guidance.

It is clear that regular observation and correction for patient setup is a necessity. Commonly, a margin of 5 to 7 mm should be added to the ITV for set-up error. However, special immobilization and image-guided devices can reduce the setup margin to 3 mm.

**Quality Assurance**    The sensitivity of lung cancer and normal-tissue response to radiation, along with published errors in radiotherapy,[182,183] drives the need to establish and perform quality assurance procedures to facilitate patient safety and treatment accuracy. Imaging devices for optimal use require image quality assessment, dose measurement, and geometric fidelity tests. Because of their complexity, treatment planning systems, and by extension, the linear accelerators that they model, require a broad range of assessments as there are many variables that affect the dose distribution, such as the energy, field size, gantry angle, couch angle, collimator angle, beam-defining devices, patient position, and patient heterogeneities. Linear accelerators, and any additional in-room image devices, require alignment of the optical, laser, mechanical, and radiation coordinate systems to ensure radiation delivery accuracy. The output dose, under various different conditions, needs to be measured. The development of a quality assurance program, and oversight of its implementation is one of the tasks of the medical physicist.

For guidance, the AAPM have several freely available Task Group reports pertaining to quality assurance for imaging,[184] treatment planning,[185] and treatment delivery,[186] applicable to all radiotherapy, as well as reports on dose calculation,[111,187] and motion management[112] that are particularly important for lung cancer radiotherapy.

# CONCLUSION

Modern lung cancer radiotherapy is a complex combination of many processes—imaging, treatment planning, and treatment delivery—to individualize the delivery of therapeutic radiation to each patient. It involves several dedicated personnel, including radiation oncologists, medical physicists, dosimetrists, and radiation therapists, as well as several peripheral specialists from biology, molecular imaging, medical oncology, pathology, pulmonology, radiology, and surgery.

Ongoing advances in imaging, treatment planning, image guidance, motion management, and adaptive radiotherapy strategies lead to a continued increase in complexity, together with the increased efficacy. The accuracy with which lung tumors can be

targeted with radiation, and normal tissues spared the toxic effects of radiation, is constantly improving. Similarly, we are learning more about normal-tissue tolerances from clinical data during conventional and stereotactic regimens (see Chapter 43) and also in the concurrent chemoradiotherapy setting. It is expected that clinical outcomes, with time, will reflect the evolving technological improvements and clinical understanding of the effects of radiation in lung cancer.

# Biological Basis of Fractionation and Timing of Radiotherapy

## THE BIOLOGY OF DOSE FRACTIONATION IN RADIOTHERAPY

Radiation biology is the study of the biological effects of ionizing radiation; clinical radiation biology is concerned with the clinical response of human tumors and normal tissues to the doses normally used in radiation therapy. Basic and clinical radiation biology together form the scientific basis for application of radiation as an anticancer agent and provide the framework for understanding dose-fractionation and dose–volume effects as well as the rational basis for combining radiation with cytotoxic or molecular targeted agents.

Although advances in molecular radiation biology of tumors[1,2] and normal tissue[3] play an increasingly important role in further developing the scientific basis for radiation therapy, the conceptual basis for dose fractionation is still, to a large extent, rooted in the target-cell hypothesis, that is, the hypothesis that the main biological effect of ionizing radiation on cells and tissues is direct cell killing and loss of proliferative capacity of surviving cells. Therefore, much of the current chapter describes dose-fractionation effects within the target-cell framework, often referred to as "classical radiobiology." However, the more recent thinking in the field will be brought in, where this is relevant for understanding some of the newer trends in radiation dose fractionation.

### The Physical–Biological Interactions of Radiation

The basic interaction of radiation with matter has been well understood since the first third of the 20th century. When a radiation beam traverses through matter, energy is deposited along its path. Compton scattering is the dominating interaction for radiation beam energies used clinically (Fig. 41.1). The Compton effect is an inelastic scattering of photons by an electron (i.e., the photon loses some of its energy in the event), leading to ionization events either within the molecules of the critical cells (direct effect) or in adjacent water molecules (indirect effect).[4] These direct and indirect effects result in the formation of unstable and highly reactive free radicals that are responsible for the biological effects on DNA and tissues. Cellular damage and cell killing occurs when critical molecular target(s) such as DNA are damaged within the cell.[5] Cancer cell killing can be defined as the loss of the cell's reproductive ability. Most cells do not die immediately when they are critically damaged. They usually proceed to mitosis and either may fail to complete mitosis or may progress through one or more cycles before failing at a subsequent mitosis. However, some cell types, such as lymphocytes, die before reaching mitosis in a process called apoptosis or "programmed cell death."[6] In the apoptotic process, the radiation damage initiates signaling cascades, whereby preset mechanisms are evoked to cause cellular self-destruction. Characteristic histological features are seen in apoptotic cells such as blebbing and fragmentation of the nucleus.[7]

In addition to the "direct-targeted" effects of ionizing radiation on cells, there is increasing evidence for nontargeted effects of radiation such as bystander cell killing.[8] The therapeutic implications, if any, of this mode of cell killing are not well understood.

### The Cell Survival Curves
The target cell hypothesis postulates that the response of tumors and normal tissues to ionizing radiation is a direct result of the loss of reproductive ability of the irradiated cells. This can be assessed in vitro by the ability of cells in culture to continue sustained cellular division to form a colony. A plot of the colony-forming ability of cells as a function of dose is called a cell survival curve. The parameters that influence cell survival curves will be described later in this chapter. The cell survival curve was first described by Puck and Marcus[9] in 1956, who examined the survival of HeLa tumor cells as a function of radiation dose. The cell survival curve shape for early- and late-reacting tissues (see discussion that follows) is represented in Figure 41.2, in which the cell's survival fraction is plotted against dose on a semilogarithmic scale. In general, at very low radiation doses, the cell survival curve is relatively shallow, whereas at higher doses, the survival curve bends more, reflecting the greater cell kill per unit Gu as dose

⁺positron
annihilation reaction with free electron
**FIGURE 41.1**   Radiation tissue interaction effects. **A:** The photoelectric effect occurs when the incident photon strikes one of the bound inner shell electrons around the atomic nucleus and transfers its entire energy to the electron, causing the electron to be ejected from its orbit. This electron may then collide with other orbiting electrons and result in a chain of further strikes, electron expulsion, ionization, and other collisions. The incident photon disappears when its energy is used up. **B:** Compton process differs from the photoelectric effect in that only a portion of the energy of the incident photon is used in ejecting the orbiting electron, and the remaining energy is emitted in a secondary photon of less energy. This secondary photon can subsequently cause further ionization either through the photoelectric or Compton process. **C:** Pair production process is the least common therapeutic method of energy absorption. This only occurs when an incident photon interacts with an atomic nucleus and its energy is completely transformed into two particles (a positron and an electron). These two particles do not come from the atom, so no single charged particle has been lost; therefore, there is no ionization of the atom. The positron can then react with an orbital electron of another atom resulting in an "annihilation" reaction producing two photons of 0.51 MeV. For this process to occur, the initial incident photon must have energy of least 1.02 MeV. A pair production chain reaction never results because the annihilation photons never have energy greater than 0.51 MeV. (From Khoo V, Bidmead M. Chapter 1. Physical basis of radiotherapy. In: Huddart RA, Murthy V, eds. *Cancer Radiotherapy: Methods and Protocols.* Clifton, New Jersey, Humana Press, 2007.)

increases. This shape of the cell survival curve with an initial shallow slope followed by a "broad-shoulder" curve is typical of low–linear energy transfer (LET) radiation (e.g., photons, which are commonly used for lung radiotherapy). In contrast, cell survival curves for high LET radiation, such as neutrons and $^{12}$C-ions have very little "shoulder" but are approximately straight lines in semilogarithmic coordinates.

Several mathematical models have been devised to describe the cell survival curve shape. Of these models, the most widely adopted is the linear-quadratic model[10] that appears to provide the best description of cell survival within the range of doses used clinically. The linear-quadratic equation is expressed mathematically as follows:

$$S = e^{-\alpha \cdot d - \beta \cdot d^2}$$

where $S$ = survival of a cell population after a dose of radiation (d) and where $\alpha$ and $\beta$ are constants. Assuming that the effect

per fraction is constant, it is easily shown that the effect of n fractions of size d is:

$$S = e^{-\alpha \cdot D - \beta \cdot d \cdot D}$$

where D = nd is the total dose after n fractions. It follows from this equation that a total dose $D_1$ delivered with dose per fraction $d_1$, will result in the same biological effect as a total dose $D_2$ delivered with dose per fraction $d_2$ if (and only if):

$$D_2 = D_1 \cdot \frac{d_1 + \frac{\alpha}{\beta}}{d_2 + \frac{\alpha}{\beta}}.$$

This equation is known as Withers' formula.[11] This formula can be interpreted operationally as a means of adjusting for dose per fraction—irrespective of any underlying mechanistic interpretation at the cellular level. It can be seen from the mathematical form of Withers formula that it is the ratio between $\alpha$ and $\beta$, rather than the parameter values themselves,
**FIGURE 41.2** The dose–survival curves for early- and late-responding tissues. The cell survival curve for late-responding tissues is more "curvy" than for early-responding tissues and at least some cancer types. The $\alpha/\beta$ ratio is approximately 2 Gy for late-responding tissues and 10 Gy for some cancers or early-responding tissues.

which determines the change in total dose as a function of a change in dose per fraction that will be required to maintain the same level of biological effect.

The $\alpha/\beta$ ratio will be specific to different normal-tissue side effects and can be seen, as mentioned previously, as a measure of fractionation sensitivity of an end point.[12] Early side effects are generally characterized by a high $\alpha/\beta$ ratio, in the order of 10 Gy, and these occur, for example, in the gastrointestinal epithelium, skin, and bone marrow (Fig. 41.2). Late end points such as radiation myelopathy or radiation-induced fibrosis will typically have a low $\alpha/\beta$ ratio in the range from 1 to 5 Gy (Fig. 41.2). There are relatively sparse data on $\alpha/\beta$ for human tumors, but it is often assumed that it is in the same range as for early normal-tissue effects of radiation.

This differential in fractionation sensitivity between, at least, some human tumors and some types of late-occurring side effects of radiotherapy provides a rationale for dividing the total prescribed radiation dose into many smaller doses delivered over a period of time. This difference has been exploited by investigators using altered fractionation schemes to manipulate the therapeutic ratio in favor of improved tumor control while reducing damage to normal structures or late-responding tissues. A good example of this fractionation strategy is the development of the continuous hyperfractionated accelerated radiotherapy (CHART) regime in lung cancer.[13,14]

**The Four R's of Radiotherapy**   Several biological parameters influence the response of both normal tissues and cancers cells to fractionated radiotherapy. Following Withers,[15] these are memorized as the four R's of radiotherapy: Repair, Redistribution, Repopulation, and Reoxygenation. All of these are processes taking place in the interval between fractions, and

the differential between tumors and normal tissues in these four R's form the classical rationale for dose fractionation as well as the "Radiosensitivity" of cells/tissues. Steel[16] subsequently advocated to add this fifth R, namely Radiosensitivity, as a co-factor in determining cellular response to radiation. However, this R is clearly of a different nature than the original four R's. These R's of radiotherapy are summarized in Table 41.1 and will briefly be described in the following.

**Repair**   Both normal and cancer cells show split-dose recovery, expressed as a higher in vitro cell survival if the same physical dose is split in two, with a sufficient time interval between irradiations. This phenomenon is thought to reflect chemical and enzymatic repair of DNA damage in the interval between doses.[17]

The clinical implication of this is that if multiple fractions are being given within a single day, then there must be an adequate time interval given between fractions (minimum 6 hours, preferably 8 or 10 hours) in order to permit repair of sublethal damage. As previously mentioned, the shoulder of the cell survival curve is repeated for each dose fraction as shown in Figure 41.3, provided that cellular recovery is complete between fractions. The broader the shoulder, the greater the repair capacity of the cells. This is in particular seen in late-responding tissues with low $\alpha/\beta$ ratios. These tissues can be spared from accumulating radiation DNA damage by fractionation.

In general, these repair processes will affect the response of both normal tissues and tumors to a course of radiation.

| TABLE 41.1 | The Four R's of Radiotherapy |
|---|---|
| | **Radiobiological Effect** |
| Repair | Cellular damage is repaired in the time interval between one fraction and the next. Sometimes referred to as "recovery" to avoid the impression that this reflects DNA damage repair only. |
| Redistribution | Progression of surviving cells from relatively more radioresistant to more sensitive phases of the cell cycle. |
| Repopulation | Repopulation, often referred to as accelerated repopulation, is the active proliferative response to a cytotoxic insult mounted by some tumors and (early-responding) normal tissues. |
| Reoxygenation | Hypoxic cells are more resistant to both radiation and chemotherapy. This means that surviving cells will preferentially be found in hypoxic regions of a tumor. As tumor cells are killed, the metabolic consumption of oxygen is reduced and this is thought to lead to reoxygenation of the remaining tumor cells, thus effectively increasing their sensitivity to subsequent dose fractions. |
**FIGURE 41.3** The target cell hypothesis and the rationale for low dose per fraction. The cell survival curve for late-responding tissues is more curved than that for tumors or early-responding tissues as shown in Figure 41.2. When radiation dose is fractionated, and provided that the interfraction interval is sufficiently long, the shoulder portion of the respective curves is repeated, following each fraction. Fractionation will tend to spare late-responding tissues such as spinal cord, heart, and kidney relative to the tumor or early-responding tissues such as skin or gastrointestinal cells. With increasing number of fractions, there is greater kill of tumor cells—with a possible added effect from redistribution and reoxygenation—but with a potential benefit being reduced by accelerated repopulation is the overall treatment time is extended. Late-responding tissues are less affected by the overall treatment time but are relatively more sensitive to fraction size, as reflected by their lower $\alpha/\beta$ ratio. Thus, if large dose per fraction is used, then the total dose needs to be reduced in order to maintain the same level of normal-tissue toxicity.

Using daily fractionation with time intervals of approximately 24 hours between fractions, there is adequate time for repair to occur. If the radiotherapy factions are too close together (i.e., less than 6 hours) then, unrepaired damage will accumulate. Although this may be beneficial for tumor cell killing, it can result in substantial normal-tissue damage and increase the rate of treatment-related complication, thereby reducing the potential therapeutic ratio.

**Redistribution** A general schema divides the biological cell cycle into four phases: (a) mitosis, or M phase; (b) G1 phase; (c) DNA synthesis, or the S phase; and (d) G2 phase. Cells in the late G2 and M phase of the cell cycle tend to be most sensitive to irradiation, whereas those in the mid-late S and early G2 phase are more radioresistant.[18] This means that after irradiating a population of proliferating cells, surviving cells will predominantly be in the radioresistant late S and early G2 phases. During a course of fractionated radiotherapy, these surviving cells will progress through the cell cycle and "redistribute" into more radiosensitive phases in the interval between fractions and will be "caught" in a relatively more sensitive phase by the next fraction of radiation.

Radiation blocks cell progression through the cell cycle at the G2-M and the G1-S checkpoints. These checkpoints are controlled by several genes. The radiation induced G1 block is p53 dependent,[19] but as many tumors are p53 deficient, the G2 block may be more important in tumors receiving radiation. The duration of the G2 block is dose dependent.[20,21]

**Repopulation** Cells in both normal tissues and tumors may respond to a cytotoxic insult by accelerated repopulation.[22,23] Early-reacting tissues, such as the gastrointestinal mucosa, have a high cellular repopulation capacity, and this is an important component of their response to chemotherapy and radiation therapy. A reduction in overall treatment time will reduce the time available for repopulation in these tissues and lead to more side effects. Late-reacting tissues proliferate slowly and show less of a proliferative response to cytotoxic therapy, thus changing the treatment intensity is less important for these tissues. Accelerated repopulation, as reflected by the overall time factor, has been demonstrated in many cancers. Most convincingly, this has been shown by the outcome of a large number of randomized controlled trials of intensified radiation therapy for squamous cell carcinoma of the head and neck.[24] In head and neck squamous cell carcinoma (HNSCC), there are relatively reliable estimates of the dose recovered (or lost) per day because of proliferation, and this is consistently estimated at around 0.6 Gy/day.[25] This represents the increased total dose required to compensate for tumor repopulation, resulting from a 1-day protraction of treatment. This implies that if 2 Gy/day was used, the effective dose would only be 1.4 Gy as 0.6 Gy would be lost to counteract the effect of tumor repopulation. The lag time before repopulation takes effect will vary between different tissues and tumors and likely between patients. This lag time period may be in the region of 2 to 3 weeks[24] for HNSCC.

**Reoxygenation** Human tumors often contain hypoxic regions, and it was hypothesized as early as the 1950s[26] that this may be associated with radiation resistance. Hypoxic radioresistance has been documented and extensively studied in cells in vitro as well as in small animal tumor models. Oxygen is thought to inhibit the cellular repair of DNA damage induced by free radicals thereby "fixing" the radiation damage. More recently, it has been shown that hypoxic tumors also have a poorer outcome after chemotherapy or surgery, and a link has been established between malignant progression and hypoxia.[27] Research has shown that tumor cells under hypoxic conditions switch on several survival pathways that let them survive in a hypoxic microenvironment and confer resistance against cytotoxic therapy. Reoxygenation refers to the process by which previously hypoxic cells become better supplied by oxygen as they are brought closer to well-perfused regions when tumor cells in these oxygenated areas die during a course of radiation.

The fact that tumor oxygenation assessed at baseline (i.e., before the start of any therapy, by means of polarographic), microelectrodes is associated with survival after fractionated

radiotherapy in HNSCC proves that reoxygenation cannot completely offset the detrimental effect of hypoxia.[28] Whether this is because reoxygenation is not 100% efficient in countering radiobiological hypoxia or a result of the link between hypoxia and malignant, progression remains to be clarified.

## HYPERFRACTIONATED AND ACCELERATED RADIOTHERAPY

Cancer radiotherapy was widely introduced in clinical practice in the early 20th century, and it soon became apparent that the way radiotherapy was delivered over time had a major influence on tumor and normal-tissue effects. Indeed, as discussed earlier in this chapter, fractionated radiotherapy was introduced as a method to take advantage of the differential in the four R's between (most) tumor histologies and dose-limiting normal tissues. Even in those early days, the overall treatment time (i.e., the time elapsed between the first and the last day of radiotherapy), was recognized as a factor determining side effects.

Most of the altered radiotherapy fractionation schedules have explored two types of modification: hyperfractionation (HFX) and accelerated fractionation (AF). There is no consensus as to the definition of these two concepts, and some authors have proposed definitions based on a more or less complicated link between the time–dose factors of a fractionated regime of radiotherapy, namely the dose per fraction, number of fractions, daily or weekly dose, overall treatment time, and total dose. This has led to some confusion regarding the classification of radiotherapy schedules, and there is a need to return to more general definitions, directly reflecting the different rationales underpinning nonconventional schedules.[29] Indeed, the concept of HFX is essentially linked to dose fraction size and not to time. Therefore, any schedule employing a dose per fraction of less than 1.8 Gy is classified as *hyperfractionated*. AF relates to the intensity of therapy over time and, therefore, a schedule in which the rate of dose accumulation exceeds 10 Gy/wk is classified as *accelerated*. This simple definition, besides its pedagogic character, has the advantage of being applicable to all altered fractionation schedules. In addition, it clearly separates the issues of dose/fraction from overall treatment time and total dose, which result from distinct radiobiological concepts. In a schedule using a dose per fraction different from 2 Gy, the rate of dose accumulation is estimated from the total dose converted into the biologically equivalent dose in 2-Gy fractions ($EQD_2$) using the linear-quadratic model with an assumed $\alpha/\beta$ of 10 Gy for non–small cell lung cancer (NSCLC). Similarly, a schedule employing a dose per fraction exceeding 2.2 Gy is classified as *hypofractionated*.

**Hyperfractionation**    The biological basis of HFX is to exploit the postulated different capacity of target cells in tumor tissue and late-responding normal tissue to recover from sublethal radiation damage, given that the time interval between the two fractions is sufficiently long. The latter condition is not entirely trivial as there are data suggesting that the recovery

half-time in human tissues may be considerably longer, in the order of 4 to 8 hours, than what was derived from in vitro and experimental animal studies.[30–32] That HFX might be useful to improve the therapeutic ratio of radiotherapy relies on the putative difference in fractionation sensitivity between tumors and late effects. In patients with HNSCC, this rationale is supported by the results of randomized clinical trials.[33] Thus, from a radiobiological perspective, HFX with increased total dose compared to conventional fractionation appears to be a promising option to improve local control and survival in NSCLC, without increasing the risk of late normal-tissue damage.

Dose-escalated HFX was compared with conventional or moderate hypofractionation in three randomized trials in NSCLC.[34] A metaanalysis of these three trials found a significantly improved overall survival after HFX compared with conventional fractionation or hypofractionation, with an odds ratio (OR) for death of 0.69 (95% confidence interval [C.I.], 0.51 to 0.95; $p = 0.02$).

In summary, based on radiobiological data, there is good reason to believe that dose-escalated HFX may improve survival in NSCLC. However, there appears currently no strong evidence from randomized trials supporting this approach, possibly, because of the fact that only a relatively small number of patients were included in these trials.

**Accelerated and Accelerated Hyperfractionated Radiotherapy**    The biological rationale for AF is to counteract the so-called time factor of fractionated radiotherapy (i.e., the loss of local tumor control with increasing overall treatment time). This time factor is generally thought to reflect rapid repopulation of clonogenic tumor cells during treatment, although alternative mechanisms may contribute.[23,35] A significant time factor has so far been demonstrated in randomized clinical trials for NSCLC[36–39] and small cell lung cancer (SCLC).[40] In contrast to tumors, overall treatment time has no or little impact on classical late radiation damage such as lung fibrosis and spinal cord damage.[41] Short overall treatment times increase acute normal-tissue reactions such as esophagitis but also radiation pneumonitis.[41] From a radiobiological perspective, AF might increase the therapeutic ratio between local tumor control and late toxicity in NSCLC.

The combination of HFX with AF, leading to a short overall treatment time, resulted in the CHART schedule in which 54 Gy is delivered in 12 days (3 times 1.5 Gy/day). In a large phase III trial, CHART was subsequently compared to the conventional schedule of 60 Gy in 30 fractions.[38] In the CHART arm, the 3-year local tumor control was 17% versus 13% in the conventional arm, and the corresponding 3-year survival data were 20% versus 13% ($p = 0.008$). The CHART trial proves the concept that accelerated proliferation of tumor clonogens is an important reason for treatment failure.

In Eastern Cooperative Oncology Group (ECOG) 2597, patients were randomized after induction chemotherapy to conventional fractionation (64 Gy/6.5 wk) or hyperfractionated accelerated radiotherapy (HART) (57.5 Gy in

2.5 weeks).[37] This schedule delivered 1.5 Gy per fraction with three fractions per day, 5 days a week. This is a strongly accelerated schedule, delivering the equivalent dose in 2-Gy fractions of 22 Gy/wk. The HART trial closed prematurely after recruiting 144 of a planned 388 patients, resulting in a loss of statistical power to detect the hypothesized improvement in median survival from 14 to 21 months. The actual observed median survival was 14.9 and 20.3 months ($p = 0.28$) after conventional fractionation and HART, respectively.

## SEQUENCING OF RADIATION AND CHEMOTHERAPY

In general, when radiotherapy is used with curative intent, it is delivered in relatively small daily doses, typically 1.8 to 2.0 Gy/day, 5 days per week. As described earlier, there are sound radiobiological arguments for doing so, resulting in relative sparing of normal tissues. Similarly, chemotherapy is often administered with intervals of about 3 weeks between each treatment. This is because many of these drugs cause damage to proliferating hematological precursor cells in the bone marrow. It typically takes about 3 weeks for adequate repopulation from bone marrow stem cells and their progeny to replenish the cellular damage from a cytotoxic insult.

Although protracting the overall treatment time allows increased repopulation of cells in normal tissues, surviving tumor cells will repopulate as well, leading to an increase in the number of tumor cells that must be eradicated. There is extensive experimental and clinical evidence, as reviewed previously, that the repopulation of tumor cells limits the effectiveness of radiation therapy, and that tumor cell repopulation might accelerate during a course of radiotherapy. However, tumor cell repopulation may also be triggered by chemotherapy (and possibly surgery) and occur during the time intervals between cycles of chemotherapy, and thereby limit its effectiveness.

Accelerated repopulation is consistently observed in rodent models after cytotoxic injury.[42–46] Less is known about repopulation in human tumors after chemotherapy. In these studies, tumor cell proliferation was assessed from biopsy samples taken at various intervals after the last course of chemotherapy. Bourhis et al.[47] found that in patients with oropharyngeal cancer, the estimated potential doubling time shortened after chemotherapy, indicative for accelerated repopulation, which was associated with a poor response to treatment. In contrast, in a small study of patients with ovarian cancer treated with platinum-based chemotherapy, Davis et al.[48] found that, at variable times after the last chemotherapy (mean 33 days), the percentage of Ki67 (a nuclear protein associated with proliferation) positive tumor cells was increased in 4 patients, reduced in 12, and unchanged in 5 patients.

It is clear that much more work has to be done to investigate accelerated proliferation in relation to chemotherapy, the importance of the effect and the associated molecular tumor characteristics.

The possible triggering of accelerated tumor cell proliferation by either chemotherapy or radiotherapy, as well as the

potential for radiosensitization of the tumor, has been one of the theoretical advantages of delivering chemotherapy and radiotherapy concurrently instead of sequentially.[49] In many cancers, including head and neck and NSCLC, concurrent chemotherapy and radiotherapy has consistently lead to improved survival although a higher incidence and severity of early toxicity may become dose limiting for one or both modalities. Therefore, some investigators have tried to deliver radiotherapy during the last part of chemotherapy. Moreover, in lung cancer, both local tumor failure and distant metastases remain a clinical problem. Therefore, delaying local radiation could theoretically allow more adequate delivery of chemotherapy.

**Timing of Chest Radiotherapy**   The issue of timing and sequencing of chemotherapy and radiotherapy has been subject to several randomized phase III trials, both in locally advanced NSCLC and limited disease small cell lung cancer (LD-SCLC).

In locally advanced NSCLC, only one phase III trial in which induction chemotherapy followed by concurrent chemoradiation was compared to chemoradiation alone has been published as a full-length article at the time of writing.[50] Readers are referred to Chapter 55 for the details. No differences were observed between both arms regarding overall survival or the incidence of distant metastases. However, more toxicity occurred in the induction arm.

In contrast to the paucity of data in NSCLC, many phase III studies have investigated the timing of chest radiation in LD-SCLC.[51,52] When all studies were considered, the delivery of early versus late thoracic irradiation did not influence the survival. However, when the most active chemotherapy regimen (platinum based) was administered concomitantly with chest radiotherapy, long-term survival was increased at the expense of a higher incidence of severe, though, transient esophagitis. Interestingly, lung toxicity was not different according to the timing of radiotherapy. Because a time interaction between chest radiation and chemotherapy was suspected, an integrated approach was proposed.[53] It was hypothesized that accelerated repopulation was triggered by the first dose of any effective cytotoxic agent and that in order to obtain local tumor control; the last tumor clonogen should be killed by the end of radiotherapy. It follows from these two assumptions that the long-term survival should decrease with increasing time between the start of *any* treatment to the end of radiotherapy (SER). A metaanalysis of published data showed superior long-term survival if the SER was kept less than 30 days in LD-SCLC (Fig. 41.4).

These results are consistent with accelerated proliferation of tumor clonogens triggered by radiotherapy and/or chemotherapy. As expected, accelerated treatments also cause more toxicity in rapidly proliferating tissues such as the esophageal mucosa.

In conclusion, for limited-stage SCLC, current evidence supports the early administration of thoracic radiotherapy with concurrent platinum-based chemotherapy. In locally advanced NSCLC, induction chemotherapy administered before
**FIGURE 41.4**    The survival at 5 years as a function of the SER (start of *any* treatment to the end of radiotherapy). Each dot represents a single trial ± S.E.

concurrent chemotherapy and radiotherapy seems not beneficial, but in view of the limited data, this conclusion should not be viewed as definitive.

**Timing of Prophylactic Cranial Irradiation**    From a theoretical point of view, delaying prophylactic cranial irradiation (PCI) should reduce its potential benefit. Indeed, PCI is given because chemotherapy fails to achieve therapeutic concentrations in the brain because of the blood-brain barrier. Delaying PCI would reduce the probability that proliferating cells in micrometastases in the brain would be controlled. A metaanalysis based on individual patient data in LD-SCLC indeed found a significantly lower hazard ratio (HR) when patients were randomized to PCI within 4 months after the initiation of induction therapy.[54] The HRs with 95% CI for developing brain metastases were 0.27 (0.16, 0.46), 0.50 (0.35, 0.72), and 0.69 (0.44, 1.08) for delays after induction therapy of less than 4 months, between 4 and 6 months, and more than 6 months, respectively.

No data are available on PCI timing in NSCLC.

# BIOLOGY OF TUMOR CELL REPOPULATION

## Models of Repopulation

**Radiotherapy**    As described in the previous sections, solid tumors have a high spontaneous rate of cell loss, which may be as high as 80% to 90% of the rate of cell production.[55] The potential doubling time of a tumor (see previous discussion) is therefore much shorter than its actual doubling time. In a model proposed by Fowler,[56] well-oxygenated cells in the vicinity of blood vessels die and are removed following radiotherapy. As a consequence, the nutritional and oxygen status

of the remaining cells improves, with the result that the rate of spontaneous cell death decreases. This is magnified over a course of fractionated radiotherapy. The decrease in the spontaneous death of tumor cells is then the predominant factor, which leads to accelerated repopulation.

Other investigators have proposed a model based on proliferation and differentiation during the renewal of normal tissues.[57,58] In this model, tumor stem cells normally produce more of themselves as well as cells that undergo terminal differentiation. When repopulation occurs during radiotherapy, a larger proportion of the progeny of stem cells is assumed to retain clonogenic capacity. The rate of proliferation of clonogenic tumor cells might also be faster, with fewer aborted cell divisions. Alterations in the cellular microenvironment may also influence such mechanisms and may be relevant to both models.[59]

The molecular mechanisms that underlie accelerated repopulation during radiotherapy are being unraveled. Ionizing radiation has been shown to activate the epidermal growth factor receptor (EGFR) and other members of the ERBB family of tyrosine kinases, leading to activation of mitogen-activated protein kinase (MAPK) pathways and the stimulation of cellular proliferation.[60–64] In an experimental model, it was shown that radiotherapy induced the proliferation of human squamous cell carcinoma and that this response was mediated through EGFR autophosphorylation, which observed over a clinically relevant dose range.[65] The levels of EGFR and cyclin D1, a downstream effector of EGFR, were found to correlate with radiocurability of nine murine epithelial carcinoma cell lines.[66,67]

In humans, the prognostic and predictive value of EGFR expression is unclear in relation to the selection of patients who are likely to benefit from accelerated radiotherapy schedules and/or concurrent chemoradiation. An indication that high EGFR expression in the primary tumor may be predictive for a favorable outcome after accelerated radiotherapy comes from studies in head and neck cancer.[68] EGFR expression may thus be necessary for accelerated tumor repopulation. In contrast, Ki-67 expression did not predict a favorable outcome after accelerated radiotherapy in head and neck cancer.[69] EGFR inhibition is thus a logical way to combine with radiotherapy in order to decrease accelerated proliferation and has indeed been shown to produce a benefit when added to fractionated radiotherapy in HNSCC.[70] It is too early to evaluate the results of this strategy in NSCLC.

**Chemotherapy**    Investigating the spatial origin of cells that contribute to accelerated repopulation after treatment of multicellular tumor spheroids by chemotherapy showed that there is a gradient of decreasing cell proliferation with increasing distance from the surface of spheroids, similar to that from tumor blood vessels.[71–73] Most anticancer drugs are preferentially toxic to proliferating cells, and many drugs have poor penetration into solid tissue.[74–76] Cells near to the periphery of spheroids are, therefore, more likely to be killed by chemotherapy, and subsequent repopulation occurs because of entry into the cell cycle of originally quiescent cells near the center of spheroids,

probably because of improved nutrition. This mechanism was confirmed in a human colon cancer xenograft by measuring the uptake of bromodeoxyuridine (BrdU) after treatment with gemcitabine. Initially, gemcitabine inhibited the proliferation of most cancer cells, but repopulation was observed starting from cells that were more distant from tumor blood vessels, which had lower rates of proliferation before therapy.[77]

From the preceding discussion, it is likely that as a result of chemotherapy, tumor cells close to blood vessels are most likely to be killed because of their higher rate of proliferation (and resultant chemosensitivity) and better drug access. When these cells die or shut down their metabolism, nutrition of the more distant cells improves, death of the distal cells decreases, and the distal cells reenter the cell cycle and repopulate the tumor. This model provides a mechanism for the paradox that some cancer cells might survive that would have died in the absence of treatment.

The proliferation of tumor cells after chemotherapy depends ultimately on the activation of cyclin/cyclin-dependent kinase complexes that control the entry of cells into the cell cycle and their passage through the cell cycle. Like after radiotherapy, activation of these proteins might occur through signaling from receptors, such as the EGFR, but little is known about changes in activity of these pathways in tumors treated with chemotherapy.

## CONCLUSION

Understanding the biological parameters that influence radiation response can provide opportunities for treatment optimization to improve the therapeutic ratio. Among these include strategies to increase radiation tumor kill, limit cellular repair by tumor, deal with tumor-related accelerated repopulation and hypoxia, and incorporation of targeted systematic therapies with radiotherapy.

As accelerated repopulation is one of the main reasons for treatment failure after radiotherapy and chemotherapy, strategies to inhibit this process are of obvious interest.

More recently, the delivery of external beam radiotherapy may be further optimized to exploit the radiobiological rationale for large dose per fraction or hypofractionation in order to provide improved tumor kill and minimize tumor cellular repair (see earlier discussion, "The Four R's of Radiotherapy"). The therapeutic ratio for hypofractionation can only be of benefit if late normal-tissue complications can be realistically minimized. Technically, in tumors that move considerably such as lung cancers caused by diaphragmatic excursions, hypofractionation should be best achieved through the use of respiratory-gated extracranial stereotactic radiotherapy treatments or tracking of lung tumors using implanted radiopaque fiducial markers within the target region and delivery of radiotherapy fractions when the target is within a predefined treatment zone. These recent radiotherapy strategies have been collectively termed image-guided radiotherapy (IGRT). The emphasis of IGRT is to ensure both improved tumor volume definition for the target as well as four-dimension (4D) (in which the fourth dimension represents the time during and in between each radiotherapy fraction) verification for quality assurance of any temporal–spatial uncertainties in treatment delivery.

Moreover, the molecular mechanisms underlying accelerated repopulation are being rapidly unraveled. Inhibition of repopulation should ideally be specific for cancer cells as otherwise no gain of the therapeutic ratio can be expected. Apart from accelerated radiotherapy schedules and the delivery of radiotherapy with chemotherapy, discussed in this chapter, the combination of targeted drugs together with radiotherapy or concurrent chemoradiation is a rational choice.

Examples of molecular-targeted agents include small molecule inhibitors and antibodies against specific proteins that are related to crucial cancer pathways such as proliferation. These agents should not only be used concurrently with chemotherapy and radiotherapy, but also in between courses of treatment. Because EGFR inhibitors have been introduced successfully in clinical trials and because this pathway plays a major role in accelerated repopulation, their combination with chemoradiation is being investigated actively.[70]

Besides EGFR inhibitors, agents that target the MAPK pathway have been found to modulate radiosensitivity in preclinical studies and are in early trial with radiotherapy.[78] The rapamycin analogue CCI-779 is a cytostatic agent that is active against tumors with mutation of the tumor suppressor gene phosphatase and tensin homologue (PTEN). Phase I trials demonstrate that it is feasible to combine these agents with radiation and cisplatin with in mouse models no increase of pulmonary toxicity.[79,80]

Targeted agents are primarily cytostatic, and as a consequence, tumor response (basically, shrinkage on CT scans) is relatively rare, and when it occurs, it is usually delayed. Delivering these agents concurrently with chemotherapy (with or without radiation) could, therefore, lead to disappointing results as the cytostatic effects of targeted agents might render tumor cells less sensitive to cycle-specific chemotherapy. Kim and Tannock[23] therefore suggested to give cytostatic agents between courses of chemotherapy to inhibit repopulation, with the stopping of such treatment before the next round of chemotherapy to allow cells to reenter the cycle and regain sensitivity to cycle-active drugs. This method would obviously also be applicable for concurrent chemoradiation.

Besides repopulation, hypoxia still remains an important area of research. Identifying hypoxic cells in human tumors has improved by the help of new imaging and physiologic techniques.[81] Indeed, surrogate noninvasive techniques to identify hypoxia, such as circulating osteopontin and positron emission tomography (PET) imaging with hypoxia tracers such as ^{18}F-misonidazole have enabled the selection of patients with head and neck cancer that have a better outcome with hypoxic cell sensitizers such as nimorazole and tirapazamine. An updated systematic review identified 10,108 patients in 86 randomized trials designed to modify tumor hypoxia in patients treated with curative attempted primary radiation therapy alone.[82] Overall modification of tumor hypoxia significantly improved the effect of radiotherapy, with an OR of

0.77 (95% CI, 0.71 to 0.86) for the outcome of locoregional control and with an associated significant overall survival benefit (OR = 0.87; 95% CI, 0.80 to 0.95). No significant influence was found on the incidence of distant metastases or on the risk of radiation-related complications.

Further trials will build on more insights of molecular biology, imaging, and physiology, all leading to a further increase of the efficiency of radiotherapy in the treatment of lung cancer.

# Radiotherapy for Locally Advanced Lung Cancer: Stages IIIA and IIIB

## THE SCOPE OF THE PROBLEM

Lung cancer is the leading cause of cancer deaths in the United States and non–small cell lung cancer (NSCLC) accounts for approximately 80% to 85% of all cases.[1] The 1997 revision of the lung cancer staging system[2] classifies stage IIIA as T1–3N2 and T3N1 disease, whereas stage IIIB includes either N3 or T4 disease. In the Surveillance, Epidemiology, and End Results (SEER) 2004 registry, 29.7% of new NSCLC cases presented with stage III disease, of which 12.1% were stage IIIA and 17.6% were stage IIIB.[3] The International Association for the Study of Lung Cancer (IASLC) Lung Cancer Staging Project database (see Chapter 30) of 67,725 cases of NSCLC revealed 5-year overall survival figures for clinically staged IIIA and IIIB disease of only 18% and 8%, respectively, and for pathologically staged IIIA and IIIB disease, it was 25% and 19%, respectively.[4] The poor outcomes observed are caused by locoregional failure rates between 30% and 55%, with distant failure rates in the range of 40% to 60%.[5]

## TREATMENT STRATEGIES FOR STAGE III NSCLC

**Staging Subsets of Stage III NSCLC** Strategies to improve outcomes have centered on improved staging and tailoring aggressive treatment regimens to subcategories of stage III disease that are most likely to benefit. This population is heterogeneous in terms of presentation and outcomes—an issue that is being addressed in the forthcoming seventh edition of the TNM stage groupings.[4] This chapter will not address the treatment of three categories of patients with stage III disease, namely, (a) stage T3N1 that are generally resectable, (b) tumors of the superior sulcus where the addition of surgery is considered useful,[6,7] and (c) stage IIIB patients with malignant pleural effusions.

Improvements in staging modalities, such as positron emission tomography with ^{18}F-fluorodeoxyglucose (FDG-PET),

multislice computed tomography (CT), and endoscopic techniques, have had a profound effect on the pretreatment evaluation of NSCLC. The routine use of PET is now recommended by the American College of Chest Physicians (ACCP) as a standard staging investigation for stages IB to IIIB prior to a curative treatment[8] (see Chapter 27). The false-positive and false-negative rates with CT scans alone are unacceptably high.[9–11] FDG-PET has a higher sensitivity of 84% and specificity of 89%, and the sensitivity improves to 93% and specificity to 95% when using combined PET-CT.[12–14] As false-positive rates range from 10% to 15%, it has been recommended that any positive PET findings should be confirmed by cytopathology in patients who are candidates for surgery.[14–16] However, the same approach can be taken for patients who are candidates for high-dose concurrent chemoradiotherapy (CRT).[17] Up to 30% of conventionally staged patients with stage III cancer referred for radical radiotherapy are excluded after a PET scan, mainly because of the detection of occult metastatic disease.[18] At least part of the incremental survival benefit seen in stage III NSCLC over the last decade may be a result of the migration of patients with otherwise occult metastases to stage IV. Although mediastinoscopy is still considered, the gold standard for confirming N2 disease,[19] only a minority of patients treated in nonsurgical trials have undergone this invasive procedure. In recent years, minimally invasive staging by techniques such as biopsy during endoscopic ultrasound (EUS-FNA) and transbronchial needle aspiration without (TBNA) or with endobronchial ultrasound guidance (EBUS-TBNA) are increasingly used to minimize invasive staging procedures[20–22] (see Chapters 28 and 29). Radiation oncologists with access to endoscopic staging can use this approach to optimally define nodal target volumes in patients with stage III disease.

**Factoring in Tumor and Patient Characteristics** An appropriate treatment strategy for stage III NSCLC can only be formulated once the extent of disease, any comorbidity, and general fitness of a patient has been fully characterized. The ACCP guidelines have chosen to classify N2 tumors into

four subsets for the purpose of generating rational treatment guidelines.[23] Nodal metastases found either after or during a surgical resection are denoted as IIIA$_1$ and IIIA$_2$, respectively. Nodal disease identified preoperatively is IIIA$_3$, whereas bulky or fixed multistation N2 disease is classified as IIIA$_4$. Although there is no uniform definition of what constitutes "bulky" nodal disease, the ACCP recommendation includes nodes of 2 cm or larger in short-axis diameter as measured by chest CT, multistation nodal disease, and/or groupings of multiple positive smaller lymph nodes.[23]

Patients with lung cancer generally tend to have significant smoking-related comorbidities, suboptimal pulmonary function and impaired performance score. Each of these factors may impact on their ability to tolerate potentially curative treatment, and each is exacerbated with increasing age.[24] The median age of presentation for NSCLC cases from a SEER database analysis was 67,[3] and this is expected to rise in the future.

**Primary Treatment**  The choice of optimal local treatment has been the topic of active research in the last 2 decades. Current guidelines recommend that platinum-based combination CRT should be the primary treatment in patients with stage IIIA NSCLC and ipsilateral mediastinal disease identified preoperatively.[23] The same strategy is also recommended for patients with stage IIIB NSCLC and a good performance score with minimal weight loss ($\leq$5%).[25]

The role of surgery in stage III disease was evaluated in two large randomized trials, which concluded that the addition of surgery did not improve survival in comparison to either sequential chemoradiotherapy (CT-RT)[5] or concurrent CRT[26] alone (see Chapter 55). Subgroup analysis has suggested that surgical outcomes were more favorable in patients with "downstaged" N2 disease, and in whom a radical resection was achieved with a lobectomy rather than a pneumonectomy.[26] However, conditions that favor postsurgical survival are generally established only after a resection. The majority of patients with N2 disease will still have persistent disease despite induction therapy, and "gaps" in CRT, arising during mediastinal restaging risk exposing such patients to a poorer survival caused by longer overall treatment time.[27]

Radiotherapy alone is an inappropriate treatment for fit patients as an updated metaanalysis by the NSCLC Collaborative Group revealed a significant survival benefit for sequential CT-RT versus radiotherapy alone.[28] When concurrent CRT was compared to radiotherapy alone, a survival advantage was seen for the former (HR = 0.88; 95% CI, 0.81 to 0.95), with an absolute benefit of 3.2% (from 13.4% to 16.6%) at 3 years.[28] Concurrent CRT also improved the progression-free survival, and there was no evidence that any patient subgroup benefited more or less from concurrent CRT.

A second metaanalysis based on 6 trials and 1199 patients evaluated overall and progression-free survival after the concurrent administration of chemotherapy and radiation versus the sequential administration of both modalities.[29] At a median follow-up of 5 years, a significant survival benefit was observed for concurrent CRT with an absolute benefit of 6.6%

(from 18.2% with sequential CT-RT to 24.8% with concurrent CRT) at 3 years. Concurrent CRT decreased locoregional progression (HR = 0.76; 95% CI, 0.62 to 0.94) but distant progression rates were similar. Concurrent CRT increased acute grade 3 and 4 esophageal toxicity from 3% to 18%, but no significant difference in acute pulmonary toxicity between both approaches was observed.

**Choice of Systemic Agents with Concurrent Radiotherapy**  Platinum-based concurrent CRT regimens improve outcomes in several malignancies, including lung cancer.[29] A scheme widely used in recent phase III trials consists of cisplatin 50 mg/m$^2$ on days 1, 8, 29, and 36, and etoposide 50 mg/m$^2$ on days 1 through 5 and 29 to 33.[6,26] Cisplatin given at full dose provides both a radiosensitization effect within the irradiated volume, and an overall survival benefit related to reduced distant metastases, as demonstrated in the lung adjuvant cisplatin evaluation (LACE) metaanalysis.[30] Significant pathological response rates were observed using an induction scheme of cisplatin-etoposide for stage III NSCLC with only 45 Gy of concurrent radiation in INT 0139, with an 18% pathologic complete response (pT0N0) and 46% complete nodal response (T$_{any}$N0).[26]

Immunohistochemical analysis in resected NSCLC for excision repair cross-complementation group 1 (ERCC1) protein expression suggested that adjuvant cisplatin-based chemotherapy was only beneficial in ERCC1 negative tumors.[31] Studies are currently underway to prospectively validate this finding in the adjuvant setting, and the likely role of ERCC1 expression in selecting chemotherapy schemes in primary CRT remains to be elucidated.

Although the use of concurrent low-dose carboplatin-paclitaxel is widespread in the United States, the outcomes of some recent trials with this combination have been disappointing.[32] This finding may be explained by the fact that three randomized clinical trials of carboplatin plus radiotherapy have not been shown to be superior to radiotherapy alone.[33–35]

**Adjuvant Management of Completely Resected Stage III NSCLC**  The adjuvant management of stage III disease consists of cisplatin-based chemotherapy[30,36,37]; however, locoregional failure rates of 20% to 40% persist in this setting.[36,37] In the Adjuvant Navelbine International Trialist Association (ANITA) trial, a nonrandomized subanalysis comparing 5-year overall survival in N2 patients who did or did not receive postoperative radiotherapy (PORT) found higher survival rates in patients receiving radiotherapy in both the observation and chemotherapy arms (21% vs. 17% and 47% vs. 34%, respectively).[36] A retrospective SEER study also reported superior survival rates associated with PORT in N2 disease.[38] This has renewed interest in adjuvant radiotherapy for resected patients—a strategy that fell out of favor after the PORT metaanalysis of 2128 patients with stage I to III disease reported a significant adverse effect of PORT on survival in 1998.[39] This metaanalysis has been criticized as many of the included trials used radiotherapy techniques that are now considered suboptimal, leading to higher morbidity

and mortality rates than more recent studies.[40,41] A phase III European Intergroup trial (LungART), designed to address this issue, opened in 2007 and will compare three-dimensional (3D) conformal PORT to no PORT.[42] Present guidelines do not recommend adjuvant radiotherapy for completely resected stage IIIA disease[23,43] but do suggest PORT when the risk of nodal recurrence is elevated because of extranodal spread, close or microscopically positive resection margins, or involvement of multiple nodal stations.

### Options for Poor Performance Status Patients

A significant proportion of patients with stage III cancer cannot tolerate aggressive CRT regimens because of considerable comorbidities. Decisions to withhold concurrent CRT in patients who are fit to receive cisplatin-containing regimens have to be made carefully, however, as every subgroup in the NSCLC Collaborative Group metaanalysis demonstrated a survival benefit as compared to sequential CT-RT.[29] In high-risk patients, sequential CT-RT remains a viable option.[44] Radiation oncologists have flexibility in tailoring treatment to a reduced dose and/or volume in patients who are deemed too frail. Postplanning assessment of a proposed treatment includes a calculation of the $V_{20}$ (percentage volume of normal lung minus planning target volumes [PTV], which receives doses of 20 Gy or more).[45] Patients with a $V_{20}$ in excess of 35% have not only an increased risk of high-grade radiation pneumonitis, but also a significantly poorer survival.[46] Large fields, often required in stage III disease, lead to a higher risk of esophagitis with CRT.[47]. Presentations such as extensive N2 involvement, bilateral hilar node disease, and a peripheral tumor in the lower lobe with contralateral upper mediastinal nodes are examples of cases where clinicians can assume a large $V_{20}$ will result from any radiotherapy plan, and thus make alternate decisions regarding treatment up front.

## TARGET DEFINITION IN STAGE III NSCLC

The last 2 decades has witnessed a dramatic shift from two-dimensional (2D) radiotherapy, where bony landmarks and planar images were used to guide field setup, to four-dimensional (4D) radiotherapy, where CT-contoured target volumes are modified to account for intrafraction motion. The use of 2D radiotherapy for lung cancer carries a risk for target miss in up to 15% of patients,[48] and may partly account for the poor local control rates seen in NSCLC trials performed to date. Target volumes drawn on CT images now represent the minimum standard of care.

### Defining the Gross Tumor Volume for the Primary Lung Tumor

Precise definition of the gross tumor volume (GTV) is important, as contouring errors are compounded when volumetric expansions are made to account for microscopic tumor spread, motion, and setup errors. The boundary between macroscopic tumor and the lung parenchyma is best defined when viewing CT images with proper window width and level settings. Distinguishing the tumor border is more difficult when atelectasis or pulmonary effusions are present, potentially leading to an overestimation of the GTV. Reviewing diagnostic scans in which intravenous contrast has been given, or using contrast for CT simulation, may be helpful. PET scans have been used to avoid atelectatic lung in the target volume,[49] but data to validate this approach are awaited.[50]

PET and PET-CT images (where functional and anatomical data are coregistered as a result of being obtained during the same procedure) may serve a far greater purpose in NSCLC delineation than crude tumor identification. Using PET for radiotherapy planning results in a reduction in interobserver contouring variability, and more consistent delineation of GTV.[51] Some groups have proposed using PET-CT for generating GTVs automatically by using a standardized uptake value (SUV) threshold,[50] an approach that may be confounded by factors, including (a) heterogeneous uptake of FDG within the tumor as a result of necrosis, hypoxia, or degree of tumor differentiation, (b) elevated SUV levels as a result of inflammatory processes, and (c) low SUVs from small tumors caused by partial volume effects.[52] It has been recommended that radiation oncologists should work closely with their nuclear medicine counterparts to interpret PET scans, and caution has been advised when using automatic delineation.[50]

### Involved-Field Nodal Radiotherapy

Radiotherapy fields have traditionally encompassed the radiologically normal mediastinum, and occasionally, the ipsilateral supraclavicular region, in order to treat potential subclinical disease. The presumed benefits of this approach, referred to as prophylactic or elective nodal irradiation (ENI),[53] have never been clearly demonstrated. Advances in the nonsurgical assessment of the mediastinal nodes, together with analyses of recurrence patterns following involved-field radiotherapy (IFRT) have called into question the need for routine ENI.

A growing body of data from patients with stage III NSCLC where ENI was omitted show that isolated nodal failures outside the PTV occur in less than 7% of patients[54–58] despite the fact that only one of these trials used information from PET scans for radiotherapy planning.[55] In a phase III study of CRT where patients were randomized between IFRT and ENI, significantly fewer IFRT patients had a $V_{20}$ of greater than 20% and fewer experienced radiation pneumonitis.[58] Only 7% of patients randomized to the IFRT arm experienced elective nodal failure compared to 4% in the ENI arm at 5 years. IFRT is advocated on the basis of allowing dose escalation to improve local control while avoiding the toxicity experienced with larger fields (Fig. 42.1).[59]

An increasing number of patients with stage III NSCLC have pathologically confirmed N2 disease, but sampling often fails to evaluate all nodal stations. Definition of the nodal GTV is often based on CT imaging alone, with a short-axis diameter of 10 mm, commonly used to define the upper limit of normal.[60,61] The correlation between size and positivity is tenuous, however, as up to 44% of tumor-bearing nodes are less than 10 mm in size and 18% of patient with pathologically confirmed N2 disease do not have any nodes greater than 10 mm.[62] Data from the
**FIGURE 42.1**    Treatment portals (*in yellow*) for an anterior field used in elective nodal irradiation **(A)** and involved-field radiotherapy **(B)** in the same patient. Uninvolved nodal regions, including the contralateral upper mediastinum, are routinely treated with the first approach, leading to higher doses to the contralateral lung and esophagus. (See color plate.)

surgical literature, in addition to trials investigating staging techniques such as PET, are very useful to the radiation oncologist in helping to define the nodal target volumes for IFRT.

The limitations of PET scans for defining nodal target volumes should be appreciated. European Society for Thoracic Surgery guidelines caution that invasive nodal staging should be carried out in patients with central tumors, bronchioalveolar carcinoma, hilar N1 disease seen on PET, and when large PET-negative lymph nodes (i.e., ≥16 mm) are present.[63] General guidelines for the inclusion of suspicious nodes are provided in Table 42.1, with supportive data obtained from surgical series.[64] Integrated PET-CT systems provide further improvements over visually correlated studies with excellent spatial resolution,[65] making it the preferred tool in radiotherapy planning. In the absence of contradictory histologic findings, PET-positive nodes should be included in the GTV with the understanding that the positive predictive value of PET is only in the range of 80%.

| TABLE 42.1 | Schema for Defining Mediastinal Nodal GTV in NSCLC | | |
| --- | --- | --- | --- |
| **Nodal Diameter (Short Axis)** | **PET Status** | **Approach** | **Comment** |
| <1 cm | Positive | Include in GTV | Positive predictive value higher for PET than CT, biopsy when possible |
| <1 cm | Negative | Exclude from GTV | High negative predictive value for PET, small probability of N2 disease[64] |
| >1 cm | Positive | Include in GTV unless representative cytology from the node is negative | Sensitivity for TBNA is inferior to EBUS or EUS-TBNA,[21] thus consideration of sampling method is required |
| 1–1.5 cm (and no cytology available) | Negative | Exclude from GTV if primary tumor is PET positive, unless cytology or histology is positive | High negative predictive value for PET, small probability (5%) of N2 disease[64] |
| ≥1.5 cm (and no cytology available) | Negative | Include in GTV | 21% probability of N2 disease[64] |

EBUS, endobronchial ultrasound; EUS, endoscopic ultrasound; GTV, gross tumor volume; NSCLC, non–small cell lung cancer; PET, positron emission tomography; TBNA, transbronchial needle aspiration.

### Defining a Clinical Target Volume around the Primary Tumor

Data from pathological specimens represent the "gold standard" for determining margins to be added for subclinical disease (i.e., GTV to clinical target volume [CTV] margins). A study performed on NSCLC surgical specimens recommended margins of 8 mm for adenocarcinomas, and 6 mm for squamous cell carcinomas in order to account for 95% of all microscopic extension.[66] A similar analysis in resected proximal tumors revealed microscopic bronchial extension of malignant cells in 24% of cases, and recommended a bronchial margin of 15 mm from macroscopic tumor in order to provide clear margins in 93% of all patients.[67]

### Clinical Target Volume Margins around Nodal Disease

Nodal extracapsular extension (ECE) has been shown to predict both recurrence and survival.[68,69] In one report of resected mediastinal nodes, ECE was found in 80% of nodes $\geq 1$ cm but the majority of nodes studied were greater than 3 cm in size.[69] A similar analysis, limited to nodes less than 3 cm in size, found ECE in 41.6% of patients with a significant positive correlation with nodal size.[70] To ensure coverage of 95% of the ECE observed, the authors recommended a margin of 3 mm for nodes with a short-axis diameter of 20 mm or less, and an 8-mm margin for nodes greater than 20 mm.

### Individualized Planning Target Volumes and Motion Management

Radiotherapy planning based on scans acquired during quiet respiration can introduce motion artefacts that incorrectly characterize the geometric shape and extent of a tumor.[71] This may result in tumors being imaged in two or more distinct parts, with the axial slices being shuffled out of order. As even tumors adherent to the chest wall[72] and mediastinal lymph nodes[73–75] can move to a significant degree, plans based on a conventional CT scan may lead to inaccurate information on the actual dose distribution in these structures. Until recently, standard "safety" margins were added around tumors in order to ensure target coverage. Studies have shown that even these margins may be insufficient to account for extremes of mobility[76,77] and may increase the risks of toxicity to surrounding organs, which in turn limits the total dose that can be given. Patient-specific margins are required as no clear correlation exists between mobility and anatomical tumor location in the thorax.[78,79]

The addition of individualized margins to the CTV can be used to derive the internal target volume (ITV), as defined by the International Commission on Radiation Units and Measurements (ICRU). The ITV plus setup margin is used to derive the PTV.[80] A large analysis of respiration-induced tumor motion in mainly stage III NSCLC patients reported that the principal component of motion was in the superior–inferior (SI) direction, with 10.8% of tumors moving greater than 1 cm.[72] The proportion of tumors with motion of greater than 5 mm during normal breathing (the value at which a strategy for respiratory motion management was recommended by the American Association of Physicists in Medicine [AAPM] Task Force 76)[81] was 39.2%, 1.8%, and 5.4%, respectively, along the SI, lateral, and anterior–posterior axes.

Several 4D imaging techniques can be used to derive an ITV and determine an approach for motion management. During 4DCT (or respiration-correlated) scanning, spatial and temporal information on organ mobility are generated using cine scans, whereas the respiration waveform is synchronously recorded during imaging.[82,83] One approach involves recording respiratory signals using infrared-reflecting markers on the upper abdomen of the patient during quiet free breathing.[77] The markers are illuminated by infrared-emitting diodes surrounding a camera, which captures the motion of these markers. Generating a single 4DCT scan during quiet respiration is relatively simple, and it poses no problems to patients with poor pulmonary function. The 4DCT scanning procedure of the entire thorax takes about 90 seconds. Ten respiration-correlated 3D datasets are commonly derived from a single 4D dataset, and each represents the patient's anatomy during a single respiratory phase. Options for deriving ITVs from 4DCT scans include (a) contouring the GTV in all phases of the 4DCT, (b) contouring the GTV in only the extreme phases of respiration, and (c) using a maximum intensity projection (MIP) of all phases of the 4DCT.[84]

## RADIOTHERAPY PLANNING AND DELIVERY TECHNIQUES THAT INCREASE THE THERAPEUTIC RATIO

A total dose ranging from 60 to 66 Gy, delivered in once-daily fractions of 1.8 to 2 Gy, has arguably been the most common scheme used with full-dose chemotherapy.[26,32,85–87] Phase I/II studies in selected patients assigned with stage III given concurrent chemotherapy have shown the feasibility of dose escalation to 74 Gy.[88,89] However, there is little evidence to support the routine use of a dose greater than 60 Gy when full-dose CRT is used, and the issue is being addressed in an ongoing Radiation Therapy Oncology Group (RTOG) study (0617) of 60 Gy versus 74 Gy.

Interest in altered fractionation regimens led to randomized clinical trials evaluating the radiobiologic hypothesis that radiation delivered over a shorter period of time can minimize the amount of accelerated tumor-cell repopulation observed once cytotoxic therapy is initiated.[90] In the setting of advanced NSCLC, daily doses are increased and usually divided into two or three treatments per day, with time allowed between each dose to minimize late radiation toxicity. A European phase III randomized trial tested the CHART regimen (continuous, hyperfractionated, accelerated radiation therapy) of 1.5 Gy tid to 54 Gy in 12 consecutive days versus a standard regimen of 60 Gy in 6 weeks. A 9% survival benefit for CHART was observed at 2 years.[91] Concurrent chemotherapy schemes have not been evaluated with CHART in phase III trials, and the CHART schedule has not been widely adopted because of high rates of acute mucosal toxicity in addition to the logistics required. In patients who are unfit for concurrent CRT, accelerated fractionated regimens have both radiobiological advantages and increased convenience for patients, when compared to conventional 1.8 to 2 Gy/day

regimens. Data from a recent phase III study using once-daily fractions of 2.75 Gy after induction chemotherapy indicated that a dose of 66 Gy can safely be delivered in 5 weeks.[92]

### Minimizing Toxicity of Chemoradiotherapy

The target volume for stage III tumors lies in close proximity to several important organs at risk such as spinal cord, lung, heart, and esophagus. Therefore, dose intensification or adding concurrent chemotherapy accentuates the need to produce highly conformal radiotherapy plans that restrict high-dose regions to the PTV by varying beam arrangements, technique, fractionation, and dose. Radiation myelitis is rarely seen clinically, but is a potentially devastating complication. Therefore, a majority of radiation oncologists limit doses to the spinal cord to between 45 and 50 Gy. Attempts to deliver doses that exceed this amount will require beam arrangements that usually lead to increased dose deposition to the lungs. Cardiac dose is usually not a limiting factor as the majority of involved nodes lie above the atria, but can be a consideration in central or retrocardiac tumors. The esophagus is a mediastinal structure that usually runs the entire length of the PTV, resulting in a sixfold increase in grade 3 or greater esophagitis with concurrent CRT.[29] Management of acute esophagitis is therefore a key component of any stage III NSCLC radiotherapy treatment, but it is rarely dose limiting.

A few key developments in the technology of radiation planning and delivery have allowed radiotherapy departments to produce plans that are closer to the "ideal" than ever before. They include the availability of improved dose-calculation algorithms, respiratory-gated radiotherapy (RGRT), intensity-modulated radiotherapy (IMRT), and image acquisition during a course of treatment leading to the possibility of adaptive radiotherapy.

### Improved Radiation Dose Calculation

Good clinical decisions can only be made if the dose estimated by a treatment planning system accurately portrays reality. Corrections for density differences within the thorax results in more accurate dose distributions, with studies showing that previous lung plans that ignored density differences often delivered 5% to 10% in excess of the intended dose.[93] The AAPM Task Group 65 recommends that lung inhomogeneity correction always be used.[94] Not all modern treatment planning algorithms accurately perform this correction, however, and significant discrepancies may still exist.[95] Unfortunately, despite incorporating motion within a suitable treatment volume, planning systems that adjust dose calculations for 4D motion have not been released as of yet. Plans for mobile tumors are currently mainly based on a single intermediate phase of respiration.

### Respiratory-Gated Radiotherapy

Several strategies for mobility management are entering routine clinical practice, including full incorporation of target motion, freezing target motion, intercepting target motion, or tracking the tumor.[96] It is essential that a department first consider the accuracy, work load, patient tolerance, imaging dose, and resources required for the chosen approach.[97] The use of RGRT permits a reduction in field sizes as irradiation can be limited to phases in which the mobile target volume is in a predetermined position (Fig. 42.2). An analysis in stage III NSCLC suggested a potential benefit of RGRT using three consecutive phases at end-tidal expiration.[98] Specifically, gating reduced the $V_{20}$ and mean lung dose by 5% and 3 Gy, respectively, and was most beneficial for the more mobile tumors located in the middle and lower lobes.

### Intensity-Modulated Delivery of Radiotherapy

IMRT abandons the traditional static, coplanar fields of conventional radiotherapy in order to give highly conformal dose delivery. The intensity of beams are modulated by moving small leaves in and out of the field aperture, resulting in individual fields that deliver a heterogeneous dose but when summed from a number of different directions deliver a homogenous dose to a target with excellent conformality. IMRT can be used to limit the amount of high-dose radiation to normal lung and to produce complex concavities in dose distributions that spare

**FIGURE 42.2** Planning target volumes (*red*) and corresponding treatment portals (*yellow*) for a patient with stage III NSCLC. **(A)** is derived from a single 3DCT scan with the addition of standard planning margins,[98] **(B)** is an internal target volume (ITV) encompassing all motion observed on 4DCT scan acquired during quiet respiration, and **(C)** is the ITV from motion in three phases at end inspiration for audio-coached gated radiotherapy. The amount of right lung tissue outside the portal is maximal with approach **C**. (See color plate.)

dose to structures like spinal cord and esophagus.[99] IMRT delivery is sensitive to target motion, however, based on the summation required to deliver a homogenous dose. Furthermore, the use of IMRT has led to an increase in the $V_5$ (percentage volume of normal lung receiving more than 5 Gy), which may in turn increase treatment-related pneumonitis rates.[100,101] IMRT combined with concurrent chemotherapy has yet to be compared to conventional radiotherapy with concurrent chemotherapy in randomized clinical trials.

**Adaptive Radiotherapy**     The reproducibility of NSCLC volumes generated at time of simulation over an entire course of radiotherapy has been investigated by several groups[102–104] with the intent of potentially reducing the irradiated volume to treat a PTV that has potentially shrunk over time. In a group of stage I tumors treated with stereotactic radiotherapy,[105] repeat 4DCT showed no significant change in the ITV. Studies that have included patients with stage III cancer have shown conflicting results[106,107] and prospective data to show that reduced margins will not increase local recurrence rates secondary to inadequately treated microscopic disease are awaited.

## CONCLUSION

Radiotherapy remains a key treatment modality for stage III NSCLC, with improvements in survival attributed mainly to combined treatment with cisplatin-containing chemotherapy. Locoregional control remains suboptimal, however, and recent efforts have been aimed at incorporating the technological advances in multimodality imaging and radiotherapy planning to further improve the therapeutic ratio.

# Stereotactic Techniques for Lung Cancer Treatment

Historically, the term *stereotactic* is related to the correlation of tumor target position to reliable fiducials position that could be readily identified from various imaging platforms.[1] Radiation treatments guided by such fiducials were referred to as *stereotactic radiation therapy*. Fiducials define a coordinate system that can be used to target the tumor, orient the treatment planning process, and ultimately guide the therapy toward the intended location in the body. These fiducials were typically placed in a rigid frame outside the patient.[2] Today, with sophisticated real-time image guidance, the tumor itself can serve as the fiducial negating the need for external markers that have classically characterized stereotactic treatments. [3–6] In the end, modern stereotactic radiotherapy is a little about "stereotaxy" and a lot about dose fractionation, target definition, motion control (four-dimensional [4D] therapy), image guidance, conformal and compact dose distributions, and high levels of quality assurance in treatment conduct.[7] Irrespective of the current significance of the term "stereotaxy," modern treatments to lung tumors using such technology intensive techniques and giving less than five potent treatments are referred to as stereotactic body radiation therapy (SBRT).[8,9]

SBRT, or synonomously stereotactic ablative radiotherapy (SABR), is biologically unique from conventional fractionated radiation therapy (CFRT). Whereas CFRT is typically administered in small daily doses in the range of 1.8 to 2.0 Gy to total doses of 60 to 70 Gy, SBRT is intended to be ablative. These ablative treatments are very potent because considerably higher doses per fraction are applied, generally in the range of 10 to 20 Gy per fraction. Biologically, affected cells are both unable to divide and unable to perform intended cellular functions (e.g., secretion, transport oxygen, etc.). Such high doses per treatment were historically out of bounds because limitations in treatment delivery technology did not allow the radiation oncologist to avoid catastrophic toxicity when large volumes of normal tissues were exposed to so much radiation each treatment. With improvements in tumor imaging, image guidance, computerized dosimetry, and treatment delivery devices, such very large dose-per-fraction treatments are no longer out of bounds. Indeed, they are showing dramatic utility for their ability to safety eradicate cancer.

SBRT has been shown to be particularly effective in eradicating the primary tumor in early stage lung cancer.[10–17] SBRT offers an elegant, noninvasive, and highly efficient treatment option that is preferred by patients because of its convenience. SBRT has not been generally used in patients with lymph node metastases, however, because of difficulty in targeting the entire extent of tumor as well as toxicity concerns relating to the central chest. In metastatic lung cancer, SBRT may be used as an ablative or cytoreductive agent in selected patients.

Because of its normal-tissue dose sparing facilitated by the unique dose distribution and imaging technology, frail patients can tolerate the treatment surprisingly well. It is considered a standard treatment in such patients with stage I non–small cell lung cancer (NSCLC).[18] Despite its ability to treat the frailest patients, SBRT should still be viewed as the most potent radiation treatment with clinical experience in fighting gross tumor deposits. Local control with SBRT has been shown to be dramatically superior to historical controls using CFRT for early stage lung cancer. Indeed, local control with SBRT rivals surgical resection for most indications. Limitations definitely exist as will be discussed in this chapter. With careful clinical testing and implementation, SBRT is finding a prominent place within the cancer treatment arsenal.

## DEVELOPMENT OF STEREOTACTIC BODY RADIATION THERAPY

The success of brain radiosurgery pioneered by Swedish neurosurgeon Lars Leksell[1] forms the basis of SBRT. Leksell not only developed what would become the modern day Gamma Knife, he departed from the current practice of the time to deliver radiation in a protracted fractionation schedule. With the newly developed technology, large dose-per-fraction treatments given in a single treatment at dose levels that would have historically resulted in considerable calamity were able to be routinely

delivered in the dose intolerant brain. The new treatment conduct went to great lengths to avoid prescription level dose to normal tissues. Whatever normal tissue was included, either by being adjacent to the target or by inferior dosimetry, was likely damaged. However, if this damaged tissue was small in volume or noneloquent, the patient did not suffer clinically apparent toxicity, even as a late event. On the other hand, it is undeniable that the large dose-per-fraction treatments are biologically extremely potent by overwhelming repair mechanisms.[19] Targeted tumors are disabled and toxicity is avoided by simply missing most normal tissue.

Hamilton et al.[20] performed the earliest examples of treatments mimicking the stereotactic radiosurgery (SRS) treatments outside of the brain. These treatments employed the same rigid immobilization principles of SRS in the spine by screwing a frame to the spinous processes. Although reports were encouraging, the conduct of the treatment was not as gratifying as natural and inherent motion confounded accuracy. The brain can be practically immobilized by immobilizing the skull. Once the skull is immobilized, targets within the brain have very little additional movement. Such is not the case outside of the skull. Tumors in the body may be displaced as a function of time by forces exerted by muscle contraction, breathing, gastrointestinal peristalsis, cardiac activity, and many other important physiological processes. It is not possible to eliminate or account for all of these forces. As a result, SBRT is inherently less accurate than SRS.

As with the Gamma Knife, researchers again from Sweden, Ingmar Lax and Henric Blomgren, set out to overcome these problems by constructing a body frame that would both comfortably immobilize the patients torso as well as dampen the internal motion relating to respiration.[21,22] Subsequently, they treated patients with localized tumors using dosimetry plans that mimicked SRS.[23] The dosimetry was constructed using multiple noncoplanar beams with aperture dimensions on the order of the target dimensions. Each of the many beams carried relatively lower weight than with CFRT such that the target dose at the convergence could be dramatically escalated. Blomgren and Lax treated patients with mostly metastases initially. Local tumor control was better than expected, leading them to treat more limited stage cancer patients. Blomgren et al.[24] shared their results via publications and eventually trained others in this new technique.

Meanwhile, investigators from Japan were exploring radiosurgery-like treatments in the chest. Shirato et al.[25] pioneered investigation into characterization and accounting of respiratory motion. Initially, they used CFRT dose schedules, but the understanding of target motion control was very important for the ultimate feasibility of SBRT, as it currently exists. Uematsu et al.[26–28] again from Japan worked in the early 1990s on developing technologies for delivering multiple focused beams of radiation for extracranial targets. In addition, Uematsu's group treated patients with lung tumors primarily from primary non–small cell cancer.

Prospective testing of SBRT began with acquisition of the technology by the groups from the University of Heidelberg, University of Wurzburg, Kyoto University, and Indiana University.[11,14,29,30] Initially, dose-escalation toxicity studies were carried out in the liver and lung trying to find the most potent dose schedules for typically radioresistant primary and metastatic tumors. These prospective trials have been reported but are still maturing and will add a wealth of understanding for the use of SBRT. It is already clear that local tumor control will be higher with SBRT than has been observed with CFRT. SBRT is now a standard treatment for patients with peripheral tumors from early stage lung cancer with simultaneous medical problems precluding surgery. However, toxicity from large dose-per-fraction radiation schedules often appears quite "late" from time of treatment. Therefore, the total impact of treatment, good and bad, will require many years of follow-up to fully appreciate.

## DEFINITIONS AND NOMENCLATURE OF STEREOTACTIC BODY RADIATION THERAPY

SBRT is best defined by its conduct. The proper performance of SBRT requires a team approach to carry out the following tasks[31]:

1. Secure yet comfortable immobilization avoiding patient movement for the typical long treatment sessions.
2. Accurate repositioning of the patient from planning sessions to each of the treatment sessions.
3. Proper accounting of inherent internal organ motion, including breathing motion consistently between planning and treatment.
4. Construction of dose distributions confidently covering tumor and yet falling off very rapidly to surrounding normal tissues. The dosimetry must be extremely conformal in relation to the prescription isodose line compared to the target outline but may allow very heterogeneous target dose ranges.
5. Registration of the patient's anatomy, constructed dosimetry, and treatment delivery to a three-dimensional coordinate system as referenced to fiducials. Fiducials are "markers" whose position can be confidently correlated to both the tumor target and the treatment delivery device. A "stereotactic" treatment is one directed by such fiducial references.
6. Biologically, potent dose prescriptions using a few (i.e., one to five) fractions of very high dose (e.g., generally a minimum of 6 Gy per fraction but often as high as 20 to 30 Gy per fraction).

A working group from the American College of Radiology and American Society for Therapeutic Radiology and Oncology had formulated guidelines for the conduct of SBRT.[8] In general, SBRT is used to treat well-demarcated visible gross disease up to 5 to 7 cm in dimension. It is not used for prophylactic (adjuvant) treatment, as the intent is to totally disrupt clonogenicity and likely disrupt all cellular functioning of the target tissues (i.e., the definition of an ablative therapy).[32–36]

Tissues exposed to the prescription dose level or nearby are likely to be ablated. Such a treatment, properly directed would constitute a most potent form of cancer therapy. In turn, if misdirected or used too liberally, SBRT could lead to debilitating toxicity. At any rate, SBRT is very different from conventionally fractionated radiation therapy (CFRT) in its conduct, toxicity, and ability to control cancer. To this end, it is clear that all forms of radiotherapy do not constitute a black box.

## MOTION ISSUES FOR LUNG STEREOTACTIC BODY RADIATION THERAPY

Treatment plans are generally static with no specific accounting of motion that is typical in the treated patients. Still, the geometry and dose distribution from the radiation therapy treatment plan should be a reasonably true characterization of what is actually delivered to the patient. With the typical large volume of treatment and homogeneous dose-distributions characteristic of CFRT, such an emphasis on the proper correlation of the treatment plan and actual treatment is probably not so critical. However, for SBRT, claims regarding accuracy of equipment, quality of dose distributions, and dose tolerance should not be made based on the virtual computer simulation of the treatment plan; rather, on actual delivery of dose to treated patients. This is particularly true for predicting normal-tissue toxicity from SBRT where both heterogeneous dose and differential volume effects may equally affect outcome.

Although there is a general fascination within the radiotherapy community for electronic or sophisticated mechanical solutions to motion, passive immobilization can be extremely effective. Body frames, vacuum pillows, thermal plastic restraints, and other equipment have been used to try to achieve relocalization similar to the position of simulation,[22,37–49] Other systems will effectively relocate a reference position within the patient prior to each treatment, without the aid of frames or other immobilization devices (i.e., "frameless" systems).[27,50–52] Both approaches have advantages and disadvantages, and no clearly superior method has been identified in clinical practice. In the end, it is most critical to be practical. SBRT treatment sessions are longer than CFRT sessions. Hence, it is important that the positioning system be comfortable and avoids awkward positions or positions fighting against gravity. In addition, the system employed must be properly utilized. As such, staff training and properly administered quality assurance programs are more essential than using a particular brand of equipment.

To minimize treatment margins for coverage, tumor (and normal tissue) motion must be characterized, controlled, or compensated. Motion control accounting approaches fall into three general categories: (a) dampening, (b) gating, and (c) chasing. Within the category of dampening includes the systems of abdominal compression aimed at decreasing one of the largest contributors to respiratory motion related to the diaphragm.[22,41,44–46,49] Also included in this category

are the systems employing breath-hold maneuvers to "freeze" the tumor in a reproducible stage of the respiratory cycle (e.g., deep inspiration).[53–56] Gating systems follow the respiratory cycle using a surrogate and employ an electronic beam activation trigger, allowing irradiation to only occur during a specific segment (e.g., end expiration).[50,57–59] Tracking systems literally move the radiation beam along the same path as the tumor from the beam's eye view.[25,60–63] Tracking may be accomplished by moving the entire accelerator, the aperture (e.g., with the multileaf collimator), or moving the patient on the couch counter to the motion of the tumor. In the case of gating and breath hold, the beam is triggered on and off, constituting a duty cycle avoided by the other systems. In any case, the acquisition of planning information must include the same consideration for motion accounting as the treatment to achieve accuracy. Despite available motion control equipment, some uncertainty continues to require that planning treatment volume (PTV) is larger than gross tumor volume (GTV). In general, for typical dose prescriptions, this enlargement should not be greater than 1.0 cm in the cranial caudal plane and 0.5 cm in the axial plane.

## BIOLOGICAL ASPECTS OF STEREOTACTIC BODY RADIATION THERAPY

**Tumor Biology**    The cell survival curve (logarithm of surviving fraction vs. dose) after exposure to sparsely ionizing radiation, such as photons and gamma rays, follows a characteristic shape starting with a curving portion called the "shoulder" and then becoming linear with increasing dose. With CFRT, daily treatment is given on the shoulder of the survival curve (daily dose range of 1.5 to 3.0 Gy), where cells are able to repair some of the inflicted damage. The survival data in this region can be mathematically "fit" by a second order polynomial to give a simple functional representation. The predictive model related to is called the linear-quadratic (LQ) model.[64–66] Although this formula had served the field of radiobiology quite well for decades, several authors have pointed out that this formalism is not applicable in the range of high doses applied with SBRT.[67–69] In effect, the LQ model grossly overestimates the potency of treatment for daily dose delivery beyond the shoulder (i.e., 6 to 8 Gy for most tumor cell lines) caused by erroneous extrapolation outside the area of fit. Guerrero and Li[69] have proposed modifying the LQ formula by incorporating features of the so-called lethal–potentially lethal (LPL) model. The LPL model differs from the LQ model primarily insofar as it accounts for ongoing radiation repair processes that occur *during* the radiation exposure. Marks[68] and Park et al.[67] have borrowed formalism from the older multitarget model[70] to determine a "single fraction equivalent dose" for hypofractionated treatments with daily dose levels greater than 7 to 10 Gy that avoids any use whatsoever of the erroneous LQ model. The net result of more appropriate estimation from tumor cell kill models is a substantial difference in the predicted tumor cell kill at SBRT-level doses. For example, for a dose of approximately 20 Gy, the LQ

model would erroneously predict several orders of magnitude greater cell kill than the LPL model.[69]

This debate has practical clinical implications when trying to make comparisons to different dose-fractionation schemes for SBRT. In addition, proper modeling has an impact on the understanding of dose-rate effects. Benedict et al.[71] evaluated clonogenic survival in vitro doses in the range of 12 to 18 Gy, using a glioma cell line. For a dose of 18 Gy, increasing the length of treatment from approximately 1.5 to 2 hours corresponded to an order of magnitude decrement in cytotoxicity. Fowler et al.[72] have reviewed this topic of loss of biological effect with length individual treatment delivery and concluded that any treatment administration that lasts more than half an hour might be associated with a clinically significant loss of cytotoxicity.

### Normal-Tissue Biology and Tolerance

With large dose-per-fraction treatment given with SBRT, it is useful to define tissues according to their basic organizational structure. Linear or branching structures such as nerves, airways, and bowel passageways are called *serial* (borrowed from electrical circuit nomenclature), because damage at any point effects function downstream. In contrast, redundant repeating structures such as acini within glands, alveoli within the lung, and nephrons within the kidney are called *parallel*, because injury to one does not necessarily imply that neighbors will be affected. Within the lung itself, there are various tissues that possess unique radiation tolerance characteristics, namely, the airways (both large and small functioning as serial structures), vascular trunks and pedicles, following similar routes as the bronchial tree (functioning as serial structures), and the alveoli/capillary complexes (functioning as parallel structures).[73,74] In addition, the thoracic cavity includes the serially functioning esophagus, serially functioning nerve tissue (e.g., phrenic nerves, brachial plexus, etc.), heart, pericardium, and pleura (all difficult to categorize as parallel or serial), and the bones and musculature of the chest wall. All of these structures will have a unique mechanism of injury and tolerance after SBRT.

CFRT commonly causes large serially functioning airway irritation, such as cough, but, rarely, dose-limiting toxicity. In contrast, high-dose SBRT schemes may cause significant large airway damage by both mucosal injury and ultimate collapse of the airway. Along the routes of bronchial airways, a similar injury is experienced by blood vessels following a similar route. Altogether, this collective radiation injury appears to mostly affect oxygenation parameters including diffusing capacity of lung for carbon monoxide ($D_{LCO}$), arterial oxygen tension (pressure) on room air ($PO_2$), and supplemental oxygen requirements ($FIO_2$).[29] Decline in spirometry indices, including forced expiratory volume in 1 second ($FEV_1$) and forced vital capacity (FVC), are less commonly observed. Because the degree of this airway injury toxicity is related to the proximity of the target to proximal trunks of the branching tubular lung structure, great care should be taken when considering treatment to tumors near the hilum or central chest.

Again, one can show dramatic differences in normal-tissue response between a similar dose of CFRT and SBRT. Although acute and, sometimes, severe esophageal toxicity is commonly seen after CFRT for lung cancer, most of the injury is self-limiting and resolves after treatment. After high-dose SBRT, esophageal strictures may form as a late effect. Another more unique toxicity from SBRT relates to pericardial injury. Pericardial effusions may result after SBRT treatment for tumors treated adjacent to the heart. Probably, by a similar mechanism, pleural effusions commonly develop after SBRT treatment of tumors treated adjacent to the chest wall. Usually, these fluid collections will reabsorb without intervention after several months of follow-up. Rarely, such fluid collections will need to be drained via thoracentesis in patients symptomatic with shortness of breath, pleurisy, or hypoxia.

The term *late effect* implies that it may not first manifest for long periods after delivery of the therapy. Most reports of SBRT do not include long-term follow-up data. As such, there may be unexpected toxicities that need to be recognized, monitored, and evaluated. Particularly, with large doses per fraction, there may be unexpected injury related to nerve tissue and vascular tissue. Ideally, dose to brachial plexus, spinal cord, phrenic nerves, and intercostal nerves will be kept low via prudent treatment planning. Furthermore, avoiding large blood vessels in the central chest would be reasonable as well. Neurovascular calamities including aneurysms, fistulae with bleeding, or neuropathies (including phrenic or vagal nerve palsies) have rarely been reported but may only manifest after many years of follow-up.

In contrast to large volume of irradiation CFRT, direct injury to pulmonary alveoli is considerably less with SBRT owing to the much smaller volumes that receive intermediate and high dose. However, toxicity related to serially functioning tissues is more predominant with SBRT, especially in the central chest. Ideally, SBRT should demonstrate a high degree of conformality between the prescription dose and the target. Lung within the target exceeds tolerance and is no longer functional after high-dose SBRT. A dose-falloff region exists outside of the target, the volume of which depends on the size of the target, the location of the target within the chest, the quality of the radiation dosimetry (e.g., number of beams, beam arrangements, radiation energy, etc.), and the type of radiation (e.g., photon vs. proton, etc.). This dose-falloff region, also called the gradient region, constitutes unintended radiation exposure and should be kept as small as possible.

## PHYSICS AND DOSIMETRY OF STEREOTACTIC BODY RADIATION THERAPY

It is essential that the dosimetry for SBRT be highly conformal between the target margin and the high-dose distribution. In addition, it is essential that the dose outside the target falls off very rapidly, ideally in all directions. Both of these conditions generally require the use of multiple shaped beams.[75–77] Highly shaped beams are desired because high dose is best

eliminated in normal tissues by sharp collimation of primary beam fluence outside of the target from the beam's-eye-view. Conversely, smaller nonshaped beams may be used to treat successive regions of the target.[78] Scatter dose is less easily controlled, even by highly shaped beams. Most modern SBRT treatments for lung targets use around 10 to 15 highly collimated beams. To avoid overlap dose between entrance and exit trajectories, these beams are ideally nonopposing and have as large hinge angles between them as possible. In addition and in an effort to assure that dose gradients fall off rapidly in all directions, the beams should generally be noncoplanar. Coplanar treatments such as those that are commonly utilized in CFRT particularly with IMRT result in low and intermediate dose "spillage" that surrounds the tumor in an annular fashion. Ideally, this spillage dose would be distributed in a geometry potentially capable of treating occult microscopic extension of tumor (even though not specifically accounted for in the target). Except, perhaps, for targets in the vertebral bodies of the spine, there is no reason based on anatomy, tissue function, or known patterns of tumor spread to construct such a predominantly axial dose distribution around the target. Collisions between the patient and accelerator head or the couch and accelerator head will limit the ability to create truly isotropically decreasing dose gradients around targets, but effort should be made to mimic such ideal distributions as much as possible.[78,79]

Unlike with CFRT, for SBRT it is assumed that the GTV is nearly identical to the clinical target volume (CTV) for conduct of the treatment. Because of target motion and setup inaccuracies, an additional margin must encompass the GTV/CTV target to avoid missing the intended target during part or all of the treatment session. This expanded target called the PTV constitutes the final target for high-dose conformal coverage. Some centers divide the addition margin in the PTV between margin needed to encompass tumor motion (called the internal target volume or ITV) and setup error. In addition to the PTV and its contents, ablation is likely to occur in the shell of normal tissue immediately outside of the target in the regions of intermediate to high dose. As such, side effects will or will not occur depending on (a) how essential this inner shell of tissue is for normal function of the organ and (b) the thickness or volume of this shell as it relates to the quality of the dosimetry. This *high-dose spillage* is likely the culprit in most of the toxicity related to serially functioning tissues like tubular structures in the lung, gastrointestinal tract, and liver, causing obliteration of the lumen and subsequent downstream effects. Furthermore, the quality of the dose distribution will affect the volume and geometry of low-to-intermediate dose distributions. This *intermediate-dose spillage* is characterized by the maximum dose at a defined distance away from the target (e.g., 2 to 3 cm) or by the volume of tissue encompassed by an intermediate isodose line (e.g., the 50% of prescription isodose line). Intermediate-dose spillage can affect the organ more globally, similar to the historically large fields associated with CFRT, damaging parallel functioning tissues, but may also cause focal organ injury if the prescription dose is high enough.

The degree to which the prescription isodose volume and the target volume are coincident is generally quantified by a conformality index and a percent coverage. The conformality index is the ratio of the prescription isodose volume to the PTV volume. Generally, this ratio should be kept below 1.2. Achieving this degree of conformality is easier with larger targets. The percent coverage indicates what percent of the volume of the PTV is covered by the prescription dose. The percent coverage should generally be 95% to 100%. Although CFRT results in mostly homogeneous target dose distributions, SBRT may have dramatic heterogeneity of dose. It must be insured that regions within the PTV target is not underdosed relative to the minimum prescription dose; however, overdosage is probably of no consequence and may even be advantageous in centrally hypoxic tumors. It is critical, however, that high-dose "hot spots" associated with this dose heterogeneity are not physically located outside of the PTV. This would be an extreme form of *high-dose spillage* and can generally be avoided by using additional highly shaped beams with unique entrance angles.

Organ exposure limits must be respected with SBRT. It has been known that radiation tolerance of specific organs is related to total dose (and fractionation), volume, and inherent radiosensitivity. However, most quoted tolerances are generally quantified as essentially dose limits. Such characterization is clearly inadequate for SBRT where toxicity is more often related to exceeding a specified volume of tissue receiving a given dose than the absolute dose level itself. Data is accumulating for dose–volume tolerances for specific organs affected by SBRT. Because volume effects are poorly understood, absolute point limits were implemented for critical organs like the spinal cord, esophagus, and major bronchial airways. One of the biggest benefits of enrolling SBRT patients on to multicenter prospective trials is the opportunity to collect dose, volume, and patient outcome data, so that the proper limits for SBRT fractionation might be determined with follow-up.

Particularly for targets within the lung, beams to travel through tissues of variable electronic density en route to the target. Ideally, then, the planning system would include algorithms for accurate accounting of tissue heterogeneity effects as it relates to dose deposition from both attenuation and scattering events. Some planning systems do a good job of modeling these effects; however, some do a very poor job.[80,81] Indeed, published reports show that using a primitive heterogeneity correction algorithm may lead to greater inaccuracies of dose representation at the edge of the PTV than using no correction at all.[82] As such, it seems most reasonable that either sophisticated heterogeneity corrections be implemented (e.g., collapsed cone) or that no heterogeneity corrections should be used for SBRT treatments in or near the lungs.

Beam arrangements for a typical SBRT treatment for treating a primary lung cancer is shown in Figure 43.1. The beam angles were chosen by first considering the realm of attainable beam angles for a tumor in this location, avoiding collisions with the accelerator head. Within this subset of attainable beam angles, a beam weight optimization algorithm was used

**FIGURE 43.1** Typical beam arrangement for SBRT for primary early stage lung cancer. Ten nonopposing and noncoplanar beams coming from various incident directions converge on the demarcated tumor target. (See color plate.)

to select these particular 10 angles using the Radiation Therapy Oncology Group (RTOG) tolerances to construct avoidance structures.[31] In the end, the beams are noncoplanar, nonopposing, and are separated by fairly large hinge angles. Beam weights are divided fairly equal between all beams so as to spread out entrance dose. Figure 43.2 shows the dose–volume histogram for the optimized treatment plan. The PTV target receives a minimum of 95% coverage by the prescription line, which is 60 Gy in this case. Despite the high prescription dose, note that the volume of lung that receives 20 Gy or more is only 5% for this typical case. This is in striking contrast to the 20% to 30% levels commonly seen with CFRT for this parameter known to predict radiation pulmonary toxicity.

## CLINICAL EXPERIENCE WITH STEREOTACTIC BODY RADIATION THERAPY

SBRT is a potent local modality and not particularly suitable for adjuvant or prophylactic therapy because of a high likelihood of serious collateral damage to normal tissues. In contrast, CFRT has been most successful as an adjuvant therapy capable of eradicating occult micrometastatic tumor deposits without catastrophic injury to the tissues, which bear these deposits. As SBRT is very effective at eradicating gross visible targeted tumor, diseases with demarcated tumor, the extent of which is mostly visible on available imaging such as CT scans, should be the ideal SBRT diseases. Diseases with high

likelihood of regional or distant spread or for which staging is inaccurate should not be treated with SBRT, at least as a sole modality. As such, small cell lung cancer and advanced stages of non–small cell cancer are not ideal SBRT diseases. Early stage non–small cell cancer with no evidence of regional or distant spread would be much better clinical models for testing SBRT. In addition, limited lung metastases, especially in patients with otherwise good systemic control and longer disease free interval, would be reasonable diseases for SBRT. Indeed, these diseases have been studied prospectively using SBRT as will be outlined in this section.

**Medically Inoperable Patients with Stage I Cancer** Early retrospective experience using SBRT in lung cancer showed that tumor shrinkage early after therapy was very likely, even with more modest dose prescriptions. There was wide variability of both the number of fractions and the dose prescribed per fraction, even within a single institution experience. Some reports had very small numbers followed short periods of time, yet made strong conclusions regarding adequacy of dose and late effects. Of note, tumor recurrence after an effective therapy will occur much later than after an ineffective therapy because of population growth kinetics. Furthermore, toxicity of high dose-per-fraction therapy will likely occur quite late after therapy. Therefore, it is most rational to investigate the role of SBRT in NSCLC using clearly defined selection, consistent treatment, strict quality assurance measures, and uniform follow-up policy. In addition, follow-up should make mandatory that all patients are assessed and published reports await mature evaluation

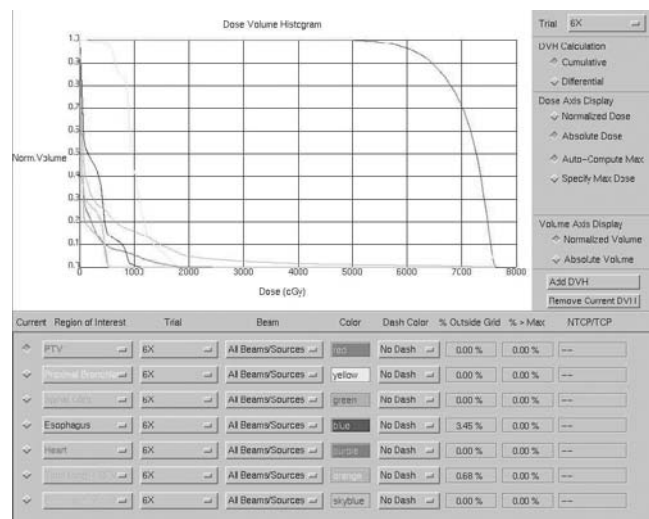

**FIGURE 43.2** Dose–volume histogram for an optimized dosimetry plan using the beam arrangements from Figure 43.1. The red line is for the PTV, the yellow for the proximal bronchial tree, the green for the spinal cord, the dark blue for the esophagus, the purple for the heart, the orange for the total lung minus GTV, and the light blue for the proximal trachea. (See color plate.)

of outcome data. Such constraints can only be met by regimented prospective testing.

Indiana University performed a formal phase I dose escalation toxicity study with 47 patients with medically inoperable lung cancer.[29,83] The starting dose was 8 Gy per fraction times three, 24 Gy total. All patients were treated with three fractions at all dose levels. Independent dose escalation trials were carried out in three separate patient groups: patients with T1 tumor, patients with <5-cm T2 tumor, and patients with 5- to 7-cm T2 tumor. There was no restriction regarding the location of the tumor in the lung as both central and peripheral tumors were treated. Seven dose levels were tested. The maximum tolerated dose (MTD) was never reached for T1 tumors and T2 tumors less than 5 cm despite reaching 60 to 66 Gy in 3 fractions. For the largest tumors, dose was escalated all the way to 72 Gy in 3 fractions, which proved to be too toxic. Dose-limiting toxicity in that subset included pneumonia and pericardial effusion. Therefore, the MTD for tumors 5 to 7 cm in diameter was 66 Gy in 3 fractions, whereas the MTD for smaller tumors lies at an undetermined level beyond this dose. Classic radiation pneumonitis (fever, chest pain, shortness of breath, dry cough, and infiltrative x-ray findings), which had been erroneously predicted to be the dose-limiting toxicity, only occurred sporadically.

At the lower doses (i.e., 24 to 36 Gy in 3 fractions), very impressive tumor responses with little normal-tissue effects were observed by 3 months as indicated in Figure 43.3. Unfortunately, with longer follow-up, often past several years, many of these patients ultimately had tumor recurrence. As the dose was escalated beyond 42 to 48 Gy, striking imaging changes began to appear near the treated tumor by around 6 to 12 months. This seemed to be related to a bronchial toxicity, which was not commonly described with CFRT. Radiographic changes by themselves were not considered dose limiting, and most of these imaging changes were asymptomatic. In many cases, the radiographic changes mimic tumor recurrence.[84,85] With no salvage therapy in this population, patients were followed without treatment. Repeat positron emission tomography (PET) scans and biopsies showed no evidence of tumor recurrence in most patients treated at the higher dose levels. In the end, a dose of 60 to 66 Gy in 3 fractions was determined to be reasonably safe for enrolled medically inoperable NSCLC patients.

With a potent tumor dose confirmed to be reasonably tolerable from the phase I study, the Indiana group embarked on a 70-patient phase II study in the same population. The phase II study was aimed at validating toxicity in a larger patient population and determining efficacy (local control or survival) using a total dose of 60 Gy in 3 fractions for the small tumors and 66 Gy in 3 fractions for the large tumors (35 patients for each group). The target control rate for the statistical power calculation was 80%, which is dramatically higher than the typical 30% to 45% control seen with CFRT. All high-grade adverse events (e.g., emergency room visits, surgical procedures, hospitalizations, and deaths) were reviewed by an independent data safety monitoring panel to determine if the event was treatment related (i.e., treatment-related toxicity). In addition, this panel was responsible for final scoring of efficacy such as determining local recurrence.

The preliminary results of the phase II study were published early because of the discovery of a serious toxicity not appreciated in the phase I study.[86] The actuarial 2-year local control for this potent dose regimen is 95%, and isolated hilar or mediastinal nodal relapse is extremely rare despite clinical staging. The overall 2-year survival for this frail population is poor at 56%, with most of the deaths related to comorbid illness rather than disease progression or toxicity. The protocol placed no time limits on scoring treatment-related toxicity, and many late toxic events have been recorded. Fewer than 20% of patients have experienced high-grade toxicity confirming the phase I model. However, interim analysis showed that severe toxicity (grade 3 to 5) was significantly more likely in patients treated for tumors in the regions around the proximal bronchial tree or central chest region. In fact, the risk of severe toxicity is 11 times greater when treating central tumors as compared to peripheral tumors.

**FIGURE 43.3** Patient with a solitary pulmonary nodule treated on the Indiana University phase I trial using SBRT. After just 3 months, the tumor has dramatically reduced in size, but a remnant remains.

Similar experience relating to efficacy has been reported in Europe and Japan. Active groups from Sweden, Denmark, Germany, the Netherlands, and Italy have reported rates of local control and toxicity similar to the Indiana experience at similar dose levels.[17,87–89] Various dose and fractionation schemes have been used, however, generally fewer than five total fractions have been employed. As with the Indiana group, Wulf et al.[90] from Wurzburg have demonstrated a clear dose–response relationship with better control at higher dose levels. As shown in Table 43.1, clinical results are favorable for tumor control when single fraction equivalent dose (SFED) levels of 40 Gy or higher are used. SFED is a far more ideal method for comparing different SBRT fractionation schemes as compared to biologically equivalent dose (BED) because it does not grossly overestimate the potency of large dose-per-fraction treatments as BED comparisons based on the linear quadratic model (see previous discussion under "Biological Aspects of Stereotactic Body Radiation Therapy").[67,68] With SFED of 40 Gy, actuarial tumor control is consistently 75% to 80% at 2 to 3 years, whereas for SFED of 50 Gy or higher, tumor control consistently exceeds 90%. This level of primary tumor control rivals surgical lobectomy.

RTOG 0236 using SBRT for medically inoperable lung cancer in patients with peripherally situated tumors completed its accrual of 56 patients in 2006. This trial used SBRT to a dose of 60 Gy in 3 fractions for T1, T2, and peripheral T3 tumors less than 5 cm in diameter. Treatment dosimetry was carried out without the use of heterogeneity correction factors, and subsequent dosimetric analysis showed the actual dose for RTOG 0236 was around 54 Gy in 3 fractions. Extensive accreditation, conduct, and dosimetry constraints were developed in the RTOG Lung, Physics, and Image-Guided Therapy Committees to form a basis for meaningful quality assurance and consistent treatment for a multicenter trial. Three toxicity analyses were performed during the trial, which showed no excessive toxicity warranting trial closure. The first formal report of toxicity was presented at the American Society of Therapeutic Radiology and Oncology annual meeting in Los Angeles.[18] The rate of protocol defined severe toxicity was around 10%, whereas at time of analysis (median follow-up 13 months), only 1 patient out of 55 evaluable had a local recurrence. Another trial in patients with centrally situated tumors, RTOG 0813, is being planned that will use a more gentle fractionation scheme for medically inoperable patients.

The Japan Clinical Oncology Group (JCOG) 0413 trial is a phase II trial using SBRT for peripheral lesions in two groups: operable and medically inoperable patients with stage I cancer. The treatment dose is 48 Gy in 4 fractions to the isocenter based on the Kyoto experience. Accreditation was carried out for enrolling institutions.[91] Like RTOG 0236, quality assurance is being monitored through the Advanced Technology Consortium with a requirement that all institutions submit digital plans for review. The medically operable

group enrolled quickly and those patients are being followed. The medically inoperable group is still enrolling.

### Operable Patients with Stage I Cancer

Surgery continues to be the standard of care for operable patients with stage I cancer. However, some patients are adverse to the idea of surgical resection and have opted to be treated with SBRT. Most of the work in this population has been carried out in Japan. Onishi et al.[13,92] performed a large retrospective chart review of patients treated at several Japanese centers using SBRT in early stage NSCLC. Although dose and number of fractions varied considerably, all patients were treated with small radiation fields under stereotactic guidance. This report included a large number of operable patients that were analyzed separately. For such patients who received dose levels such that the biological effective dose (BED) was greater than 100,[93] local control and survival rivaled best surgical series according to the authors. The 3-year overall survival in this group was 88%. This report, along with the experience from Kyoto, has formed the basis for enrolling patient with operable tumors onto a separate arm of the JCOG 0403 trial for peripheral T1N0 stage I patients. As noted previously, this trial completed enrollment and patients are being followed.

In the United States, very few patients with operable stage I NSCLC have been treated on clinical trials. That situation will change with the enactment of RTOG 0618 for operable patients. Based on best surgical literature from North America, it will be required that SBRT attain a local control rate of 90% or better to compete with lobectomy.[94] As such, very potent dose prescriptions will be required. RTOG 0618 is modeled after RTOG 0236 except eligibility is for healthier patients capable of tolerating thoracotomy. The potent prescription dose is 60 Gy in 3 fractions and frequent tumor status assessments are made to identify failure early and attempt surgical salvage.

## CONCLUSION

Ablation of deadly lung tumors has been made possible by technological developments delivered to the clinic by important engineering and physics research. However, they serve to allow the utilization of the most potent biological form of radiotherapy delivered to date.[95] Ablation of tumor using total dose or dose per fraction well beyond conventional radiation promises in the end to serve to improve outcome. This new collaboration between technology innovators and biological researchers holds considerable promise for improving the outcome of a large population of patients with lung cancer.

At one time, it was felt that improvements in systemic therapy would lead to a decrease in utilization of local therapies like surgery and radiotherapy. Interestingly, the opposite has occurred. As systemic treatments become more effective, local disease becomes the prominent mode of failure. Radiotherapy will be used more selectively to target isolated deposits of gross disease.[96] Currently limited to treatment with curative intent in stage I to III disease, radiotherapy will likely be used more

often in stage IV disease either as a measure for consolidation or to ablate cancer deposits resistant to systemic therapy. With exploitation of technology and biological understanding, this is an ideal role for radiotherapy as an effective and cost-effective modality for local control of gross disease.

Patients would be best served if their cancer therapy was customized according to the exact nature and threat of their specific tumor. The goal of technical, biological, and clinical research in radiation oncology as well as in collaboration with surgical and medical oncologists is to facilitate adaptive therapy.[97–99] In this paradigm, pretreatment diagnostic information including imaging, staging, tissue samples (proteomic, genomics, etc), and other predictive assays are integrated to make therapy selection.[100] Having chosen the correct approach, the patient is started on therapy while monitoring progress. Early assessments relating to accuracy of delivery, tumor response, metabolic changes, tolerance, and others can be used to change the therapy appropriately during therapy.[101–103] Soon after treatment, imaging and metabolic assessment may direct the need for adjuvant therapies or avoid toxicity. Rather than a "one-size-fits-all" cancer therapy, the adaptive process uses a tailored approach that constantly re-evaluates and responds to redirect the therapy toward a better outcome. Until this goal is achieved, patients will continue to be enrolled onto well-designed prospective trials such that SBRT might be refined to its optimal potential.

# Radiation Treatment–Related Lung Damage

More than 50% of patients with lung cancer receive radiation during case management. Because treatment sometimes requires that a large volume of lung be exposed to high doses of radiation, definitive radiation therapy requires total doses that can result in late sequelae: lung injury. These late sequelae were observed as early as the 1920s, less than 2 decades after the discovery of x-rays.[1] The two phases of lung damage—radiation pneumonitis and radiation fibrosis—were first described in 1925 by Evans and Leucutia,[2] who divided the damage into these now well-recognized sequelae of lung irradiation. Although almost a century of studies of patients and experimental models has provided a wealth of information on these two potentially fatal complications, we remain unable to circumvent these untoward reactions completely. Both continue to limit radiation's effectiveness against malignant tumors of the lung.

Since the third edition of this book was published, significant advances have been made in understanding the molecular and physical basis of radiation-induced lung damage and how genetic regulation functions within it. The radiation dose–volume effect in mouse lung has been clearly defined, and experimental findings have been substantiated by clinical studies. As three-dimensional (3D) conformal radiation therapy has become the norm for treating lung cancer, new methods of estimating the risk of pulmonary injury from dose–volume histograms (DVHs) and normal-tissue complication probability models (NTCPs) have been developed. The development of such advanced radiation therapy technologies as intensity-modulated radiation therapy (IMRT), image-guided radiation therapy (IGRT), and proton beam therapy (PBT) has reduced the risk and severity of radiation-induced lung damage and morbidity, and clinical outcomes have been promising. The radiotherapy target in lung cancer may be more carefully delineated and not necessarily include the large volumes of lung once thought necessary and standard. The goal of this chapter is to review information in these areas and to present new findings regarding the development of quantitative and easily accessible markers of lung damage and predictive assays of pulmonary radiosensitivity.

## DAMAGE VERSUS MORBIDITY

The terms *damage* and *morbidity* are often used interchangeably, but they are quite different concepts. In clinical practice, some degree of radiation-induced lung damage, either pneumonitis or fibrosis, is considered acceptable because of the large functional reserve of this tissue. The whole organ does not fail to function if some part of it is destroyed. Morbidity, on the other hand, is a clinical term that describes how well an individual patient feels or how well a specific organ functions. The morbidity of treatment is determined by many factors, including the damage to the tissue, the effect of this damage on organ function, and the effect of both of these factors on the patient's well-being and lifestyle. Because of the functional reserve of the lung, structural damage is not necessarily reflected in clinical morbidity, assessed in terms of whole-lung function.

The dissociation between damage and morbidity in the lung reflects the organization of those anatomical units responsible for lung function.[3] Morbidity is a reflection of two parameters: (a) the survival of sufficient numbers of cells to maintain tissue function and (b) the organization of those cells into units that carry out tissue function. The spatial relationship between these functional subunits differs between tissues and is a critical determinant of the relationship between damage and any resultant morbidity.

Anatomically, the lung is a system of branching ducts and accompanying blood vessels that ultimately terminate in the alveoli, the site of gas exchange. The functional subunit in the lung is most likely the *acinus*, which is structurally well defined, beginning at the ramification of the terminal bronchiole to the respiratory bronchioles and terminating in the alveolar sacs, each of which bears numerous alveoli. Each acinus is a self-contained entity independent of its neighbor. Presumably, destruction of one acinus will have no measurable effect on lung function in a normal healthy lung, and functional damage, particularly total lung function, will be manifested only when a critical number of these units are destroyed. A useful analogy is a strand of sequential lights arranged in parallel.

When one burns out (damage), none of the others is affected, and the overall effect is not diminished; that is, the damage is below the threshold of the human eye to distinguish it (no morbidity). However, when sufficient numbers of lights burn out such that damage is noticeable (the threshold for damage detectable by the human eye is exceeded), the overall effect is diminished (morbidity occurs).

Many assays are available to quantify radiation-induced damage and morbidity in the lungs in experimental animals and in patients. In humans, regional pulmonary function or the extent of pneumonitis and fibrosis evident on radiographs can be quantified by using functional imaging modalities such as single photon emission computed tomography (SPECT), ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET), and ventilation planning computed tomography (CT), thereby providing systems by which damage can be scored.[4–15] In rats and mice, the experimental animals most commonly used to study radiation- and drug-induced lung injury, measurements of regional lung function are difficult and pulmonary function tests most often assess total lung function, a measure of morbidity.[16–20] The diffusion capacity, measured as DLCO (diffusing capacity of lung for carbon monoxide) is the most useful clinical tool of functional lung oxygen exchange. When sufficient functional reserve units are destroyed, either as preexisting lung damage from smoking, or as new damage from treatment, this can be a sensitive measure of that injury. In patients, structural damage can be quantified by noninvasive methods, for example by CT scanning; in experimental animals, such damage is most often assessed in autopsy specimens. In this chapter, clear distinctions will be made between damage and morbidity and the assessment of each.

## RADIATION-INDUCED LUNG DAMAGE

**Pathophysiology** Radiation-induced damage to the lung occurs in distinct phases characterized by differences in when after irradiation they occur and their histologic or molecular manifestations (Table 44.1).[21] Damage to the human lung has long been described as occurring in four clinical phases: a phase

| TABLE 44.1 | Principal Histopathologic Abnormalities after Irradiation of the Thorax in Animals | | |
|---|---|---|---|
| | **Abnormalities after Irradiation** | | |
| **Site** | **Immediate and Early (0–2 mo)** | **Intermediate (2–9 mo)** | **Late (9+ mo)** |
| Capillaries | 2 hr: Endothelial cell changes, increased capillary permeability | Marked capillary abnormalities with widespread obstruction caused by platelets, fibrin, and collagen | Loss of many capillaries, regeneration of new capillaries |
| | 2–7 day: Marked endothelial cell changes and separation from basement membrane and sloughing, producing obstruction of lumen | Regeneration of capillaries; reduced capillary permeability | Reduced capillary permeability |
| | 1+ mo: Many capillaries swollen and obstructed | | |
| Type I pneumocytes | Degenerative changes or normal | Decreased number | Further decrease in number |
| Type II pneumocytes | Very early degenerative changes becoming more marked with time or normal | Large increase in size and number, abnormal appearance | Return to normal size and number |
| Basement membrane | Early swelling, indistinct, later very irregular | Folded and thickened | Folded and thickened |
| Interstitial space | Edema and debris, infiltrated with inflammatory cells and basophils; slight increase in connective tissue | Infiltrated with mononuclear cells, mast cells, inflammatory cells, and connective tissue | Few inflammatory cells; large increase in collagen |
| Alveolar space | Fibrin, hemorrhages, and debris; Increased number of alveolar macrophages | Becomes smaller | Small or absent, distortion of architecture |
| Bronchial epithelium | Early transient inflammatory reaction; cillary paralysis, increase in goblet cells or normal | Epithelial proliferation | — |

Note: Changes are dependent on mouse strain

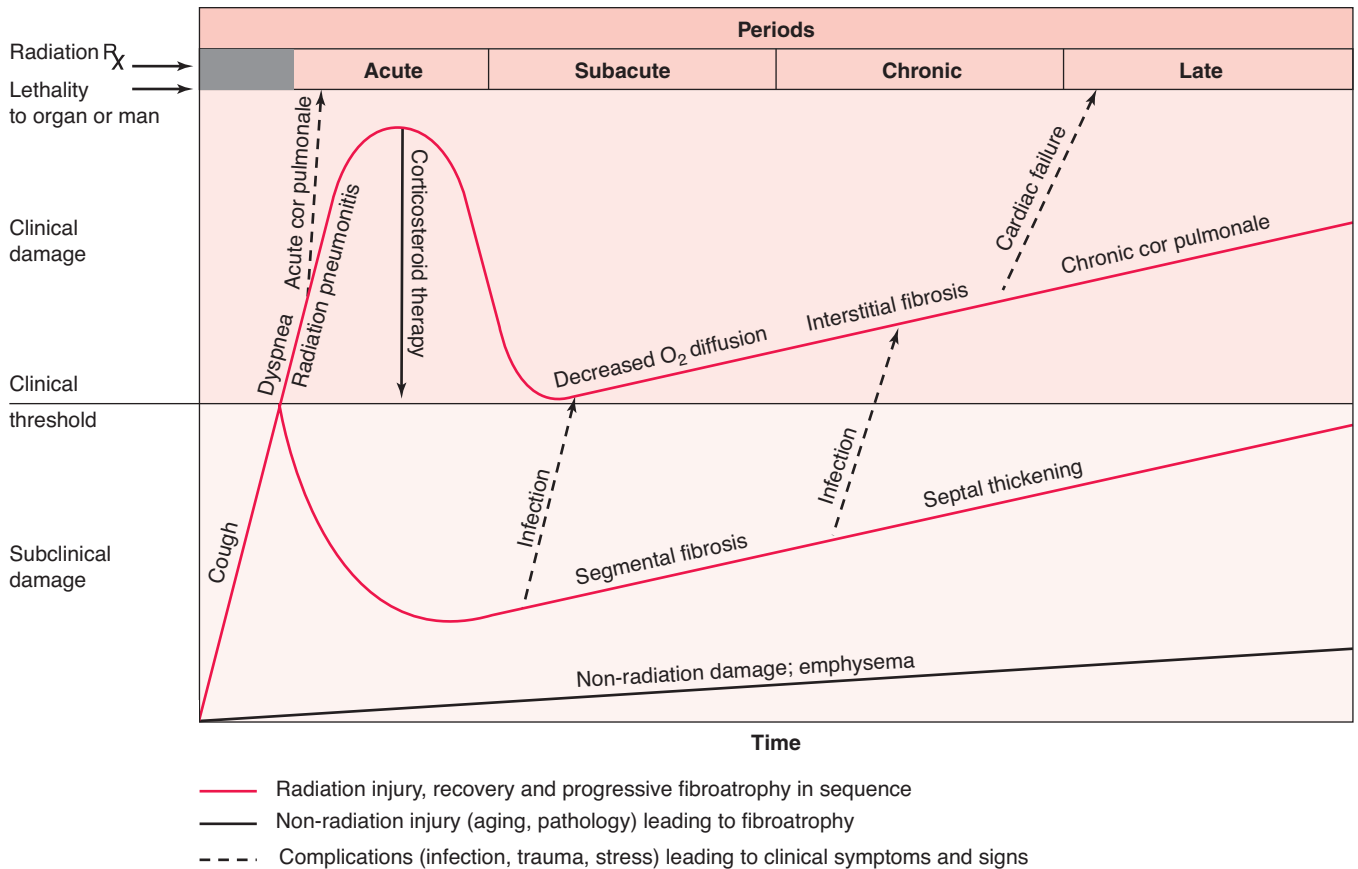
From Gross NJ. Pulmonary effects of radiation therapy. *Ann Intern Med* 1977;86:81–92, with permission.[21]


**FIGURE 44.1**    The clinical course of radiation-induced pulmonary damage consists of four phases, each having distinct pathologic and clinical signs and symptoms. These changes are dependent on dose, as depicted in the upper curve (high dose) and the lower curve (low dose). The changes in the acute phase after high doses are those generally associated with radiation pneumonitis, whereas those occurring during the chronic and late phase are associated with pulmonary fibrosis. After low doses, the pathologic changes are subtle, consisting mostly of interstitial fibrosis, which is usually not sufficiently severe to cause clinical symptoms.[26] (From Rubin P, Casarett GW. *Clinical Radiation Pathology*. Philadelphia: WB Saunders, 1968;459, with permission.)

of acute injury termed *radiation pneumonitis*, a subacute phase, a chronic phase characterized by lung fibrosis, and a late phase (Fig. 44.1).[22–26] Two of these phases are clearly separated in time: pneumonitis occurs from 3 to 6 months after the beginning of treatment, whereas fibrosis occurs from 1 year onward. Both pneumonitis and fibrosis have been well defined histopathologically under controlled conditions in animals. However, because animals can be sacrificed and studied at predetermined times after irradiation, an additional earlier, asymptomatic phase of damage has been defined—the latent phase.[26–28] The characteristics of radiation-induced lung damage during each of these five phases are described further in the following sections.

**Latent Phase**    The weeks to months preceding the overt appearance of radiation pneumonitis is referred to as the "latent" period, because no overt histopathologic, radiographic, or clinical signs and symptoms of radiation damage can be observed. In most cases, overt pulmonary reactions are not expressed either clinically or histologically in humans or

in animal models for the first 2 or 3 months after irradiation, regardless of the volume of lung irradiated. Although no changes can be observed at the light microscopy level during this latent period, electron microscopy reveals degranulation and loss of type II cells (with attendant loss of surfactant), loss of basal laminar proteoglycans (resulting in swelling of the basement membrane), and transudation of proteins into the alveolar spaces (indicating increased capillary permeability and suggesting a loss of endothelial cells) within the first month after whole-lung irradiation.[24,25,27] Endothelial cells themselves become vacuolated and pleomorphic and may slough, leading to denudation of the basement membrane and changes in capillary permeability.[29] Although these changes are dose related and diffuse throughout the lung, they are not in themselves sufficiently severe to result in death during this time. Deaths do not occur before overt histologic damage appears.

It was formerly assumed that during the latent phase, a series of biochemical events occurred later manifest as overt

expression of damage during the next phase of lung injury (pneumonitis), although no such events had been identified. New molecular techniques and tools suggest that dramatic changes do occur during this period and, depending on the radiation dose, may resolve or may progress to the next phase, which is characterized by overt signs and symptoms of radiation pneumonitis. These molecular changes are discussed next.

**Acute Phase: Classic Radiation Pneumonitis**   Evidence of structural changes in the lung appear within the first 6 months after irradiation of all or part of the lung of humans or experimental animals, resulting in diffuse alveolar damage.[1,26–28] Although this phase of damage occurs relatively long after the lung irradiation, histologically, it is an acute effect that is characterized by a prominent inflammatory cell infiltrate consisting of macrophages, lymphocytes, and mononuclear cells in the pulmonary interstitium, which is normally devoid of cells, and in the air sacs.[3,22,24–28] In animal models, neutrophils usually do not predominate in this inflammatory cell infiltrate. Although loosening and widening of the interstitium indicates interstitial edema, only after high doses is edema observed in the air spaces. When the whole of both lungs is irradiated in humans or experimental animals, the damage is diffuse and, if sufficiently severe, fatal.

This acute phase of damage in the lung is generally referred to as *pneumonitis*, a term that usually refers to an inflammatory reaction in the lung caused by local growth of bacteria, fungi, or parasites. In such situations, the cellular infiltrate contains polymorphonuclear leukocytes, a cell type rarely found in the "sterile" inflammatory infiltrate in the irradiated lungs of experimental animals. When present, these cells are indicative of a superimposed infection and the cause of death—radiation, infection, or both—is unclear. Perhaps a more appropriate term for this phase of diffuse alveolar damage after lung irradiation is *alveolitis*, which refers to an inflammatory reaction, in this case a pathological condition not caused by a microorganism.[30] Although an inflammatory cell infiltrate in the interstitium and the air sacs is a prominent component of radiation alveolitis, the relative contribution of these inflammatory events versus direct tissue injury from radiation in the pathogenesis of this syndrome is unclear.

In mice, pneumonitis begins at 3 months after radiation is administered and persists for up to 6 months, with most deaths occurring between 4 and 5 months posttreatment. The latency period for the appearance of damage depends on the radiation dose, appearing sooner after high doses than after low doses. To account for the dose-dependent difference in the latency period and to include all responders in the assay, researchers set the standard time for scoring deaths from pneumonitis in animal experiments between 3 and 7 months. Techniques used to quantify this phase of lung damage in experimental animals include functional assays such as breathing rate[16,18,20] and carbon monoxide uptake[17]; CT scans[19]; quantitative morphometry[28,31]; and, of course, lethality from the syndrome.[3] These measures provide steep dose–response curves from which estimates of an effect dose for a given severity of injury can be obtained. Generally, the dose that prompts a certain effect in 50% of animals ($ED_{50}$) or the dose that kills 50% of the population ($LD_{50}$) is used. In mice, estimates of the $LD_{50}$ from radiation pneumonitis occurring between 3 and 6 months after whole-lung irradiation range from 9 Gy to greater than 16 Gy, depending on the mouse strain. In the clinic, the use of large single doses to the upper half of the body or to the whole body has provided information on radiation dose–response curves for radiation pneumonitis in humans.[32] When either the incidence of pneumonitis[33–36] or evidence of damage on CT scans[9,37] is used to quantify increases in lung density in patients, the shape of the resultant dose–response curves for lung damage in humans parallels those for mice. The $ED_{50}$ for pneumonitis in humans, 9 to 10 Gy, is within the range of $LD_{50}$s for pneumonitis measured for different mouse strains, although on the low end of the range. In one study, the relationship between regional dose and radiation pneumonitis response was linear when pneumonitis was evaluated with FDG–PET/CT imaging.[14] Although treatment of lung cancer can involve irradiation of large volumes of lung, rarely is the whole lung irradiated, and thus, fatal pneumonitis is relatively uncommon, occurring in 1% to 4% of cases.[38,39] However, that the range in irradiated patients is 2% to 33% for severe pneumonitis,[38–42] and an even higher proportion (up to 77%) demonstrate CT scans lung changes consistent with pneumonitis.

Previously, diffuse alveolitis had been considered characteristic of the acute phase of radiation-induced lung damage in humans and animals, but the histopathologic differences between mouse pneumonitis and human pneumonitis could not be explained. For example, a characteristic histologic finding in irradiated human lung is the presence of hyaline membranes. Mice do not develop fibrosis during the pneumonitis phase, but focal areas of fibrosis have been reported in patients within the first month or two after lung irradiation, the time generally associated with the infiltrative, exudative lesions of radiation pneumonitis. These discrepancies between mice and humans have been partially resolved by the work of Sharplin and Franko,[43] who report that the pathology depends on the strain of mouse used. For example, mice of the C3H and CBA strains showed a classic diffuse alveolitis (pneumonitis) without evidence of fibrosis, whereas the C57B16 strain exhibited protein-rich edema, hyaline membranes, and focal fibrosis, with few of the changes characteristic of pneumonitis (Fig. 44.2). These findings indicate that the choice of mouse strain is critical in studies of radiation lung damage. In fact, mouse strains used to study pneumonitis would be different from those chosen to study fibrosis. Clearly, the mechanism of damage varies between strains, and the underlying mechanisms may vary in humans as well.

**Intermediate (Subacute) Phase**   If the radiation dose is low, or if less than a critical volume of lung is irradiated, the acute pneumonitis phase resolves. Although few data are available on this phase in humans, irradiated mouse lung experiments
**FIGURE 44.2**   Characteristic changes in the lungs of C3Hf/Kam **(A)** mice and C57/BL6 **(B)** mice after equivalent single doses of radiation or cobalt-60 gamma rays to the whole thorax. The C3H mouse was sacrificed at 3.5 months because of overt signs of severe respiratory distress; the C57 mouse was sacrificed at 5 months. The lungs of the C3H mouse show a classic radiation alveolitis (pneumonitis), whereas the lungs of the C57 mouse show collapsed atelectatic alveoli with collagen. Superimposed alveolitis is not a feature.

provide a model.[18] In mice that survive the acute pneumonitis phase, lung function, as measured by breathing rate, improves. The lungs, though, are not totally normal, and foci of foamy macrophages with hyperplasia of type II epithelial cells in the air spaces are the dominant findings; however, no deaths occur during this phase of damage. Thus, this phase appears to be one of resolution of the early exudative alveolitis.

**Late Phase: Radiation Fibrosis**   In contrast to the effects of acute alveolitis, the effects of radiation in humans that are chronic are observed from months to years later, even though biochemical and histologic changes occur months earlier. Pulmonary fibrosis develops insidiously and may stabilize after 1 to 2 years. Although numerous studies have attempted to elucidate the mechanism(s) leading to pulmonary fibrosis, the pathogenesis of this late lung response remains elusive and controversial.

Pulmonary fibrosis is the end stage of a complex process of abnormal repair of damage that may be preceded by an inflammatory response dominated by macrophages and lymphocytes. Radiation-induced lung fibrosis is generally thought to be the repair process that follows radiation pneumonitis or radiation alveolitis. Fibrosis of the pulmonary parenchyma may occur as a diffuse or focal lesion, but the designation of pulmonary fibrosis is usually reserved for diffuse or widespread multifocal collagen deposition involving the peripheral air spaces. Although often termed *interstitial fibrosis*, collagenous thickening of alveolar walls is often a consequence of the incorporation of intra-alveolar exudate into the interstitium and the subsequent reepithelialization, which leads to a revision of alveolar architecture. In fact, it is often suggested that severe exudative alveolitis of long-standing duration results in a generalized fibrotic thickening of the alveolar septa.[30,44] Loss of pulmonary function results from focal microcollapse of alveoli and apposition of alveolar walls, leading to irreversible remodeling of pulmonary architecture.

Although lung irradiation studies in mice indicate that pneumonitis and fibrosis are directly related,[28,45–47] other studies, also in murine models, show that these two sequelae of lung irradiation can be dissociated from each other. They also indicate that radiation-induced lung fibrosis can and does occur without a preceding inflammatory event.[48–50] These studies suggest that this phase of injury may result from different pathogenic mechanisms than those underlying pneumonitis.

In mice, the exact form of lung fibrosis that occurs after lung irradiation depends on the strain. In early studies of radiation-induced lung damage, mice were killed at 7 months after irradiation, when the pneumonitis phase of damage ended. However, in later studies, mice surviving to 7 months were followed for periods of up to a year after thoracic irradiation. A diffuse thickening of the alveolar septa characterized by collagen deposition was observed at necropsy in these long-surviving mice.[49,50] The air spaces were clear and patent, and pulmonary architecture was preserved, though the lungs were stiff. Sharplin and Franko[31,43] reported that radiation-induced lung fibrosis in mice was not always manifested as a diffuse thickening of the alveolar septa and that some strains exhibited atelectasis accompanied by collagen deposition in the collapsed area, resulting in a focal contracted scar. In this form of lung fibrosis, alveolar architecture is obliterated. We too have found a difference in the fibrotic lesions in irradiated mouse lung, with the C57B1/6J mice exhibiting collapsed atelectatic alveoli with superimposed collagen and the C3H strain showing a more diffuse fibrosis of the alveolar walls and small stellate scars surrounded by patent alveoli.[51] In C57B1/6J mice, the collagen appears in organized bundles, making it easily distinguishable on light microscopy with collagen-specific stains; in C3H mice, the initial deposition of the collagen as fine, wispy fibrils in the alveolar wall makes this type of fibrosis more difficult to resolve with light microscopy. In addition to these distinct histologic features, these two forms of fibrosis are

distinguished further by the time at which they appear in the two strains after irradiation. Fibrosis in the C57B1/6J strain occurs within the first 6 months after irradiation, a period during which only pneumonitis is found in the C3H strain. In the C57B1/6J strain, fibrosis of the alveolar walls does not occur until 9 months (or later) after irradiation.

The suggestion from these mouse studies that the pathogenesis of radiation-induced pulmonary fibrosis may not be uniform across strains suggests that there may be three different pathways to lung fibrosis that may depend on the toxic agent: *luminal fibrosis*, in which granulation tissue buds into the air spaces; *mural fibrosis*, in which exudate is incorporated into the alveolar walls; and *atelectatic induration*, which involves partial or complete collapse of alveoli and permanent apposition of alveolar walls followed by fibrous tissue proliferation and collagen deposition in the area.[30] Franko et al.[52] have suggested from breeding studies in inbred strains of mice that radiation-induced lung fibrosis results from two independent pathways that may involve different genes. Further support for the hypothesis that pulmonary fibrosis can arise through several mechanisms comes from studies of the colon, in which two distinct types of fibrosis have been shown to occur after irradiation, possibly as a result of two distinct mechanisms.[53]

Most studies in mice involve irradiating the whole lung, which is not the standard procedure for radiation-based treatment of lung cancer in humans, in which limited volumes of lung are irradiated. Thus, the question remains as to how relevant findings from experimental animal models are to the radiation-based treatment of lung cancer in humans. For example, hemithoracic irradiation in mice and rats does not produce the same mortality and morbidity as that of whole-lung irradiation because of hypertrophy of the contralateral lung; however, the mechanisms of collapse and fibrosis of the irradiated lung may differ from those that occur after whole-lung irradiation. In studies of the kidney (a paired organ such as the lung), nephrectomy 1 day after bilateral kidney irradiation was found to induce a proliferative response in the remaining irradiated kidney that in turn resulted in partial restoration of kidney function compared with kidney function in irradiated nonnephrectomized mice.[54] Although these differences between animal experiments and radiation-based treatment of humans for lung cancer must be borne in mind, clinical observations indicate that similar-appearing damage occurs in humans and in mice after lung irradiation, supporting the use of these animal models for mechanistic studies. What is most important is that the studies in mice that identified the form and severity of radiation-induced lung fibrosis as being related to the strain of mouse suggest that this late consequence of lung irradiation may be genetically regulated. Identifying, mapping, and cloning the gene(s) for radiation-induced lung fibrosis could provide a means to identify "sensitive" individuals in the population before treatment commences.

**Sporadic Radiation Pneumonitis** Because one of the characteristic features of classic radiation pneumonitis is that

the damage is confined to the irradiated area, it has been suggested that radiation damage that appears outside the irradiated field, anecdotal evidence of which has been available for more than 40 years,[55–58] represents a hypersensitivity pneumonitis. First suggested by Holt in 1964,[59] this syndrome has been given little attention for two reasons: first, it is rare, and second, in most cases the contralateral lung also received some dose, although the actual quantity was unknown. Three factors suggest that this clinical syndrome may be different from the classic form of radiation-induced lung damage: (a) it affects 10% to 15% of patients; (b) symptoms often resolve without sequelae; and (c) it often develops earlier than classic pneumonitis that is within 2 to 6 weeks after the completion of therapy. In an extensive study of four women treated for breast cancer who experienced bilateral changes after radiation confined solely to one lung, Gibson et al.[60] found marked lymphocytosis in bronchioalveolar lavage samples from both the irradiated and nonirradiated lungs. Gallium scanning confirmed these findings, indicating increased gallium uptake in both the irradiated and nonirradiated lungs. In all four patients, symptomatic improvement was prompt after corticosteroid administration. With these observations, these authors concluded that finding equal abnormalities in both the irradiated and nonirradiated fields was not consistent with simple direct radiation-induced damage but rather implied an immunologically mediated mechanism such as hypersensitivity pneumonitis.

More recently, several investigators have challenged the idea that bilateral radiation pneumonitis after unilateral lung irradiation is relatively uncommon.[61,62] These authors contend that the extreme dyspnea experienced by patients with radiation-induced pneumonitis seems to be out of proportion to the volume of lung irradiated and cannot be explained on the basis of localized tissue destruction. Calveley et al.[63] investigated the early activation of inflammatory cytokines and macrophages in different regions of the lung after partial volume irradiation and found evidence of an inflammatory response triggered by the partial volume irradiation in the whole rat lung at very early times after irradiation; that response is maintained in a cyclic pattern until later, when the onset of functional symptoms would be expected. The extent of elevation of cytokines and activated macrophages was similar both in the field of treatment and out of it, although more micronuclei were present in field than out of field. Reactive oxygen species induced by this response were thought to play an important role in the induction of both in-field and out-of-field DNA damage.[63] In a prospective study of 17 women with breast cancer, bronchioalveolar lavage analysis and gallium scanning showed diffuse lymphocytosis, increased gallium scan uptake, and decreased alveolar volume and vital capacity in both the irradiated and nonirradiated lungs. Further analysis of the lymphocyte infiltrate in a patient with clinical radiation pneumonitis showed that these cells were almost exclusively recently activated CD4+ helper T cells, cells that have been implicated in hypersensitivity pneumonitis after other insults. In a further analysis of these patients plus an additional

five patients with clinical features of pneumonitis, these investigators found no statistically significant differences between bronchioalveolar findings on the irradiated and nonirradiated sides of the chest either before or after treatment or with or without clinical pneumonitis. Although bilateral lymphocytosis was found in 13 of the 17 patients (76.5%), only 2 had clinical features of radiation-induced pneumonitis. Symptoms resolved spontaneously in the other 11 patients. The other four patients did not demonstrate subclinical or clinical symptoms. Based on these findings, these authors suggested that bilateral involvement of both lungs after the irradiation of one lung represents an immune-mediated hypersensitivity pneumonitis that leads to clinical radiation pneumonitis in only 10% of the irradiated population. Because this syndrome seems to result from an entirely different pathogenetic mechanism than classic radiation pneumonitis, these authors suggested that this form of radiation-induced lung damage be distinguished from the classical form and be called "sporadic radiation pneumonitis." What distinguishes this type of lung damage from the classic type is that it occurs in an unpredictable manner and involves nonirradiated portions of the lung.

At this time, no animal model for sporadic radiation pneumonitis has been identified. However, in a study of CT changes after irradiation of only the right lung of rats, Geist and Trott[64] observed fluctuations in the radiologic density in the shielded left lung of the irradiated rats that were greater than those observed in control rats and parallel to those occurring in the irradiated right lung, similar to the sporadic pneumonitis in humans. However, a study of rabbits indicated that irradiation of one lung resulted in a decrease in the number of alveolar macrophages, but only in the irradiated lung.[65]

## Pathogenesis

**The Target Cell Concept** It has been hypothesized that radiation depletes some critical "target" cells in the lung and that this depletion after a latent period, initiates late sequelae of pneumonitis and fibrosis.[66] The expression of radiation damage also is generally thought to require cell division. Therefore, in tissues like the lung in which damage is not overtly expressed for months after treatment is completed, the long latency period was thought to reflect slowly proliferating target cells. For these reasons, a major research effort has been mounted to identify the target cells with the intention of protecting them from radiation damage, and thereby preventing or at least minimizing the severity of radiation-induced pneumonitis and fibrosis without compromising tumor cell kill and tumor control. The two most likely candidate target cells were thought to be type II cells[26,67–74] and vascular endothelial cells.[26,75–84] Type II cells divide more frequently than do other types of lung parenchymal cells. They are responsible for synthesizing, storing, and secreting surfactant, the surface-active material that prevents alveolar collapse. Vascular endothelial cells also divide more quickly than do other cell types in the lung. Furthermore, edema, a consistent finding in the interstitium and air spaces after lung irradiation, indicates vascular leakage, which in turn implies the radiation-induced killing and depletion of vascular endothelial cells.

**Type II Cells** The first evidence to support the hypothesis that type II cells were the target cells for radiation pneumonitis was published in 1982 by Shapiro et al.,[69] who showed that in mice, local irradiation of both lungs with a range of single doses of x-rays produced dose-dependent changes in phospholipids in lung lavage fluid and in lung tissue as early as 24 hours after irradiation. These changes persisted for the first 4 weeks after irradiation, indicating that changes in the function of type II cells occurred long before tissue damage was perceivable with light microscopy. Although the relationship of these early events to the later incidence of pneumonitis and fibrosis was unclear, these findings were the first indication that the latent period was not really latent at all. These investigators then sought to identify biochemical markers of surfactant that could be assessed in patients during radiation therapy, before the onset of clinical and pathologic pneumonitis, with the aim of identifying patients at high risk of developing severe radiation pneumonitis.[85] Their discovery that surfactant apoprotein in the serum was an accurate predictor and marker of radiation pneumonitis in rabbits led to further testing in the context of a clinical trial for patients with lung cancer. In that trial, surfactant apoprotein was measured in serum from blood samples collected before treatment, weekly during treatment, and at 1 week after treatment, and the findings were compared with the incidence and severity of radiation pneumonitis and fibrosis assayed by CT scans every 3 months after treatment and by chest radiography at 1 year after treatment.

**Endothelial Cells** The suggestion that vascular damage was the underlying mechanism of radiation pneumonitis and fibrosis was based primarily on the hypothesis that the lung cell most likely to divide soon after irradiation was the capillary endothelial cell. The parenchymal cells, particularly the type II cells, were thought to divide more slowly than endothelial cells. This hypothesis was substantiated by pathologic findings in humans and experimental models that pneumonitis after irradiation was characterized by edema in the air spaces and interstitium and an inflammatory cell infiltrate. Among the many investigators attempting to elucidate the role of the vasculature in radiation-induced lung damage, Ward et al.[86–89] undertook comprehensive studies to correlate changes in four parameters of endothelial function (angiotensin-converting enzyme activity, plasminogen activator activity, and prostacyclin and thromboxane production) with histopathologic and ultrastructural changes in rat lungs irradiated with the same doses and with changes measured by arterial perfusion, a vascular functional assay. Those studies showed dose-dependent changes in all endothelial function parameters and good agreement between these functional changes and pathologic changes in the lungs of the rats. These findings suggest that changes in vasculature do occur after lung irradiation, but they do not necessarily implicate the endothelial cell as the target cell.

**TABLE 44.2** **Target Cells and Growth Factors Associated with Radiation-Induced Pneumonitis and Fibrosis**

| Pathophysiologic Target Cells | Biochemical Marker | Growth Factors | Lesion or Event |
|---|---|---|---|
| Type II pneumocyte | Surfactant released into alveolus | TGF-$\alpha$ TGF-$\beta$ | Acute pneumonitis |
| Capillary endothelial cell | Surfactant protein enters into blood serum through altered permeability | FGF IL-1 PDGF | Acute pneumonitis and/or fibrosis |
| Macrophage | Surfactant persists for days or weeks because of decrease in macrophases essential to its removal | IL-1 PDGF TGF-$\alpha$ TGF-$\beta$ | May protect against pneumonitis, increase septal fibrosis |
| Septal fibrocyte | Procollagen III appears preceding fibrosis buildup; also, metaloprotease appears, as does elastase and collagenase | | |

Abbreviations: TGF, transforming growth factor; FGF, fibroblast growth factor; IL, interleukin; PDGF, platelet-derived growth factor.

# BIOLOGICAL BASIS OF RADIATION-INDUCED LUNG DAMAGE

Changes in both the pulmonary parenchyma and pulmonary vasculature contribute to radiation pneumonitis and fibrosis (Table 44.2), and these sequelae of lung irradiation arise from dynamic interactions among different cell types, the major players being type II pneumocytes and endothelial cells, as well as fibroblasts, macrophages, and lymphocytes (Fig. 44.3).[90,91] However, the concept that one or more target cells are solely responsible for radiation-induced pneumonitis and pulmonary fibrosis has been replaced by the paradigm that it is not only cells but also the messages that those cells send that determine the final outcome.

**Molecular and Tissue Responses during Radiation-Induced Lung Damage** Radiation is but one of many insults that prompt the release of trophic factors that subsequently act through various signaling pathways to

**FIGURE 44.3** Diagram of hypothesized interaction of different lung target cells and cytokines and growth factors in the development of alveolitis and fibrosis. *EGF,* epidermal growth factor; *IGF,* insulin-like growth factor; *IFN,* interferon; *IL,* interleukin; *PDGF,* platelet-derived growth factor; *PGE,* prostaglandin E$_2$; *TGF,* transforming growth factor; *TNF,* tumor necrosis factor; *UFDGF,* unidentified fibroblast-derived growth factor; *UMDGF,* unidentified macrophage-derived growth factor. produce the pathologic end results of radiation pneumonitis and fibrosis.[92–97] The messages are delivered via the diffusion of soluble mediators over short distances; such mediators may have been secreted by one population of cells and then act locally on either another population (paracrine stimulation) or the same population (autocrine stimulation), or they can interact with membrane-associated molecules that activate receptors on adjacent target cells (juxtacrine stimulation). These soluble mediators, known as cytokines or growth factors, are crucial in stimulating cells to overproduce the extracellular matrix components that characterize fibrosis.[23,92–94,98] After their initial contact with the cell surface, these molecules are postulated to activate intracellular signaling pathways, which in turn leads to activation of complex genetic programs characteristic of the fibrotic response.

Two concepts have been proposed to explain how cells read signals from cytokines.[93,99,100] In the first concept, cytokine signaling pathways are not insular or isolated paths or devices but rather are segments in a dense network that monitors itself through various crosstalk and feedback links and adjusts the activity of each constituent pathway. The nature of those adjustments, in turn, determines the nature and timing of the signals conveyed. In the second concept, the pathway provides the cell with information about the arrival of a certain cue but does not provide precise instructions. The cell, more than the pathway, determines the outcome of the signal.[100] In either event, cytokines are known to mediate the development of pneumonitis and fibrosis, both of which represent tissue responses to the damage induced by ionizing radiation. Several such cytokines, including transforming growth factor $\beta$ (TGF-$\beta$), tumor necrosis factors (TNF-$\alpha$ and TNF-$\beta$), the interleukins, KL-6, and the intracellular adhesion molecule (ICAM)-1, are discussed further in the following paragraphs.

**Transforming Growth Factor $\beta$**    The TGF-$\beta$ cytokine family regulates the proliferation and differentiation of cells, embryonic development, wound healing, tumor progression, and angiogenesis[101,102] and can trigger a bewildering diversity of responses depending on the genetic makeup and environment of the target cells.[100] TGF-$\beta$ regulates cellular process by binding to three high-affinity cell-surface receptors known as types I, II, and III (TGF-$\beta$: TGF-$\beta$1, TGF-$\beta$2, and TGF-$\beta$3). Each isoform is encoded by a distinct gene and is expressed in both a tissue-specific and a developmentally regulated fashion. The type I and II receptors contain serine-threonine protein kinases in their intracellular domains that initiate intracellular signaling by phosphorylating several transcription factors know as Smads (derived from the Sma and MAD gene homologues in *Caenorhabditis elegans* and *Drosophila melanogaster*). Of the 10 Smads, Smads 2 and 3 are phosphorylated by activated type I TGF-$\beta$ receptors, whereas Smads 6 and 7 block the phosphorylation of Smads 2 and 3.[102] Deregulation of TGF-$\beta$ signaling pathways has been implicated in the development of several major diseases, including cancer; atherosclerosis; fibrotic disease of the kidney, liver, and lung; and autoimmune diseases.[102] Mutations in the genes for TGF-$\beta$, its receptor, or intracellular signaling molecules associated with TGF-$\beta$

are also important in the pathogenesis of disease, particularly cancer and hereditary hemorrhagic telangiectasia.[101]

TGF-$\beta$ is an important mediator of tissue damage in various abnormal conditions associated with excess collagen production. TGF-$\beta$1 in particular is often associated with lung fibrosis in response to several types of toxic insult, including radiation.[23,98,103] The TGF-$\beta$ signal is transduced to the nucleus through the activation of its receptors, which in turn activate one or more Smad transcription factors, which then act on one or more of many potential target genes (Fig. 44.4).[102,104]

**FIGURE 44.4**    Mechanism of signal transduction mediated by transforming growth factor $\beta$ (TGF-$\beta$). In the extracellular space, TGF-$\beta$ binds either to the type III TGF-$\beta$ receptor (RIII), which presents it to the type II receptor (RII), or directly to RII on the cell membrane. The binding of TGF-$\beta$ to RII then leads to binding of the type I receptor (RI) to the complex and the phosphorylation of RI (*small spheres*). This phosphorylation activates the RI protein kinase, which then phosphorylates the transcription factor Smad2 or Smad3. Phosphorylated Smad2 or Smad3 binds to Smad4, the common Smad, and the resulting complex moves from the cytoplasm into the nucleus. In the nucleus, the Smad complex interacts in a cell-specific manner with various other transcription factors to regulate the transcription of TGF-$\beta$–responsive genes and mediate the effects of TGF-$\beta$ at the cellular level. Inhibitory Smad6 and Smad7 lack the region normally phosphorylated by RI and thus interfere with the phosphorylation of Smad2 or Smad3 by RI.[102] (From Blobe GC, Schiemann WP, Lodish HF. Role of transforming growth factor beta in human disease. *N Engl J Med* 2000 May 4; 342[18]:1350–1358.)

In vivo, TGF-$\beta$ stimulates the recruitment of lymphocytes and fibroblasts to sites of damage, promotes fibroblast proliferation, and stimulates the production of collagen and fibronectin—the effect being a net increase in extracellular matrix material, which eventually replaces the normal architecture of the tissue. TGF-$\beta$ also increases the production of type I plasminogen activator inhibitor while simultaneously decreasing the production of plasminogen activators, resulting in not only an increase in the production of connective tissue but also a decrease in its breakdown, leading ultimately to maturation of this excess connective tissue and the formation of scars.[51,102]

Rubin et al.[91] were the first to report that alveolar macrophages obtained from bronchial lavage specimens from irradiated rabbits demonstrated increased production and release of TGF-$\beta$ relative to macrophages from normal lungs. Those investigators suggested that the fibroblast proliferation and extracellular matrix production seen after irradiation resulted from the release of cytokines such as TGF-$\beta$ from parenchymal cells. Johnston et al.[105] reported an increase in the expression of TGF-$\beta$1 messenger RNA (mRNA) in radiation-fibrosis–prone but not in radiation-fibrosis–resistant strains of mice. That increase in TGF-$\beta$ mRNA correlated with an increase in extracellular matrix protein expression in the irradiated lung tissue. Finkelstein et al.[92] studied whether changes in early expression of collagen precursors or cytokines known to be involved in the fibrotic process were expressed during the latent period, before damage was manifested histologically. These investigators used two single whole-thorax radiation doses to C57B1/6J mice, a strain known to be sensitive to the fibrogenic effects of lung radiation. The lower dose (5 Gy) is well below the threshold known to induce clinical symptoms and pathologic changes of radiation pneumonitis and fibrosis, and the higher dose (12.5 Gy) is closer to the reported LD$_{50}$ for radiation-induced lung damage in this strain, although this dose itself does not cause death from lung damage. The results showed that mRNAs for all three isoforms of TGF-$\beta$ (i.e., TGF-$\beta$1, -$\beta$2, and -$\beta$3) were increased in the lungs of C57B1/6J mice at 14 days, but a consistent dose–response relationship was not found. Thus, radiation doses that cause neither clinical signs nor pathologic changes indicative of radiation lung damage can lead to changes in the expression of this fibrogenic cytokine before the onset of overt lung damage and may ultimately lead to the development of chronic fibrosis.

The importance of TGF-$\beta$1 in the development of radiation-induced lung damage has been underscored in human studies as well as in animal experiments.[106–109] The feasibility of using TGF-$\beta$1 levels to identify patients who can safely tolerate radiation dose escalation was tested in 38 patients with non–small cell lung cancer (NSCLC).[106,110] At the end of the initial radiation treatment, patients with TGF-$\beta$1 levels lower than pretreatment levels and patients with TGF-$\beta$1 levels of less than 7.5 ng/mL were selected for subsequent radiation dose escalation (86.4 vs. 73.6 Gy) to the primary tumor and enlarged lymph nodes. The predominant severe (grade $\geq$ 3) late toxicity in that study was not pulmonary but rather was esophageal, suggesting that monitoring

plasma TGF-$\beta$1 levels might be useful for identifying patients resistant to both radiation-induced lung damage and esophageal toxicity.[106,107,110] In a later study, TGF-$\beta$1 levels were found to be elevated ($>$20 ng/mL) before treatment in 51% of 68 patients with NSCLC.[111] Plasma TGF-$\beta$1 levels after radiation therapy were associated with both pretreatment levels ($p = 0.001$) and with mean radiation dose to lung, and the mean ratio of plasma levels at weeks 4 to 6 of treatment to pretreatment levels predicted radiation pneumonitis, according to Southwest Oncology Group criteria ($p = 0.01$) but not that defined by other scoring systems. However, this study was criticized for its high TGF-$\beta$1 baseline values, which were thought to be artifacts from the methods of blood collection and processing.[111]

**Inflammatory Cytokines**  Just as depletion of one type of target cell is unlikely to trigger the complex pathologic process of radiation pneumonitis and fibrosis, it is equally unlikely that the overexpression of a single cytokine initiates and promulgates the fibrogenic process in the lung. Much more likely is that the damage, repair, and restructuring of the lung after irradiation (as well as after other toxic insults) are the results of a cytokine network orchestrated by a few key cytokines, such as TNF-$\alpha$/$\beta$ and TGF-$\beta$. Several classes of cytokines can contribute to the risk of radiation pneumonitis, among which the interleukins, TNF-$\alpha$, and TGF-$\beta$1 have been recognized to play major roles. At the core of the inflammatory response after radiation exposure is the production of such proinflammatory cytokines as TNF-$\alpha$ and interleukin-1 and interleukin-6 (IL-1 and IL-6) and macrophages, lymphocytes, and other lung cell types.[112–114] Thus, it may be the balance of a few positive profibrogenic cytokines and negative antifibrogenic cytokines generated from the interaction of several cytokines constituting these networks that may finally determine the outcome of lung injury and inflammation. Unfortunately, dissecting the specific role of any of these cytokines in lung damage and repair is not easy; however, one approach to determining the role of various cytokines in lung fibrosis is to take advantage of known differences in susceptibility to radiation-induced fibrosis among inbred mouse strains.

Johnston et al.[115] used the fibrosis-prone C57B1/6J mouse strain and the fibrosis-resistant C3H/HeJ mouse strain to show that the elevation of mRNA levels of several chemokines implicated in the recruitment of inflammatory cells to sites of pulmonary damage was not different between the two strains when assessed at 8 weeks after irradiation. However, by 26 weeks after irradiation, messages encoding transcripts produced predominantly by macrophages and lymphocytes were elevated only in the fibrosis-prone mice. These findings indicate that lymphocytic recruitment and activation are key components of radiation-induced fibrosis, but their role in the pathogenesis of this process remains unclear.

Clinical studies have shown that elevation of IL-1$\alpha$, IL-6, and IL-10 are associated with the risk of radiation-induced lung damage.[116–118] In fact, IL-1$\alpha$ and IL-6 have been used as markers for the diagnosis or prediction of radiation

pneumonitis.[118] TNF-$\alpha$[119] vascular endothelial growth factor, and fibroblast growth factor (FGF) have also been shown to be associated with radiation lung injury.[120–122] Arpin et al.[116] found that IL-6 levels were significantly higher ($p = 0.047$) during 3D conformal radiation therapy in patients who later were diagnosed with radiation pneumonitis and that covariations of IL-6 and IL-10 levels during the first 2 weeks of that therapy were independently predictive of radiation pneumonitis ($p = 0.011$). Chen et al.[118] also confirmed the importance of IL-6 measurements for the prediction of radiation pneumonitis. These results suggest that levels of one or more cytokines could be useful as biomarkers to monitor tissue response during the early course of radiation therapy with the goal of identifying patients who may benefit from adaptive redesign of that therapy.

Patient smoking status has also been linked with the risk of radiation pneumonitis. An in vitro study showed that cigarette smoke extract augmented the release of IL-8 from bronchial epithelial cells in a concentration- and time-dependent manner.[123] That study also showed that IL-8 in bronchoalveolar lavage samples from smokers was higher than that in samples from nonsmokers.[123] Other work has shown that exposure to tobacco smoke suppressed the expression of pro-inflammatory cytokine mediators.[124] In 2005, Hart et al.[125] reported that pretreatment IL-8 levels were four times higher in patients who did not develop symptomatic radiation-induced lung damage than in patients who did, suggesting that the IL-8 level might be useful for predicting who may develop radiation pneumonitis before the treatment is begun.

**KL-6**   The antigen KL-6 is a mucinlike high–molecular weight glycoprotein that is expressed on type II pneumocytes and bronchiolar epithelial cells and has been used as a serum marker of interstitial pneumonitis. The group that discovered KL-6 noted that 60% of patients with various kinds of interstitial pneumonitis had abnormally high KL-6 levels and that serum KL-6 levels correlated with the degree of clinical disease activity, as measured by gallium-67 citrate scintigraphy and the clinical course.[126] KL-6 also seems to be a useful marker for detecting severe pneumonitis and estimating its prognosis.[126–128] In another study of patients who developed severe radiation pneumonitis, serum KL-6 levels tended to increase before or after the clinical diagnosis of extensive radiation pneumonitis outside the radiation fields, but no change was noted before or after localized radiation pneumonitis inside the radiation fields. Moreover, patients whose serum KL-6 levels rose more than 1.5 times higher than their pretreatment serum KL-6 level were at greater risk of developing severe radiation pneumonitis that was unresponsive to steroid hormones and resulted in death.[129] In a study of women undergoing adjuvant radiation therapy for breast cancer, posttreatment serum levels were significantly different between patients with radiation pneumonitis and those without radiation pneumonitis.[130] Other investigators studying patients with primary and metastatic lung tumors who had been given single-fraction stereotactic radiotherapy found that the ratio of serum KL-6 levels at 2 months after treatment and

levels at baseline correlated with the occurrence of radiation pneumonitis.[131] This 1- to 2-month gap between the time at which predictive measurements are the most accurate and the diagnosis of radiation pneumonitis, however, limits the predictive value of KL-6 for this purpose.

**Intercellular Adhesion Molecule–1**   ICAM-1 is an intercellular adhesion molecule of the immunoglobulin supergene family involved in adherence of leukocytes to the endothelium and in leukocytic accumulation in pulmonary injury. ICAM-1 is upregulated in association with inflammation in response to numerous types of inducing factors. In normal lung tissue, the expression of ICAM-1 on alveolar type I epithelial cells is stronger than on alveolar macrophages and on endothelial cells.[132] Selective ICAM-1 expression was detected on the surface of type I alveolar epithelial cells and, to a lesser extent, on the pulmonary capillary endothelium and on alveolar macrophages. Bleomycin-induced lung fibrosis demonstrated altered ICAM-1 distribution at the alveolar epithelial surface, and soluble ICAM-1 was detected by Western blot analysis.[132] The expression of ICAM-1 on pulmonary endothelial cells after stimulus and subsequent binding of neutrophils is a first step leading to lung injury. A similar process may dictate the binding of tumor cells to the pulmonary endothelium during metastasis. TNF-$\alpha$ upregulates ICAM-1 expression in a dose- and treatment interval–dependent fashion.[80]

Expression of ICAM-1 can also be upregulated by gamma irradiation through the action of catalase. Furthermore, catalase, c-Jun N-terminal kinases (JNKs), and activator protein 1 (AP-1) activation induce ICAM-1 upregulation through a sequential process.[133] ICAM-1 and lymphocyte function–associated antigen–1 (LFA-1) expression on alveolar macrophages was significantly increased starting 1 week after irradiation, whereas their expression on lung tissue was not elevated up to 8 weeks after irradiation, suggesting that adhesion molecules play a role in the development of radiation-induced lung injury.[134] Using immunohistochemical assay for upregulation of adhesion molecules associated with recruitment, transendothelial migration, and proliferation of bronchoalveolar macrophages, researchers found significant upregulation of vascular cell adhesion molecule–1 (VCAM-1) and ICAM-1 at 100 days after 20 Gy to total lung irradiation with further increases up to the time of death. Increases were first detected in endothelin-positive endothelial cells. These data suggest an association between late irradiation-induced pulmonary fibrosis and the upregulation of adhesion molecules and disclose potential targets for intervention in the pulmonary vascular endothelium.[135]

Clinically, expression of human leukocyte–associated antigen (HLADR) and ICAM-1 on T cells in bronchoalveolar lavage fluid increased in patients who developed radiation pneumonitis after radiation for lung cancer. A significant association was seen between the incidence of ICAM-1 expression on T cells and the number of days from the initiation of radiotherapy to the onset of radiation pneumonitis.[136] In another study, 30 patients were irradiated with a total dose of approximately 60 Gy. Blood samples were taken before, midway, and after radiotherapy.

Bronchoalveolar lavage was also performed before and after radiation therapy in seven cases. A total of 12 out of 30 (40%) cases developed radiation pneumonitis. Serum levels of soluble ICAM-1 after radiation therapy were significantly elevated in patients who developed pneumonitis compared with those who did not. In some of the cases, sICAM-1 levels began to increase at an early phase of irradiation. These findings suggest that ICAM-1 may have an important role in the development of radiation pneumonitis and that sICAM-1 may be a useful marker for the early detection of radiation pneumonitis.[137]

Thus, despite abundant evidence that expression of a multitude of cytokines is elevated in radiation-induced pneumonitis and lung fibrosis, their actual in vivo role and the mechanism of their upregulation remain to be determined. Regardless of our lack of understanding of how these factors mediate damage and repair in the lung, it is clear that the latent phase preceding the overt expression of radiation damage in the lung is not a quiescent time. Molecular changes are occurring that may later ultimately result in the clinical and histopathologic picture of pneumonitis and fibrosis. The events that lead to the overt expression of radiation-induced lung damage involve several complex cellular and molecular processes, which explain why both the inflammatory responses and the triggering mechanism that induces the fibrotic response in the lung remain poorly understood.

## Genetic Regulation

**Animal Studies**   Animal studies, particularly those showing strain-dependent outcomes, indicate that genetics are implicated in vulnerability to pneumonitis and fibrosis. Twenty years ago, Steel et al.[138] reported an anomalous finding after irradiation of the whole thorax of C57B1 mice that the survival time of this inbred strain of mice was significantly longer than the standard 80 to 180 days reported in other strains with radiation pneumonitis. Subsequent studies by Down et al.[139,140] in several inbred mouse strains showed that the incidence of radiation pneumonitis and fibrosis was strain dependent. Although strain-dependent differences could result from several factors, genetics offers a plausible explanation. In an in-depth survey of the incidence of radiation pneumonitis and fibrosis in nine inbred mouse strains, Sharplin and Franko[43] showed that the strains could be categorized as fibrosing, nonfibrosing, or intermediate, based on quantitative histologic findings. Further studies by these authors showed that crossbreeding strains with different proneness to fibrosis produced hybrids with the same sensitivity of the parent least prone to fibrosis: the hybrid of a fibrosing and a nonfibrosing strain was uniformly nonfibrosing, whereas a cross of an intermediate with a fibrosing strain produced an intermediate hybrid,[141] suggesting that sensitivity to radiation-induced fibrosis is an autosomal recessive trait. Supporting this hypothesis is a report from Haston et al.[51] that one locus on chromosome 17 segregates with the fibrosing phenotype and that this locus, which is within the region containing the major histocompatibility locus (MHC), was linked to both bleomycin-induced lung

fibrosis[142] and susceptibility to ozone-induced lung damage in mice.[143] These researchers also showed that a quantitative trait locus on chromosomes 17 influenced susceptibility to radiation-induced pulmonary fibrosis. Chromosome 6 (logarithm of the odds [LOD] = 4.6), which has an additional region containing a quantitative trait locus, showed linkage in female mice only. The evidence for linkage to chromosome 18 weakened when it was analyzed jointly with other markers. These loci—on chromosomes 1, 6, 17, and 18—were estimated to account for 70% of the genetic contribution to this trait, with chromosome 17 accounting for 28% and chromosome 1 for 24%. Furthermore, the quantitative trait locus on chromosome 17 for radiation-induced lung fibrosis is within the same region as a quantitative trait locus identified for lung damage after other insults (e.g., from bleomycin, ozone, and particle exposure) as well as from asthma, suggesting that this region of chromosome 17 may harbor a "universal" lung injury gene.[144] These findings suggest that although other loci have been shown to be insult dependent, at least one genetic factor regulating pulmonary fibrosis may be universal and independent of the etiology of that fibrosis.

Also supporting a genetic sensitivity theory is that other pathologic processes in the lung are known to be under genetic regulation. Pulmonary inflammation is well-known to be controlled by genes in the H-2 complex.[145–147] Mice with an H-2$^k$ locus are high responders, and those with an H-2$^b$ locus are low responders.[145,147,148] In the studies of Sharplin and Franko[43] and Down et al.,[140] pneumonitis was found to be strain dependent and related to the H-2 locus; that is, an inflammatory cell infiltrate was not a feature of pneumonitis in the highly fibrogenic strain, and, conversely, an inflammatory cell infiltrate was the most prominent characteristic of the pneumonitis phase in the weakly fibrogenic strain. Although these observations refute the hypothesis that immune-inflammatory processes usually precede fibrosis, they clearly indicate that pneumonitis after irradiation of mouse lung is genetically regulated. However, the strain sensitivity to radiation pneumonitis is exactly opposite for that of radiation-induced fibrosis.

Two forms of lung fibrosis have been described.[31] One form of fibrosis is a collagen deposition in the interstitium and air spaces, resulting in contracture and collapse of the alveoli, an obliteration of normal lung architecture, and an attendant loss of pulmonary function resulting in the death of the mouse. Another form of fibrosis is characterized by collagen deposited only in the interstitium, a process that maintains alveolar structure, and was largely ignored because it was suggested that this lesion alone would not produce sufficient functional impairment to cause death. The genetic regulation that controls these two forms of fibrotic processes may not be identical to that controlling interstitial fibrosis, although there may be overlap between the two. Furthermore, interstitial fibrosis in the lung[18] and colon[53] can result in death in animal studies.[139]

Evidence suggests that the fibrosis evident in mouse lung after exposure to radiation can arise through two independent mechanisms: one is controlled by two autosomal recessive

determinants that act additively, and the other is regulated independently by two additional genes, one of which is X-linked.[45] Similar strain variations in pulmonary fibrosis after other kinds of insults have been reported. Particularly interesting are the results obtained after treatment with bleomycin, another DNA-damaging agent often used to induce lung fibrosis in model systems. The most striking observation after bleomycin treatment is that[149–152] the findings were remarkably similar to those observed after radiation. These findings, like those reported by Haston et al.,[144] suggest that genetic factors related to susceptibility to lung fibrosis may operate independently of the etiologic agent.

**Clinical Evidence**    Intrinsic sensitivity to radiation is known to differ among individuals. Estimates indicate that, given the same standardized radiation dose, technical and clinical factors account for about one third of the interpatient variation in normal-tissue reactions, and genetic differences between patients account for the greater proportion of differences in sensitivity.[153] Certainly the severity of treatment-related complications, including the severity of radiation-induced pneumonitis and fibrosis after definitive radiation therapy for lung cancer, have been evident clinically for some time. Geara et al.[154] demonstrated considerable patient-to-patient heterogeneity in a group of 56 patients with limited small cell lung cancer treated with chemoradiation therapy, suggesting that the risk of lung fibrosis is strongly affected by inherent factors that vary among individuals.

Evidence is increasing that indicates that genetic variations in a few selected cellular pathways, such as those involved in DNA repair, cell cycle, and inflammation, may affect radiation sensitivity, treatment response, and toxicity.[155–162] For example, patients with the genetic syndromes of ataxia telangiectasia, Nijmegen breakage syndrome (NBS1), or Bloom syndrome (BLM) demonstrate hypersensitivity to radiation,[163–165] and genes that are defective in these syndromes (ataxia telangiectasia mutated [ATM], NBS1, or BLM, respectively) are known to play critical roles in DNA repair, particularly double-strand break repair. In vitro studies in cell lines that are hypersensitive to radiation have demonstrated that the repair genes for double-strand breaks, x-ray repair cross-complementing 1 gene (XRCC1) to x-ray repair cross-complementing 7 genes (XRCC7), are responsible for hypersensitivity. Patients with immune deficiencies arising from defects in double-strand break repair genes, such as defects in the DNA-dependent protein kinase catalytic subunit (DNA-PKcs) (XRCC7), Ku70 (XRCC6), and Ku86 (XRCC5) genes, exhibit high radiation sensitivity.[166–168]

Family studies also suggest a genetic predisposition to radiosensitivity. Roberts et al.[169] studied the heritability of radiation sensitivity in peripheral blood lymphocytes in families of patients with breast cancer. They found that 62% of the first-degree relatives of radiation-sensitive patients were also sensitive compared with 7% of the first-degree relatives of patients with normal sensitivity. Segregation analysis of 95 family members showed clear evidence of high heritability of radiation sensitivity.

# PHYSICAL BASIS OF RADIATION-INDUCED LUNG DAMAGE

## Fractionation, Volume, and Dose

**Fractionation**    The sparing effects of fractionating dose in radiotherapy has been known since the experiments performed on rams' testicles in the 1920s and 1930s. Assuming that the testes were a model of a rapidly growing tumor and the skin of the scrotum was representative of normal tissues, researchers found that a ram could not be sterilized by a single dose of radiation without causing extensive damage to the skin; however, spreading the dose over several weeks resulted in sterilization without producing unacceptable skin reactions. The basis of fractionation lies in the understanding that dose fractionation spares normal-tissue reactions by allowing repair of sublethal damage and repopulation of target cells during treatment while increasing tumor cell kill by allowing reoxygenation and reassortment of cells into more sensitive parts of the cell cycle.[170–174] For years, the standard fractionation regimen consisted of radiation delivered in doses of 1.8 to 2.0 Gy per fraction over treatment times of 4 to 6 weeks. Modification of this conventional treatment schedule by increasing the dose per fraction in the treatment of lung cancer resulted in unacceptable sequelae in tissues such as the spinal cord. However, it was not until the early 1980s that radiation oncologists began to understand differences in normal tissues' fractionation sensitivity.

Lung is a *late-responding normal tissue*; that is, damage is not evident until weeks to months after completion of a standard course of radiotherapy. In contrast, tissues such as intestinal mucosa, which are acutely responding normal tissue, manifest damage during and shortly after completion of a course of treatment. An analysis of experimental data for a variety of both acutely and late-responding normal tissues by Thames et al.[175] demonstrated a clear and consistent difference between fractionation effects in these two categories of tissues. By plotting the total dose for an isoeffect specific to various tissues versus the dose per fraction, it was found that the total dose for a given effect in any late-responding normal tissue increased more rapidly as the dose per fraction was decreased than did the total dose for an effect in any acutely responding normal tissue. This pattern was observed consistently in all acutely and late-responding tissues analyzed and suggests that late-responding tissues such as the lung are more sensitive than acutely responding tissues to changes in dose per fraction. These data imply that decreasing the dose per fraction should spare late-responding tissues such as the lung more than acutely responding tissues as well as the tumor, if tumors respond like acutely responding normal tissues. It has been suggested that the difference in fractionation response for acutely and late-responding normal tissues is because of differences in the repair capacity or shoulder shape of the underlying dose–response curves for these two classes of tissues(the dose–response curve for the late-responding tissues is curvier [has a narrower shoulder] than that for acutely responding tissues).[175] One way of defining these differences is by the $\alpha/\beta$ ratio, which derives

from the linear quadratic model of cell killing.[175–179] In brief, this model assumes that there are two components of cell killing by radiation, one that is proportional to dose and the second that is proportional to dose.[2] The $\alpha/\beta$ ratio, then, is the dose at which the linear and quadratic contributions to cell killing are equal. For late-responding tissues, such as the lung, the dose-response curve bends at lower doses than for acutely responding tissues, and therefore, the dose at which the $\alpha$ and $\beta$ contribution to cell killing is equal is lower in late-responding than acutely responding tissues. In general, the $\alpha/\beta$ ratio is below 5 Gy for late-responding normal tissues and greater than 5 Gy for acutely responding normal tissues. For the lung, the $\alpha/\beta$ is about 3 Gy.[173,180–183] In clinical radiotherapy, then, significant sparing of normal lung damage can be gained by decreasing the dose per fraction.

A second factor in the sparing of normal tissues is repopulation of surviving cells during treatment. The lung's late response, occurring weeks to months after completion of treatment, means that repopulation does not occur during a conventional 4- to 6-week treatment schedule. Although retreatment studies in the lung suggest that this may not be totally correct and that repopulation may occur within the first 4 weeks after irradiation,[184] it remains a general axiom that conventional fractionation schedules extending for 6 weeks do not allow triggering of proliferation and subsequent repopulation in the lung. Therefore, prolonging overall clinical radiation treatment time will have little, if any, sparing effect on the lung.

Supporting this hypothesis are clinical data that demonstrate that lung fibrosis incidence increases with increasing total dose greater than a threshold of 30 to 35 Gy, with concurrent use of cisplatin and etoposide chemotherapy, with accelerated fractionation (Fig. 44.5).[185] Other support for this hypothesis comes from a meta analysis of 24 series that included 29 treatment groups and 1911 patients. Investigators evaluated such factors as the radiation dose per fraction, total radiation dose, fractionation scheme (split or continuous), type of chemotherapy and intended dose intensity, overall treatment time, histology (small cell lung cancer or NSCLC), and treatment schedule (concurrent or induction, sequential, or alternating chemotherapy). The median total dose of radiation used in the trials analyzed was 50 Gy (range, 25 to 63 Gy). The median daily fraction dose used was 2.0 Gy (range, 1.5 to 4.0 Gy). Nineteen series included 22 treatment groups and 1745 patients treated with single daily fractions. Among these patients, 136 received a daily fraction greater than 2.67 Gy. Five series used twice-daily radiation therapy and included 166 patients (fraction dose, 1.5 to 1.7 Gy). The incidence of radiation pneumonitis was 7.8%. In a multivariate analysis, only radiation dose per fraction, number of daily fractions, and total dose were significantly associated with the risk of radiation pneumonitis ($p < .0001$, $p < .018$, and $p < .003$, respectively). The use of a fraction dose greater than 2.67 Gy was the most significant factor associated with an increased risk of radiation pneumonitis. High total dose also seemed to be associated with an increased risk, but twice-daily irradiation seems to reduce

**FIGURE 44.5** Fibrosis. Graphs show the average probability of physician-identified radiographic grade 1, 2, or 3 fibrosis or any fibrosis occurring as a function of dose for each fractionation and chemotherapy combination. For doses of 30 to 55 Gy and cisplatin and etoposide (PE) chemotherapy, the risk of fibrosis (any grade) with the accelerated fractionation schedule (bid, twice daily) was $2.01 \pm 0.34$ times higher than that with conventional (*conv,* i.e., once-daily) fractionation ($p < .005$). The probability of fibrosis with the PIE chemotherapy (cisplatin-etoposide [PE] plus ifosfamide) was not statistically significantly different from either of the other schedules (error bars, $\pm 1$ standard error).[185] (From Rosen II, Fischer TA, Antolak JA, et al. Correlation between lung fibrosis and radiation therapy dose after concurrent radiation therapy and chemotherapy for limited small cell lung cancer. *Radiology* 2001 Dec;221[3]:614–622, with permission.)

the risk expected had the same total daily dose been given as a single fraction (Fig. 44.6).[186] In a comparison of incidence of radiation pneumonitis for patients who received single daily fractions of $\leq 2.67$ Gy, split doses in twice-daily treatment, or once-daily irradiation using fractions $> 2.67$ Gy, patients who received daily doses exceeding 2.67 Gy had the highest incidence of radiation pneumonitis.[186] Hence, the size of the dose per fraction of radiation delivered to the lung is the dominant factor in determining lung damage, and overall treatment time has relatively little influence. The more important consideration is that prolonging treatment time may decrease tumor response because of the accelerated repopulation of surviving and proliferating tumor cells during treatment.[187–189]

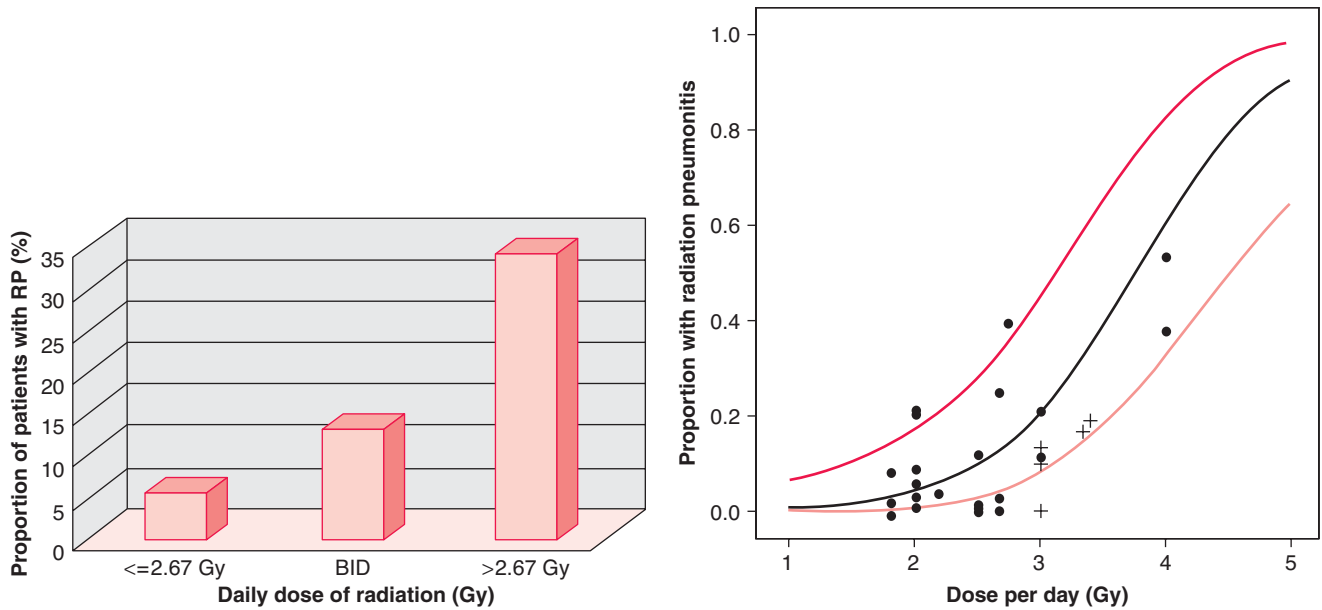
These radiobiological findings have been translated into the clinical treatment of lung cancer using fractionation protocols that vary from the conventional protocols by reducing the size of the dose and giving more than one fraction per day while keeping the overall treatment time the same as in traditional schedules. To compensate for the loss of cell killing in the tumor by the reduction in dose per fraction, radiation oncologists give higher total doses. Thus, the goal is holding the lung damage constant by reducing dose per fraction while simultaneously increasing tumor control by giving a higher total dose. The fractionation schedule most commonly used


**FIGURE 44.6**   Relationship of dose per day and probability of radiation pneumonitis. Incidence of radiation pneumonitis for patients who received single daily fractions of ≤2.67 Gy, twice-daily treatment, or once-daily irradiation using fractions >2.67 Gy are shown in the bar graph (**left**). Patients who received a daily dose >2.67 Gy had the highest incidence of radiation pneumonitis. Curve (**right**) represents predicted proportion of patients who experienced radiation pneumonitis based on 27 treatment groups (+, studies with twice-daily fractions) and includes 95% confidence intervals. Curve was generated using the mean proportion as a function of daily dose, assuming a total dose of 48 Gy. Note a rapidly increasing incidence of radiation pneumonitis is predicted for daily fractions >2.5 Gy. Twice-daily irradiation was associated with a lower incidence than expected.[186] *BID*, twice daily; *RP*, radiation pneumonitis. (Adapted from Roach M III, Gandara DR, Yuo HS, et al. Radiation pneumonitis following combined modality therapy for lung cancer: analysis of prognostic factors. *J Clin Oncol* 1995 Oct;13(10):2606–2612, with permission.)

in this type of treatment, termed *hyperfractionation*, gives two doses of 1.2 Gy per day. In initial clinical trials, the total doses given ranged from 60 Gy, the same total dose given in conventional schedules using one fraction of 2 Gy per fraction, to 69.6 Gy.[190–192] The risk of both acute and late effects was found to be acceptable, and there was a dose response for survival, with survival significantly improved in patients receiving the highest total dose. In a second trial, total doses were escalated to a maximum of 79.2 Gy, but this increase in total dose did not result in a significant survival advantage, although lung toxicity remained acceptable.

**Irradiated Lung Volume**   It is well accepted in radiation oncology that in addition to using and modifying fractionation, reducing the volume of normal lung irradiated is an effective technique for lowering morbidity. The use of 3D treatment planning and conformal radiation therapy has allowed the use of more than the traditional two to four opposing treatment fields, making it possible to tailor the treatment plan to the individual patient and tumor; however, the dose distributions in these nontraditional plans may be very different from those used in standard two- or three-field treatments. For example, some plans may deliver a small dose to a larger volume of lung than in opposed fields, making it difficult for the radiotherapist to extrapolate from experience a prediction of the probability

of incurring morbidity. In addition, the lung is a paired organ and has a large functional reserve; thus, it is expected that it would exhibit a threshold volume, that is, a subvolume below, which irradiation causes no detectable injury, even at very high doses.[3,174,193,194] However, such useful information as the threshold volume or measures indicating the relationship of the volume of lung irradiated to dose and/or morbidity have not been defined because most experimental studies have been performed using whole-lung irradiation.

**Volume Effect and Spatial Heterogeneity**   In the late 1990s, with the increasing use of conformal therapy and increasing questions from radiotherapists regarding the volume response of the lung, experimental mouse studies have been initiated in several laboratories to address these questions. Most of the data for partial lung irradiation have been obtained from hemithoracic irradiation studies in mice and rats. In these studies, single-dose irradiation of only one lung led to dose-dependent increases inbreathing rate but not in lethality (Travis, unpublished observations). The initial increase in breathing rate was followed by a decrease that was suggested to be coincident with compensatory hypertrophy of the nonirradiated lung and/or the formation of new alveoli that increased the surface area of the lung. Both breathing rate and lethality are indications of total lung function, both the irradiated half
**FIGURE 44.7** Dose–response curves of lethality after irradiation of two partial volumes of the lungs of C3H mice: 70% to 75% (**top**) or 50% (**bottom**), located in the apex or base of the lung. The dose–response curve for whole lung is shown for comparison. These data show a clear volume effect. The lethal dose that kills 50% of the population (LD$_{50}$) for irradiation of 50% in either the base or apex is higher than the irradiation of the larger volume of 75% in these same two sites. In addition, these data show that the LD$_{50}$ is dependent on the site of the lung irradiated. The isoeffect dose is less for both volumes irradiated in the base than in the apex, suggesting that the base is more sensitive than the apex. These data indicate that the volume effect is dependent not only on the volume of lung irradiated but also on the site of the lung irradiated. (From Liao ZX, Travis EL, Tucker SL. Damage and morbidity from pneumonitis after irradiation of partial volumes of mouse lung. *Int J Radiat Oncol Biol Phys* 1995;32:1359–1370, with permission.)

and the nonirradiated half, and assays of both show clearly that the lung has a large functional reserve. Other studies using blood flow changes in mice and rats undergoing hemithoracic irradiation showed that vascular changes in the irradiated lung were similar to those after whole-lung irradiation.[79] Thus, this assay of regional function showed no difference between whole- versus partial-lung irradiation.

A series of mouse experiments has been undertaken to define the relationship of radiation dose and volume to lung damage, assessed histopathologically, and morbidity, assessed by two tests of total lung function—breathing rate and lethality.[195,196] In these studies, a range of lung volumes,

from 20% to 100%, were irradiated. Matched volumes were also irradiated in the base or in the apex of the lung to test the hypothesis that the functional subunits were randomly and homogeneously distributed. Figure 44.7 shows the proportion of dead mice after irradiation of two of the matched volumes in the apex and base of the lung, 50% and 75%. Figure 44.8 shows breathing rate and lethality as a function of the percentage volume of lung irradiated in the apex or the

**FIGURE 44.8** Breathing rate (ED$_{50}$) (**top**) and lethality (LD$_{50}$) (**bottom**) for radiation pneumonitis, plotted as a function of partial volume irradiated in the apex or base of the lung. The curves are second-order regression fits to the data. The curve for irradiation of a range of volumes in the base is consistently displaced below that for irradiation of the same volumes in the apex; that is, the isoeffect doses for both breathing rate and lethality are lower for all volumes irradiated in the base than in the apex. These data show clearly that the base is more sensitive than the same volume in the apex for the induction of radiation pneumonitis.[196] (From Travis EL, Liao ZX, Tucker SL. Spatial heterogeneity of the volume effect for radiation pneumonitis in mouse lung. *Int J Radiat Oncol Biol Phys* 1997;38:1045–1054, with permission.)

base of the lung.[196] These findings clearly show that for any given volume, the base of the lung is more sensitive than the same volume in the apex, that is, that the isoeffect doses for both breathing rate and lethality are lower for all irradiated volumes in the base than in the apex.

Although the underlying mechanism of this spatial heterogeneity in the response of the mouse lung to radiation is unknown, Travis et al.[196] suggested that the target cells or functional subunits are heterogeneously distributed in the lung because of the anatomy of the tracheobronchial tree. The alveoli are concentrated in the periphery of the lung, whereas the midregion of the lung is most occupied by conducting airways, which are not involved in gas exchange. Thus, the base of the lung is more sensitive because there is a higher concentration of alveoli and fewer conducting airways in this region, whereas a large portion of the midregion of the lung is occupied by large branching bronchi and bronchioles. Boersma et al.[197] suggested that these regional differences in the incidence of pneumonitis could be accounted for by differences in functionality of cells in the base and apex rather than to a difference in density. Khan et al.[198,199] ascribed these regional differences in the incidence of radiation pneumonitis to differences in the amount of DNA damage sustained by the cells in the apex and the base. They proposed that during irradiation the cells in the base sustain more DNA damage than those in the apex, whereas out-of-field effects are observed primarily in the upper lung (i.e., after lower lung irradiation). Interestingly, this differential in DNA damage between cells isolated from the apex or base of the lung disappears, whereas the left lung sustains more damage than the right lung when the whole lung is irradiated.[199]

Regardless of the mechanism underlying these regional differences, the morbidity of lung irradiation is related not only to the volume of lung irradiated but also to the location of the irradiated subvolume within the lung. These findings, then, would suggest that morbidity would be greater when the irradiation portal includes the base than when it includes the apex. These findings also suggest that the volume irradiated in the base in the course of conformal therapy be kept as small as possible.

Regardless of the mechanism of the heterogeneity of the lung's response to partial-volume irradiation, these findings influence the use of less conventional treatment techniques such as 3D conformal radiation therapy and, more recently, IMRT for the treatment of lung cancer. Both of these techniques treat larger volumes of normal lung than do conventional treatment techniques, although the normal lung would get a smaller dose. However, the question of whether giving a lot of radiation to a little volume (conventional treatment) is better or worse than a giving a little to a lot (3D and IMRT) has not been answered. Using the mouse data, Tucker et al.[200] calculated the incidence of pneumonitis for subvolumes of the lung irradiated with a fixed dose. The complication rate varied over the entire range of possible responses, from a 100% incidence after irradiation of the base to a 0% incidence after irradiation of the mid lung, with an intermediate incidence after irradiation of the apex (Fig. 44.9).[200] These data indicate that relatively small changes in the location of the irradiated subvolume in lung may

**FIGURE 44.9** Effect of subvolume location on response calculated using estimates of cell density in different subvolumes of the lung. The *solid curve* shows the predicted incidence of pneumonitis in mice after irradiation of a subvolume of fixed size (70%) with a fixed dose (22 Gy), plotted as a function of the location in the lung of the irradiated subvolume. The complication rate varies over the entire range, from a 100% incidence rate after irradiation of the base to a 0% incidence after irradiation of the mid-lung to an intermediate incidence after irradiation of the apex. The 95% confidence band (*dashed curves*) around the predicted curve is based on the uncertainty in the estimated cell density parameters.[200] (From Tucker SL, Liao ZX, Travis EL. Estimation of the spatial distribution of target cells for radiation pneumonitis in mouse lung. *Int J Radiat Oncol Biol Phys* 1997;38:1055–1066, with permission.)

correspond to significantly greater changes in the incidence of pneumonitis than moderate changes in either the dose or the size of the irradiated subvolume. With the mouse data, Tucker et al.[200] used a constant integrated dose of 12.7 Gy and found that the risk of pneumonitis varied enormously depending on the site of the irradiated subvolume (Fig. 44.10), whereas for both the apex and the midregion of mouse lung, a little to a lot was found to be worse that a lot to a little, provided that the integrated dose (the product of volume and dose) was kept constant. However, a quite different picture emerges for the base, where irradiation of 50% to 70% of the lung is predicted to be worse than irradiation of either larger or smaller subvolumes, again provided that the integrated dose is kept constant. After volumes larger than 70%, the decrease in the probability of pneumonitis occurs because the increase in the number of cells irradiated is more than offset by the decrease in dose required to maintain the constant integrated dose. In terms of the threshold volume, that is, the volume below, which radiation causes no detectable injury even at very high doses, the predicted size of this volume depends on the region of lung irradiated and ranges from 10% in the base to 30% to 40% in the apex.

Interestingly, clinical studies[42,201–203] have found that the risk of pneumonitis in patients varies with the location of the irradiated site, just as had been observed in mouse lung. In a study of 60 patients treated with radiation and chemotherapy
**FIGURE 44.10** Predicted incidence of pneumonitis in mouse lung as a function of irradiated volume where the integrated dose (dose × volume) is kept fixed at 12.7 Gy, equal to the whole-lung $LD_{50}$. The upper, middle, and lower curves represent volumes in the base, apex, or midregion of the lung, respectively. Stippled regions around the curves represent the 95% confidence limits. It is clear that whether a lot to a little is better than a little to a lot is critically dependent on the location of the irradiated subvolume. In the base, the risk of pneumonitis is highest after irradiation of an intermediate subvolume with an intermediate dose, whereas in the apex, a little to a lot is generally worse than a lot to a little.[200] (From Tucker SL, Liao ZX, Travis EL. Estimation of the spatial distribution of target cells for radiation pneumonitis in mouse lung. *Int J Radiat Oncol Biol Phys* 1997;38:1055–1066, with permission.)

given either sequentially or concurrently for lung cancer, the site of irradiation was evaluated by dividing the whole lung into three-by-three areas, that is, the right and left lung were divided into three equal areas from upper to lower lung field. When the risk of pneumonitis was analyzed by irradiated site, it was found that when the lower lung field was irradiated, the incidence of pneumonitis was 70%, compared with 20% for other fields ($p <0.01$). Multivariate analysis revealed a significant relationship between irradiated field and the risk of pneumonitis ($p = 0.0096$). In another study of 106 patients, registered chest CT and SPECT lung perfusion scans were obtained before curative or radical radiation therapy for NSCLC. The mean lung dose (MLD) was calculated. The SPECT perfusion data were used to weight the MLD with perfusion, resulting in a mean perfusion-weighted lung dose. In addition, the lungs were geometrically divided into different subvolumes. The mean dose for each region was calculated and weighted with the perfusion of each region to obtain a mean perfusion-weighted regional dose. The incidence of radiation pneumonitis correlated significantly with the MLD and mean regional dose of the posterior, caudal, ipsilateral, central, and peripheral lung subvolumes ($p \leq 0.05$). A statistically significant difference ($p = 0.01$) in the incidence of radiation pneumonitis was found between patients with cranial and caudal tumors (11% and 40%, respectively). When a

dose-independent offset NTCP parameter for caudal tumors was included in the NTCP model, most correlations were significantly improved, confirming that patients with caudal tumors have a greater probability of developing radiation pneumonitis.[202] These results are consistent with those from mouse studies indicating that irradiation of the base of the lung is significantly associated with a higher risk of pneumonitis.

**Clinical Evidence of a Volume Effect** Animal studies have demonstrated conclusively that a low dose scattered over a large lung volume causes more early toxicity than an extreme dose confined to a small volume.[204] Since the introduction of 3D conformal radiation therapy, many clinical studies have reported an association between the volume of lung irradiated and the risk of radiation pneumonitis.[40,41,74,203,205,206] The dose–volume parameters thought to be crucial for the development of radiation pneumonitis have varied among investigators: Willner et al.[74] found rV10, V20, V30, and V40 to be the most important, whereas Fay et al.[205] found rV30, V40, and V50 and Wang et al.[41] found V5 to be the significant parameters. Clinical evidence supports the findings from animal studies that a little radiation to a lot of lung is not safe. In a study of 223 patients with NSCLC treated with concurrent chemoradiation, the rV5 was found to be the only independent factor associated with grade ≥3 radiation pneumonitis in multivariate analysis.[41] This finding suggested that damage to the lung, which has functional subunits arranged in parallel, may depend more on the volume irradiated than on the radiation dose. This finding is supported by Gopal et al.,[207] who observed a sharp loss in the diffusing capacity for carbon monoxide of normal lung exposed to as little as 13 Gy. The investigators concluded that a small dose of radiation to a large volume of lung could be much worse than a large dose to a small volume in functional lung damage. Yorke et al.[208] also reported that the risk of complications rises steeply above a MLD of 10 Gy, indicating a need to limit widespread irradiation of normal lung tissue, even at low doses. Furthermore, fatal pneumonitis was reported when a large volume of normal lung received low-dose irradiation.[209] Nonetheless, findings have not been uniform. Willner et al.[74] reported, in contrast, that logistic regression curves for V10, V20, V30, and V40 demonstrated sharper increases in risk of radiation pneumonitis at higher doses, and the investigators concluded that a small dose, such as 10 Gy, to a large volume of normal lung is preferable to a large dose, such as 40 Gy, to a small volume.

In contrast to the data from lung function tests, no volume effect was found for damage in the studies of Liao et al.[195] In their animal studies, a characteristic pneumonitis was found in all mice regardless of the volume of lung irradiated. These results illustrate the necessity to define whether damage or morbidity is being assessed in both clinical and animal studies, as different answers may be obtained. These findings also indicate that measures of total lung function that are a sum of the function in the irradiated volume and the function of normal lung in the nonirradiated volume will be different from regional lung function measures that assess damage only in the irradiated area.

## Dose–Volume Relationship in Patients

### Assessing Regional Lung Function: CT Density

Approximately 50% to 0% of patients who undergo lung irradiation will have radiographic or pulmonary function abnormalities following treatment; however, the significance of these changes in terms of morbidity varies from minimal to severe, depending on lung volume irradiated. A comprehensive study of radiation pneumonitis after partial volume fractionated irradiation in patients was conducted by Mah et al.[33] The end point was an increase in lung density observed within the irradiated volume on CT in the posttreatment period. The estimated single-dose equivalent ($ED_{50}$) was $10 \pm 4$ ED units, at the low end of the dose range for pneumonitis in various mouse strains (Fig. 44.11).[33] However, no information was obtained for the effect of these changes on pulmonary function. More recent studies by Boersma et al.[4,6] and Marks et al.[11] in which changes in regional lung function were quantified showed that the dose–effect curves for both functional parameters studied—perfusion and ventilation (Fig. 44.12)—were less steep than the dose–effect curve for structural changes as measured by density changes on CT published previously by Mah et al.[9,37] The lack of correlation between CT changes as a measure of structural damage and tests of regional lung function was clearly observed in one study by Boersma et al.,[4] in which all assays were performed in the same patients. These data suggest that lung density may be a different biological end point from perfusion and ventilation, the former representing the late phase of fibrosis, whereas the latter measure the ability of the irradiated lung within that area to perform gas exchange.

**FIGURE 44.11**    Dose–response curve for the incidence of acute radiation pneumonitis after fractionated radiation therapy of the whole lung in humans. The solid curve is the best fit sigmoid to the data points as determined by probit regression. An $ED_{50}$ of 1000 ED units with a standard error of 40 ED units is predicted. Vertical error bars are the standard deviation of the points.[33] (From Mah K, Van Dyk J, Keane T, et al. Acute radiation-induced pulmonary damage: a clinical study on the response to fractionated radiation therapy. *Int J Radiat Oncol Biol Phys* 1987;13:179, with permission.)

**FIGURE 44.12**    Dose–incidence curves for perfusion **(A)**, ventilation **(B)**, and lung-density changes **(C)** greater than 20%, indicating the fraction of patients with average local changes greater than 20%. The *solid lines* are logistic fits to the data points; the *error bars* on the points indicate the 68% confidence limits.[4] (From Boersma LJ, Damen EM, de Boer RW, et al. Dose-effect relations for local functional and structural changes of the lung after irradiation for malignant lymphoma. *Radiother Oncol* 1994;32:201–209, with permission.)

**Assessing Regional Lung Function: SPECT** Numerous studies in the literature describe changes in local lung function using several assays, such as those described previously and others such as SPECT scanning.[10,11,202,210–215] In a study of 184 patients who were treated before the 3D conformal therapy era, Marks et al.[216] calculated dose function–volume histograms by correlating pretreatment CT data with SPECT data. Within 6 months of radiation therapy, 80% of the radiation-induced symptoms were noted. Neither was there an association between the presence or absence of radiation-induced pulmonary symptoms and the frequency of radiation-induced radiographic changes, nor in the dose–response curve for radiation-induced reductions in regional perfusion, because these end points did not consider the volume of lung affected.[214] Another study that sought to correlate the changes in pulmonary function test results after radiation therapy with radiation dose, tumor regression, and changes in lung perfusion included 82 patients who were treated during the 3D conformal radiation therapy era (DVHs were available).[217] In a multivariate analysis, the total tumor dose and MLD were not associated with a reduction in pulmonary function. Tumor regression resulted in a significant improvement of forced expiratory volume in one second ($FEV_1$), but it was also associated with a reduction of total lung diffusion capacity (TL,COc). The mean perfusion-weighted lung dose (MpLD) and the predicted perfusion reduction showed a significant ($p \leq 0.04$) but low correlation ($r \leq 0.31$) with the reduction of both $FEV_1$ and TL,COc. The perfusion-related dose variables (the MpLD or the predicted perfusion reduction) are the best parameters for estimating pulmonary function after radiation therapy.[217]

In summary, prediction of radiation pneumonitis based on SPECT data DVHs was not superior to standard DVHs, nor was the overall predictability of radiation-induced lung damage improved when receiver operating characteristic curves, a plot of the true-positive rate versus the false-positive rate, were applied to evaluate SPECT perfusion-based dose-function histograms. Interestingly, in the subgroup of patients with pretreatment single-breath carbon monoxide diffusing capacity ($DL_{CO}$) >40%, SPECT-based dosimetric parameters were more predictive than the CT-based ones.[215] Despite the potential benefit of integrating SPECT into predictive models, the latter has not yet become a standard practice.

**Assessing Regional Lung Function: FDG-PET** FDG-PET can detect metabolic changes in regions of the normal tissue that have been irradiated.[14,218,219] Guerrero et al.[14] quantified the relationship between the local radiation dose received and the posttreatment PET/CT FDG uptake in the lung in 36 patients with esophageal cancer who were treated with preoperative concurrent chemoradiation. These patients provided a good clinical normal-lung model, because their lungs were not diseased and they had good lung function. Their treatment planning CT was registered with the restaging PET/CT. The median time between radiation therapy completion and FDG–PET imaging was 40 days (range, 26 to 70 days). The median of the mean standard uptake value in the lung that received 0 to 5 Gy was 0.63 (range, 0.36 to 1.27), 5 to 10 Gy was 0.77 (range, 0.40 to

1.35), 10 to 20 Gy was 0.80 (range, 0.40 to 1.72), and >20 Gy was 1.08 (range, 0.44 to 2.63). Statistical modeling found a linear relationship. The slope of this relationship varied over an order of magnitude, reflecting the range of the underlying biological response to radiation among the study population. (Fig. 44.13[14]) Furthermore, Hassaballa et al.[218] tried to determine whether acute changes in shielded lungs could be detected by FDG-PET in 16 patients with NSCLC. They found that 13 of 16 patients (81.3%) showed increased FDG uptake in shielded nonirradiated lung in four distinct patterns: contralateral peripheral pleural uptake, ipsilateral peripheral pleural uptake, bilateral peripheral pleural uptake, and bilateral diffuse background uptake. This last patient developed clinically evident radiation pneumonitis. The role of functional images, such as SPECT and FDG–PET scans, in predicting the risk of radiation pneumonitis is limited because the information for comparison and prediction is only available after the completion of radiation, when damage to the lung has been done, hence, defeating the purpose of prediction.

**Quantifying the Dose–Volume Relationship** However, what is critical in 3D conformal treatment in which both dose and volume are changing is the effect of these changes

**FIGURE 44.13** Radiation pneumonitis: local dose versus ^{18}F-fluorodeoxyglucose (FDG) uptake response in irradiated lung.[14] Radiation dose and FDG positron emission tomography (PET) response are illustrated for examples of high (case 1) and low (case 2) response. Case 1: **(A)** isodose distribution for patient with esophageal cancer shown overlaying single transaxial section from treatment planning computed tomography (CT) scan; **(B)** corresponding restaging FDG-PET scan (high response), after image registration, shown overlaying transaxial treatment planning CT scan. The pulmonary region with high FDG uptake is indicated by horizontal arrows. Case 2: **(C)** isodose distribution shown overlaying transaxial section from treatment planning CT scan; **(D)** corresponding restaging FDG–PET scan shown overlaying transaxial treatment planning CT scan. The pulmonary region of high dose and its corresponding PET region are indicated by diagonal arrows. These two cases represent the range of FDG uptake response found in all 36 cases evaluated.[14] (From Guerrero T, Johnson V, Hart J, et al. Radiation pneumonitis: local dose versus [18F]-fluorodeoxyglucose uptake response in irradiated lung. *Int J Radiat Oncol Biol Phys* 2007 Jul 15;68[4]:1030–1035.) (See color plate.)

in regional function and structure on whole-lung function. In other words, as the volume of normal lung irradiated increases, should the dose be decreased, and if so, by how much? Clearly, the correlation of clinical symptoms or changes in whole-lung function depends greatly on the volume of functioning lung remaining. What is well accepted is that there is a clear separation between whole organ and regional organ tolerance. The impact of changes in regional lung function and structure on whole-lung function will depend on the DVH.

Numerous studies have shown that the risk of radiation pneumonitis is strongly influenced by the distribution of radiation doses to normal lung. In particular, the MLD has been shown to be significantly associated with the incidence of radiation pneumonitis.[38,40,41,203,205,206,220–226] For example, Graham et al.[38] reported that when the MLD exceeds 20 Gy, the incidence of radiation pneumonitis is more than 20%. Many other studies have identified associations between the proportion of lung exposed to doses exceeding a threshold dose ($V_{Dose}$) and subsequent radiation pneumonitis incidence.[38,40,41,74,203,205,206,220–229] When multiple dose–threshold volumes are investigated (e.g., $V_{10}$, $V_{20}$, $V_{30}$, and $V_{40}$), all of the dose–volume parameters are typically found to be highly correlated with one another[41,202] making it challenging to determine the relative importance of the individual parameters[41,202] (Fig. 44.14, a correlation of dosimetric factors, from Wang et al.[41]). This observation also suggests that the shape of the DVH is perhaps more important than single points

**FIGURE 44.15** Dose–volume histogram (DVH) constraints. Three DVH constraints are compared: *curve A*, the most stringent set of lung DVH constraints, with $V_{20} \leq 25\%$, $V_{25} \leq 20\%$, $V_{35} \leq 15\%$, and $V_{50} \leq 10\%$; *curve B*, constraints of curve A relaxed by 10 percentage points each: $V_{20} \leq 35\%$, $V_{25} \leq 30\%$, $V_{35} \leq 25\%$, and $V_{50} \leq 20\%$; *curve C*, constraints of curve B relaxed by a further 10 percentage points each: $V_{20} \leq 45\%$, $V_{25} \leq 40\%$, $V_{35} \leq 35\%$, and $V_{50} \leq 30\%$.[230] (From Jin H, Tucker S, Liu H, et al. Dose–volume thresholds and smoking status for the risk of treatment-related related pneumonitis. *Radiother Oncol* 2009 Jun;91[3]:427–432.)

**FIGURE 44.14** Correlation of dosimetric factors and treatment-related pneumonitis (TRP). Comparison of time to TRP of grade 3 or higher in patient subgroups divided according to magnitude (%) of relative volume of lung receiving more than a threshold dose (D) of radiation (dose, 5 to 80 Gy). Comparisons reported here are those for which each subset of the cohort included at least 10% of the patients (*small dots*) and comparisons for which the comparison of time to grade ≥3 TRP in the corresponding subgroups reached statistical significance ($p < 0.05$) by log–rank test (*solid circles*).[41] (From Wang S, Liao Z, Wei X, et al. Analysis of clinical and dosimetric factors associated with treatment-related pneumonitis [TRP] in patients with non-small-cell lung cancer [NSCLC] treated with concurrent chemotherapy and three-dimensional conformal radiotherapy [3D-CRT]. *Int J Radiat Oncol Biol Phys* 2006 Dec 1;66[5]:1399–1407, with permission.)

on the DVH curve, such as $V_{20}$, $rV_5$, or MLD, in predicting the probability of radiation pneumonitis. The ideal shape of the DVH would drop steeply in lung volume in the low-dose (5 Gy) region and be flattened in the moderate-dose (20 to 50 Gy) region. Most recently, a study from MD Anderson Cancer Center[230] demonstrated that if lung DVH met a set of "threshold" constraints (Fig. 44.15) (i.e., $V_{20} \leq 25\%$, $V_{25} \leq 20\%$, $V_{35} \leq 15\%$, and $V_{50} \leq 10\%$ (curve A in Fig. 44.15), the incidence of treatment-related pneumonitis of grade 3 or higher was extremely low at only 2% at 1 year. When the constraints were relaxed by 10% each (i.e., $V_{20} \leq 35\%$, $V_{25} \leq 30\%$, $V_{35} \leq 25\%$, and $V_{50} \leq 20\%$) (curve B in Fig. 44.15), the incidence of pneumonitis of grade 3 or higher among patients meeting these constraints but not the more stringent constraints (group B) was 16% (Fig. 44.15). As the constraints were relaxed still further by another 10% (i.e., $V_{20} \leq 35\%$, $V_{25} \leq 30\%$, $V_{35} \leq 25\%$, and $V_{50} \leq 20\%$) (curve C in Fig. 44.15 [230]), the 1-year incidence of pneumonitis in patients whose DVHs met these constraints but not the previous ones (group C) was 25%. For those patients whose lung DVHs violated one or more of the constraints defined by curve C (group D), the rate of pneumonitis of grade 3 or higher at 1 year was 36% (Fig. 44.16).[230] Until the effects of different dose levels on lung toxicity are better understood, we propose using the shape of the DVH curve, rather than a single point on the DVH, as a guide to limiting incidence of treatment-related pneumonitis. [230] What is of importance is that these dosimetric factors useful for predicting who will experience radiation pneumonitis in response to radiation therapy,
**FIGURE 44.16**   Freedom from treatment-related pneumonitis of grade 3 or higher in patients stratified by the lung dose–volume histogram (DVH) constraints defined by curves A to C defined in Figure 44.15. Four groups are compared: *group A*, patients with lung DVHs satisfying the constraints of curve A; *group B*, patients with DVHs satisfying the constraints of curve B but not of curve A; *group C*, patients with DVHs satisfying the constraints of curve C but not of curve B; *group D*, patients whose DVHs fail to meet one or more of the constraints of curve C.[230] *RT*, radiation therapy; *TRP*, treatment-related pneumonitis. (From Jin H, Tucker SL, Liu HH, et al. Dose–volume thresholds and smoking status for the risk of treatment-related pneumonitis in inoperable non-small cell lung cancer treated with definitive radiotherapy. *Radiother Oncol* 2009 Jun;91[3]:427–432.)

such as the percentage of the CT-defined total lung volume receiving >5, >20, and >30 GyE (Gray equivalent), and MLD, were not predictive for radiation pneumonitis after carbon-ion radiation therapy (Koto et al.[231] in Table 44.3).

# RISK PREDICTION OF RADIATION-INDUCED LUNG DAMAGE

**Methematical Modeling**   The dose distribution to normal tissues during radiation therapy for malignant disease is known to influence the incidence of radiation-induced complications. The modern knowledge of normal-tissue tolerance comes from a seminal publication by Emami et al.[232] These authors compiled tolerance dose values for uniform irradiation of 28 critical structures based on literature data and personal experience. In an accompanying article, Burman et al.[233] fit the tolerance dose data into a phenomenological NTCP model proposed by Lyman.[234]

The Lyman NTCP quantifies the probability of injury for a given uniform dose to an organ by the integral of a Gaussian probability function from $-\infty$ to the uniform dose.[234] The parameters defining the Gaussian function are the mean (the uniform dose for 50% probability of injury) and standard deviation ($\sigma$). Because the lung dose distribution is nonuniform, the equivalent uniform dose was approximated using the generalized equivalent uniform dose formulation as

$$\text{uniform dose} = (\Sigma_i V_i D_i^\alpha / \Sigma_i V_i)^{1/\alpha},$$

where $V_i$ is the volume at dose $D_i$. Thus, the three unknown parameters are the uniform dose for 50% probability of injury, $\sigma$, and the generalized equivalent uniform dose exponent $\alpha$. These three parameters are fitted to the data using the maximum likelihood estimation technique. Because the Lyman model is defined for uniform irradiation and normal tissues are rarely irradiated uniformly, several algorithms that convert a heterogeneous dose distribution into a uniform dose distribution resulting in the same NTCP have been designed. An effective volume method for DVH reduction proposed by Kutcher and Burman[235] is the most commonly used. The combined formalism is often referred to as the Lyman–Kutcher–Burman model in the literature. The Lyman model is the most widely used NTCP model and is implemented in many radiation treatment-planning systems.

NTCP models are most often fitted to binary data, in which each patient is scored yes or no according to whether or not the specified complication is observed; however, this approach can lead to false negatives, because some patients scored as no might have experienced the end point with longer follow-up. To limit the number of false negatives, investigators often restrict NTCP analyses to patients having a minimum follow-up time, based on the time interval during which the majority of complications are expected to occur. In the case of pneumonitis, a common requirement is that patients be followed for at least 6 months after the end of radiation therapy.[216,223] In some studies, patients having <6 months follow-up but experiencing radiation pneumonitis before 6 months are also included.[208,236] Moreover, the standard Lyman model does not incorporate nondosimetric risk factors such as comorbidities and other patient characteristics.

Radiation pneumonitis among patients with inoperable NSCLC is an example of a normal-tissue toxicity for which analysis with the standard Lyman model may not be appropriate. Severe radiation pneumonitis (grade 3 or higher), when it occurs, is observed within the first year after radiation therapy. Unfortunately, many patients with inoperable NSCLC succumb to disease during that same period. As improvements in treatment are developed that raise survival rates for these patients, cases of radiation pneumonitis are likely to occur that would otherwise have been masked by disease-related deaths. It would be desirable to have a model of radiation pneumonitis risk that remains accurate as improvements in disease control are made. Knowledge of accurate parameter estimates is essential for incorporating NTCP models into biologically based treatment planning. Several investigators have attempted to estimate the parameters for the Lyman NTCP model by using data from a single institution or by analyzing multi-institutional toxicity data for the lung and other organs.[215,237–242] Although many parameter estimates for different NTCP models and critical structures continue to appear in the literature, it is difficult to justify the use of any single parameter set obtained at a selected institution for the purposes of biologically based treatment planning. Parameters estimated based on cumulative experience at various institutions are thought to be more representative of the overall

practice of radiation therapy and could be more confidently incorporated into clinical use.[223,240]

Considerable evidence suggests that the risk of radiation pneumonitis is influenced not just by dose–volume parameters but also by nondosimetric factors as well, including poor performance status,[243] poor pulmonary function before radiation therapy,[243] chronic obstructive pulmonary disease,[244] low partial pressure of oxygen (PaO$_2$) (>80 mm of mercury) before radiation therapy,[245] lower lobe tumor location,[42,202,236] neoadjuvant chemotherapy,[246–248] concurrent chemotherapy,[42] high total radiation dose, and high radiation dose per fraction.[186] Although when these clinical factors are analyzed together with dosimetric factors, the clinical factors lose their predictive value for radiation pneumonitis in most studies.[38,205,221,228,249,250] A few factors, such as smoking status,[206,230] a history of chronic obstructive pulmonary disease,[244,251] or induction chemotherapy with mitomycin,[244] have retained independent predictive value, suggesting that, besides dose–volume effect, other clinical and biologic factors play a role in pulmonary complications.

To improve predictive accuracy, thereby steepening the dose–response curves, investigators have found it important to incorporate additional covariates into the modeling. A recent analysis of data from 570 patients with lung cancer treated

with radiation therapy suggested that the risk of radiation pneumonitis was significantly lower among smokers than among nonsmokers (1-year incidence, 14% vs. 39%), with an intermediate risk for former smokers (24%).[230] Moreover, smoking status was found to be independent of every dose–volume factor investigated.[230] To take the smoking status into consideration, Jin et al.[252] presented two alternatives to the standard Lyman NTCP model: a generalized Lyman model and a generalized log-logistic model. Both of these alternatives are suitable for predicting radiation pneumonitis and other end points that might be unobserved because of censoring. Whereas the standard Lyman model is fitted to binary (yes/no) event data, the generalized models are fitted to censored time-to-event data. The value of such a model is that it should remain more accurate in its NTCP predictions than the standard Lyman model as evolving treatment regimens lead to prolonged patient survival. Accordingly, the generalized model leads to higher NTCP estimates than the standard Lyman model (Fig. 44.17).

In another study, Das et al.[237] tried to augment the predictive capability of the parametric dose-based Lyman NTCP metric by combining it with weighted nonparametric decision trees that use dose and nondose inputs and by adding a decision tree using a "boosting" process that enhances the accuracy of prediction. A simplified model was developed that

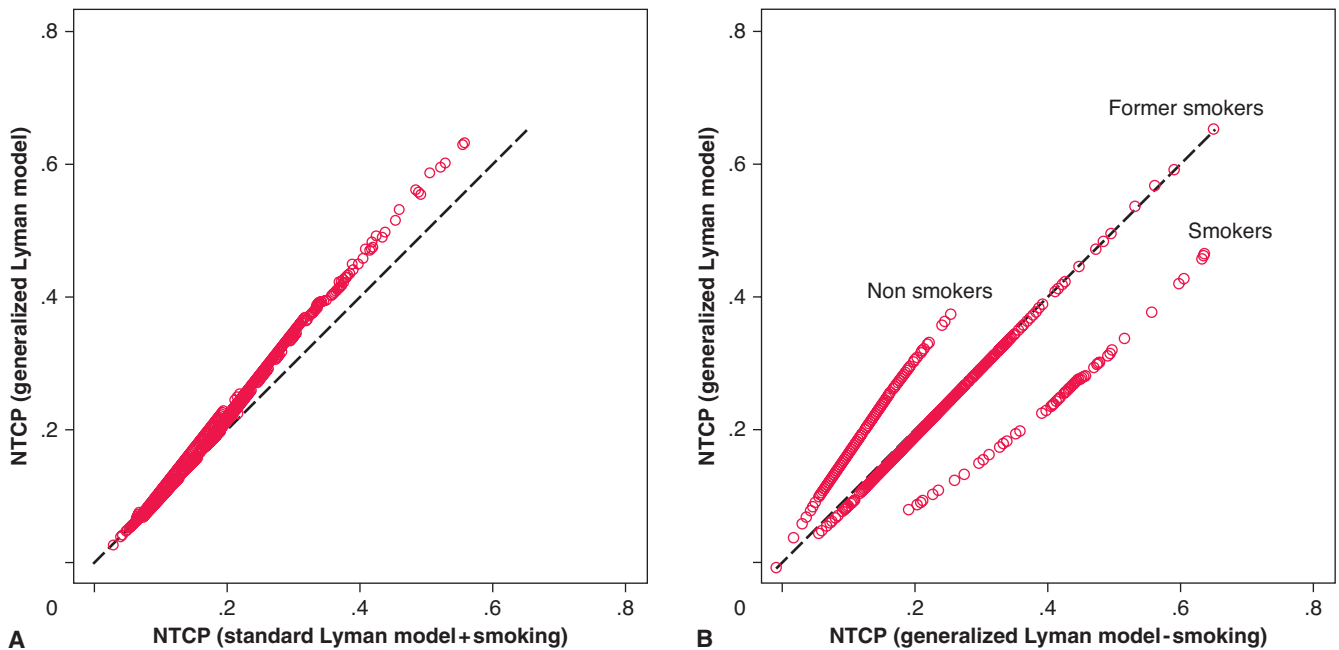

**FIGURE 44.17** **A:** Comparison of NTCP values computed using the generalized Lyman model and those computed using the standard Lyman model with covariates added to reflect patient smoking status but with toxicities regarded as binary (yes/no) events. For both models, the volume parameter was fixed at n = 1, and patient smoking status was taken into account. Because the generalized model "anticipates" additional toxicities, it produces NTCP values that are, on average, higher than those from the standard model.[252] **B:** NTCP values computed using the generalized Lyman model, with or without covariates to represent smoking status, are compared. With smoking status included in the model, the generalized Lyman model produced NTCP values that were up to 18 percentage points lower for smokers and up to 12 percentage points higher for nonsmokers than the NTCP values obtained by omitting smoking status from the fit.[252] *NTCP*, normal-tissue complication probability. (From Tucker SL, Liu HH, Liao Z, et al. Analysis of radiation pneumonitis risk using a generalized Lyman. *Intl J Radiat Oncol Biol Phys*, 2008;72[2]:568–574.)

incorporated nondosimetric variables to produce a measure of injury: such as Lyman NTCP, sex, histologic type, chemotherapy schedule, and treatment schedule. For a given patient's radiation treatment plan, injury prediction was highest for the combination of preradiation chemotherapy, once-daily treatment, and being female and lowest for the combination of no preradiation chemotherapy and nonsquamous cell histologic type. Application of the simplified model to the example cases revealed that injury prediction for a given treatment plan can range from very low to very high, depending on the settings of the nondose variables.[237]

Several groups have also shown that the anatomic region of lung exposed to radiation, as previously mentioned, influences the risk of complications.[38,42,195,196,202,203,208,224,236,253] Others have noted the influence of patient and clinical factors, such as chronic obstructive pulmonary disease or use of chemotherapy.[244] A summary of the association of dosimetric, clinical, and biologic factors with radiation pneumonitis as reported in the literature is provided in Table 44.3.[11,38,40,41,74,203,206,221,223–225,228–231,244,254] Markers of individual susceptibility to radiation pneumonitis, such as genetic information or cytokine expression levels, are likely to improve the prediction of radiation pneumonitis risk.

## Radiation-Sensitivity Testing

### Genetic Testing of Susceptibility to Radiation Pneumonitis by Analysis of Single-Nucleotide Polymorphisms

As discussed previously in this chapter, pathologic processes in the lung are known to be controlled genetically, and individuals differ in their intrinsic sensitivity to radiation. Therefore, genetic testing before radiation is a promising approach to identify a particular patient's risk of radiation pneumonitis. One genetic test relies on the detection of single-nucleotide polymorphisms (SNPs).

SNPs represent the most abundant type of sequence variation in the human genome. A great deal of research has been done to determine if this type of genetic germline variation influences a variety of oncology-related phenotypes, such as cancer susceptibility, disease outcome, and treatment response. The involvement of SNPs in normal-tissue complications after radiation therapy treatment is also being extensively studied.[255] The mechanisms by which SNPs affect phenotype and influence complex diseases vary according to their locations on the genes. Substitutions in coding regions may affect the amino acid sequences of predicted proteins, reducing or abolishing functions such as DNA binding, catalytic activity, and receptor-ligand contact. SNPs may interrupt the initiation or the termination codon or introduce errors in the reading frame shift, all with consequences for insufficient or prematurely truncated peptides. SNPs located in regulatory regions may influence gene expression, whereas SNPs in noncoding sequences may affect splicing or RNA cleavage, stability, and export.[256]

SNPs may be correlated with clinical normal-tissue radiosensitivity in patients.[257–259] SNPs in TGF-$\beta$1, DNA repair genes, and DNA damage response pathways have been linked with clinical radiosensitivity.[156,159,260–263] Many association studies have been published recently that implicate germline genetic variations in a few select cellular pathways (particularly those involved in DNA repair, cell cycle, and inflammation), and these may modify radiation sensitivity, treatment response, and toxicity.[155,157–162,260,262]

In parallel with this pharmacogenomic approach, a new term—*radiogenomics*—was coined to reflect the emerging field of predicting tumor and normal-tissue radiation therapy response using genetic biomarkers, particularly polymorphisms in critical pathways relevant to radiation action.[162,260,264] A broad international effort has been organized, comprising investigators from the United States, France, Switzerland, Denmark, and Israel, to create the Gene-PARE project (Genetic Predictors of Adverse Radiotherapy Effects). In the early stages of this project, which involves more than 2000 patients from five countries undergoing radiation therapy, a handful of selected functional polymorphisms in double-strand break repair (base excision repair, or BER) and inflammation pathways were screened for their association with radiosensitivity, and a few positive associations were identified, including polymorphisms in XRCC1, x-ray repair cross-complementing 3 gene (XRCC3), and TGF-$\beta$1 genes.[161] Preliminary findings from the Gene-PARE project, from other cancer risk association

studies, and from pharmacogenetic studies strongly indicate that cancer risk and clinical outcome (e.g., radiosensitivity) are complex genetic traits that depend on the effect of multiple DNA sequence variants. Any one variant may not exert a dramatic effect, but the aggregation of multiple polymorphisms in the same or relevant pathways may amplify the effect of individual polymorphisms and produce higher risk estimates that may be clinically relevant.[265]

Of the particular importance are the polymorphisms in the TGF-$\beta$1 gene. TGF-$\beta$1 possesses a highly polymorphic, extensive regulatory region that likely has an impact on the pathogenesis of numerous TGF-$\beta$1–related diseases through altered TGF-$\beta$1 expression due to polymorphisms.[266] Comprehensive examination of function and diversity for the TGF-$\beta$1 promoter region and exon 1 ($-2665$ to $+423$) demonstrated that the TGF-$\beta$1 alleles clustered into three phylogenetic groups based on the common functional SNPs c.$-1347$C $>$ T (commonly known as $-509$C-T) and c.$+29$T $>$ C (commonly known as $+869$T-C), suggesting three phenotypic groups.[266] The common TGF-$\beta$1 promoter SNP c.$-1347$C $>$ T ($-509$C-T, rs1800469) has been linked to a nearly twofold difference in plasma levels among individuals and with risk, progression, and outcome of numerous diseases and it was suggested that the molecular mechanism for the difference in TGF-$\beta$1 plasma levels linked to $-1347$ is a result of transcriptional suppression by activator protein 1 binding to $-1347$C.[266] SNPs in TGF-$\beta$1 gene are associated with otosclerosis,[267] Alzheimer disease,[268] renal allograft rejection,[269] chronic obstructive pulmonary disease,[270,271] increased risk of lung cancer,[272] colorectal neoplasia,[273] invasive breast cancer,[264] and normal-tissue reactions and clinical toxicity in patients[156,262,263] with breast cancer and gynecologic cancer after radiation therapy.

Three recent studies demonstrated that polymorphisms in the TGF-$\beta$1 gene had strong associations with normal-tissue reactions and clinical toxicity in patients with breast cancer and gynecologic cancer after radiation therapy.[156,262,263] For example, Quarmby[263] found that the patients with the $-509$TT or $+869$CC genotypes were between 7 and 15 times more likely to develop severe fibrosis. Goitopoulos et al.[274] found that patients homozygous (TT) for the TGF-$\beta$1 C509T variant allele had a 15-fold increased risk of fibrosis after radiation therapy compared with patients with the homozygous (CC) variant. This association was most pronounced[259,261,263] when the mutant homozygous genotype was compared with the wild-type genotype, and a strong link between the $-509$C $>$ T and Leu10Pro polymorphisms was reported. However, the reported results have been controversial. Andreassen et al.[156,260] first reported a possible association between selected SNPs and the risk of subcutaneous fibrosis in 41 Danish breast cancer patients given postmastectomy radiation therapy and in 26 early stage breast cancer patients after breast conservation treatment, a confirmatory study of 120 patients by the same group failed to demonstrate any association between risk of radiation-induced subcutaneous fibrosis and SNPs in TGF-$\beta$1, XRCC1, XRCC3, SOD2 (manganese superoxide dismutase gene) or ATM genes after postmastectomy radiation therapy.[157]

Theoretically, using SNP for genetic testing of radiation sensitivity and risk of radiation pneumonitis is ideal, because the risk is known before the treatment begins. This type of biological marker should, if validated clinically, be able to increase the accuracy of the risk prediction models. However, the data in this area are quite sparse and more extensive research is warranted.

### Radiosensitivity of Ex Vivo Lung Fibroblasts

As discussed previously in this chapter, radiosensitivity varies in the same normal-tissue cell type from different individuals, suggesting that radiosensitivity is genetically regulated. Studies of patients with ataxia telangiectasia have established not only that these individuals are highly sensitive to ionizing radiation but also that in survival assays, fibroblasts isolated and cultured from these patients are more radiosensitive by several logs than are fibroblasts from unaffected individuals.[275–278] Even in the normal population, a wide range of radiosensitivities is known to exist. If normal-tissue radiosensitivity has a genetic component, then the radiosensitivity of cultured cells isolated from an individual should reflect the genetics of the individual.

Several studies have been done to determine the relationship between fibroblast radiosensitivity, as measured by the function of cells surviving a dose of 2 Gy (SF2 Gy), and late tissue damage in patients.[275,279,280] Although early studies reported variable results, more recent findings suggest that fibroblast radiosensitivity may be a useful predictor of late radiation damage in vasculoconnective tissues. However, most of these studies have been done with skin fibroblasts cultured from women with breast cancer. Fibroblast radiosensitivity as measured by SF2 has been compared with both acute and late end points; although no clear relationship was demonstrated between fibroblast radiosensitivity and chronic skin damage, the findings seemed nevertheless to be promising.[275]

In the case of patients with lung cancer, two issues must be resolved experimentally. First, is there a correlation between lung fibrosis and survival of cultured lung fibroblasts? Also, because it would be difficult to obtain biopsies of normal lung from patients with lung cancer before treatment, the second issue is whether the radiosensitivity of fibroblasts isolated from another tissue, for example skin, from the same patient will be similarly radiosensitive as lung fibroblasts. Both of these questions have been investigated using two inbred strains of mice with documented differences in radiation-induced lung fibrosis.

Dileto and Travis[281] determined the radiosensitivity of fibroblasts cultured from the lung and skin of the fibrosis-prone C57B1/6 strain and the fibrosis-resistant C3Hf/Kam strains of mice. In these mouse models, lung fibroblast radiosensitivity was not different as measured by survival at 2.0 Gy (SF2), despite a more than 20-fold difference in fibrosis scores 5.1% and 0.2% in the fibrosis-prone and fibrosis-resistant strains, respectively. Similar SF2 values were obtained for skin fibroblasts from the two strains, indicating that the radiosensitivity of fibroblasts isolated from lung and skin of the same strain is

the same. These data indicate that the in vitro radiosensitivity of lung fibroblasts as assayed by survival at 2 Gy does not correlate with the development of lung fibrosis, at least in the two strains of mice used in the studies of Dileto.[281] Thus, the usefulness of the fibroblast radiosensitivity as measured by SF2 for predicting lung fibrosis remains unclear.

### Circulating Biomarkers

A second approach to identifying at risk patients would be to identify the expression of cytokines, growth factors, or other factors during treatment that correlate with the later incidence of radiation induce lung damage. The underlying rationale of this approach is to identify and intervene in the early expression of gene products that may participate in the pathogenesis of radiation-induced lung damage. The goal would be to define factors that could be monitored regularly and routinely during treatment. The requirement of such a test would be that these factors be easily accessible for multiple sampling.

### Transforming Growth Factor $\beta$

As discussed previously in this chapter, TGF-$\beta$1 has a particularly important role in the development of radiation-induced lung injury.[106–109] In an animal study, a dose-dependent induction of TGF-$\beta$1 in the lung tissue of fibrosis-prone mice after radiation was reported,[282] and soluble TGF-$\beta$1 type II receptor gene therapy reduced the tissue level of active TGF-$\beta$1 and consequently ameliorated acute radiation-induced lung injury.[108] Anscher et al.[106,109,110,228] reported that a normal plasma TGF-$\beta$1 by the end of radiation therapy was more common in patients who did not develop radiation pneumonitis. A return of the plasma TGF-$\beta$1 to normal levels accurately identified patients who would not develop radiation pneumonitis, with a sensitivity and positive predictive value of 90%. Changes in plasma TGF-$\beta$1 levels during radiation therapy were found to be useful in identifying patients at low risk for complications in whom higher doses of radiation up to 86.4 Gy (1.6 Gy twice daily) could be safely delivered.[222] Furthermore, a trend of a decrease in plasma TGF-$\beta$1 concentration to below the pretreatment value during radiation treatment in patients who did not develop pulmonary complications after radiation therapy supports the use of this biomarker as a predictive factor.[283] However, De Jaeger et al.[111] did not find an association between increased levels of TGF-$\beta$1 at the end of radiation therapy and symptomatic radiation pneumonitis, although the TGF-$\beta$1 level at the end of radiation therapy was significantly associated with the MLD and the pretherapy level.

In an early study, Anscher et al.[284] measured the circulating levels of TGF-$\beta$ in patients with breast cancer undergoing bone marrow transplantation and correlated these values with the later incidence of pulmonary fibrosis and hepatic venoocclusive disease, both of which are significant side effects of this treatment. TGF-$\beta$ was determined initially after induction chemotherapy but before the administration of high-dose chemotherapy and subsequently after high-dose chemotherapy and transplantation. Hepatic venoocclusive disease and lung fibrosis were observed clinically between 1 and 3 weeks and

40 and 75 days after transplantation, respectively. Analysis of the TGF-$\beta$ levels after induction chemotherapy with the later incidence of liver and pulmonary fibrosis in individual patients showed that plasma levels of TGF-$\beta$ had a positive predictive value of more than 90% for the development of fibrosis in either of these organs in a given patient. Although plasma levels of TGF-$\beta$ were not determined before any treatment, and thus, its usefulness in selecting patients more likely to develop lung damage before treatment begins is unknown, these data suggest that routine monitoring of plasma TGF-$\beta$ in individual patients undergoing radiation or chemotherapy for lung cancer could be useful as a predictor of lung fibrosis. More recently, Anscher et al.[106] investigated in a prospective study the usefulness of TGF-$\beta$1 as a predictive marker for the development of radiation-induced lung damage. In this study, 73 lung cancer patients were treated with curative intent, and all treatment parameters were similar in this patient cohort. TGF-$\beta$1 levels were measured before, weekly during treatment, and at each follow-up to 6 months after the completion of radiation therapy, when the study was ended. The end point was the development of radiation pneumonitis at 6 months after treatment, which was defined by the National Cancer Institute Common Toxicity Criteria (http://ctep.cancer.gov/reporting/ctc.html). Only 15 (21%) of these patients developed symptomatic pneumonitis. In this study, a normal plasma TGF-$\beta$1 level by the end of radiation therapy was more common in patients who did not develop pneumonitis (Fig. 44.18). A return of TGF-$\beta$1 plasma levels to normal accurately identified with a positive predictive value of 90% patients who would not develop pneumonitis, indicating that the level of this cytokine may be useful in identifying patients at low risk for the development of radiation pneumonitis. These patients could then be considered for dose escalation.

However, results concerning the predictive value of TGF-$\beta$1 for the risk of radiation pneumonitis have been inconsistent.[111,285] Though some investigators have reported that a return of the plasma TGF-$\beta$1 value to normal levels identified with a sensitivity and positive predictive value of 90% patients who would not develop radiation pneumonitis,[106,110] others have failed to confirm this finding.[111,283,286,287] Moreover, TGF-$\beta$1 can be produced by both tumor and normal tissue, and numerous factors, including improper handling of the blood samples or inadequate centrifugation[285] can artificially increase the circulating TGF-$\beta$1 level. Such studies provide the impetus to search for other early markers of radiation- and drug-induced lung damage in the hope of preventing the potentially fatal complications associated with radiation pneumonitis.

**Inflammatory Cytokines** As discussed previously in this chapter, proinflammatory, profibrotic, and proangiogenic cytokines have been implicated in radiation lung damage.[94] Some of these cytokines have been considered as potential markers for radiation lung damage in humans including IL-1$\alpha$, IL-6, IL-8, and IL-10.[95,116,125,288]

Chen et al.[289] was among the first to assess the IL-1$\alpha$ and IL-6 plasma levels prospectively in a series of 31 patients with lung cancer and thymoma. Negative predictive value of IL-1$\alpha$, measured before and throughout radiation therapy, was ≤50%, whereas it was slightly higher for IL-6, with the highest negative predictive value of 54% for levels at 3 weeks of radiation therapy. These biomarkers were unable to distinguish patients at low risk of radiation lung damage who could benefit from dose

**FIGURE 44.18** Plasma TGF-$\beta$ levels as a function of time for patients with an elevated pretreatment plasma TGF$\beta$ level who did not (*open symbols*) or did (*closed symbols*) develop radiation pneumonitis. Although both groups experienced a reduction in TGF-$\beta$ levels during treatment, in one group this decrease was transient, and the TGF-$\beta$ levels returned to high levels. This group had a significantly higher risk of developing pneumonitis than those patients whose TGF-$\beta$ levels remained within control values.[106] *TGF-$\beta$*, transforming growth factor $\beta$. (From Anscher MS, Kong FM, Andrews K, et al. Plasma transforming growth factor $\beta$1 as a predictor of radiation pneumonitis. *Int J Radiat Oncol Biol Phys* 1998;41:1029–1035, with permission.)

escalation. Arpin et al.[116] prospectively followed 90 patients with NSCLC with serial blood testing. Although changes in IL-6 plasma levels after 2 weeks of treatment were significantly correlated with the occurrence of radiation pneumonitis seen at 6 to 8 weeks after the end of radiotherapy, that correlation disappeared for radiation pneumonitis seen at 6 months, despite the putatively sustained character of radiation lung damage.

More recent studies have considered multiple cytokines. Hart et al.[125] reported a fourfold increase in median IL-8 plasma levels in patients without symptomatic radiation lung damage compared with those who did develop symptomatic lung damage or with healthy control subjects: 1.49 pg/mL versus 0.34 pg/mL and 0 pg/mL ($p$ <0.001), suggesting a negative predictive value of 91.1%. However, that study was limited by its retrospective nature, patient selection criteria (availability of plasma samples), and uncertainty between the authors' assumptions of incidence of symptomatic radiation lung damage and its actual incidence in the subset of studied patients (of 55 patients, 22 patients had symptomatic lung damage), preventing any conclusive statement about the correlation between IL-8 levels and the end point. Hartsell et al.[288] studied serum markers (surfactant apoprotein, procollagen type III, IL-1, IL-6, and TNF-$\alpha$) in 127 patients with inoperable NSCLC treated on Radiation Therapy Oncology Group (RTOG) trial. The median survival time was 10.9 months, with 43% of patients living 1 year and 10% living 3 years. Elevated levels of serum IL-6 after 10 Gy of lung irradiation appear to predict acute lung toxicity of grade 2 or greater, and high serum levels of surfactant apoproteins at 20 Gy that correlated with late pulmonary toxicity of grade 2 or greater. These findings need to be confirmed but could be useful in a model to predict risk of pulmonary injury with high doses of radiation. For future studies, it is necessary to evaluate serum markers at multiple time points during treatment, and quality control is critical during the collection, storage, and analysis of these serum markers.[288]

**Other Potential Biomarkers**    Molecules other than interleukins have also tested as predictors of radiation pneumonitis, including soluble ICAM-1 (sICAM-1), KL-6, the cytokeratin 19 fragment (CYFRA 21-1), and pulmonary surfactant proteins A (SP-A) and D (SP-D). However, to date most of the studies investigating the predictive role of circulating biomarkers have had small numbers of patients, discrepancies in the end points used, different treatment regimens, and no standard procedure for processing the blood samples. Until these issues are addressed, the use of circulating cytokine levels to predict risk of radiation lung damage and to identify which patients can tolerate radiation dose escalation remains investigational.

## RISK REDUCTION AND PERSONALIZATION OF CANCER TREATMENT

### Advanced Treatment Technologies for Reducing Lung Dose and Volume    Because radiation pneumonitis is known to be strongly associated with lung dose–volume

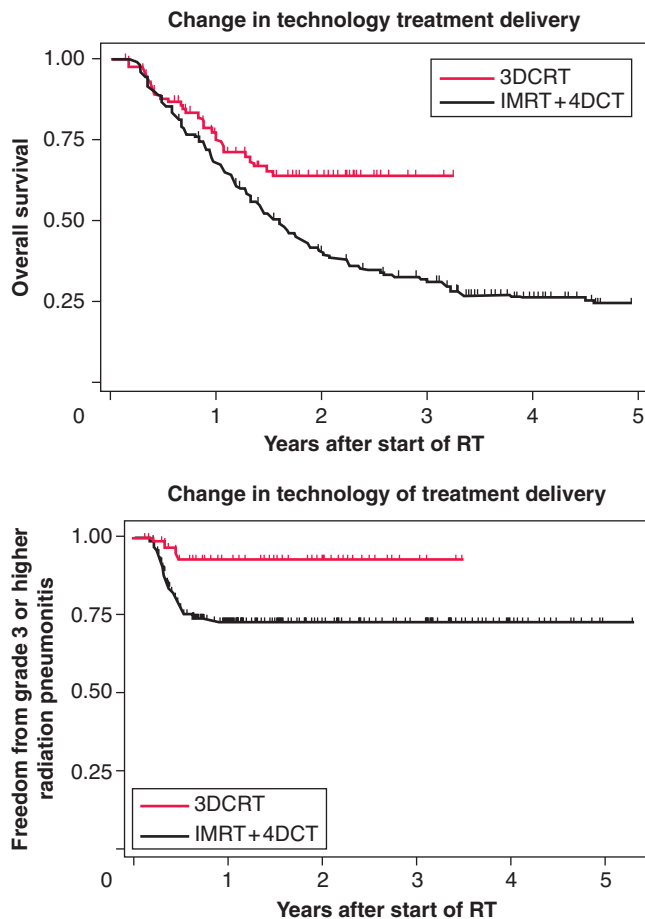
parameters, the possibility of using advanced radiation techniques to reduce lung exposure during radiation therapy has been explored. Murshed et al.[290] demonstrated dosimetric improvements with respect to tumor dose conformity and normal tissue sparing by using IMRT rather than 3D conformal radiation therapy in a treatment planning study. The results showed that, using IMRT, the median absolute reduction in the percentage of lung volume irradiated to >10 and >20 Gy was 7% and 10%, respectively. This corresponded to a decrease of >2 Gy in the total lung mean dose and a statistically significant decrease in the corresponding risk of radiation pneumonitis estimated with the Lyman NTCP model. The size of the estimated risk reduction depended on the choice of parameters for the Lyman model: using the parameters published by Burman et al.,[233] the median radiation pneumonitis risk would decrease from 36% with the 3D conformal plans to 9% with the intensity-modulated plans, whereas using the parameters of Hayman et al.,[291] the median radiation pneumonitis risk would decrease from 13% for the 3D conformal treatment to 7% with the intensity-modulated treatment. Based on the encouraging preclinical study described previously, during the past 4 years, IMRT has been adapted to treat thoracic malignancies. The first report of clinical experience included 68 patients with NSCLC whose disease extent was not amenable to treatment by 3D conformal radiation therapy (68%) or whose medical history indicated previous thoracic irradiation (14%), poor lung function (3%), or prior surgery (16%).[39] That retrospective study showed a significant reduction in radiation pneumonitis with the use of IMRT rather than 3D conformal radiation therapy. At 1 year after therapy, the rates of radiation pneumonitis of grade 3 or higher were 8% among patients treated with IMRT and 32% among patients treated with 3D conformal radiation therapy ($p$ = 0.002). Compared with 3D conformal radiation therapy, use of IMRT led to significantly lower median volumes of normal lung treated with multiple dose levels, ranging from 15 to 65 Gy ($p$ <0.01). Recently, the same group further compared the effects of IMRT and 3D conformal radiation therapy on the end points of toxicity and disease outcomes in a subset of 496 patients treated with concomitant chemoradiation therapy between 1999 and 2006 (Fig. 44.19)[292] from our data set. Among these, 318 were treated with 3D conformal therapy using standard CT scans for planning, and 91 were treated with IMRT using 4D CT scans for planning. The end points for analysis were locoregional progression, distant metastasis, overall survival, and grade ≥3 radiation pneumonitis. The hazard ratios for 4D-CT/IMRT were <1 for all end points, and values were statistically significantly lower for overall survival and radiation pneumonitis, indicating IMRT's ability to reduce risk. Freedom from distant metastasis was nearly identical in the two groups, suggesting that stage migration did not play a major role in influencing the observed differences in the disease and treatment-related toxicity end points. These findings, therefore, suggest that the use of IMRT was associated with a real therapeutic gain, with increased survival and decreased radiation pneumonitis of grade 3 or higher. Such


**FIGURE 44.19** Pneumonitis risk reduction and overall survival rates using advanced technology. The curves compare the patients treated with 3D conformal radiation therapy (3D CRT) and those treated with intensity-modulated radiation therapy with four-dimensional computed tomography planning (IMRT + 4DCT). The latter was associated with significant reductions in radiation pneumonitis and significantly better overall survival rates.[292] (From Liao ZX, Komaki RR, Thames HD Jr, Liu et al. Influence of Technologic Advances on Outcomes in Patients With Unresectable, Locally Advanced Non-Small-Cell Lung Cancer Receiving Concomitant Chemoradiotherapy. *Int J Radiat Oncol Biol Phys* 2009.

an improvement in therapeutic ratio suggests that with IMRT, the radiotherapist has the ability to further increase dose to the tumor while staying within normal thoracic tissues' range of tolerance.[292] The results prompted a prospective clinical trial to confirm the clinical benefit of IMRT.

Wang et al.[41] showed that $V_5$ was a strong predictor of radiation pneumonitis in patients with locally advanced NSCLC receiving concurrent chemotherapy. Taking advantage of the physics characteristics of proton radiation with low entrance and exiting dose, these investigators explored the possibility of using this modality for 108 patients with locally advanced NSCLC treated with chemotherapy and proton therapy (31 patients) or IMRT (75 patients) from January 2003 to September 2007. Median dose was 74 cobalt Gy equivalent

(CGE) (i.e., 1 CGE = 1 Gy) (range, 63 to 74 CGE) in the proton group, and 63 Gy (range, 60 to 76 Gy) in the IMRT group. Proton therapy significantly reduced $V_5$ ($p <0.0001$), $V_{10}$ ($p <0.0001$), and $V_{20}$ ($p = 0.005$) compared with IMRT. The rates of grade 2 to 5 radiation pneumonitis were 19.4% with proton radiation and 33% with IMRT ($p = 0.15$). No patients treated with proton radiation experienced grade 3 or greater radiation pneumonitis, but 9.3% of those undergoing IMRT did ($p = 0.07$). These results indicate that proton radiation is associated with a reduction in the frequency of radiation pneumonitis in spite of delivering a higher total cumulative dose than IMRT.[293] In a separate treatment planning study[294] in which the same investigators compared the effectiveness of proton therapy with that of IMRT in shaping dose distributions and in boosting the dose to the gross tumor volume (GTV), they found that the GTV dose could be increased from 66 to 84 CGE while maintaining the same level of doses to normal tissues. As the trends in preferred treatment technologies move from 3D conformal radiation therapy to IMRT to proton therapy, radiation oncologists are progressively gaining more capability to customize the radiation dose delivered to the lung tumor while protecting the surrounding normal tissues.

**Biological Interventions for Radiation-Induced Lung Damage** Although changes in dose-fractionation schedules and information on the effect of irradiated volume on the incidence and severity of radiation pneumonitis and fibrosis have led to advances in the treatment of lung cancer, the challenge is to identify agents that either protect against lung damage or specifically intervene in the pathogenesis of pneumonitis or fibrosis. Although it has been generally thought that interventional techniques would not work, recent studies on the events occurring during the latent period could prove useful in designing compounds that specifically intervene in these processes.

Much information has been obtained at the cellular and molecular level on the biology of connective tissue formation and the pathophysiology of connective tissue diseases. The knowledge that pharmacologic interventions can be specifically targeted at varying strategic points in the life cycle of fibroproliferative processes has broadened considerably the realm of therapeutic modalities that might be investigated to control these processes. Numerous approaches designed to control collagen deposition remain untested in the lung. It would be useful to develop delivery methods that exploit the unique aspects of the lung to overcome the toxicity associated with collagen inhibitors. Collagen degradation, steroidal and nonsteroidal anti-inflammatory drugs, and cyclic nucleotides offer opportunities to control the accumulation of extracellular matrix in the lung.

**Gene Therapy** Gene therapy has for almost 2 decades been considered a promising interventional approach to treat human disease and prevent therapeutic toxicities. Because TGF-$\beta$ is closely involved in the process of radiation-induced lung damage, it seems a logical step to manipulate the TGF-$\beta$

gene as part of a therapeutic strategy to prevent this complication. Gene therapy strategies that used a recombinant human adenoviral vector that carried a soluble TGF-$\beta$1 type II receptor induced an increase in circulating levels of soluble receptors, reduced the tissue level of active TGF-$\beta$1, and consequently ameliorated acute radiation-induced lung damage histologically and functionally.[108,295] Furthermore, the adenoviral-mediated soluble TGF-$\beta$ receptor may have potential as a therapeutic intervention for radiation-induced pulmonary damage,[296] because the expression of the exogenous Smad7 gene that blocked the signal transduction of TGF-$\beta$ reduced the level of TGF-$\beta$, the level of type I collagen and type III collagen deposition in the lung, and the level of hydroxyproline.[297]

Radiation-induced apoptosis is thought to underlie the toxicity of radiation to normal tissues as well as to cancer cells. Bcl-2 is an antiapoptotic molecule that when expressed ectopically reduced radiation-induced apoptosis in normal cells including cells in lung (not in cancer cells).[298] Epperly et al.[299] reported that overexpression of superoxide dismutase (MnSOD) in the lungs of mice before irradiation prevents irradiation-induced acute and chronic damage evidenced by decreased levels of mRNA for IL-1, TNF-$\alpha$, and TGF-$\beta$ in the days immediately following irradiation and the decrease in the percentage of lung demonstrating fibrosis or organizing alveolitis at 132 days. Furthermore, MnSOD-PL administration before irradiation decreased both BrdU incorporation and delayed expression of VCAM-1 and ICAM-1, suggesting that late irradiation-induced pulmonary fibrosis is associated with the upregulation of adhesion molecules, and that potential targets for intervention may focus on the pulmonary vascular endothelium.[135]

### Inhibition of Cellular Pathways
Increasing evidence suggests that a few cellular signaling pathways, such as those involved in DNA repair, cell cycle, and inflammation, may affect radiation sensitivity, treatment response, and toxicity.[155,157–162,260] Therefore, interventions that regulate certain pathways might prove novel approaches in modulating normal-tissue toxicity. A few preclinical studies have tested this hypothesis.

### Tumor Necrosis Factor $\alpha$
Radiation-induced lung toxicity limits the delivery of high-dose radiation to thoracic tumors. Zhang et al.[300] investigated the potential of inhibiting the TNF-$\alpha$ pathway as a novel radioprotection strategy for radiation-induced lung damage and found that radiation-induced lung TNF-$\alpha$ production correlates with early cell apoptosis and latent lung function damage. Inhibition of lung TNFR1 was selectively radioprotective for the lung without compromising tumor response. These findings support the development of a novel radioprotection strategy using inhibition of the TNF-$\alpha$ pathway.

### Stem Cells
Murine mesenchymal stem cells are capable of differentiating in vitro into different lineages under stimulation with certain cytokines, growth factors, and chemicals; however, the true capacity of these cells to contribute to different cell types in vivo is still unclear, especially under minimal injury conditions. Investigators have described a method of purifying murine mesenchymal stem cells from bone marrow and efficiently transducing them using a lentivirus vector expressing the enhanced green fluorescent protein (eGFP) reporter gene. In this experiment, lentivirus-transduced mesenchymal stem cells retained their in vitro ability to differentiate into adipocytes, osteocytes, and chondrocytes as well as into myocytelike and astrocytelike cells.

In brief, the eGFP mesenchymal stem cells were delivered systemically into minimally injured syngeneic mice. Tracking and tissue-specific differentiation were determined by polymerase chain reaction and immunohistochemical staining, respectively. We found donor-derived hepatocytes, lung epithelial cells, myofibroblasts, myofibers, and renal tubular cells in some of the recipient mice. Our findings indicate that even in the absence of substantial injury, phenotypically defined murine mesenchymal stem cells could acquire tissue-specific morphology and antigen expression and thus contribute to different tissue cell types in vivo.[301]

### Cytokines
It is well documented that radiation promotes the expression of cytokine genes in the lung after single and fractionated doses. The overexpression of cytokine genes has included mTNF-$\alpha$, mIL-1$\alpha$, mIL-1$\beta$, mIL-2, mIL-3, mIL-4, mIL-5, mIL-6, and mIFN-$\gamma$. IL-1$\beta$ was the major cytokine induced in the lungs of C3H/HeJ mice within the first day after thoracic irradiation. Radiation doses as low as 1 Gy were effective. Responses to 20 Gy peaked within 4 to 8 hours and subsided by 24 hours. With the exception of IL-1$\alpha$ and TNF-$\alpha$, the other cytokines that were investigated had undetectable pretreatment mRNA levels and could not be induced by radiation. Pretreatment with dexamethasone reduced basal and induced IL-1 levels, but complete inhibition was not achieved. Dexamethasone was also effective if given immediately after irradiation. Fractionated daily doses of radiation (4 Gy/day) helped to maintain cytokine gene expression for a longer period.[302] Studies of the events occurring during the latent phase of radiation lung injury have shown that several of these molecules and growth factors are activated during this time, some of which may be exploited interventionally.

### Basic Fibroblast Growth Factor
A cytokine investigators are proposing as useful in protecting against radiation pneumonitis in mice is basic fibroblast growth factor (bFGF). Fuks et al.[82,303,304] have shown that this cytokine protects against radiation-induced apoptosis in bovine arterial endothelial cells in vitro[303,304] as well as against apoptosis in endothelial cells in irradiated lungs and the central nervous system of mice.[82,305] They found bFGF also protected mice against the lethal effects of radiation pneumonitis.[82,305] However, neither the time of death nor the histologic changes observed were consistent with classic radiation pneumonitis. Hemorrhage and edema in the air spaces was a consistent finding at 8 to 10 weeks, when the mice were sacrificed because they were moribund. In a separate study in which bFGF was given after pneumonitis-inducing

radiation to the whole lung, no protection against the classic form with bFGF was found.[306] Although the reason for the discrepancy between the findings in these two studies is not clear, it is possible that the higher doses used by Fuks et al.[82] produced sporadic pneumonitis, whereas the lower doses used in the study by Tee[306] induced a classic pneumonitis. Despite these unresolved differences, these studies do indicate the potential for intervening in these reactions. These studies also indicate our incomplete understanding of the events that occur after chest irradiation.

**Interferon-γ** The rationale for the use of interferon α in modulating radiation pneumonitis is that interferon-γ has been shown to reduce the severity of bleomycin-induced fibrosis in mouse lung[307] and to inhibit acute inflammation.[308,309] Thus, if radiation-induced fibrosis is a sequelae of an acute inflammatory response, that is, pneumonitis, then interferon-γ could potentially reduce the severity of lung fibrosis after irradiation. In a study in rats, Rosiello et al.[310] showed that interferon-γ markedly reduced the neutrophil influx and protein leak into the alveoli after irradiation of rat lung with a single dose of 15 Gy, suggesting that prophylactic administration of interferon-γ could reduce the severity of radiation pneumonitis in humans. However, long-term follow-up of these animals showed that although interferon-γ reduced early inflammatory events in irradiated lungs, the tissue response at 35 days, at the end of the study, showed that the number of cells and exudate in the irradiated lungs of the interferon-γ–treated rats was not different from that in rats only irradiated. Thus, it is unclear whether interferon-γ could be useful in modulating either radiation pneumonitis or fibrosis.

**Antioxidants** Pulmonary oxidant stress plays an important pathogenetic role in disease conditions, including acute lung injury/adult respiratory distress syndrome, hyperoxia, ischemia-reperfusion, sepsis, radiation injury, lung transplantation, chronic obstructive pulmonary disease, and inflammation. Reactive oxygen species released from activated macrophages and leukocytes or formed in the pulmonary epithelial and endothelial cells damage the lungs and initiate cascades of proinflammatory reactions propagating pulmonary and systemic stress. Diverse molecules, including small organic compounds (e.g., glutathione, tocopherol [vitamin E], flavonoids) serve as natural antioxidants that reduce oxidized cellular components, decompose reactive oxygen species, and detoxify toxic oxidation products. Antioxidant enzymes can either facilitate these antioxidant reactions (e.g., peroxidases using glutathione as a reducing agent) or directly decompose the reactive oxygen species (e.g., superoxide dismutases and catalase).

Many antioxidant agents are being tested for treatment of pulmonary oxidant stress. The administration of small antioxidants via the oral, intratracheal, and vascular routes for the treatment of short- and long-term oxidant stress has shown rather modest protective effects in animal and human studies. Intratracheal and intravascular administration of antioxidant

enzymes is being currently tested for the treatment of acute oxidant stress. For example, intratracheal administration of recombinant human superoxide dismutase is protective in premature infants exposed to hyperoxia. However, animal and human studies show that more effective delivery of drugs to cells experiencing oxidant stress is needed to improve protection. Diverse delivery systems for antioxidants including liposomes, chemical modifications (e.g., attachment of masking PEGylated groups) and coupling to affinity carriers (e.g., antibodies against cellular adhesion molecules) are being employed and currently tested, mostly in animal and, to a limited extent, in humans, for the treatment of oxidant stress. Further studies are needed, however, to develop and establish effective applications of pulmonary antioxidant interventions useful in clinical practice. Although beyond the scope of this review, antioxidant gene therapies may eventually provide a strategy for the management of subacute and chronic pulmonary oxidant stress.[311]

**Preventing Focal Scarring or Collagen Formation**

Because radiation damage in the lung is manifested as alveolitis followed by focal scarring with an attendant increase in collagen, many studies have focused on identifying drugs active against either one or both of these. One of the first drugs to be used clinically was the steroid prednisolone, which was hypothesized to modify radiation pneumonitis by reducing the inflammatory and exudative portion of lung injury. Both animal and human studies showed that prednisolone did protect against the early phase of pneumonitis. However, when drug administration was terminated, the alveolitis reappeared and in mice the $LD_{50}$ for pneumonitis was not changed.

A second approach of these early studies was to attempt to intervene in the fibrotic process with collagen antagonists. Perhaps the most widely tested was D-penicillamine, a compound shown in experimental studies to inhibit collagen accumulation significantly in rat lung for up to 1 year after irradiation.[89,312] This biochemical effect translated into significant improvement in pulmonary function. Although shown to be effective in rats at a concentration that produced no deleterious side effects, D-penicillamine has not been widely tested clinically, perhaps because it requires continuous administration to be effective.

Endothelial dysfunction plays an important role in the pathogenesis of radiation-induced pneumonitis and fibrosis. A time- and dose-dependent decrease in angiotensin-converting enzyme activity, a marker of endothelial function, was observed after irradiation of either the whole thorax or hemithorax, a finding in good agreement with pulmonary perfusion scans.[86–88] Irradiation plus cyclophosphamide caused a chronic pneumonitis with septal fibrosis and vasculitis affecting, in particular, small caliber pulmonary arteries and arterioles, with markedly elevated concentrations of hydroxyproline, thromboxane ($TxA_2$), and prostaglandin ($PGI_2$) (two markers of pulmonary endothelial damage).[313–315] A significant increase in alpha actomyosin staining was also observed in vessels, septa, and macrophages of the same animals that also overexpressed

TGF-$\beta$. Supplementing the radiation plus cyclophosphamide treatment with the angiotensin type II receptor antagonist L 158809 or the angiotensin-converting enzyme inhibitors captopril and enalapril led to significant amelioration of the histologic damage as well as the overexpression of alpha-smooth muscle actin (SMA). Lung concentrations of hydroxyproline, PGI$_2$, TxA$_2$, and TGF-$\beta$ were also observed in these animals so that the values of these compounds were closer to those measured in untreated control rats than to their radiation- and cyclophosphamide-treated counterparts. Angiotensin II plays an important role in the regulation of TGF-$\beta$ and alpha-SMA, two proteins involved in the pathogenesis of pulmonary fibrosis. The finding that angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers protect the lungs from radiation-induced pneumonitis and fibrosis reaffirms the involvement of angiotensin II in this inflammatory process and suggests an additional indication of treatment of this condition, thus opening a new potential pharmacologic use of these drugs.[315] However, clinical studies have yet to prove the value of these drugs for this indication.

## CONCLUSION

Evidence promises improved local control and overall survival with increased radiation dose, but prescribed doses are limited by the risk of injury to surrounding normal tissues, particularly the lung and esophagus. Risk models have been developed to predict treatment-related toxicity based on radiation treatment parameters, and the potential to individualize treatment plans based on such models has been demonstrated. Delivery of such individualized plans can now be realized through such recent improvements in radiation treatment techniques as 3D conformal radiation therapy, IMRT, and proton therapy all becoming readily available.

Although intervening in the process that results in radiation-induced fibrosis is certainly one way of reducing the morbidity of thoracic irradiation for lung cancer, this approach would be reactive rather than proactive and would not necessarily facilitate tumor control by increasing the radiation dose to the tumor. The ultimate goal is to identify individuals who are at a higher risk of developing treatment-related pneumonitis and fibrosis before treatment begins. Clinically, a wide variation exists in the severity of lung fibrosis exhibited by individual patients treated similarly. These and other data in other normal tissues demonstrate that variations in radiosensitivity exist in the same normal-tissue cell type from different individuals. However, "tolerance" doses of both drugs and radiation are determined empirically from population averages and may be skewed by a genetically oversensitive minority. These data imply then that most patients could be treated with higher doses of either modality without exceeding their individual tolerance to the treatment. One approach to increasing tumor control while maintaining an acceptable level of lung morbidity is to be able to identify those sensitive individuals

before treatment begins and to design treatment accordingly, creating so-called personalized radiation.

Personalized radiation therapy trials in general are investigating the feasibility of using an individualized total tumor dose to the limit of normal-tissue tolerance to achieve the highest therapeutic ratio.[316] Investigators found that the total tumor dose is most often limited by MLD and spinal cord exposure. Other studies investigated an individualized 3D margin, higher fraction dose,[317] and dose escalation based on normal-tissue dose constraints.[318,319] RTOG-93-11 was a radiation dose escalation study that used a threshold volume of lung receiving more than 20 Gy to stratify patients according to the risk of radiation lung toxicity and incorporated three dose categories for customizing the dose escalation. This trial identified an association between increasing gross tumor volume and poor progression-free survival.[320,321] Efforts to identify patients at risk for pneumonitis have focused on physical factors, such as dose and volume.[41,322] Recently, the underlying molecular biological mechanisms behind radiation-induced lung injury have come under study. Elevation of plasma TGF-$\beta$1 level after 4 weeks of radiation therapy was significantly predictive of radiation-induced lung toxicity,[109] and TGF-$\beta$1 genotypes had a role in mediating pulmonary dysfunction in patients with cystic fibrosis[323] and radiation fibrosis.[156] Improved knowledge of the molecular events associated with radiation-induced lung injury may translate into a better ability to individualize therapy.

Individual differences in susceptibility to radiation injury (which may be associated with genetic predisposition) are known to exist, and it is the most sensitive patients who limit the radiation doses used clinically, because standard doses are selected based on population-averaged toxicity. Thus, adding genetic factors to predictive models combining clinical and physical factors will likely strengthen risk assessment and improve its reliability. In addition, biomarkers, particularly cytokines, have been shown to mediate the process of radiation injury. Thus, cytokine measurement during treatment may provide an early warning for the onset of toxicity posttherapy. By proactively monitoring cytokines and updating the risk prediction during treatment, we can customize therapy in an ongoing manner using repeat imaging and treatment planning. This is the strategy that will allow us to tailor radiation therapy effectively to prevent the risk of major toxicity while pursuing and achieving curative individual radiation intervention.

# Chemotherapy for Advanced Non–Small Cell Lung Cancer

Lung cancer is the leading cause of cancer-related mortality worldwide.[1,2] In North America and Europe, an estimated 40% of all newly diagnosed non–small cell lung cancer (NSCLC) patients present with advanced-stage disease (stage IIIB with pleural effusion or stage IV). Moreover, a significant number of patients who present with early stage NSCLC will eventually relapse with extrathoracic metastases. When managed with supportive care alone, these patients experience a median survival of approximately 4 to 5 months and 1-year survival rates of around 10%.[3,4] For more than 6 decades, clinical investigators have labored to improve on these results with little success.[5,6] Early efforts were hampered by the use of relatively inactive cytotoxic agents.[7] Subsequent attempts to improve outcome were predicated on the supposition that combination therapies could increase antitumor activity while minimizing host toxicity.[8] However, with rare exception, the early clinical trials comparing combination chemotherapy to supportive care alone failed to yield a meaningful survival benefit. Although the negative outcome of these trials was commonly attributed to lack of efficacy of the available drugs, some experts posited the initial studies simply lacked adequate statistical power to detect a modest, but clinically important improvement in survival. To remedy this shortcoming, a metaanalysis of the extant data was undertaken in 1995.[9] This landmark study confirmed the lack of a survival benefit with chemotherapy regimens comprised of alkylating drugs or vinca alkaloids; however, NSCLC patients treated with cisplatin-based therapy were shown to have a survival advantage over those given supportive care alone (hazard ratio [HR] = 0.73; $p <0.0001$). The survival advantage amounted to a 1.5-month increase in median survival and a 10% improvement in 1-year survival. Platinum-based chemotherapy was subsequently shown to be cost-effective and capable of improving quality of life.[10,11]

In a recent update of the 1995 metaanalysis, six randomized clinical trials (RCT) and an additional 1702 patients were added to the previously analyzed database.[12] In total, the updated analysis included 15 randomized studies involving 2666 patients. Eleven of the trials employed cisplatin-based chemotherapy, whereas four studies involved a comparison of single agents (etoposide, vinorelbine, gemcitabine, or paclitaxel) and supportive care alone. The results of the updated metaanalysis affirmed the previously identified survival benefit of chemotherapy (HR = 0.78; 95% CI, 0.71 to 0.84; $p <0.000001$). Somewhat surprisingly, there was no apparent difference in the magnitude of effect between trials that used cisplatin-based regimens or the single agents. Moreover, there was also no evidence that any patient subgroup as defined by age, sex, stage, or histology benefited more or less from chemotherapy. The absolute survival benefit of chemotherapy at 1-year did vary according to World Health Organization (WHO)/Eastern Cooperative Oncology Group (ECOG) performance status (PS) 0 = 8% (from 26% to 34%), PS 1 = 8% (from 18% to 26%), PS 2 = 5% (from 6% to 11%), and PS 3 = 4% (from 5% to 9%). The updated metaanalysis suggests the effectiveness of newer agents such as vinorelbine, paclitaxel, and gemcitabine is similar to that of cisplatin combined with older agents such as vindesine or mitomycin (see succeeding discussion) and also reaffirms the substantial and consistent relative survival benefit of chemotherapy in advanced NSCLC.[12]

Although the improvement in the survival of patients with advanced NSCLC is caused, in part, by better chemotherapy, as outlined previously, changes in the natural history of NSCLC may have also played a role. Wakelee et al.[13] analyzed all advanced NSCLC ECOG trials conducted between 1981 and 2000. These investigators first assessed changes in demographic factors and treatment regimens and then correlated these findings with survival outcome among patients diagnosed between 1981 and 1990 compared to those diagnosed from 1991 to 2000. Survival was clearly better, in the trials conducted between 1991 and 2000, explained in part by favorable changes in eligibility criteria (e.g., more women and more favorable patterns of metastases). However,

these investigators also observed a change in the natural history of the disease. For example, there was a longer time to progression suggesting that improved chemotherapy yielded improved survival in the post–1990 era. They also observed a longer interval between disease progression and death, suggesting second-line therapies and supportive care options improved after 1990. Although these observations are conceivably caused by the enrollment of patients with more indolent disease after 1990 or the earlier detection of less symptomatic, advanced NSCLC, this seems less likely. Regardless, the results of this retrospective analysis are consistent with the hypothesis that the improved survival observed over the past decade in patients with advanced NSCLC is indeed multifactorial.

## THE EVOLUTION OF CHEMOTHERAPY IN ADVANCED NSCLC

In the latter part of the 20th century, a number of new cytotoxic agents, including vinorelbine, paclitaxel, docetaxel, gemcitabine, irinotecan, and pemetrexed, were found to possess single-agent activity in advanced NSCLC.[14] Collectively, these agents are known as third-generation drugs to distinguish them from older agents such as etoposide, ifosfamide, mitomycin, and vindesine, which are often referred to as second-generation drugs. In some cases, single-agent administration of these third-generation drugs has yielded a modest survival benefit when compared to supportive care (Table 45.1).[14–16] When a third-generation drug is combined with a platinum compound, objective response and survival rates are improved compared to the same third-generation drug used alone[17–20] (Table 45.2). Similarly, a third-generation drug combined with a platinum agent produces better responses and improved survival compared to single-agent cisplatin[21–23] (Table 45.3). Under either circumstance, however, the higher response rates and improved survival come at a cost of increased host toxicity albeit with no increase in treatment-related mortality.[20] In general, and most importantly, third-generation platinum-based doublet chemotherapy regimens tend to produce higher response rates and superior overall survival (OS) compared to second-generation platinum-based dou-

blet therapies[24–28] (Table 45.4). Interestingly, the survival improvement observed with some of the third-generation agents used alone is comparable to that achieved with platinum doublets employing second-generation drugs[29,30] (Table 45.4).

Following the development of third-generation platinum-based regimens, randomized trials were undertaken to compare their respective activities[31–37] (Table 45.5). Typical of these studies was a trial conducted by the ECOG (E1594) in which chemotherapy-naive patients with advanced NSCLC were randomized to receive cisplatin plus paclitaxel, considered a reference regimen based on an earlier ECOG trial,[26] or one of three regimens employing a third-generation drug: cisplatin plus gemcitabine, cisplatin plus docetaxel, or carboplatin plus paclitaxel.[31] Overall response rates and survival did not differ significantly between the reference regimen of cisplatin and paclitaxel and the three investigational arms. Comparable outcomes have been reported by others.[32–37] Although there were some modest differences in the responses rates and survival among these trials, they are almost certainly a result of subtle, although critical differences in the study population characteristics.[13] For example, the survival rates in the TAX-326 study appear superior to other trials[35]; however, approximately one third of the participants in TAX-326 had stage III disease, compared with just 13% of the patients enrolled in the ECOG study E1594.[31] In some cases, the toxicity profiles appear to be quite different, especially among studies carried out exclusively in Asia.[36] Most likely, the different toxicity profiles are caused by ethnic differences in drug metabolism.[38] Regardless, no truly clinically relevant survival differences have emerged among the commonly used third-generation platinum-based doublet regimens. Taken together, these data indicate that third-generation platinum-based doublets represent the current standard of care in patients with advanced NSCLC and good PS (PS 0 to 1).[4,14]

**Triplet versus Doublet Platinum-Based Drug Combinations** A time-honored strategy for improving the effectiveness of cytotoxic therapy is to combine multiple agents with different mechanisms of action and nonoverlapping toxicities.[39] Thus, adding a third active drug to the aforementioned third-generation platinum doublets has considerable theoretical appeal given their improved activity and favorable toxicity profiles.[40,41] In fact, triple-drug combinations have demonstrated good tolerability and excellent activity in both phase II and phase III trials.[29] However, in two separate metaanalyses of the extant data, improved overall response rates failed to result in an increase in OS[40,42] (Table 45.6). In addition, host toxicity is greater with triple drug therapy.[30,40] Together, these data indicate triplet drug chemotherapy is not appropriate for patients with advanced NSCLC outside the confines of a clinical trial.

**Duration of Therapy** The duration of initial chemotherapy administration in advanced NSCLC is a matter of some controversy.[30] American Society of Clinical Oncology (ASCO) practice guidelines recommend no more than six cycles in responding patients, the American College of Chest Physicians guidelines recommend no more than three to four cycles, whereas the National Comprehensive Cancer Network (NCCN) guidelines are basically noncommittal on this topic.[43–45] The lack of agreement among the various guidelines is perhaps not too surprising given the relative paucity of adequately powered prospective studies addressing this issue[46–49] (Table 45.7). Among the first to tackle this issue were Smith et al.[46] who randomized advanced NSCLC patients to three versus six cycles of mitomycin, vinblastine, and cisplatin. Median (6 vs. 7 months) and 1-year survival rates (22% vs. 25%; $p = 0.2$) as well as the median durations of symptom relief (4.5 months in both arms) were essentially identical in the two arms. Quality-of-life parameters also were the same or improved for patients randomized to only three courses, including a significant decrease in fatigue ($p = 0.03$) and a trend toward decreased nausea and vomiting ($p = 0.06$). von Plessen et al.[48] reported nearly identical results using carboplatin plus vinorelbine. Both studies employed relatively modest doses of platinum drug, which may have influenced the outcomes. However, there is little evidence for a cisplatin-dose response in NSCLC[50,51] rendering this potential criticism somewhat mute. Moreover, in patients

with stages IIIB or IV NSCLC, investigators at the University of North Carolina compared four cycles of standard doses of carboplatin and paclitaxel every 3 weeks to continuous treatment with these agents until disease progression.[47] Fifty-seven percent of patients allocated to four cycles completed the intended course of chemotherapy. Patients randomized to the continuous treatment arm received a median of four cycles of chemotherapy; 42% received ≥5 cycles of carboplatin and paclitaxel. Overall response rates (22% vs. 24%; *p* = 0.80), median survival (6.6. vs. 8.5 months), and 1-year survival rates (28% vs. 34%; log rank *p* = 0.63) were comparable and not statistically different. Hematologic and nonhematologic toxicity rates also were similar between the two arms, whereas neuropathy was more common in the continuous treatment arm (14% vs. 27%; *p* = 0.02). There were no differences

in quality-of-life parameters. The frequency of patients who received second-line therapy was identical in the two groups as well (42% vs. 47%; *p* = 0.42).

The likely death knell for prolonged duration therapy came from a study conducted by the Korean Cancer Study Group.[49] Patients with advanced NSCLC who had not progressed after two induction courses of a third-generation platinum-based chemotherapy were subsequently randomized to four or six additional cycles of chemotherapy. The study population presumably represents a subset of patients with the highest probability of benefiting from extended duration of therapy because they had already demonstrated "platinum sensitivity." Nonetheless, there was no improvement in response rate (43% vs. 42%) or survival (15.9 vs. 14.9 months) with six additional cycles of chemotherapy although time to

disease progression was improved. Moreover, patients randomly assigned to four cycles were more likely to receive second-line treatment, experienced less toxicity, and regained their functional status more rapidly than those patients randomly assigned to six cycles.

A recent metaanalysis including 13 trials and 2416 patients found a significant improvement in progression-free survival (PFS) (HR = 0.78; 95% CI, 0.72 to 0.86; $p$ <0.0001) but no improvement in OS (HR = 0.94; 95% CI, 0.87 to 1.10; $p$ = 0.1) as well as increased toxicity and decreased quality of life for longer duration chemotherapy[52] (Fig. 45.1). The improvement in PFS was greater for third-generation regimens (HR = 0.73 vs. 0.92; $p$ = 0.02). Interestingly, when a trial of maintenance pemetrexed conducted by Ciuleanu et al.[53] (see next discussion) was added to the analysis there was a significant, albeit modest improvement in OS (HR = 0.92, 95% CI, 0.86 to 0.99; $p$ = 0.03).[52] This trend is likely caused by the fact that the Ciuleanu study enrolled 663 patients, almost 3 times the number of all other studies included in the analysis, therefore, significantly influencing the study results. In addition, the addition of the Ciuleanu study to the metaanalysis is questionable as all other trials included in the analysis compared maintenance doublet chemotherapy to no further therapy, whereas the study by Ciuleanue et al. used maintenance single-agent therapy.

Collectively, these data indicate treatment beyond three to four cycles of platinum-based therapy is of limited to no benefit in patients with advanced NSCLC.[30,54,55] Rather than employing prolonged administration of a first-line platinum-based therapy, a more patient-friendly strategy would appear to be the attentive use of sequential single active agents after initial induction therapy.[56] Future research efforts should concentrate on diagnostic methodologies that would allow oncologists to select patients who are more likely to benefit from a particular therapy instead of continued efforts to *optimize* treatment duration with existing therapies.[56]

**Maintenance Therapy**   Two large randomized controlled trials have demonstrated improvements in PFS[57,58] and OS[57] when chemotherapy, paclitaxel and carboplatin[57] or gemcitabine and cisplatin[58] were combined with bevacizumab, a monoclonal antibody targeting vascular endothelial growth factor (VEGF) in patients with nonsquamous NSCLC. Based on these results, Patel et al.[59] conducted a phase II trial of pemetrexed and carboplatin plus bevacizumab with maintenance pemetrexed and bevacizumab in patients with advanced nonsquamous NSCLC and found a response rate of 55% (95% CI, 51% to 69%) median PFS of 9.3 months and OS of 13.5 months (Table 45.8).

Ciuleanu et al.[53] conducted a randomized phase III trial in patients who had responded to four cycles of platinum-based chemotherapy comparing maintenance single-agent pemetrexed to best supportive care. Early treatment with pemetrexed was associated with a significant improvement in PFS (4.04 vs. 1.79 months; $p$ <0.00001) and trend toward improvement in OS (13.0 vs. 10.2 months; $p$ = 0.060). Similar to prior studies evaluating pemetrexed in NSCLC, the benefit was limited to patients with nonsquamous cell histology NSCLC.[37] It should be noted that in this trial, only 50% of patients receiving best supportive care received second-line chemotherapy of which only 11.2% received pemetrexed. It is not known how many patients in the best supportive care arm that received third-line chemotherapy, which was administered to 37% of pemetrexed-treated patients. Treatment with pemetrexed was associated with significantly more serious adverse events (4.3% vs. 0%) and grade 3 or 4 adverse events (14.3% vs. 3.6%; $p$ <0.001).

Maintenance therapy with gefitinib after three cycles of chemotherapy was compared to continued platinum-doublet

chemotherapy, up to six cycles of carboplatin plus paclitaxel, cisplatin plus irinotecan, cisplatin plus vinorelbine, cisplatin plus docetaxel, or cisplatin plus gemcitabine in Asian patients with advanced NSCLC.[60] Chemotherapy was associated with a significantly higher incidence of anemia (22% vs. 13.3%), whereas rash and elevations in liver function tests occurred in 4% and 11% of gefitinib-treated patients, respectively. The median number of chemotherapy cycles was three in both treatment groups. There was a similar response rate between treatment groups. Patients treated with gefitinib had a significant, albeit, small improvement in PFS (4.6 vs. 4.3 months; $p < 0.001$) but no difference in OS (13.7 vs. 12.9 months; $p = 0.10$). In a prespecified subset analysis of patients with adenocarcinoma, approximately 80% of study patients, treatment with maintenance gefitinib was associated with a significant improvement in OS (15.4 vs. 14.3 months; $p = 0.03$). Although not significant, patients with nonadenocarcinoma receiving maintenance gefitinib had a worse OS compared to chemotherapy alone (7.7 vs. 9.2 months; $p = 0.24$). When patients were stratified by smoking status, never-smokers appeared to have a better OS regardless of therapy compared to smokers. Smokers with adenocarcinoma appeared to have an improvement in OS with maintenance gefitinib compared to chemotherapy alone (13.6 vs. 10.0 months; $p = 0.003$). Interestingly, although not significant, never-smokers receiving maintenance gefitinib appeared to have a worse OS compared to chemotherapy alone (21.6 vs. 23.5 months; $p = 0.72$). Therefore, it appears that maintenance gefitinib following platinum-based chemotherapy may be beneficial in a subset of patients with adenocarcinoma. A large randomized phase III trial, comparing maintenance erlotinib to placebo following treatment with carboplatin and paclitaxel with or without bevacizumab (ATLAS), has closed to accrual in North America and results are expected to be reported in late 2009.

## Cisplatin versus Carboplatin

Whether to use cisplatin or carboplatin as the platinum agent of choice in frontline therapy is another of the more enduring controversies surrounding the treatment of advanced NSCLC.[61,62] The controversy intensified with the publication of two prospective trials that demonstrated a superior survival in advanced NSCLC patients treated with cisplatin-based third-generation doublets as compared to carboplatin-based third-generation doublets[35,63] (Table 45.9).

Two recent metaanalyses have examined the clinical relevance of cisplatin versus carboplatin in frontline treatment for advanced NSCLC.[61,62] The first of these was a literature-based analysis of eight trials that directly compared cisplatin- and carboplatin-based doublets, five of which employed a third-generation doublet.[61] A total of 2948 patients were enrolled in these trials. Cisplatin-based chemotherapy produced a statistically significant higher response rate (OR = 1.36; 95% CI, 1.15 to 1.61; $p < 0.001$) but no survival advantage (HR = 1.050; 95% CI, 0.907 to 1.216; $p = 0.515$). However, in the subgroup of trials that employed third-generation drugs, cisplatin-based combinations yielded a survival benefit compared to carboplatin-based doublets (HR = 1.106; 95% CI, 1.005 to 1.218; $p = 0.039$).

The second metaanalysis, the so-called CISCA (CISplatin vs. CArboplatin) study,[62] was based on individual patient data from nine randomized trials that involved a total of 2968 patients.[31,35,63–68] The objective response rate was higher for patients treated with cisplatin than in the cohort treated with carboplatin (30% vs. 24%, respectively; OR = 1.37; 95%

CI, 1.16 to 1.61; $p$ <0.001). Notably, carboplatin treatment was associated with a nonstatistically significant increase in the hazard of mortality relative to treatment with cisplatin (HR = 1.07; 95% CI, 0.99 to 1.15; $p$ = 0.100) (Fig. 45.2). Cisplatin-treated patients experienced a median survival and 1-year survival rate of 9.1 months and 37%, respectively, whereas carboplatin-treated patients had a median survival of 8.4 months and a 1-year survival rate of 34%. In patients with *nonsquamous* tumors and those treated with third-generation chemotherapy, carboplatin-based chemotherapy was associated with a statistically significant increase in mortality (HR = 1.12; 95% CI, 1.01 to 1.23 and HR = 1.11; 95% CI, 1.01 to 1.21, respectively). The authors opined that cisplatin-based third-generation regimens should remain the standard reference for the treatment of selected patients with advanced-stage NSCLC.[62] Parenthetically, it may be worth noting that the subset of patients who seemingly derived the greatest benefit from cisplatin is the same subset of patients that appear to benefit from the addition of bevacizumab to frontline chemotherapy (see succeeding discussion).

Taken together, these data suggest cisplatin is the preferred platinum compound in good PS patients with advanced NSCLC if survival benefit is the principal goal of therapy.[69] Relative to carboplatin-based therapy, cisplatin-based therapy imparts an approximate 3% to 4% improvement in 1-year survival, an increase that is roughly comparable to that achieved with the use of third-generation as opposed to a second-generation agents.[70,71] The incidence of treatment-related deaths is more or less equivalent (4% vs. 3%, respectively).[61,62] However, cisplatin-based chemotherapy is clearly associated with more severe nausea and vomiting and nephrotoxicity, whereas carboplatin-based chemotherapy is associated with more severe thrombocytopenia. Accordingly, it is reasonable to consider substituting carboplatin for cisplatin in selected circumstances where cisplatin toxicities could be particularly problematic (i.e., preexisting neuropathy, hearing difficulties, renal dysfunction, etc.). Of note, even after all these years of use, the optimal doses of cisplatin and carboplatin are not well defined although randomized trials have shown that higher doses of cisplatin (i.e., $\geq$100 mg/m$^2$) are not required to achieve the results outlined previously.[50] By contrast, a dose of cisplatin less than 60 mg/m$^2$ every 3 to 4 weeks appears to produce suboptimal outcome.[72] Comparable dose–response data for carboplatin are lacking.

Favors carboplatin-based chemotherapy ← → Favors cisplatin-based chemotherapy

**FIGURE 45.2** Overall survival of carboplatin- versus cisplatin-based chemotherapy. To describe the effect of carboplatin on mortality, the log-rank statistic (the observed minus the expected number of deaths) and its variance were computed for each trial. Combining these statistics, the event rate ratios of all trials and their weighted average were calculated with 95% confidence intervals (CIs). The test statistics U and Q were used for hypothesis testing about treatment difference and presence of heterogeneity across studies, respectively. The summary hazard ratio was 1.07 (95% CI, 0.99 to 1.15; $p$ = 0.100). (From Ardizzoni A, Boni L, Tiseo M, et al. *J Natl Cancer Inst* 2007;99[11]:847–857.)

### Platinum- versus Non–Platinum-Containing Chemotherapy

Although improvement in survival is clearly a crucial factor in choosing a particular chemotherapy regimen, serious consideration also should always be given to other factors, such as tolerability, quality of life, convenience, and cost.[44] Accordingly, there has been considerable interest in developing non–platinum-based chemotherapy regimens.[73] As one recent example, Greek investigators found no difference in the response or survival rates in advanced NSCLC patients treated with gemcitabine plus docetaxel compared to the combination of cisplatin plus docetaxel.[74] Gemcitabine and docetaxel also possessed a superior toxicity profile suggesting that it was a reasonable alternative first-line regimen to platinum-based therapy. In spite of this encouraging report, however, other studies indicate non–platinum-based chemotherapy may be less efficacious than extant platinum-based regimens.[32]

To address this question, D'Addario et al.[75] performed a literature-based metaanalysis that compared the activity, efficacy and toxicity of platinum- and non–platinum-based chemotherapy in patients with advanced NSCLC. The analysis included data from 37 randomized phase II and phase III trials involving more than 7500 patients. Compared to nonplatinum therapies, platinum-based chemotherapy was associated with a 62% increase in the odds ratio for response (OR = 1.62; 1.46 to 1.8; $p$ <0.0001) and a 5% increase in 1-year survival rate (34% vs. 29%) (OR = 1.21; 1.09 to 1.35; $p$ = 0.0003). This effect was also statistically significant for the comparison of platinum-based regimens versus single-agent nonplatinum therapy (1-year survival = 35% vs. 25%; $p$ = 0.0001) and for platinum-based regimens compared to third-generation–based nonplatinum regimens (37% vs. 31%; $p$ = 0.0057). However, when single-agent trials were excluded from the analysis, there was not a statistically significant increase in 1-year survival with platinum-based therapies as compared to third generation–based combination regimens (36% vs. 35% respectively; OR = 1.11; 0.96 to 1.28; $p$ = 0.17). Platinum-based regimens had significantly higher hematologic toxicity, nephrotoxicity, and nausea and vomiting whereas neurotoxicity, rate of febrile neutropenia, and toxic death rates were similar. As the metaanalysis was literature-based and included some studies in which platinum-based therapy was compared with a nonplatinum single agent, some experts have questioned the value of these data. An accompanying editorial made the following observation: "By no means [does] the meta-analysis indicate that non–platinum-containing regimens are preferred for most patients. None of the randomized studies showed a significant survival advantage for the nonplatinum combinations, and in many the survival was slightly inferior in the non-platinum arm. Noninferiority analyses were not conducted in these trials."[73]

A second literature-based metaanalysis excluded phase II data and included only randomized phase III trials that directly compared a platinum- to non–platinum-based chemotherapy as first-line chemotherapy.[71] Fourteen trials were included; experimental arms were gemcitabine/vinorelbine (n = 4),

**FIGURE 45.3** Overall 1-year survival with platinum-based versus non-platinum chemotherapy regimens. The summary odds ratio for the risk of death within 1 year was 0.88 (95% CI, 0.78–0.99, $p$ = 0.044) indicating a 2.94% survival benefit at 1 year for patients treated with a platinum-based chemotherapy doublet. (From Pujol JL, Barlesi F, Daures JP. Should chemotherapy combinations for advanced non-small cell lung cancer be platinum-based? A meta-analysis of phase III randomized trials. *Lung Cancer* 2006;51[3]:335–345.)

gemcitabine/taxane (n = 7), gemcitabine/epirubicin (n = 1), paclitaxel/vinorelbine (n = 1), and gemcitabine/ifosfamide (n = 1). The comparator was a doublet of a platinum compound plus a third-generation agent for all but two studies. The primary end point of this analysis was the 1-year survival rate. Patients treated with a platinum-based regimen benefited from a statically significant reduction in the risk of death at 1 year (OR = 0.88; 95% CI, 0.78 to 0.99; $p$ = 0.044), equal to an approximate 3% survival improvement at 1-year (Fig. 45.3), and a lower risk of being refractory to chemotherapy (OR = 0.87; 0.73 to 0.99; $p$ = 0.049). The risks of grades 3 and 4 gastrointestinal and hematological toxicities were substantially higher with platinum-based chemotherapies. There was also a nonsignificant increase in the risk of febrile neutropenia ($p$ = 0.063) and a trend toward an increase in treatment-related deaths on the platinum-based regimens (1.9% vs. 1.3%; $p$ = 0.08). The authors concluded platinum-containing regimens were associated with a statistically significant reduction in the risk of death when compared with platinum-free chemotherapy without a perceptible increase in risk of toxic death.[71] However, they also suggested that non–platinum-chemotherapy regimens were appropriate for patients in whom platinum-associated toxicities are a major concern; for the majority of good PS patients with advanced disease, however, platinum-based therapy remains the preferred initial treatment of choice.

### Palliation of Tumor-Related Symptoms

Advanced NSCLC is accompanied by various debilitating symptoms that may include incessant coughing, anorexia and weight loss, dyspnea, chest pain, hemoptysis, fatigue, among others.[76] More than 60 years ago, Karnofsky et al.[5] demonstrated that even the marginally active cytotoxic agent nitrogen mustard

could ameliorate many of these symptoms. Indeed, symptom improvement with cytotoxic therapy may occur even in the absence of a classic tumor response[77,78] and is often achieved within the first two cycles of therapy.[5,77,79] However, some practitioners still prefer to avoid platinum-based chemotherapy for palliative purposes because of the known side effects of these agents. Fortunately, newer agents with favorable toxicity profiles such as gemcitabine, paclitaxel, docetaxel, and vinorelbine can be used with beneficial effects.[15,16,80,81] For example, in one study, patients treated with gemcitabine were far less likely to require palliative radiotherapy at 2 months compared to those treated with supportive care alone (7% vs. 42%).[81] The median time to initiation of palliative radiation therapy was 7 months for patients receiving gemcitabine versus 1 month for patients treated with supportive care. Duration of symptom relief achieved varied considerably but resulted in a median relief of 3 to 5 months for dyspnea, cough, and chest pain and 2 to 3 months for anorexia and hemoptysis.[82] It turns out that symptomatic relief derived from chemotherapy is not limited to first-line therapy. In patients with recurrent NSCLC, second-line docetaxel provided greater improvement in tumor-related symptoms, including asthenia, pain, pulmonary, and neurologic symptoms compared with supportive care as well as a survival benefit.[83]

## SPECIAL POPULATIONS WITH ADVANCED NSCLC

**Elderly Patients**   Lung cancer is primarily a disease of older individuals; the median age at diagnosis is 68 years and as many as 40% of patients may be 70 years at diagnosis.[84] Because older NSCLC patients tend to have substantial comorbidities, oncologists may be reticent to administer standard chemotherapy regimens fearing excessive toxicity.[84,85] However, when deciding a treatment strategy, the biological rather than the chronological age should be carefully assessed, and treatment should only be modified or withheld for very good reasons.[86] This applies equally to surgery and radiotherapy as well as chemotherapy as numerous prospective studies have clearly demonstrated the benefits of chemotherapy in the elderly. Randomized trials have confirmed the superiority of single-agent vinorelbine to supportive care and to combination therapy with vinorelbine and gemcitabine.[80,87] In addition, retrospective analyses of multiple cooperative group phase III studies indicate patients age 70 years and older experience survival and quality-of-life benefits of platinum-based chemotherapy similar to their younger counterparts.[18,31,35,88] However, the role of platinum-based chemotherapy needs to be investigated formally in phase III prospective randomized trials.

In general, little data exist regarding the outcome of chemotherapy in NSCLC patients aged 80 or more, a rapidly expanding, potentially vulnerable population cohort. In an age-specific subset analysis of trial ECOG 1594, investigators observed only nine patients more than 80 years of age (<1% of all enrollees).[89] It is notable that only one of these

nine patients was able to complete four cycles of chemotherapy. Efficacy in this group was very poor with no objective responses noted and a median survival of just 4.2 months. These patients fared worse than patients aged 70 to 79 when treated with platinum-based combinations with time to progression and survival roughly half that observed in the much larger cohort of patients 70 to 79 years of age.[89]

A combined analysis of a trial conducted by the Southwest Oncology Group (SWOG; S0027) and a second investigator-initiated trial performed in elderly patients provides additional insight.[90] Both trials were confined to patients ≥70 years old. The SWOG trial employed sequential vinorelbine followed by docetaxel and included 23 patients aged 80 or older.[91] The second trial compared weekly docetaxel to every 3-week docetaxel, and enrolled 26 patients aged ≥80 years.[92] Tolerance to treatment was similar between patients aged 70 to 79 and those over 80 years. For patients with PS 0 to 1, median survival was actually shorter in the octogenarian group compared to patients aged 70 to 79 (7 months vs. 11 months). For PS 2 patients, survival was equally poor in both groups (4 months vs. 5 months). The authors concluded that these chemotherapy regimens were associated with an encouraging disease-control rate (54%) in patients 80 years or older with advanced NSCLC and were well tolerated. Thus, selected octogenarians with advanced NSCLC may benefit from single-agent chemotherapy. Clearly, more studies in this age group need to be conducted.

Recently, a panel of international experts in geriatric oncology was convened to develop guidelines for the treatment of elderly patients with NSCLC.[85] The panel recommended single-agent chemotherapy with a third-generation agent (vinorelbine, gemcitabine, docetaxel, or paclitaxel), as an option for elderly patients with advanced NSCLC. Several factors must be considered when selecting a particular drug including the expected toxicity profile of the agent, pharmacokinetics, organ function, and comorbidities as well as the patient's preferences. The expert panel also indicated that a platinum-based chemotherapy regimen represented a valid option in older patients with a good PS and adequate organ function.

**Poor Performance Status Patients**   Poor PS (i.e., ECOG PS ≥2) is a strong negative prognostic factor in advanced NSCLC and administration of chemotherapy in this setting is controversial.[93,94] Although chemotherapy fails to improve survival in PS 2 patients, there is nevertheless a potential for an improved quality of life.[10,95,96] Accordingly, the approach taken in clinical practice is highly variable.[97] Many patients are desirous of treatment even when informed of the minimal survival benefits. In such settings, single-agent chemotherapy with one of the third-generation cytotoxic agents (e.g., vinorelbine, gemcitabine, or a taxane) or newer formulations of these agents (e.g., paclitaxel poliglumex [PPX]) may provide clinical benefit with minimal host toxicity.[94] However, some of the newer third-generation platinum-based combination regimens appear to improve survival modestly without engendering excessive host toxicity.[18,98] For example, in CALGB trial 9730, a randomized trial of single-agent paclitaxel versus carboplatin plus paclitaxel,

PS 2 patients had a significantly worse outcome compared with patients with PS 0 or 1 (median survival of 3.0 vs. 8.8 months and 1-year survival of 14% vs. 38%, respectively).[18] However, PS 2 patients treated with carboplatin plus paclitaxel had a better survival rate than those treated with paclitaxel alone (median survival 4.7 vs. 2.4 months; 1-year survival = 18% vs. 10%; *p* = 0.016) (Table 45.10).

Given the significance often attached to ECOG trial E1594, it is worth remembering that the study was initially designed to include patients with an ECOG PS of 0, 1, or 2. However, grade 3 to 4 hematologic toxicities occurred in more than half of the initial 68 PS 2 patients enrolled along with 5 deaths (7.4%). Only two of the deaths were clearly attributed to therapy, but the study was nonetheless amended to exclude PS 2 patients thereafter. The overall response rate for the 64 evaluable patients was 14%, and the overall median survival was 4.1 months. Notably, a nonsignificant trend toward increased median survival was observed with cisplatin plus gemcitabine and carboplatin plus paclitaxel. In addition, nonhematologic grade 3 to 4 toxicities occurred significantly less often in the paclitaxel and carboplatin arm (*p* = 0.0032). These observations prompted ECOG investigators to conduct a randomized phase II trial in which PS 2 patients were randomized to slightly modified regimens of cisplatin plus gemcitabine or the standard regimen of carboplatin plus paclitaxel every three weeks. The trial was designed to detect an absolute 10% increase in 1-year survival compared with historic controls. The 1-year survival rate of PS-2 patients enrolled onto ECOG 1594 was approximately 20%.[99] The toxicity of both regimens in this trial was deemed acceptable but was fairly substantial. Carboplatin plus paclitaxel featured substantially more grade 3 or higher neutropenia than did the cisplatin plus gemcitabine (59% vs. 33%); the relative incidence of grade 4 neutropenia was 34% and 10%, respectively. Carboplatin

plus paclitaxel also featured significantly more grade 3 sensory neuropathy (10% vs. 0%) and grade 2 sensory neuropathy (16% vs. 2%). However, cisplatin plus gemcitabine resulted in significantly more grade 3 or higher thrombocytopenia (38% vs. 14%). It also yielded significantly more grade 3 nausea and emesis (23% vs. 6%), grade 3 fatigue (22% vs. 12%), and grade 1 or higher creatinine elevation (43% vs. 6%). Overall response was 23% with cisplatin plus gemcitabine and 14% with carboplatin and paclitaxel. Median and 1-year survival rates were 6.9 months and 25.5% and 6.2 months and 19.6%, respectively.

A randomized phase III trial Selected Targeted Efficacy in Lung Cancer to Lower Adverse Reactions 3 (STELLAR3) compared carboplatin plus paclitaxel to carboplatin plus PPX in chemotherapy naive PS 2 patients.[100] Although treatment with carboplatin plus paclitaxel had a significantly higher response rate (37% vs. 20%), there was no difference in time to progression (4.6 vs. 3.9 months) or OS (7.9 vs. 7.8 months). Treatment with PPX was associated with a significantly higher incidence of thrombocytopenia, neutropenia, and fatigue; 27% of PPX-treated patients discontinued treatment for adverse events compared to 20% of paclitaxel-treated patients. There was no difference in quality of life between treatment groups. In multivariate analysis, the presence of extrathoracic metastasis, weight loss ≥5% and lung cancer subscale (LCS) score <18 were associated with poorer outcome. A second randomized phase III trial (STELLAR4) compared single-agent PPX to vinorelbine or gemcitabine in the same patient population and found a similar response rate (11% and 15%) and OS (7.3 vs. 6.6 months; HR = 0.95; *p* = 0.686) between treatment groups.[101] Lilenbaum et al.[102] performed regression analysis pooling patient datasets from STELLAR 3 and 4 and identified four factors that were significant predictors of survival; albumin <3.5 gm, presence of extrathoracic metastases

(excluding brain), >2 comorbid conditions and history of tobacco use. Patients with none of these factors had a median survival of 15.6 months, whereas patients with all four factors had a survival of 3.1 months. Outcome did not differ between single-agent and doublet chemotherapy

Finally, the favorable toxicity profile of the oral EGFR inhibitors gefitinib and erlotinib makes them an attractive option for PS 2 patients as well. However, a cautionary note is warranted. In a randomized phase II trial, PS 2 patients seemed to fare better with standard doublet chemotherapy than with erlotinib as initial therapy.[103] Hence, empiric use of a targeted agent in this setting with the assumption that it is automatically less toxic and therapeutically equivalent to conventional chemotherapy is not supported by the literature. There remains a critical need for novel therapeutic strategies for all patients with NSCLC and especially for those with a poor PS.

## COMBINING CHEMOTHERAPY PLUS TARGETED THERAPIES

A casual perusal of the lay or scientific press will easily demonstrate the high level of enthusiasm for the burgeoning field of so-called targeted therapy in the management of multiple cancers including NSCLC.[104] The initial attempts to incorporate targeted agents into the treatment of NSCLC concentrated on patients with advanced, metastatic disease, which is not necessarily the optimal setting in which to test these drugs. However, this approach is a time-honored one and was based, in part, on data derived from preclinical studies indicating some targeted agents yielded additive or even synergistic cytotoxic activity when combined with chemotherapy.[105,106] Unfortunately, with one notable exception,[57] most of these initial efforts failed to demonstrate a survival improvement.[107–113]

**Combination Chemotherapy plus EGFR Tyrosine Kinase Inhibitors** The epidermal growth factor receptor (EGFR) is a receptor tyrosine kinase of the ErbB family that is abnormally activated in many epithelial tumors.[114] Several mechanisms lead to the receptor's aberrant activation in cancers, including receptor overexpression, mutation, ligand-dependent receptor dimerization, and ligand-independent activation.[114] More recently, point mutation or small in-frame deletions in specific EGFR gene exons such as those codifying for the tyrosine kinase domain (mostly exons 19 and 21) have been described in a subset of NSCLC as described in Chapters 5 and 49.[115,116] Two classes of anti-EGFR agents are currently FDA approved for the treatment of patients with cancer: gefitinib and erlotinib, oral, low–molecular weight, adenosine triphosphate-competitive inhibitors of the receptor's tyrosine kinase and cetuximab (Erbitux), a chimeric IgG1 monoclonal antibody directed at the extracellular domain of the receptor.[114,117] Gefitinib and erlotinib yielded antitumor activity in patients with refractory NSCLC and additive cytotoxicity when combined with cytotoxic drugs in preclinical studies.[105,106]

Accordingly, several groups of investigators sought to combine gefitinib or erlotinib with standard front-line platinum-based chemotherapy in advanced NSCLC.[107–110] (Table 45.9). Unfortunately, none of the studies yielded a significant survival improvement. These studies were later criticized because of the lack of patient selection using such selection factors as EGFR expression, somatic mutations, or other putative markers of tyrosine kinase inhibitors (TKI) efficacy.[118,119] However, neither EGFR mutations nor amplification appeared to identify distinct subsets of NSCLC with an increased response to gefitinib in the phase II/III randomized trials nor did the combination of gefitinib with chemotherapy improve survival in patients with tumors expressing these particular molecular markers.[120] Parenthetically, a similar lack of correlation with these putative markers of EGFR TKI activity has been observed in second line therapy as well.[121] However, the lack of correlation may well be a result of technical differences in how these studies were carried out. Interestingly, never-smokers treated with erlotinib and chemotherapy seemed to experience an improvement in survival in one of these trials.[109] Never-smoking has been associated with a greater probability of response to EGFR TKIs and may represent a surrogate marker for the presence of EGFR mutations.[122] Some experts have speculated that these studies failed because EGFR inhibitors act mainly by reducing proliferation in wild-type EGFR tumor cells.[123] Because proliferating tumor cells are those most affected by chemotherapy, an antagonistic effect between EGFR TKIs and chemotherapy may occur. In any case, neither erlotinib nor gefitinib combined with standard chemotherapy regimens confers a survival advantage over chemotherapy alone in *unselected* chemo-naive patients with advanced NSCLC.[109]

IPASS was a large randomized phase III noninferiority trial conducted in Asia comparing first-line gefitinib to carboplatin plus paclitaxel in chemotherapy naive patients who were never or light ex-smokers with advanced NSCLC[124] (Table 45.11). Treatment with gefitinib was associated with a significant improvement in response rate (43% vs.

Cb, carboplatin; CT, chemotherapy; EGFR, epidermal growth factor receptor; HR, hazard ratio; IPASS, Iressa Pan-Asia Study; MST, preliminary median survival time; NSCLC, non–small cell lung cancer; Pac, paclitaxel; PFS, progression-free survival available for all patients reported as HR by mutation status; RR, response rate.

32%, $p = 0.0001$) compared to chemotherapy. PFS initially favored chemotherapy-treated patients; however, 12-month PFS was superior for gefitinib-treated patients (25% vs. 7; $p < 0.0001$). The final OS data is still pending but appears to be similar at this time, 18.6 months for gefitinib-treated patients compared to 17.3 months for chemotherapy-treated patients. On progression 38% of gefitinib-treated patients received carboplatin plus paclitaxel, whereas 39% of carboplatin plus paclitaxel-treated patients received an EGFR TKI. Grade 3, 4, or 5 toxicities were more common for patients receiving carboplatin plus paclitaxel (57% vs. 17%). Quality of life favored treatment with gefitinib. Approximately one third of patients had samples available for EGFR expression, copy number and mutation analysis. EGFR mutation positive patients had a superior response to both gefitinib (71%) and chemotherapy (47%) compared to EGFR mutation negative patients of whom 1% responded to gefitinib and 23.5% responded to chemotherapy. As predicted, treatment with gefitinib was favored over chemotherapy in patients with a positive EGFR mutation (HR = 0.48; 95% CI, 0.36 to 0.64; $p < 0.0001$), whereas chemotherapy was favored in patients with a negative EGFR mutation (HR = 2.85; 95% CI, 2.05 to 3.98; $p < 0.0001$). The results of this trial suggest that gefitinib could be considered first line therapy in a subset of patients with advanced NSCLC who have a positive EGFR mutation.[124]

## Combination Chemotherapy plus HER-1/2 Antibodies

As noted previously, the EGFR is a receptor tyrosine kinase of the ErbB family that is abnormally activated in many epithelial tumors the activation of which is a common mechanism for autonomous, dysregulated cancer cell growth in many human epithelial cancers.[114] EGFR overexpression has been generally associated with advanced disease and poor prognosis and with the development of resistance to anticancer treatments.[125] Cetuximab (Erbitux) is a chimeric IgG1 monoclonal antibody directed at the extracellular domain of the receptor thereby preventing ligand binding and activation of the receptor.[117] The resultant blockage of the downstream signaling of EGFR results in impaired cell growth and proliferation. Cetuximab has also been shown to mediate antibody-dependent cellular cytotoxicity (ADCC). The observation that the addition of cetuximab to chemotherapy could seemingly overcome chemotherapy resistance in some patients with colon cancer or with head and neck cancer,[117] and promising phase II data suggesting a similar survival benefit in NSCLC,[126] prompted the initiation of a prospective multinational randomized phase III trial known as FLEX (for First-Line treatment for patients with EGFR-EXpressing advanced NSCLC) in patients with advanced NSCLC. In this trial, patients with stage IIIB with pleural effusion or stage IV NSCLC and immunohistochemical evidence of EGFR expression on tumor tissue were randomized to cisplatin plus vinorelbine and cetuximab, followed by maintenance cetuximab or cisplatin plus vinorelbine alone (Table 45.12). Treatment with chemotherapy and cetuximab resulted in no difference in PFS compared to placebo, there

was, however, a significant increase in response rate (36% vs. 29%; $p = 0.012$) and OS (11.3 vs. 10.1 months) compared to placebo (HR = 0.87; 95% CI, 0.762 to 0.996; $p = 0.044$). A prespecified subset analysis showed no improvement in OS among patients of Asian ethnicity receiving cetuximab compared with placebo (17.6 vs. 20.4 months). However, fewer patients treated with cetuximab received poststudy treatment with EGFR TKI (50% vs. 73%). There was, however, a significant improvement in OS for white patients treated with chemotherapy plus cetuximab compared to placebo (10.5 vs. 9.1 months; $p = 0.003$); this appeared true regardless of histology. This data would suggest that chemotherapy with cisplatin and vinorelbine plus cetuximab is a reasonable alternative to patients with advanced NSCLC.[127]

HER-2/neu is also a member of the ErbB family of receptor tyrosine kinases. The knowledge that HER-2/neu plays a role in the pathogenesis and progression of lung cancer dates back to at least 1990 when Kern et al.[128] described a negative impact of HER-2/neu expression on the survival of patients with lung adenocarcinomas. Subsequently, these investigators found that a monoclonal antibody to HER-2 inhibited the growth of HER-2/neu-expressing lung cancer cell lines in a dose-dependent manner.[129] This important observation went more or less unexplored until nearly a decade later when several groups initiated phase II trials designed to assess the impact of trastuzumab on the response rate and survival of lung cancer patients.[130–133] Support for these trials came from preclinical studies indicating that trastuzumab could inhibit growth of lung cancer cell lines in vitro.[134] Moreover, a significant synergistic effect was seen when trastuzumab was combined with cytotoxic agents (i.e., gemcitabine, cisplatin, vinorelbine, and paclitaxel) in HER-2/neu positive cell lines.[134] Unlike the preclinical studies with EGFR, treatment effect was shown to correlate with the level of HER-2/neu expression.[134] However, in spite of these encouraging preclinical data, the results of the completed phase II studies are generally thought to be insufficient to carry forward into larger phase III studies, in large part, because of the low rate of HER-2/neu overexpression (only 6% to 8% of NSCLC tumors have 3+ overexpression).[135,136] Likewise, increased gene copy number as determined by fluorescence in situ hybridization (FISH) is quite rare.[136] Positive HER-2/neu expression is most often seen in adenocarcinomas but rarely in squamous cell carcinomas or large cell carcinomas, further limiting the population from which patients might be drawn for a large-scale study. Thus, to conduct a phase III trastuzumab trial in NSCLC potentially would require the screening of an extremely large number of patients to identify the relatively small percentage of patients with tumors overexpressing HER-2/neu. Many experts feel such a study would be logistically difficult, if not impossible. Nonetheless, the recent discovery of somatic mutations in HER-2/neu has rekindled interest in HER-2/neu as a potential target.[137,138] Stephens et al.[137] identified in-frame and missense mutations in the kinase domain of HER-2/neu in 4% of 120 primary lung tumors. This figure is remarkably similar to the

aggregate number of 3+ HercepTest patients screened for the published clinical trials.[130–133] Collectively, these data suggest that inhibitors of HER-2/neu should be considered for retesting in NSCLC although in a more defined way. However, unlike previous studies, trastuzumab should probably be tested in the subset of lung adenocarcinomas that overexpress HER-2 protein, have an increased gene copy number or carry a HER-2/neu mutation. In support of such a trial, Gatzemeier et al.[132] noted an overall response rate of 83% and a median PFS of 8.5 months in HER-2/neu 3+ and FISH positive NSCLC patients when trastuzumab was combined with platinum-based chemotherapy. Although performing a phase III study in a population selected for a molecular abnormality that occurs in less than 5% of patients is a daunting challenge, it can be done efficiently under the right circumstances. Simon et al.[139] calculated that a randomized trial in as few as 138 patients could detect a 20% survival improvement over baseline, provided one has a validated molecular target and a means of testing for the presence of the target.

## Combination Chemotherapy with Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) belong to a family of enzymes that digest extracellular matrix and basement membrane components, and facilitate tumor growth, metastasis, and angiogenesis.[140,141] Certain MMPs, including MMP-2 and MMP-9, are often upregulated in tumor tissue and are associated with a poor prognosis in NSCLC.[141] With the advent of MMP inhibitors, it was postulated that inhibition of these enzymes might slow tumor progression and improve survival in many tumors including NSCLC.[142] However, two large studies failed to demonstrate any evidence of survival improvement.[111,112] For example, BMS-275291 is a sulfhydryl-based second-generation MMP inhibitor that selectively inhibits MMP-1, MMP-2, MMP-8, MMP-9, and MMP-14. The combination of BMS-275291 with carboplatin and paclitaxel, however, failed to yield an improved response rate or OS in patients with advanced NSCLC compared to chemotherapy alone.[112] Similar negative results were observed with prinomastat, a synthetic hydroxamic acid derivative that inhibits MMP-2, MMP-9, MMP-13, and

MMP-14, when combined with cisplatin plus gemcitabine[111] (Table 45.12).

### Combination Chemotherapy with Toll-like Receptor 9 Agonists

The toll-like receptor 9 (TLR9) is part of the family of toll-like receptors that are involved in the immune systems detection and response to infectious challenges.[143] Droemann et al.[144] found that human lung cancer tissues express a functionally active TLR9, although there is only weak TLR9 expression in normal-lung tissue. Preclinical data showed promising activity for a TLR9-agonist in combination with chemotherapy in vitro.[145] A randomized phase II trial reported a median survival of 12.3 months with the addition of PF-3512676, an oligodeoxynucleotide TLR9 agonist, to platinum-taxane chemotherapy compared to 6.8 months with chemotherapy alone.[146] However, two large randomized phase III trials evaluating the addition of PF-3512676 to chemotherapy with paclitaxel plus carboplatin and cisplatin plus gemcitabine in patients with advanced NSCLC were closed early because of lack of efficacy and added toxicity compared to chemotherapy alone[147,148] (Table 45.12)

### Combination Chemotherapy plus Insulin-like Growth Factor Receptor Inhibitors

The insulin-like growth factor receptor 1 (IGFR-1) is a transmembrane protein involved in the growth and survival of cancer cells.[149] The binding of insulin-like growth factor (IGF) I and II to the extracellular domain of IGFR-1 triggers signal transduction through the Ras/Raf and phospoinositol-3-kinase (PI3K) transduction pathways.[150] Ludovini et al.[150] measured IGFR-1 and EGFR expression using immunohistochemistry in 125 patients with early stage NSCLC and found positive IGFR-1 expression ($>$10% of cells) in 36% of samples. Although IGFR-1 expression was more prominent in larger tumors, expression alone was not predictive of either overall or disease-free survival. High coexpression of IGFR-1 and EGFR was associated with worse disease-free survival (HR = 2.51; 95% CI, 1.21 to 5.12; $p$ = 0.012) in all patients and a trend toward poorer OS in patients with stage I NSCLC (HR = 2.19; 95% CI, 0.86 to 5.56; $p$ = 0.08). A randomized phase II trial compared standard chemotherapy with carboplatin plus paclitaxel to carboplatin plus paclitaxel and CP-751, 871 (10 mg/kg and 20 mg/kg), an antibody to the IGFR-1, in patients with advanced NSCLC[151]

(Table 45.12). There was a higher incidence of neutropenia and hyperglycemia in patients treated with chemotherapy plus CP-751, 871. Chemotherapy plus CP-751, 871 was associated with a higher response rate (54% vs. 41%, $p$ $<$0.00001); regardless of histology responses appeared to be highest at the 20 mg/kg dose level. There was a trend toward improved PFS for CP-751, 871 20 mg/kg compared to chemotherapy alone (5.0 vs. 4.3 months, $p$ = 0.07). Patients with squamous cell histology appeared to derive the greatest benefit from treatment with CP-751, 871 with a response rate of 78% and PFS of 5.6 months. Studies of CP-751, 871 in combination with carboplatin and paclitaxel in patients with nonadenocarcinoma are currently underway.

### Combination Chemotherapy plus Inhibitors of Vascular Endothelial Growth Factor

Over the past decade, inhibition of angiogenesis has been a major thrust of new drug development in many solid tumors including lung cancer.[152–154] Drugs that target the VEGF pathway include bevacizumab, sunitinib, sorafenib, axitinib, AZD2171, ABT-869, AMG 706, and VEGF trap many of which are under active investigation in NSCLC.[155,156] In NSCLC, the most advanced of these drugs is bevacizumab, a recombinant humanized monoclonal antibody to the VEGF. In a randomized phase II trial, bevacizumab combined with carboplatin and paclitaxel improved both overall response rates and times to disease progression.[157] However, bevacizumab was associated with a high rate of life-threatening pulmonary hemorrhage, mainly in patients with squamous cell carcinomas. When an analysis was performed that excluded patients with squamous histology, the results looked even more promising with a numerically superior overall response and an improved time to progression. Median survival exceeded 18 months in a subset of patients with nonsquamous carcinomas. To confirm these preliminary results, ECOG undertook a phase III trial in which patients were randomized to chemotherapy with or without bevacizumab. The confirmatory trial was limited to patients with nonsquamous histology, an absence of significant hemoptysis (defined as $\leq$ 0.5 teaspoon at baseline) and no brain metastases.[57] Patients receiving bevacizumab experienced an improved response rate (35% vs. 15%; $p$ $<$0.001), PFS (6.2 vs. 4.5 months; HR = 0.66; $p$ $<$0.001) and OS (12.3 vs. 10.3 months; HR = 0.79; $p$ = 0.003) (Table 45.13). The survival benefit was consistent among all prespecified stratification

groups including measurable or nonmeasurable disease, prior radiation therapy or no prior radiation therapy, weight loss ≥5% or <5%, and stage IIIB disease with pleural effusion or stage IV disease, or recurrent disease. In an exploratory analysis of the treatment groups according to baseline characteristics, bevacizumab was beneficial in all subgroups with the possible exception of women (Fig. 45.4). Possible explanations for this finding including imbalances between the two groups with respect to known or unknown baseline prognostic factors, imbalances in the use of second- and third-line therapies, or a true sex-based difference. Given the lack of gender-specific bevacizumab-related survival differences in colon or breast cancers[158]; it is quite likely this observation represents a statistical aberration. These survival benefits came at a cost that included more treatment-related deaths (15 vs. 5 deaths; $p = 0.001$) and a higher rate of clinically significant bleeding (4.4% vs. 0.7%; $p < 0.001$) with bevacizumab. Nonetheless, the substantial improvement in OS indicates that bevacizumab plays a key role in the management of selected NSCLC patient with metastatic disease.

Confirmation of the ECOG data seemingly stems from a European trial (BO17704; also known as Avastin in Lung Cancer [AVAiL] trial) in which advanced NSCLC patients were randomized to one of two doses of bevacizumab (7.5 mg/kg or 15 mg/kg) or a placebo in combination with cisplatin and gemcitabine.[58] The study was designed to detect a 30% reduction in the risk of a PFS with bevacizumab compared with chemotherapy alone using a two-sided log-rank test (alpha = 2.5%) with 80% power. Both bevacizumab-containing arms

BPC Better    PC Better

exhibited a statistically significant prolongation of PFS compared to chemotherapy alone (Table 45.13). However, the numeric difference in PFS among the three arms is minimal and the clinical significance is unknown in the absence of OS data. Of note, the PFS in the bevacizumab arms is consistent with that observed in the ECOG trial. What is striking, however, is the nearly 2-month difference in PFS in the ECOG study versus just 2- to 3-week difference in PFS in the European study. Also, although the PFS of 4.5 months with chemotherapy alone in the ECOG trial is consistent with previous ECOG studies employing carboplatin plus paclitaxel, these data are interesting in light of the possible inferiority of carboplatin vis-à-vis cisplatin in advanced NSCLC (see earlier discussion). Could it be that the ECOG trial yielded an OS benefit with bevacizumab simply because carboplatin-based therapy is inherently less effective than cisplatin-based therapy? In other words, did bevacizumab simply increase OS with carboplatin-based chemotherapy to what would be achieved with cisplatin-based therapy? This is an issue that warrants additional study. Finally, it should be noted that there was *not* a statistically significant increase in life-threatening bleeding in the bevacizumab-containing arms of the European trial compared to chemotherapy alone in this trial.

## PERSONALIZING CHEMOTHERAPY IN ADVANCED NSCLC

Ideally, clinicians would prefer to develop customized treatment plans for each individual patient that improve survival and minimize toxicities. Fortunately, such an approach may be feasible in the not too distant future, as modern techniques have facilitated the identification of specific genetic factors that may play a role in disease progression and patient response to therapy.[159] For example, the nuclear excision repair (NER) pathway is highly specialized process for the repair of damage caused by polycyclic aromatic hydrocarbons, ultraviolet light, or exogenous chemicals that induce bulky DNA adducts.[160,161] Alkylating agents such as platinum components interfere in the DNA-replication process by inducing DNA adducts that lead to cell death.[162] As a consequence of their increased capacity of DNA repair, some cancer cells are resistant to the effects of chemotherapy.[163,164] The excision repair cross-complementation group 1 (ERCC1) enzyme plays a rate-limiting role in the NER pathway that can recognize and remove cisplatin-induced DNA adducts.[165] In vitro studies have linked platinum resistance to the expression of ERCC1 mRNA in various cell lines.[166] These data suggest knowledge of ERCC1 status may permit greater precision in selecting a chemotherapy regimen for advanced NSCLC patients. Toward that end, Spanish investigators performed a landmark trial in advanced NSCLC in which ERCC1 mRNA expression was determined by quantitative real-time reverse transcriptase PCR using RNA isolated from pretreatment biopsies.[167] Patients were randomized to either a control or genotypic arm (1:2 ratio) before ERCC1 assessment. In the genotypic arm, patients with low ERCC1 levels received docetaxel plus cisplatin and those with high levels received a nonplatinum regimen (docetaxel plus

gemcitabine). Patients in the control arm all received standard docetaxel plus cisplatin. The primary end point was the objective response rate. The response rate in the control arm was 39% and 51% in the genotypic arm ($p = 0.02$). OS was not significantly different; nonetheless, these data strongly suggest that ERCC1 mRNA levels can predict response to platinum-based therapy. In fact, in resected early stage NSCLC, patients with tumors overexpressing ERCC1 protein did not appear to benefit from platinum-based adjuvant chemotherapy, whereas patients with ERCC1 negative tumors did.[168]

Ribonucleotide reductase M1 (RRM1) encodes the regulatory subunit of ribonucleotide reductase, the rate-limiting enzyme in DNA synthesis.[169] Ribonucleotide reductase converts ribonucleotide 5′-diphosphate to deoxyribonucleotide 5′-diphosphate. Notably, gemcitabine competes with ribonucleotide 5′-diphosphate for incorporation into DNA. Consequently, the overexpression of ribonucleotide reductase would be expected to interfere with the efficacy of gemcitabine. Preclinical studies[170] and two recently completed clinical studies support the potential predictive value of RRM1.[171,172] For example, among a group of NSCLC patients treated with cisplatin plus gemcitabine, Spanish investigators found low RRM1 mRNA expression levels were associated with a significantly longer median survival than those with high levels (13.7 vs. 3.6 months; 95% CI, 9.6 to 17.8 months; $p = 0.009$)[171] (RRM1 and ERCC1 mRNA was assessed in paraffin-embedded samples by real-time quantitative reverse transcription-PCR). Bepler et al.[169] reported that the levels of RRM1 expression was significantly ($p = 0.002$) and inversely correlated ($r = -0.498$) with disease response after two cycles of gemcitabine and carboplatin in patients with locally advanced NSCLC.

Beta-tubulin is one of the major components of microtubules.[173] Taxanes bind to beta-tubulin and produce growth arrest at the G2-M phase of the cell cycle. High levels of beta-tubulin, which exists as multiple isotypes, are associated with resistance to taxanes.[173] More specifically, high levels of class III beta-tubulin are associated with taxane resistance in lung cancer cell lines.[174] The clinical relevance of this observation has been highlighted by Sève et al.[175] who assessed the prognostic and predictive value of class III beta-tubulin in tumors taken from patients with locally advanced or metastatic NSCLC treated with paclitaxel-based or other nontubulin-binding agents. Tumor samples were obtained before treatment with a paclitaxel-based regimen or a nontubulin-binding agent. Treatment response, PFS, and OS were then correlated with the expression of class III beta-tubulin protein. The response rate was 37.5% among patients receiving paclitaxel. Patients whose tumors expressed low levels of class III beta-tubulin isotype had a better response rate ($p < 0.001$), longer PFS ($p = 0.004$), and OS ($p = 0.002$), whereas this variable was not found to be predictive in patients receiving regimens without tubulin-binding agents. Taking into account sex, age, histology, stage, and class III beta-tubulin a multivariate analysis confirmed that low-level class III beta-tubulin expression was independently correlated with PFS ($p = 0.003$) and OS ($p = 0.003$). These findings suggest that the expression levels

Adapted from Scagliotti GV, Parikh P, von Pawel J, et al. Phase III study comparing cisplatin plus gemcitabine with cisplatin plus pemetrexed in chemotherapy-naive patients with advanced-stage non-small-cell lung cancer. _J Clin Oncol_ 2008;26(21): 3543–3551.

of class III beta-tubulin in tumor cells may predict response to therapy and survival toutcome in patients with advanced NSCLC receiving paclitaxel-based chemotherapy; however, expression level is not a general prognostic factor.

Thymidylate synthase (TS) catalyzes the methylation of dUMP to dTMP and is the rate limiting irreversible step in de novo DNA synthesis.[176] As the sole source of de novo thymidylate in the cell, it is an important target for chemotherapy drugs such as 5-fluorouracil (5-FU), methotrexate, capecitabine and other novel folate-based drugs such as pemetrexed.[177] TS expression has been shown to be an independent prognostic and predictive factor in several cancers, including lung cancers, and overexpression of TS has been linked to resistance to these drugs.[176,178–182] TS mRNA levels ($p < 0.0001$) and protein levels ($p = 0.027$) have been shown to be significantly higher in squamous cell carcinomas of the lung as compared with adenocarcinomas.[183] Keeping in mind that pemetrexed targets TS, the potential significance of this finding is highlighted by the results of a large phase III trial in which cisplatin plus pemetrexed was found to be more effective than cisplatin plus gemcitabine in adenocarcinomas and large cell carcinomas, whereas cisplatin plus gemcitabine was noted to yield a better survival in squamous carcinomas compared to the pemetrexed regimen[37] (Table 45.14). The observed survival difference may have been related to differences in intratumoral TS expression although no definitive data pertaining to intratumoral TS expression have yet been presented.

In summary, the available evidence clearly indicates that the identification and exploitation of genetic markers, predictive of response to specific cytotoxic drugs, is an achievable goal. Moreover, these early results indicate that the application of pharmacogenomics has the potential to profoundly influence outcomes and improve OS.

## CONCLUSION

For much of the 20th century, advances in the systemic treatment of advanced NSCLC were modest at best.[3,184] In fact, in 1998, the noted oncologist B.J. Kennedy derisively opined on the "snail's pace" of progress in the management of late stage NSCLC.[6] Fortunately, much has changed since Dr. Kennedy's rather pessimistic commentary. It is now well established that modern chemotherapy can prolong survival of NSCLC patients with late stage disease as well as improve the symptoms and quality of life and do so in a cost-effective manner.[3,4] It is now well accepted that doublet platinum-based chemotherapy with a third-generation drug is the preferred treatment for physically fit patients with advanced NSCLC. No single regimen stands apart as the optimal program for all patients. Nonplatinum therapy is a reasonable alternative approach in selected circumstances where cisplatin or carboplatin is not appropriate. Subtle differences among the extant regimens allow clinicians flexibility to choose among toxicity profiles, convenience, and cost. For a subset of patients, namely those with adenocarcinoma, no brain metastases or hemoptysis, the addition of bevacizumab to chemotherapy appears to be warranted based on a significant improvement in OS. Whether the addition of bevacizumab to doublets other than carboplatin and paclitaxel is beneficial remains to be determined. The available data indicate that no more than three to four cycles of chemotherapy regimen are required to achieve optimal survival results and minimize host toxicity. Older patients who are not physically fit and patients with a poor initial PS may be candidates for monotherapy with a third-generation drug or possibly one of the newer so-called targeted agents (e.g., erlotinib). Finally, all therapy in the setting of metastatic disease is ultimately palliative. Consequently, treatment decisions need to be tempered by this very sobering reality.

# Chemotherapy for Recurrent or Refractory Advanced Non–Small Cell Lung Cancer

Publication of the Non–Small Cell Lung Cancer (NSCLC) Collaborative Group metaanalysis in 1995 established that first-line platinum-based chemotherapy is associated with a modest improvement in survival for patients with metastatic disease.[1] In general, most patients experience disease progression within a short time, with a median time to progression of approximately 4 months.[2–4] However, at the time of progression, many patients maintain a good performance status (PS) and may be candidates for further systemic therapy. Even as recently as 1997 though, guidelines for the management of NSCLC stated, "there is no current evidence that either confirms or refutes that second-line chemotherapy improves survival in patients with advanced NSCLC."[5]

Fortunately, substantial progress has been made over the last decade, and currently, numerous systemic therapeutic options are available for the treatment of advanced and metastatic NSCLC (Table 46.1). Several chemotherapeutic agents have been evaluated in the second-line setting. More recently, molecularly targeted agents have also shown benefit in this group of patients. Agents targeting the epidermal growth factor receptor (EGFR) and vascular endothelial growth factor (VEGF) have been widely investigated. As a result, multiple options now exist for second and subsequent lines of therapy for these patients.

This chapter will examine the available evidence for second-line treatment options for patients with NSCLC, progressing after first-line chemotherapy. Recommendations are based on data from randomized trials examining second-line treatment options for NSCLC. Published data were identified from a literature search using MEDLINE, as well as review of conference proceedings from meetings of the American Society of Clinical Oncology (ASCO), the International Association for the Study of Lung Cancer (IASLC), European Society of Medical Oncology (ESMO), and European Conference on Clinical Oncology (ECCO).

## DOES SECOND-LINE CHEMOTHERAPY IMPROVE SURVIVAL AND/OR QUALITY OF LIFE?

Studies of second-line therapy in NSCLC are summarized in Table 46.2. The TAX 317 trial represents a milestone in the recent approach to second-line therapy for NSCLC.[6] This was a randomized trial of docetaxel versus best supportive care (BSC) for patients who previously had been treated with a platinum-containing (cisplatin or carboplatin) chemotherapy regimen. BSC could include treatment with antibiotics, analgesics, blood transfusions, and palliative radiation. Patients could have received more than one prior chemotherapy regimen, but were not eligible if they had received a prior taxane including paclitaxel. The study included patients with Eastern Cooperative Oncology Group (ECOG) PS 0 to 2. The primary outcome of TAX 317 was overall survival. Secondary outcomes included response rate, response duration, time to disease progression, and quality of life (QOL) (measured by the Lung Cancer Symptom Scale in North America and European Organization for Research and Treatment of Cancer quality of life questionnaire in Europe). In patients with measurable disease, response was assessed using bidimensional response criteria.

The planned dose of docetaxel was initially 100 mg/m². However, an interim safety analysis by the Data Safety and Monitoring Committee identified five toxic deaths among 49 patients randomized to docetaxel 100 mg/m² (D100). As a result, the protocol was amended and the dose of docetaxel was reduced to 75 mg/m² (D75) in the second half of the study. The two dose levels of docetaxel were analyzed together in the primary analysis. Patients randomized to docetaxel could continue to receive chemotherapy until disease progression was documented, or there was unacceptable toxicity.

There were 204 patients randomized on the trial (BSC = 100; D100 = 49; D75 = 55). Baseline characteristics were generally well balanced between the groups. The TAX 317

| TABLE 46.1 | Major Advances in Second-Line Treatment of NSCLC over the Past Decade and a Half |
|---|---|

| Year | Advance |
|---|---|
| 1995 | Metaanalysis showed first-line therapy improves survival[1] |
| 2000 | Docetaxel shown to improve survival in two randomized phase III trials[6,7] |
| 2004 | Pemetrexed shown to be noninferior to docetaxel[27] |
| 2005 | Erlotinib shown to improve survival in second- and third-line setting[52] |
| 2007 | Gefitinib shown to be noninferior to docetaxel[60] |

Hematological toxicities occurred commonly in patients receiving docetaxel. Grade 3 or 4 neutropenia was seen in 76% of patients, with febrile neutropenia occurring in 11.5% of patients overall, but only 1.8% of patients in the 75-mg/m$^2$ group. Nearly 11% of patients had grade 3 or 4 anemia, but interestingly, a similar rate was observed among BSC patients. The predominant nonhematological toxicities occurring in the docetaxel group included asthenia, fever, infection, diarrhea, fluid retention, nausea, stomatitis, and neurologic. However, asthenia and infection were common adverse effects in the BSC group as well.

Supportive evidence that docetaxel is an effective second-line therapy for patients with NSCLC comes from the TAX 320 trial reported by Fossella et al.[7] In this trial, patients were randomized to receive D100, D75, or a control arm (vinorelbine/ifosfamide [V/I]) of either ifosfamide (2 gm/m$^2$ days 1 to 3 every 21 days) or vinorelbine (30 mg/m$^2$ day 1, 8, and 15 every 21 days). In the docetaxel 100-mg/m$^2$ group, granulocyte colony-stimulating factor (G-CSF) was used in subsequent cycles to manage prolonged neutropenia, or febrile neutropenia. As in the Tax 317 trial, participants could have received one or more prior therapy and the trial included patients with PS 0 to 2. However, unlike the trial by Shepherd et al.[6] participants could have received prior paclitaxel. QOL was measured using the Lung Cancer Symptom Scale.

trial demonstrated that docetaxel significantly improved survival compared to BSC, in patients who had received prior platinum containing chemotherapy ($p = 0.047$). The median and 1-year survival for patients randomized to docetaxel were 7 months (95% confidence interval [CI], 5.5 to 9.0) and 29%, respectively, compared with 4.6 months (95% CI, 3.7 to 6.0) and 19% for patients randomized to BSC (Fig. 46.1). The magnitude of this difference was slightly greater for patients randomized during the second phase of the trial to D75 or BSC (7.5 vs. 4.6; 1-year survival = 37% vs. 12%, $p = 0.01$).

**FIGURE 46.1** Overall survival of docetaxel versus best supportive care (BSC; Tax 317). (From Shepherd FA, Dancey J, Ramlau R, et al. Prospective randomized trial of docetaxel versus BSC in patients with non-small-cell lung cancer previously treated with platinum-based chemotherapy. *J Clinic Oncol* 2000;18[10]:2095–2103.)

A total of 373 patients were randomized (D75 = 125; D100 = 125, V/I = 123). Compared to TAX 317, the patients were more heavily pretreated. A greater number of patients had received two or more prior chemotherapy regimens and more patients had disease progression as the best response to their last therapy. Between 31% and 42% of patients had received prior paclitaxel. Patients in the D75 group received more cycles of chemotherapy than those in the D100 group (median number of cycles 10 vs. 6). Both docetaxel groups had a significantly higher response rate than the V/I group (D100 = 10.8%, $p$ = 0.001; D75 = 6.7%, $p$ = 0.036; V/I = 0.8%). The response rate for patients who received prior paclitaxel was similar to the response rate for all patients. The median time to progression was similar among the three groups. However, progression-free survival (PFS) at 26 weeks favored the docetaxel groups (D100 = 19%, $p$ = 0.013; D75 = 17%, $p$ = 0.031; V/I = 8%). There were no significant differences in overall survival (median survival D100 = 5.5 months; D75 = 5.7 months; V/I = 5.6 months). However, there was a significant improvement in 1-year survival rate for the D75 group (D100 = 21%; D75 = 32%, $p$ = 0.025; V/I = 19%). The observed toxicity was similar to that seen in the TAX 317 trial.

QOL was assessed in both TAX 317 and TAX 320,[8,9] with the results demonstrating improvements in symptom scales in patients randomized to docetaxel. Dancey et al.[8] reported a significant improvement in pain scores favoring

docetaxel over BSC. Trends were also noted in favor of docetaxel for overall LCSS score, fatigue, and appetite. Mean overall QOL scores declined less in the docetaxel group than the BSC group.

These two landmark studies established the survival and QOL benefit from second-line chemotherapy with docetaxel for patients with NSCLC. These data are reflected in the 2003 updated ASCO guidelines for the treatment of unresectable NSCLC, which now recommend the use of docetaxel as second-line therapy for patients with adequate PS who have progressed following platinum-based chemotherapy.[10] Increasingly though, the decision to implement treatment guidelines has incorporated economic arguments in addition to data on therapeutic efficacy. As such, Leighl et al.[11] performed an economic evaluation of the TAX 317 trial to determine the cost-effectiveness of docetaxel versus BSC in the Canadian environment. Costs were determined from resource utilization for patients entered on the trial from one tertiary academic center. Given the short survival overall for this group of patients, discounting was not employed. Efficacy data were taken from the overall trial results. The incremental cost of docetaxel was $57,749 per life year gained. However, the cost-effectiveness of D75 was only $31,776 per life year gained. In comparison to other health interventions, this is within a range of expenditure generally considered reasonable.

# WHAT ARE THE APPROPRIATE DOSE AND SCHEDULE OF ADMINISTRATION OF DOCETAXEL?

The trials by Shepherd et al.[6] and Fossella et al.[7] established D75 administered every 21 days as the standard of care for second-line therapy for NSCLC. Over recent years, various investigators have explored alternate schedules of docetaxel in an attempt to improve the therapeutic ratio (Table 46.3). Nonrandomized comparisons of D100 and D75 in the TAX 317 trial showed no difference in efficacy and significantly more toxicity.[6] Quiox et al.[12] evaluated this question in a randomized phase II trial. Patients were randomized to D75 (n = 94) or D100 (n = 89). The response rate (7.4% vs. 7.6%) was similar as was the rate of disease control (45.7% vs. 57%). There were no significant differences in time to progression (D75 = 1.5 months; 95% CI, 1.3 to 2.0 months vs. D100 = 2.1 months; 95% CI, 1.3 to 2.7 months), or overall survival (D75 = 4.7 months; 95% CI, 3.8 to 5.9 months vs. D100 = 6.7 months; 95% CI, 4.8 to 7.1 months). More grade 3 and 4 neutropenia (72.7% vs. 44%) and asthenia (19.1% vs. 8.6%) were observed with the higher dose of docetaxel. However, there was no difference in the rate of febrile neutropenia (6.8% vs. 6.7%). The rates of other nonhematological toxicities were similar between the two groups. The authors conclude that D75 every 3 weeks is the preferred dose because of a more favorable toxicity profile.

Doc 33, Docetaxel 33.3 mg/m$^2$ weekly for 6 weeks followed by 2-week rest; Doc 35, Docetaxel 35 mg/m$^2$ days 1,8,15, every 28 days; Doc 36, Docetaxel 36 mg/m$^2$ weekly for 6 weeks followed by 2-week rest; Doc 40, Docetaxel 40 mg/m$^2$ days 1 and 8 every 21 days, or weekly for 6 weeks followed by 2-week rest; Doc 75, Docetaxel 75 mg/m$^2$ day 1 every 21 days; NA, not applicable; NR, not recorded; OR, objective response; PD, progressive disease; SD, stable disease; TTP, time to progression.

Some variation exists in the dose of docetaxel. In Japan, the dose of docetaxel routinely used is 60 mg/m$^2$ every 3 weeks. This is based on data from a phase I clinical trial in which the maximum tolerated dose of docetaxel was found to be 70 mg/m$^2$ every 3 weeks.[13] As a result several Japanese phase II trials evaluated docetaxel at a dose of 60 mg/m$^2$.[14–16] Response rates, survival, and toxicity all appear comparable to the observed efficacy of docetaxel at a dose of 75 mg/m$^2$ every 3 weeks in western populations. It is postulated that pharmacogenomic differences may exist between Japanese and North American populations to account for this difference.[17,18]

Five trials have evaluated docetaxel given in a weekly schedule versus the standard three weekly schedule.[19–23] Di Maio et al.[24] recently published an individual patient metaanalysis of these trials.[24] The five trials randomized 865 patients to three weekly docetaxel (n = 433), or a weekly schedule (n = 432). Doses of docetaxel, in the weekly schedule, ranged from 33.3 mg/m$^2$ to 40 mg/m$^2$ weekly, either for 6 weeks followed by a 2-week rest, or for 3 weeks followed by a 1-week rest. There was no difference in survival between the two schedules of docetaxel (hazard ratio [HR] = 1.09; 95% CI, 0.94 to 1.26). The median survival for patients treated with three weekly docetaxel was 27.4 weeks compared with 26.1 weeks for patients treated with a weekly schedule. One- and two-year survival rates were 24.8% versus 27% and 10.3% versus 6.8%, respectively. Response rates were similar between the two groups (8.1% vs. 6.7%; $p$ = 0.43). Weekly docetaxel was associated with significantly less grade

3 and 4 neutropenia (18% vs. 5%) and febrile neutropenia (6% vs. <1%). The available data suggest, therefore, that both the three weekly and weekly schedules of docetaxel can be used as second-line therapy for NSCLC. The toxicity advantages of weekly docetaxel may be counterbalanced by the increased frequency of treatment visits and associated increased resource utilization.

## ALTERNATIVE CHEMOTHERAPY OPTIONS TO DOCETAXEL

Pemetrexed is a multitargeted antifolate with a broad spectrum of activity. It inhibits thymidine synthase, which is important in pyrimidine synthesis, as well as dihydrofolate reductase and glycinamide ribonucleotide formyltransferase, which are important enzymes in purine synthesis. Phase II trials have demonstrated activity of pemetrexed in NSCLC.[25,26] Based on the phase II activity of pemetrexed, Hanna et al.[27] conducted a randomized phase III trial of second-line therapy in NSCLC comparing pemetrexed to docetaxel.

The JMEI trial randomized patients to a standard arm of D75 every 21 days, or pemetrexed 500 mg/m$^2$ every 21 days.[27] Patients on the pemetrexed arm all received vitamin supplementation with folic acid and vitamin B$_{12}$ based on data from a trial of pemetrexed in malignant pleural mesothelioma.[28] Dexamethasone premedication was used in both arms of the trial. Patients were excluded if they had received more than one prior chemotherapy for advanced disease, had

prior docetaxel or pemetrexed, weight loss ≥10% in preceding 6 weeks, significant peripheral neuropathy (≥ grade 3), were unable to interrupt nonsteroidal anti-inflammatory drugs, or had uncontrolled pleural effusions (not further defined). The last two criteria relate to concerns about pemetrexed clearance. The study was designed to show that overall survival of patients randomized to pemetrexed was noninferior to that of docetaxel.

Five hundred and seventy-one patients were randomized (pemetrexed 283, docetaxel 288). The groups were well balanced regarding baseline characteristics. No differences were seen in any of the outcomes. The response rates (9.1% vs. 8.8%) and rates of disease stability (45.8% vs. 46.4%) were almost identical for pemetrexed and docetaxel, respectively. Prior paclitaxel therapy did not predict for any differential response. There were no differences in the PFS of pemetrexed compared with docetaxel (median PFS = 2.9 months vs. 2.9 months; HR = 0.97; 95% CI, 0.82 to 1.16). Median survival (8.3 months vs. 7.9 months) and 1-year survival (29.7% vs. 29.7%) of patients randomized to pemetrexed was not statistically different to that of docetaxel (HR = 0.99; 95% CI, 0.8 to 1.20; Fig. 46.2). The assumption of noninferiority was assessed using two methods. Using the percent retention method, the trial met its primary outcome of noninferiority. The alternate method of noninferiority defined pemetrexed as ≤10% worse than docetaxel. The trial did not meet this outcome of noninferiority as the upper limit of the 95% CI exceeded an HR of 1.11. Although this has created issues with some regulatory authorities, pemetrexed is generally considered to be an equally effective alternative to docetaxel as second-line therapy for NSCLC.

Although there were no differences in any of the efficacy parameters, there were some differences observed between the

**Pts at risk**

**FIGURE 46.2** Overall survival of docetaxel versus pemetrexed (JMEI). (From Hanna N, Shepherd FA, Fossella FV, et al. Randomized phase III trial of pemetrexed versus docetaxel in patients with non-small-cell lung cancer previously treated with chemotherapy. *J Clin Oncol* 2004;22[9]:1589–1597.)

toxicities of pemetrexed compared with docetaxel. There was more hematological toxicity in patients receiving docetaxel compared with pemetrexed, and the rates of grade 3 and 4 neutropenia (40.2% vs. 5.3%) and febrile neutropenia (12.7% vs. 1.9%) were significantly higher in the docetaxel group. This resulted in a higher rate of hospitalization and G-CSF use. There were differences in nonhematological toxicities as well with more alopecia (37.7% vs. 6.4%), diarrhea (24.3% vs. 12.8%), and neurosensory toxicity (15.9% vs. 4.9%) among patients receiving docetaxel, but more nausea (16.7% vs. 30.9%), rash (6.2% vs. 14%), and liver enzyme abnormalities (1.4% vs. 7.9%) among patients receiving pemetrexed. Interestingly, despite these differences in toxicity, there were no differences in QOL between the two treatment groups.

A retrospective analysis of this trial was undertaken to explore predictors of survival for patients in the second-line setting.[29] In univariate analyses, the following variables demonstrated associations with survival: sex (females = 9.4 months vs. males = 7.2 months, *p* = 0.001); stage at diagnosis (stage III = 9.5 months vs. stage IV = 7.8 months, *p* = 0.036); histology (adenocarcinoma = 9.1 months vs. squamous carcinoma = 6.5 months vs. other = 7.8 months, *p* = 0.004); PS (PS 0 = 12.7 months vs. PS 1 = 8.3 months vs. PS 2 = 2.6 months, *p* <0.001); best response to prior therapy (complete response [CR]/partial response [PR] = 15.8 months vs. stable disease [SD] = 10.5 months vs. progressive disease [PD] = 4.6 months, *p* <0.001); time from first-line to second-line therapy (≤3 months = 6.9 months vs. 3 to 6 months = 9.2 months vs. ≥6 months = 9.3 months, *p* = 0.001); and first-line regimen (platinum-gemcitabine = 9.1 months vs. platinum-taxane = 7.4 months vs. other = 7.8 months, *p* = 0.63). The authors conclude that these variables should be used as stratification variables in future randomized trials. However, given the retrospective nature of these analyses, these variables should not be used to select between docetaxel and pemetrexed.

A further retrospective analysis of the JMEI trial suggested that there may be a difference in the effectiveness of pemetrexed compared with docetaxel based on histology.[30] Previous research has suggested thymidine synthase expression may be higher in squamous carcinoma compared with other histological subtypes.[31] This is postulated to reduce the sensitivity of squamous carcinoma to pemetrexed. Peterson et al.[30] reported that survival of patients with squamous carcinoma treated with pemetrexed was less than that of patients treated with docetaxel (6.2 months vs. 7.4 months; HR = 1.563; 95% CI, 1.079 to 2.264). Interestingly, they also observed an improvement in survival for patients with nonsquamous histology treated with pemetrexed (9.3 months vs. 8.0 months; HR = 0.778; 95% CI, 0.607 to 0.997).

As a result of the JMEI trial, pemetrexed is considered a reasonable option to docetaxel for second-line therapy of metastatic NSCLC. It is considered to be a less toxic chemotherapy option than docetaxel by many physicians. It is unclear whether histology should be used to select between pemetrexed and docetaxel. However, there are substantial cost
differences between the two agents. There are no published economic analyses comparing pemetrexed to docetaxel, but economic considerations should be considered in the choice of second-line chemotherapy.

The maximum tolerated dose of pemetrexed was established prior to the routine implementation of supplementation with vitamin $B_{12}$ and folic acid. As a result of the routine use of vitamin supplementation, it became apparent that the dose of pemetrexed could be increased beyond 500 mg/m$^2$. Cullen et al.[32] undertook a randomized trial comparing a standard dose of pemetrexed with pemetrexed 900 mg/m$^2$. A total of 588 patients were randomized (pemetrexed 500 = 295, pemetrexed 900 = 293). Escalating the dose of pemetrexed did not result in any improvement in efficacy. The median survival for patients randomized to pemetrexed 500 mg/m$^2$ was similar to that of pemetrexed 900 mg/m$^2$ (6.7 months vs. 6.9 months; HR = 1.013; 95% CI, 0.837 to 1.226). There were no differences in time to progression (2.6 months vs. 2.8 months), or response rate (7.1% vs. 4.3%). Patients receiving the higher dose of pemetrexed received slightly fewer cycles of treatment (mean 4.3 cycles vs. 3.5 cycles) and required more dose reductions (4.2% vs. 1.1%). There was more grade 3 and 4 neutropenia (7.9% vs. 3.4%), anemia (5.8% vs. 4.5%), thrombocytopenia (5.4% vs. 2.8%), and elevated aspartate aminotransferase (AST) (1.3% vs. 0%) among patients randomized to the higher dose of pemetrexed. Based on these data, the standard dose of pemetrexed should remain 500 mg/m$^2$ every 3 weeks.

Another chemotherapeutic agent that has been evaluated as second-line therapy for NSCLC is oral topotecan.[33] A phase II trial of oral topotecan demonstrated response and survival data consistent with docetaxel.[34] Based on these data, Ramlau et al.[33] conducted a randomized trial of oral topotecan 2.3 mg/m$^2$ day 1 to 5 every 21 days versus D75. Dose escalation in subsequent cycles of topotecan was allowed in the absence of any grade 3 toxicity. The design of this trial was similar to that of other second-line chemotherapy trials except that patients who had received prior taxane were excluded. The trial had a noninferiority design assuming that the 1-year survival of oral topotecan was ≤10% worse than docetaxel. A total of 414 patients were randomized to receive topotecan and 415 to receive docetaxel. The objective response rate for both groups was 5%. The study met its primary outcome of noninferiority as the difference in 1-year survival was −3.6% (95% CI, 9.6% to 2.5%). However, there was a trend toward improved overall survival in favor of docetaxel (log rank $p$ = 0.0568). Furthermore, after adjustment for stratification variables, there was a significant improvement in survival for patients randomized to docetaxel (HR = 1.23; 95% CI, 1.06 to 1.44).

The available data suggest that oral topotecan may not be as effective as docetaxel. Despite demonstrating noninferiority in 1-year survival, trends in the overall survival favor docetaxel. Although the option of an oral agent has appeal, the efficacy concerns preclude widespread adoption of oral topotecan as second-line chemotherapy for NSCLC.

One additional trial compared second-line vinflunine, a vinca alkaloid, with docetaxel.[35] Vinflunine was administered at a dose of 320 mg/m$^2$ intravenously every 3 weeks, compared with D75 every 3 weeks. The trial was designed to show the PFS of vinflunine was noninferior to docetaxel (lower limit of 95% CI HR >0.755). All patients had received prior platinum-based chemotherapy and were stratified for type of prior chemotherapy (vinka alkaloid vs. paclitaxel vs. other), PS (0/1 vs. 2), and stage at diagnosis (IIIB vs. IV vs. other). Baseline characteristics were well balanced.

A total of 551 patients were randomized (vinflunine 274, docetaxel 277). The trial met its primary outcome of noninferiority for PFS of vinflunine compared with docetaxel (2.3 months vs. 2.3 months; HR = 1.004; 95% CI, 0.841 to 1.199; $p$ = 0.965). There were no differences between vinflunine and docetaxel in response rates (4.4% vs. 5.5%), or overall survival (6.7 months vs. 7.2 months; HR = 0.973; 95% CI, 0.805 to 1.176). There were differences observed in toxicity between the two arms. Patients randomized to vinflunine had more anemia, neutropenia, nausea, abdominal pain, and constipation, but less alopecia, nail changes, edema, and diarrhea than patients randomized to docetaxel. Although vinflunine provides another choice of second-line chemotherapy for NSCLC, its toxicity profile does not offer any clear advantages over existing second-line options, and it is unlikely to have a major impact on practice.

## COMBINATION CHEMOTHERAPY IN THE SECOND-LINE SETTING

In the *first-line* treatment of metastatic NSCLC, multiple trials have examined two-drug combinations versus single-agent chemotherapy. Metaanalyses of these trials demonstrate that the addition of a second agent improves response rates and overall survival.[36,37] Given these data, several investigators have evaluated the addition of a second chemotherapy drug for second-line therapy in NSCLC (Table 46.4).[38–43] As a rule, these trials have failed to demonstrate superiority of a two-drug combination over docetaxel.

Irinotecan combinations have been evaluated in five trials.[39–43] Two randomized phase II trials evaluated the addition of irinotecan to docetaxel.[42,43] Wachters et al.[43] randomized patients to receive D75, or docetaxel 60 mg/m$^2$ and irinotecan 200 mg/m$^2$ day 1 followed by lenograstim 150 mg/m$^2$ day 2 to 12, every 21 days. Pectasides et al.[42] used the standard schedule of docetaxel compared with docetaxel 30 mg/m$^2$ and irinotecan 60 mg/m$^2$ both on days 1 and 8, every 21 days. Neither trial showed an advantage to the combination arm. There were no differences in response, time to progression, or overall survival. Furthermore, both trials showed additional toxicity from the addition of irinotecan. This was predominantly more diarrhea in the combination arm. Therefore, the addition of irinotecan to docetaxel does not improve the therapeutic ratio of docetaxel and cannot be recommended.

CBX, celecoxib; ID, irinotecan docetaxel; IG, irinotecan gemcitabine; NR, not recorded; OR, objective response; PD, progressive disease; SD, stable disease; TTP, time to progression.

One randomized trial of first-line therapy for NSCLC showed marginal superiority for a docetaxel and cisplatin combination.[2] Therefore, in some parts of the world, docetaxel is routinely used in first-line chemotherapy combinations. The Helenic Oncology Research Group (HORG) has conducted two trials of second-line chemotherapy combinations in patients previously treated with docetaxel.[39,40] One trial randomized patients previously treated with cisplatin and docetaxel to receive irinotecan and gemcitabine, or irinotecan alone.[40] The second trial randomized patients previously treated with a taxane and gemcitabine to receive irinotecan and cisplatin, or irinotecan alone.[39] Gemcitabine plus irinotecan resulted in a significantly higher response rate than irinotecan alone. However, there was no improvement in survival in the combination arm of either trial. Neither of these trials included a control arm previously demonstrated to improve survival in the second-line setting; therefore, they do not add to the available second-line chemotherapy options for NSCLC.

In a phase II study, Lilenbaum et al.[41] randomized patients to receive docetaxel and irinotecan, or gemcitabine and irinotecan, with or without celecoxib. Survival in patients randomized to chemotherapy plus celecoxib was numerically *inferior* to chemotherapy alone (median 8.99 vs. 6.31 months, 1-year survival

36% vs. 24%). Survival in both the chemotherapy combination arms was similar to that expected from single-agent docetaxel or pemetrexed, suggesting little incremental benefit from the addition of irinotecan. Takeda et al.[44] evaluated the addition of gemcitabine to docetaxel in Japanese patients. They observed a high rate of interstitial lung disease (ILD) in the combination arm, with a 5% death rate from ILD. There was a slight numeric advantage for the combination arm in both response rate and overall survival, but this appeared to be too toxic a regimen to evaluate further in this population.

One additional trial evaluated the proteosome inhibitor bortezomib.[38] This trial randomized patients to bortezomib 1.5 mg/m² days 1, 4, 8, and 11, every 21 days versus D75 and bortezomib 1.3 mg/m² days 1, 4, 8, and 11, every 21 days. One hundred and fifty-five patients were included (bortezomib = 75, docetaxel and bortezomib = 80). Response rates were similar (8% vs. 9%), but there was a longer median time to progression for patients receiving the combination of bortezomib plus docetaxel (4.0 months vs. 1.5 months). Overall survival for the two groups was similar (median 7.8 vs. 7.4 months; 1-year survival 33.1% vs. 38.7%). There was more hematological toxicity associated with the combination arm, but the rate of nonhematological toxicity was similar between the groups. It is difficult

to comment about the role of bortezomib as a second-line treatment option for NSCLC as this trial did not include a standard arm of docetaxel alone. However, the results for the combination arm are similar to that expected from docetaxel alone, suggesting that bortezomib does not add significantly to the therapeutic efficacy of docetaxel. Therefore, for the present time, bortezomib remains an investigational treatment for NSCLC.

## WHAT IS THE ROLE OF EPIDERMAL GROWTH FACTOR RECEPTOR INHIBITORS AS SECOND-LINE THERAPY?

The trials described previously demonstrate a modest improvement in survival from second-line chemotherapy. Although second-line therapy with either docetaxel or pemetrexed improves outcomes for patients with NSCLC, there remains a need for additional treatment options for this group of patients. A greater understanding of the molecular abnormalities associated with NSCLC has led to the evaluation of new therapeutic targets for NSCLC. The EGFR is one targeted commonly overexpressed in NSCLC.[45–47] Early phase clinical trials showed that receptor tyrosine kinase inhibitors (TKIs) of the EGFR such as gefitinib and erlotinib had antitumor activity, and this prompted further evaluation in advanced NSCLC (Table 46.5) (see Chapter 49).[48]

Two randomized phase II trials were undertaken comparing two dose levels of gefitinib (250 vs. 500 mg daily) in patients considered not to be candidates for further chemotherapy.[49,50] The Iressa Dose Evaluation in Advanced Lung Cancer (IDEAL) 1 trial was conducted in Japan, Europe, South Africa, and Australia,[49] whereas the IDEAL 2 trial was

conducted primarily in the United States.[50] Very similar results were observed in both trials. There were no differences in the response rates for the 250- and 500-mg doses. Disease control rates as high as 54% were observed, and approximately 40% of patients demonstrated improvement in disease-related symptoms. The most significant improvements were observed in pulmonary symptoms such as shortness of breath, cough, and chest tightness.[51] The toxicity profile of gefitinib was different to that commonly seen with chemotherapy. The most common side effects included skin rash, pruritis, and diarrhea, but treatment was seldom discontinued for toxicity.

Around this same time, another EGFR TKI, erlotinib, was evaluated as a second- or third-line therapy for NSCLC. This phase III trial, conducted by the National Cancer Institute of Canada Clinical Trials Group (BR.21), randomized patients to erlotinib or placebo.[52] The intent of the trial was to evaluate erlotinib as a third-line treatment option for NSCLC, but also allowed patients who were not candidates for second-line docetaxel. Therefore, patients were eligible if they had received one or two prior chemotherapy regimens if they were not considered eligible for further chemotherapy. A total of 731 patients were randomized in a 2:1 ratio (488 erlotinib, 243 placebo). Approximately 50% of patients had received only one previous therapy prior to trial entry. In general, treatment was well tolerated. The side effects occurring significantly more commonly in the erlotinib arm compared with placebo were rash (76% vs. 17%), diarrhea (55% vs. 19%), anorexia (69% vs. 56%), stomatitis (19% vs. 3%), and infection (34% vs. 21%). The response rate to erlotinib was 8.9%. Erlotinib significantly improved the time to disease progression compared with placebo (2.2 months vs. 1.8 months; HR = 0.61; 95% CI, 0.51 to 0.74). A significant improvement in survival was also observed for patients receiving erlotinib (6.7 months vs. 4.7 months; HR = 0.70; 95% CI, 0.58 to 0.85; Fig. 46.3). Subgroup analyses of these data suggest that there were no subgroups in which a survival benefit was not apparent. The benefit was similar for patients receiving erlotinib as second- or third-line therapy. Additionally, a benefit was seen in patients with poor PS as well as good PS. In a multivariate analysis, variables associated with improved survival in addition to therapy with erlotinib included adenocarcinoma histology, Asian origin and never having smoked.

QOL analyses demonstrate that patients randomized to erlotinib experienced improved QOL compared with the placebo group.[53] QOL was assessed with the European Organisation for Research and Treatment of Cancer (EORTC) QLQ30 and the EORTC QLQ-LC13. The primary QOL analysis examined time to symptom deterioration. Patients randomized to erlotinib had significantly longer time to deterioration in cough (4.9 vs. 3.7 months, $p = 0.04$), dyspnea (4.7 vs. 2.9 months; $p = 0.04$), and pain (2.8 vs. 1.9 months; $p = 0.03$). Statistically significant differences favoring erlotinib were seen for physical functioning, pain, cough, dyspnea, and constipation. Patients achieving an objective

response to therapy were more likely to demonstrate QOL improvements.

The results of the IDEAL 1 and 2 trials resulted in regulatory approval of gefitinib in many countries including the United States. However, the Food and Drug Administration (FDA) requested additional postmarketing studies, including a placebo-controlled randomized trial to assess the survival advantage of gefitinib in the second- and third-line setting. The ISEL trial randomized patients who had received one or two prior chemotherapy regimens to gefitinib 250 mg daily or placebo.[54] The inclusion criteria were similar to the National Cancer Institute of Canada Clinical Trials Group (NCIC CTG) BR.21 trial with the exception that patients were required to

be refractory to (progressed within 90 days), or intolerant of their last chemotherapy. ISEL randomized 1692 patients (gefitinib 1129, placebo 563). The trial failed to demonstrate a significant improvement in survival for patients randomized to gefitinib (Fig. 46.4). The median survival for gefitinib was 5.6 months versus 5.1 months for control (HR = 0.89; 95% CI, 0.77 to 1.02). There was a slightly greater benefit in the predefined subpopulation of patients with adenocarcinoma, although this difference still did not achieve statistical significance (HR = 0.84; 95% CI, 0.68 to 1.03). Subgroup analyses did, however, show significant improvements in survival among patients of Asian origin (HR = 0.66; 95% CI, 0.48 to 0.91; $p = 0.01$)[55] and never-smokers (HR = 0.67; 95% CI, 0.49 to 0.92; $p = 0.012$).

Different interpretations have been made of results from the ISEL trial. One interpretation is that gefitinib is less effective than erlotinib given it did not improve survival in the second- and third-line setting of NSCLC. Others have suggested that the outcome may have been better had a higher dose of gefitinib been used. However, the results of the two IDEAL trials do not support this hypothesis. An alternative explanation is that the differences in outcomes between the NCIC CTG BR.21 and ISEL trials may have resulted from differences in the inclusion criteria between the two trials. Limiting the ISEL trial to refractory patients only, may have inadvertently selected a group of patients less likely to benefit from any therapeutic intervention. Nevertheless, following release of the ISEL data, several regulatory authorities, including the U.S. FDA modified gefitinib's licence, effectively removing the drug from the market.

Patient and tumor characteristics associated with improved *response* to EGFR TKIs include female gender, adenocarcinoma histology, Asian origin, and absence of smoking history. However, there is not a direct correlation between clinical factors associated with response to treatment and factors associated with improved *survival*, and patients without these characteristics (males, smokers, squamous cell carcinoma) can also respond to EGFR inhibition, as seen in the BR.21.[52] There has also been extensive translational research to better understand the molecular predictors of response and survival in patients treated with EGFR TKIs. This topic is covered in more details in Chapter 49. At the laboratory level, EGFR status, whether defined as EGFR protein expression, *EGFR* gene copy number or *EGFR* mutation status, has been shown to influence response and survival benefit in patients treated with erlotinib and gefitinib.[56–58] More recently, markers of resistance have also been identified including the T790M mutation on *EGFR* exon 20 and the presence of *KRAS* mutations.

In conclusion, erlotinib represents a third option for treatment of NSCLC after failure of platinum-based chemotherapy, and is approved as a second- or third-line therapy in many countries worldwide. It is important to emphasize that in both of the large randomized trials of erlotinib and gefitinib, patients who were treated as second-line therapy were considered unsuitable for further chemotherapy. By definition, this is a more restrictive population of patients that were included in the trial of second-line docetaxel and pemetrexed. Although the magnitude of benefit from erlotinib is similar to that of second-line docetaxel or pemetrexed, there are methodological issues that limit the ability to make direct comparisons between trials with the available data. Direct comparisons are needed to help identify the best way in which to sequence chemotherapy and EGFR TKI therapy and to determine whether it is appropriate to use EGFR TKIs as second-line treatment in patients who are fit for chemotherapy. The selection of patients for therapy based on molecular characteristics awaits prospective biomarker validation trials.

## COMPARISON OF SECOND-LINE CHEMOTHERAPY AND EGFR TKI

Several second-line therapy trials comparing an EGFR TKI with docetaxel have recently been reported.[59–61] As a result, the issue of sequencing of therapy following failure of platinum-based chemotherapy is much clearer. Cufer et al.[59] reported the results of a randomized phase II trial comparing D75 with gefitinib 250 mg daily. The SIGN trial was a multicenter trial whose primary outcome evaluated symptom improvement using the Lung Cancer Subscale (LCS) of the Functional Assessment of Cancer Therapy–Lung (FACT-L). Additional outcomes included total scores measured by FACT-L, response rate and overall survival. Patients who received prior taxane therapy were ineligible. A total of 68 patients were randomized to gefitinib and 73 to docetaxel. Compliance in completing QOL questionnaires was more than 85%. Symptom improvement on the LCS was defined as >2 point increase in scores. More patients randomized to gefitinib demonstrated symptom improvement assessed by LCS (38.8% vs. 26%). Similar differences were seen with the overall FACT-L scores. Response rates for gefitinib were similar to docetaxel (13.2% vs. 13.7%), and there were no differences seen in overall survival (median 7.5 months vs. 7.1 months). There were fewer drug-related adverse events for patients receiving gefitinib (51.5% vs. 78.9%).

The SIGN trial suggested that gefitinib was similarly effective and associated with better QOL. However, it was underpowered to make firm conclusions about the relative effectiveness of an EGFR TKI and second-line chemotherapy. Two phase III trials of similar design were reported in 2007.[60,61] The V-15-32[61] trial in Japan and Iressa Non–small cell lung cancer Trial Evaluating REsponse and Survival against Taxotere (INTEREST)[60] trial done internationally were both phase III noninferiority trials comparing gefitinib with docetaxel. In the V-15-32 trial, 489 Japanese patients were randomized to gefitinib 250 mg daily (n = 245) or docetaxel 60 mg/m$^2$ every 21 days (n = 244). The predefined criterion for noninferiority was an HR ≤1.25. Patients randomized to gefitinib demonstrated a significantly higher response rate (22.5% vs. 12.8%, $p$ = 0.009). PFS for gefitinib was similar to docetaxel (2 vs. 2 months; HR = 0.90; 95% CI, 0.72 to 1.12). However, the median survival of docetaxel was 14 months compared with 11.5 months for gefitinib and the trial failed to demonstrate noninferiority in the overall survival of gefitinib compared with docetaxel (HR = 1.12; 95% CI, 0.89 to 1.40). Significantly, more patients randomized to gefitinib demonstrated symptom improvement assessed by FACT-L (23.4% vs. 13.9%; $p$ = 0.023). An important distinction in the V-15-32 trial is that there were differences in the rate of further therapy following disease progression. Fifty-three percent of patients randomized to docetaxel received gefitinib at the time of progression, whereas only 36% of patients randomized to gefitinib received docetaxel on progression. This difference may explain the small difference in overall survival observed between the groups.

The INTEREST trial[60] presented at the 2007 IASLC World Conference provides a clearer answer to the question of second-line EGFR TKI or chemotherapy. This trial randomized 1466 patients to receive gefitinib or placebo. The trial was designed to demonstrate that the survival of patients randomized to gefitinib was not inferior to that of docetaxel (HR <1.154). Based on emerging data from translational research, a coprimary outcome was added that gefitinib was superior to docetaxel in patients who had high EGFR gene copy number as measured by fluorescent in situ hybridization (FISH). Baseline characteristics were well matched between the groups. The likelihood of response to therapy was similar for gefitinib and docetaxel (9.1% vs. 7.6%; $p$ = 0.33). PFS was also very similar for the two groups (2.2 vs. 2.7 months; HR = 1.04; 95% CI, 0.93 to 1.18). The trial met its primary outcome of noninferiority for survival. The median survival for gefitinib was 7.6 months compared with 8.0 months for docetaxel (HR = 1.02; 95% CI, 0.905 to 1.150). One-year survival was almost identical for the two groups (32% vs. 34%). There was no subgroup in which survival favored gefitinib over docetaxel including patients who were EGFR-FISH positive.

Differences were observed in QOL measures between the two groups. A greater proportion of patients randomized to gefitinib demonstrated improvement in total FACT-L scores (25.1% vs. 14.7%; $p$ <0.001), and the trial outcome index (17.3% vs. 10.3%; $p$ = 0.0026). More patients showed improvement in the LCS (20.4% vs. 16.8%; $p$ = 0.13) but this did not achieve statistical significance. Patients on gefitinib experienced more rash and diarrhea, whereas patients on docetaxel experienced more hematological toxicity, asthenia, alopecia, and neurotoxicity.

However, INTEREST did not show superiority for gefitinib in the coprimary outcome. EGFR gene copy number was assessed centrally in patients with available tissue. Among patients with high EGFR gene copy number, there were no significant differences between gefitinib and docetaxel patients in PFS (HR = 0.84; 95% CI, 0.59 to 1.19) or overall survival (HR = 1.09; $p$ = 0.62). There was no evidence of any differential effect on survival between gefitinib and docetaxel for any of the biomarkers examined (EGFR-FISH, EGFR protein expression, *EGFR* mutations, *KRAS* mutations).

Unlike the V-15-32 trial, the proportion of patients receiving further therapy following progression of their disease was similar between the two groups. Just over half of patients received no further therapy upon progression. Among patients randomized to docetaxel, 37% received an EGFR TKI upon progression and 31% of patients randomized to gefitinib received docetaxel at the time of progression. This balance in subsequent therapy may explain the nearly identical survival in INTEREST in comparison with the Japanese trial.

Based on the results of the INTEREST trial, we now have direct evidence that second-line therapy of NSCLC with an EGFR TKI will result in survival outcomes similar to that achieved with second-line chemotherapy. Available data do not support the use of clinical characteristics (females, adenocarcinoma, Asian origin, never-smokers) to select therapy. The important lesson inferred from the comparison of INTEREST

and the Japanese trial is that the sequence of therapy is probably not as important as maximizing the delivery of third-line therapy as well. Therefore, second-line therapy with an EGFR TKI should not be thought of as a means of avoiding further chemotherapy, except for patients whose clinical condition declines to a point where further therapy is unlikely to produce meaningful benefit.

## COMBINATIONS OF TARGETED AGENTS WITH CHEMOTHERAPY

Combining EGFR TKIs with chemotherapy in the second-line therapy is not an appealing strategy. Four trials have evaluated either erlotinib or gefitinib in combination with first-line chemotherapy and failed to show any improvement in progression or survival outcomes.[62–65] However, inhibition of VEGF in combination with first-line chemotherapy has shown improvement in survival.[66] Evaluation of this approach is, therefore, also warranted in the second-line treatment of NSCLC. Initial investigation of this approach has shown promise. Two randomized phase II trials have shown improvements in intermediate outcomes.[67,68] Heymach et al.[68] undertook a randomized phase II trial of docetaxel alone, or in combination with two dose levels of vandetanib. Vandetanib is an oral receptor TKI known to inhibit both EGFR and VEGFR. Patients received standard doses of docetaxel, docetaxel plus vandetanib 100 mg daily, or docetaxel plus vandetanib 300 mg daily. One hundred and twenty-seven patients were randomized. Higher response rates were seen with the combination of docetaxel and vandetanib 100 mg (26%) or vandetanib 300 mg (18%) than with docetaxel alone (12%). The primary outcome of this phase II trial was PFS. PFS was longer in the vandetanib 100-mg arm (18.7 weeks) and 300-mg arm (17 weeks) than docetaxel alone (12 weeks). Based on the results of this trial, a randomized phase III trial of docetaxel versus docetaxel plus vandetanib 100 mg daily has been conducted. A total of 1391 patients were randomized (D = 694, DV = 697). There was a significant improvement in response rate (17% vs. 10%; $p$ <0.001) and PFS (HR = 0.79; 97% CI, 0.70–0.90; $p$ <0.001). There was no significant improvement in overall survival (HR = 0.91; 97% CI, 0.78–1.07, $p$ = 0.20).[69]

An additional randomized phase II trial has evaluated bevacizumab in combination with second-line therapies. Bevacizumab is a monoclonal antibody against circulating VEGF-A. It has been shown to improve activity of first-line chemotherapy.[66] Herbst et al.[67] conducted a randomized phase II trial of docetaxel alone, docetaxel plus bevacizumab, and erlotinib plus bevacizumab. One hundred and twenty-two patients were randomized. The combination of bevacizumab with docetaxel, or bevacizumab with erlotinib appeared more active than docetaxel alone. The median PFS for docetaxel (3.0 months) was less than docetaxel plus bevacizumab (4.8 months) or erlotinib plus bevacizumab (4.4 months). Similar differences were seen for overall survival (8.6 vs. 12.6 vs. 13.7 months). This trial has also moved on to a confirmatory

phase III comparison. The BETA trial randomized patients to erlotinib plus bevacizumab, or erlotinib plus placebo. There were 636 patients randomized. A significant improvement in PFS was observed in favour of the combination therapy (3.4 vs. 1.7 months; $p$ <0.0001; HR = 0.62; 95% CI, 0.52–0.75). However, the results from this trial did not confirm the survival analysis from the randomized phase II trial. No differences were observed in overall survival between the two groups (9.3 months [B + E] vs. 9.2 months [E]; $p$ = 0.75; HR = 0.97; 95% CI, 0.80–1.18).[70]

Although the addition of drugs inhibiting VEGF, or VEGFR holds promise for improved efficacy of second-line treatment approaches, these agents have toxicities not typically associated with cytotoxic agents. Common adverse events include hypertension, hemorrhage, fatigue, and diarrhea. As these agents gain greater use in the treatment of NSCLC, oncologists will need to carefully consider these differing toxicities in selecting patients for appropriate therapy.

## CONCLUSION

The last decade has seen a rapid expansion of second-line therapies in NSCLC. We have moved from a situation where there was insufficient information to recommend the routine use of second-line therapy, to one where there are now multiple agents available, with survival gains demonstrated for second as well as third-line options. Docetaxel, pemetrexed, and erlotinib are all approved for use in NSCLC in many countries. Data exist for the use of gefitinib as well; however, this agent is not currently available in many non-Asian parts of the world. The important issue for oncologists treating NSCLC is to select patients appropriately to ensure that as many patients as possible have the opportunity to consider both second- and third-line treatment options. Treatment decisions should reflect careful consideration of the toxicity profile of the agents together with individual patient preferences. The importance of economic considerations varies from region to region, but the issue should not be avoided given the cost of many of these new agents.

Therapeutic options following progression from platinum-based chemotherapy is an area of intense clinical trial activity. Multiple classes of agents are under evaluation. Oncologists should be encouraged to seek out clinical trial opportunities to ensure that we continue to advance the treatment of second and subsequent lines of therapy for NSCLC over the next decade.

# Pharmacogenomics in Lung Cancer: Predictive Biomarkers for Chemotherapy

Commonly used platinum-based chemotherapy regimens have shown comparable activity in randomized studies of advanced stage non–small cell lung cancer (NSCLC) patients.[1–3] In a similar fashion, both platinum/etoposide and platinum/irinotecan are highly active in the frontline treatment of small cell lung cancer (SCLC).[4,5] However, outcomes vary greatly among individual patients with the same histology, ranging from a best response of complete remission (CR) to that of progressive disease (PD). Despite the introduction of new chemotherapy drugs and molecular targeted agents in recent years, therapeutic outcomes in lung cancer patients remain poor; thus, there is a critical need for development of predictive factors to optimize selection of chemotherapy regimens for both NSCLC and SCLC and in advanced and early stages. Equally important, predictive molecular biomarkers of efficacy and toxicity could also reduce chemotherapy-related toxicity by eliminating those patients least likely to benefit, as well as those predicted to have unacceptable levels of toxicity.

Although clinical prognostic factors for lung cancer are well established, they do not provide the basis for selection of chemotherapy in individual patients. A pooled analysis by Mandrekar et al.[6] of 1053 patients with advanced-stage NSCLC undergoing first-line chemotherapy showed that gender, age, performance status, and hematologic parameters were significant predictors of severe adverse events. In another analysis, the incidence of grade 3 and 4 neutropenia was associated with advanced age (odds ratio = 7), low baseline white blood cell count (odds ratio = 5), and chronic hepatitis B or C virus infection (odds ratio = 3) in patients with advanced NSCLC undergoing second-line chemotherapy with docetaxel.[7] Thus, clinical parameters such as performance status or age are commonly used by the practicing oncologist to decide which patients may not be suitable for standard chemotherapy approaches or who may need upfront dose reduction. On the other hand, when Borges et al.[8] analyzed the potential predictive value of 22 clinical factors, including tumor histology, to predict tumor response following first-line chemotherapy in 1052 patients with NSCLC, none of the clinical factors accurately predicted response. Pursuing an alternative approach, Shaw et al.[9] prospectively collected tumor tissue from 165 patients with NSCLC and SCLC, tested the chemosensitivity of tumor cells in vitro, and assigned individualized therapy based on these results. Despite efficient specimen collection (viable tumor specimens were available for 98% of the patients) and state-of-the-art culture methodology, only 28% of the patients received individualized chemotherapy based on laboratory results. This disappointing result precluded the comparison between treatment arms as well as the correlation between in vitro and clinical response to specific drugs. Although other groups have reported more optimistic results, in vitro drug sensitivity testing remains challenging and is not broadly accepted for clinical application at present.[10–12]

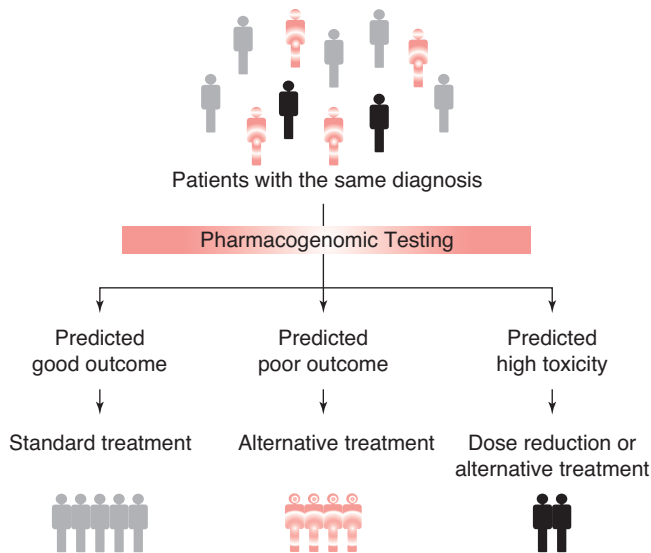
Conversely, a biomolecular approach to individualized chemotherapy, attempting to exploit individual patient differences in underlying tumor or host biology, is emerging as a more promising strategy for personalizing therapy (Fig. 47.1). The field of pharmacogenomics originated from the observation that inheritance plays an important role in individual variation in drug metabolism and disposition. In a broader sense, pharmacogenomics incorporates the entirety of molecular factors that modify drug activity and toxicity in individual patients. The development of this field occurred in parallel with recent advances in genomic science.[13,14] Although the principle of individualizing chemotherapy for lung cancer patients is not new, the tools available to implement such an approach have previously been limited. Unfortunately, although clinical characteristics can give some insight into likelihood of response (i.e., the associations between female gender and good performance status with a higher response rate), they cannot reliably predict an individual patient's response to chemotherapy. Similarly, past attempts at in vitro drug sensitivity testing have identified significant problems with the feasibility and reproducibility of this approach. Recent advances in genomic technologies and our understanding of the molecular mechanisms of chemotherapy, however, have brought forward several promising biomarkers with prognostic and/or predictive potential. Also, significant contributions toward a comprehensive understanding of the genetic variations underlying individual differences in drug metabolism have been made. In the near future, these advances


**FIGURE 47.1** Concept of individualized chemotherapy. Activity and tolerability of chemotherapy varies among individual patients. Pharmacogenomic testing has the potential to predict who is likely to benefit from a specific drug (or drug combination) and who will have no benefit or may even be harmed by this treatment. Customized therapy may thus ultimately improve patient outcome.

are expected to impact on clinical decision making and ultimately improve the outcome of patients with lung cancer.

In this chapter, two distinct aspects of pharmacogenomics are reviewed: (a) tumor-related factors including molecular drug targets that regulate the biochemical and physiological effects of drugs and their mechanisms of action and (b) host-related factors including metabolizing enzymes and transporters that regulate drug metabolism and disposition.

## TUMOR-RELATED FACTORS: SINGLE-GENE BIOMARKERS

**Biomarkers of Platinum Resistance** The backbone of systemic treatment for both NSCLC and SCLC remains platinum-based chemotherapy.[5,15] Among the platinum compounds, cisplatin (cis-diammine-dichloro-platinum, CDDP) is reported to have superior activity over carboplatin in NSCLC, in terms of response rate and, in patients with nonsquamous tumors, survival.[16] The mode of action for cisplatin relates to the aquation equilibrium, a process by which a chloride ligand of cisplatin is displaced with water, allowing cisplatin to cross-link DNA via displacement of its second chloride ligand.[17] The leaving ligand for carboplatin (cis-1,1-cyclobutanedicarboxylato-diammineplatinum[II]) is bidentate cyclobutane dicarboxylate (CBDCA); whether there are consequences of this difference for biomarker development remains to be determined. Cross-linked DNA activates the nucleotide excision repair (NER) machinery, which includes a large complex consisting of at least 30 proteins, including ERCC1 (excision repair cross-complementing rodent

repair deficiency, group 1), XPA (xeroderma pigmentosa group A), XPB/ERCC3, XPC, XPD/ERCC2, XPF/ERCC4, XPG/ERCC5, Cockayne syndrome protein A (CSA/ERCC8), CSB/ERCC6, and others (Fig. 47.2).[18,19] If repair proves inadequate, NER triggers apoptosis. Thus, it is the balance between DNA damage and repair that determines the fate of cancer cells exposed to platinum. ERCC1, which forms a heterodimer with XPF, appears to be the rate-limiting step in NER, hence, its implication in platinum resistance. In preclinical models, ERCC1 levels correlated with the removal capacity of the cisplatin-induced DNA adducts as well as the relative cisplatin resistance.[20–22] ERCC1-knockout cells were highly sensitive to DNA cross-linking agents, and transfection with ERCC1 exhibited an increase in the DNA repair capacity and cisplatin resistance.[23,24]

In view of these preclinical data, ERCC1 has emerged as an attractive single gene target in biomarker development for platinum-based chemotherapy. Indeed, clinical translation of these findings is highlighted by results in both advanced-stage NSCLC as well as in the adjuvant chemotherapy setting. In 2002, Lord et al.[25] first reported that ERCC1 messenger RNA (mRNA) expression was significantly associated with response to cisplatin/gemcitabine chemotherapy in patients with advanced-stage NSCLC.

**FIGURE 47.2** Molecular mechanisms of nucleotide excision repair (NER). DNA cross-linking by cisplatin (Pt) is recognized by XPC-R23, which recruits other proteins to form the active NER-complex. Only a few of these proteins are depicted here. For example, TFIIH unwinds the DNA, and ERCC1-XPF plus XPG cut out the damaged DNA strand. The gap is filled by polymerases (POL) and the ends are connected by ligases. These events restore the configuration of the damaged DNA strand. *ERCC1*, excision repair cross-complementing 1; *POL*, polymerase; *RPA*, replication protein A; *TFIIH*, transcription factor IIH; *XP*, xeroderma pigmentosum.

The genomic international lung trial (GILT) of customized chemotherapy by the Spanish Lung Cancer Group also demonstrated the predictive value of ERCC1 for platinum-based chemotherapy but tested the role of nonplatinum chemotherapy as well.[26] In this prospective phase III trial of individualized chemotherapy, 444 patients with previously untreated advanced NSCLC were randomized in a 1:2 ratio to either a control arm of docetaxel/cisplatin or a genotypic arm in which treatment was assigned based on the level of tumor ERCC1 mRNA expression, quantified by real-time reverse transcription polymerase chain reaction (RT-PCR). Patients in the genotypic arm, with tumors expressing ERCC1 mRNA levels lower than the median, received docetaxel plus cisplatin, whereas those with higher levels received docetaxel plus gemcitabine. With a significantly better response rate in the genotypic arm compared with the control arm (51.2% vs. 39.3%; $p = 0.02$), the study reached its primary end point. In multivariate analysis, low ERCC1 was an independent predictor of tumor response to cisplatin (Fig. 47.3). Neither median progression-free survival (PFS) (6.1 vs. 5.2 months; hazard ratio [HR] = 0.9; $p = 0.30$), nor overall survival (OS) was significantly different between the control and genotypic arm overall. However, there were interesting differences in outcomes between ERCC1-negative and -positive patients within the genotypic arm. Although response rates in the genotypic arm were relatively similar between ERCC1-negative patients treated with docetaxel/cisplatin (53%) versus the ERCC1-positive group receiving docetaxel-gemcitabine (47%), both PFS (6.7 vs. 4.7 months) and OS (10.3 vs. 9.4 months) were numerically higher in the ERCC1-negative group. These results suggest that although ERCC1-negative patients do well with platinum-based therapy, alternatives may be needed for the ERCC1-positive group, which extend beyond currently available nonplatinum regimens, such as that, used in this trial. The prognostic and predictive value of ERCC1 protein expression, assessed by immunohistochemistry, was reported by the International Adjuvant Lung Cancer Trial Biologic Program (IALT-Bio), a correlative science component of the IALT phase III trial testing adjuvant chemotherapy in early stage NSCLC reported (Fig. 47.4).[27] The previously reported prognostic value of ERCC1 expression was confirmed in the control arm of IALT (surgery only), where ERCC1 positivity was associated with longer survival (HR = 0.66; 95% CI, 0.49 to 0.90; $p = 0.009$) compared with ERCC1 negativity. In the chemotherapy arm of IALT, only patients with ERCC1-negative tumors benefited from treatment (ERCC1-negative tumors: HR = 0.65; 95% CI, 0.50 to 0.86; $p = 0.002$), demonstrating the predictive value of this biomarker (ERCC1-positive tumors: HR = 1.14; 95% CI, 0.84 to 1.55; $p = 0.40$). These findings raise the question of whether patients with ERCC1-positive tumors would benefit from alternative therapies, such as nonplatinum-based chemotherapy regimens, or whether they would be best served by receiving no chemotherapy at all.

Ribonucleotide reductase M1 (RRM1) is the regulatory subunit of ribonucleotide reductase, which provides deoxyribonucleotides for de novo DNA synthesis and DNA repair. Gemcitabine, a nucleoside analogue that replaces cytidine during DNA replication, inhibits RRM1. High expression levels of RRM1 have been associated with gemcitabine resistance in NSCLC cell lines.[28] Thus, RRM1 and ERCC1 may cooperate in resistance to platinum-based chemotherapy, especially platinum–gemcitabine combinations. In a study of 70 patients with advanced NSCLC, mRNA expression levels of ERCC1 and RRM1 (r = 0.624; $p <0.001$) were strongly correlated, and for the 33 patients treated with cisplatin plus gemcitabine, concomitant low levels of ERCC1 and RRM1 were predictive of better survival (14.9 vs. 10.0 months; $p = 0.03$).[29] Bepler et al.[30] in advanced NSCLC demonstrated that RRM1 mRNA expression correlated with tumor response from carboplatin plus gemcitabine. A prospective phase II trial (MADEIT) conducted by Simon et al.[31] tested the feasibility and efficacy of patient selection for chemotherapy based on tumor ERCC1 and RRM1 mRNA levels. Median expression values were used to separate patients into four groups and patients were treated accordingly, with gemcitabine plus carboplatin (RRM1 low, ERCC1 low), gemcitabine plus docetaxel (RRM1 low, ERCC1 high), docetaxel plus carboplatin (RRM1 high, ERCC1 low), or docetaxel plus vinorelbine (RRM1 high, ERCC1 high). A median survival of 13.3 months was achieved, comparing favorably with previous results at the same institution and suggesting the clinical applicability of this approach. Zheng et al.[32] used a newly developed fluorescence staining methodology for automated quantitative protein expression analysis (AQUA) to evaluate both ERCC1 and RRM1 protein in 187 patients with surgically resected NSCLC. RRM1 and ERCC1 expression were significantly correlated (r = 0.3; $p = 0.001$). With a median survival of 120 months, the 55 patients with concomitant high levels of RRM1 and ERCC1 lived significantly longer than other subgroups ($p = 0.02$). Based on the data reviewed previously, the Southwest Oncology Group will investigate the prognostic and predictive role of ERCC1 and RRM1 assessed by AQUA for adjuvant chemotherapy in patients with resected stage I NSCLC in a feasibility study, S0720.[33] Patients with concomitantly high tumor levels of ERCC1 and RRM1 will receive no adjuvant chemotherapy, based on a good prognosis and predicted poor outcome from platinum chemotherapy, whereas all other patients will receive adjuvant chemotherapy with gemcitabine and cisplatin. Because adjuvant chemotherapy is not standard of care in stage I disease, this group is appropriate for such a study.[34]

| | | | HR | P value |
|---|---|---|---|---|
| Control arm | → | CDDP/Doc | 1 | |
| Genotypic arm | | | 1.59 | 0.02 |
| ERCC1 low | → | CDDP/Doc | 1.77 | 0.03 |

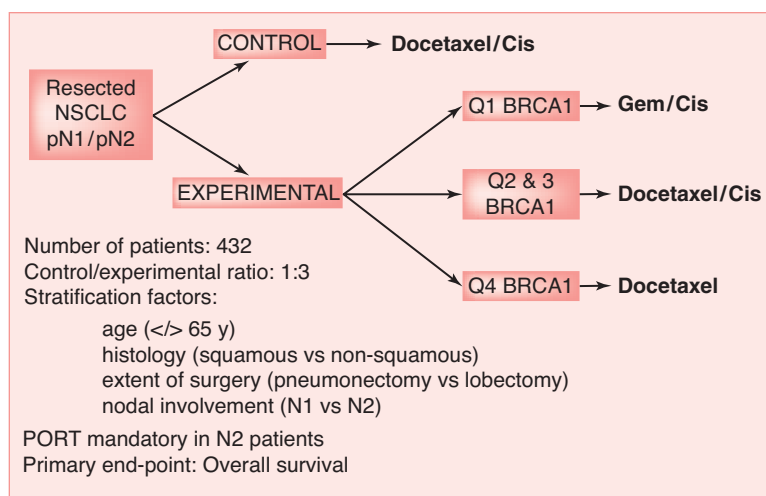
The primary end point is feasibility, gauged by the percentage of patients in which a tumor specimen can be collected in a group-wide setting, assessed by AQUA, and results applied for treatment assignment.

Another emerging factor in platinum resistance is BRCA1 (breast cancer 1, early onset). Although the involvement of BRCA1 in hereditary breast cancer and other malignancies is well known, other functions of this gene are still incompletely understood. A particular feature of BRCA1-deficient cells, as well as many cells showing a defect in homologous recombination, is sensitivity to the DNA cross-linking agents.[35] In breast cancer cells, the absence of BRCA1 results in high sensitivity to cisplatin; conversely, BRCA1 expression increased sensitivity to antimicrotubule agents.[36] Based on these findings, Taron et al.[37] used real-time quantitative PCR (RTqPCR) to measure BRCA1 expression in 55 surgically resected tumors of patients with NSCLC who had received neoadjuvant gemcitabine/cisplatin chemotherapy. In this study, patients with low BRCA1 expression levels had better outcomes than those with high levels. More

recently, Rosell et al.[38] studied the prognostic impact of BRCA1 expression in 126 specimens of resected early stage NSCLC. In this study, patients with high tumor expression of BRCA1 had significantly poorer survival. These results, taken together, led the Spanish Lung Cancer Group to initiate a pilot study of customized adjuvant chemotherapy based on BRCA1 mRNA levels in resected stage II to IIIA NSCLC patients, where adjuvant chemotherapy was customized based on BRCA1 mRNA levels in 84/100 completely resected N1 and N2 NSCLC patients. A total of 11 with high BRCA1 levels received docetaxel (doc); 29 patients with intermediate BRCA1 levels received doc/cisplatin (cis); 44 patients with low BRCA1 levels received cis/gemcitabine (gem). As of American Society of Clinical Oncology (ASCO) 2008, median survival had not been reached in patients with high or intermediate BRCA1 levels, although it was 25.6 months (m) in patients with low levels ($p = 0.04$). In a multivariate analysis for survival in all 84 patients, the HR were 5.23 for patients with high BRCA1 levels ($p = 0.07$) and 3.57 for patients with tumor size >4 cm ($p = 0.07$). In the multivariate

**FIGURE 47.5** Schema for the SCAT (Spanish customized adjuvant treatment in completely resected N1 and N2 non–small cell lung cancer) trial showing customized BRCA1 adjuvant treatment. See text for details. *BRCA1*, breast cancer 1; *Cis*, cisplatin; *Gem*, gemcitabine; *NSCLC*, non–small cell lung cancer; *PORT*, postoperative radiation therapy.



analysis of 42 N2 patients, the HRs were 0.13 for 18 patients receiving postoperative radiotherapy ($p = 0.04$) and 22 for 15 patients with intermediate or high BRCA1 levels ($p = 0.01$). These interim analyses were interpreted to reveal that single-agent doc had no detrimental effect on survival in comparison with doc/cis. In addition, high BRCA1 mRNA expression could be a poor prognostic marker.[39]

These encouraging results led the Spanish Lung Cancer Group to initiate the ongoing Spanish customized adjuvant trial (SCAT) study. This phase III randomized study is testing the concept of customized adjuvant chemotherapy based on BRCA1 mRNA levels in completely resected stages II to IIIA NSCLC patients. (Fig. 47.5)

In summary, ERCC1, RRM1, and BRCA1 are, at present, the most promising single predictive biomarkers for patients with NSCLC planning to undergo platinum-based chemotherapy (Table 47.1).[25–27,29–31,37,40–46] At least in the adjuvant setting, additional testing for the cell cycle regulator

| TABLE 47.1 | Markers for Platinum Resistance in NSCLC | | | | |
|---|---|---|---|---|---|
| **Marker** | **Stage** | **Chemotherapy** | **Correlation** | **N** | **Method** |
| ERCC1 | IIIB/IV | Cis/gem[25] | Low ERCC1 and good survival | 56 | RTqPCR |
| | IIIB/IV | Cis/gem[46] | None | 33 | IHC |
| | I–IIIA | Adjuvant platinum based (IALT)[27] | Low ERCC1 and survival benefit with chemotherapy | 761 | IHC |
| | Recurrence after surgery | Platinum based[41] | Low ERCC1 and good survival | 67 | IHC |
| | IIIB/IV | Platinum based[42] | None | 66 | RTqPCR |
| | III | Neoadjuvant platinum based[43] | Low ERCC1 and tumor response | 35 | IHC |
| | IV | Customized (GILT)[26] | Low ERCC1 and tumor response | 444 | RTqPCR |
| ERCC1 +RRM1 | IIIB/IV | Gem based[44] | Low RRM1/ERCC1 and good survival | 100 | RTqPCR |
| | IIB–IIIB | Neoadjuvant cis/gem[45] | Low RRM1 and tumor response | 67 | RTqPCR |
| | IIIB/IV | Cis/gem[29] | Low RRM1/ERCC1 and good survival | 70 | RTqPCR |
| | IIIB/IV | Customized (MADE IT)[31] | RRM1 and ERCC1 coexpression | 55 | RTqPCR |
| RRM1 | Inoperable II–III | Gem/carb[30] | Low RRM1 and tumor response | 40 | RTqPCR |
| p27[KIP1] | I–IIIA | Adjuvant platinum based (IALT)[47] | Low p27[KIP1] and survival benefit with chemotherapy | 778 | IHC |
| BRCA1 | III | Neoadjuvant cis/gem[37] | Low BRCA1 and poor survival | 55 | RTqPCR |
| p53 | IB–II | Adjuvant cis/vin (BR.10)[48] | High p53 and greater survival benefit with chemotherapy | 253 | IHC |

Modified from Gautschi O, Mack PC, Davies AM, et al. Pharmacogenomic approaches to individualizing chemotherapy for non-small cell lung cancer: current status and future directions. *Clin Lung Cancer* 2008;9(Suppl 3):S129–S138.

BRCA1, breast cancer 1, early onset; carb, carboplatin; cis, cisplatin; ERCC1, excision repair cross-complementing rodent repair deficiency complementation group 1; gem, gemcitabine; GILT, genomic international lung trial; IALT, International Adjuvant Lung Cancer Trial; IHC, immunohistochemistry; RTqPCR, reverse transcription quantitiative polymerase chain reaction; RRM1, ribonucleotide reductase M1; vin, vinorelbine.

$p27^{KIP1}$ and for p53 may provide further important information, as suggested by IALT and JBR.10 trial results.[47,48] Thus, future efforts should focus on the integration of these markers into robust predictive models.

**Biomarkers for Antimitotic Drugs** Paclitaxel and docetaxel bind to the beta subunit of tubulins, block microtubule disassembly, and lead to mitotic arrest and cell death.[49] Conversely, vinca alkaloids bind tubulin but prevent microtubule polymerization, promote depolymerization, and lead to metaphase blockade.[50] In humans, at least six distinct beta-tubulin classes (I, II, III, IVa, IVb, and VI) exist. Expression of class III beta tubulin (TUBBIII) is specific to neurons, testis cells, and some types of cancer, including NSCLC. In vitro studies demonstrate that TUBBIII overexpression lowers the affinity of paclitaxel for microtubules, suggesting that TUBBIII may be a natural antagonist for this class of drug.[51] Following this line of reasoning, high tumor TUBBIII expression has been correlated with resistance to paclitaxel and vinorelbine in patients with advanced NSCLC.[52,53] The adjuvant JBR.10 trial provided an interesting basis for testing the prognostic and predictive value of TUBBIII.[54] Tumor specimens from 265 patients were available for immunohistochemical analysis of TUBBIII protein expression. In the control arm (surgery only), TUBBIII positivity was associated with poor relapse-free survival (HR = 1.92; 95% CI, 1.16 to 3.18; $p = 0.01$) and poor overall survival (HR, 1.72; 95% CI, 1.02 to 2.88; $p = 0.04$). TUBBIII-positive patients showed a benefit from chemotherapy in terms of relapse-free survival (HR = 0.45; 95% CI, 0.27 to 0.75; $p = 0.002$). This was contrary to the expected result, and the authors speculated a differential predictive value of TUBBIII in early versus advanced NSCLC. Thus, the predictive value of TUBBIII as a single-gene biomarker in NSCLC remains unclear. A similar conclusion can be made with regard to tubulin mutations. Although mutations of class I beta tubulin clearly are observed in preclinical models, clinical data have shown mixed results, and the clinical relevance of true beta-tubulin mutations may apply to only a small patient subset.[55–57]

In breast adenocarcinomas, the microtubule-associated protein Tau is expressed at higher levels in docetaxel-sensitive tumors than in docetaxel-resistant ones.[58] Rouzier et al.[59] demonstrated that in patients with breast cancer undergoing neoadjuvant chemotherapy with paclitaxel, tumors with pathologic complete remission (pCR) had significantly lower Tau mRNA levels. Small interfering RNA to downregulate Tau increased sensitivity to paclitaxel in vitro, and incubation of tubulin with Tau resulted in decreased paclitaxel binding and reduced paclitaxel-induced microtubule polymerization. It was thus speculated that low Tau expression may be used as a marker to select patients for paclitaxel therapy, and that Tau inhibition might be exploited as a therapeutic strategy to increase sensitivity to paclitaxel. These data led Dumontet et al.[60] to study Tau expression in NSCLC. Although Tau protein was expressed in 9 out of 18 (50%) NSCLC samples, no correlation with patient outcome after taxane-based chemotherapy

was observed. An analysis of Southwest Oncology Group (SWOG) data revealed strong Tau positivity in only 5% of the NSCLC specimens tested and no association with response to mitotic drugs (unpublished data). Aside from promising BRCA1 data described previously, these studies illustrate the current lack of predictive biomarkers for antimitotic drugs and the need for more translational work in this important area.

**Multiparameter Models and Gene Signatures** In view of the heterogeneity and complex tumor biology underlying NSCLC, a multiparameter approach to individualizing chemotherapy may offer significant advantages.[61] Kwiatkowski et al.[62] first described the value of a multivariate model, including p53, KRAS and HRAS, for determining prognosis in stage I resected NSCLC. Mack et al.[63] subsequently demonstrated that a score derived from five markers (ERCC1, TUBBIII, p53, p27KIP1, and Ki-67) predicted survival in patients with advanced NSCLC undergoing platinum-based chemotherapy, whereas each marker failed when used alone. Recently, with the broad availability of gene expression microarrays, it has became possible to explore the potential prognostic and predictive value of gene expression profiles.[64] Potti et al.[65] reported a genomics prognostic model, the lung metagene score (LMS), which correlated with recurrence in a training cohort of 89 surgically resected NSCLC patients and in two subsequent validation cohorts. The LMS outperformed recognized clinical prognostic factors, and was accurate in all early stages of NSCLC. Cancer and Leukemia Group B (CALGB) has proposed a clinical trial (C30506) for patients with resected stage I NSCLC 2 to 4 cm in size, a group not routinely recommended for adjuvant chemotherapy. Patients with a low LMS, who are felt to be at low risk for recurrence, are observed, whereas those with unfavorable score are randomized to either adjuvant chemotherapy or to standard observation. The two primary objectives of the trial are to validate the positive prognostic value for survival of a low LMS and to determine if a survival advantage exists for adjuvant chemotherapy in patients with a high LMS. As discussed in a recent review by Minna et al.,[66] this powerful methodology is also being utilized to identify gene expression profiles that correlate with drug sensitivity. In lung cancer, Oshita et al.[67] carried out genome-wide complementary DNA (cDNA) microarray screening and correlated gene expression profiles with chemoresistance in 37 patients with advanced NSCLC and SCLC. Transbroncheal biopsy specimens of tumors were obtained before chemotherapy, and the expression levels of 1176 genes were analyzed. Allogenic inflammatory factor, human leukocyte antigen DR (HLA-DR)–associated invariant subunit and major histocompatibility complex (MHC) class II HLA-DR-beta precursor were independently associated with chemoresistance in the multivariate analysis. In a separate study using in vitro drug sensitivity data coupled with microarray data, Hsu et al.[68] developed gene expression signatures to predict sensitivity to cisplatin and pemetrexed. Signatures were then validated using 59 samples from patients

previously treated with cisplatin. Interestingly, ERCC1 was part of the signature for cisplatin resistance, and an inverse correlation was seen between cisplatin and pemetrexed sensitivity in vitro and in patient samples. Based on this finding, a clinical trial has been proposed in which tumors from patients with metastatic NSCLC will be screened for platinum sensitivity by microarray.[69] Patients with predicted platinum-sensitive tumors will receive cisplatin plus gemcitabine, whereas patients with predicted platinum-resistant tumors will receive pemetrexed and gemcitabine. Inherent in these studies is the question of broad applicability, for example, the quality of fresh frozen biopsies obtained in the clinical setting, and whether similar results may be obtained with microarrays using paraffin-embedded tissue.

## HOST-RELATED FACTORS

A completely independent paradigm for personalizing chemotherapy exploits interindividual differences that are host related rather than tumor related. Single nucleotide polymorphisms (SNPs), substitutions of a single base in a DNA sequence, account for approximately 90% of genetic variation in humans. It is estimated that SNPs occur as frequently as every 100 to 300 bases, and, by definition, must be present in at least 1% of the population. SNPs are found in both coding and noncoding sequences and may alter DNA transcription rates, RNA splicing, translation efficiency, and protein function.

Chemotherapy metabolism and detoxification are influenced by a large number of SNPs.[70] As a key example, polymorphisms in the UGT1A1 gene (uridine diphosphate glucuronosyltransferase 1A1) have a significant effect on gastrointestinal and myelosuppressive toxicity accompanying treatment with irinotecan by altering the glucuronidation rate of its active metabolite SN-38.[71,72] Polymorphic variance in cytochrome P450 (CYP) proteins are also recognized as a determinant of chemotherapy activity and toxicity. This large and diverse family of enzymes catalyzes the metabolism of xenobiotics, including many anticancer agents.[73] CYP3A members are the most abundant type of CYP in the small intestine and liver, with substantial interindividual and interracial variation in expression attributed to SNPs.[74,75] CYP3A expression affects the pharmacokinetic disposition of multiple drugs and may impact on the metabolism of environmental procarcinogens, thus influencing an individual's predisposition toward cancer. The role of SNPs in drug metabolism and disposition is complex, and efforts to define their utility for personalized medicine are underway.[76,77]

Interindividual differences in host DNA repair capacity may also affect response to chemotherapy. Multiple SNPs have been identified in genes involved in NER, double-strand DNA break repair, nucleotide synthesis, and other DNA repair processes[78,79] Decreased DNA repair capacity resulting from SNPs appears to contribute to lung cancer risk, particularly in patients who are young, female, and light smokers or nonsmokers.[80] However, reduced DNA repair has also been

associated with improved survival following platinum-based therapies.[81–83]

Although such host-related differences are typically viewed on an individual patient basis, in a broader sense, genotyping studies may help to explain differences in patient outcomes based on ethnic or racial background (i.e., population-related pharmacogenomics). For example, variations in taxane metabolism between Japanese and white populations have been reported and purported to account for differences in patient outcome from taxane-based chemotherapy.[84] To address this question, joint studies between Japanese and U.S. investigators have been designed to identify population-related differences in drug pharmacogenomics using a "common arm" approach.[85] In such studies, separate phase III trials evaluating paclitaxel-carboplatin in advanced-stage NSCLC incorporated similar study criteria for patient eligibility and treatment. In a preliminary report, differences in allelic distribution for genes involved in paclitaxel disposition or DNA repair were observed between Japanese and U.S. patients. Genotype-associated correlations with clinical outcomes were observed for PFS with CYP3A4*1B and for response with ERCC2 K751Q. This research strategy may assist in determining whether the significant differences in efficacy and toxicity observed between Japanese and U.S. patients are attributable to population-related genetic variance.

The recent development of high-throughput genomic arrays should facilitate incorporation of SNP analysis into multiparameter predictive models, which could be tested internationally. The recent availability of highly sensitive methods to detect SNPs, as well as tumor-derived DNA mutations, in peripheral blood, now provides the opportunity for the noninvasive molecular analysis and serial monitoring of patients.[86–90] This promising methodology will require additional validation and prospective confirmation in appropriately designed clinical trials.

## FUTURE DIRECTIONS

Contrary to prior reports showing no strong correlations between tumor histology and response to chemotherapy, a recent randomized clinical trial suggested that histology may indeed have implications for tumor response to chemotherapy, at least in the case of pemetrexed, an antifolate drug that inhibits several enzymes, including thymidylate synthase (TS), dihydrofolate reductase (DHFR), and glycinamide ribonucleotide formyl transferase (GARFT).[91] In this large phase III trial in advanced-stage NSCLC, Scagliotti et al.[92] compared the activity of pemetrexed plus cisplatin versus gemcitabine plus cisplatin. In a preplanned subset analysis, patients with nonsquamous carcinomas had significantly better survival in the pemetrexed arm compared with the gemcitabine arm. Correlative science results from this study are awaited with great interest, to see whether any potential biomarkers for pemetrexed, platinum, or gemcitabine match with the histology-based results. In line with these data, Ceppi et al.[93] previously reported higher mRNA and protein levels for TS in squamous cell lung carcinomas compared with other histotypes. Thus, TS is one of

several candidate predictive markers in the differential response of lung cancers to pemetrexed. In vitro drug sensitivity testing with freshly isolated tumor specimens demonstrated that the expression levels of DHFR and GARFT correlated with chemosensitivity to pemetrexed.[94] Because the drug classification for pemetrexed is that of a multitargeted antifolate compound, it would not be unexpected that a number of factors may be related to pemetrexed activity, as suggested by gene expression microarray data detailed previously.

Transcriptional profiling can only reveal gene expression at the mRNA level, which does not always correlate with the protein level, as demonstrated for ERCC1.[32] Proteomics is a promising approach to more directly and globally address current biological and pharmacological issues related to drug sensitivity.[95] Ma et al.[96] determined whether proteomic signatures of untreated cancer cells were sufficient to predict drug response in vitro. The authors used the databases at the National Cancer Institute on the proteomic profiles of the NCI-60 cell line panel and the activity of 118 drugs tested. By combining the two databases, the feasibility of using proteomic approaches for predicting chemosensitivity was shown. Although EGFR pathways are discussed in detail elsewhere in this text, we note the work of Taguchi et al.,[97] who reported the value of proteomic profiling in patient serum to predict survival benefit from EGFR tyrosine kinase inhibition in NSCLC. The predictive value of the serum proteomic profile in this study was restricted to erlotinib and gefitinib, but offers promise that a similar approach will prove useful in predicting tumor response to chemotherapeutic agents in individual patients.

## CONCLUSION

In the past 5 years, significant progress has been made in the identification of prognostic and predictive single biomarkers and gene expression profiles for lung cancer. Although individualized chemotherapy for lung cancer remains investigational at this point, it is anticipated that clinical applicability will be established for at least some biomarkers in the near future. The results of the ongoing prospective trials designed to personalize therapy for lung cancer patients are awaited with great interest.

## ROLE OF ANGIOGENESIS IN SOLID TUMORS

Tumor development is a multistep and complex process, requiring the transformation of a normal cell into a tumor cell through the accumulation of genetic alterations and the expansion of cell populations that have acquired growth and invasion advantages. However, in addition to the genetic and epigenetic alterations of transformation, another discrete process is required to allow tumor growth and metastasis—the induction of tumor vasculature known as the "angiogenic switch" (see also Chapter 8). Small tumors with a diameter <2 mm are dormant, receiving oxygen and nutrients by diffusion. Malignant growth and metastatic progression requires the tumor to develop an independent capillary network through two distinct processes, vasculogenesis and angiogenesis.[1] In vasculogenesis, new blood vessels are formed when endothelial precursor cells (angioblasts) migrate and differentiate in response to stimuli such as growth factors. These nascent vascular trees are then remodeled and extended through angiogenesis. During tumor growth, circulating endothelial progenitor cells (derivatives of stem cells) can contribute to neovascularization.[2] In contrast to vasculogenesis, angiogenesis is the formation of new blood vessels from preexisting vasculature.

Like many other physiological processes, angiogenesis is tightly orchestrated, regulated by a dynamic balance of proangiogenic and antiangiogenic molecules that drive and inhibit angiogenesis, respectively. The primary factor controlling angiogenesis is a lack of oxygen (hypoxia). Low oxygen tension triggers the secretion of proangiogenic factors and stimulates new vessel formation to increase oxygen supply. Tumor progression relies on tipping the balance in favor of molecules that drive angiogenesis. To achieve this, tumors undergo an angiogenic switch, creating an imbalance between the proangiogenic and antiangiogenic factors, resulting in increased angiogenesis and subsequent tumor progression and metastasis.[3,4] The timing of this angiogenic switch during tumor progression is influenced by various factors including tumor type and environment.

Angiogenesis in tumors is aberrant, and tumor blood vessels have multiple structural and functional abnormalities. They are unusually dynamic and naturally undergo sprouting, proliferation, remodeling, or regression. The vessels are irregularly shaped and lack the normal architectural arrangement of arterioles, capillaries, and venules. Endothelial cells in tumors have abnormalities in gene expression, require growth factors for survival, and have defective barrier function to plasma proteins. Pericytes are relatively undifferentiated cells associated with the walls of physiologically normal small blood vessels and are also important elements of the vascular support structure of tumors, regulating endothelial cell survival and directing capillary growth.[5] Pericytes on tumor vessels are also abnormal and, together with aberrant endothelial cells, generate a defective basement membrane. The effects of agents that inhibit factors involved in angiogenesis include stopping the growth of tumor vasculature, modifying existing vessels, and normalizing surviving vessels,[6] indicating that tumor vasculature is reliant on continued expression of these factors for growth and survival.

Proangiogenic molecules that promote proliferation and migration are mainly receptor tyrosine kinase ligands, such as vascular endothelial growth factor (VEGF), fibroblast growth factors, platelet-derived growth factor (PDGF), and epidermal growth factor, but can also be of very different origin, such as lysophosphatic acid. Antiangiogenic molecules include statins such as angiostatin (a fragment of plasminogen that binds adenosine triphosphate [ATP] synthase and annexin II), endostatin, tumstatin, and canstatin (fragments of collagens that bind to integrins). Table 48.1 lists the known proangiogenic and antiangiogenic molecules. Changes in the balance of these proangiogenic and antiangiogenic molecules mediate the angiogenic switch.[4] The precise role of many of these factors remains unclear; it is likely that ongoing and future research will attempt to further define the roles of these factors.

| TABLE 48.1 | List of Known Proangiogenic and Antiangiogenic Molecules and Agents | |
|---|---|---|
| **List of Known Angiogenic Growth Factors** | **List of Known Angiogenesis Inhibitors in the Body** | |
| Angiogenin | Angioarrestin | |

From Understanding angiogenesis. Angiogenesis Foundation Web site. http://www.angio.org/understanding/understanding.html.

Angiogenesis does occur normally in the human body at specific times in development and growth; for example, it is an integral part of fetal development in utero. However, angiogenesis has a limited physiological role in healthy adults, where its functions are restricted to wound healing and the female menstrual cycle for a few days each month as new blood vessels form in the lining of the uterus. Inhibiting angiogenesis, therefore, has minimal adverse effects on normal physiological processes. As angiogenesis is essential for tumor growth, it is a rational therapeutic target. Agents targeting the effects of VEGF, one of the most important proangiogenic factors, and its downstream signaling pathways have been developed for the first-line treatment of patients with advanced non–small cell lung cancer (NSCLC) as well as other solid tumors, including metastatic colorectal, breast, and renal cell carcinoma.

# VEGF: THE KEY MEDIATOR OF ANGIOGENESIS

VEGF directly stimulates angiogenesis and is a key protein for sustaining tumor growth. VEGF is first synthesized inside tumor cells and then secreted into the surrounding tissue. When the VEGF ligand encounters endothelial cells, it binds to its main cell surface receptor, VEGF receptor 2. Ligand-receptor binding activates the endothelial cell and sets in motion a cascade of events that lead to the creation of new blood vessels (Fig. 48.1).[7] First, the activated endothelial cell produces matrix metalloproteinases, a special class of degradative enzymes. These enzymes are released from the endothelial cell into the surrounding tissue where they degrade the extracellular matrix, allowing the migration of endothelial cells. As they migrate into the surrounding tissues, activated endothelial

cells begin to divide, organize into hollow tubes, and gradually evolve into a mature network of blood vessels.[8,9]

VEGF and the VEGF signaling pathway have been the focus of an increasing number of studies as cancer targets. VEGF is expressed by many solid tumors, including melanoma,[10] gastrointestinal,[11] breast,[12] central nervous system (CNS),[13] ovarian,[14] cervical,[15] lung,[16] hepatic,[17] head and neck,[18] and kidney[19] carcinomas. Analysis of microvessel density can provide an indirect measure of angiogenesis. In many studies, VEGF levels have been shown to correlate with microvessel density, which is higher in advanced tumors compared with early stage tumors.[20–24] A study of 105 patients with NSCLC demonstrated a significant association between VEGF expression and new vessel formation ($p < 0.0001$), overall survival ($p = 0.00003$), and disease-free survival ($p = 0.0004$).[21] In another study of specimens from 223 patients with operable NSCLC, 46.6% of cases had high VEGF expression. VEGF positivity was associated with high vascular grade disease ($p = 0.009$) and was prognostic for poor survival ($p = 0.02$).[20] Several other studies have now confirmed a strong association between VEGF positivity and tumor grade and prognosis in NSCLC: Prognosis for patients with VEGF-positive tumors has been consistently shown to be significantly worse than that for patients with VEGF-negative tumors ($p = 0.003$[22] and $p = 0.019$[23]).

VEGF exists in at least seven isoforms that result from alternative patterns of splicing of VEGF mRNA.[8,9] One study evaluating the correlation between the expression of four different VEGF mRNA isoforms suggests that expression of $VEGF_{189}$ mRNA isoform shows a greater correlation with survival and postoperative relapse time than expression of $VEGF_{121}$, $VEGF_{165}$, and $VEGF_{206}$ mRNA isoforms.[24] High $VEGF_{189}$ mRNA isoform expression was associated with short survival (<24 months; $p = 0.001$) and early postoperative relapse (<12 months; $p = 0.001$), whereas no correlation was seen with $VEGF_{165}$ and $VEGF_{206}$, suggesting that only expression of certain VEGF isoforms may be prognostic indicators for NSCLC.[24]

Structurally, VEGF (sometimes referred to as VEGF-A or vascular permeability factor[25]) belongs to the platelet-derived growth factor (PDGF) family of cystine-knot growth factors.[8] Other closely related proteins have been discovered (placenta growth factor [PlGF], VEGF-B, VEGF-C, and VEGF-D), and together these comprise the VEGF subfamily of growth factors.[8] Several VEGF-related proteins are produced by viruses (VEGF-E) and in the venom of some snakes (VEGF-F).

VEGF growth factor ligands have specific VEGF receptors to which they bind to produce their physiological effects. VEGF-A binds to both VEGF receptor 1 (Flt-1) and

2 (KDR/Flk-1), but VEGF receptor 2 is believed to mediate almost all known cellular responses to VEGF.[8] The function of VEGF receptor 1 is less well defined, although it is thought to modify VEGF receptor 2 signaling.[8] Another function of VEGF receptor 1 may be to act as a decoy receptor, sequestering VEGF from VEGF receptor 2 binding, and this may be particularly important during embryonic vasculogenesis.[26] A third receptor has been discovered (VEGF receptor 3), but VEGF-A is not a ligand for this receptor. VEGF receptor 3 mediates lymphangiogenesis in response to VEGF-C and VEGF-D binding.[8,9,16]

The biological effects of VEGF are thus initialized primarily through binding to VEGF receptor 2,[27] which is expressed predominantly on vascular endothelial cells.[28] VEGF receptor 2 is similar in structure to other tyrosine kinase receptors. It consists of seven extracellular immunoglobulin-like domains, a transmembrane region, and an intracellular domain with tyrosine kinase activity.[29,30] VEGF binding to VEGF receptor 2 and subsequent receptor homodimerization are essential for stimulation of VEGF receptor 2-induced intracellular signaling, which is in turn essential to the VEGF signaling pathway.

## MECHANISM OF ACTION OF ANTIANGIOGENIC AGENTS

Neutralizing the biological activity of VEGF reduces tumor vascularization and consequently inhibits tumor growth.[6,31] A nonspecific tyrosine kinase inhibitor of the VEGF receptor prevented migration of endothelial cells, blocked capillary-like tubule formation, and prevented tumor blood vessel formation.[31] Inhibition also prevented the formation of lung metastases and slowed progression of tumor growth. Importantly, for a potential therapeutic target, VEGF receptor inhibition had minimal effects on established blood vessels or

blood flow. These findings indicate that a potent therapeutic role for VEGF inhibitors may be to prevent the formation of new blood vessels. Inhibition of VEGF signaling by blocking VEGF receptor 2 also inhibits angiogenesis, tumor growth, and invasion. VEGF receptor 2 blockade causes vessel regression and normalization as well as stromal maturation, resulting in a reversion to a noninvasive tumor phenotype. Importantly, this study suggests a crucial role for the stromal microenvironment (see Chapter 50) in regulating tumor phenotype and thus maintained and continuous VEGF inhibition may be essential for prolonged tumor suppression, which, in the clinical setting, may translate to prolonged progression-free survival (PFS).[32–34]

"Ghosts" or "tracks" of basement membrane and accompanying pericytes left behind after endothelial cells degenerate may provide a "scaffold" for microvascular regrowth in the absence of inhibition of angiogenesis. Given the transient and reversible effects of VEGF inhibition on tumors, with revascularization documented within weeks of withdrawal of inhibition,[32–34] eradication of pericytes and ghosts of basement membrane may augment and prolong VEGF-inhibitor activity by decreasing the potential for vascular regrowth.[34] Preclinical data suggest that dual targeting of pericytes and endothelial cells may be a more effective antiangiogenic strategy than anti-endothelial cell targeting alone.[5]

**Antiangiogenic Approaches**   As discussed, the evidence for the central role of VEGF-regulated angiogenesis in tumor growth and progression has provided a strong rationale for the development of agents that exert their antitumor effects through inhibition of various stages of the VEGF pathway. As such, the majority of antiangiogenic approaches to date have focused on the inhibition of this key proangiogenic factor. Of these, the most promising approaches are monoclonal antibodies directed at VEGF ligand and small molecule tyrosine kinase inhibitors that block the VEGF receptor(s) (Fig. 48.2).

**FIGURE 48.2** Agents targeting the vascular endothelial growth factor (VEGF) pathway. *TKIs,* tyrosine kinase inhibitors; *VEGF,* vascular endothelial growth factor.

## Anti-VEGF Antibodies

**Bevacizumab**    Bevacizumab, developed from the murine antihuman antibody A4.6.1, is a monoclonal antibody with a high affinity for VEGF.[35,36] A4.6.1 was shown to potently suppress neovascularization and tumor growth and was humanized by site-directed mutagenesis to facilitate therapeutic use. The recombinant humanized antibody, bevacizumab, was able to bind VEGF with similar affinity to that of the original murine antibody and inhibit VEGF-induced proliferation of endothelial cells in vitro and tumor growth in vivo with potency and efficacy similar to A4.6.1. Bevacizumab exerts its antiangiogenic effects by binding to free, circulating VEGF, thereby inhibiting the binding of VEGF to its receptors, preventing VEGF ligand-receptor downstream signaling.[36] To date, first-line bevacizumab combined with standard platinum-based chemotherapy has demonstrated clinical activity in a phase II trial[37] and two phase III trials in patients with NSCLC.[38,39]

In the phase II trial, bevacizumab in combination with carboplatin and paclitaxel improved overall response and time to progression in patients with untreated advanced or recurrent NSCLC.[37] In this trial, 99 patients were randomized to carboplatin/paclitaxel every 3 weeks (n = 32) or carboplatin/paclitaxel with bevacizumab 7.5 mg/kg (n = 32) or 15 mg/kg (n = 35) every 3 weeks. Patients with progressive disease who had received chemotherapy alone went on to receive single-agent bevacizumab. The combination of bevacizumab 15 mg/kg with carboplatin/paclitaxel increased response rate (31.5% vs. 18.8%) and prolonged time to progression (median 7.4 vs. 4.2 months; $p = 0.023$) with a 46% reduction in the risk of progression during treatment. With bevacizumab 7.5 mg/kg, there was a modest increase in response rate (28.1% vs. 18.8%) but no difference in time to progression (median 4.3 vs. 3.2 months). One-year survival was 47% for patients (n = 19) receiving chemotherapy alone who progressed and went on to receive single-agent bevacizumab. Bleeding was the most prominent adverse event (AE), mainly evident as minor mucocutaneous hemorrhage and major hemoptysis. Severe pulmonary hemorrhage was observed in six patients (9.1%) and led to four fatalities. An exploratory analysis identified increased risk of bleeding in patients with squamous cell histology, tumor necrosis and cavitation, and disease location close to major blood vessels.[40] Further analysis excluding patients with squamous histology suggested that both doses of bevacizumab increased response rate, time to progression, and survival compared with chemotherapy alone and with only a small increased risk of bleeding (~4%).[37]

Based on the positive results of the phase II trial, a randomized phase III trial of bevacizumab-based first-line therapy was conducted by the Eastern Cooperative Oncology Group (ECOG).[38] In the E4599 trial, 878 patients with recurrent or advanced NSCLC (stage IIIB or IV) were randomized to bevacizumab 15 mg/kg with carboplatin/paclitaxel (n = 434) or carboplatin/paclitaxel alone (n = 444) every 3 weeks for six cycles until disease progression or unacceptable toxicity.[38] The 15 mg/kg dose was chosen based on its activity in the phase II trial and based on exploratory analyses from the phase II trial,

patients with squamous histology were excluded from E4599. Patients with brain metastases or clinically significant hemoptysis were also excluded. The primary end point was overall survival.

A survival advantage was demonstrated for bevacizumab-based first-line therapy compared with conventional chemotherapy alone. Median overall survival was 12.3 months for bevacizumab-based therapy compared with 10.3 months for chemotherapy alone (hazard ratio [HR] = 0.79; $p = 0.003$). Median PFS was 6.2 and 4.5 months, respectively (HR = 0.66; $p < 0.001$), with corresponding response rates of 35% and 15% ($p < 0.001$). Exclusion of patients with squamous cell histology resulted in a reduction in the rates of clinically significant bleeding compared with the earlier phase II trial.[37] Notably, the incidence of severe pulmonary hemorrhage in E4599 was reduced when compared with the patients with nonsquamous histology in the phase II trial (1.9% vs. 4%, respectively). There were 15 treatment-related deaths among patients receiving bevacizumab-based therapy, including five from pulmonary hemorrhage. VEGF levels before treatment were measured and found not to correlate with overall survival. An exploratory analysis found that despite improvements in PFS, there was no improvement in overall survival for women treated with bevacizumab-based therapy compared with chemotherapy alone (13.3 vs. 13.1 months). This was not true for men (11.7 vs. 8.7 months). The reasons for this are not clear.

In a pre-planned subset analysis of patients in E4599 with adenocarcinoma histology, bevacizumab-based therapy extended median overall survival to 14.2 months compared with 10.3 months for chemotherapy alone (HR = 0.69, a 31% reduction in the risk of death).[41] A retrospective subset analysis of elderly patients (≥70 years of age), representing 26% of study patients, found a trend toward higher response rates (17% vs. 29%) and PFS (4.9 vs. 5.9 months) but no difference in overall survival (12.1 vs. 11.3 months) for paclitaxel/carboplatin versus paclitaxel/carboplatin plus bevacizumab, respectively. Paclitaxel/carboplatin plus bevacizumab was also associated with a significantly higher incidence of grade 3 to 5 toxicities than paclitaxel/carboplatin (61% vs. 87%; $p < 0.001$).[42]

The improved outcome for bevacizumab-based first-line therapy in NSCLC has recently been confirmed in a second randomized phase III trial of bevacizumab in combination with cisplatin/gemcitabine. In the Avastin in lung (AVAiL; BO17704) trial, the combination of bevacizumab with cisplatin/gemcitabine improved PFS when compared with the platinum-based regimen alone.[39] In this trial, 1043 patients with advanced or recurrent nonsquamous NSCLC were randomized to receive cisplatin/gemcitabine for up to six cycles plus bevacizumab 7.5 mg/kg (n = 345), bevacizumab 15 mg/kg (n = 351), or placebo (n = 347) every 3 weeks until disease progression or unacceptable toxicity. As in E4599, patients with squamous cell histology, baseline hemoptysis, or brain metastases were excluded to minimize toxicity. In this trial, patients with tumors in proximity to or abutting major vessels were also excluded. Following the positive survival results of the E4599 trial for bevacizumab-based therapy versus chemotherapy alone, the primary end point of AVAiL was amended from overall survival to PFS.

Both doses of bevacizumab-based therapy demonstrated a significant PFS benefit compared with chemotherapy alone. Median PFS for bevacizumab 7.5 mg/kg and 15 mg/kg versus placebo was 6.7 versus 6.1 months (HR = 0.75; $p$ = 0.003) and 6.5 versus 6.1 months (HR = 0.82; $p$ = 0.03), respectively. Objective response rates were 34.1%, 30.4%, and 20.1% for bevacizumab 7.5 mg/kg, 15 mg/kg, and placebo, respectively. The PFS benefit did not translate into a significant overall survival benefit, possibly due to the high use of efficacious second-line therapies in the trial. Median overall survival for bevacizumab 7.5 mg/kg and 15 mg/kg versus placebo was 13.6 versus 13.1 months (HR 0.93; $p$ = 0.420) and 13.4 versus 13.1 months (HR 1.03; $p$ = 0.761), respectively.[43] The majority of AEs were grade 1 or 2 and the incidence of grade ≥3 AEs was similar across arms. Although 9% of patients received therapeutic anticoagulation, severe pulmonary hemorrhage rates were ≤1.5% for all arms, highlighting the role of patient selection in managing the risk of bleeding. The AE fatality rate (from any cause) was similar across treatment groups (4% to 5%). Although the AVAiL trial was not powered to compare the two bevacizumab doses directly, efficacy and safety data were similar for both doses. Table 48.2 presents a summary of results for the clinical trials of bevacizumab-based first-line therapy in NSCLC.

In addition to the two phase III trials, E4599 and AVAiL, the safety and clinical activity of bevacizumab-based therapy is being investigated in the Safety of Avastin in lung (SAiL; MO19390) trial. SAiL is a large (n = >2,100 patients are expected), open-label, multicentre, single-arm trial that is being conducted to generate further safety and efficacy data for bevacizumab combined with a range of standard first-line chemotherapy regimens in a broad 'real-life' clinical population of patients with advanced non-squamous NSCLC. The primary objective is to evaluate the safety profile of bevacizumab-based therapy. Interim results show that no new safety signals have been reported in this large study and that the safety profile of bevacizumab-based therapy is consistent with that reported in previous phase III trials.[44] Interim results from SAiL further confirm the safety profile of bevacizumab when used in combination with a wide range of chemotherapies. Final data, including efficacy outcomes, are anticipated in 2010. The clinical potential and therapeutic advance offered by bevacizumab are being evaluated further in an ongoing clinical research program. The majority of these (approximately 80%) are phase II trials with most evaluating the potential benefit of the addition of bevacizumab to different chemotherapy regimens, including pemetrexed/oxaliplatin,[45,46] pemetrexed/carboplatin,[47–49] docetaxel/carboplatin,[50] oxaliplatin/gemcitabine,[51] and gemcitabine/carboplatin.[52] However, many trials are combining bevacizumab not only with standard chemotherapy but with other biological therapies, most notably erlotinib in almost one quarter of trials listed. More creative approaches are also being studied, including novel combinations with targeted therapies and improved prognostic profiling to identify those patients most likely to benefit from specific therapeutic interventions. The increasing sophistication of clinical trials reflects the number of innovative agents available or in development, and our improved understanding of the underlying pathogenesis and tumorigenic processes that allow for rational combination of therapies with potentially complementary antitumor activity. Several of the significant ongoing bevacizumab trials, including trials in the neoadjuvant setting and trials in specific patient populations, deserve a special mention and are summarized later.

## Combining Bevacizumab with Other Targeted Agents

The concept of using two novel agents, such as an epidermal growth factor receptor (EGFR) inhibitor and an anti-VEGF agent, is intriguing. As discussed, the angiogenesis pathway is crucial in lung cancer development. Data have also demonstrated the significant therapeutic involvement of the

EGFR pathway in tumorigenesis.[53] Therefore, inhibiting both pathways to exert a greater combined antitumor effect, but with fewer nonspecific toxicities than chemotherapy,[54] represents a rational therapeutic approach.

Erlotinib (Tarceva), an oral HER-1 (human epidermal receptor 1)/EGFR tyrosine kinase inhibitor has shown a survival benefit in the treatment of lung cancer in phase III trials and is approved for the treatment of locally advanced or metastatic NSCLC in patients failing at least one prior chemotherapy regimen.[55] A phase I/II trail of 40 patients with advanced, nonsquamous NSCLC who had failed at least one prior chemotherapy regimen demonstrated a 20% response rate, 6.2 months PFS, 12.6 months overall survival, and no grade III/IV toxicity when bevacizumab (15 mg/kg) was combined with erlotinib (150 mg daily).[56] These results led to a randomized phase II trial comparing chemotherapy alone (docetaxel 75 mg/m$^2$ or pemetrexed 500 mg/m$^2$ every 3 weeks) to chemotherapy plus bevacizumab (15 mg/kg) or bevacizumab plus erlotinib (150 mg daily) in 120 patients with nonsquamous NSCLC who had progressed following platinum-based chemotherapy. Grade 3/4 toxicities were greater in the chemotherapy treatment arms with a higher proportion of patients discontinuing treatment caused by AEs (24% for chemotherapy alone vs. 28% for chemotherapy plus bevacizumab and 13% for erlotinib plus bevacizumab). The response rate was higher for the erlotinib plus bevacizumab combination (18%), versus 12% for chemotherapy alone and 13% for chemotherapy plus bevacizumab. Compared with chemotherapy alone, patients who received chemotherapy plus bevacizumab and erlotinib plus bevacizumab had superior outcomes, respectively, in terms of median PFS (3.0 vs. 4.8 vs. 4.4 months), overall survival (8.6 vs. 12.6 vs. 13.7 months), and 1-year survival (33% vs. 53.8% vs. 57.4%).[57]

Based on these results, the BeTa lung trial (OSI3364g/NCT00130728) has opened. This phase III trial will compare erlotinib with erlotinib plus bevacizumab in 655 patients with nonsquamous NSCLC who have progressed following standard first-line therapy. The primary end point is overall survival; secondary end points are PFS, response rate, and response duration. ATLAS (AVF3671g/NCT00257608) is another phase III trial assessing the efficacy and safety of maintenance bevacizumab with or without erlotinib following chemotherapy (carboplatin/paclitaxel, cisplatin/gemcitabine, or carboplatin/docetaxel) plus bevacizumab before randomization to bevacizumab with or without erlotinib, in 1150 previously untreated patients. The primary end point is PFS and secondary end points include safety of bevacizumab during the chemotherapy phase (by chemotherapy regimen) and safety of bevacizumab plus erlotinib versus bevacizumab plus placebo. Of note, patients with squamous cell histology and brain metastases are excluded from this trial.

Given that bevacizumab is administered until disease progression, a key issue to address is when it is appropriate to add erlotinib, which is approved in the second- or third-line settings. The value of earlier versus delayed initiation of erlotinib should be assessed, as should the optimal timing of bevacizumab/erlotinib therapy in the disease pathway.

A two-stage phase II trial evaluating up-front administration of erlotinib (150 mg daily) with bevacizumab (15 mg/kg every 21 days) is currently ongoing. Preliminary data from 33 patients indicate major toxicities (>10% of patients) to be rash and diarrhea. The primary end point of nonprogression at 6 weeks has been met in 75% of patients. With a median follow up of 6.3 months, the median time to progression is 5.5 months.[58] More mature data with correlative studies are pending.

These studies will shed light on how biologically active therapies can be best combined and possibly also identify subgroups of patients who derive most benefit from these interventions.

**Bevacizumab in the Adjuvant Setting**   Based on results of the E4599 study, ECOG is conducting a phase III randomized trial in 1500 patients, evaluating the addition of bevacizumab to standard chemotherapy (cisplatin/gemcitabine, cisplatin/vinorelbine, or cisplatin/taxotere) in the adjuvant setting. Carboplatin/paclitaxel is not being utilized after the lung adjuvant cisplatin evaluation (LACE) metaanalysis demonstrated superior outcomes for patients treated with cisplatin-based regimens in the adjuvant setting.[59] Patients receive bevacizumab every 3 weeks for up to 1 year. The primary end point for this trial is overall survival and secondary end points are disease-free survival and toxicity. Analysis of tissue and blood samples for identification of predictive factors and evaluation of outcome according to smoking status is also planned.

**Bevacizumab in the Neoadjuvant Setting**   Three trials are evaluating the potential of bevacizumab in the neoadjuvant setting. If effective, this approach may reduce tumor burden and either facilitate or negate the need for resection. The first of these is the randomized phase II BEACON study (NCT00130780) in patients (n = 70) with resectable (stage IB to IIIA) NSCLC. Patients are randomized based on histology, tumor, and patient factors. Patients with adenocarcinoma will receive presurgical treatment with bevacizumab (15 mg/kg) for 2 weeks followed by bevacizumab plus docetaxel/cisplatin, whereas patients with squamous cell histology, central tumor location, or recent hemoptysis will receive presurgical docetaxel/cisplatin alone. All patients receive adjuvant bevacizumab for 1 year following surgical resection. The primary goal of the study is to assess whether the addition of bevacizumab improves the rate of pathologic downstaging, defined as any decrease in the final pathologic stage compared with the clinical stage before induction therapy. Secondary end points include combined overall survival for both groups. Preliminary analyses show a similar rate of downstaging in both groups (5/9 patients in the bevacizumab treatment group and 5/8 patients in the chemotherapy-alone treatment group) and a low incidence of significant AEs (one patient developed hemoptysis preoperatively, and one patient had an upper gastrointestinal bleed postoperatively). Single-agent bevacizumab can regress tumors after 2 weeks and can be safely administered in the neoadjuvant and adjuvant setting.[60]

In another phase II neoadjuvant trial (NCT00025389), bevacizumab is being combined with carboplatin/paclitaxel in approximately 29 patients with resectable (stage IB to IIIA)

NSCLC. End points are clinical and pathologic response rate, resectability rate, and safety. This study, led by the National Cancer Institute, has now completed accrual. A final study (NCT00293332) combines bevacizumab with docetaxel/carboplatin in 50 patients. The primary end point is clinical response rate. Secondary end points include pathologic response rate, resectability rate, overall survival, time to treatment failure, and safety. Analysis of VEGF levels before and after treatment and/or resection is also planned.

Trials of bevacizumab in the neoadjuvant setting should elucidate the risks of bleeding and wound-healing complications in patients with NSCLC when bevacizumab is administered prior to surgery. In accordance with the recommendations in the Avastin Summary of Product Characteristics, elective major surgery should be delayed for at least 28 days following the last bevacizumab dose.[61] The administration of bevacizumab >28 days after major surgery appears to be feasible and safe in patients with colorectal cancer.[62] Of note, in the BEACON study, surgery occurs at least 42 days after the last bevacizumab administration, whereas in the NCT00025389 trial, patients underwent surgical resection 4 to 6 weeks after receiving two cycles of bevacizumab in combination with chemotherapy. Given the clear rationale for the use of bevacizumab in the neoadjuvant setting, it is important to obtain further information on the safety profile of neoadjuvant bevacizumab in patients with NSCLC.

### Bevacizumab in Specific Patient Populations: Squamous Cell Histology

Based on phase II data and the increased incidence of severe pulmonary hemorrhage in patients with squamous cell histology,[37] later phase III trials have generally excluded these patients[38,39] and bevacizumab is not indicated in patients with predominantly squamous histology. The precise reason for the increased risk of bleeding in particular patient subsets remains unknown. What makes squamous cell tumors particularly susceptible to bleeding with anti-VEGF therapy? These tumors tend to be more centrally located[63] and perhaps associated with increased local invasion. Large central lesions, which may undergo early cavitation, may increase the risk for bleeding complications. Furthermore, of all bronchogenic carcinomas, squamous cell carcinoma is the most likely to cavitate (about 15% of cases).[64] It is also possible that these tumors might form an integral component of the pulmonary arterial wall or be adjacent to another vital vascular structure. Finally, it is possible that bleeding complications are caused by an anti-VEGF class effect or a profound tumor response.

However, following preliminary positive efficacy data from an exploratory subgroup analysis of bevacizumab-based therapy in patients with squamous cell histology in the phase II trial AVF0757g,[37] the safety and efficacy of bevacizumab in these patients is now being specifically evaluated in further phase II studies. BRIDGE (AVF3744g/NCT00318136) is a pilot study of first-line bevacizumab in combination with carboplatin/paclitaxel (n = 40). The rate of grade ≥3 bleeding is the primary end point and rate of other AEs and PFS are secondary end points.

### Bevacizumab in Specific Patient Populations: Brain Metastases

Exclusion of patients with brain metastases from trials of bevacizumab in NSCLC[37–39] was a conservative approach based, in part, on the occurrence of a severe cerebrovascular bleeding event in a patient with hepatocellular carcinoma treated with single-agent bevacizumab in a phase I study (n = 25).[65] As trials to date have excluded patients with brain metastases, the balance between potential risk and potential benefit for bevacizumab-based therapy in this patient population remains to be assessed. Two ongoing phase II trials are evaluating the safety and efficacy of bevacizumab in combination with pemetrexed in the second-line setting (n = 40; NCT00227019) and in combination with first- or second-line chemotherapy (n = 110; PASSPORT trial; NCT00312728). The primary end point for both trials is the incidence of cerebrovascular bleeding, with other AEs and survival (PFS or overall) as secondary end points. Results from these trials are awaited. Based on safety data showing that the risk of bleeding in patients with untreated brain metastases is similar for patients who receive bevacizumab and those who do not,[66] the European Medicines Agency in March 2009 removed the restriction on the use of bevacizumab in patients with untreated brain metastases. No such restriction has ever existed in the USA. Data from ongoing phase IV trials of bevacizumab, in combination with a range of commonly used chemotherapy regimens involving 2000 (NCT00451906; SAiL) and 6000 (NCT00388206; ARIES) patients, should help to identify patient populations most suitable for, or likely to derive most benefit from, bevacizumab-based therapy.

Although bevacizumab is the first anti-VEGF therapy to be approved for NSCLC, other approaches are in rapid development. Table 48.3 provides an overview of drugs currently in development that target the VEGF pathway. The most promising of these approaches are reviewed in the remainder of this chapter.

### Bevacizumab in Specific Patient Populations: Small Cell Lung Cancer

Microvessel count (MVC), as a measure of angiogenesis, is a significant predictor of increased risk of metastatic disease and worse overall survival in patients with NSCLC.[67,68] The median MVC in SCLC is higher than seen in NSCLC. Elevated MVC and VEGF expression are associated with a worse prognosis in SCLC.[69] ECOG conducted a phase II trial (E3501) in 64 patients with chemotherapy-naive extensive stage SCLC. In this trial, bevacizumab (15 mg/kg) was added to standard chemotherapy with cisplatin (60 mg/m² on day 1) and etoposide (120 mg/m² on days 1 to 3) for four cycles.[70] Patients without disease progression continued on bevacizumab until progression or unacceptable toxicity. The most common grade 3/4 toxicities (>10% of patients) were neutropenia, thrombocytopenia, fatigue, hypertension, febrile neutropenia, and dehydration; two patients experienced grade 5 toxicities (hypertension and infection with grade 3/4 neutropenia). There was 69% response rate. PFS was 4.7 months and overall survival was 11.1 months.[70] CALGB conducted a similar phase II study (CALGB 30306) in which bevacizumab (15 mg/kg) was combined with cisplatin (30 mg/m² on days 1 and 8) and irinotecan (85 mg/m²

on days 1 and 8) in 72 chemotherapy-naive patients with extensive stage SCLC. Grade 3/4 toxicities included cytopenias, hypertension, fatigue, diarrhea, nausea, bowel perforation, infection, and heart failure. One patient died from hemorrhage secondary to a stroke. Compared with findings of the ECOG E3501 study of etoposide/cisplatin plus bevacizumab,[70] response rate (75%) was greater and PFS (7.1 months) was longer, but overall survival was similar (11.7 vs. 11.1 months).[71] A third phase II trial of 50 patients with extensive stage SCLC is evaluating the benefits of maintenance bevacizumab (10 mg/kg) for 6 months in patients who do not progress following initial chemotherapy with carboplatin (area under the curve [AUC] = 4 on day 1) and irinotecan (60 mg/m[2] on days 1, 8, and 15) for four to six cycles. Preliminary data indicates the regimen is well tolerated; the most common grade 3/4 toxicities (>10% of patients) include diarrhea, fatigue, and neutropenia. Survival data is immature.[72] Based on these results, a randomized phase II study of cisplatin/etoposide with or without bevacizumab is planned.

A multicenter phase II trial evaluated the role of bevacizumab in patients with limited-stage SCLC.[73] In this trial, 57 patients with limited-stage SCLC received combined modality therapy: 61.2 Gy of radiation therapy, and chemotherapy with carboplatin (AUC = 5) and irinotecan (50 mg/m[2] on days 1 and 8) for four cycles. Those patients without progressive disease went on to receive consolidation treatment with bevacizumab (10 mg/kg) every 2 weeks for 10 doses. Major grade 3/4 toxicities (>10% of patients) included neutropenia, thrombocytopenia, and vomiting during combined modality treatment. Less than 10% of patients receiving bevacizumab alone experienced grade 3/4 toxicities. There were two treatment-related deaths, both caused by respiratory failure. The response rate of 80%, the 1- and 2-year PFS rates of 63% and 54%, respectively, and the 1- and 2-year overall survival rates of 71% and 29%, respectively, are similar to outcomes seen with traditional chemotherapy with cisplatin/etoposide.[73–75]

**Small Molecule Kinase Inhibitors** Tyrosine kinase activity is intrinsic to the signaling activity of many membrane-bound receptors, including VEGF receptors. Activity is mediated by ligand binding to the extracellular region of the receptor, which stimulates tyrosine phosphorylation of the intracellular domain via ATP binding and subsequently activates intracellular signaling cascades.[25] Tyrosine kinase inhibitors block or compete with ATP binding, thus inhibiting the intracellular signaling cascade stimulated by a receptor or several receptors. As such, they are involved in many cellular processes such as proliferation, metabolism, survival, and apoptosis. Evidence suggests that several tyrosine kinases are activated in cancer cells and drive tumor growth and progression. Therefore, blocking tyrosine kinase activity represents a rational approach to cancer therapy.

VEGF receptor tyrosine kinase inhibitors exert their effects by inhibiting downstream signaling from VEGF receptors following stimulation by VEGF. By blocking the activity of VEGF receptors, and potentially other receptors, it might be suggested that these tyrosine kinase inhibitors have the potential to exert broader activity than VEGF inhibitors targeting a single ligand. However, VEGF is the ligand for several receptors (VEGF receptors 1 and 2, neuropilin-1 [NRP-1]) with several targets each. Therefore, VEGF-ligand inhibition limits further paracrine and autocrine stimulation via VEGF, and also prevents further downstream activation of the VEGF-mediated angiogenesis pathways. The clinical relevance of multiple receptor inhibition will be discussed. A summary of the clinical activity of these small molecule kinase inhibitors can be found following discussion of the individual agents in Table 48.4.[76–91]

**Sorafenib** Sorafenib (Bay 43-9006; Nexavar) is an oral multikinase inhibitor targeting both tumor proliferation via inhibition of Raf, stem cell factor receptor (c-kit), fms-like tyrosine kinase-3 (Flt-3), and angiogenesis by targeting VEGF receptors 2 and 3 and PDGF-receptor (PDGFR)-$\beta$.[92–94] In preclinical models,

‡Sunitinib administered daily for 4 weeks of 4-week cycle.

§Cisplatin and gemcitabine.

bid, twice daily; CBDCA, carboplatin; CDDP, cisplatin; NR, not reported; PFS, progression-free survival; RR, response rate.

sorafenib has been found to inhibit tumor growth, including NSCLC, when administered alone and/or in combination with vinorelbine, cisplatin, or gefitinib.[95,96] Phase I studies, which have included patients with NSCLC, determined sorafenib 400 mg twice daily to be safe and well tolerated.[97,98] Clinical studies in patients with solid tumors, including NSCLC, demonstrated disease stabilization following treatment with single-agent sorafenib, regardless of prior chemotherapy regimen.[76,77,97,98]

**SINGLE-AGENT SORAFENIB.** In a multicenter, uncontrolled phase II trial, 54 patients with relapsed or refractory NSCLC received sorafenib (400 mg twice daily continuously for 28-day cycle). Patients with a history of significant bleeding in the previous month were excluded from the trial, although patients with squamous cell histology and asymptomatic brain metastases were included. Median PFS was 2.7 months and overall survival was 6.8 months. Although there were no confirmed partial responses in the 51 evaluable patients, disease tumor shrinkage was observed in 29% of patients, whereas 59% of patients had stable disease. The most common toxicities (>25% of patients) were diarrhea, hand–foot syndrome, fatigue, and nausea. Hypertension was also

observed in 2% of patients. In many cases, hypertension is amenable to management with standard antihypertensive therapy; however, severe or persistent hypertension or hypertensive crisis despite institution of antihypertensive therapy may require permanent discontinuation. Less common sorafenib-related events that may require interruption or termination of therapy include bleeding and cardiac ischemia. In this phase II trial, four patients had a bleeding event thought to be associated with treatment with sorafenib. Of these, three patients had epistaxis and one patient with a central cavitary lesion and squamous cell histology had a fatal pulmonary hemorrhage (30 days after stopping treatment with sorafenib).[77] In a two-stage design phase II trial, patients who had failed one prior chemotherapy regimen were treated with sorafenib (400 mg twice daily continuously for 28-day cycle). Response was evaluated by dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI). Five patients were assessable for response and six for toxicity. Best response was one partial response (41% tumor reduction at week 8, sustained to week 28). Additional responses included one partial response (unconfirmed at week 3), two stable disease (16 and 19 weeks), and one progressive disease after 8 weeks of treatment. Toxicities included

those previously mentioned in addition to anemia, hyponatremia, keratoacanthoma, and vasculitis. DCE-MRI of one patient showed decrease in tumor permeability and size; however, this was not observed in two other patients responding to therapy.[76] Single-agent sorafenib does not appear to adversely affect health-related quality of life in patients with advanced NSCLC.[99] In a first-line study, 25 patients with stage IIIB (pleural effusion) or IV NSCLC were treated with sorafenib (400 mg twice daily continuously for 28-day cycle) prior to receiving standard chemotherapy. Although the study did not meet stage I efficacy criteria (only one confirmed partial response in the first 20 patients), the authors concluded that the median survival of 8.8 months and objective response rate of 12% suggests single-agent sorafenib achieves similar activity compared with two-drug combinations and should be considered for combination studies with standard chemotherapy regimens.[100]

**COMBINATION THERAPY.** In a phase I dose-escalation trial of 31 patients, 12 patients with locally advanced or recurrent NSCLC were treated with sorafenib (200 or 400 mg twice daily) plus gefitinib (250 mg daily). An additional 20 patients were treated with single-agent sorafenib or gefitinib for 21 days followed by a 7-day washout period with crossover to the other agent for 21 days, followed by a 7-day washout period and the combination of sorafenib (400 mg twice daily) and gefitinib (250 mg daily for 28-day cycle). No dose-limiting toxicities were observed at the sorafenib 200 mg daily dose level. One dose-limiting toxicity (elevated alanine transaminase [ALT]) was observed at the sorafenib 400 mg daily dose level, the dose selected for phase B of the study. The most common AEs included dermatologic effects, diarrhea, and elevated ALT, with the latter two being the most common grade 3/4 AEs. Serious AEs each occurring in one patient included dyspnea, fever, elevated ALT, and diarrhea. Although gefitinib had no effect on sorafenib pharmacokinetics, sorafenib did effect the pharmacokinetics of gefitinib. There was one partial response and 20 stable disease of ≥4 months' duration. Sorafenib 400 mg twice daily and gefitinib 250 mg daily oral is the recommended dose for future studies.[78,101]

In a phase I/II trial, carboplatin (AUC = 6)/paclitaxel (225 mg/m$^2$ intravenously [iv] on day 1) were combined with sorafenib (100, 200, or 400 mg twice daily on days 2 to 18 of a 21-day cycle) in patients with advanced NSCLC. An encouraging median PFS of 8.5 months was achieved in addition to a 79% disease control rate (29% partial response and 50% stable disease). The most common adverse reactions were similar to single-agent treatment (rash, hand–foot syndrome, and gastrointestinal symptoms). Grade 1/2 bleeding events were seen in three patients.[79] Based on these results, the ESCAPE trial was opened. This was a randomized phase III trial evaluating sorafenib (400 mg twice daily on days 2 to 19) in combination with carboplatin (AUC = 6)/paclitaxel (200 mg/m$^2$ every 21 days for six to eight cycles), in 926 newly diagnosed patients with stage IIIB/IV NSCLC. Patients with squamous cell histology were eligible for this trial. Patients were ineligible if they had a history of brain metastases, uncontrolled hypertension, and anticoagulation. The primary end point was overall survival. Secondary end points

included tumor response, duration of response, patient reported outcomes, and biological correlates. Major grade 3/4 toxicities (>10% of patients) were neutropenia, thrombocytopenia, infection, and fatigue. There were two cases of fatal hemorrhage (one in each treatment group). Patients receiving chemotherapy plus sorafenib had similar PFS (5.1 vs. 5.4 months) and overall survival (10.6 vs. 10.7 months) compared with patients receiving chemotherapy alone. Interestingly, patients with squamous cell histology appeared to do significantly worse when sorafenib was added to chemotherapy compared with those receiving chemotherapy alone (PFS: 4.4 vs. 5.8 months; overall survival: 8.9 vs. 13.6 months). There was no difference in survival for those with nonsquamous cell histology.[80]

A search for sorafenib and NSCLC on the http://www.ClinicalTrials.gov database identifies 15 clinical trials involving approximately 2700 patients (as of January 23, 2008).[102] One of these studies, NEXUS, is a large phase III trial investigating first-line sorafenib in combination with standard platinum-based doublet therapy (carboplatin/paclitaxel; gemcitabine/cisplatin). Another phase III trial, which investigated sorafenib in combination with carboplatin/paclitaxel, was closed early after an independent data monitoring committee determined that the trial would not meet its primary end point of improving overall survival. Phase I and II trials in chemonaive patients with locally advanced or metastatic disease are investigating sorafenib added to pemetrexed/carboplatin or carboplatin/paclitaxel/bevacizumab regimens. Further phase I/II studies in inoperable stage III disease are ongoing to assess sorafenib as part of a multimodality approach administered concomitantly with radiotherapy or as consolidation therapy following induction with cisplatin/etoposide/radiotherapy. The application of single-agent sorafenib in the treatment of patients with recurrent, refractory, or progressive disease (second line) is also being further examined. A phase II trial has been opened in chemotherapy-naive patients with NSCLC who are either ≥70 years of age and ECOG performance status (PS) 0 to 2 or <70 years of age and ECOG PS 2. In this trial, sorafenib (400 mg twice daily) will be administered in combination with gemcitabine 1200 mg/m$^2$ (days 1 and 8 every 21 days for maximum six cycles) or erlotinib (150 mg daily oral until disease progression).[103]

**Vandetanib** Vandetanib (AZD6474, Zactima) is an oral inhibitor of angiogenesis targeting VEGF receptors 2 and 3 as well as tumor growth with activity against RET, and EGFR/HER-1.[104,105] Vandetanib has been shown to be active against a wide range of tumor cells in preclinical studies.[106] In phase I studies, single-agent vandetanib was well tolerated in patients with various solid tumors including NSCLC.[107–109] The recommended daily dose is 300 mg.

**SINGLE-AGENT VANDETANIB.** Therapy with vandetanib (100, 200, or 300 mg daily) was evaluated in a randomized double-blind phase II dose-finding study of 53 Japanese patients with NSCLC. Toxicities included rash, diarrhea, and asymptomatic QTc prolongation. One patient died from treatment-related interstitial lung disease. An 11% partial response and 51%

disease control rate were observed.[110] In a randomized phase II trial of 168 patients, single-agent vandetanib (300 mg daily) was compared with gefitinib (250 mg daily) in patients after failure of first- or second-line platinum-based therapy. Of note, patients with hemoptysis, thromboses, squamous cell carcinoma, and brain metastases were permitted to enter this trial. Median PFS was 2.5 months for vandetanib compared with 1.9 months for patients receiving gefitinib. Objective responses were seen in 8% of vandetanib patients compared with 1% of gefitinib-treated patients, with disease control achieved in 37/83 (45%) versus 29/85 (34%) of patients, respectively. The most common toxicities (>10% of patients) seen in patients treated with vandetanib included nausea, diarrhea, rash, headache, dizziness, hypertension, and asymptomatic QTc prolongation. On progression, patients were allowed to switch to the alternative regimen after a 4-week washout period. In patients who switched therapies, disease control >8 weeks was seen in 16/37 (43%) patients who switched to vandetanib and 7/29 (24%) patients who switched to gefitinib. Overall survival was not significantly different between treatment arms (6.1 months for vandetanib and 7.4 months for gefitinib-treated patients).[81]

**COMBINATION THERAPY.** In a phase II randomized, placebo-controlled trial of 127 patients with stage IIIB/IV NSCLC, who had failed platinum-based chemotherapy, treatment with daily vandetanib (100 or 300 mg) plus docetaxel (75 mg/m$^2$ every 3 weeks) was compared with docetaxel alone. Patients with squamous cell histology were permitted to enter the trial, as were patients with clinically stable, previously treated brain metastases (without steroid treatment for 1 week at study entry). Patients in the run-in phase of this trial received vandetanib 100 mg/day or 300 mg/day plus docetaxel and were then randomized to receive further treatment with either vandetanib (100 or 300 mg/day) with docetaxel or placebo with docetaxel. Preliminary results reported an improvement in PFS with combination therapy, 4.4 and 3.9 months, for vandetanib 100 and 300 mg, respectively, compared with 2.8 months for docetaxel alone. However, no statistically significant difference in overall survival was noted between the three arms. AEs were similar to those mentioned previously. Nonfatal hemoptysis was reported in four patients with squamous cell histology.[82,111,112] The results of this study have led to a phase III trial comparing vandetanib plus docetaxel with docetaxel alone as a second-line treatment option for patients with advanced NSCLC. In a randomized phase II trial of 181, chemotherapy-naive patients with IIIB/IV NSCLC, treatment with single-agent vandetanib (300 mg daily) was compared with vandetanib plus paclitaxel (200 mg/m$^2$ iv) and carboplatin (AUC = 6 every 3 weeks)/paclitaxel and carboplatin alone. Patients with CNS metastases and squamous cell histology were permitted to enter this trial. The vandetanib monotherapy arm was stopped early after a planned interim analysis met the criterion for discontinuation. Combination therapy with vandetanib with carboplatin and paclitaxel prolonged PFS compared with carboplatin and paclitaxel alone (5.5 vs. 5.3 months). Overall survival was not significantly different. The objective

response rates were 7% for vandetanib alone, 32% for combination therapy, and 25% for chemotherapy alone. Toxicities, although more common with vandetanib-treated patients were similar to those seen with single-agent therapy.[84,113]

A phase II randomized trial in patients with SCLC (limited or extensive disease) compared maintenance vandetanib (300 mg daily) with placebo in patients who had responded to platinum-based chemotherapy (complete or partial response) and completed radiation therapy (thoracic and prophylactic cranial). There was no significant difference in PFS or overall survival for patients treated with vandetanib compared with placebo, 2.7 versus 2.8 months and 10.6 versus 11.9 months, respectively. Patients treated with vandetanib were more likely to experience toxicities (gastrointestinal and rash) requiring dose reductions. In a planned subgroup analysis, a significant interaction was noted in patients based on disease extent; patients with limited disease randomized to vandetanib had a longer overall survival (HR = 0.45; one-sided $p$ value 0.07), whereas those with extensive disease treated with vandetanib had a shorter overall survival (HR = 2.27; one-sided $p$ value 0.996).[85]

The ongoing clinical trial program is further examining the clinical application of vandetanib in the first-, second-, and third-line settings. A search of the http://www.ClinicalTrials.gov database for vandetanib and NSCLC identifies 11 clinical trials involving approximately 4350 patients (as of January 23, 2008).[102] Three phase III trials are ongoing to examine vandetanib either in combination (pemetrexed or docetaxel) or as monotherapy (vs. erlotinib) in the second- or third-line settings, with data expected during 2009. An additional large, phase III trial in a planned 930 patients is evaluating vandetanib versus best supportive care in the second- or third-line setting. Smaller phase II trials are investigating vandetanib with carboplatin/paclitaxel as neoadjuvant treatment and in combination with standard chemotherapy regimens as a first-line treatment option.

## Sunitinib

Sunitinib (SU11248, Sutent) is a novel, multitargeted, small molecule inhibitor of the receptor tyrosine kinases involved in tumor proliferation and angiogenesis, including VEGF receptors 1, 2, and 3, PDGF receptor-$\alpha$ and -$\beta$, Flt-3, c-kit, and the receptor encoded by the *ret* proto-oncogene (RET; rearranged during transfection), and Flt-3.[114] Of note, it has been suggested that combined inhibition of PDGF receptor and VEGF receptor 2-mediated signaling may be particularly potent in the inhibition of angiogenesis.[115] Sunitinib demonstrated antitumor activity against several tumor cell lines including NSCLC in preclinical studies.[116,117] The recommended dose of sunitinib is 50 mg daily for 4 consecutive weeks of a 6-week cycle. The 2-week rest period is required because of the long half-life of sunitinib (80 hours for the active metabolite), which causes drug accumulation. However, in the clinical setting, this administration schedule may also allow some vascular regrowth.

**SINGLE-AGENT SUNITINIB.** A phase II trial of 64 patients evaluated sunitinib (50 mg daily for 4 weeks in a 6-week cycle) as second- or third-line therapy in patients with advanced NSCLC. Patients with recent grade 3 hemorrhage or recent

gross hemoptysis, brain metastases, uncontrolled hypertension, or patients who had received surgery within 4 weeks of study entry were excluded from this trial. Patients with squamous cell histology were eligible, although a history of cardiac disease, cerebrovascular accident, or pulmonary embolism precluded patients from entering this trial. Treatment with sunitinib resulted in a 9.5% partial response and 42.9% stable disease. Median duration of response was 12.2 weeks. Median PFS was 2.6 months and overall survival was 5.5 months. Major toxicities included fatigue/asthenia, pain/myalgia, nausea and vomiting, dyspnea, and stomatitis/mucosal inflammation. There were two incidences of pulmonary hemorrhage (in patients with squamous cell histology, although only one event was believed to be sunitinib related) and one cerebral hemorrhage.[86] A subsequent phase II study evaluated 47 patients with previously treated stage IIIB/IV NSCLC treated with sunitinib (37.5 mg daily continuously for 4-week cycles). Patients with brain metastases and significant hemoptysis were excluded. One patient had a confirmed partial response and nine patients had stable disease. Median PFS was 2.8 months and overall survival was 8.6 months. AEs were similar to those mentioned previously in addition to congestive heart failure, hypomagnesemia, and hypoxic respiratory failure.[87] The results of these studies supports further investigation for sunitinib in combination with other treatments for NSCLC.

**COMBINATION THERAPY.** A phase I study in untreated patients with stage IIIB/IV NSCLC evaluated sunitinib (37.5 or 50 mg daily for 14 days) in combination with cisplatin (100 mg/m$^2$ iv on day 1)/gemcitabine (1000 mg/m$^2$ or 1250 mg/m$^2$ iv on days 1 and 8 of a 21-day cycle). No dose-limiting toxicities were seen with sunitinib 37.5 mg, whereas two were noted (neutropenia and infection) at the 50-mg dose. Additional grade 3/4 toxicities included anemia, neutropenia, and thrombocytopenia. Three patients achieved a partial response at the 50-mg dose level. Sunitinib 37.5 mg appears to be the recommended dose with this chemotherapy combination. Studies with the higher dose of gemcitabine and sunitinib administration on a continuous dosing schedule are currently ongoing.[88] A second phase I study in 37 patients with advanced solid tumors evaluated sunitinib (20, 37.5, or 50 mg daily for 4 weeks in a 6-week cycle or 2 weeks in a 3-week cycle) in combination with docetaxel (60 or 75 mg/m$^2$ iv every 3 weeks). Thirteen patients with NSCLC were enrolled. Neutropenia (with or without fever) was seen in five patients. One patient had pulseless electrical activity and pulmonary hemorrhage. With greater than 50% stable disease seen at both dose levels, the combination of sunitinib 37.5 mg daily for 2 weeks of a 3-week cycle and docetaxel 75 mg/m$^2$ iv has been recommended with ongoing pharmacokinetic and efficacy studies to determine the utility of further evaluation of this regimen.[118]

Searching the http://www.ClinicalTrials.gov database using the terms sunitinib and NSCLC identifies eight clinical trials involving approximately 1500 patients (as of January 23, 2008).[102] A phase III trial is evaluating sunitinib in combination with erlotinib versus erlotinib alone in 956 patients in the second- or third-line settings. Phase I and II trials are ongoing to investigate sunitinib added to standard first-line regimens

(carboplatin/paclitaxel; carboplatin/paclitaxel/bevacizumab; carboplatin or cisplatin/pemetrexed; gemcitabine/cisplatin).

**Cediranib** Cediranib (AZD2171, Recentin) is a potent inhibitor of both VEGF receptors 1 and 2, it also has activity against c-kit, PDGFR-$\beta$, and Flt-4 at nanomolar concentrations, but is selective against other serine/threonine kinases studied. Cediranib has been shown to inhibit VEGF signaling with once-daily oral dosing. Cediranib 45 mg once daily has been shown to be well tolerated in patients with a broad range of solid tumors.[102] Most common toxicities include diarrhea, dysphonia, and hypertension.[119]

**COMBINATION THERAPY.** Cediranib (20, 30, or 45 mg daily) has been evaluated in phase I studies in combination with various chemotherapy regimens, including pemetrexed (500 mg/m$^2$ every 3 weeks) and docetaxel (75 mg/m$^2$ every 3 weeks), two agents commonly employed in the treatment of patients with NSCLC. In this group of heavily pretreated patients with advanced solid tumors, the safety profile of cediranib was similar to that observed in single-agent cediranib studies with the most common grade 3 toxicities including diarrhea, fatigue, and hypertension. Response rates were promising, and cediranib did not appear to effect the pharmacokinetic profile of either agent.[120] A second phase I study in patients with previously treated advanced solid tumors evaluated cediranib (20, 30, or 45 mg daily) in combination with gefitinib (250 mg daily). Cediranib 30 mg or lower appeared to be well tolerated. The most common toxicities were diarrhea, rash, abdominal pain, and hypertension, with only the latter side effect attributed to cediranib.[121] A phase I study in stage IIIB/IV chemotherapy-naive NSCLC patients evaluated cediranib (30 or 45 mg daily on day 2) in combination with carboplatin (AUC = 6)/paclitaxel (200 mg/m$^2$ day 1) every 3 weeks. Patients with prior hemoptysis or bleeding were ineligible for this trial. One patient at each of the 30 and 45 mg doses experienced a dose-limiting toxicity, grade 3 ALT, and febrile neutropenia with mucositis, respectively. Hypertension grade $\geq2$ was seen in six patients, prompting the institution of a standard algorithm to manage this expected toxicity. Other toxicities included fatigue, anorexia, mucositis, and diarrhea. Of the 15 patients evaluable for response, there were six patients with a partial response and eight with stable disease.[89] A second phase I study in the same population evaluated cediranib (30 or 45 mg) in combination with gemcitabine (1250 mg/m$^2$ on days 1 and 8) and cisplatin (80 mg/m$^2$ on day 1 every 3 weeks). A total of 14 patients were enrolled: five patients at the 30-mg dose and nine patients at the 45-mg dose. Toxicities including diarrhea, fatigue, hypertension, and voice changes were seen at both levels. Grade 4 toxicities included one patient with reversible ischemia and another with fatigue. Cediranib did not appear to affect gemcitabine pharmacokinetics. Responses were seen at both dose levels. Further testing of this combination has been recommended with 30-mg cediranib as the recommended dose level.[90]

In addition to those studies mentioned previously, searching the http://www.ClinicalTrials.gov database for NSCLC trials of cediranib identifies six clinical trials involving approximately

1000 patients (as of January 23, 2008).[102] However, the National Cancer Institute of Canada recently closed BR-24, a phase II/III trial of cediranib in combination with carboplatin/paclitaxel as the planned end of phase II efficacy and tolerability analysis by the study's Data Safety Monitoring Committee revealed an imbalance in toxicity. A phase II trial in 74 patients is investigating cediranib in combination with pemetrexed for the second-line treatment of NSCLC. A further phase I trial is evaluating cediranib plus gefitinib in patients with NSCLC or head and neck cancer.

**Motesanib** Motesanib (AMG 706) is a potent, oral, multikinase inhibitor with activity against VEGF receptors 1, 2, and 3, PDGF receptor, kit, and RET. Preclinical studies demonstrated inhibition of VEGF-induced angiogenesis and inhibition of tumor growth in vivo.[122] A phase I study evaluated motesanib (continuously for 3 weeks of a 4-week cycle) by DCE-MRI in 65 patients with advanced solid tumors. The most frequent toxicities (>10% of patients) were hypertension, fatigue, diarrhea, nausea, vomiting, and headache. Most events were mild to moderate in severity and reversible. Of note, early trials suggested that there was cause for concern with some patients who had received motesanib developing cholecystitis and gallbladder enlargement. Ongoing studies have continued to gather data on this issue, subject to protocol amendments to ensure that physicians are aware of the possibility that these conditions might occur. However, latest reports suggest that these events are manageable. Of 56 evaluable patients, there was a 4% partial response and 61% stable disease rate. DCE-MRI showed reductions up to 61% in AUC on day 21 of treatment. Motesanib 125 mg daily was well tolerated and has been recommended for phase II studies.[123]

COMBINATION THERAPY. A phase I trial evaluated motesanib (50 or 125 mg daily or 75 mg twice daily) in combination with gemcitabine (1000 mg/m² weekly for 7 of 8 weeks, then 3 of 4 weeks for up to 11 cycles) in 26 patients, including two patients with NSCLC. Motesanib pharmacokinetics did not appear to be affected by the schedule of gemcitabine administration. There were two dose-limiting toxicities: grade 4 neutropenia and grade 3 deep vein thrombosis. Other toxicities (>10% of patients) included lethargy, fatigue, headache, nausea, and diarrhea. Two unconfirmed partial responses and seven cases of stable disease were noted. Further testing of this regimen has been recommended.[124] In another phase I study, motesanib (50, 75, 100, 125 mg daily and 75 mg twice daily) was combined with panitumumab (9 mg/kg on day 1) plus cisplatin (75 mg/m² on day 1)/gemcitabine (1250 mg/m² on days 1 and 8 of a 21-day cycle) in 36 patients with advanced solid tumors, including 19 patients with NSCLC. Of the patients included in this trial, 42% had received one prior line of chemotherapy. There was a 39% rate of thromboembolism, one grade 5 pulmonary embolism was seen. Additional toxicities (>25% of patients) included nausea, fatigue, and hypertension. Of the 29 evaluable patients, there was one complete response with a partial response rate of 31% (including six cases seen in patients with NSCLC) and 59% of patients had stable disease. Motesanib pharmacokinetics at a daily dose of 125 mg were not affected by other therapies. Although this combination appears to

be effective, the rate of thromboembolism needs to be compared with treatment with cisplatin/gemcitabine alone.[125,126]

The largest motesanib phase III, multicenter, placebo-controlled, double-blind trial, was planned to randomize 1240 patients to receive first-line motesanib with carboplatin/paclitaxel or placebo with carboplatin/paclitaxel. Patients with untreated or symptomatic CNS metastases, a history of pulmonary hemorrhage or gross hemoptysis (approximately 3 mL of bright red blood or more) within 6 months prior to randomization, or uncontrolled hypertension are not eligible to enter this trial. However, patients with squamous cell histology are eligible. The primary end point for this trial was overall survival; secondary end points include PFS, objective tumor response rate, and duration of response. Enrollment in the trial was suspended in November 2008, following a planned safety data review of 600 patients by the study's independent Data Monitoring Committee (DMC), which revealed higher early mortality rates in the motesanib group compared to the placebo group. In addition, the DMC recommended that the patients with squamous NSCLC immediately discontinue motesanib therapy based on an observation of a higher incidence of hemoptysis. The DMC did not recommend discontinuation of motesanib therapy for the patients with nonsquamous NSCLC.

A phase II head-to-head trial with bevacizumab to evaluate the difference in objective response rates between first-line motesanib plus carboplatin/paclitaxel and bevacizumab plus carboplatin/paclitaxel is also currently recruiting patients. Eligibility criteria for this trial reflect the bevacizumab eligibility profile (i.e., nonsquamous NSCLC, no history of or current CNS metastases, no history of pulmonary hemorrhage or gross hemoptysis, and no uncontrolled hypertension).

**Axitinib (AG-013736)** Axitinib is a small molecule tyrosine kinase inhibitor of VEGF receptors 1, 2, and 3, PDG receptor-$\beta$, and c-kit. A phase I dose escalation study evaluated axitinib (5 to 30 mg orally daily for 28-day cycle) in 36 patients with solid tumors (including NSCLC) who were refractory to standard therapy. The maximum-tolerated dose and the recommended dose for phase II/III trials is 5 mg twice daily. Three confirmed partial responses were observed with other evidence of antitumor activity. Dose-limiting toxicities (>10% of patients) associated with axitinib therapy included hypertension, fatigue, nausea, vomiting, diarrhea, headache, stomatitis, and erythema; however, the complete AE profile is not yet known. Cavitation of lung lesions was observed in the two patients with NSCLC, both subsequently died from hemoptysis (one was believed to be axitinib related). Similar treatment effects have been seen in patients treated with bevacizumab and may be a marker of antiangiogenic activity.[127] A phase II trial evaluated the activity and safety of axitinib (5 mg twice daily) in 32 patients with stage IIIB/IV NSCLC. Patients may have had prior chemotherapy, radiation therapy, or surgery, 13% of patients were treatment naive. Median duration of response was 9.4 months, PFS was 5.8 months, and overall survival was 12.8 months. Three responses were noted. Toxicities (occurring in 5% of patients) included fatigue, diarrhea, hypertension, and hyponatremia.[79]

The clinical trial program for axitinib in NSCLC is in development; a search of the http://www.ClinicalTrials.gov database for NSCLC trials of axitinib identifies only two clinical trials (as of January 23, 2008).[102] However, the first, a phase II study of new agents with and without docetaxel, was withdrawn prior to beginning recruitment. The second, a phase II trial of second- or third-line axitinib in patients with advanced NSCLC, is expected to report data during 2008.

**Other Therapies**   Pazopanib (GW786034) is an oral, small molecule tyrosine kinase inhibitor targeting VEGF receptors 1, 2, and 3, PDGF receptor-$\alpha$ and -$\beta$, and c-kit. A phase I study in 43 patients with advanced solid tumors (including NSCLC). The most common AEs were nausea, diarrhea, fatigue, hypertension, anorexia, and vomiting. Hair depigmentation was observed at higher doses. Tumor shrinkage was noted in patients with renal cell cancer. One patient with NSCLC was included in the six patients with stable disease who remained on therapy for 6 months or more.[128] The clinical trial program for pazopanib in NSCLC is still in its infancy; searching the http://www.ClinicalTrials.gov database for NSCLC trials of pazopanib identifies only two ongoing/planned clinical trials (as of January 23, 2008).[102] A phase II trial evaluated the safety and efficacy of pazopanib in the neoadjuvant setting as presurgical therapy in patients with stage IA/B, resectable NSCLC. This open label, multicenter, phase II study was designed to assess the activity of pazopanib when given to 35 treatment-naive patients with stage I to II NSCLC prior to surgery. Pretreatment and posttreatment high-resolution computed tomography (HRCT) scans measuring tumor size showed that 30 patients (86%) had experienced a tumor volume reduction. Overall, patients experienced changes in tumor size ranging from a reduction of 86% to an increase of 17%. After an initial biopsy, 35 eligible patients had received 800 mg of pazopanib orally, once daily for 2 to 6 weeks, followed by a treatment free period of 7 days prior to scheduled surgery to allow the administered drug to be eliminated from the body. The median duration of pazopanib therapy was 16 days. Grade 3 toxicities were seen in five patients while participating in study. These toxicities included elevated liver enzymes (2), hypertension (1), shortness of breath (1), pneumonia (1), urinary tract infection (1), reduced white blood cell count (1), potassium increase (1), and rash (1). One grade 4 toxicity of a pulmonary embolus was seen in a patient in relation to surgery, 18 days after finishing pazopanib treatment. One patient discontinued treatment because of AEs. Twelve patients required adjustment or initiation of antihypertensive medication during the study.

A second phase II trial (n = 40) is investigating the safety and efficacy of single-agent pazopanib in the second- and third-line treatment settings.

XL647 is another oral, small molecule tyrosine kinase inhibitor with activity against VEGF receptor 2, EGFR, erbB2/HER-2, and EphB4. Initial phase I studies administered XL647 daily for 5 days in a 14-day schedule to 41 patients with advanced solid tumors. The maximum tolerated dose was 350 mg daily for 5 days. One patient with NSCLC had a partial response and an additional 14 patients had stable disease. Toxicities include diarrhea, fatigue, rash, and QTc prolongation.[129,130] In a second phase I study by the same group, XL647 was administered on a continuous daily schedule to patients with advanced solid tumors. To date, 12 patients have been evaluated; 300 mg daily is the highest dose administered with no dose-limiting toxicities. Four patients have stable disease beyond 3 months.[131] A modest clinical development program is ongoing for the development of XL647 in NSCLC, with two phase II clinical trials identified in a search of the http://www.ClinicalTrials.gov database (as of January 23, 2008).[102] Both monotherapy trials will enroll a planned ~40 patients each. One trial will evaluate the efficacy and safety of XL647 in the first-line setting, whereas the other will assess XL647 in patients who have relapsed NSCLC following failure of gefitinib or erlotinib.

## CONCLUSION

Despite improvements in cytotoxic chemotherapy, it remains nonspecific, targeting rapidly dividing normal and tumor cells. Thus, chemotherapy is widely associated with several toxic side effects. A therapeutic plateau has been reached with chemotherapy in terms of efficacy with no recent improvements in survival and unpredictable tumor response. Realization of a new generation of molecular targeted therapies that interfere with factors intrinsic to tumor growth and metastases offers a highly specific approach with more acceptable toxicity. As such, these agents are being combined with standard chemotherapy regimens, improving patient outcomes.

Angiogenesis remains a rational therapeutic target in NSCLC and novel approaches include the development of anti-VEGF ligand and anti-VEGF receptor strategies. Specific and highly selective antibodies have been designed, binding only to the VEGF ligand. By binding all free circulating VEGF, these antibodies prevent VEGF ligand/receptor interaction at all binding sites (VEGF receptors 1 and 2 and the NRP-1 coreceptor). Synthetic soluble receptors currently in development, such as VEGF-Trap, also bind directly to the VEGF ligand; however, they have a much shorter half-life than antibodies directed against the VEGF ligand. These receptors may be less specific; binding other VEGF family members, including VEGF-B and PlGF. To date, little is known about the effects of inhibiting PlGF and VEGF-B functions. However, VEGF mediates its effects through stimulation of VEGF receptor 2 in an exclusive fashion (i.e., only VEGF binding to VEGF receptor 2 stimulates effects such as endothelial cell growth and vascular permeability).[3] Related molecules such as PlGF cannot stimulate these effects.[26] In conclusion, the proangiogenic effects of VEGF mediated through all of the receptors to which it binds can be inhibited by targeting VEGF.

Agents targeting VEGF receptors include small molecule inhibitors, antibodies, and ribozymes. Antibodies and ribozymes are highly specific, targeting a single receptor. As a result, VEGF signaling through a single receptor may be completely blocked; however, ligand interactions with other receptors will not be inhibited. Small molecule kinase inhibitors have the potential to

inhibit the kinase activity of several receptors. As such, these molecules are not highly specific or selective and may inhibit activity mediated by receptors other than VEGF receptors 1 and 2.

Both the VEGF ligand and VEGF receptors are viable and promising targets for anticancer therapy, each with possible benefits and limitations. Leading the way are the positive data from phase III trials with the humanized anti-VEGF ligand monoclonal antibody bevacizumab, which has proven benefit as a first-line therapy in NSCLC.[38,39,41,43] Data for bevacizumab have made the first steps toward the future of antiangiogenic therapy, proving that the concept that antiangiogenesis in general, and VEGF inhibition in particular, is an effective anticancer option, adding to the efficacy of chemotherapy without overlapping toxicity.

The clinical relevance of multiple receptor inhibition remains under evaluation and several agents have demonstrated promising efficacy. These molecules are not as specific as antibodies developed against the VEGF ligand as they inhibit several tyrosine kinase receptors, including VEGF receptors 1 and 2. Although, as the influence of VEGF and other proangiogenic factors changes with disease progression, the relative nonspecificity of multitargeted tyrosine kinase inhibitors may be beneficial, conveying continued activity late in disease. However, with these broader actions, it is not clear whether all intended targets are inhibited equally at the therapeutic dose. For example, the tyrosine kinase inhibitor vandetanib has affinity for VEGF receptor 2 and EGFR, with higher affinity for VEGF receptor 2.[132] Therefore, depending on the dose used, the EGFR pathway may remain active, compensating for lost VEGF receptor 2 signaling. In addition, their broader activity leads to increased off-target AEs, similar to, and sometimes overlapping those seen with cytotoxic chemotherapy. In addition to those AEs widely accepted as being associated with antiangiogenic therapy (e.g., bleeding, hypertension, proteinuria, neutropenia), their toxicity profile also includes fatigue, rash, hand–foot syndrome, and diarrhea. Other dose-limiting toxicities of note include heart failure and QTc interval prolongation. Whether these agents can be safely combined with chemotherapy with acceptable toxicity profiles is being further evaluated in ongoing clinical trials.

The number of agents and approaches currently in clinical development and the large number of ongoing clinical trials are testimony to the considerable research into the application of antiangiogenic therapy and the commitment to transform the future of NSCLC care.

# Anti-EGFR Therapies: How to Select Patients

Epidermal growth factor receptor (EGFR) inhibitors have proven effective in some patients with advanced non–small cell lung cancer (NSCLC) previously untreated and/or treated with chemotherapy.[1] Most data are published on the EGFR tyrosine kinase inhibitors (TKIs) gefitinib and erlotinib. Objective response rates in phase II studies with gefitinib and erlotinib are 10% to 18% in western populations and up to 27% in Asian populations.[2–8] In addition, a substantial fraction of NSCLC patients, who failed previous chemotherapy, achieve long-term stable disease (SD), leading to disease control rate (DCR) exceeding 50% of patients and often associated with symptomatic improvement and prolonged survival. Thus, developing a biomarker capable of predicting DCR is equally if not more important than one predicting only those who have objective response.

Two large placebo controlled randomized studies were performed with EGFR TKIs as second- or third-line therapy.[6,7] The BR.21 study with erlotinib showed for the first time a survival benefit for a targeted therapy in NSCLC, whereas the Iressa Survival Evaluation in Lung Cancer (ISEL) study with gefitinib did not demonstrate a significant survival advantage, although subset analysis in the latter study did show survival benefit in certain clinical subgroups (i.e., never-smokers and Asians).[7] In both studies, clinical effect of EGFR TKIs on survival was seen also in patients with "unfavorable" clinical characteristics (e.g., men, smokers, and patients with tumors of squamous histology).[7,8] Thus, clinical features appear insufficient for identifying those patients who would and would not have survival benefit from these new agents.

After encouraging results of EGFR TKIs in relapsed patient categories, it was natural to test these drugs in combination with standard first-line chemotherapy of advanced NSCLC. In large prospective randomized studies, standard chemotherapy doublets were given in combination with EGFR TKIs or placebo, followed by maintenance with active drugs or placebo.[9–12] No benefit from adding EGFR TKIs to standard chemotherapy was observed in any of the four studies, and

again clinical characteristics (except for never-smoking status in the TRIBUTE study) could not identify subsets of patients who benefited from combination therapy.

Thus, the search for other measures (i.e., biomarkers) for selection of patients for the EGFR TKIs was mandatory.

The use of monoclonal antibodies, mainly cetuximab has been studied in NSCLC, and most recently the results from the FLEX (**F**irst Line in **L**ung Cancer with **E**rbitu**X**) study, which is a comparison of cisplatin/vinorelbine with or without cetuximab in EGFR immunohistochemistry (IHC) positive was presented (see later).[13] The latter study showed a survival benefit for patients having cetuximab added to the chemotherapy in first-line therapy for advanced NSCLC patients with EGFR protein-expressing tumors. Although the survival benefit (median survival, 11.3 vs. 10.1 months; hazard ratio [HR] = 0.87) was statistically significant, the efficacy seems not to be dramatically improved, and the study calls for a better biomarker selection of patients to this type of therapy. Another study (BMS 099), which compared chemotherapy with or without cetuximab as first-line therapy in advanced unselected NSCLC did not meet the primary end point of prolonged progression-free survival (PFS).[14] Thus, selection of NSCLC patients to EGFR inhibitors based on EGFR markers might be crucial for outcome both with EGFR TKIs as well as with monoclonal antibodies. Potential clinical and molecular biomarkers for selection of patients to EGFR inhibitors for NSCLC is discussed later.

## CLINICAL FACTORS

### Early Clinical Trials

In the phase I trials of gefitinib, tumor response was exclusively seen in NSCLC (4/16 in NSCLC and 0/48 in other types of cancer in United States/European study, 5/23 in NSCLC and 0/8 in other types of cancer in Japanese study).[2,3] Especially in Japanese study, all four responders were with adenocarcinoma and three fourths were female patients.[2]

Two phase II trials of gefitinib, Iressa Dose Evaluation in Advanced Lung Cancer (IDEAL) 1 and 2, showed that certain patient subgroups appeared to have a higher response rate, namely women, adenocarcinoma, and Japanese.[4,5] In IDEAL 1 conducted in Japan and European countries, 210 patients with one or two prior chemotherapy regimens were randomly assigned either to have 250 or 500 mg of gefitinib. Objective tumor response rate was similar between the two groups (18.4% and 19.0% for 250- and 500-mg group, respectively). In contrast, adverse events were more common in the 500-mg group. In the 250-mg group, 15.5% of the patients had AEs requiring a short-treatment interruption, and none required a dose reduction, 28.3% and 10.4% of the patients in the 500-mg group required a treatment interruption and a dose reduction, respectively. Response rate was higher for Japanese patients than non-Japanese patients (27.5% vs. 10.4%; $p = 0.0023$). Multivariate analysis revealed that performance status (PS), sex, histology, and prior immuno/hormonal therapy were significant predictive factors at the 10% significance level. A similarly designed randomized phase II trial conducted in the United States (IDEAL 2) revealed that overall response rate was 10% (12% in 250-mg group and 9% in 500- mg group). In this trial, patients with stage IIIB/IV diseases, for which they had received at least two chemotherapy regimens, were eligible. Response rate was again higher in women (19%) than in men (3%), in adenocarcinomas (13%) than other histologic types (4%).

Miller et al.[15] were the first to report that smoking history as well as bronchioloalveolar pathologic subtypes predict sensitivity to gefitinib. Overall, a partial radiographic response was observed in 21 (15%) of 139 patients with advanced NSCLC. Never-smokers have a significantly higher response rate than former/current smokers (36% vs. 8%; $p < 0.001$).[15] In addition, adenocarcinoma with bronchioloalveolar features had higher response rate (38%) than other adenocarcinomas (14%, $p < 0.001$).[5] Multivariate analysis confirmed that these two factors were independent predictors of response ($p = 0.006$ and 0.004, respectively). However, gender was not identified as a significant predictor in both univariate and multivariate analyses. The authors speculated that this was because of co-migration of smoking and gender.[15]

### Subsequent Studies

Following this observation, various groups confirmed that response to gefitinib or erlotinib very much affected patients' clinical backgrounds. In observation of over 4000 patients taken from previously published literature (Table 49.1), TKI response was dependent on smoking history (never-smokers 38% vs. former/current smokers 10%), gender (men 13% vs. women 36%), histologic type (adenocarcinoma 27% vs. nonadenocarcinoma 7%), and ethnicity (East Asians 29% vs. others 8%).

Several authors further showed that higher response rate was linked to longer survival in each patient subset. For example, Ando et al.[16] showed that median survival time (MST) after gefitinib treatment was 16.6 and 7.7 months in female and male patients, 15.6 and 7.6 months in never-smokers and former/current smokers, and 12.1 and 6.3 months in patients with adenocarcinoma and with other histologic types, respectively. In addition, multivariate analysis by the Cox regression model revealed that women, no smoking history, adenocarcinoma as well as absence of metastatic disease, good PS, previous chest surgery are independent prognostic factors.[16]

### Clinical Predictors in Randomized Phase III Trials

Aforementioned trends were also seen in randomized controlled clinical trials. In four randomized trials comparing TKI plus platinum doublet chemotherapy versus platinum doublet chemotherapy, namely Iressa NSCLC Trial Assessing Combination Treatment (INTACT) 1 and 2 using gefitinib, TALENT and TRIBUTE using erlotinib, addition of TKI did not yield survival advantage over platinum doublet.[9–12] However, subgroup analysis of TRIBUTE showed that addition of erlotinib to carboplatin plus paclitaxel confer an advantage in overall survival in patients who reported never smoking (MST, 23 vs. 10 months; HR, 0.49; 95% confidence interval [CI], 0.28 to 0.85).[12] None of other factors including gender, race, PS, or histology were predictive for overall survival.[12] The favorable predictive role of never smoking was also demonstrated for patients with bronchioloalveolar carcinomas (BAC).[17]

In a randomized, placebo-controlled trial to determine whether erlotinib prolongs survival in NSCLC patients after the failure of first- or second-line chemotherapy (BR.21), erlotinib significantly prolongs survival with MST of 6.7 versus 4.7 months (HR, 0.70; $p < 0.001$).[6] In this trial, tumor response was significantly better in never-smokers than former/current smokers (25% vs. 4%; $p < 0.001$).[12] Furthermore, smoking history was an independent prognostic factor ($p = 0.048$), as well as erlotinib treatment ($p = 0.002$), Asian ethnicity ($p = 0.01$), and adenocarcinoma histology ($p = 0.004$). In their exploratory subgroup analyses, a benefit from erlotinib was dependent on smoking history, with HR of 0.9 ($p = 0.14$) in former/current smokers and 0.4 ($p < 0.001$) in never-smokers.[6]

In contrast, similar placebo-controlled randomized trial using gefitinib in place of erlotinib, ISEL trial, failed to show overall survival advantage in gefitinib treatment group (median survival, 5.6 vs. 5.1 months; $p = 0.087$).[7] However, gefitinib prolongs survival in never-smokers (MST, 8.9 vs. 6.1 months; $p = 0.012$) as well as in Asian patients (MST, 9.5 vs. 5.5 months; $p = 0.010$) in preplanned subset analyses.[7]

The results of two randomized phase II trials comparing gefitinib with docetaxel were recently reported. V15-32 conducted in Japan failed,[18] but similarly designed Iressa Non–small cell lung cancer Trial Evaluating REsponse and Survival against Taxotere (INTEREST)[19] was able to show noninferiority of gefitinib to docetaxel in patients with NSCLC having been treated with one or two chemotherapy regimens. None of clinical parameters such as sex, PS, smoking status, age, ethnicity (INTEREST only) significantly affected overall survival in the both trials.[18,19] These somewhat unexpected observations are at least partly attributed to high crossover rate especially in V15-32, that is, 53% of patients with docetaxel arm received gefitinib upon progression and 36% of patients with gefitinib

arm received docetaxel,[18] whereas the rates were 31% and 37% in INTEREST,[19] respectively. Other concern was that rates of nonsmokers were not equal in V15-32 (i.e., 29% of gefitinib arm were nonsmokers, whereas 36% of docetaxel arm were nonsmokers).[18]

## Clinical Trials for Patients Selected by Clinical Factors

Prompted by these observations, Lee et al.[20] conducted phase II trial to evaluate the efficacy of gefitinib as a first-line therapy in never-smokers with advanced or metastatic adenocarcinoma in Korea. Out of 36 patients who were assessable for response, 25 patients (69%) had partial response and 4 (19%) had stable disease, yielding 88% of disease control rate.[16] This amazingly high rate could be achieved possibly because patients had a combination of three predictors of good response. Interestingly, they did not see difference in response between adenocarcinoma with bronchioloalveolar features (3/7, 43%) and that without bronchioloalveolar features (22/29, 76%) ($p = 0.16$).[20]

Although the contribution of each factor to the positive results is unknown, this study clearly supports the further study of EGFR TKI as a first-line therapy in certain subsets of NSCLC patients. This was prospectively investigated in Iressa Pan-Asia Study (IPASS), a phase III trial investigating gefitinib versus carboplatin/paclitaxel doublet chemotherapy as first-line treatment in selected subjects with stage IIIB/IV adenocarcinoma having no or light smoking history in East and South East Asia.[21] The result was recently reported to be positive and details were discussed later in this chapter.

## Histology

As shown in Tables 49.1, response rate for patients with adenocarcinoma was 27% compared with 7% in patients with other histologic types. As discussed earlier, Miller et al.[15] reported that patients with bronchioloalveolar histologic type predict sensitivity to gefitinib. Out of 139 NSCLC patients they reviewed, 21 (15%; 95% CI, 9% to 21%) experienced a partial radiographic response. In this study, the authors defined NSCLC of bronchioloalveolar subtype as adenocarcinoma with bronchioloalveolar features, bronchioloalveolar carcinoma with focal invasion, or pure bronchioloalveolar cancer. However, this definition of bronchioloalveolar features are not strictly followed to World Health Organization (WHO) criteria in which bronchioloalveolar cell carcinoma is defined as noninvasive, in situ carcinoma.[15] However, these observations do not preclude patients with nonadenocarcinoma histology from candidates of EGFR-TKI therapy. In aforementioned BR.21 trial comparing erlotinib with best supportive care, patients with nonadenocarcinoma histology also had a survival benefit with an HR of 0.8 ($p = 0.07$).[6]

Adenosquamous carcinoma is defined as having components of both squamous cell carcinoma and adenocarcinoma with each comprising at least 10% of the tumor. Although the majority of patients with this histologic type are smokers, several investigators reported similar incidence of EGFR mutation in adenosquamous cell carcinoma, one of putative predictive markers as discussed later. For example, Kang et al.,[22] Toyooka et al.,[23]

and Sasaki et al.[24] reported that EGFR mutation was present in 11/25, 3/11, and 4/26 adenosquamous carcinomas, respectively. Although most patients were not treated with EGFR TKI, patients with adenosquamous histology harboring EGFR mutation can be candidates for EGFR-TKI therapy. Interestingly, these authors agree in that identical EGFR mutation is present in both squamous and adenocarcinoma components in the same adenosquamous tumor.[22–24] In addition, at least a part of patients with squamous cell carcinoma who responded to EGFR TKI in the literature may, in fact, be those with squamous cell carcinoma with adenocarcinoma component with EGFR mutation.

Similarly, Fukui et al.[25] reported that one of six patients with combined small cell carcinoma and adenocarcinoma of the lung had EGFR L858R mutation. This mutation was again present in both small cell and adenocarcinoma components.

## Skin Toxicity

Skin toxicity is most common adverse event relating to EGFR-TKI therapy. For example, during treatment with gefitinib 250 mg/day or erlotinib 150 mg/day, skin toxicity occurred in 62%[4] and 75% of the patients.[26] In a phase II trial of erlotinib, skin rash correlated with tumor response and overall survival. MSTs for patients without rash, those with grade 1, and those with grade 2 or 3 were 1.5, 8.5, and 19.6 months, respectively.[8] Similarly, Jänne et al.[27] reported a correlation between skin rash and survival in patients on an expanded access study. MST for patients with skin toxicity of any grade was 10 months that was significantly longer than 4.5 months for patients without skin toxicity ($p = 0.0001$).[27]

In general, data from multiple studies with cetuximab and erlotinib show a consistent relationship between rash and response/survival in NSCLC as well as other tumor types.[28] However, this relationship is less consistent for gefitinib, reason for this discrepancy is currently not known.[28]

## Other Clinical Factors Related to Efficacy of EGFR TKIs

Several other factors are reported to be associated with response/survival of patients treated with gefitinib or erlotinib. These included absence of metastatic disease,[16] good performance status,[4,16,26,27,29,30] previous chest surgery,[16] younger age,[7,13] presence of prior platinum chemotherapy.[6]

## Interstitial Lung Disease

In Japan, considerable fraction of patients with gefitinib treatment suffer from fatal interstitial lung disease (ILD).[32] Large multi-institutional retrospective analysis conducted by West Japan Clinical Oncology Group (WJOG) revealed that 70 (3.5%) cases and 31 deaths (1.6%) from gefitinib induced ILD among 1976 patients.[16] In a prospective study conducted by AstraZeneca Japan, incidence of ILD was 5.81% (193/3322) and 83 died of disease (2.5% mortality).[33] In combined analysis of two phase II studies of erlotinib monotherapy in Japan, ILD was observed 5 of 108 (4.6%).[34] In WJOG study, gefitinib-induced ILD was significantly associated with male sex, smoking history, and coincidence of interstitial pneumonia.[16] In AstraZeneca study, poor PS, smoking history, preexisting ILD, and prior history of chemotherapy were independently associated with ILD.[33]

However, incidence of ILD appears to be lower in other Asian countries than Japan except Taiwan. Chiu et al.[35] from Taiwan reported that four patients with NSCLC having brain metastases out of 76 patients (5.8%) developed ILD. In contrast, ILD was observed in 3/485 patients treated with erlotinib compared with 3/242 patients in the placebo group in BR.21 study in which about 13% of patients are of Asian ethnicity.[6] Similarly, the number of patients experiencing ILD as higher in Asian population than in the overall population; however, no difference was observed between the gefitinib and placebo groups (3% vs. 4%) in ISEL study in which about 20% of patients are of Asian ethnicity.[7] From Korea, no cases of gefitinib-related ILD was observed in 111 patients with advanced NSCLC on expanded access program.[29] It is difficult to understand difference of incidence of ILD among countries especially among several East Asian countries. However, variability in the criteria for ILD should exist making it difficult to estimate true incidence of gefitinib or erlotinib induced ILD among different countries. Therefore, eliminating patients with multiple risk factors for ILD from candidates of EGFR-TKI therapy is important for patient selection at least in several East Asian countries including Japan.

## *EGFR* GENE COPY NUMBER

In breast cancer patients, amplification of the *HER-2* gene (HER-2 is a member of the EGFR family) detected by fluorescence in situ hybridization (FISH) is a strong predictive factor for treatment benefit from anti-HER-2 monoclonal antibody, trastuzumab, and recommended for use in clinical practice.[36] EGFR is an important signaling pathway for lung carcinogenesis[37] and was demonstrated to have a negative prognostic impact.[38,39] Thus, it was hypothesized that genomic gain of *EGFR* is a factor contributing to growth advantage of NSCLC cells and may be an important biomarker of sensitivity to EGFR TKIs. Investigators from the University of Colorado Cancer Center developed an original scoring system for *EGFR* gene copy number assessed by FISH in which tumors were classified into six categories, based on ascending number of gene copies per cell.[40] FISH-negative samples were classified as those with no or low genomic gain ($\geq$ four copies of the gene per cell in <40% of cells), and FISH-positive samples were defined as tumors with high gene copy number ($\geq$ four copies of the gene per cell in $\geq$40% of cells) or gene amplification (tight gene clusters and a ratio of gene/chromosome per cell $\geq$2, or $\geq$15 gene copies per cell in $\geq$10% of the cells). To date, several major studies have addressed the association between *EGFR* gene copy number by FISH and treatment outcome to EGFR TKIs. All the published studies demonstrated clinically important treatment benefit in patients with high *EGFR* gene copy number with EGFR TKIs versus placebo, and this test is now being validated in prospective clinical studies in enriched population of NSCLC patients.

**Association between EGFR FISH and Outcome with EGFR TKIs as Second-Line Therapy**  Cappuzzo et al.[40] analyzed 102 gefitinib-treated patients according to

EGFR protein expression, phospho-Akt expression, *EGFR* gene copy number by FISH, and *EGFR* mutations. Patients who were FISH positive had significantly higher response rate (36% vs. 3% in FISH-negative patients), median time-to-progression (9.0 vs. 2.5 months, respectively) and median overall survival (18.7 vs. 7.0 months, respectively). The association of FISH positivity and superior survival was confirmed in multivariate survival analysis. Evaluation of *EGFR* gene copy number by FISH was also performed in tumor samples from 81 participants of the Southwest Oncology Group (SWOG) 0126 study, which assessed the role of gefitinib in bronchioloalveolar carcinoma and adenocarcinoma with bronchioloalveolar features. In this study, FISH-positive patients had about 50% reduction in the risk of death as compared with FISH-negative patients.[41] Data evaluating FISH in the ISEL trial are based on a subset of 370 patients, representing the largest evaluation of this biomarker in the study of EGFR TKIs in advanced NSCLC, and favor *EGFR* gene–copy number assessment by FISH as a clinically useful predictor of treatment benefit from gefitinib versus placebo.[42] The response rate in FISH-positive patients was 16% as compared with 3% in FISH-negative patients, and the median survival was almost doubled (8.3 in gefitinib treated FISH-positive patients vs. 4.5 months in FISH-positive patients treated with placebo, corresponding to an HR of 0.61). Patients with high *EGFR* copy number treated with placebo had slightly inferior survival when compared with patients with low *EGFR* gene copy number (4.5 vs. 6.2 months, respectively), indicating that increased *EGFR* gene copy number by FISH is purely predictive for the benefit from EGFR TKI and not a prognostic indicator. The lack of prognostic value of EGFR FISH is also supported by the results of *EGFR* gene copy number assessment from surgically treated NSCLC patients,[38] and in NSCLC patients treated with chemotherapy alone.[43] Molecular analysis of tumor samples from the BR.21 trial was performed using FISH according to the same criteria, although at a different institution. Although FISH result could be obtained only in 125 out of 221 samples (57%), the subset of FISH-positive patients achieved significant treatment benefit from erlotinib (20% response rate and an HR of 0.44), whereas this benefit was modest in FISH-negative patients (2% response rate and an HR of 0.85).[44]

Although the ISEL study and the BR.21 studies both compared EGFR TKI with placebo, randomized studies comparing EGFR TKIs with standard chemotherapy in the second-line setting were presented. The largest of these studies was the INTEREST study, which compared gefitinib with docetaxel as second-line treatment.[19] The trial included more than 1400 patients, and the results met the primary end point of noninferiority in the overall survival between the two arms. EGFR FISH analysis was included as a clinical end point; however, EGFR FISH results were available only for 26% of overall study population. No difference in outcome was seen between the FISH-positive and -negative patients between the treatment arms. Based on the previous published retrospective data, it would be expected that the EGFR FISH–positive patients would perform better with gefitinib as compared with docetaxel. One reason for the lack of expected result in the FISH-positive patients is that

this particular subset of patients has a poor prognosis without any systemic therapy, which has been reported by our group,[38] and that this poor overall survival would be improved by chemotherapy per se. Although, the same classification for EGFR FISH assessment was used in the INTEREST study as in previous studies technical differences from one laboratory to another cannot be ruled out on this stage.

### Association between EGFR FISH and Outcome with EGFR TKIs as First-Line Therapy

EGFR TKIs have been studied in combination with standard chemotherapy as first-line treatment in patients with advanced NSCLC (outlined in the introduction). Neither of the four studies could demonstrate any survival advantage of adding a EGFR TKI to standard chemotherapy. EGFR FISH analysis has only been performed in the TRIBUTE study, and preliminary data have been presented.[45] Although no difference in the overall population could be demonstrated, the FISH-positive patients had a statistically significant longer PFS compared with the FISH-negative patients. Interestingly, this difference in PFS emerged after 6 months, which is the time when the patients stopped chemotherapy and continued with erlotinib alone. Furthermore, a lower response rate was seen in the EGFR FISH–positive group receiving chemotherapy and erlotinib as compared with those receiving chemotherapy and placebo (11.6% vs. 29.8%; $p = 0.495$). The immediate interpretation of these results and the raised hypothesis are that during the treatment with the combination of chemotherapy and EGFR TKI, the agents are acting antagonistic. This hypothesis remains in agreement with observation previously raised by the investigators from the University of California at Davis.[46] An EGFR-TKI therapy results in a G1-phase cell-cycle arrest and makes the activity of the G2/M phase-specific chemotherapy suboptimal. Based on this hypothesis, a pharmacodynamic separation between the chemotherapy and the EGFR TKI would be more optimal and this hypothesis is today studied in prospective clinical trials.[47]

Data from three phase II clinical studies were recently presented with EGFR FISH as a predictive marker for gefitinib monotherapy in chemonaive patients. In the INSTEP study, 201 chemonaive NSCLC patients with poor performance status (PS 2 to 3) were randomized to gefitinib versus placebo.[48] Consistently with previous observations, a subset analysis from patients with available tumor biopsies demonstrated that FISH-positive patients had an HR = 0.44 for survival compared with HR = 1.02 in the FISH-negative patient category. In the INVITE study, 196 chemonaive NSCLC patients ≥70 years old were randomized to gefitinib versus vinorelbine. In this trial, the HR for PFS in the FISH-positive patients was 3.13 compared with 0.93 in the FISH-negative category.[49] These results, together with the results of previously discussed INTERST trial,[19] indicate that EGFR FISH does not appear to predict who should be treated with EGFR TKIs versus who should be treated with chemotherapy, either in the first- or second-line setting. More data on this important issue are urgently needed.

Gefitinib was also tested in a phase II clinical trial (ONCOBELL Study) involving 42 untreated NSCLC patients with at least two of the following criteria: never-smoking history, EGFR FISH positivity, or phospho-Akt positivity by immunohistochemistry.[50] Patients who were EGFR FISH positive had higher response rate (68% vs. 9%), longer median time-to-progression (7.6 vs. 2.7 months), and a trend to longer survival as compared with EGFR FISH–negative patients. Although these results are encouraging, small patient numbers, multiple selection criteria, and lack of control group do not allow us to assess predictive value of EGFR FISH based on this trial.

### Association between EGFR FISH and Outcome with Anti-EGFR Monoclonal Antibodies

Although most of the studies performed in NSCLC patients with EGFR antagonists utilized orally available small molecule TKI, anti-EGFR monoclonal antibodies have shown promising results in phase II trials,[51–54] but no definitive predictive marker for outcome and selection of patients has so far been identified. Several new compounds are currently actively investigated, but most clinical data available are for cetuximab. SWOG recently presented preliminary results from the phase II study 0342, in which the patients were randomized in between chemotherapy and cetuximab given either concomitantly or sequentially. EGFR FISH analysis was done in biopsies from the subset of patients who participated in this study. A doubling of PFS from 3 to 6 months and of median overall survival from 7 to 15 months was seen for FISH-negative and -positive patients, respectively.[51] Thus, these data indicate that EGFR FISH might also be strongly associated with outcome after the cetuximab therapy. Interestingly, the best outcome in the FISH-positive patients was seen in the concurrent arm with a median survival of 16 months compared with 7 months in the FISH-negative group. Thus, the concurrent therapy with monoclonal antibody and chemotherapy seems to give the expected synergistic effect in the FISH-positive patients, in contrast to the combination of chemotherapy and EGFR TKIs, where antagonistic effect is observed.

Two large prospective randomized studies with cetuximab in patients with advanced NSCLC have just been reported. The BMS 099 study comparing carbotaxel/cisplatin with or without cetuximab was performed in unselected NSCLC patients and did not meet the primary end point of superiority in overall survival in the experimental arm.[14] The other study, the FLEX trial (first-line treatment for patients with EGFR-expressing advanced NSCLC), compared cisplatin/vinorelbine with and without cetuximab in EGFR immunohistochemistry–positive patients. The results from the latter study showed significantly better survival by adding cetuximab.[13] In light of contradictory results of two studies described previously, selection of patients for cetuximab therapy based on molecular criteria seems to be crucial. Studies with other anti-EGFR antibodies in NSCLC have not reported on EGFR FISH status.[55,56]

### Prognostic Association of EGFR Gene Copy Number in NSCLC

The predictive value of EGFR gene copy number for outcome to EGFR inhibitors cannot

be determined without knowledge about the prognostic association independent of any therapy. Unfortunately, very few studies have addressed this question. Hirsch et al.,[38] studied tumors from about 200 surgically resected NSCLC patients and found a tendency, but not statistically significant, shorter survival for patients with tumors being EGFR FISH positive compared with the patients with EGFR FISH tumors.[38] Thus, similar to several publications showing an unfavorable prognosis associated to increased EGFR protein expression by IHC, increased EGFR gene copy number seems to be associated with an unfavorable prognosis without treatment with EGFR inhibitors, but data are not conclusive.

For advanced NSCLC patients treated with chemotherapy alone, no difference in outcome were observed between EGFR FISH+ and FISH patients.[43]

### Ongoing Prospective Studies Validating EGFR FISH as a Predictive Marker for EGFR Inhibitors in NSCLC

To prospectively validate EGFR gene copy number detected by FISH as a predictive marker for EGFR inhibitors in NSCLC, several prospective studies have been launched: in a U.S. Intergroup study initiated by National Cancer Institute, United States and the CPATH Institute (Critical Pathology Institute in the United States), and in collaboration with the U.S. Food and Drug Administration (FDA), a prospective randomized study for second-line therapy for advanced NSCLC comparing erlotinib with pemetrexed has been launched, in which a prospective validation of several biomarkers, but primarily EGFR FISH, is the primary goal. The study is called the MARVEL study (**MAR**ker **V**alidation of **E**GFR in **L**ung Cancer). All patients with tumor tissue available for EGFR FISH testing will be randomized to either erlotinib or pemetrexed. The study will include about 1000 patients, and the EGFR FISH assay is standardized and centralized. Two other prospective studies are also validating the role of the EGFR FISH assay. One study initiated by OSI Pharmaceuticals is a prospective randomized phase II study for advanced NSCLC patients comparing erlotinib versus chemotherapy and erlotinib in EGFR-postive patients as first-line therapy. The study has completed accrual and results from about 150 will be presented in 2009. The other study, the RADIANT study, is an adjuvant phase III study comparing erlotinib with placebo in EGFR-positive patients. The study is international and planned to include about 1200 patients.

To further validate EGFR FISH as a predictive marker for cetuximab based on the results from the SWOG 0342 study,[51] a prospective randomized phase III study is planned by the SWOG, which will compare chemotherapy (carboplatin/pclitaxel with or without bevacizumab depending on bevacizumab eligibility) with or without cetuximab in patients with advanced NSCLC. The study will include about 500 patients.

### Methodological Considerations

EGFR gene copy number may be heterogeneous within different areas of the same tumor and between the primary and metastatic site, influencing the result of the FISH analysis.[58] Clinical significance of tumor heterogeneity with regard to sensitivity to EGFR TKIs is presently unknown. Other techniques of gene copy number assessment include quantitative polymerase chain reaction (qPCR) and chromogenic in situ hybridization (CISH). In the former method, copy number of the gene of interest is usually compared with that of the housekeeping gene, and expressed as a relative ratio. Direct comparison of EGFR gene copy number assessment by FISH and qPCR in 82 advanced NSCLC patients showed no significant association between FISH-positivity and qPCR results.[59] In this study, EGFR gene copy number by qPCR was not associated with outcome of gefitinib-treated patients. Molecular analysis of IDEAL (phase II) and INTACT (phase III studies comparing chemotherapy and gefitinib vs. chemotherapy and placebo) demonstrated no predictive value of EGFR gene amplification by qPCR for treatment outcome.[60] In a study from Japan on 66 gefitinib-treated patients, increased EGFR gene copy number by qPCR was linked to higher response rate and increased time to progression, but not overall survival.[61] At present, we need more definitive data to explain why the results of EGFR gene copy number quantification by FISH and qPCR are different with respect to its predictive value for EGFR TKI treatment benefit. Quantification of gene copy number by FISH is possible in individual tumor cells, whereas qPCR techniques assess gene copy number in a pool of cells, which may also contain inflammatory and stromal components. Tumor microdissection may help to ensure that the assessment is carried out in areas abundant in tumor cells, but this procedure significantly increases the assay cost. In qPCR technique, quantification of the reference gene copy number presents additional challenge because of the possibility of its deletion or amplification in tumor cells. CISH technique implements an enzymatic reaction to detect the DNA probe hybridized to the gene of interest. The main advantage of this technology is the use of light instead of fluorescent microscope enabling the reader to score the signals in histological sections. Data on CISH gene copy number evaluation and sensitivity to EGFR TKIs are sparse. In a group of 44 NSCLC patients treated with gefitinib or erlotinib, EGFR gene copy number by CISH did not associate with response rate.[62] A comparison study between CISH and FISH is currently ongoing.

In summary, retrospective studies have shown a significant survival benefit in pretreated NSCLC patients with high EGFR gene copy number evaluated by FISH, as demonstrated in several studies involving almost 700 patients. Several prospective clinical studies with patient selection based on FISH or combination of FISH and other biomarkers are currently underway in the adjuvant, first- and second-line setting. The value of EGFR FISH for the prediction of clinical outcome to EGFR TKIs compared with first- or second-line chemotherapy is not yet established. Ongoing large prospective adjuvant studies with EGFR TKIs (i.e., the RADIANT study) in selected patients based on EGFR expression will further shed light to the use of EGFR FISH for selection of NSCLC patients to adjuvant therapy. The association of EGFR FISH and outcome of NSCLC patients treated with chemotherapy and anti-EGFR monoclonal antibodies is compelling and will be further prospectively studied.

**EGFR Protein Expression** EGFR protein expression detected by IHC was initially thought to be a good predictor for response and outcome to EGFR inhibitors. However, clinical studies in NSCLC have not been able to demonstrate that IHC should be better than other measures. Some association to outcome was seen both in BR.21 study (HR = 0.68; $p$ = 0.02) and the ISEL study with gefitinib (HR = 0.77; $p$ = 0.13).[42,44] Most recently, however, results from the European FLEX study was presented (chemotherapy ± cetuximab as first-line therapy), which was based on EGFR IHC–positive patients as defined by one positive cell.[13] The study demonstrated superior survival for cetuximab treated patients, whereas the other similar study in the United States (BMS/Imclone 099 study) in unselected NSCLC patients did not meet the primary end point of superior PFS for cetuximab-treated patients.[14] Whether the IHC selection was crucial for

the difference in outcome or other factors played a role are not yet clarified as PFS was not superior for cetuximab in the FLEX trial either.

Methodological aspects of EGFR IHC assessments are still to be solved. More specific EGFR antibodies have to be developed. Several scoring systems for EGFR IHC assessments have been applied. However, a comparison between different scoring systems and "cutoff" levels for positive and negative results did not show significant difference between the use of H-score (e.g., Hybrid score), which is defined by intensity (0 to 4) times frequency of IHC-positive cells (0% to 100%) or the more commonly used "DAKO scoring system."[63] The role of phosphorylated EGFR protein expression has been less studied because of the instability of the phosphorylated antibodies and its variability to various fixation procedures (Table 49.2).

## EGFR MUTATIONS IN NSCLC

**Identification of EGFR Mutations** The phase II and III clinical studies of EGFR TKIs gefitinib and erlotinib demonstrate that the patients who are most likely to achieve radiographic responses included women, those with adenocarcinoma, never-smokers, and patients from Japan.[4,6,15] These clinical observations and the dramatic nature of occasional clinical responses to gefitinib led several investigators to sequence *EGFR* from patient's tumors and led to the identification of somatic *EGFR* activating mutations.[64–66] The initial descriptions of the correlation of *EGFR* mutations with response to gefitinib examined a series of 14 patients who had dramatic clinical and/or radiographic responses to gefitinib.[64,65] A total of 13 out of the 14 patients had *EGFR* mutations, whereas none of the 11 patients who progressed on gefitinib treatment had mutations. The association between *EGFR* mutations and clinical response to gefitinib and erlotinib was subsequently been documented around the world. Soon after the initial studies, reports from other institutions in the United States, Japan, Taiwan, and Korea have confirmed that more than 70 of the 87 patients (80%) with clinical responses to gefitinib and erlotinib had detectable somatic mutations of *EGFR*.[64–70]

Somatic mutations in *EGFR* are found in 10% to 15% of whites and in 30% to 40% of Asian NSCLC patients. *EGFR* mutations are present more frequently in never-smokers, women, those with adenocarcinoma, and in patients of East Asian ethnicity.[71] These are the clinical features of patients previously identified as most likely to benefit from gefitinib or erlotinib.[4,6,17] The reason behind the ethnic variation in *EGFR* mutation frequency is currently not understood. It is estimated that up to 20,000 to 25,000 of newly diagnosed NSCLCs in the United States will harbor *EGFR*-activating mutations. As lung cancer is such a common disease, there are more *EGFR* mutant NSCLC patients diagnosed annually in the United States than those with chronic myeloid leukemia (CML) and gastrointestinal stromal tumors (GISTs) combined.[72] Only one familial report of inherited *EGFR* mutations has so far been described.[73] Members of this family possessed a germline mutation in *EGFR* (EGFR T790M), associated with resistance to gefitinib and erlotinib, and were predisposed to the development of lung cancers.[73] Interestingly, the actual lung cancers in these patients also contained an *EGFR*-activating mutation in addition to *EGFR* T790M.

Clinically significant *EGFR* mutations are found in the first four exons[40,61,75,76] of the tyrosine kinase domain of EGFR. The mutations reported thus far have been predominantly of two types: ~45% are deletions involving at least 12 nucleotides in exon 19, eliminating a conserved LRE motif, and ~40% are a single-point mutation in exon 21 (L858R) (Fig. 49.1). In addition, rare point mutations in exons 18, 20, and 21 and insertion/duplications in exon 20 have been reported.[40,64,66,68,71,74] The common exon 19 deletions and L858R are also the ones that have been most extensively evaluated to date and are most closely linked to in vitro and in vivo sensitivity to gefitinib and erlotinib.

**FIGURE 49.1** Schematic representation of EGFR with gefitinib bound to the ATP-binding pocket. (Courtesy of Dr. Michael Eck, Dana Farber, Cancer Institute, Boston, MA.)

*EGFR*-mutant tumors also often contain a concurrent increase in *EGFR* copy number.[40,61,75,76] Several studies to date suggest that in these cancers, there is preferential amplification of the *EGFR* mutation containing allele.[75,77] The clinical and biologic significance of the impact of a concurrent copy number gain is currently not well defined. Additional studies are needed to further define whether there are any clinical differences in *EGFR*-mutant lung cancers compared with those without a concurrent *EGFR* copy number gain. Furthermore, the relationship between a concurrent copy number gain and the specific subtype of an *EGFR* mutation (exon 19 deletion or L858R) has not been determined.

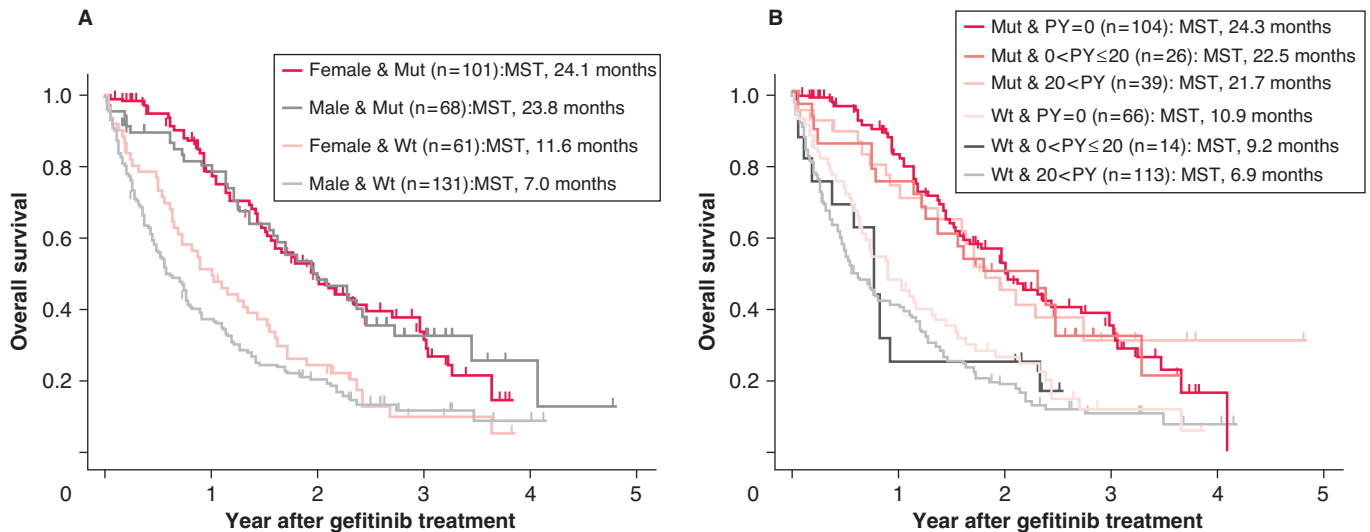
**EGFR Mutations versus Clinical Factors** As discussed previously, adenocarcinoma histology, smoking history, and female gender are a good predictor of response as well as survival for patients treated with EGFR TKIs. Are patient clinical characteristics just as good in predicting the response to EGFR TKIs as knowing the *EGFR* mutation status? To address these matters, investigators from three institutions in Japan established a large-scale database and evaluated the factors that were related to clinical outcome of lung adenocarcinoma patients treated with gefitinib.[78] In 408 Japanese patients treated with gefitinib, 362 were adenocarcinoma, 200 were men and 170 were never-smokers. Survival curves according to gender and *EGFR* mutation (Fig. 49.2A), or smoking status and *EGFR* mutation (Fig. 49.2B) are shown.[78] It is clear that *EGFR* mutation is far superior to gender or smoking status


**FIGURE 49.2** Survival curves of patients who were treated with gefitinib according to gender and *EGFR* mutational status **(A)** and according to smoking history and *EGFR* mutational status **(B)**. *MST*, median survival time; *Mut*, EGFR mutation positive; *PY*, pack year; *Wt*, EGFR wild-type. (From Toyooka S, Takano T, Kosaka T, et al. Epidermal growth factor receptor mutation, but not sex and smoking, is independently associated with favorable prognosis of gefitinib-treated patients with lung adenocarcinoma. *Cancer Sci* 2008;99:303–308.)

for predicting longer survival. Multivariate analysis revealed that EGFR mutation was the only significant prognostic factor (HR = 0.48; $p$ <0.001), but female gender (HR = 1.0; $p$ = 0.98) and smoking status (HR = 0.81 for light smoker to heavy smoker, HR = 0.33 for never-smokers to heavy smokers, $p$ for trend = 0.61).[78] These findings would suggest that genotype rather than phenotype is a better marker of benefit from EGFR TKIs.

**The Biology of EGFR Mutations** Mutant *EGFR* is a bona fide oncogene. Mutant *EGFR* causes transformation and anchorage independent growth of NIH-3T3 cells in soft agar.[79] This occurs in a ligand-independent process, whereas wild-type *EGFR* is not transforming in the absence of ligand.[79] Similarly, *EGFR* mutations lead to interleukin 3 (IL-3) independent growth of Ba/F3 cells.[80] Furthermore, mutant *EGFR* alone is sufficient to lead to the development lung adenocarcinomas when expressed in the alveolar epithelium of mice.[81,82]

Several *EGFR*-mutant NSCLC cell lines harboring the common *EGFR* mutations found in NSCLC patients have also been identified and extensively characterized.[75,83,84] Laboratory-based studies using these cell lines as well as model systems harboring *EGFR* mutations have been invaluable to the understanding of the differences in EGFR signaling in *EGFR*-mutant compared with wild-type cancers. *EGFR*-mutant tumors are dependent or "addicted" to EGFR signaling for their growth and survival.[83,85,86] Studies to date suggest that, in these cancers, several (if not all) of the critical downstream signaling pathways including the PI3K/AKT, STAT, and ERK 1/2 pathways are solely controlled by EGFR. Thus, when these tumors are exposed to EGFR inhibitors, these intracellular pathways are turned off, and the cancer cells undergo apoptosis.[75,83–85]

In contrast, EGFR does not singularly regulate these pathways in most other lung cancers, including in most *EGFR* wild-type lung cancer cell lines, and in such cancers, EGFR inhibitors are marginally, if at all, effective.

The PI3K/Akt-signaling pathway is the most critical of the downstream signaling pathways for the efficacy of EGFR kinase inhibitors. PI3K/Akt signaling must be turned off in order for gefitinib or erlotinib to be effective in an *EGFR*-mutant cancer. In fact, ectopic activation of PI3K/Akt signaling *alone* is sufficient to render resistance to gefitinib in vitro.[87] The detailed molecular events that lead to activation of EGFR and downstream signaling, including PI3K/Akt signaling, are beginning to be understood. EGFR is one of a family of four ERBB family members, and two other family members, HER-2 and ERBB3, are highly implicated in promoting EGFR activation of downstream signaling. ERBB3 is a unique member of this family in that is believed to be "kinase dead" (Fig. 49.3A). However, upon heterodimerization with other ERBB family members, it is phosphorylated on tyrosines and serves as a scaffold to activate downstream signaling. In lung cancers that are sensitive to EGFR inhibitors, PI3K/AKT is activated by binding to phosphorylated ERBB3.[34] In contrast, cancers that are not sensitive to EGFR inhibitors primarily use non-ERBB3 mechanisms for activating PI3K.[88] There are now several studies reporting a correlation between gefitinib sensitivity and ERBB3 expression in NSCLC cell lines and at least one clinical study that identified ERBB3 expression as a predictor of clinical benefit from EGFR inhibitors.[75,88–90]

There are two main reasons why gefitinib and erlotinib are effective therapies against *EGFR*-mutant cancers. The first, as discussed previously, is a biologic dependence or addiction to EGFR signaling in *EGFR*-mutant cancers.[86] The second is a

**FIGURE 49.3** EGFR signaling in gefitinib/erlotinib sensitive and resistant EGFR-mutant NSCLCs. **A:** EGFR phosphorylates ERBB3 to activate PI3K/Akt signaling in gefitinib-/erlotinib-sensitive NSCLCs. In such cancers, following gefitinib/erlotinib treatment, EGFR, ERBB3 and Akt phosphorylation are turned off. **B:** Gefitinib and erlotinib are unable to inhibit EGFR phosphorylation in the presence of *EGFR* T790M. EGFR signaling persists in the presence of gefitinib/erlotinib leading to persistent ERBB3 and Akt phosphorylation. **C:** MET can also activate PI3K/Akt signaling through ERBB3. In NSCLCs with *MET* amplification, gefitinib/erlotinib can still inhibit EGFR phosphorylation but not ERBB3 phosphorylation. This leads to persistent activation of PI3K/Akt signaling via ERBB3 in an EGFR-independent manner. **D:** Other potential mechanisms of gefitinib/erlotinib resistance. These potential mechanisms include alternative ways of maintaining PI3K/Akt signaling such as by an oncogenic *PIK3CA* or by other receptor tyrosine kinases that could activate PI3K/Akt signaling in an ERBB3 independent fashion. In such cancers, gefitinib/erlotinib would be expected to inhibit EGFR and ERBB3 phosphorylation but not Akt phosphorylation. *AKT*, AKT8 virus oncogene homologue; *EGFR*, epidermal growth factor receptor; *ERBB3*, v-erb-b2 erythroblastic leukemia viral oncogene homologue 3; *MET*, mesenchymal-epidermal transection factor; *PI3K*, phosphatidylinositol 3 kinase. (Adapted from Arteaga CL. HER3 and mutant EGFR meet MET. *Nat Med* 2007;13:675–677, copyright 2007, Macmillan Publishers.)

pharmacologic advantage that occurs in the context of an *EGFR* mutation. The wild-type EGFR can adopt an inactive or an active conformation (when ligand activated). *EGFR* mutations promote the formation of the active conformation, and gefitinib and erlotinib preferentially bind the active conformation of EGFR.[91] The affinity of gefitinib for the mutant EGFR is ~30 times greater than for a wild-type EGFR.[91] Consequently, in *EGFR*-mutant cell line models, 10 to 100 times less gefitinib or erlotinib is required to completely inhibit phosphorylation of

EGFR and downstream Akt and ERK 1/2 than is required to inhibit NSCLC cell lines with wild-type *EGFR*.[64,75,83]

## EGFR Mutations and Relationship to Cigarette Smoking

The initial clinical observations suggested that gefitinib and erlotinib had their greatest effect in never-smokers with NSCLC.[6] The subsequent molecular studies demonstrated that *EGFR* mutations were more frequent in never-smokers with NSCLC.[71,92–94] The highest frequencies of

*EGFR* mutations are found in both Asian (~60% to 70%) and white (30% to 50%) never-smokers,[71,92–94] with increasing cigarette smoke exposure, the frequency of an *EGFR*-mutant lung cancer decreases. However, some ethnic differences have also emerged. Even in never-smokers, the EGFR mutation frequency is significantly higher in Asian lung cancer patients compared with white lung cancer patients. Similarly, in white current smokers, the *EGFR* mutation frequency is <5%, whereas in Japanese patients, it is 22%.[92,93] Collectively, these findings raise the possibility that etiologies other than cigarette smoke are responsible for the genesis of *EGFR* mutant NSCLC. The apparent negative correlation between incidence of EGFR mutation and smoking dosage is a result of diluting the number of tumors with EGFR mutations with an increased number of tumors with wild-type EGFR as smoking dose increases. Indeed, this was suggested in our recent case-control study.[94] It will be critical to determine the other potential causes of NSCLC in never-smokers and their relationship to *EGFR* mutations as that may lead to the identification of another (in addition to smoking) preventable cause of lung cancer. Furthermore, as mentioned previously in this chapter, given that not all never-smokers with NSCLC, especially white patients, harbor *EGFR* mutations, assessment of smoking status alone may not be an adequate surrogate for clinical benefit from gefitinib or erlotinib.

## EGFR-Targeted Agents and Their Efficacy in EGFR-Mutant Cancers

Many EGFR-targeted agents have been developed, and several of them have been evaluated preclinically or clinically in *EGFR*-mutant cancers. The EGFR-targeted agents fall into several major categories (Table 49.3). Gefitinib and erlotinib are examples of reversible ATP mimetics and compete for ATP binding in the EGFR kinase domain. Irreversible EGFR inhibitors are similar in that they are also ATP mimetics but in addition covalently bind Cys-797 of EGFR. Many of these agents are also effective inhibitors of ERBB2 and ERBB4.[95–97] There are also now several multitargeted EGFR kinase inhibitors that have a broader spectrum of activity not solely against EGFR but against other kinases outside the ERBB family (Table 49.3). Several EGFR-targeted

antibodies have also been developed and either interfere with ligand binding to EGFR (cetuximab and panitumumab) or effect EGFR dimerization (matuzumab).[98]

Gefitinib and erlotinib are most effective against the common EGFR exon 19 deletion and L858R mutant forms for the receptor.[75,83,84] This has been extensively studied in vitro and clinically in NSCLC patients. However, they are not effective against all types of *EGFR*-activating mutations. One example is the exon 20 insertion mutations that make up 2% to 3% of all EGFR mutations.[71] Although these are *EGFR*-activating mutations, they confer resistance to gefitinib and erlotinib in preclinical models and in NSCLC patients.[50,79,99] Lapatinib, which is a better ERBB2 inhibitor than gefitinib or erlotinib, also inhibits EGFR. However, it appears to be less effective against mutant EGFR likely because unlike gefitinib or erlotinib, it binds the inactive conformation of EGFR.[91,100] The irreversible EGFR inhibitors are, in general, more effective than gefitinib or erlotinib against all classes of *EGFR*-activating mutations.[95,96,101] However, some specific differences have also emerged in vitro. HKI-272, BIWB2992, and PF00299804 are all more effective against EGFR L858R than gefitinib or erlotinib. Similarly, BIBW2992 and PF00299804 also more effectively inhibit the growth of models harboring EGFR exon 19 deletions.[95,96,101] However, HKI-272 is less effective in vitro against many of the exon 19 deletion variants than erlotinib. Whether these in vitro differences will ultimately translate into clinical differences remains to be determined. All of the irreversible EGFR inhibitors tested to date effectively inhibit the growth and EGFR phosphorylation of cell line models harboring the exon 20 insertion mutations.[95,96,101] Thus, these agents may also be clinically effective in NSCLC patients harboring EGFR exon 20 insertion mutations. In addition to inhibiting EGFR, the irreversible EGFR inhibitors are effective against lung cancer models harboring either amplification or somatic mutations in ERBB2.[95,97] These genomic alterations are detected in 2% to 5% of NSCLC patients and irreversible EGFR inhibitors may be effective therapies in this patient population.[102,103]

The multitargeted EGFR inhibitors have also been evaluated in some *EGFR*-mutant models. As vandetanib, XL647, and BMS-690514 inhibit VEGR2, the full potential of these agents is difficult to evaluate in vitro.[104,105] In vitro, these agents appear to have similar effects on models harboring *EGFR*-activating mutations as gefitinib or erlotinib.[104,105] In contrast, the EGFR-directed antibodies may be less effective against *EGFR*-mutant cancers. Cetuximab has been most extensively evaluated in models harboring *EGFR* mutations. Cetuximab has several potential effects in *EGFR*-mutant cancers. First, it can bind the ligand-binding site of EGFR. Second, it can lead to internalization or degradation of EGFR. In vitro, cetuximab is less effective at inhibiting the growth of NSCLC cell lines harboring *EGFR* mutations than gefitinib.[84] This is a result of the inability to turn off EGFR phosphorylation. In both xenograft and transgenic mouse models, cetuximab has been found to be effective against some models with *EGFR*-activating mutations. In these models, cetuximab leads

| TABLE 49.3 | Summary of Different Classes of EGFR Inhibitors | | |

to degradation of EGFR, and hence to tumor shrinkage, because these cancers are EGFR dependent.[81,106,107] However, as discussed later, the limited experience to date suggests that cetuximab is not effective in NSCLC patients harboring EGFR mutations.[84]

## EGFR Mutations, Prognosis, and the Clinical Efficacy of EGFR-Targeted Therapies

**Prognostic Significance** In addition to being a predictive marker of efficacy of EGFR kinase inhibitors, *EGFR* mutations also confer some prognostic significance. That is, NSCLC patients whose cancers harbor an *EGFR* mutations likely have a better prognosis independent of EGFR inhibitor therapy. This has been examined both in surgically resected NSCLC patients as well as those with advanced NSCLC. The prognostic role of *EGFR* mutations is mixed when it has been examined in surgically resected tumor specimens. Some studies suggest that patients with *EGFR* mutations have a better outcome, whereas others suggest that it is similar to those whose tumors are *EGFR* wild-type.[71,108,109] However, many are limited by small patient numbers and future studies may be difficult to interpret as many patients would ultimately go on to receive EGFR inhibitor–based therapies. The impact of *EGFR* mutations in advanced NSCLC has been studied including in randomized phase III clinical trials.[44,60,110,111] In the phase III BR.21 trial of erlotinib compared with placebo, patients in the placebo arm with *EGFR* mutations had a longer median survival (9.1 vs. 3.5 months) than *EGFR* wild-type patients.[44] The prognostic role of EGFR mutations was also examined in the phase III clinical trials of chemotherapy with or without gefitinib (INTACT-1 and INTACT-2) or erlotinib (TRIBUTE).[12,60] In the INTACT-1 and -2 studies, NSCLC patients mutations had a better outcome when treated with chemotherapy-alone compared with *EGFR* wild-type patients (19.4 vs. 9.2 months; HR = 0.48; 95% CI, 0.29 to 0.82). In the TRIBUTE trial, the median survival of *EGFR* wild-type patients treated with chemotherapy alone was approximately 10 months, whereas it had not been reached (>15 months) for *EGFR*-mutant patients at the time of the analysis.[111] When the treatment arms (chemotherapy alone or with erlotinib) were combined, the median survival of patients that were *EGFR* wild-type was 10 months and had not been reached in patients with *EGFR* mutations ($p$ <0.001). Together, these studies suggest that in addition to conferring a predictive role, sensitivity to EGFR kinase inhibitors, *EGFR* mutations also confer a prognostic role. This needs to be considered in the design and interpretation of end points in clinical studies involving patients with known *EGFR* mutations or populations of patients known to harbor a high frequency of *EGFR* mutations such as East Asian NSCLC patients.

## Detection of EGFR Mutations
The initial studies that identified *EGFR* mutations used direct sequencing of EGFR exons 18 to 24 from patients' tumor specimens.[64–66] These studies were feasible only in a limited number of

patients, because only a limited number of patients with advanced NSCLC have sufficiently sized tumor specimens available for direct DNA sequencing. Many patients with advanced NSCLC are diagnosed by bronchoscopy or by a fine needle aspirate. These methods are sufficient for the diagnosis of lung cancer but are often too small to be used for molecular diagnostic studies. This limitation has prompted the development of alternative nonsequencing-based mutation detection methods. Such methods include, variations of allele-specific PCR, a DNA heteroduplex analysis combined with a DNA endonuclease (Surveyor), and mass spectrometry.[112–118] Many of these methods have been examined in clinical settings or validated against direct DNA sequencing–based methods. An additional advantage of such methods is that they do not require microdissection or macrodissection of tumor material (which is often needed for DNA sequencing), and they are often more sensitive than direct DNA sequencing.[119] In addition to tumor-based studies, several investigators have pursued noninvasive genotyping methods using either tumor-derived DNA isolated from plasma or circulating tumor cells.[119–121] These techniques also hold the promise of being able to in a noninvasive manner sample the tumor multiple times during the course of a patient's treatment.

## Prospective Phase II Trials of EGFR Inhibitors in EGFR-Mutant NSCLC
The observations linking the sensitivity of *EGFR* mutations with EGFR kinase inhibitors were from retrospective studies of patients treated with either gefitinib or erlotinib.[64–66] Several prospective phase II clinical trials have been initiated and have now been published or presented (Table 49.4). These trials have all patients screened for the presence or absence of an *EGFR* mutation and then treated only the *EGFR*-mutant patients, either those that are chemotherapy naive or those that have failed one prior systemic therapy, with either gefitinib or erlotinib. The collective findings from these trials is remarkably similar (Table 49.4). The radiographic response rates range from 55% to 82% and the median times to progression from 8.9 to 13.3 months. These findings are substantially different than what is usually observed with cytotoxic chemotherapy and has prompted the initiation of randomized phase III clinical trials.[122] Furthermore, even though Asian lung cancer patients have a significantly higher frequency of *EGFR* mutations, the outcome of Asian lung cancer patients with *EGFR* mutations is also similar to white lung cancer patients with *EGFR* mutations. These findings suggest that it is the presence of the *EGFR* mutation, not ethnicity, that is the key determinant of the efficacy of EGFR kinase inhibitors.

There are no prospective clinical trials of second-generation EGFR inhibitors or of the multitargeted EGFR inhibitors in patients with *EGFR* mutations. Many such trials are currently underway. The relationship of EGFR mutations and cetuximab has also been examined. Only on phase II clinical trial of single-agent cetuximab has been

conducted.[123] In this clinical trial, the radiographic response rate was 4.5%.[123] Tumor analysis of the responding patients demonstrated that they were all *EGFR* wild-type. Some of the patients with either stable disease or progressive disease had *EGFR* mutations.[123] In addition, a small case series examined *EGFR*-mutant NSCLC patients treated sequentially with single-agent cetuximab and gefitinib.[84] Although cetuximab treatment led to stable disease, all of the patients achieved a partial response when treated with gefitinib. Collectively, these studies suggest that at least as a single agent, cetuximab has limited if any clinical efficacy in *EGFR* mutant NSCLC.

## Ongoing and Completed Phase III Clinical Trials

The impressive findings from the prospective phase II clinical trials of treating EGFR mutant NSCLC patients with EGFR TKIs has prompted the initiation of several randomized clinical trials. These trials are either comparing the efficacy of an EGFR TKI with chemotherapy or the addition of chemotherapy to an EGFR TKI. Three phase III clinical trials are evaluating the efficacy of an EGFR TKI compared with chemotherapy. The first, IPASS (Iressa Pan-Asian Study), randomized 1217 chemotherapy-naive lung cancer patients to either gefitinib or carboplatin/paclitaxel. The eligibility for this Asian trial required the patients to be either never (<100 cigarettes/lifetime) or former (quit at least 15 years) light (≤10 pack-years) cigarette smokers with adenocarcinoma. The median age of these patients was younger[57] than that seen in the West, and included 79% women, and 94% never-smokers. Thirty-six percent of the trial population were able to have EGFR mutation results reported. The primary end point is PFS. Even though this is not a trial specifically for *EGFR* mutant patients, the clinical enrichment would predict that at least 60% of the patients will harbor *EGFR*

mutations.[21] First-line gefitinib proved superior to paclitaxel and carboplatin, with 25% versus 7% of the respective treatment groups progression free at 1 year. (Fig. 49.4A)

PFS was higher for chemotherapy initially but subsequently was higher for gefitinib from about 5 months until the end of the study period. The PFS rate was higher among gefitinib-treated patients with an EGFR mutation compared with those receiving chemotherapy only: 27% versus 14% (Fig. 49.4B).

Overall, about 60% (201 patients) of a sample of 437 patients evaluated for EGFR mutations tested positive. Patients without EGFR mutations fared worse on gefitinib (PFS rate of 2% vs. 13% for those treated with carboplatin and paclitaxel). The objective response rates were significantly higher for gefitinib than chemotherapy—43% versus 32%. In patients positive for EGFR mutation, the rates were 71% for gefitinib and 47% for carboplatin and paclitaxel. In patients who did not have the EGFR mutation, the objective response rates were 1% for gefitinib but 23.5% for carboplatin/paclitaxel (Fig. 49.4C).

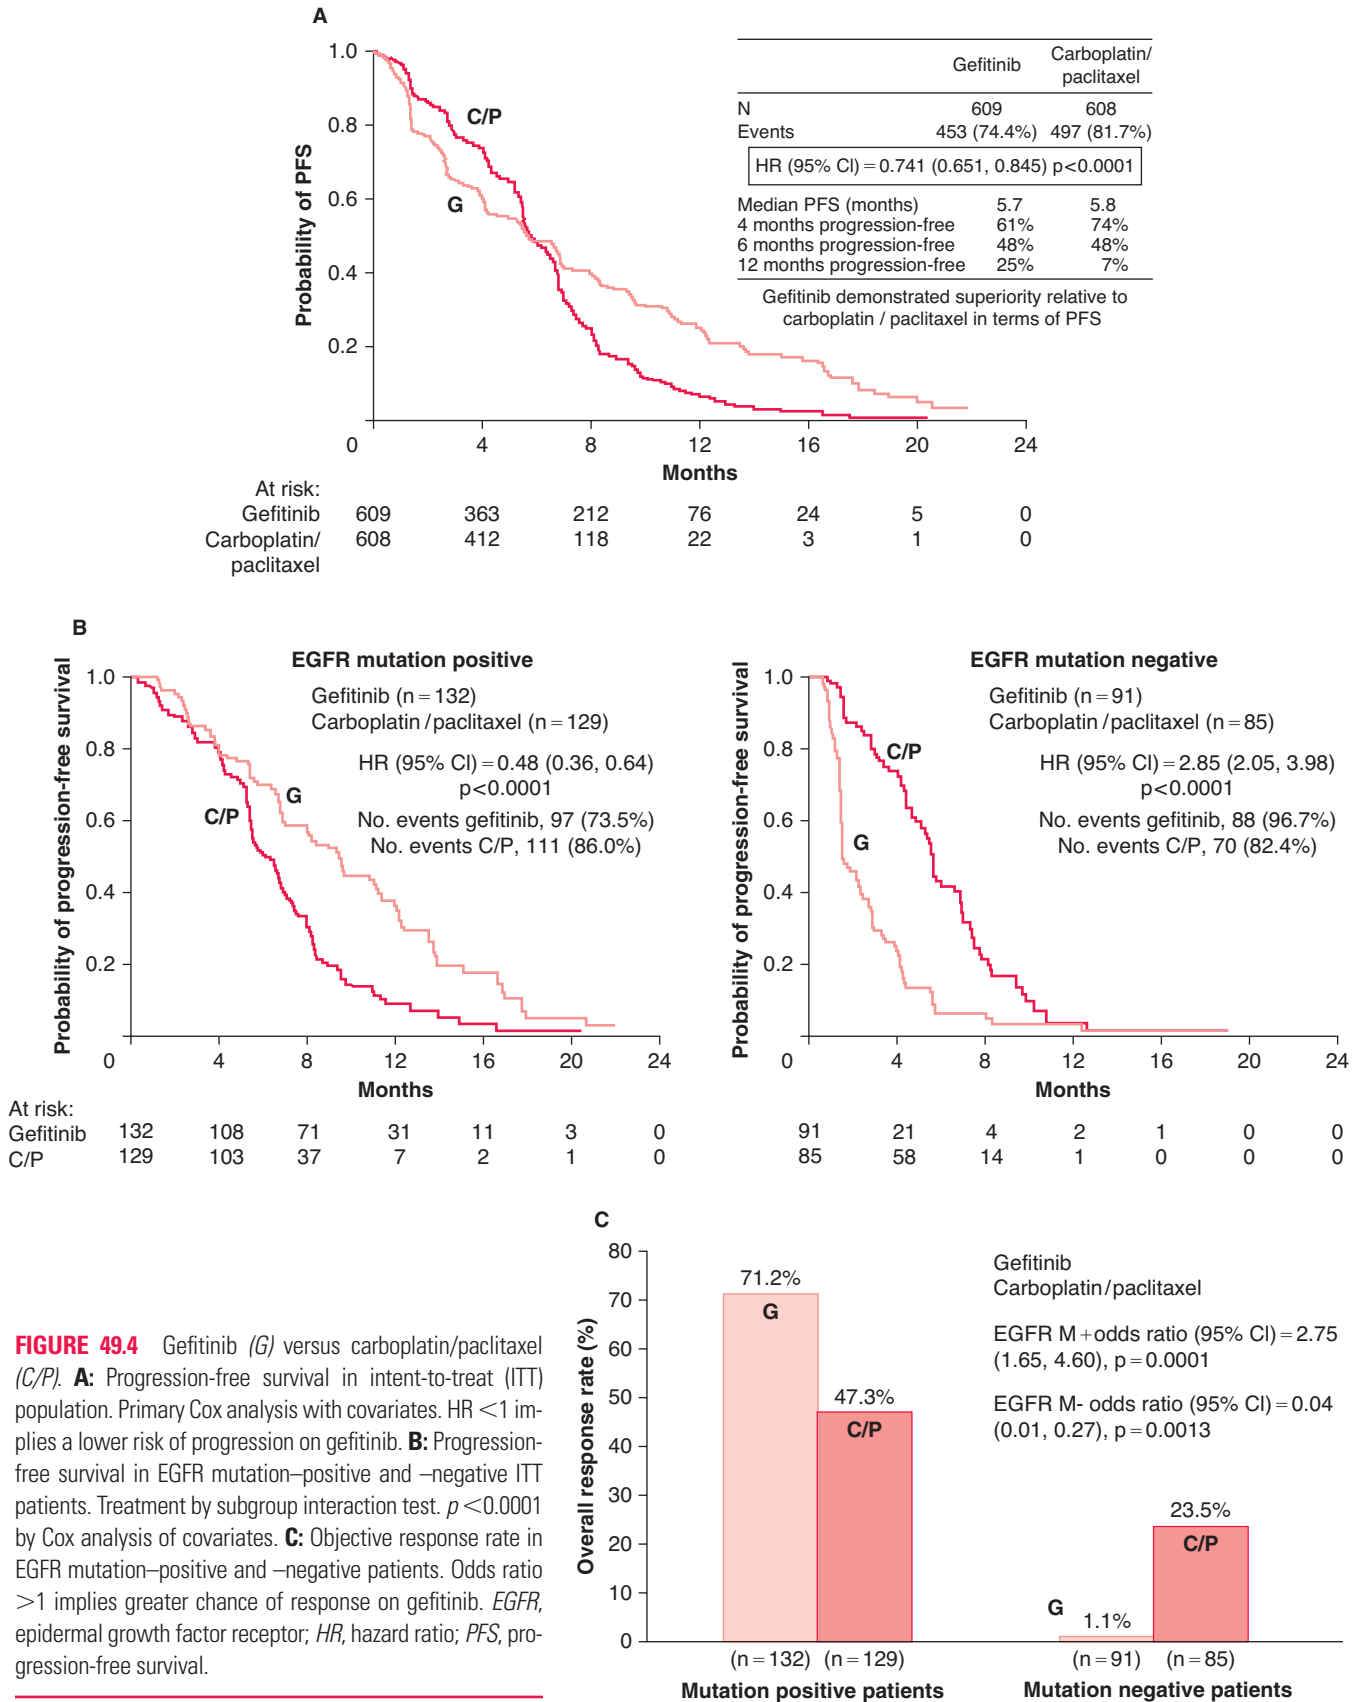
A second trial, conducted in Spain, is specifically randomizing (n = 146) chemotherapy-naive patients with known *EGFR* mutations (exon 19 deletion and L858R) to either erlotinib or to chemotherapy (cisplatin/gemcitabine or cisplatin/docetaxel). The primary end point of this trial is also PFS. Two additional trials, both being conducted in Japan, are asking a similar question. The first, conducted by the West Japan Oncology Group, is randomizing (n = 200) *EGFR*-mutant (exon 19 deletion or L858R) patients with postoperative recurrence to either gefitinib alone or to cisplatin/docetaxel (WJTOG 3405 trial). The second, conducted by the North East Japan Group, is randomizing (n = 300) patients with *EGFR* mutations (exon 19 deletions, L858R G719X, and L861Q) to either gefitinib or carboplatin/paclitaxel (NEJ 002 trial). The primary end point of both trials is PFS. The results of these two Japanese trials were recently reported.[123a,123b]


**FIGURE 49.4** Gefitinib *(G)* versus carboplatin/paclitaxel *(C/P)*. **A:** Progression-free survival in intent-to-treat (ITT) population. Primary Cox analysis with covariates. HR <1 implies a lower risk of progression on gefitinib. **B:** Progression-free survival in EGFR mutation–positive and –negative ITT patients. Treatment by subgroup interaction test. *p* <0.0001 by Cox analysis of covariates. **C:** Objective response rate in EGFR mutation–positive and –negative patients. Odds ratio >1 implies greater chance of response on gefitinib. *EGFR,* epidermal growth factor receptor; *HR,* hazard ratio; *PFS,* progression-free survival.

PFS of patients with EGFR mutation treated with gefitinib in NEJ 002 and WJTOG 3405 were 10.4 and 9.2 months, while PFS of those treated with platinum-doublet therapy were 5.5 and 6.3 months, respectively.[123a,123b] HR of these studies were 0.357(95% CI, 0.25 to 0.51) and 0.489 (95% CI, 0.336 to 0.710), respectively.[123a,123b]

These studies clearly confirmed that the determinant of clinical efficacy of gefitinib is a presence of EGFR mutations and not clinical background of patients.

Another clinical question that is being evaluated is the impact of chemotherapy in addition to erlotinib. The hypothesis is based on a subset analysis of the phase III clinical trial (TRIBUTE) of chemotherapy-positive or -negative erlotinib. Although there were no differences in the treatment arms (chemotherapy alone vs. chemotherapy/erlotinib) when all patients were examined, an analysis of never-smokers revealed remarkable differences.[12] When never-smokers were treated with erlotinib in addition to the same chemotherapy regimen, the median survival increased to 22.5 months ($p = 0.01$). The response rate to chemotherapy with erlotinib was also higher than when the never-smoking patients were treated with chemotherapy alone (30%; 95% CI, 20% to 43% for erlotinib vs. 11%; 95% CI, 4% to 25% for placebo) ($p = 0.02$).[12] This clinical observation has prompted the initiation of a randomized phase II clinical trial being conducted through the Cancer and Leukemia Group B (CALGB). NSCLC patients who are never ($\leq$100 cigarettes/lifetime) or former light ($\leq$10 pack-years and quit $\geq$1 year ago) smokers are randomized to receive either erlotinib alone or carboplatin/paclitaxel/erlotinib in combination. EGFR mutation status will be examined in all patients. This trial will prospectively compare the efficacy of erlotinib alone or in combination with chemotherapy in EGFR mutant and EGFR wild-type patients.

These ongoing prospective clinical trials will provide additional information on the predictive and prognostic nature of EGFR mutations. Furthermore, they will provide a formal comparison to the standard of care (chemotherapy) and determine whether EGFR TKIs should be the treatment of choice for EGFR mutant chemotherapy-naive NSCLC patients with advanced disease.

### Genotype/Phenotype Correlations

The two common EGFR mutations, exon 19 deletions and L858R, account for ~80% to 85% of all EGFR mutations. Whether these mutations confer the same degree of benefit from EGFR TKIs has been examined in both retrospective and prospective clinical trials. Two retrospective studies demonstrated that NSCLC patients with EGFR exon 19 deletion mutations treated with gefitinib or erlotinib had a significantly longer time to progression (24 vs. 10 months [$p = 0.04$] and 12 vs. 5 months [$p = 0.01$], exon 19 deletion vs. L858R, respectively) and survival (38 vs. 17 months [$p = 0.04$] and 34 vs. 8 months [$p = 0.01$], exon 19 deletion vs. L858R, respectively) times.[124,125] These findings have also been observed in some but not all prospective clinical trials of erlotinib and gefitinib.[126,127] This clinical observation may be caused by a pharmacologic effect, as analyses using purified intracellular EGFR kinase–domain constructs demonstrate that erlotinib is 20-fold less effective at inhibiting

L858R compared with the exon 19 deletion.[128] This also raises the possibility that some of the second-generation EGFR inhibitors (irreversible EGFR inhibitors) may be more effective against the EGFR L858R mutation. Conformation of this hypothesis awaits findings from the ongoing clinical trials.

## RESISTANCE MECHANISMS TO EGFR-TARGETED THERAPIES

The prospective phase II clinical trials have demonstrated that gefitinib and erlotinib are effective therapies for EGFR-mutant NSCLC. However, *all* patients will ultimately develop resistance (acquired resistance) to these agents.[153] It will be critical to understand the mechanisms of acquired resistance because it may lead to the development of effective therapies for patients who clinically develop acquired resistance to gefitinib or erlotinib. It is important to note that the mechanisms of acquired resistance to date have been identified in EGFR-mutant NSCLC patients. Whether these same mechanisms are responsible for resistance that develops in EGFR wild-type patients that benefit from gefitinib or erlotinib remains to be determined.

Two main mechanisms of acquired resistance have been identified in EGFR-mutant NSCLC patients. The first is a secondary EGFR mutation, T790M, that renders gefitinib and erlotinib ineffective inhibitors of EGFR kinase activity (Fig. 49.3B).[129,130] EGFR T790M has been detected both from tumors of EGFR-mutant NSCLC patients who have developed clinical resistance to gefitinib or erlotinib and from in vitro gefitinib-resistant EGFR-mutant cell lines.[87,129–133] To date, the EGFR-T790M mutation is found in 50% of tumors (93/116) from patients that have developed acquired resistance to gefitinib or erlotinib.[131,132,134] The mechanisms by which EGFR T790M causes gefitinib/erlotinib resistance was originally thought to be through steric hindrance analogous to the T315I mutation in the ABL kinase, which effects imatinib binding.[135,136] However, more recent studies have revealed that gefitinib can still effectively bind EGFR T790M but that the mutation alters the affinity of the receptor to bind ATP.[137] EGFR T790M is typically found on the same allele as the original EGFR-activating mutation, and together the two mutations increase EGFR kinase active compared with either mutation alone.[138,139] Gefitinib- or erlotinib-resistant cancers harboring EGFR T790M are still EGFR dependent for their growth that has prompted the search for alternative ways of inhibiting EGFR. The class of irreversible EGFR inhibitors are able to inhibit the growth and EGFR phosphorylation in model systems harboring EGFR T790M.[95,96] These agents are now in clinical development in patients that have developed acquired resistance to gefitinib or erlotinib. In addition, inhibitors of heat shock protein (HSP)90 are effective in preclinical models of EGFR T790M and are also undergoing clinical evaluation.[140] EGFR is an HSP90 client protein, and the mutant EGFR is degraded more effectively than wild-type EGFR.[140,141]

The second known mechanism of gefitinib/erlotinib resistance is amplification of the *MET* oncogence.[134,142] This was originally identified in an *EGFR*-mutant lung cancer cell line that had been made resistant to gefitinib in vitro. MET is a unique resistance mechanisms, because MET is not the immediate or downstream target of gefitinib or erlotinib. In fact, MET causes resistance because it creates a bypass signaling track and activates PI3K signaling through ERBB3 in the presence of gefitinib (Fig. 49.3C). This "redundant" activation of ERBB3 permits the cells to transmit the same downstream signaling in the presence of EGFR inhibitors. Thus, unlike for *EGFR* T790M, concomitant inhibition of *both* EGFR and MET is required to kill MET-amplified gefitinib- or erlotinib-resistant cells. The combination therapeutic approach of MET inhibitors with erlotinib are being evaluated in clinical trials. *MET* amplification has been detected in ~20% of *EGFR*-mutant NSCLC patients that have developed acquired resistance to gefitinib or erlotinib. Intriguingly, *MET* amplification and *EGFR* T790M are not mutually exclusive. In fact, resistant NSCLC patients have been identified harboring both *EGFR* T790M and *MET* amplification.[134,142] They have been detected in the same resistant tumor specimen and have been found to occur independently in different metastatic sites in the *same* patient.[134,142] Thus, a therapeutic strategy aimed solely at inhibiting *EGFR* T790M or *MET* amplification may not be very effective or lead only to regression of a subset of metastases that contain the particular mechanism of resistance. A more comprehensive and potentially effective strategy may be a combination of an irreversible EGFR and a MET kinase inhibitor. Alternatively, strategies such as HSP90 inhibitors may also be effective because both EGFR and MET are known HSP90 client proteins.[141,143]

*EGFR T790M* and *MET* amplification account for approximately 60% to 70% of all known causes of acquired resistance to gefitinib or erlotinib. Thus, other mechanisms of acquired resistance are likely to be discovered. The understanding of EGFR signaling both in gefitinib-sensitive and -resistant models has helped define how the likely additional resistance mechanisms will arise. Future resistance mechanisms are likely to lead to maintenance of PI3K/Akt signaling in the presence of gefitinib/erlotinib. This could occur through ERBB3 (such as for *EGFR* T790M or *MET* amplification) or by an ERBB3-independent mechanism (Fig. 49.3D). One recently identified mechanisms is the activation of insulin-like growth factor receptor (IGFR) signaling, which was identified in an EGFR wild-type gefitinib- or erlotinib-sensitive cell line model.[144] However, this mechanisms has not yet been validated in acquired resistant NSCLC patient specimens. It will be important to continue to study preclinical models and tumors from NSCLC patients that have developed gefitinib/erlotinib resistance to uncover novel resistance mechanisms.

### *KRAS* Mutations

It has been hypothesized that KRAS mutation is a good "negative" predictive marker for therapy with EGFR inhibitors in NSCLC. In contrast to colorectal cancer (CRC), in which KRAS mutations occurs in 40% to 50% and has demonstrated to be associated with lack of response and shortened survival,[145] the situation for NSCLC might be different. KRAS mutations in codons 12 to 13 occur in about 15% to 20% of unselected NSCLC patients, somewhat higher in adenocarcinomas (25% to 30%) and significantly less frequent in tumors with squamous histology (5% to 10%). It has been demonstrated in several studies that KRAS mutations in NSCLC are associated with poor prognosis independent of given therapy.[111,146]

It has been shown in several studies in patients with NSCLC treated with EGFR TKIs, that those with tumors harboring KRAS mutations most likely will not respond to EGFR inhibitors, and they have a dismal prognosis. However, it is not clear yet whether the negative association between KRAS mutations and outcome is only caused by the poor prognostic association and/or an inherent resistance to the EGFR TKIs. In the BR.21 study, an update of the biomarker analysis showed for patients with tumors having KRAS a median survival of 7.5 months with erlotinib and 3.4 months with placebo (HR = 0.69; $p$ = 0.03), whereas patients having KRAS mutations had median survival of 3.7 months with erlotinib versus 7.0 months with placebo (HR = 1.67; $p$ = 0.3).[147]

**Serum Proteomics** Investigators from Colorado and Vanderbilt Universities have developed a proteomic profile, which in several retrospective studies have demonstrated to classify NSCLC patients in a "bad" and "good" outcome group after EGFR TKI therapy, both as second-line therapy as well as first-line therapy.[148] The 11-peak proteomic profile is now commercialized by Biodesix (Steamboat Spring, Colorado) under the name Veristat® and is currently prospectively validated in several prospective studies in NSCLC.

# Other Signal Transduction Agents

Alex A. Adjei

Cancer represents a multitude of diseases characterized by uncontrolled cellular proliferation and is the second most common cause of death in Western society.[1] Despite advances in diagnosis and treatment, overall survival (OS) remains poor.[2] Radiotherapy and chemotherapy are relatively nonspecific, affecting normal cells as well as rapidly proliferating tumor cells,[3] and cause toxicities that limit their long-term utility. Tumor responses from cytotoxic chemotherapy are usually transient and unpredictable.[4] Furthermore, resistance to chemotherapy is common in all malignancies.

Novel targeted agents that represent improvements over traditional treatments are therefore needed. These agents would ideally have high specificity toward tumor cells, resulting in minimal side effects.[5] Increased understanding of molecular mechanisms underlying tumor growth, progression, and metastasis over the past decade have identified promising anticancer targets; in particular, protein kinases—enzymes that modify cellular proteins by catalyzing the transfer of phosphate from adenosine triphosphate (ATP) to either serine/threonine or tyrosine amino acid residues.[6] Approximately 90 tyrosine kinases, of the transmembrane receptor type or the cytoplasmic nonreceptor type,[7] which regulate pivotal signaling pathways that control normal cellular function and development,[6,8] have been identified. Their activity is normally tightly controlled and highly regulated.[7] Dysregulated kinase activity, resulting from oncogenic gene mutation or overexpression, has a major role in carcinogenesis.[6] For example, overactivation of these enzymes increases tumor cell proliferation and growth, induces antiapoptotic effects, and promotes angiogenesis and metastasis.[4]

In this chapter, we discuss the discovery, biology, signaling pathways, and pharmacology of protein kinase targets (Fig. 50.1) as a well as a few nonkinase targets involved in cell proliferation, metastasis, and apoptosis. These targets include receptor tyrosine kinases (RTKs) with roles in proliferation—insulin-like growth factor receptor 1 (IGFR-1), mesenchymal-epithelial transition factor (c-Met), c-Kit, Flt-3, and RET (rearranged during transfection); and cytoplasmic nonreceptor kinases involved in proliferation and/or prevention of apoptosis—the serine/threonine kinases

Raf, MEK, mammalian target of rapamycin (mTOR) and Aurora kinases, and tyrosine kinases Bcr-Abl and Src.

The kinases involved in angiogenic signaling as well as the epidermal growth factor receptor (EGFR) signaling are discussed elsewhere in this volume.

## PROLIFERATIVE RECEPTOR TYROSINE KINASES

**IGFR/PI3-Kinase Pathway**  The phosphatidyl-inositol 3 kinase (PI3K) pathway is one of the most important oncogenic pathways, with estimates suggesting that activating mutations in the p110$\alpha$ catalytic subunit occurs in up to 30% of all human cancer, although this is uncommon in non–small cell lung cancer (NSCLC). The most common mechanism of its aberrant activation though is the loss of the regulatory phosphatase and tensin homologue (PTEN) lipid phosphatase, which occurs frequently in NSCLC. PI3K is activated by Ras and RTKs such as EGFR, c-met, and IGF receptor pathway. Autocrine production of IGF as well as overexpression of its cognate receptor, IGF-1R, are well documented in NSCLC, with downstream signaling chiefly mediated by the PI3K–Akt pathway.

Regardless of the mechanism of its dysregulation, Akt is the chief mediator of downstream signaling through various targets. One key target is the mTOR, a serine/threonine kinase that serves as a key component regulating transcriptional and translational proteins that control cell growth, angiogenesis, apoptosis, as well as amino acid and glucose metabolism. This pathway has been implicated in mediating resistance to cytotoxic chemotherapy as well as resistance to novel agents such as the EGFR tyrosine kinase inhibitors (EGFR TKIs).

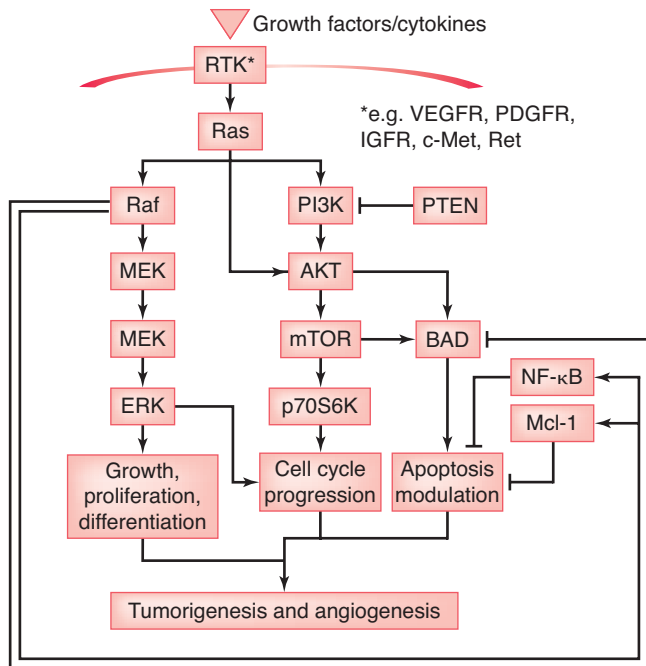
**IGF Receptor**  The IGFs help regulate normal cell metabolism, growth, proliferation, differentiation, cell–cell and cell–matrix adhesion, and survival.[9] The IGF-1R is expressed in most cells, has ligand-activated tyrosine kinase activity,[10] and


**FIGURE 50.1** Overview of the key protein kinase signaling pathways involved in tumorigenesis. *AKT*, AKT8 virus oncogene homologue; *BAD*, Bcl2-antagonist of cell death; *c-Met*, growth factor receptor c-met; *ERK*, extracellular signal regulated kinase; *IGFR*, insulin-like growth factor 1 receptor; *Mcl-1*, myeloid cell leukemia sequence 1; *MEK*, MAPK/Erk kinase; *mTOR*, mechanistic target of rapamycin; *NF-κB*, nuclear factor kappa-light-chain-enhancer of activated B cells; *PDGFR*, platelet-derived growth factor receptor; *PI3K*, phosphatidylinositol 3-kinase; *PTEN*, phosphatase and tensin homologue; *Raf*, root abundant factor; *Ras*, ras protein; *Ret*, ret oncogene; *RTK*, receptor tyrosine kinase; *VEGFR*, vascular endothelial growth factor receptor.

activates several downstream signaling pathways, including Raf/MEK/extracellular signal-regulated kinase (ERK).[9] IGF bioactivity is influenced by a family of six IGF-binding proteins (IGFBPs) that sequester IGFs, thereby preventing excessive cell growth and/or promoting apoptosis.[11] Increased circulating levels of IGF, or an increased ratio of IGF to IGFBP, are implicated in the development of several types of tumors, including breast,[12] prostate,[13] lung,[14] and colon carcinomas.[15] Several monoclonal antibodies (MoAbs) and small molecule inhibitors of IGF-1R are in clinical testing.

CP-751,871 is a fully humanized IgG2 MoAb antagonist of IGF-1R with preclinical anticancer activity.[16] The MoAb interrupts the binding of IGF-I to IGF-1R, IGF-1R autophosphorylation and induces downregulation of IGF-1R in vitro and in tumor xenograft models. In a phase I study, CP-751,871 was administered intravenously every 21 days in advanced solid tumor patients.[17] CP-751,871 was escalated to the maximally feasible dose (based on duration of infusion) of 20 mg/kg without any dose-limiting toxicities (DLTs). The correlative studies revealed increased expression of serum insulin and human growth factor hormone, presumably, through a negative feedback loop. The most common adverse events were hyperglycemia, anorexia, nausea, elevated liver transaminases, hyperuricemia, and fatigue. In an exploratory assay, IGF-1R-expressing circulating cancer cells (CTCs) were analyzed. Three patients with detectable IGF-1R expressing CTCs at baseline were reported to have decreased level of CTCs following CP-751,871 administration that rebounded at the end of the 21-day period.[17,18] Preliminary phase II results of a randomized first-line advanced NSCLC phase II study of paclitaxel and carboplatin plus/minus CP751,871 were presented at American Society of Clinical Oncology (ASCO) 2007. A total of 46% of patients in the experimental arm achieved objective responses (22/48 patients) versus 32% (8/25 patients) in the control arm.[19] An unplanned subgroup analysis by histology has suggested a greater benefit in patients with squamous histology within this trial, but the mature results with additional patient numbers remain to be published. Based on these promising phase studies of CP-751,871 in combination with paclitaxel and carboplatin, phase III studies comparing this combination with chemotherapy alone as frontline therapy in NSCLC has commenced. In addition, a phase III trial of erlotinib with or without CP-751,871 is also ongoing, as are studies in multiple myeloma and other tumor types.[20–23]

AMG-479 is a fully humanized anti-IGF-1R MoAb with broad preclinical antitumor activity. The agent showed potent inhibition of the PI3k/Akt axis with increased antitumor effect when combined with anti-EGFR therapies in pancreatic cancer xenograft models.[24] In phase I testing of AMG-479, 16 patients with advanced solid tumors received escalating dose of the agent intravenously.[25] At 20 mg/kg every 2 weeks, one patient experienced grade 3 dose-limiting thrombocytopenia. No greater than grade 2 hyperglycemia was observed. The agent is currently being tested in non-Hodgkin lymphoma, Ewing sarcoma, and desmoplastic small round cell tumors.[26,27] Phase I studies in combination with gemcitabine or panitumumab, as well as phase I/II studies in combination with irinotecan and panitumumab in colorectal cancer are being planned at the time of writing.[28]

Other anti-IGF-1R agents under phase I/II evaluation include the MoAbs IMC-A12, R-1507, and BIIB022. As well as the oral small molecule inhibitors, XL-288, OSI-906, and nordihydrohuareacetic acid are also being tested.

**mTOR** mTOR is a serine/threonine kinase, acting downstream of PI3K/AKT.[29] The PI3K pathway is activated by Ras, which is often overstimulated in tumors where it contributes to cell cycle progression, inhibits apoptosis, and increases metastatic potential.[30] mTOR promotes RTK-induced cell growth, proliferation, and prolongs cell survival via its target, P70S6 kinase, which binds to mitochondrial membranes and inactivates the pro-apoptotic molecule Bcl2-antagonist of cell death (BAD).[31]

Overactivation of mTOR can also arise through inactivating mutations of the tumor suppressor PTEN gene, resulting in overstimulation of the PI3K/AKT signaling pathway. Loss of the PTEN gene is associated with poor prognosis, resistance to chemotherapy, and various solid tumors, including

glioblastoma multiforme,[32] melanoma,[33] thyroid,[33] breast,[34] ovarian, and prostate carcinoma.[29] Dysregulation of mTOR signaling is also important in hematologic malignancies, including mantle cell lymphoma.[35]

The mTOR protein was discovered in the 1990s when the mechanism of action of rapamycin was investigated.[36] Rapamycin (sirolimus) is a macrolide isolated from *Streptomyces hygroscopicus*, a bacterial species native to Easter Island, and has been used widely as an immunosuppressant in organ transplantation.[37] Rapamycin has been evaluated orally as an anticancer agent in solid tumors and pancreatic cancer.[38,39] mTOR complexes with raptor (regulatory-associated protein of mTOR) and rictor (rapamycin-insensitive companion of mTOR) to form mTOR complex-1 (mTORC1) and mTORC2, respectively. mTORC1 is downstream to Akt and is susceptible to inhibition by rapamycin and its analogs, whereas mTORC2 is an upstream regulator of Akt and the activity is upregulated in certain circumstances as a compensatory response to mTORC1 inhibition.[40,41] Interestingly, recent evidence refuted the belief that mTORC2 is rapamycin resistant. It has been demonstrated that mTORC2 can, in fact, be inhibited by rapamycin and its analogs in a time- and cell line–dependent manner.[42,43]

Temsirolimus (CCI779) is a water-soluble synthetic rapamycin ester available in oral and intravenous formulations.[44] The drug is the first of the class to receive Food and Drug Administration (FDA) approval for the treatment of poor-risk untreated advanced renal cell carcinoma (RCC) patients.[45,46] In the pivotal randomized trial, temsirolimus was superior to interferon-α alone or in combination with interferon-α in prolonging survival. The most common grade 3 or 4 toxicities were asthenia, anemia, and dyspnea. The recommended dose of temsirolimus for this indication is 25 mg weekly intravenous administration. The drug is currently under testing in various tumor types either alone or in combination therapy.[46–49] A cohort of patients with NSCLC treated with temsirolimus as first-line therapy was assessed in a phase II study conducted by the North Central Cancer Treatment Group (trial 0323).[50] In a report of 50 evaluable patients primarily with stage IV disease, partial response (PRs) were observed in four patients (8%) and stable disease for a minimum of 56 days was observed in 15 patients (30%), suggesting an overall clinical benefit rate of 38%. Median progression-free survival (PFS) and OS were 2.3 and 6.6 months, respectively. Temsirolimus was noted to be well tolerated in this population of patients. A phase II study assessed the effect of temsirolimus alone as consolidation treatment in patients with extensive-stage small cell lung cancer (SCLC) in complete remission.[51] Temsirolimus was administered until the time of progression and in 85 evaluated patients, the median OS was 8 months. These results have prompted several studies of temsirolimus in combination with chemotherapy in SCLC.

Everolimus (RAD001) is an oral mTOR inhibitor with similar antineoplastic activity as other rapalogs.[52,53] In a phase I study in solid tumor patients, the optimal biologic dose for everolimus was determined as 20 mg weekly. This dose achieved pharmacokinetic and pharmacodynamic changes cor-

related with antineoplastic effects in animal models. Toxicities at this dose were mild and include anorexia, fatigue, rash, mucositis, headache, hyperlipidemia, and gastrointestinal disturbances.[54] When administered on a daily continuous manner, everolimus was well tolerated at a 10-mg dose in patients with refractory or relapsed hematological malignancies. No DLTs were reported and activity was seen in patients with myelodysplastic syndrome.[55] The dose of 5 mg/m$^2$ was the maximum tolerated dose (MTD) in pediatric solid tumor patients and DLTs (included diarrhea, mucositis, and elevation of alanine transaminase).[56] No objective tumor responses were observed. Everolimus was further tested in a clinical trial exclusively enrolling patients with NSCLC.[57] Patients in this phase II trial had an Eastern Cooperative Oncology Group (ECOG) performance status (PS) of ≤2 and had failed ≤2 cycles of platinum-based therapy (arm 1) or ≤2 cycles of platinum-based therapy with an EGFR antagonist (arm 2). Patients were treated with everolimus at a dose of 10 mg daily. In a preliminary report including 85 patients (42 patients on arm 1; 43 patients on arm 2), everolimus was administered as first- or second-line therapy in 64.3% of patients. With response data available for 74 patients in arms 1 and 2, a best response of PR was experienced in 5.3% and 2.8% of patients, respectively. Median PFS was 11.3 and 9.7 weeks on arms 1 and 2, respectively. The most frequent adverse events observed in the study were stomatitis/mucositis, cough, and dyspnea. Although therapy with everolimus was generally well tolerated, the limited antitumor activity led to discontinuation of the study.

A separate phase II study examined the efficacy of everolimus in the setting of refractory SCLC.[58] Patients enrolled in this trial had relapsed disease after 1 to 2 previous regimens, no evidence of brain metastases, and ECOG PS of ≤2. Everolimus was administered at a dose of 10 mg daily until disease progression or unacceptable toxicity. At an interim analysis in which 16 evaluable patients had been assessed, three patients had stable disease as a best response, whereas 81% of patients had progressive disease. Similar to the outcome in the aforementioned trial in patients with NSCLC, everolimus was well tolerated but showed limited efficacy in the setting of SCLC. The agent is being tested in non–small cell lung, kidney, prostate, colorectal, and breast cancers as either single-agent or combination therapies.[59–64]

Deforolimus (AP-23573) is the other mTOR inhibitor currently under clinical testing.[65–67] During phase I testing, the MTD was 18.75 mg/day and mouth sores was the DLT. Antitumor activity was seen in NSCLC, carcinosarcoma, RCC, and Ewing sarcoma. Phase II studies in sarcoma are ongoing.

## Combination of Motor Inhibitors with Other Agents for Treatment of Lung Cancer

A phase I study of gefitinib and everolimus therapy in 10 enrolled patients resulted in 2 DLT (grade 5 hypotension and grade 3 stomatitis), and 2 PRs were observed in 8 evaluable patients.[68] A phase II trial in previous smokers with stage IIIB/IV NSCLC[69] enrolled 2 cohorts of patients including previously untreated patients and patients with previous therapy with a platinating agent and

docetaxel. Partial responses were observed in 4 of 23 evaluable patients (17%). This observed response rate in a group of smokers, for whom gefitinib has lessened antitumor activity, was encouraging. Frequently encountered toxicities with the regimen included diarrhea, rash, and mucosal ulcerations.

A phase I clinical trial combining everolimus with erlotinib[70] in patients with advanced NSCLC who had failed ≤2 chemotherapy regimens with an ECOG PS of ≤2 revealed 1 complete response and 3 PRs in 38 evaluable patients.

## PKC Inhibitors

Overexpression and increased activity of protein kinase C-$\beta$ (PKC-$\beta$) have been implicated in transformation and tumorigenesis in NSCLC,[71–73] and recent evidence suggests a link between the PKC and protein kinase B/AK transforming (AKT) pathways.[74,75]

Enzastaurin, an oral serine/threonine kinase inhibitor, targets the PKC and AKT pathways and so inhibits phosphorylation of glycogen synthase kinase-3$\beta$ and S$^6$kinase.[76] In a phase I dose–escalation study of daily oral enzastaurin (20 to 750 mg), four patients with advanced lung cancer had stable disease for 3 to 12 months.[77]

A phase II trial of enzastaurin to determine the 6-month PFS rate in 55 patients with advanced, metastatic NSCLC did not achieve its primary end point of a 20% PFS rate; however, 13% of the patients had PFS for ≥6 months.[78]

## Akt Inhibitors

Akt, also known as protein kinase B (PK-B), is a serine/threonine kinase upstream to mTORC1 and is implicated in the formation and maintenance of malignancies.[79] Akt is an attractive target as mTOR because of its role in several important cellular functions, including cell cycle progression, protein translation and transcription, apoptosis, and cellular metabolism. The side effects from Akt inhibition could theoretically be more severe than mTOR, given its key role in the axis, and the fact that its upstream of mTOR. The development of this class of agents has been challenging and disappointing so far.

Perifosine, a lipid-based derivative of miltefosine, is perhaps the best-characterized Akt inhibitor in clinical development now. The compound inhibits Akt translocation to the cell membrane and exhibits in vitro antiproliferative effects in several cancer cell lines.[80] It should be noted, however, that perifosine is a relatively nonspecific AKT inhibitor, and that by interrupting with cell membrane biology, pleiotropic effects on several signaling pathways and molecules are seen. Perifosine was tested as a daily oral dose on a 3-week cycle in patients with advanced solid tumors.[81] The patients reported dose-dependent gastrointestinal adverse events, such as nausea, diarrhea, and vomiting, which led to early therapy discontinuation in increasing number of patients at higher dose levels. The MTD was determined at 200 mg/day. An alternative loading/maintenance dosing schedule was tested in patients with advanced solid tumors.[82] The MTD was a loading dose of 150 mg every 6 hours for 4 doses followed by 100 mg once daily for maintenance. The DLTs during the loading period were nausea, diarrhea, dehydration, and fatigue and were manageable with prophylactic antiemetics. However, the side effects were more difficult to manage during the maintenance period.

Despite encouraging evidence in preclinical studies, perifosine failed to demonstrate significant single-agent anticancer activity in sarcoma, melanoma, pancreatic, and head and neck cancers during phase II testings.[83–93] Perifosine continues to be evaluated as single-agent or combination therapies. GSK690693 is another Akt inhibitor planned for phase I testing.[94] Several lipid- and peptide-based Akt inhibitors are being evaluated preclinically.[95]

Currently, there is limited clinical experience with inhibitors of PI3k and 3-phosphoinositide-dependent protein kinase-1 (PDK-1). The **PI3k inhibitors** undergoing phase I evaluation include PI-103, BGT-226, BEZ-235, XL-765, and XL-147.[96–100] Current **PDK-1 inhibitors** are derivatives of staurosporin and celecoxib.[95] UCN-01 is a staurosporin derivative that inhibits multiple kinases including PDK-1 and has in vitro pro-apoptotic activity.[101,102] The drug is synergistic with cytotoxic agents in preclinical studies but the pro-apoptotic activity seemed to be from the inhibition of checkpoint homologue (Chk1), a cell cycle checkpoint kinase.[103] UCN-01 can be administered intravenously as an initial 72-hour continuous infusion on a monthly schedule or short infusion over 3 hours every 28 days with the second and subsequent doses at 50% of the first.[104,105] However, the clinical activity of UCN-01 was not associated with PI3k/Akt/mTOR pathway inhibition and its role as a PDK-1 inhibitor remains ambiguous. OSU-03012 is a celecoxib derivative that inhibits PDK-1 and induced apoptosis in rhabdomyosarcoma cell lines.[106] This drug is currently still under preclinical evaluation.

## c-Met

The protein product of *c-Met* proto-oncogene is a transmembrane RTK that is activated by the multifunctional cytokine hepatocyte growth factor (HGF)/scatter factor (SF),[107] which increases signaling through the Raf/MEK/ERK pathway.[108] HGF/SF mediates epithelial cell morphogenesis, migration, invasion, and differentiation.[107] HGF/SF is produced predominantly by mesenchymal cells, whereas c-Met is expressed primarily in epithelial cells.

Overexpression of c-Met is implicated in several tumor types, including glioblastomas, RCC,[109] hepatocellular carcinoma (HCC),[110] pancreatic adenocarcinomas,[111] thyroid carcinomas,[112] melanoma,[113] breast,[107] gastric,[114] pancreatic,[115] prostate, and lung cancers.[116,117]

There are currently several HGF/c-MET inhibitors under clinical evaluation. AMG-102 is a fully humanized immunoglobulin G2 (IgG2) MoAb against HGF with antitumor activity in preclinical models.[118] The interim result of the phase I study was reported at American Society of Clinical Oncology (ASCO) annual meeting in 2007.[119] The agent was administered intravenously at 0.5-, 1-, 3-, 5-, 10-, or 20-mg/kg dose levels. Patients with advanced solid tumors received a single dose followed by a 4-week treatment free period to assess safety and pharmacokinetic profile. The treatment was subsequently resumed at a 2 weekly schedule. Thirty-one patients were treated at doses up to 20 mg/kg. DLTs include dyspnea/hypoxia (at 0.5-mg/kg dose) and gastrointestinal bleed (at 1-mg/kg dose). Common treatment-related side effects include fatigue, constipation, anorexia, nausea, and vomiting. Pharmacokinetic

analysis showed a linear relationship in the dose range of 0.5- to 20-mg/kg and no anti-AMG-102 antibodies were detected following administration. The 20-mg/kg dose was deemed tolerable and safe and the agent is being tested in RCC and malignant glioma.[120,121]

XL-880 is an oral small molecule inhibitor of c-MET and has activity against vascular endothelial growth factor receptor 2 (VEGFR2), PDGFR-$\beta$, kit, FLT3, Tie-2, and Ron. The interim result of the phase I study was presented at ASCO 2007 and two schedules were tested: a "5-day on/ 9-day off" schedule and a daily fixed-dose schedule.[122] Fifty-one solid tumor patients were enrolled and hypertension was universally observed. The DLTs with the first schedule were proteinuria and elevated lipase and liver enzymes. The MTD was 3.6 mg/kg and the MTD for the second schedule was not reached at the time of analysis, and common side effects include hypertension and fatigue. Correlative studies showed inhibition of c-MET, RON, Erk, Akt, and increased apoptosis at dose levels less than MTD. The agent is being evaluated in papillary RCC gastric and head and neck cancers.[123–125]

ARQ-197 and PF-02341066 are similar oral small-molecule c-Met inhibitors that are in early phase trials.[126] The recommended phase II dose for ARQ-197 was determined to be 120 mg twice daily. Common side effects include fatigue, diarrhea and constipation, and grade 3 elevated liver enzymes were the more severe toxicity.[127] Compounds with activity against the HGF/c-MET axis in the preclinical pipeline include MGCD-265, SU-11274, and MGCD-265.[128–131]

**c-Kit** Stem cell factor signaling through its transmembrane RTK c-Kit is essential for development of erythrocytes, melanocytes, germ cells, and mast cells. Cellular responses mediated by the c-Kit RTK include proliferation, survival, adhesion, secretion, and differentiation.[132] Overexpression of the c-Kit proto-oncogene results in the development of tumors,[133,134] including oncocytomas and chromophobe RCC,[135] SCLC,[136] uveal melanoma,[137,138] acute myeloid leukemia (AML),[139] colorectal cancer (CRC),[140] gastrointestinal stromal tumor (GIST),[141] and HCC.[142] Overactivation of c-Kit protects colon carcinoma cells against apoptosis and enhances their invasive potential.[143]

**Flt-3** The growth factor ligand Flt-3 stimulates proliferation of hematopoietic progenitor cells of lymphoid and myeloid origin[144] and helps modulate cell proliferation and hematopoiesis.[145] Overexpression of Flt-3 leading to its constitutive activation increases proliferation and prolongs cell survival of leukemic blasts in AML. Activating internal tandem duplication (ITD) mutations of the Flt-3 (Flt-3-ITD) gene are the most frequent molecular abnormalities in AML, occurring in ~30% of cases,[146,147] and are associated with poor OS.[148]

**RET** The RET proto-oncogene encodes a transmembrane RTK that contains several internal autophosphorylation sites, which can activate the Raf/MEK/ERK, PI3K/AKT, p38, or c-Jun N-terminal kinase signaling pathways.[149]

Oncogenic RET promotes invasion and metastasis by increasing cell survival through AKT-mediated nuclear factor kappa-light-chain-enhancer of activated B cells (NF-$\kappa$B) activation, BAD inactivation, and cyclin D1-mediated cell cycle progression.[150] RET mutations are responsible for the development of familial medullary thyroid carcinoma (MTC), papillary thyroid carcinoma (PTC), and multiple endocrine neoplasia 2A and 2B, which share clinical features of MTC.[151] Somatic chromosomal rearrangements of RET occur in 5% to 30% of sporadic and 60% to 70% of radiation-associated PTCs.[151] Somatic mutations constitutively activate RET to upregulate expression of the chemokine receptor CXCR4 in metastatic MTC.[152] Vandetanib is a novel, selective inhibitor of RET kinases, VEGFRs 2 and 3, and EGFR. Laboratory studies in human lung cancer cell line models demonstrated that vandetanib is comparable to other EGFR inhibitors in causing regression of established HCC827 xenografts.[153]

Vandetanib also was effective in cell lines with acquired resistance to EGFR inhibition (T790M mutation) and in cell lines with overexpression of K-ras.

Two phase I clinical trials with vandetanib established that daily oral doses up to 300 mg were generally well tolerated, with the most common adverse events consisting of mild-to-moderate rash, diarrhea, and asymptomatic QTc prolongation.[154,155]

Moreover, in Tamura's study, there were objective responses in four of nine Japanese patients with advanced NSCLC. A phase II, randomized, double-blind comparison of vandetanib and gefitinib in previously treated patients with advanced or metastatic NSCLC revealed that patients in the vandetanib arm achieved a statistically significant improvement in PFS compared with the gefitinib arm with a hazard ratio of 0.69 (95% confidence interval [CI], 0.50 to 0.96) and a two-sided $p$ value of 0.025. Vandetanib achieved disease control in 16 of 37 patients (43%) who were initially treated with gefitinib. However, gefitinib achieved disease control in only 7 of 29 patients (24%) initially treated with vandetanib. A run-in feasibility study of docetaxel combined with vandetanib followed by a 3-armed phase II randomized trial of docetaxel, 75 mg/m$^2$ every 3 weeks alone or combined with 100 mg/day or 300 mg/day of vandetanib 5. One hundred twenty-seven patients were entered into the trial, and both vandetanib arms produced an improvement in PFS compared with the docetaxel control arm, but only the 100-mg dose level of vandetanib combined with docetaxel achieved the study end point, with a hazard ratio of 0.64 (95% CI, 0.38 to 1.05).[156] A phase III trial of second-line alimta compared to vandetanib has completed accrual.

## Proliferative and Anti-apoptotic Cytoplasmic Nonreceptor Kinases

**Raf Kinase** Raf is a serine/threonine kinase member of the Raf/MEK/ERK signaling pathway,[157] which regulates many cellular processes, including growth, proliferation, differentiation, motility, and survival, in response to growth factors and cytokines.[157] Activation of Raf is initiated by association with

Ras-GTP, which then phosphorylates MEK, resulting in activation of ERK.[158] There are three functional isoforms of Raf (A-Raf, B-Raf, and Raf-1 [C-Raf]); B-Raf has the highest basal kinase activity; Raf-1 is ubiquitously expressed in tissues.

Dysregulated signaling through Raf is associated with several solid tumor types, including RCC,[159] HCC,[160] CRC,[161] and thyroid cancer.[162] Activating Ras mutations that increase Raf activity are present in ~30% of human cancers.[163] Oncogenic-activating B-Raf mutations are associated with ~60% of malignant melanomas[164] and are found in PTC,[165] colorectal,[166] pancreatic,[167] ovarian carcinomas,[168] and some cases of NSCLC.[164] Approximately 90% of B-Raf mutations involve a Glu-for-Val substitution at residue 599 (V599E, now termed V600E), which upregulates the kinase activity leading to constitutive activation of ERK.[158] Raf-1 can directly prolong cell survival independently of MEK/ERK by upregulating the anti-apoptotic proteins NF-$\kappa$B[169] and Mcl-1, or directly inhibiting pro-apoptotic proteins, such as BAD,[170] apoptosis signal-regulating kinase,[171] and MST-2.[172]

Inactivating mutations within the von-Hippel Lindau (VHL) tumor suppressor gene, leading to overexpression of hypoxia-regulated genes, including VEGF, PDGF-$\beta$, and transforming growth factor $\alpha$ (TGF-$\alpha$), results in uncontrolled stimulation of Raf-1.[173] VHL mutations are associated with various tumors, including RCC,[174] eye and CNS hemangioblastomas, and pheochromocytoma.[175]

Sorafenib (BAY43-9006) is an oral dual inhibitor of Raf and VEGFR. The molecule demonstrated preclinical antineoplastic activity against a wide spectrum of human cancers.[176] It has potent in vitro inhibitory effects against Raf-1, B-Raf, VEGFR2, PDGFR, and VEGFR3.[177,178] Sorafenib is approved by FDA for the treatment of advanced RCC and HCC.[177,179] The DLTs reported during phase I development were diarrhea, fatigue, and skin rashes.[180] The recommended dose is 400 mg twice daily on continuous basis. Rash, diarrhea, fatigue, and hand–foot syndrome were the common side effects during phase II and III studies.[181,182] Correlative studies showed mitogen-activated protein kinase (MAPK) pathway inhibition in peripheral lymphocytes with a sorafenib dose above 200 mg, indicating the potential usefulness of this pharmacodynamic assay in the development of Raf inhibitors.[180]

However, the contribution of Raf inhibition to sorafenib's clinical efficacy is difficult to assess. The success of bevacizumab and sunitinib in RCC indicated that the drug's anticancer effects may be related more to its antiangiogenic effects.[183,184] The real benefit of Raf inhibition in cancer therapy will perhaps only be answered by specific Raf inhibitors. A discussion of sorafenib lung cancer trials is found in Chapter 48.

XL-281 and PLX-4032 are oral inhibitors that are, reportedly, highly selective against Raf currently in phase I testing.[185–187] RAF-265 (CHIR-265) is another oral inhibitor of Raf and VEGFR in early phase trial.[188,189]

**MEK** Raf/MEK/ERK cascades form a three-kinase signaling module involved in transmitting membrane signals to the cell nucleus; MAPK (ERK) activated by MAP/ERK kinase (MEK, MAPKK), which, in turn, is activated by a MEK kinase (Raf, MEKK, MAPKKK).[190] Stimulation of MEK results in phosphorylation and activation of ribosomal S6 kinase and transcription factors, such as *c-Jun*, *c-Myc*, and *c-Fos*, resulting in the switching on of genes associated with proliferation.[157,191] MEK has roles in gene regulation,[156,190] promoting G1 cell cycle progression before DNA replication,[192] and spindle assembly during both meiotic and mitotic cell division.[193] Overactivation of the Raf/MEK/ERK pathway, through oncogenic mutations, can result in cellular transformation tumorigenesis.[194,195]

The Ras/Raf/MEK/ERK pathway is constitutively activated in various tumor cell lines and primary human tumor types.[196] Although MEK has not been identified as an oncogene product, it is the focal point of many mitogenic signaling pathways that are hyperactivated by oncogenes. MEK can also be hyperactivated by autocrine signaling through VEGFR, PDGFR, or EGFR in tumor cells. Inhibition of MEK inhibits several cellular processes, including proliferation, differentiation, apoptosis, and angiogenesis.[197]

CI-1040 is one of the first MEK inhibitors to be developed clinically. The oral agent demonstrated encouraging preclinical effects on tumor proliferation, survival, invasion, and angiogenesis.[198] Phase I study showed that the drug had poor metabolic stability and bioavailability that high doses had to be administered in phase II trials.[199,200] The encouraging antitumor activity seen in phase I development was not seen in phase II studies, leading to the termination of the agent's development. Despite this, correlative studies from phase I trial showed adequate target inhibition with CI-1040 and subsequent research effort was focused on improving on CI-1040.

PD0325901 is a second-generation MEK inhibitor that is structurally related to CI-1040. PD0325901 has a higher potency, better bioavailability, and induces more sustained MEK inhibition than CI-1040. Preclinical studies showed antitumor activities against a broad spectrum of human cancer cell lines.[201] The DLTs reported during phase I development include acneiform rash, syncope, and elevated liver enzymes.[202] Visual disturbances such as halos, spots, and decreased acuity were also reported. Antitumor effects were seen in melanoma, colon, and NSCLC. Phase II trials in melanoma, breast, lung, and colon cancers had ceased enrolling patients at the time of writing.[203,204]

AZD-6244 (ARRY-142886) is another second-generation, highly selective MEK inhibitor. The drug inhibited Erk phosphorylation, and was associated with growth inhibition in cell lines containing B-Raf and Ras mutations, and tumor regression in preclinical xenograft models.[205] The DLTs during phase I development were hypoxia, rash, and diarrhea, and common adverse events include nausea, fatigue, peripheral edema, altered taste, and blurred vision.[206] The recommended phase II dose was determined to be 200 mg twice daily. The best response was stable disease observed in three melanoma and one NSCLC patients. AZD6244 is being tested in phase II trials of various cancers, including lung, liver, colorectal, pancreas, and ovary.[207–210] Other MEK inhibitors under phase I testing include XL-518 and RDEA-119.[211,212]

**Aurora Kinases**    Aurora kinases are microtubule-associated serine/threonine kinases that help control cell division. The three family members of the mammalian serine/threonine Aurora kinases, Aurora-A, -B, and -C, have roles in regulating the mitotic processes required for genome stability.[213] The Aurora-A gene is located on chromosome 20q13.2–13.3. Aurora-A localizes to centrosomes/spindle poles, facilitates assembly of the mitotic spindle,[213] and can promote neoplastic transformation. Overexpression of Aurora-A may result in abnormal mitosis because of the inability of chromosomes to orientate correctly on the mitotic spindle.[214] In cells with functional p53, this results in cell cycle arrest and apoptosis.[214] However, in cells lacking functional p53, Aurora-A overexpression leads to uncontrolled cell cycle progression, with abnormal segregation of the chromosomes and aneuploidy.[214] This can result in the overexpression of oncogenes, loss of tumor suppressor genes, and development of a malignant phenotype.[214] MLN8054 is a novel small molecule oral Aurora A kinase inhibitor, which has demonstrated specificity and potency against its Aurora kinase and also demonstrated broad activity both in vitro and in vivo at doses that were well tolerated. Phase I trials with the molecule are underway.

The Aurora-B gene is located on chromosome 17p13. Aurora-B is a chromosome passenger protein required for phosphorylation of histone H3, chromosome segregation, and cytokinesis.[213] Dysregulation of Aurora-B can also lead to aneuploidy.[215] Aurora-C also appears to act as a chromosome passenger that cooperates with Aurora-B,[216] localizing to the spindle poles during late-stage mitosis.[217] Overexpression of Aurora-A and/or -B has been reported in breast,[218] colon,[219] ovarian,[220] bladder,[221] and gastric tumors.[222] Furthermore, Aurora-B is overexpressed in human androgen-independent prostate cancer cells.[223]

**Bcr-Abl**    The fusion protein Bcr-Abl is a nonreceptor tyrosine kinase created by the translocation of the "bcr" gene (chromosome 22) to the "abl" gene (chromosome 9), which generates the characteristic Philadelphia (Ph) chromosome and leads to the formation of the "bcr-abl" oncogene.[7] Bcr-Abl is constitutively active and overstimulates mitogenic pathways that promote cell division and oncogenesis. Whereas Abl can translocate to the nucleus to induce apoptosis, Bcr-Abl is retained in the cytoplasm and has no pro-apoptotic effect. The Ph chromosome is found in most cases of chronic myelogenous leukemia (CML) and many cases of adult acute lymphoblastic leukemia.[224]

**Src**    The product of the SRC proto-oncogene, c-Src, is a nonreceptor tyrosine kinase that regulates cell division, adhesion, migration, invasion, resistance to apoptosis, and angiogenesis.[225–227] c-Src is associated with cancers of the breast,[228] colorectum,[229] lung (NSCLC),[230] stomach, pancreas, brain, and blood, and, to a lesser extent, melanomas.[227] Protein levels of c-Src are elevated 2- to 50-fold relative to normal tissue in ~70% of breast tumors.[228,231,232] c-Src may also promote tumor growth by augmenting signaling pathways initiated by oncogenes or growth factors, such as EGF.[233]

Accumulating data suggest that Src plays an important role in affecting cancer cell mitosis, adhesion, invasion, motility, and progression.[234] Src mediates the mitogenic signals between growth factor receptors, such as EGFR, c-Met, and IGF-1R, and downstream signaling cascades, such as focal adhesion kinase (FAK), MAPK, and PI3k/Akt/mTOR.[235,236] Dysregulated Src activity has been implicated in the development and progression of several human cancers, including breast, colorectal, lung, ovary, and hematological malignancies.[237,238] As such, much interest exists in developing Src-targeting compounds for cancer therapy.

Dasatinib (BMS-354825) is an orally available dual-specific Src and Abl kinase inhibitor with antiproliferative activity against a broad spectrum of hematological and solid cancer cell lines.[239] The compound has less stringent conformational requirement for Abl kinase inhibition than imatinib, dasatinib is active against many imatinib-resistant Bcr/Abl mutants in preclinical models.[240–242] Dasatinib was granted accelerated approval by FDA in 2006 for treatment of chronic phase, accelerated phase, or myeloid or lymphoid blast phase CML with resistance or intolerance to prior imatinib therapy following the pivotal large randomized trial.[243,244] In addition, dasatinib was approved for Ph chromosome-positive acute lymphoblastic leukemia. The toxicities include superficial edema, pleural effusion, constitutional and gastrointestinal and hematological events. Bleeding was reported in 40% of patients, of which 14% had gastrointestinal bleed. The recommended dosing schedules include 70 mg twice daily and 100 mg once daily. As a multikinase inhibitor, dasatinib is being evaluated in breast, lung, colorectal, and pancreatic cancers.[245–249] The effect of dasatinib on NSCLC cells is cell line dependent and includes cell cycle arrest, apoptosis, and/or reduced invasion. EGFR status/independency seems to be predictive of response. A phase II study of 13 chemonaive NSCLC patients performed at MD Anderson Cancer Center using oral dasatinib 100 mg twice daily (bid) revealed one partial response and five stable disease effects as of February 2008. A phase II trial of progressive NSCLC after EGFR TKI failure is presently accruing patients at Memorial Sloan-Kettering Cancer Center in New York.

Bosutinib (SKI-606) is another potent oral Src inhibitor, with anti-Abl activities. The compound demonstrated antitumor activities in preclinical models and clinical development in hematological and solid malignancies are underway.[250–252] AZD-0530, XL-999, and XL-228 are other Src inhibitors undergoing early phase testing.[253,254] Most of these small molecules have activities against other kinases as well.

## CONCLUSION

In recent years, advances in the understanding of the cellular signaling pathways involved in tumorigenesis have led to the discovery of novel molecular targets for therapeutic intervention.[5] In particular, protein kinases are important regulators of intracellular signal–transduction pathways and have critical

roles in modulating growth-factor signaling. Dysregulation of these enzymes is associated with the pathogenesis and progression of tumors.[6] Targeted inhibition of protein kinases is an attractive anticancer strategy and represents an advance in the management of advanced refractory tumors.[255] Targeted therapy has the potential to reduce the problems of toxicity associated with cytotoxic chemotherapy. At present, the most successful approach to inhibiting cell signaling appears to be the utilization of agents inhibiting multiple kinase targets (sorafenib, sunitinib) and MoAbs against these targets (bevacizumab, cetuximab, panitumumab).

It will become important to identify biomarkers to help predict the success of targeted agents and aid selection of patients most likely to respond to these therapies. For example, overactive Bcr-Abl tyrosine kinase is critical to the pathogenesis of CML.[223] c-Kit mutations are pivotal in GIST, and evaluation of the c-Kit gene may have prognostic and therapeutic significance.[140]
