# Lung Cancer Vaccines

Anecdotal observations of spontaneous regression of tumors in patients with cancer provided the initial evidence of the presence of an inborn antitumor immune response. Additionally, the observation of paraneoplastic autoimmunity that can accompany occult malignancies indicates the existence of immunologic activity. Historically, the first reports of therapeutic immune induced tumor regression came over a century ago when William Coley treated cancer patients by nonspecifically activating the immune system with inoculations of live bacterial cultures. However, little progress was made until the 1980s, when Rosenberg et al.[1] studied the use of high doses of interleukin 2 (IL-2) in individuals with metastatic kidney cancer or melanoma and achieved objective cancer regressions in 15% to 20% of treated patients.

Classic prophylactic vaccines that have had great success in the prevention of infectious diseases have relied mainly on generation of high titers of neutralizing antibodies. This chapter discusses therapeutic vaccines that elicit an active specific immune response. These vaccines aim at inducing strong antigen-specific T-cell responses. The requirements for therapeutic vaccine development are different and far more complex than those of prophylactic vaccines. The first important issue in vaccine design is that of antigen delivery. Therapeutic vaccines are divided into subunit vaccines or cell-based vaccines (Table 51.1). The subunit vaccine approach is based on the selection of well-defined antigens as targets. The term *subunit vaccine* may include a gene or gene product, representing part of or an entire polypeptide fragment carrying an antigen recognized by T cells. These include plasmid DNA, messenger RNA, peptides, recombinant proteins, or bacterial/viral vectors carrying gene inserts coding for tumor antigens. Cellular vaccines rely on the approach of using whole tumor cells for vaccination. Either irradiated tumor cells or lysates have been used. Tumor cells may be modified by gene transfer to express cytokines that may enhance their overall immunogenicity.

The focus of most lung cancer vaccines has been the generation of a T-cell response against antigens expressed by tumors. Cancer vaccination is based on the premise that an effective antitumor response can be elicited by the induction of major histocompatibility complex (MHC) class I-restricted cytotoxic T lymphocytes (CTLs), capable of recognizing and lysing tumor cells. Gene-modified tumor vaccines (GMTV) and dendritic cell vaccines (DCV), the two main classes of cellular vaccines investigated in lung cancer, utilize this approach.

GMTV use gene transfer technology to transduce tumor cells with genes encoding cytokines or other immunogenic proteins. DCV utilize antigen modification of autologous dendritic cells (DCs) to elicit a specific T-cell activation against cancer cells. Experimental studies of xenografted animals demonstrated that these vaccines considerably increased the immunogenicity of tumor cells, which, in many cases, induced tumor rejection and regression.[1a,2–4] Several GMTV platforms have been evaluated for cytokine and gene delivery. These include autologous tumor vaccines, allogeneic tumor vaccines, and bystander vaccines. Autologous tumor cell vaccines involve surgically harvested tumor cells that are genetically modified to increase immune recognition. More commonly, allogeneic vaccines are made up of tumor cell lines that express tumor-associated antigens (TAAs) and are genetically modified to express immunogenic cytokines and proteins. A bystander vaccine is a hybridization of both aforementioned approaches. It utilizes autologous tumor cell antigens, "bystander" cells, in combination with cytokine-secreting allogeneic tumor cells to recruit and activate immune effector cells.

The role of DCs in cell-mediated immunity has been extensively investigated.[1a,5–8] DCs have been found to play a central role in the induction of antitumor immunity in tumor-bearing host by a process of antigenic cross-presentation and have displayed activity in non–small cell lung cancer (NSCLC)[2] They efficiently display antigens on major histocompatibility complexes (MHC II) ultimately stimulating proliferation and activation of CD4+ and CD8+ T cells. CD4+ cells further augment the activity of natural killer (NK) cells and macrophages, in addition to amplifying antigen-specific immunity by local secretion of cytokines.[3,4,9–11] These attributes make DCs a central component in therapeutic strategies of many current immune-based therapies in NSCLC.

| TABLE 51.1 | Approaches to Lung Cancer Vaccines and Immunotherapy | |
| --- | --- | --- |
| **Design** | **Characteristics** | **Examples** |
| Intent | Prophylactic | Nicotine, HPV |
| | Therapeutic | Antigen vaccine |
| Immune response | Nonspecific | BCG |
| | Specific | Dendritic cell |
| Immunity | Passive antibody | Cetuximab |
| | Active | Antigen vaccine |
| Active component | Noncellular | Tumor peptide |
| | Cellular | CTL, dendritic |
| Material | Tumor peptide | MUC-1, MAGE-3 |
| | Cancer cells | GVAX, Lucanix |

BCG, Bacillus Calmette-Guérin; CTL, cytotoxic T lymphocyte; HPV, human papillomavirus; MAGE, melanoma antigen E; MUC, mucin.

Despite progress made in understanding the molecular biology behind carcinogenesis and advancements in our technical proficiency, clinical application of immune-based cancer vaccines have yielded modest results. There are several hypotheses to explain potential lack of activity, including ineffective priming of tumor-specific T cells, lack of high avidity of primed tumor-specific T cells, and physical or functional disabling of primed tumor-specific T cells by the primary host and or tumor-related mechanism. For example, in NSCLC, a high proportion of the tumor-infiltrating lymphocytes are immunosuppressive T-regulatory cells (CD4+ CD25+) that secrete transforming growth factor $\beta$ (TFG-$\beta$) and express a high level of CTL antigen-4.[12,13] These cells have been shown to impede immune activation by facilitating T-cell tolerance to TAAs rather than cross-priming CD8+ T cells, resulting in the nonproliferation of killer T cells that recognize the tumor and will not attack it.[12–18] Elevated levels of IL-10 and TFG-$\beta$ are found in patients with NSCLC. Animal models have shown immune suppression is mediated by these cytokines serving as a defense for malignant cells against the body's immune system.[19–28]

As our understanding of the pathogenesis of cancer steadily evolves, researchers are continuously developing novel therapies designed to overcome each new challenge. This chapter will discuss recent vaccine therapeutic strategies in lung cancer, focusing on clinical trials that have contributed to our overall understanding of the immune system and its utilization in the treatment of lung cancer.

## NON–SMALL CELL LUNG CANCER CELLULAR VACCINES

**Lucanix** Lucanix is a nonviral gene-based allogeneic vaccine that incorporates the TFG-$\beta$2 antisense gene into a cocktail of four different NSCLC cell lines.[29] Elevated levels of TFG-$\beta$2 are linked to immunosupression in cancer patients.[30–35] Systemic levels of TFG-$\beta$ are inversely correlated with prognosis in patients with NSCLC.[36] TFG-$\beta$2 has an antagonistic effect on NK cells, lymphokine-activated killer cells, and DCs.[21,25,26,37–39] Using an antisense gene to inhibit TFG-$\beta$2, several researchers have demonstrated an inhibition of cellular TFG-$\beta$2 expression resulting in an increased immunogenicity of gene-modified cancer cells.[40–48]

In a recent phase II study involving 75 early stage (n = 4) and late stage (n = 61) patients, a dose-related effect of Lucanix was defined. Twenty-nine patients were randomized to one of the three-dose cohorts ($1.25 \times 10^7$, $2.5 \times 10^7$, or $5 \times 10^7$ cells/injection $\times$ 16 injections). Injections were administered one time each month or every other month until progressive disease criteria were fulfilled. Treatment was well tolerated with only one grade 3 toxic event attributed to the vaccine (arm swelling). A significant survival advantage at dose levels $\geq 2.5 \times 10^7$ cells/injection compared with the low dose level of $1.25 \times 10^7$ cells/injection was demonstrated with an estimated 2-year survival of 47% (Tables 51.2 and 51.3). This also compared favorably with the historical 2-year survival rate of <20% of comparable stage IIIB or IV NSCLC patients.[49–54] Furthermore, a correlation of positive outcome with induction of immune enhancement of tumor antigen recognition was observed. Immune function was explored in the 61 advanced stage IIIB or IV patients. Patients who achieved stable disease or better had increased frequency in the production of cytokines (interferon-$\gamma$ [INF-$\gamma$], $p$ = 0.006; IL-6, $p$ = 0.004; IL-4, $p$ = 0.007) and positive clinical outcomes were correlated with development of human leukocyte antigen (HLA)-antibody response to the vaccine. A total of 11 out of 20 patients with stable disease or better-developed novel HLA-antibody reactivity to one or more allotypes of the vaccinating cell lines compared with 2 of 16 progressive disease patients ($p$ = 0.014). It was concluded that further phase III investigation of Lucanix is justified and warranted.

**GVAX Lung** Given the histological heterogeneity of NSCLC and the relative absence of information on the relevant immunodominant antigens in this disease, in initial trials, autologous tumor cells were selected as the source of tumor antigens in NSCLC.[55] The first pilot study of autologous GVAX Lung was conducted by Glenn Dranoff at the Dana-Faber Cancer Institute using a first-generation adenoviral vector and recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF).[56] A total of 35 patients underwent tumor harvest and 33 patients received vaccine treatment at three different dose levels. The vaccine was administered weekly for 2 weeks then biweekly until the supply was exhausted. Vaccines were well tolerated with the most common toxicity being local, self-limited vaccine site reactions and mild flulike symptoms in a minority of patients. Antitumor immunity was demonstrated by induction of delayed-type hypersensitivity (DTH) reaction to injections of irradiated, genetically unmodified autologous tumor cells in 82% of patients as well as the presence of inflammatory infiltrates in metastatic tumor biopsies. In addition, one patient demonstrated evidence of tumor regression (mixed response) and two others have remained recurrence

**TABLE 51.2** **Demographics for Recent Vaccine Trials in NSCLC**

| Vaccine | Vaccine Administration | Number of Patients | Stage | Reference |
|---|---|---|---|---|
| Lucanix | $1.25 \times 107 - 5 \times 107$ c/i q m or qo m $\times$ 16 | 75 | II–IV | 29 |
| GVAX Ad autologous | $1 \times 106 - 10 \times 106$ c/i q wk $\times$ 3 then qo wk | 35 | IV | 56 |
| GVAX Ad autologous | $5 \times 106 - 10 \times 107$ c/i qo wk $\times$ 6 | 43 | IB/II/IIIB/IV | 57 |
| GVAX bystander | $5 \times 106 - 80 \times 106$ autologus cells + $2.5 \times 106 - 40 \times$ 106 allogeneic GM-CSF secreting cells qo wk $\times$ 3–12 | 49 | IIIB/IV | 58 |
| L523S | pVAX/L523S 8 mg day 0 and 14 then Ad/L523S at 1, 20, and $400 \times 109$ vp/i on day 28 and 56 | 13 | IB/II | 61 |
| L-BLP-25 | 20 or 200 $\mu$g sc wk 0, 9, 5, 9 | 17 | IIIB/IV | 77 |
| L-BLP-25 | 1000 mg q wk $\times$ 8 then q 6 wk | 88 | IIIB | 78 |
| EP2101 | 5 mg q 3 wk $\times$ 5 then qo m $\times$ 4 then q 3 m $\times$ 4. | 135 | IIIB/IV | |

free for more than 5 years following resection of isolated metastatic sites for vaccine preparation.

The subsequent study was a multicenter phase I/II trial investigating again an autologous NSCLC tissue vaccine. Manufacturing processes were modified in this trial to enable more rapid commercial development. This study also involved both patients with early and advanced stage disease.[57] Patients were enrolled in two cohorts. Cohort A included patients with stage IB or II NSCLC with planned primary surgical resection and no preoperative or postoperative chemotherapy or radiotherapy. Patients in cohort B had surgically nonresectable stage III or IV NSCLC with an accessible tumor to harvest for vaccine processing.

Vaccines were administered subcutaneously every 2 weeks for a total of three to six vaccinations. The vaccine dose was individualized on the basis of yield, and each dose contained $5 \times 10^6$ to $10 \times 10^6$ cells per vaccination, $10 \times 10^6$ to $30 \times 10^6$ cells per vaccination, and $30 \times 10^6$ to $100 \times 10^6$ cells per vaccination (Tables 51.2 and 51.3).

A total of 83 patients underwent tumor harvest (20 in cohort A, 63 in cohort B) and 43 initiated vaccine treatment (10 in cohort A, 33 in cohort B). All 10 patients in cohort A completed vaccine treatment. The median number of vaccines

in cohort B was five. The median number of days from tumor harvest to vaccine release was 31 and that from harvest to initiation of vaccine treatment was 49 days. Vaccines were successfully manufactured in 80% of patients in cohort A and 81% of patients in cohort B. The majority of manufacturing failures resulted from an insufficient number of tumor cells.

The most common vaccine-related adverse events were local vaccine injection site reactions (93%); followed by fatigue (16%), nausea (12%), and pain; arthralgia, and upper respiratory infection (each at 5%). Two grade 4 (pericardial effusion) and six grade 3 (dyspnea, fatigue, injection site reaction, hypokalemia, malignant ascites, and pulmonary embolism) possibly related events were reported. There was no association between vaccine dose and the total number of adverse events or grade 3 and 4 adverse events.

Vaccine reaction size (skin induration) was positively associated with level GM-CSF secretion from the transfected autologous malignant cells used as the product. Analysis of vaccine site biopsy specimen showed dense infiltration with CD4+ and CD8+ T cells, CD1a+ DCs, and eosinophils.

Three patients in cohort B achieved durable, complete tumor regressions lasting 6, 18, and 22 months. In addition, there was one minor response (30% decrease in a lung nodule)

**TABLE 51.3**    **Results of Recent Vaccine Trials in NSCLC**

| Vaccine | Side Effects | Median Survival | 1-Year Survival | Response | Reference |
|---|---|---|---|---|---|
| Lucanix | Grade 3: arm swelling (n = 1) | 441 days (IIIB/IV only) | 54% | 6 PR | 29 |

CR, complete response; EGFR, epidermal growth factor receptor; GAR, good antibody response; HA, headache; HTN, hypertension; MAGE, melanoma antigen E; MR, minor response; NA, not applicable; NSCLC, non–small cell lung cancer; PD, progression; PR, partial response; SD, stable disease.

and two mixed responses; seven patients had stable disease with a mean duration of 7.7 months. Correlation of dose to survival was demonstrated to be significant at a threshold of 40 ng of GM-CSF per $10^6$ cells per 24 hours expressed from an aliquot of the vaccine prior to the first injection. Long-term follow-up of two of the patients (stage IV refractory disease to prior cytotoxic therapy) achieving complete response reveals continued disease-free survival now more than 5 years after initial GVAX vaccination (unpublished data).

Salgia et al.[56] also conducted the first phase I trial of GVAX in NSCLC using an autologous vaccine strategy. A total of 37 patients with stage IIB to IV NSCLC were enrolled and 34 vaccines were successfully manufactured at three different dose levels ($1 \times 10^6$, $4 \times 10^6$, $1 \times 10^7$ cells). The vaccines were administered weekly for 2 weeks then biweekly until the supply of vaccine was exhausted. Of these patients, 25 received ≥6 vaccinations. Toxicities were limited to grade 1 to 2 erythema and induration at the injection site, as well as fatigue and flulike symptoms (Tables 51.2 and 51.3).

A total of 18 out of 25 patients who received six vaccinations showed significant local reactions. At the vaccination site, these 18 patients showed infiltration of DCs, macrophages,

eosinophils, neutrophils, and lymphocytes. The intensity and frequency of the reaction was related to the dosage administered. Five patients showed stable disease after 33, 19, 12, 10, and 3 months (Tables 51.2 and 51.3). Based on the outcomes of the study, Salgia et al. concluded that GVAX enhances antitumor immunity in some patients with metastatic NSCLC.

In an effort to remove the requirement for genetic transduction of individual tumors and to optimize GM-CSF transgene expression (given that this correlated with improved survival), a second approach was developed called bystander GVAX, which is a vaccine composed of autologous tumor cells mixed with an allogeneic GM-CSF–secreting cell line (K562 cells)[58] and a phase I/II trial of this vaccine in advanced stage NSCLC was conducted. Tumors were harvested from 86 patients, tumor cell processing was successful in 76 patients, and 49 proceeded to vaccination. Serum GM-CSF pharmacokinetics were consistent with secretion of GM-CSF from vaccine cells for ≤4 days, with associated transient leukocytosis confirming the bioactivity of vaccine-secreted GM-CSF. Evidence of vaccine-induced immune activation was demonstrated. However, objective tumor responses were not seen despite a 25-fold higher GM-CSF secretion concentration with the bystander GVAX vaccine (Tables 51.2 and 51.3). The frequency of vaccine site reactions, tumor response, time to progression, and survival were all less favorable to autologous GVAX, although results were similar to historical cytotoxic therapy for second-line NSCLC.

Overall, these results suggest that autologous malignant tissue transfection with adenovirus-delivered GM-CSF is superior to the bystander approach, despite variability of GM-CSF expression levels and practical limitations inherent to surgically harvested tumor tissue.

**L523S Vaccine**   L523S is a lung cancer antigen originally identified through screening of genes differentially expressed in cancer cells versus normal tissue.[59,60] L523S is shown to be expressed in approximately 80% of NSCLC cell lines.[59,60] In preclinical studies, the immunogenicity of L523S in humans was initially shown by detecting the presence of existent antibody and CD4+ T cell responses to L523S in patients with lung cancer. Subsequent studies further validated L523S's immunogenicity, demonstrating that human CTLs could specifically recognize and kill cells that express L523S. It has demonstrated preclinical safety when the gene is injected intramuscularly as an expressive plasmid (pVAX/L523S) and when delivered by E1B-deleted adenovirus (Ad/L523S).

A phase I clinical trial of 13 stage IB, IIA, and IIB NSCLC patients was conducted using a prime/boost vaccination strategy first with pVAX/ L523S at a dose of 8 mg on days 0 and 14 then Ad/ L523S at three dosing cohorts of 1, 20, and $400 \times 10^9$ viral particles on days 28 and 56 (Tables 51.2 and 51.3).[61] No significant toxic effects related to the vaccination were reported. Although, all but one patient demonstrated at least a twofold increase in antiadenovirus antibodies, only one patient demonstrated a significant immune response to L523S. The reasons for the minimal detection of immune response are unknown, but suggest that alternate formulations and/or regimens need to

be considered in addition to other surrogate immune function parameters. Two patients developed disease recurrence, and all patients were alive after the 290-day follow-up. The significance of the disease-free survival cannot be assessed because of the small sample size, however, one cannot exclude the possibility that the vaccine may induce a T-cell response that is below the threshold of detection in peripheral blood. The results of this trial suggest an excellent safety profile, but limited evidence of L523S-directed immune activation.

**B7.1 Vaccine**   B7.1 (CD80+) is a costimulator molecule associated with induction of a T-cell and NK cell response.[62–65] Tumor cells transfected with B7.1, and HLA molecules have been shown to stimulate an avid immune response by direct antigen presentation and direct activation of T cells, in addition to allowing cross-presentation.[66–68] In a phase I trial, Raez et al.[69] used an allogeneic NSCLC tumor cell line (AD100) transfected with B7.1 and HLA-A1 or A2 to generate CD8+ CTL responses. Patients who were HLA-A1 or -A2 allotype received the corresponding HLA-matched vaccine. A total of 19 patients with stage IIIb or IV NSCLC were treated, and most had received prior chemotherapy. Patients who were neither HLA-A1 nor -A2 received the HLA-A1–transfected vaccine. Each patient received three intradermal vaccinations of $5 \times 10^7$ cells every 2 weeks. If the disease remained stable and toxicity was low, treatment was continued.

A total of 18 patients received at least one full course (three vaccinations) of treatment. One patient was removed before the completion of the first course caused by a serious adverse event not associated with the vaccine. Three more patients experienced serious adverse events, which were also not associated with the vaccine. Side effects associated with the vaccine included minimal skin erythema in four of the patients (Tables 51.2 and 51.3).

All but one patient had a measurable CD8+ response after three vaccinations. There was no statistically significant difference in CD8+ response depending in weather or not the patients were HLA matched. One patient showed a partial response for 13 months, and five patients had stable disease ranging from 1.6 to >52 months.[69,70] Based on the six surviving patients, the tumor vaccine appears to elevate immune response for at least 150 weeks. Overall, the Kaplan-Meier estimate for the median survival of 19 patients was 18 months. One-year survival was estimated at 52% (Tables 51.2 and 51.3). The low toxicity and good survival in this study suggested benefit from clinical vaccination. Further clinical investigation is ongoing.

## NON–SMALL CELL LUNG CANCER SUBUNIT VACCINES

**L-BLP-25 Liposomal Vaccine**   Mucin (MUC) 1 is a high–molecular weight integral membrane protein on the apical surface of MUC-secreting epithelial cells. The extracellular domain of MUC1 contains a heavily glycosylated peptide core composed of a tandemly repeating sequence of 20 amino

acids.[71] It is expressed in many cancers, including NSCLC.[72] Although the MUC1 glycoprotein is expressed on the cell surface of many normal epithelial tissues and carcinomas, it has been selected as a target because of its high levels of over-expression and aberrant glycosylation patterns on carcinoma cells over normal cells, thereby conferring potentially high immunogenicity.[73] Recent studies have identified that MUC1 is associated with cellular transformation, as demonstrated by tumorigenicity,[74] and can confer resistance to genotoxic agents.[75] Both the oligosaccharide portion and the tandem repeat of the MUC extracellular domain have the potential for immunotherapeutic activity.

Clinical testing of an MUC1-directed vaccine called L-BLP-25 (Stimuvax) is ongoing. The L-BLP-25 vaccine consists of a synthetic lipopeptide with a sequence matching a part of the peptide core of the mucinous glycoprotein MUC1, immunoadjuvant, monophosphoryl lipid-A, and three lipids: cholesterol, dimyristoyl phosphatidylglycerol, and dipalmitoylphosphatidylcholine. Upon reconstitution with saline, lipopeptide and monophosphoryl lipid A associate with the lipid bilayer of liposomes. The vaccine is injected into four anatomical sites to stimulate an increased number of lymph nodes to increase the likelihood of an immune response.

Trials of the L-BLP-25 vaccine in stage III and IV NSCLC patients showed the vaccine to be safe but did not demonstrate a statistically significant survival benefit.[76,77] A phase I dose–comparison trial of 20- and 200-$\mu$g vaccine demonstrated that the agent could be administered safely. The relative safety and potential for efficacy found in phase I trials lead to the initiation of a randomized phase IIB study of L-BLP-25 in 171 advanced stage NSCLC patients.[78] Patients with Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 2, stable or responding stage IIIB or IV NSCLC following standard first-line chemotherapy were randomized to either L-BLP-25 plus best supportive care (n = 88) or best supportive care (n = 83). Patients on the L-BLP-25 arm received a single dose of cyclophosphamide 300 mg/m$^2$ intravenously followed by 8 weekly subcutaneous immunizations with 1000 $\mu$g of L-BLP-25 (Tables 51.2 and 51.3). Maintenance immunizations (same dose) were given at 6-week intervals.

The overall survival results indicate a 4.4 month longer median survival for patients on the L-BLP-25 arm (17.4 vs. 13 months); however, this did not reach statistical significance (Tables 51.2 and 51.3). In a retrospective analysis searching for a potential subset of patients with greater therapeutic benefit, a closer look was given to the patients with stage IIIB disease without pleural effusions. With a median follow-up of 53 months, patients on the L-BLP-25 arm had a median survival of 30.6 months compared to 13.3 months for the control group $p = 0.16$ (n = 75). A favorable toxicity profile was evident in all trials of L-BLP-25 with modest erythema at the injection site and mild flulike symptoms.

Although this study failed to demonstrate a statistically significant survival difference between the L-BLP-25 and control arms in advanced NSCLC, the survival trend in stage III disease may be of clinical benefit in this subgroup that have been downstaged by chemotherapy and thoracic irradiation.

A phase III multicenter (North America, Europe, Australia, and Asia) randomized, double-blind, placebo-controlled safety/efficacy study of Stimuvax in unresectable stage III NSCLC patients will evaluate patients who have shown stable disease or an objective clinical response after completing first-line chemoradiotherapy, either sequentially or concurrently. The primary end point is survival with a planned enrollment of 1322 patients and an expected completion date of 2011.

**EP2101** EP2101 is a peptide-based vaccine designed to induce CTLs directed against carcinoembryonic antigen (CEA), p53, human epidermal growth factor receptor 2 (HER-2/neu), and melanoma antigen E (MAGE)-2/3 tumor-associated antigens.[79–87] These are frequently overexpressed in NSCLC. Analogue peptides have been shown to be capable of generating CTLs that are able to recognize wild-type epitopes expressed on tumor cell lines.[88–90] EP2101 has demonstrated immunogenicity in HLA-A2.1/k transgenic mice models.[91–93] It contains 10 lung cancer epitopes (p53, CEA, HER-2/neu, and MAGE), of which 9 out of 10 are restricted by HLA-A2.1. This potentially enables vaccination of approximately 45% of the NSCLC population in the United States.

Two phase I clinical trials examined the safety and immunogenicity of the EP2101 vaccine in patients with stage III colon cancer or stage IIA or IIIB NSCLC who were rendered disease free by standard therapy. A total of 24 patients were enrolled, 16 of whom completed 6 injections over 18 weeks. No significant toxicity was observed, and analysis of CTL response from 15 out of 16 patients who completes treatment with EP2101 indicated that the vaccine was immunogenic and effective at inducing strong and broad CTL responses in a high frequency of patients, as measured by the INF-$\gamma$ enzyme-linked immunosorbent spot assay (presented in IND #10802). A phase II study of EP2101 in 135 patients (64 HLA-A2$^{pos}$ and 71 HLA-A2$^{neg}$) with stage IIIB or IV disease has recently been completed. EP2101 was administered every 3 weeks for the first 15 weeks of the study, then every 2 months through year 1, then quarterly through year 2, for a total of 13 doses. Each injection contained 5 mg (0.5 mg of each peptide) of peptide. The study compared the survival rate of HLA-A2.1 positive patients when treated with EP2101 versus HLA-A2–negative patients who underwent standard treatment. The vaccine was well tolerated, and immune responses were seen in most patients. However, 1-year survival of HLA-A2$^{pos}$ patients (55%) versus HLA-A2$^{neg}$ patients (46%) and the median survival of 583 days (HLA-A2$^{pos}$) and 349 days (HLA-A2$^{neg}$) did not reach statistical significance (Tables 51.2 and 51.3).

**Epidermal Growth Factor Vaccine** Overexpression of epidermal growth factor receptor (EGFR) and its ligand, epidermal growth factor (EGF), has been linked with the promotion of cell proliferation, survival, and mortality. EGF transduces signaling through EGFR following binding to this cell surface receptor, ultimately resulting in cell proliferation. The immunotherapy developed by Ramos et al.[94] induces an immune response against self-produced EGF. This vaccine is a human protein from *Nisseria*

*meningitides*. Several pilot studies have been completed.[94–96] Results from these demonstrated that vaccination with EGF is immunogenic and appears to be well tolerated.

In one trial, 43 patients with stage IIIB or IV NSCLC randomly received either a single or a double dose.[94] The patients were given 4 weekly dose followed by monthly immunizations. Side effects were mild to moderate, including mainly fever (42%), chills (47%), nausea (44%), vomiting (40%), tremors (44%), anorexia (35%), and pain (49%). Slightly higher toxic percentages were seen in the patients who received double dosages of the vaccine (Tables 51.2 and 51.3).

Tumor responses against EGF were measured in 38 out of 43 patients, 15 achieved a good antibody response (GAR) against EGF following vaccination. Kaplan-Meier analysis, separating patients by dose, predicted a median estimated life expectancy of 6.4 months for patients who received the single dose and 8.4 months for the patients who received the double dose (Tables 51.2 and 51.3). Based on immune response, however, patients classified as GARs had an average survival estimated at 12 months, whereas those who had a less favorable GAR had an average survival of 7 months, thereby identifying a potentially responsive treatment population of NSCLC patients.

Two other studies conducted by Gonzalez et al.[95–97] compared the effect of different adjuvants on patients' antibody response. In the first trial, 20 patients with stage IIIB or IV NSCLC were randomly vaccinated with either EGF-p64K absorbed to alum (n = 10) or emulsified in montanide ISA 51 (n = 10). In the second trial, 20 stage IIIB or IV patients were similarly randomized, but all received a single dose of cyclophosphamide 3 days prior to the first vaccination. The vaccine consisted of EGF conjugated to a P64K *N. meningitides* carrier protein. Patients were vaccinated intramuscularly on days 0, 7, 14, 21, and 51. The patients were revaccinated when antibody titers decreased to at least 50% of their peak titer at the induction phase.

No patients experienced severe toxicity. Side effects consisted of grade 2 fever, chills, nausea, vomiting, hypertension, headache, dizziness, flushing, pain at the injection site, bone pain, mouth dryness, and hot flashes (Tables 51.2 and 51.3).

The combined data of the two Gonzalez trials suggested that higher antibody responses were obtained when the vaccine was emulsified in montanide ISA 51 or when low-dose cyclophosphamide was administered before the vaccination; however, because of the small sample size, the difference was not statistically significant. Percentages of GAR were significantly higher when montanide ISA 51 was used as an adjuvant in both trials compared with alum groups. More than 90% of all vaccinated patients were seroconverted and GAR was achieved by approximately 50% of vaccinated patients. Median survival of GAR patients was 9.1 months, whereas poor antibody responding patients had survival of 4.5 months. The median survival of all vaccinated patients was 8.2 months. In addition, patients with ≥60 days response duration showed a significant increase in survival times compared with the corresponding groups with <60 days response duration (Tables 51.2 and 51.3).

These data as well as the recent approval of EGFR inhibitors gefitinib and erlotinib justify further investigation in targeting EGF by vaccination strategy.

## Melanoma-Associated Antigen E-3 Vaccine (MAGE-3)

MAGE-AE is a 361 amino acid protein, which belongs to the category of cancer/testis tumor antigens. In normal tissue, MAGE-3 is expressed only by testicular germ cells; however, it is aberrantly expressed in a wide variety of tumors, including about 35% of NSCLC.[98] Several CD8+ T-cell epitopes of MAGE-3 have been identified in vitro,[88,89,99–105] including HLA-A1-restricted epitope 168 to 176[106] and HLA-A2-restricted epitope 271 to 279.[107] Based on these findings, synthetic peptides corresponding to these epitopes have been introduced into clinical vaccination studies in which they were associated with regression of melanoma in individual cases.[108] Clinical vaccination studies, using full-length recombinant proteins, have the advantage that this antigen potentially includes the full range of epitopes for CD4+ and CD8+ T cells. In addition, it is likely that protein vaccination leads to presentation of epitopes in the context of various HLA alleles and therefore, this type of vaccine should be applicable to any patient regardless of HLA restriction.[109] Atanackovic et al.[109] used a MAGE-3 protein as a vaccine to induce CD4+ T cells in patients with stage I or II NSCLC. All patients had undergone surgical resection of the primary lung tumor and had no evidence of disease at the onset of the study. A total of 9 of 17 total patients received 300 $\mu$g of the MAGE-3 protein alone, and 8 patients received the MAGE-3 protein combined with AS02B (Adjuvant System 2B; GlaxoSmithKline). Patients were given four intradermal injections every 3 weeks.

Of the nine patients who received the MAGE-3 protein alone, three developed an increase in antibodies against MAGE-3 protein and one had a CD8+ T-cell response. By comparison, of the eight patients who received MAGE-3 antigen combined with the adjuvant, seven showed an increase in serum concentrations of anti-MAGE-3 and four had a CD4+ response to HLA-DP4-restricted peptide.

Based on these results, further testing in a larger randomized phase II trial was conducted,[109a] involving 182 stage Ib or II completely resected NSCLC MAGE-A3+ patients (122 vaccine and 60 placebo). Patients received five vaccinations at 3-week intervals. A total of 1609 vaccinations were administered and no serious toxicities were attributed to the vaccine after preliminary analysis (Tables 51.2 and 51.3). After a median follow-up of 28 months, 30.6% had recurrence in the vaccine group versus 43.3% in the control group. The hazard ratio for progression-free survival was 0.73 (95% confidence interval [CI], 0.45 to 1.16; one-sided log-rank $p$ = 0.093). For overall survival, the hazard ratio was 0.66 (95% CI, 0.36 to 1.20; one-sided log-rank $p$ = 0.088).

Phase III investigation is underway with the MAGRIT study (MAGE A3 as Adjuvant Non-small cell lunG canceR ImmunoTherapy). This ambitious project will screen over 10,000 resected NSCLC patients for 2270 patients positive for MAGE-A3 immunohistochemistry. Eligible patients may or may not have

received adjuvant chemotherapy and will be randomized between MAGE-A3 immunotherapeutic versus placebo.

### Transcriptase Catalytic Subunit Antigen Vaccine

It has been established that human T cells recognize telomerase as a TAA.[110–113] Although telomerase is also expressed in some normal tissue, such as bone marrow, and in crypts of the gastrointestinal epithelium,[114] it is highly expressed in most cancer cell lines. GV1001 is a unique peptide corresponding to a sequence of transcriptase catalytic subunit human telomerase reverse transcriptase (hTERT) derived from its active site. It contains the 611–626 sequence of hTERT and is capable of binding to molecules encoded by multiple alleles of all three loci of HLA class II.[115] HR2822 is a second peptide corresponding to sequences 540–548 of hTERT. Brunsvig et al.[116] initiated a phase I/II trial of GV1001 (112 or 560 $\mu$g), HR2822 68 mg, and GM-CSF (30 or 75 $\mu$g). A total of 26 patients with stage III or IV NSCLC were given 4 to 21 intradermal injections of the vaccine. No clinically significant toxicities were attributed to the investigational regimen including gastrointestinal or bone marrow toxicities. Side effects were considered mild consisting mainly of flulike symptoms.

A total of 24 out of 26 patients enrolled were considered evaluable having received a minimum of 4 weeks of treatment. A total of 14 patients completed the study, whereas 10 patients were taken off the study because of disease progression. Eleven patients demonstrated an immune response against GV1001, and two patients demonstrated a response to HR2822. After receiving booster vaccinations, two additional patients converted to immune responders. One patient with stage IIIA NSCLC had a complete response and developed GV1001-specific CTLs that could be cloned from peripheral blood. The median survival time for all 26 patients was 8.5 months (Tables 51.2 and 51.3). This trial demonstrated GV1001 and HR2882 to a lesser extent are immunogenic targets and warrant further investigation.

### Dexosomes

Dexosomes are DC-derived lipid vesicles that express high levels of a narrow spectrum of cell proteins, which have been shown to play a role in the activation of immune response.[117–121] In vitro, dexosomes have the capacity to present antigen to naive CD8+ cytotoxic T cells and CD4+ T cells.[117,122] Purified dexosomes were shown to be effective in both suppressing tumor growth and eradicating an established tumor in murine models.[119] Morse et al.[123] developed a vaccine using DC-derived dexosomes loaded with MAGE tumor antigens. The phase I trial enrolled 13 patients with stage IIIB or IV NSCLC demonstrating MAGE-3A or A4 expression. Autologous DCs were harvested to produce dexosomes. They were peptide pulsed with MAGE-3A, 4A, 10A, and −3DPG4 antigens. Dexosome vaccinations were administered to nine patients at a dose of $1.3 \times 1013$ MHC II class molecules in a volume of 3 mL via subcutaneous and intradermal injection weekly for 4 weeks.

Patients experienced grade 1 and 2 toxicities including injection site reactions, flulike symptoms, edema, and pain. Three patients exhibited DTH reactions against MAGE peptides. Only one had detectable increases in T-cell precursors

frequency to MAGE-A10. Disease progression time ranges from 30 to 429 days and survival was in the range of 52 to 665 days. The study concluded that production of dexosome was feasible. The vaccine is well tolerated and produced long-term stable disease in some patients, and activation of immune effectors could be induced.

### $\alpha$(1,3)-Galactosyltransferase

$\alpha$(1,3)-Galactosyltransferase (agal) epitopes present on the surface of most nonhuman mammalian cells are the primary antigen source inductive of hyperactive xenograft rejection. Agal directs the addition of agal to N-acetyl glucosamine residues in humans. Expression of agal epitopes after gene transfer of agal (using retroviral vector) in human A375 melanoma cells prevented tumor formation in nude mice.[124]

Preliminary results by Morris et al.[125] using three irradiated lung cancer cell lines genetically altered to express xenotransplantation antigens by retroviral transfer of the murine agal gene, were recently described in seven patients with stage IV, recurrent or refractory NSCLC. Intradermal injections were given at doses of $3 \times 10^6$, $10 \times 10^6$, $30 \times 10^6$, or $100 \times 10^6$ cells/vaccine once every 4 weeks spanning a total of four doses. Only four patients received all four vaccinations, two patients received three vaccinations, and one patient received two vaccinations at the abstract was published. Toxicity involved grades 1 and 2 pain at the injection site, local skin reactions, fatigue, and hypertension. Four patients had stable disease for >16 months. Morris et al. concluded that the agal vaccine was feasible and safe. Full analysis is awaiting completion of this trial.

### Dendritic Cell Vaccines

DCs are potent antigen-presenting cells.[1a,2–5] As part of a phase II study, Hirschowitz et al.[2] recently produced a DC vaccine from CD14+ precursors, which were pulsed with apoptotic antibodies from an allogeneic NSCLC cell line that overexpressed HER-2/neu, CEA, WH1, MAGE-2, and survivin. A total of 16 patients with stage IA to IIIB NSCLC were vaccinated. The patients were immunized twice, 1 month apart.

There were 10 patients who experienced skin reaction at the injection site and 4 patients experienced minor fatigue. No patients experienced a serious adverse event. Five patients showed no antigen-independent response and six patients showed an antigen-specific response. The study concluded that the vaccine was safe and demonstrated immunologic activity. Further work is ongoing.

### Cyclophilin B

Cyclophilin-B (CypB) is a ubiquitous protein playing an important role in protein folding[126,127] and is expressed in both normal and cancerous cells. CypB-derived peptides are recognized by HLA-A24 restricted CTLs isolated from lung adenocarcinoma. CypB peptides induce CTLs from leukemic patients, but failed to induce an immune response in cells isolated from patients with epithelial cancer or normal donors. Modification of a single amino acid of the CypB gene increases its immunogenicity and results in CTL activation in both cancer patients and healthy donors.[128]

| TABLE 51.4 | Demographics for Recent Vaccine Trials in SCLC | | | |
|---|---|---|---|---|
| **Vaccine** | **Vaccine Administration** | **Number of Patients** | **Stage** | **Reference** |
| Fucosyl GM1 | 30 $\mu$g sc q wk $\times$ 4 then q4 $\times$ 2 | 13 | 9ES, 4LS | 133 |
| Fucosyl GM1 | 30, 10, or 3 $\mu$g id q wk $\times$ 4 then q4 wk $\times$ 2 | 16 | 6ES, 10LS | 134 |
| BEC2 | 2.5 mg sc qo wk $\times$ 4 then q 4 wk $\times$ 1 | 15 | 8ES, 7LS | 140 |
| PolySA | 30 $\mu$g q wk $\times$ 4 then q4 $\times$ 2 | 13 | 8ES, 5LS | 148 |
| p53 | id qo wk $\times$ 3 | 29 | ES | 155 |

ES, extensive stage; id, intradermal; LS, limited stage; sc, subcutaneous; q, every; qo, every other.

Gohara et al.[129] investigated the immune response in advanced stage lung cancer patients treated with CypB vaccine. 16 HLA-A24+ patients, 15 with NSCLC, and 1 with SCLC, were treated with CypB or modified CypB peptide vaccine following completion of chemotherapy. All patients had stable disease at 5-week follow-up. Following vaccination, IFN-$\gamma$ production by peripheral blood mononuclear cells isolated from patient sera were elevated in 3 of 12 patients. The median time to progression of patients vaccinated with CypB peptide or modified CypB peptide was 25 or 8 weeks, respectively. Overall survival for NSCLC patients receiving CypB or modified CypB vaccine was 67+ and 28+ weeks, respectively. One patient with SCLC was not evaluable for response.

## SMALL CELL LUNG CANCER

**Fucosyl GM-1**    The ganglioside fucosyl-GM1 is a carbohydrate molecule present in most cases of small cell lung cancer (SCLC),[130,131] but absent in normal lung tissue. Immunostaining has demonstrated the presence of fucosyl-GM1 in culture media from SCLC cell lines, in tumor extracts and in serum of mouse xenografts.[132] Fucosyl-GM1 was detected in the serum of 4 of 20 SCLC patients with extensive-stage disease, but was not present in the serum of 12 patients with NSCLC or

in 20 healthy volunteers.[132] The specificity of fucosyl-GM1 to SCLC makes it a potential target for immunotherapy.

Dickler et al.[133] treated 13 patients were with Fuc-GM1 isolated from bovine thyroid tissue; 10 patients completed the study and were evaluable.. All 10 patients demonstrated high titers of immunoglobulin M (IgM) and IgG antibodies to Fuc-GM1, despite recent chemotherapy and radiation. The most common toxicity was local skin reaction, lasting 2 to 5 days. Other adverse effects include transient flulike symptoms, fatigue, diarrhea, and worsening of sensory neuropathy (six patients). Three of six patients who completed the entire course of vaccinations remained relapse free at 18, 24, and 30 months from diagnosis. Krug et al.[134] administered synthetic fucosyl-GM1 following completion of conventional therapy to 17 patients. Patients were randomized to receive vaccine doses of 30, 10, or 5 $\mu$g. Five of six patients at the 30-$\mu$g dose demonstrated increased levels of antifucosyl GM1 IgM. Three of six patients receiving 10-$\mu$g doses showed antifucosyl GM1 IgM production, and none of five patients at the 3-$\mu$g dose level showed elevated IgM levels. The IgM titers for patients receiving 30- or 10-$\mu$g doses were similar to levels reached with patients treated with bovine fucosyl-GM1, whereas IgG levels were lower. Toxicities were minimal and included injection site reaction, mild flulike symptoms, myalgias, and sensory neuropathy (19%) (Tables 51.4 and 51.5).

| TABLE 51.5 | Results of Recent Vaccine Trials in SCLC | | | | |
|---|---|---|---|---|---|
| **Vaccine** | **Side Effects** | **Median Survival** | **1-Year Survival** | **Response** | **Reference** |
| Fucosyl GM1 | Grade 1–3: local skin reaction, flulike symptoms, sensory neuropathy | NA | NA | NA | 133 |
| Fucosyl GM1 | Grade 1–2: local skin reaction, myalgia, sensory neuropathy | 17.5 mo from 1st vaccination | 69% | NA | 134 |
| BEC2 | Grade 1–3: local skin reaction, fever | 20.5 mo from diagnosis | NA | NA | 140 |
| PolySA | Grade 1–4: local skin reaction, peripheral neuropathy | 22 mo from 1st vaccination | 61% | NA | 148 |
| p53 | Grade 2: fatigue, arthralgia | 11.8 mo from 1st vaccination | 11% | 1 PR, 7 SD | 155 |

NA, not available; PR, partial response; SCLC, small cell lung cancer; SD, stable disease.

**BEC2** Ganglioside GD3 is a cell surface glycosphingolipid whose expression in normal tissue is limited to cells of neuroectodermal origin and a subset of T lymphocytes.[135–137] High levels of expression have been demonstrated in SCLC tumors and cell lines.[138] Because GD3 is present at low levels in normal tissues, it is poorly immunogenic. BEC2, an anti-idiotypic IgG2b mouse antibody that is structurally similar to GD3, demonstrates strong immunogenic properties in patients with melanoma.[139]

Grant et al.[140] treated 15 SCLC patients, 8 with extensive-stage disease, and 7 with limited-stage disease, with BEC2 vaccination. Thirteen patients were evaluable for response; all developed IgM antibodies to BEC2, and three developed IgG antibodies. Duration of antibody production was variable, with at least one patient demonstrating measurable antibody production 1 year following treatment. Median survival was 20.5 months from diagnosis, and patients with measurable anti-GD3 antibodies showed the longest relapse-free intervals (Tables 51.4 and 51.5). When compared to SCLC patients treated with conventional therapy alone, the authors found patients treated with BEC2 vaccine to have longer than expected survival time, though not statistically significant. Significant toxicity was minimized to local skin irritation. There was no evidence of toxicity related to normal tissue destruction, despite the fact that GD3 is expressed by some normal tissues.

**PolySA** Polysialic acid (polySA) is found on the surface of Gram-negative bacteria (such as group B meningococcus), embryonic neural crest cells, and some malignancies of neural crest origin.[141,142] The large size and negative charge of this molecule inhibit binding of cell adhesion molecules, and it is this property that is believed to contribute to its role in neural crest cell migration and early metastasis of malignant cells.[143,144] PolySA has been shown to be expressed abundantly by SCLC tissues,[145–147] making it a potentially viable target for SCLC vaccine therapy.

Krug et al.[148] investigated the immunogenicity of polySA vaccination in 11 SCLC patients following conventional therapy. Two forms of polySA were administered to patients. Five patients received vaccination with polySA, and six patients received polySA manipulated by N-propionylation (NP-polySA), which has been shown to boost the IgG response in mice.[149] One of five patients treated with unmodified polySA demonstrated an IgM response. Of the six patients vaccinated with NP-polySA, all produced measurable IgM antibody responses. In five of the six cases, these antibodies cross-reacted with unmodified polySA. Flow cytometry confirmed the presence of IgM antibodies reactive to SCLC cell lines. Despite the demonstrable production of IgM antibodies to polySA, complement-dependent lysis of polySA-positive tumor cells with human complement could not be demonstrated. Common adverse effects were minimal and included injection site reaction and flulike symptoms lasting 2 to 4 days (Tables 51.4 and 51.5). Four patients reported sensory neuropathy.

**p53** The tumor suppressor gene p53 plays a key role in cell cycle regulation and is mutated in 90% of SCLC.[150,151] In normal tissue, the p53 protein is present in low levels because of its brief half-life. Mutant p53 in cancer cells has a prolonged half-life and is therefore present at much higher levels in these tissues. When induced, anti-p53 CTLs attack tumor tissues while sparing normal tissue in preclinical studies.[152–154]

DCs activated by p53-producing adenovirus were administered to 29 patients with extensive-stage SCLC.[155] There were 57.1% of patients who showed significant p53-specific immune responses (Tables 51.4 and 51.5). Although only one patient showed an objective clinical response following vaccination, 61.9% of the 21 patients treated with second-line chemotherapy demonstrated clinical responses, compared to 2% to 5% response in nonvaccinated patients.

**WT1** The Wilms' tumor gene (*WT1*) is responsible for Wilms' tumor, a pediatric renal cancer, and encodes a protein involved in cell proliferation and differentiation, apoptosis, and organ development.[156–158] WT1 is overexpressed in several hematological malignancies as well as various solid tumors, including lung, breast, thyroid, and colorectal cancers.[159,160] WT1-specific CTL lyse WT1 expressing tumor cells in vitro without damaging normal tissues that express WT1 physiologically.[161,162]

Oka et al.[163] treated 26 patients, including 10 lung cancer patients (histological type not specified), with WT1 vaccine following completion of conventional therapy. Three patients showed decreased serum levels of tumor markers (CEA or SLX) following vaccination; one patient also showed a decrease in tumor size radiographically. One patient had stable disease at follow-up; four patients developed progressive disease, and two were unevaluable. Three patients demonstrated increased activity of WT1-specific CTL activity. A correlation ($p = 0.0397$) between immunological and clinical response was observed for all study patients. Toxicities were limited to injection site inflammation. Despite the fact that WT1 is expressed in many normal tests, routine laboratory investigation did not reveal damage to these tissues following vaccine administration.

## CONCLUSION

The poor overall survival of patients with advanced lung cancer, combined with the toxicity associated with many treatment modalities, mandates novel approaches to clinical management of lung cancer. Traditional approaches for management of advanced stage lung cancer have likely reached a plateau with respect to survival and response advantage to singlet, doublet, or triplet cytotoxic therapy combinations. Recent data of combinations of cytotoxic therapies with angiogenesis inhibitors and/or EGFR inhibitors appear encouraging in subsets of patients. Results summarized in this review suggest immune-based therapies may also "soon" provide sufficient validation to be considered as part of the therapeutic armetarium for lung cancer. Both "targeted" peptide and gene-transduced cell-based vaccines demonstrate the ability to activate and direct adaptive immune effecter cells to

recognize and attack cancer. The activity of Lucanix, L-BLP-25, and MAGE-A3 in particular has lead to the conduct of phase III trials and the data generated from these trials will potentially serve to guide direction of these novel therapeutic modalities over the next several years. Yet, more remains to be discovered.

This chapter summarizes the current evidence of the clinical activity of immune-based vaccines in lung cancer. Through enhancement of tumor antigen recognition and immune activation, these vaccines may, one day, provide patients with a highly tolerable therapy to use in combination with traditional approaches. However, this treatment strategy is relatively new and will require continued development to determine its ultimate role in the treatment of lung cancer.

# Targeted Therapies and Radiation in Lung Cancer

The use of targeted drugs—those that attempt to render specific aspects of the cancer cell–signaling pathway ineffective—have moved forward, although slowly, in the management of advanced non–small cell lung cancer (NSCLC). Erlotinib is currently Food and Drug Administration (FDA) approved for chemorefractory NSCLC.[1] Response rates for epidermal growth factor receptor (EGFR) inhibitors are in the range of 9% to 26%,[2,3] and recent reports demonstrate that gefitinib has similar activity to docetaxel for second-line treatment in NSCLC.[4] These agents fall under the category of drugs that disrupt the EGFR-signaling pathway. Bevacizumab, an intravenously administered humanized monoclonal antibody (MAb), competes with vascular endothelial growth factor (VEGF) and is also active alone or with chemotherapy in advanced NSCLC.[5,6] Caution was emphasized when using bevacizumab in patients with central lesions and squamous histology because of increased risk of bleeding. Clinical trials incorporating agents that block VEGF receptor signaling also appear promising when compared to conventional chemotherapeutics.[7] So where are we with locally advanced lung cancer and molecularly selective drugs? Have we successfully integrated novel drugs to enhance radiation cytotoxicity? Have we increased toxicity or the therapeutic ratio?

Approaches for stage IIIA to IIIB disease typically include concurrent chemoradiation, which has been found to be superior to radiation alone or sequential chemotherapy and radiation.[8,9] Recent evidence suggests that we can indeed push the envelope so to speak and safely deliver much higher doses of radiation (in the range of 74 Gy) when we use extremely conformal techniques.[10] When we use conformal intensity-modulated radiation techniques (IMRT) with concurrent chemotherapy, we are reaching median survival rates in the 22-month range.[11–13] The Radiation Therapy Oncology Group (RTOG) is currently conducting a randomized phase III study (RTOG 0617) that will definitively answer the question of dose escalation by comparing 60 to 74 Gy, both arms incorporating concurrent chemotherapy.

Returning back to targeted agents, we have initiated a host of clinical trials combining EGFR inhibitors or antiangiogenic inhibitors with radiation or chemoradiation. The goals are to see if we can improve survival further without damaging the therapeutic ratio with increased overlapping toxicity. This chapter will review the current and recently completed studies utilizing newer generation molecularly targeted drugs with radiation. Our search for improved outcomes will begin with a review of past and recently published preclinical studies that are driving translational efforts with radiation. Finally, we will take an opportunity to discuss promising agents beyond EGFR and VEGF antagonism, which might also be rationally combined with radiation for lung cancer. A complete review of every study is beyond the scope of this chapter. Rather, we hope to provide some concepts to the reader that may enlighten and/or provoke thought in the area of molecularly targeted agents and radiation for lung cancer.

## PRECLINICAL STUDIES WITH MOLECULARLY TARGETED AGENTS AND RADIATION

### EGFR Inhibitors and Radiation
Why combine EGFR inhibitors with radiation in the first place? We have learned over the past decade or so that there are many reasons to explain the beneficial effects of this combination as seen in preclinical studies. These include cell cycle shifts into phases such as early G1, modest increases in apoptosis, and reduced angiogenesis in vivo. Remember also that ionizing radiation is supposed to damage DNA irrevocably, both through indirect production of free radicals and direct photon interaction with various parts of the DNA matrix, including the base pairs. Cancer cells, however, have a remarkable capacity to repair themselves, and we know that radiation can actually induce this process as well. The hope is that, with the proper amounts of radiation in a clinical setting, through carefully fractionated doses, the cancer cells will be unable to repair all of the damage incurred. Thus, after several cell divisions, repair necessary for mitosis will be incapacitated and the cancer cell will die. EGFR inhibitors also interfere with the repair process, as we will discuss later, and

thus contribute to the enhanced radiosensitization seen with combination therapy.

MAbs with competing activity against EGFR activation have been evaluated extensively in various disease sites. To understand progress to date, we need to review briefly early preclinical studies from over a decade ago starting with anti-EGFR MAbs. We had learned that radiocurability of human tumor xenografts in nude mice expressing EGFR was more difficult than in those without EGFR expression.[14] This finding generated a hypothesis that by preventing EGFR activation through prevention of extracellular EGFR dimerization, we might improve radioresponse. Studies performed soon thereafter did find that this was, in fact, the case in tumors expressing EGFR. By combining single or fractionated radiation with concurrent administration of EGFR antibodies, investigators found that they could reduce tumor growth in aerodigestive tract tumors.[15,16] These experiments incorporated cetuximab (C225), a human–mouse chimeric MAb, with selective and competitive binding affinity to the extracellular domain of the human EGFR. Investigators began to derive the mechanisms to explain why EGFR interference worked to enhance radiation effects—these included strategic cell cycle blocks at early G1, reduced DNA repair, and modest increases in apoptosis.[17] In this same model in vivo, angiogenic abrogation was observed as well. In 2003, further evidence confirming the rationale for blocking EGFR with radiation was evidenced by increased radioresistance observed when an EGFR expression vector was cloned into cancer cells. There was a direct correlation with the level of EGFR expression in the stable clones and radioresistance as measured by clonogenic assays by a factor of 1.28 to 1.6. Cetuximab counteracted this effect by both reducing the levels of EGFR and decreasing phosphorylation of EGFR-related AKT and mitogen-activated protein kinases (MAPK).[18]

In NSCLC models, there has been only modest exploration of antibodies against EGFR with radiation. Studies at the University of Colorado included evaluation of the EGFR status on NSCLC lines by flow cytometry—little was done at that time with fluorescence in situ hybridization (FISH) to look at EGFR gene amplification—which we have since learned, may be important in predicting response to these agents.[19–21] Cetuximab monotherapy demonstrated cytostatic effects on some, but not all, NSCLC cell lines with EGFR expression, an effect that appeared to be dose dependent. Cell cycle shifts were noted into the G1 phase, although no effect was seen in cell lines that did not express EGFR. Interestingly, cetuximab actually increased phosphorylated EGFR (pEGFR) in cell lines not stimulated with EGF in cell lines expressing EGFR; however, peak EGF-induced increases in pEGFR were reduced by cetuximab in the cetuximab-sensitive lines. Combination studies in vivo demonstrated cooperative effects between radiation and cetuximab, again only in cell lines sensitive to cetuximab alone, cell lines that did not express EGFR did not demonstrate advantages to combination therapy (Fig. 52.1). Small molecule

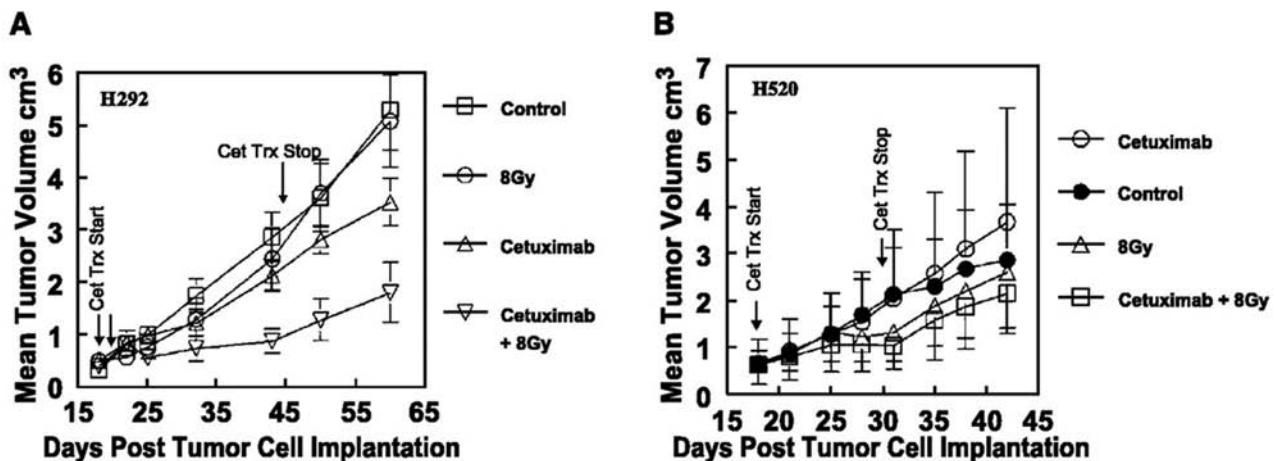

**FIGURE 52.1**    Mouse models bearing human NSCLC xenografts sensitive (H292; **A**) and insensitive (H520; **B**) to EGFR inhibition with cetuximab alone and in combination with single-fraction radiation. Treatment began when tumors had reached approximately 3 cm³. Treatments were cetuximab alone (1 mg/animal twice a week for 2 weeks), ionizing radiation (5 Gy each Monday for 2 weeks), cisplatin (8 mg/kg twice a week for 2 weeks), and combinations of cetuximab plus radiation, cisplatin plus radiation, and cetuximab plus cisplatin plus radiation treatments. Tumor volume ± SE are shown. On day 93, the H292 mean tumor volume was 4.4 cm³ in control animals, 2.2 cm³ in animals treated with irradiation alone ($p = 0.049$), 1.8 cm³ in animals treated with cisplatin plus radiation ($p = 0.024$), 1.5 cm³ in animals treated with cetuximab plus radiation ($p = 0.012$), and 1.2 cm³ in animals treated with cetuximab plus cisplatin and radiation ($p = 0.004$). The combinations produced a significant reduction in tumor volume compared with controls. Although the combination of all three agents produced the greatest reduction in tumor volume, the differences were not significant compared with cetuximab plus radiation ($p = 0.79$) or cisplatin plus radiation ($p = 0.54$). In the H520 xenografts, cetuximab alone and in combination with radiation, cisplatin or the triple combination did not significantly inhibit tumor growth. (From Raben D, Helfrich B, Chan DC, et al. The effects of cetuximab alone and in combination with radiation and/or chemotherapy in lung cancer. *Clin Cancer Res* 2005;11:795–805.)

inhibitors against EGFR-activated tyrosine kinase inhibitors (EGFR TKIs), including gefitinib and erlotinib, have also shown activity in NSCLC and head and neck squamous cell carcinoma (HNSCC) models. Explanations for their activity include competitive binding with adenosine triphosphate (ATP) to the intracellular tyrosine kinase domain of the EGFR, resulting in reduced receptor phosphorylation and activation.[22–24] Downstream interference with various pathways ensues, including the Ras-Raf-MAPK and the PI3K/Akt pathways.

In vitro combinations of radiation and erlotinib have resulted in an additive increase in apoptosis in H226 (NSCLC) cells with evidence of increased poly (adenosine diphosphate[ADP]-ribose) polymerase (PARP) cleavage. Erlotinib appeared to subdue radiation-induced pEGFR activation, which might account for rapid repopulation during radiation therapy. Adding to the story was the downregulation of Rad51, an important component of the DNA repair pathway, when erlotinib was added to H226 cells prior to radiation.[25] Inhibition of Rad51 has been shown to enhance radiosensitization. Further, erlotinib was also found to augment the effects of suboptimal fractionated radiation in animals bearing H226 flank xenografts.

The EGFR mutation story has received considerable attention over the past several years in regard to small molecule EGFR TKIs.[26,27] Specific mutations within the EGFR-binding domain that encode the ATP-binding region, located in exons 18 to 21, have been reported as more prevalent in tumors with adenocarcinoma histology, patients of Asian background, females, and never-smokers.[28] Do these same mutations also predict sensitivity or resistance to radiation in lung cancer? Recent evidence suggests that, indeed, mutant EGFR NSCLC cells have dramatically reduced survival rates measured by clonogenic assay compared with wild-type (WT) EGFR NSCLC cells in vitro.[29,30] The authors point out that the underlying reasons for this increase in radiosensitivity include delayed DNA repair kinetics. It is theorized that this select group of patients presenting with locally advanced NSCLC could be treated simply with induction EGFR inhibition followed by continued inhibition and radiation.

Adding to the molecular selection story for targeted agents and radiation is the role Kras mutations may play in determining the optimal EGFR-dependent or -independent pathway to block. Lung cancer cells with mutated Kras may drive radioresistance in different ways through EGFR-independent activation of anti-apoptotic pathways (PI3K-Akt), thus requiring different targeted agents to effectively enhance radiation cytotoxicity.[31] In this regard, blocking AKT signaling appears to enhance radiosensitivity in Kras mutated NSCLC cells primarily through reduced activation of DNA repair pathways, including interference with DNA double-strand break repair.[32,33] This certainly provides food for thought in regard to how we might design future clinical trials in locally advanced-stage NSCLC patients with Kras mutations—phase I clinical trials utilizing inhibitors of the AKT pathway with chemoradiation in these patients is the first step.

## Angiogenic Inhibitors and Radiation in NSCLC

The use of antiangiogenic agents in advanced NSCLC has been validated and accepted by the oncology community.

The benefits have been observed primarily in combination studies with chemotherapy[34,35] and the gains, although statistically significant, have been modest. As readers may recall, the Eastern Cooperative Oncology Group (ECOG) conducted a randomized phase III study in which 878 patients with recurrent or advanced NSCLC (stage IIIB or IV) were assigned to chemotherapy with paclitaxel and carboplatin alone or with bevacizumab, a humanized antibody against VEGF. This trial was limited only to nonsquamous histologies and patients without brain metastasis caused by bleeding episodes seen in the smaller phase II study. A survival advantage was seen in the bevacizumab arm (12.3 vs. 10.3 months; hazard ratio [HR] for death = 0.79; $p$ = 0.003).[35]

Is this a valid strategy for radiation therapy for unresectable, locally advanced disease or earlier stage disease patients deemed medically inoperable? The concept of interfering with angiogenesis and the potential benefits and pitfalls with radiation has been explored for many years. The reader is directed toward several reviews that summarize nicely the underlying mechanisms and sequencing issues surrounding the use of antiangiogenics to enhance radiation therapy.[36–38]

Preclinical evidence appears promising at first glance. Whereas bevacizumab competitively binds VEGF, small molecules have been developed that attack the VEGF receptor tyrosine kinases (RTKs), thus functioning to inhibit VEGF signaling. The VEGF RTK VEGF receptor 2 (VEGFR2)/fetal liver kinase 1 (Flk-1)/kinase insert domain receptor (KDR) is associated with an important role in regulating VEGF-induced angiogenesis and is expressed within the endothelial cells that nurture growing cancers.[39,40] A variety of these small molecules against VEGFR2 or the family of VEGFR receptors include agents such as ZD6474, PTK787, SU11248, YM-359445, and AZD2171. We will focus on agents that have been combined with radiotherapy in lung cancer.

Vandetanib or ZD6474 is an orally bioavailable agent that has activity against VEGFR as well as EGFR.[41] Frederick et al.[42] has recently summarized some of the pertinent studies in which ZD6474 is combined with radiation. In earlier NSCLC xenograft studies, both sequential and concurrent administration of ZD6474 and fractionated radiation were superior to either ZD6474 or radiotherapy alone, with the sequential strategy demonstrating the longest growth delays.[43] Interestingly, this was seen in the Calu-6 human NSCLC line that displays resistance to EGFR inhibitors and Kras mutations. One of the underlying reasons to block angiogenic signaling is related to the observation that VEGFR2 along with basic fibroblast growth factor (bFGF) expression markedly increase after radiation therapy in orthotopic lung tumors. The ability of ZD6474 to prevent radiation-induced VEGFR2 and EGFR activation and bFGF expression explains, in part, the additive to synergistic responses seen. Shibuya et al.[44] have recently demonstrated impressive tumor growth inhibition with the combination of radiation and ZD6474, with rates of apoptosis greater than combination paclitaxel and radiation. In addition, in an orthotopic model, reduced angiogenesis and pleural
**FIGURE 52.2** Effects of radiation (XRT), ZD6474, and combination ZD6474 plus fractionated radiation on pleural and lymph node metastasis in an orthotopic mouse model bearing human Calu-6 NSCLC tumors. (From Shibuya K, Komaki R, Shintani T, et al. Targeted therapy against VEGFR and EGFR with ZD6474 enhances the therapeutic efficacy of irradiation in an orthotopic model of human non-small-cell lung cancer. *Int J Radiat Oncol Biol Phys* 2007;69:1534–1543.)

effusion were seen with this combination (Fig. 52.2). This particular compound is being further evaluated both alone, and in combination with chemotherapy, in phase II and III clinical trials in lung cancer. Results of these studies are expected in mid-2008.

In small cell lung cancer (SCLC), overall results with ZD6474 were disappointing in a randomized phase II trial where eligible patients with complete response (CR) or partial response (PR) to combination chemotherapy (+/− thoracic or prophylactic cranial radiation) received maintenance oral ZD6474 at 300 mg/day or matched placebo for up to 2 years. Interestingly, however, when patients with limited-stage SCLC were evaluated in a planned subset analysis, a survival benefit was observed (HR = 0.45; $p = 0.07$).[45]

AZD2171 has shown promise when combined with radiation in lung cancer models. Radiation appears to activate Flk-1 signaling. In a recent study by Cao et al.,[46] AZD2171 demonstrated the ability to sensitize human umbilical vein endothelial cells (HUVEC) to radiation and thus favorably interact with it in a human NSCLC xenograft model. From a sequencing standpoint, it was encouraging to see that AZD2171 contributed to significant tumor growth delays in a Calu-6 xenograft model regardless of it being given prior to each radiation dose or after completion of fractionated radiation.[47]

Studies with PTK787, a VEGFR-TKI, suggest that the concept of antiangiogenesis makes sense based on the effects radiation has upon the surrounding vessels associated with tumor growth. Using an aerodigestive cancer model with FaDu squamous cell xenografts, Zips et al.[48] were able to show that, when tumors were implanted into irradiated tissue, growth was much slower than in unirradiated controls because of stromal changes. In addition, PTK787 was markedly more effective in inhibiting tumor growth through increased necrosis. PTK787 was essentially inactive when administered at 50 mg/kg in animals bearing FaDu tumors implanted into unirradiated tissue. This suggests that sequencing VEGFR TKIs may be critical and perhaps more effective when given later during, and possibly even after, a radiotherapy course for lung cancer patients.

Do we have any clinical data in 2008 with oral TKIs against angiogenic signaling? AE-941 is currently the only agent that has been tested in a large phase III trial. Depending on the center, patients were treated with an induction program of carboplatin-paclitaxel or cisplatin-vinorelbine followed by concurrent chemoradiotherapy using the same drugs. Patients were randomized to receive the drug or a placebo. The drug was administered orally twice daily during all the treatment and as maintenance therapy. There were 384 patients who were included in the study and 379 were eligible. AE-941 failed to improve survival: median survival times were 14.4 and 15.6 months for the drug and placebo groups, respectively.[49]

What about the potential deleterious effects of hypoxia caused by antiangiogenic agents? The cytotoxic effects of radiation are typically reduced twofold to threefold in hypoxic conditions compared to normoxic conditions. Studies by Reisterer et al.[50] indicate, in fact, that radiation abrogates the hypoxic effects of VEGFR TKIs such as PTK787. Elegant use of positron emission tomography (PET) imaging in their preclinical work showed that in contrast to PTK787 alone, adding radiation to animals bearing mammary carcinoma xenografts resulted in reduced expression or uptake of the hypoxia markers glucose transporter-1 (GLUT-1), and fluoromisonidazole (FMISO) (nitroimidazole derivative). Recurrent tumors after radiation also appear more sensitive to antiangiogenic therapy, which may again argue for giving these types of drugs at a minimum after definitive radiation. DC-101, an anti-VEGFR murine antibody, when administered to animals bearing recurrent and previously irradiated tumors, was more effective than when applied to animals bearing nonirradiated tumors. This finding is perhaps caused by increased VEGFR2 expression in previously irradiated vasculature leading to an alteration in tumor vasculature, the presence of which may work to the advantage of antiangiogenic agents.[51]

### Combinations of Targeted Agents and Radiation in NSCLC
Classic approaches to treating locally advanced NSCLC involve concurrent chemoradiation. Newer strategies are evaluating combinations of targeted agents and chemoradiation. Perhaps another intriguing approach would be to combine molecularly targeted agents against several pathways

to improve radiation response even further, with an additional opportunity to reduce toxic effects if the combinations prove effective enough to supplant traditional chemotherapy drugs. We have clearly had difficulties with local control in this disease site and have essentially reached our limits of effective radiation dose at ~74 Gy (although this is dependent on the percentage of the total lung volume that receives >20 Gy with the treatment plan (V20) and can potentially be pushed higher with radiation alone when the V20 is <25%.).[52]

There are many redundant signaling pathways that may enable a cancer cell to escape a selected pathway blockade. We have already touched on the use of dual targeted agents to block multiple pathways simultaneously. What about combinations of different molecularly selective drugs? As an example, improved tumor growth inhibition was realized in NSCLC flank xenografts with combinations of fractionated radiation, an EGFR TKI (gefitinib) and a vascular-targeting agent (ZD6126). The results were superior to radiation alone and better than gefitinib + radiation or ZD6126 and radiation.[53]

Providing further support for the rationale to attack multiple molecular pathways is the fact that tumors that become resistant to EGFR inhibitors express angiogenic signaling factors including VEGF and cyclooxygenase-2 (COX-2).[54] Dual inhibition of COX-2 and EGFR in NSCLC lines were, for the most part, additive or synergistic and triple combination therapy was favorable with blockage of G2 checkpoint controls.[55]

## Clinical Trials with Targeted Agents and Radiation in NSCLC

Success was realized in a phase III randomized trial in locally advanced head and neck cancer when cetuximab was combined with radiation therapy with superior outcomes in local control, disease-free survival and overall survival over radiation alone.[56] Have we made any progress clinically in NSCLC with biologic agents and radiation? Three trials have evaluated cetuximab (C225) with either concurrent radiotherapy or concurrent chemoradiotherapy for patients with locally advanced NSCLC. In an RTOG phase II trial (RTOG 0324), including 93 patients (87 evaluable), C225 was given on day 1 at the dosage of 400 mg/m$^2$ and after weekly at a reduced dosage of 250 mg/m$^2$ for the next 17 weeks. Chemotherapy included carboplatin and paclitaxel for four cycles (during and after radiotherapy to a dose of 63 Gy). With a 21.6 median follow-up at the time of this report at American Society of Clinical Oncology (ASCO) 2008, the median survival reached 22.7 months. The reported response rate was 62% (n = 54), and the overall survival at 2 years was 49.3%. The authors reported 20% (n = 17) of patients experienced grade 4 hematologic toxicities, 8% (n = 7) grade 3 esophagitis, and 7% (n = 6) grade 3 to 4 pneumonitis. There were 5 G 5 events as well.[57] A subset analysis has since correlated the expression of EGFR with the outcome and the pattern of failure finding that tumors with a lower EGFR level had less primary failures but more metastases; the reverse of which was seen for tumors with higher EGFR.[58] Plans are underway in the RTOG to study this in a phase III fashion.

In the Cancer and Leukemia Group B (CALGB), a randomized phase II study of thoracic radiation (70 Gy) with concurrent intravenous carboplatin (area under the curve [AUC] = 5) and pemetrexed 500 mg/m$^2$ on day 1 was administered for four cycles (every 21 days; arm A) with or without cetuximab with a loading dose of 400 mg/m$^2$ followed a week later by 250 mg/m$^2$ weekly for additional 6 weeks (arm B). All patients went onto receive consolidation pemetrexed (500 mg/m$^2$ every 21 days for 4 cycles).[59] Early toxicity data was presented at ASCO 2008. A total of 106 patients were enrolled and preliminary grade 3 or greater toxicity data included neutropenia (36% in arm A; 37% in arm B); febrile neutropenia (5% in arm A; 7% in arm B); and thrombocytopenia (30% in arm A; 34% in arm B). Esophagitis was higher in arm A without cetuximab (35% vs. 22% in arm B) and as expected, skin rash was significantly higher in arm B (23% vs. 3% in arm A). One patient reportedly died of fatal hemoptysis. In two other already reported trials, cetuximab was given concurrently with radiation at a dosage of 250 mg/m$^2$ weekly; reported toxicity concerns included mainly fatigue and skin rash.[60,61] One of these, (the Synchronous Cetuximab Radiation Therapy and Chemotherapy [SCRATCH] study) incorporated induction chemotherapy followed by cetuximab and radiation, whereas the other incorporated IMRT with cetuximab and chemotherapy (Non-small cell lung cancer, Erbitux And Radiotherapy [NEAR] trial-NCT00115518). It appears in 2008 that combinations of cetuximab and radiation or chemoradiation appear tolerable without increases in expected toxicity over and above that with chemoradiation approaches.

Can we predict response to cetuximab in NSCLC to select patients most appropriate for this type of therapy? Recently, Hirsch et al.[62] confirmed for the first time that EGFR FISH was predictive of outcomes in patients with advanced, stage IV NSCLC treated with concurrent or sequential chemotherapy and cetuximab in a randomized phase II selection trial through the Southwest Oncology Group (SWOG 0342). Patients with FISH-positive tumors had a superior median progression-free survival time of 6 months compared with 3 months for FISH-negative patients ($p$ = 0.0008). Remarkably, patients in the FISH-positive group experienced a median survival time more than double (15 months) that of the patients who were FISH negative (7 months; $p$ = 0.04). It remains to be seen if EGFR FISH will be important in determining response to radiation and cetuximab in patients with locally advanced disease.

Data with small molecule EGFR TKIs such as gefitinib are primarily derived from two phase I trials, which combined a taxane-based chemotherapy approach with concurrent radiotherapy. Those trials were designed to escalate the dose of the cytotoxic agents, whereas gefinitib was given orally at a dosage of 250 mg/m$^2$ daily.[63,64] In one study, paclitaxel could be increased to 45 mg/m$^2$ weekly (carboplatin was given at an AUC of 2) with fixed-dose gefitinib at 250 mg daily. In the other, docetaxel was increased to 25 mg/m$^2$ with radiation and gefitinib and then followed by consolidative docetaxel and gefitinib. One patient experienced a grade V interstitial pneumonia, believed to be related to the gefitinib.[63] The recently reported results of SWOG 0023, a randomized phase III of maintenance gefitinib or placebo after concurrent chemoradiation followed by docetaxel consolidation gives one
**FIGURE 52.3** Overall survival results for patients with stage III NSCLC randomized to receive maintenance gefitinib or placebo after concurrent cisplatin-etoposide and radiation (61 Gy) followed by three cycles of docetaxel. Patients treated with gefitinib had a median overall survival of 23 months compared to 35 months for patients treated with placebo (Borrowed with permission from Kelly K, Chansky K, Gaspar LE, et al. Phase III trial of maintenance gefitinib or placebo after concurrent chemoradiotherapy and docetaxel consolidation in inoperable stage III non-small-cell lung cancer: SWOG S0023. *J Clin Oncol* 2008;26:2450–2456.)

room for pause and caution (Fig. 52.3).[65] Maintenance gefitinib did not improve overall survival and in fact, with a median follow-up time of 27 months, median overall survival time was 23 months for gefitinib (n = 118) and 35 months for placebo (n = 125; two-sided *p* = .013). The authors concluded that deaths were primarily related to disease progression and not toxicity from gefitinib (2% toxic death rate). The results were somewhat perplexing, and perhaps smoking history, a predictor of response to EGFR TKIs and a factor, which was not captured in SWOG 0023, might have contributed to survival differences. The authors added that additional factors not initially captured, which might also have impacted on the inferior overall survival results, include K-ras mutations and additional therapies offered to patients after progression. It is worth mentioning that survival times in both arms were superior when compared to other published randomized phase III NSCLC clinical trials.

In a study by Choong et al.,[66] erlotinib was given daily with weekly carboplatin and paclitaxel or with cisplatin and etoposide, using the classical SWOG schedule with radiation delivered conventionally. In both instances, a dose escalation was possible from 50 to 150 mg with only minor toxicities reported (primarily skin). The group at the University of North Carolina at Chapel Hill has tested the association of erlotinib (150 mg/m$^2$ twice weekly) and bevacizumab (10 mg/m$^2$ every 2 weeks) induction together with carboplatin and paclitaxel × two cycles followed by carboplatin and paclitaxel given weekly during radiation with bevacizumab initially and later with erlotinib and bevacizumab. Both squamous and nonsquamous histologies were allowed with early stopping rules incorporated for safety. In 20 patients enrolled in the phase I portion of the trial, there was one grade 3 pulmonary hemorrhage

requiring stoppage of bevacizumab. In addition, the authors reported one grade 3 interstitial pneumonitis. A majority were able to receive the 74 planned dose. Esophagitis was most prevalent radiation induced complication with 5/15 with esophagitis (33%) having grade 3 toxicity. One grade 5 late hemorrhage occurred in a patient presenting with squamous histology. The trial is currently accruing in the phase II portion with 100 mg of erlotinib as the maximum tolerated dose (MTD). Evolving and current cooperative group trials are now including esophageal volume dose constraints in IMRT planning to reduce upper gastrointestinal toxicity further.[67]

Is there any information on alternative approaches to targeting specific pathways? Of interest has been the use of COX-2 inhibitors such as celecoxib to improve radiotherapy outcomes. A phase I trial has defined the safe dose of celecoxib given concurrently with radiation. In this cohort of 47 patients, the dose was escalated from 200 to 800 mg/day given in two equally divided doses without reaching the MTD.[68] The toxicity reported included a case of uncontrolled hypertension and two patients with hemorrhagic episodes. Soon thereafter, De Ruysscher et al.[69] tried to launch a randomized phase II trial, but it was terminated after the enrollment of only 41 patients because of poor recruitment and apparent toxicity problems with the drug.

## CONCLUSION

We have pushed the envelope with concurrent chemoradiation and have probably reached a plateau in regard to further benefits in survival with classic approaches, even with state-of-the-art radiation techniques. Our intent with this chapter was to introduce the reader to some of the promising preclinical and clinical studies that suggest potential benefits of using agents that selectively interfere with tumor growth and angiogenic signaling. The current available data suggest that many of those targeted agents may be safely used with concurrent radiotherapy or chemoradiotherapy. We are at the first of many crossroads now in the development of these strategies and need to wait for the results of ongoing phase III trials to see if there may be some benefit demonstrated. In the interim, preclinical studies are pointing us toward newer directions beyond just EGFR targeting. It is safe to say that personalized cancer care is the next step with treatment decisions made based primarily on a patient's individual tumor molecular characteristics or gene abnormalities such as mutant Kras, Akt, EGFR FISH, and ligand expression, DNA repair expression, angiogenic-related signaling molecules such as VEGFR and insulin-like growth factor receptor expression to name a few.

# Adjuvant and Neoadjuvant Approaches for Non–Small Cell Lung Cancer

Giorgio V. Scagliotti
Everett E. Vokes

# Adjuvant Chemotherapy in Completely Resected Non–Small Cell Lung Cancer

Ninety percent of lung cancers are related to tobacco smoking, and the primary prevention of lung cancer by smoking cessation remains the primary goal of any physician involved in the field of diagnosis and treatment of lung cancer. However, given the rising trend in worldwide tobacco consumption and the fact that former smokers still have higher lung cancer risk than nonsmokers (in the United States, more than 50% of lung cancers occur in former smokers),[1] lung cancer will continue to globally represent a huge social health problem for a long period of time.

Lung cancer is the most common fatal malignancy among men and women in most countries throughout the world.[2,3] Non–small cell lung cancer (NSCLC) represents more than 80% of all newly diagnosed cases of lung cancer. The reference treatment for early stage disease (from stage IA to IIB) is surgery; specific groups of patients with stage III disease may also benefit from pulmonary resection, usually in combination with other treatment modalities. Globally, the proportion of newly diagnosed NSCLC that can benefit from radical resection does not exceed 25% to 30% of the total number of cases.

The use of a systemic therapy in completely resected NSCLC is reasonably justified by follow-up studies after radical resection that have shown the predominance of distant failures over local recurrences and on some clinical and pathologic evidence of early microdissemination of the disease at the time of surgery.

Long-term survival in NSCLC following surgical resection is stage related, but even in stage IA, one third of patients will relapse and die of their disease within 5 years.[4] Most of these relapses are distant metastases, whereas the risk of a local recurrence after complete resection is less than 10%. The central nervous system is the most common site of metastatic recurrence followed closely by bone, ipsilateral and contralateral lung, liver, and adrenals. More than 80% of recurrences occur within 2 years from the time of radical surgery.

The rate of recurrence for patients with stage II disease is higher than in stage I; more than 50% of resected stage II can be expected to relapse and, again, most recurrences are distant.

The pattern of recurrence may differ by histology with more local recurrences seen for patients with squamous cell carcinoma and more distant metastases seen in patients with adenocarcinoma (Table 53.1).[5–8]

Positron emission tomography (PET) has been progressively implemented in the diagnostic workup for resectable NSCLC. Current experience indicates that metastatic disease will be found in 11% to 14% of the cases otherwise cleared for resection by conventional screening methods. In addition to distant metastases, almost all of these studies have demonstrated an increase in the rate of detection of unsuspected mediastinal and hilar nodal disease [9–11] (see Chapter 27).

Dissemination of cancer cells at much lower levels than those detected by any currently available imaging techniques, including PET scanning, seem to affect the prognosis of patients with clinical early stage NSCLC. Immunohistochemical and real-time polymerase chain reaction estimation of lymph node micrometastatic disease has been investigated in small retrospective studies evaluating the positivity for cytokeratins and carcinoembryonic antigen. Overall, the detection of positive findings in otherwise morphologically normal lymph nodes was almost invariably associated with an adverse outcome when compared with that of patients without occult micrometastatic disease.[12–15]

Quantification of free circulating DNA has also been proposed as a potential additional diagnostic tool for resected patients to detect persisting neoplastic disease.[16]

Although these studies are highly suggestive, additional confirmatory data are urgently needed to confirm the scientific hypothesis.

In addition to primary lung cancer prevention through smoking cessation campaigns, the detection of early stage disease through screening procedures represents the ultimate goal to defeat lung cancer. Unfortunately, this strategy remains investigational at this time and has not yet been proven to improve survival. Chest x-rays, analysis of cells contained in the sputum, and standard fiberbronchoscopy have shown limited effectiveness in early lung cancer detection. Newer tests

such as low-radiation, high-resolution helical computed tomography (CT) scan and molecular markers in sputum have been demonstrated to lead to earlier detection of lung cancers. However, their ability to increase survival rates of affected patients has not yet been fully accepted. Nonrandomized studies of high-resolution helical CT scan indicate an increase in the rate of detection of small resectable lung cancers, usually adenocarcinomas, and thus the frequency of lung surgery (see Chapters 15 and 16). However, as previously shown for chest x-ray screening, there may be neither a meaningful reduction in the number of advanced cancers being diagnosed nor a reduction in the number of individuals who die of lung cancer.[17] This is because of the fact that CT screening can detect small nodules that may not be malignant or represent a group of slow-growing cancers that would not interfere with a patient's life expectancy if they remained unnoticed.

Molecular markers are needed to identify tiny malignant nodules, which may be present among many nodules, often benign, that can be visualized by helical CT. Biomarkers are also needed for central lesions that cannot be identified by CT techniques, to indicate which patients should have bronchoscopic explorations to identify tiny intraepithelial central lesions. Automated, reliable, high-throughput sputum biomarker tests will ultimately replace cytomorphological techniques.

**The Rationale for Adjuvant Treatments**    Following complete resection, tumor load, if any, is theoretically minimal. The relatively small number of residual neoplastic cells present in micrometastatic disease should contain few chemotherapy- or radiation-resistant clones. The Gompertzian model of tumor growth and regression fits experimental and clinical data of most human solid cancers. If the assumption is correct,

when the tumor is clinically undetectable, its growth rate should be at its largest and, although the numerical reduction induced by cytotoxic chemotherapy is small, the fractional cell kill from an effective dose of chemotherapy should be higher. In addition, pathological staging allows better prediction of prognosis and facilitates the comparison of treatment results between different trials.

How should the more appropriate treatment to be used in the adjuvant setting be selected? Realistically, no definitive rules have been established but, at least, the chosen treatment (or regimen) should be proven active in advanced disease, associated with good tolerability[18]; in the case of cytotoxic chemotherapy, it should be platinum based, initiated sufficiently early after radical surgery and administered for not less than three to four cycles.[19]

**The Role of Adjuvant Radiotherapy**    For a long period of time, postoperative thoracic radiation therapy was the preferred adjuvant treatment. Results regarding its potential role have been reported from a large number of retrospective and prospective studies. Nine of these studies, collecting individual data from 2128 patients have been included in the Postoperative Radiation Therapy (PORT) metaanalysis and indicated postoperative radiotherapy as a treatment with significant detrimental effect on survival, especially in stages I and II.[20] These results have been further confirmed by a Cochrane systematic review and metaanalysis originally published in 2000 and substantially updated in 2004.[21] The results of this recent update indicate a significant adverse effect of PORT on survival with a hazard ratio (HR) of 1.18 or 18% relative increase in the risk of death. This is equivalent to an absolute detriment of 6% at 2 years

(95% CI, 2% to 9%) reducing overall survival from 58% to 52%. Exploratory subgroup analyses suggest that this detrimental effect was most pronounced for patients with stage I/II, whereas for patients with stage III, N2, there was no clear evidence of an adverse effect.

Most of the studies included in these two metaanalyses incorporated patients treated with older technology (cobalt-60) and different dosimetry, and these outdated parameters may be partially responsible for the higher mortality rate observed in the radiotherapy group and attributed to an excess of intercurrent deaths. The use of newer technologies and improved dosimetry may prove to be effective as more recently suggested in a retrospective review.[22] In addition, there were no sufficient data on the use of mediastinal lymph node dissection and surgical procedures, which differed from one study to the other and from one center to another. A more recent large scale analysis of PORT has been reported by Lally et al.[23] To investigate the association between survival and PORT in patients with resected NSCLC, 7465 patients coded as receiving PORT or observation with stage II or III NSCLC who underwent a lobectomy or pneumonectomy were selected within the Surveillance, Epidemiology, and End Results (SEER) database. Patients who survived less than 4 months were excluded. Median follow-up time was 3.5 years for patients still alive. Predictors for the use of PORT included age younger than 50 years, higher American Joint Committee on Cancer stage, T3 and T4 tumor stage, larger tumor size, advanced node stage, greater number of lymph nodes involved, and a ratio of lymph nodes involved to lymph nodes sampled approaching 1. On multivariate analysis, older age, T3 and T4 tumor stage, N2 node stage, male sex, fewer-sampled lymph nodes, and greater number of involved lymph nodes had a negative impact on survival. Overall, the use of PORT did not have a significant impact on survival. However, in subset analysis for patients with N2 nodal disease (HR = 0.855; 95% CI, 0.762 to 0.959; $p = 0.0077$), PORT was associated with a significant increase in survival. For patients with N0 (HR = 1.176; 95% CI, 1.005 to 1.376; $p = 0.0435$) and N1 (HR = 1.097; 95% CI, 1.015 to 1.186; $p = 0.0196$) nodal disease, PORT was associated with a significant decrease in survival. Hence, in this population-based SEER cohort, PORT use was associated with an increase in survival in patients with N2 nodal disease but not in patients with N1 and N0 nodal disease. A new large multi-institutional European phase III trial, Lung Adjuvant Radiotherapy Trial (Lung ART), compares three-dimensional conformal PORT to no PORT, and will include patients who have proven N2 disease and a complete resection irrespective of whether adjuvant or neoadjuvant chemotherapy was used.[24] Seven hundred patients will be included to show a 10% difference in terms of 3-year disease-free survival (bilateral test, power = 80%, alpha error = 5%, from 30% to 40% at 3 years), which is the primary end point. With a longer follow-up period (median of 5 years), this sample size could also show a difference in survival rate of 9% at 5 years. The secondary end points will be overall survival, patterns of relapse, local failure, secondary cancers, and treatment-related toxicity. This project is being studied by the Intergroupe Francophone de Cancérologie Thoracique (IFCT), the European Organisation for Research and Treatment of Cancer (EORTC Radiation Oncology Group and Lung Group), and the Lung Adjuvant Radiotherapy Spanish Group.

### Early Studies of Adjuvant Chemotherapy

The history of adjuvant chemotherapy in completely resected NSCLC initiated in the early 1960s and 1970s with earlier trials testing the role of alkylating agents and nonspecific immunotherapies (mainly levamisole and Bacillus Calmette-Guérin [BCG]) that uniformly failed to demonstrate any survival benefit and, occasionally, a detrimental effect was observed.[25] All the drugs used in these studies had shown very limited or at all no activity in advanced NSCLC.

Subsequently, the potential role of cisplatin-based chemotherapy was extensively tested in all the stages of resectable NSCLC. All but one of these studies failed to show clinical benefit from adjuvant therapies.[26–32]

Common findings in both of these groups of studies include the overestimation of the potential benefit of adjuvant chemotherapy in the calculation of the sample size, in some trials, the unbalance in patients and treatment characteristics (for instance, incomplete mediastinal lymph node dissection), and, in most of these studies, the impossibility to reach the planned accrual. This probably reflects the negative attitude of thoracic surgeons toward adjuvant chemotherapy and the modern multidisciplinary approach to the patient with early NSCLC may be a way to overcome this problem.

In addition, most of the trials dose delivery including both dose and dose intensity were very often reported inadequate with an average of 50% of the patients receiving the full course of treatment.

In 1995, a metaanalysis overviewed eight cisplatin-based adjuvant chemotherapy studies, including all of the aforementioned studies, and demonstrated a 13% reduction of the risk of death, which was close to the borderline of statistical significance ($p = 0.08$). Similarly, there was a 6% reduction in the risk of death in patients treated with postoperative radiotherapy and cisplatin-based chemotherapy compared with patients who received only postoperative radiotherapy ($p = 0.46$). Conversely, adjuvant chemotherapy with long-term alkylating agents was significantly detrimental.[33]

These findings failed to impact on clinical practice not because the absolute gain was too small, but because such an estimate was still imprecise, ranging from 1% detriment to a 10% benefit. In addition, the heterogeneity of surgical procedures, specific chemotherapy regimens, difference in the staging modalities, and absence of a single large prospective trial truly demonstrating increased survival as a result of the use of chemotherapy limited the applicability of the results of this metaanalysis. However, these data strongly supported additional prospective testing of

adjuvant chemotherapy, and new trials using state-of-the-art chemotherapy were initiated.

### Recent Platinum-Based Adjuvant Chemotherapy Trials

The aforementioned metaanalysis generated enthusiasm to prompt the planning of several prospective randomized phase III studies, all platinum based (positive/negative thoracic radiotherapy), evaluating the role of modern platinum-based regimens in all resectable stages of NSCLC.

The North American Intergroup trial evaluated the efficacy of four cycles of postoperative cisplatin/etoposide plus concomitant thoracic radiotherapy (total dose of 50 Gy) in comparison with PORT alone in stage II and IIIA NSCLC. A total of 463 patients were included with no significant difference between the two arms in terms of median time to progression. The relative likelihood of survival among patients assigned to receive chemotherapy plus radiotherapy, as compared with those assigned to receive radiotherapy alone, was 0.93 (95% CI, 0.74 to 1.18).[34] Toxicity of radiation caused by the concomitant administration of cytotoxic agents may explain the lack of efficacy (more striking in stage II). Biological correlative studies evaluating differential expression of p53 and K-ras did not show any relationship with outcome.[35] This study was unique in its routine use of PORT. All other studies primarily tested the efficacy of adjuvant chemotherapy versus observation alone in completely resected NSCLC, with the optional administration of sequential PORT in some of them according to an investigator choice (Table 53.2).

From 1994 to 1999, a joint effort from Adjuvant Lung Project Italy (ALPI) and EORTC enrolled 1209 patients with completely resected stage I, II, or IIIA NSCLC.[36] Patients were randomly assigned to receive chemotherapy with mitomycin, vindesine, and cisplatin (MVP) for three cycles or observation. A total of 69% completed three cycles of MVP, with half of those patients requiring dose reduction. Radiotherapy was given according to the policy of individual centers: 43% of patients received PORT. No significant difference in overall survival was seen with an HR of death of 0.96. Median overall survival was 55 months in the chemotherapy arm and 48 months in the surgery arm. Subset analysis by stage showed that HR was 0.80 (95% CI, 0.60 to 1.06) for stage II versus 0.97 (0.71 to 1.33) and 1.06 (0.82 to 1.38) for stages I and III, respectively. It is remarkable that in the subgroup of patients with stage II NSCLC, although the hazard ratio was not statistically significant, a 10% survival advantage at 5 years for chemotherapy-treated patients was reported.

ALPI, Adjuvant Lung Project Italy; ANITA, Adjuvant Navelbine International Trial Association; BLT, Big Lung Trial; CALGB4, Cancer and Leukemia Group B; IALT, International Adjuvant Lung Cancer Trial; NCIC-BR10, National Cancer Institute of Canada Clinical Trials Group; NR, not reported; NT, not tested; RT, radiotherapy.

Although the incidence of grades 3 and 4 hematological and nonhematological toxicities related to chemotherapy did not differ quantitatively and qualitatively from those commonly reported in advanced NSCLC, the marginal reduction in survival observed in the MVP arm in the first year after randomization could potentially reflect a toxicity effect. This is also indirectly confirmed by the lower percentage of patients in the MVP arm who completed subsequent thoracic radiotherapy (65% vs. 81% in the control arm).

No statistically significant association between p53 or Ki67 expression and stage or histology was found. An analysis of K-ras mutation status and survival was performed in adenocarcinomas and large cell carcinomas: mutations were found in 22% of the 117 considered samples with no relationship to survival.

The International Adjuvant Lung Cancer Trial (IALT) collaborative group was the first large study to show a significant benefit in favor of adjuvant chemotherapy. A total of 1867 completely resected NSCLC patients were randomized to chemotherapy (a doublet of cisplatin plus vindesine, vinblastine, vinorelbine, or etoposide) or observation.[37] All stages were represented, with approximately 10% having stage IA disease, 27% stage IB, 24% stage II, and 39% stage III. In the chemotherapy arm, 74% of patients received at least 240 mg/m$^2$ of cisplatin, 27% of patients received PORT. Toxicity of grades 3 and 4 was experienced by 23% of patients (0.8% of toxic deaths). Survival was significantly longer in the chemotherapy arm with an HR of 0.86 (95% CI, 0.76 to 0.98; $p$ <0.03): 5-year survival rates were 44.5% and 40.4%, and median survival was 50.8 and 44.4 months in the chemotherapy group and in the control group, respectively, whereas median disease-free survival was 40.2 and 30.5 months.

Some methodological aspects regarding the final analysis of the IALT study raise concerns: in clinical trials in which a long follow-up is required, the difference between treatments may depend on the follow-up time. That implies that in the early phase of the study, there is the potential for a biased estimate of the treatment effect. In the IALT study, the accrual was prematurely interrupted when less than 60% of expected patients had been enrolled. The follow up continued until about 65% of expected events had been observed. If the study had continued until the planned number of events was reached, the conditional power to detect, under the null hypothesis, a statistically significant difference would have been less than 50%. Moreover, the adoption of a Bayesian approach that may be more appropriate for interpreting results, when early analysis shows a potential positive treatment effect, would have suggested to prolong follow-up.[38] Bayesian analysis to determine if the IALT results were convincing enough to change clinical practice were presented at the American Society of Clinical Oncology (ASCO) 2004 and the preponderance of evidence supported at least a 3% survival advantage for adjuvant therapy.[39] Of interest, however, is that the results of the IALT study, initially reported with a 4.7-year follow-up (ASCO 2003), were recently updated (ASCO 2008) with 3 additional years of follow-up.[40] Median follow-up was 7.5 years at the cutoff

date of September 1, 2005. The survival status was known for 1807 patients. Results showed a beneficial effect of adjuvant chemotherapy on overall survival (HR = 0.91; 95% CI, 0.81 to 1.02; $p$ = 0.10) and on disease-free survival (HR = 0.88; 95% CI, 0.78 to 0.98; $p$ = 0.02). However, there was a significant difference between the results of overall survival before and after 5 years (HR = 0.86; CI, 0.76 to 0.97; $p$ = 0.01 vs. HR = 1.45; CI, 1.02 to 2.07; $p$ = 0.04); $p$ value for interaction was 0.006. Disease-free survival benefit was also different according to the follow-up duration ($p$ value for interaction: 0.04; global, first 5 years, HR = 0.85, $p$ = 0.006; after 5 years, HR = 1.33, $p$ = 0.16). The analysis of non–lung cancer deaths for the whole period showed an HR of 1.34 (CI, 0.99 to 1.81; $p$ = 0.06). These results confirmed the efficacy of chemotherapy for the first 5 years after surgery. The difference in results between less than and more than 5 years of follow-up may suggest possible late adjuvant chemotherapy-related overmortality. This potential effect underscores the need for the long-term follow-up of adjuvant lung cancer trials in order to evaluate results in terms of treatment benefits and long-term hazards.

The Big Lung Trial (BLT) was designed to evaluate the role of cisplatin-based chemotherapy across all NSCLC stages. Within the study, resected stage I to III NSCLC patients were randomly assigned to three cycles of postoperative chemotherapy (doublet of cisplatin with either vindesine or vinorelbine or a triplet with mitomycin and ifosfamide or MVP) or surgery alone. A total of 381 patients were randomized: three cycles of chemotherapy were completed in 64% of patients, with 40% of patients requiring dose reductions. PORT was given to only 14% of cases. No significant differences in terms of survival were seen in the two groups, even if this trial was underpowered to answer to the adjuvant chemotherapy benefit question, had a short follow-up of 29 months and 15% of patients with incompletely resected disease.[41]

The Adjuvant Navelbine International Trial Association (ANITA) trial randomized 840 resected stage IB to IIIA NSCLC patients to cisplatin 100 mg/m$^2$ every 4 weeks and vinorelbine 30 mg/m$^2$ weekly versus observation: 301 (36%) patients had stage IB disease, 203 (24%) had stage II disease, and 325 (39%) had stage IIIA disease. After a median follow-up of 76 months, median survival was 65.7 months in the chemotherapy group and 43.7 months in the observation group. Chemotherapy significantly reduced the risk for death (HR = 0.80; 95% CI, 0.66 to 0.96; $p$ = 0.017) with a survival advantage of 8.6% at 5 years, which was maintained at 7 years (8.4%).[42] Grade 3 and 4 neutropenia was documented in 85% of patients, febrile neutropenia in 9%, and severe infections in 11%. Among the nonhematological toxicities, the most commonly reported were asthenia (28%), nausea and vomiting (27%), and anorexia (15%).

As in many of the previously reported adjuvant studies, PORT was administered according to the policy of individual centers. A descriptive analysis from this study showed that radiotherapy could benefit patients with N2 status and could be harmful when combined with chemotherapy in patients

with N1 status. These data are in contrast with the data from North American Intergroup Group study reported previously where no benefit from concurrent use of cisplatin/etoposide and radiotherapy in patients with stages II and IIIA disease, possibly because 42% of the patients had stage II.

Differently from ALPI, IALT, BLT, and ANITA, which considered every stage of resectable NSCLC, two additional studies investigated the role adjuvant chemotherapy in very early stages (I and II).

The National Cancer Institute of Canada Clinical Trials Group (NCIC-BR10) limited enrolment to patients with stage IB-II disease. Patients were randomized to receive four cycles of cisplatin (50 mg/m$^2$, days 1 and 8 every 4 weeks) and vinorelbine 25 mg/m$^2$ weekly for 16 weeks versus observation alone. Patients did not receive PORT and were stratified by nodal status (N0 vs. N1) and K-Ras mutation (24% with mutations). The study was powered to detect a 10% improvement in 3 years' survival, and 482 resected stages IB and II (excluding T3N0) NSCLC patients were enrolled and randomized. Overall survival was significantly longer in the chemotherapy arm (94 vs. 73 months; HR = 0.69 (95% CI, 0.52 to 0.91; $p$ = 0.0009), as was recurrence-free survival (not reached vs. 47 months); 5-year survival rates were 69% and 54%, respectively, with an absolute gain of 15% at 5 years. The subset analysis by stage showed a greater benefit at 5 years for stage II (20%) than for stage I (7% not statistically significant); notably at 6 years, the benefit for stage I disappeared, and survival was greater in the control group.

Fifty-eight percent of randomized and treated patients (n = 231) received three courses of cisplatin/vinorelbine. Two patients (0.8%) died because of treatment-related toxicity, grades 3 and 4 neutropenia was documented in 73% of patients and febrile neutropenia in 7%. Nineteen percent of patients required hospitalization for medical problems related to the toxicity of chemotherapy. Quality-of-life analysis demonstrated a reversible reduction in quality of life for the treatment group.[43]

NCIC-BR10 and ANITA, two largely positive studies, unfortunately adopted doses and schedules that are not routinely used in current clinical practice. The commonest dose of cisplatin currently used is 75 mg/m$^2$ on day 1, and the cisplatin administration on days 1 and 8 (as in the BR10) is quite unusual. In addition, weekly administration of vinorelbine is quite rarely adopted in clinical practice and associated with a higher toxicity.

Cancer and Leukemia Group B (CALGB) 9633 further narrowed the adjuvant group only to patients with resected stage IB disease and was the only trial using the carboplatin–paclitaxel regimen. The study accrued slowly because of its limited range of eligible patients leading to a reduction in planned overall accrual cohort. In addition, it was closed early by its data-safety-monitoring committee because of a positive interim analysis with 90% of patients recruited based on the revised estimates. The study was powered to detect a 13% improvement in overall survival at 5 years. At the time of closure to accrual, 344 patients had been entered and randomly

assigned to receive carboplatin area under the curve (AUC) 6 and paclitaxel 200 mg/m$^2$ every 3 weeks for a total of four cycles: an early report after a follow-up time of 34 months detected a 12% absolute improvement in overall survival at 4 years (71% vs. 59%; HR = 0.62; $p$ = 0.028).[44]

The delivery of chemotherapy was excellent with nearly 85% of patients who received four cycles of chemotherapy. Toxicity in this group of patients was minimal, with only 36% of patients having grades 3 and 4 myelosuppression. There were no treatment-related deaths, which is an important aspect of an adjuvant study.

Unfortunately, a recently updated analysis could not confirm such favorable outcome after an extended follow-up (54 months) and showed only a trend toward survival improvement (59% vs. 57%) that lost significance (HR = 0.80; $p$ = 0.10).[45] It should be noted that the small sample size did not allow for adequate power to detect small differences in survival. The 3-year failure-free survival (66% vs. 57%) and the 3-year survival (79% vs. 70%; $p$ = 0.045) continued to favor the chemotherapy group. The real role of prolonging disease-free survival has not been well quantified in the adjuvant setting, and it is not known to necessarily translate into a permanent advantage in overall survival. A subgroup analysis, also presented at the follow-up at ASCO revealed that further dividing patients in CALGB 9633 into those with tumors smaller than 4 cm versus those greater than or equal to 4 cm identified a higher-risk group for which chemotherapy may be beneficial. In an unplanned subset analysis, patients in CALGB 9633 with tumors of at least 4 cm (close to 100 patients in each arm) retained an overall survival advantage (HR = 0.66; $p$ <0.04). The 74 patients in each arm with tumors smaller than 4 cm did not differ in survival (HR = 1.02; $p$ = 0.51).[46]

Overall, three studies showed a positive impact of adjuvant chemotherapy in resectable NSCLC with a survival benefit ranging from 4.1% (IALT) to 15% (NCIC-BR10) (Table 53.3). Why are there such huge difference in survival among these studies? First, there was a huge difference in the sample size calculations from one study to another (from less than 500 patients to 3300 according to the planned sample sizes) to assess a similar expected therapeutic effect in a similar patient population. The only two studies designed to observe an estimated survival advantage in an unrestricted population of early stage patients (stages I to III) in the range of that reported in the 1995 metaanalysis were the ALPI and the IALT studies that, not surprisingly, demonstrated a survival benefit relatively close to each other (3% for ALPI vs. 4.1% for IALT).

Second, in most of these studies, no information is available on the proportion of patients who, during surgical resection, underwent systematic lymph nodal dissection (SND) or mediastinal lymph node sampling (MLS). In a randomized clinical study, SND was found to significantly influence survival in every stage of resectable NSCLC.[47]

Third, lung cancer patients frequently suffer from comorbidities, including chronic obstructive pulmonary disease and cardiovascular diseases that were found to affect survival

NA, not available.

significantly.[48,49] Additionally, an unbalance in the proportion of patients who potentially quit smoking after radical surgery may potentially account for survival differences as shown in two retrospective studies in which smoking status was found to highly influence survival of resected NSCLC patients.[50,51]

One common feature of most of these studies, with the exclusion of the carboplatin-based CALGB 9633, is the less than optimal compliance to adjuvant regimens. The feasibility of three cycles of adjuvant chemotherapy (including delays and dose reductions) ranged between 58% and 74% of the cisplatin-based studies. Reasons for reduced therapeutic compliance may be related to the need of a longer time to fully recover from the surgical procedure itself for lung cancer patients in comparison with that needed for breast cancer patients. For instance, in some of these studies, the pneumonectomy rate was far exceeding that of consecutive surgical series and a specific subset analysis about tolerability of chemotherapy in this specific subgroup of patients (ALPI = 26%, IALT = 35%, ANITA = 41%) has not been performed.

Although the role of delivering the planned total dose of cytotoxic agents has not been fully evaluated in all the these studies, in adjuvant breast cancer, survival benefit was more striking in those patients receiving >85% of the intended total dose of chemotherapy.[52]

## Adjuvant Studies with Oral Chemotherapy Agents

A single randomized study tested the efficacy of oral ubenimex versus placebo administered continuously for 2 years after radical resection. This agent is a potent inhibitor of aminopeptidases and is believed to have immunomodulatory activity. Four hundred patients with completely resected stage I squamous cell carcinoma were randomized, and 5-year survival rate favored the experimental arm (81% vs. 74%; $p = 0.02$).[53]

Uracil-tegafur (UFT), an oral fluoropyrimidine combining uracil and tegafur, has been extensively studied in Japan as adjuvant single agent or combined with other intravenous agents. The largest trial of postoperative UFT therapy in resected NSCLC randomly assigned 979 patients with completely resected stage I adenocarcinoma to either oral UFT 250 mg/m$^2$ for 2 years or observation. The overall survival favored the UFT arm with an HR of 0.71 (95% CI, 0.52 to 0.98; $p = 0.04$) and a 5-year survival of 88% in the UFT group and 85% in the

control group. Subset analyses found the greatest benefit in the T2N0 subgroup (n = 263; HR = 0.48; 95% CI, 0.29 to 0.81; $p$ = 0.005) but not in T1N0 (n = 716; HR = 0.97; 95% CI, 0.64 to 1.46; $p$ = 0.87) . Compliance was limited at 74% at 12 months and only 61% at 24 months.[54] One questionable point in this trial is the absence of any advantage in disease-free survival for UFT-treated arm, and this clearly contrasts with all the positive, cisplatin-based adjuvant studies (IALT, NCIC-BR10, ANITA) where improvement in overall survival for patients receiving adjuvant chemotherapy was invariably associated with a similar or greater magnitude in disease-free survival.

Results in three other fully published studies of adjuvant UFT in smaller sample size of patients were inconsistent with the previously reported study.[55–57] In addition, there is no confirmatory data concerning the use of UFT in the adjuvant setting outside Japan. The concept of relatively mild, low-dose continuous adjuvant therapy is attractive, but the absence of confirmatory adjuvant UFT studies outside Japan strongly limit the applicability of these data into clinical practice. Additionally, questions regarding a peculiar genetic sensitivity to UFT in the Japanese population remain unanswered.

The West Japan Thoracic Oncology Group in December 2005 finished enrolling 607 patients in a phase III study comparing in stage IB to III adjuvant UFT 250 mg/m$^2$ daily for 1 year versus single-agent gemcitabine 1000 mg/m$^2$ days 1 to 8 every 3 weeks for 6 cycles. Final analysis is expected in 2010.

**Systematic Reviews and Metaanalyses**  Recently, several systematic reviews and metaanalyses have confirmed the value of adjuvant cisplatin- or UFT-based chemotherapy in resectable NSCLC[58–63] (Table 53.4). All of these reports consistently showed a benefit from adjuvant chemotherapy with HRs ranging from 0.72 for adjuvant UFT to 0.89 for cisplatin-based chemotherapy.

The largest systematic review included 7200 patients from 19 randomized adjuvant trials (12 trials with cisplatin-based therapy and 7 trials with UFT): cisplatin-based postoperative chemotherapy showed an 11% relative reduction in mortality, whereas UFT yielded a 17% reduction when compared with surgery alone.[59]

Two of these metaanalyses are based on individual patient data rather than published study reports. In a metaanalysis comparing the outcome of 2003 patients treated with adjuvant oral UFT as a single agent or in combination with other cytotoxic agents from six different studies, UFT significantly improved overall survival (HR = 0.74; 95% CI, 0.61 to 0.88), corresponding to a 4.6% benefit at 5 years ($p$ = 0.001) and 7% at 7 years ($p$ = 0.001).[58]

The Lung Adjuvant Cisplatin Evaluation (LACE) pooled analysis reported data from individual cases on 4584 patients from the five randomized adjuvant clinical trials (ALPI, ANITA, BLT, IALT, and BR10) and detected a significantly positive effect of chemotherapy in terms of overall survival (HR = 0.89; 95% CI, 0.82 to 0.96), disease-free survival (HR = 0.84; 95% CI, 0.78 to 0.90) with a relative reduction of the risk of death of 11% (HR = 0.89; 95% CI, 0.82 to 0.96) (Fig. 53.1). In stages II and III NSCLC, overall survival gain was 5.3% at 5 years (48.8% vs. 43.3%; HR = 0.83; 95% CI, 0.83 to 0.95). A small but not significant survival gain was also evident in stage IB (HR = 0.92; 95% CI, 0.78 to 1.10), but a detrimental effect was seen in stage IA (HR = 1.41; 95% CI, 0.96 to 2.1). The most active regimen seems to be cisplatin/vinorelbine mainly due to the higher number of patients treated (1888 patients, HR = 0.80) and to higher cisplatin total doses administered in combination with vinorelbine (320 to 400 mg/m$^2$).[62]

**Adjuvant Chemotherapy in the Elderly**  The consistent data on efficacy of adjuvant chemotherapy bring every

clinician to face a growing fraction of elderly patients who underwent surgery for NSCLC. More than 50% of lung cancer cases are diagnosed in patients older than 65 years, and approximately 30% are diagnosed in those older than 70.[63] The age cutoff to define elderly patients is usually established at 70 years, although it would be preferable to precisely assess the biological and not the chronological age.

Available data from younger patients do not automatically translate into a benefit in the elderly counterpart. It is well known that elderly patients tolerate chemotherapy poorly because of comorbidities and organ failure, especially the declining renal function altering drug pharmacodynamics. The prevalence of comorbidities, mainly respiratory and cardiovascular diseases, typical of heavy smokers, is higher in this subgroup of patients. Moreover, after a demanding surgery as in lobectomy or pneumonectomy, there is a higher risk of chemotherapy-induced toxicity. Higher toxicity or reduced compliance could vanish the potential survival benefit obtained with adjuvant chemotherapy. As a consequence, data are not conclusive because of the fact that elderly are generally excluded from clinical trials. Modified schedules or attenuated doses of platinum-containing chemotherapy should be investigated by specifically designed trials in the adjuvant setting.[64]

A retrospective analysis evaluated the influence of age on survival, chemotherapy compliance, and toxicity in the NCIC-BR10 study. Data from 327 young and 155 elderly patients (65 years or older) were evaluated. Histology showed a prevalence of adenocarcinoma and better performance status in younger patients. Elderly patients received significantly fewer doses of chemotherapy with no significant differences in toxicities. Overall survival in elderly patients remained significantly better with chemotherapy than with observation (HR = 0.61; *p* = 0.04) but in the few patients who are more than 75 years old (n = 23) had a significantly shorter survival than those aged 66 to 75.[65] These data suggest that in clinical practice, elderly patients fit to receive platinum-based chemotherapy should not be denied adjuvant chemotherapy.

**Targeted Therapy** In advanced NSCLC erlotinib, an epidermal growth factor receptor tyrosine-kinase inhibitor (EGFR TKI), as single agent in second/third line and bevacizumab, a monoclonal antibody against the isoform A of vascular endothelial growth factor (VEGF), as front-line treatment in combination with cytotoxic chemotherapy improve survival significantly.

Current clinical experience with EGFR TKIs in the adjuvant setting is limited and still evolving.

A pivotal Japanese phase III study planned to administer adjuvant gefitinib, another EGFR TKI, 250 mg/day or placebo to randomized patients with completely resected NSCLC (stages IB to IIIA) 4 to 6 weeks following surgery, for 2 years, until recurrence/withdrawal. However, recruitment was stopped after the randomization of 38 patients, because interstitial lung disease (ILD)-type events were being increasingly reported in Japan in the advanced disease setting leading to safety concerns in this population of potentially cured patients. Safety data for 38 recruited patients (18 gefitinib and 20 placebo) showed no unexpected adverse drug reactions, with the most common being grades 1 and 2 gastrointestinal and skin disorders in 12 and 16 patients receiving gefitinib and in five and six patients receiving placebo, respectively. Grades 3 and 4 adverse events occurred in four patients receiving gefitinib and one patient receiving placebo. ILD-type events were reported in one patient receiving gefitinib (concomitantly with other ILD-inducing drugs) who died and two patients receiving placebo. Adverse events associated with surgical complications were reported for six patients receiving gefitinib and four patients receiving placebo.[66]

In the same patient population, another phase III study from the National Cancer Institute of Canada (NCIC BR19) compared gefitinib versus placebo after four courses of

cisplatin-based chemotherapy, but it was prematurely closed after the inclusion of 503 patients as consequence of the negative outcome of other phase III studies (SWOG 0139 in stage IIIB, which tested gefitinib versus placebo in nonprogressive patients following concurrent chemoradiotherapy and maintenance docetaxel[67] and a second-line study of gefitinib versus placebo, the ISEL study.[68] An analysis of the 503 entered patients is pending at this time.

Currently, an ongoing study is testing adjuvant erlotinib versus placebo after adjuvant platinum-based chemotherapy in stage IB to III NSCLC patients positive for EGFR expression (evaluated by immunohistochemistry and/or fluorescence in situ hybridization [FISH]). Potential limitations of this study are related to the current absence of established important predictive molecular selection factors, especially the still unproven role of FISH in early stages, and the role of secondary resistance mechanisms to EGFR inhibitors such as secondary mutations or induction of other signaling pathways (mesenchymal-epithelial transition factor [c-met]). The simple quantification of the presence of the EGFR receptor as a target on tumor cells could not be shown to be sufficiently predictive of response because of the variability of the activation state of the target and heterogeneity of pathways involved in the mechanism of action.

Exploratory studies selecting patients based on EGFR mutational testing most likely will occur in the near future but also retrospective studies could be helpful in this matter. An ongoing Japanese study in completely resected stage IIIA NSCLC with EGFR mutation is assessing the efficacy of gefitinib 250 mg/day for 1 year versus the combination of carboplatin/paclitaxel administered for four courses. The planned sample size is 150 patients and the primary end point of the study is progression-free survival.

The crucial role of angiogenesis in lung cancer development is very well documented, and it is an integral part of a preoplastic lesion described as angiogenic squamous dysplasia.[69] Although other angiogenic factors have been identified, VEGF is the most potent and specific, with a well-defined role in normal and pathologic angiogenesis. VEGF stimulates proliferation of vascular endothelial cells and its expression is substantially increased in a majority of human tumors including lung cancer, when compared with the surrounding tumor-free tissues. A correlation has been noted between the degree of tumor vascularization and the level of VEGF messenger ribonucleic acid (mRNA) expression and in virtually all specimens examined, VEGF mRNA is expressed in tumor cells but not endothelial cells, whereas mRNAs for the two VEGF receptors, Flt-1 and kinase insert domain protein receptor (KDR), are upregulated in endothelial cells associated with the tumor.[70]

VEGF is a strong prognostic indicator in NSCLC and is associated with early postoperative relapse and decreased survival.[71]

The Eastern Oncology Cooperative Group (ECOG) and the U.S. Intergroup is conducting a multicenter randomized phase III trial of adjuvant chemotherapy alone (cisplatin/vinorelbine or cisplatin/gemcitabine or cisplatin/docetaxel) versus the same chemotherapy plus bevacizumab, in radically resected stage IB to IIIA NSCLC patients (ECOG 1505). An accrual of 1500 subjects is planned.

## Genetic Predictive and Prognostic Factors

In lung cancer, the choice of the cytotoxic chemotherapy is currently based on tumor (histology and disease extent) and clinical features, such as age and performance status, and it is often adjusted by considering both efficacy and toxicity. To individualize chemotherapy (i.e., to more specifically assign an effective treatment to individual patients who will likely benefit and avoid undue toxic effects to those who likely will not), a better definition of the prognostic or predictive implications of the tumors' genetic makeup as well as of the tumors' or patient's (germline) pharmacogenetic variations (the so called single-nucleotide polymorphisms) are needed. In early stage patients who undergo surgery, it is increasingly feasible to gather both kinds of indications through an extensive molecular characterization of the tumor and nonmalignant cells because of the availability of large amounts of resected neoplastic tissue and, at the same time, the easy availability of peripheral blood cells.

In the past, a large biomarker study retrospectively performed in 515 cases of resected stage I NSCLC failed to show any significant association between survival and the expression of an extensive panel of biomarkers, including EGFR, HER-2/neu, bcl-2, p53, and angiogenesis.[72]

The advent of the human genome–sequencing project and the concurrent development of many genomic-based technologies, including expression microarrays, have allowed translational researchers to explore the possibility of using expression profiles to better tune prognosis and predict tumor drug sensitivity or resistance.

Among epigenetic changes, aberrant gene promoter methylation is increasingly recognized as an extremely common event occurring early during carcinogenesis. An increasing number of genes that play a role in critical steps such as cell cycle control, DNA damage repair, growth factor regulation, invasion, and metastasis have been found highly methylated and altered very early in the carcinogenesis process.[73,74] More interestingly from a clinical perspective, patients with tumors harboring gene promoter hypermethylation have significantly worse prognosis.[75–77] This prognostic information needs to be validated prospectively with an adequate number of patients.

Several candidate signatures involving multigene expression profiles have been put forward as predictive of recurrence and survival for resected NSCLC, but these signatures need to be harmonized and crossvalidated before being used to select patients for therapy.[78–80] In one of these studies, researchers looked at 89 patients with early stage NSCLC. Gene-expression profiles (the lung metagene model) that predicted the risk of recurrence were evaluated in two independent groups of 25 and 84 patients, respectively. The lung metagene model predicted recurrence for individual patients significantly better than did clinical prognostic factors, and it was consistent across all early stages of NSCLC. When applied to other two cohorts, the model had an overall predictive accuracy of 72% and 79%.

The predictor also identified a subgroup of patients with stage IA disease who were at high risk for recurrence.[78] As a consequence of these results, the CALGB is currently planning a large randomized study in which patients who undergo surgery will then have their tumor tissue characterized by gene expression analysis and then assigned a predicted outcome of low or high risk. Low-risk patients will be only observed, whereas high-risk patients will be randomized to either observation, according to standard practice for stage IA NSCLC, or receive adjuvant chemotherapy.

Exploratory studies in advanced disease demonstrated an association between high level of mRNA expression of the excision repair cross-complementation group 1 (ERCC1) gene and cisplatin resistance[81,82] or ribonucleotide reductase M1 (RRM1) gene and gemcitabine resistance.[83]

Unfortunately, most of genetic markers are carrying on predictive and prognostic information.[84–86] In a retrospective study, RRM1 and ERCC1 expression as evaluated through a quantitative immunohistochemistry method was found to have a prognostic impact on survival after surgical treatment of early stage NSCLC. The overall survival was more than 120 months for patients with tumors with high expression of RRM1 versus 60 months for those with low expression of RRM1. Among these 187 patients, the survival advantage was limited to the 30% of patients with tumors that had a high expression of both RRM1 and ERCC1.[86] Another large retrospective study called Bio-IALT analyzed 761 tumor specimens and showed that the benefit of adjuvant chemotherapy was exclusively observed in the subgroup of tumors that were ERCC1 negative by immunohistochemistry. Thus, the low expressors are predicted to do worse without chemotherapy but to have better benefit from chemotherapy than the high expressors. In this study, the genetic marker was both prognostic and predictive.[87]

Subsequently, the expression of p27[Kip1], p16[INK4A], cyclin D1, cyclin D3, cyclin E, and Ki-67 was immunohistochemically assessed in tumor specimens of 778 patients from the IALT adjuvant study. Among patients with p27[Kip1]-negative tumors, cisplatin-based chemotherapy resulted in longer overall survival compared with controls (adjusted HR for death = 0.66; 95% CI, 0.50 to 0.88; $p$ = 0.006). In patients with p27[Kip1]-positive tumors, overall survival was not different between patients treated with cisplatin-based chemotherapy and controls (adjusted HR for death = 1.09; 95% CI, 0.82 to 1.45; $p$ = 0.54). The other cell cycle regulators and Ki-67 did not predict benefit of adjuvant cisplatin-based chemotherapy.[88]

Overexpression of class I and class III $\beta$-tubulin play a significant role in the acquisition of paclitaxel resistance.[89] Class III $\beta$-tubulin expression is also correlated with patient outcome in NSCLC patients treated with vinorelbine-based regimens.[90] The role of class III $\beta$-tubulin was assessed in the NCIC-BR10 study on 265 out of 482 patients enrolled in the trial. Higher class III $\beta$-tubulin expression was seen in women, in nonsquamous histology, in patients with Ras mutations, in patients <60 years and in performance status 1 (PS1) patients. Overexpression of class III $\beta$-tubulin was associated with worse overall survival in the observation arm (HR = 1.72; 95% CI, 1.02 to 2.88; $p$ = 0.04) but not in the chemotherapy arm. A greater benefit from adjuvant chemotherapy was seen in patients with high expression of class III $\beta$-tubulin, whereas in the setting of advanced disease, the opposite was evident.[91] Such data need larger confirmatory studies but could be useful to design experimental trials to select patients and chemotherapy regimens based on a genomic profile.

Even if both of these markers have not yet fully validated, and the used techniques (quantitative real time polymerase chain reaction [qRT-PCR] and immunohistochemistry) are not yet fully standardized, the possibility to prospectively validate this experimental hypothesis generated from retrospective studies represents a high priority.

## CONCLUSION

Phase III prospective randomized trials and metaanalyses have conclusively demonstrated that cisplatin-based adjuvant chemotherapy has a positive impact on disease-free and overall survival in postoperative stages II and III NSCLC. The efficacy of oral UFT continuously administered for 2 years has been shown only in Japanese studies and mainly in adenocarcinoma and stage I disease. The number of patients who will benefit from adjuvant treatment, however, represent a small proportion of all completely resected NSCLC patients (Fig. 53.2). Genome-wide and candidate gene approaches

**FIGURE 53.2**  Graph indicating how much limited is the proportion of patients who really benefit from adjuvant treatments. Most are still cured by surgery alone or they have micrometastatic disease already resistant to empirical systemic treatments.
have already shown through retrospective studies the potential for refining and individualizing the treatment of early stage NSCLC and improving the efficacy of cytotoxic chemotherapy. These hypothesis generating findings need to be verified in prospective studies as well as the role of molecular-targeted therapies.

# Preoperative Chemotherapy for Early Stage Non–Small Cell Lung Cancer

## BACKGROUND

Surgery remains the cornerstone of treatment for patients with early stage non–small cell lung cancer (NSCLC) and provides the best hope for cure. Operable patients with stages IA through IIIA disease are candidates for complete resection with curative intent. Patients diagnosed with these stages represent approximately one third of all lung cancer cases.[1] However, despite complete surgical resection, a large number of patients will relapse after surgery. Five-year survival rates in patients with completely resected NSCLC average 78% and 58% for stages IA and IB, 46% and 36% for stages IIA and B, and 24% for stage IIIA, respectively.[2] The most frequent cause of death for patients with NSCLC after complete resection is the development of distant metastases. Although the frequency of intrathoracic recurrence averages 10% to 15% across stages, the frequency of distant metastasis as site of first relapse increases from 15% in stage IA over 40% in stage II to 60% in stage IIIA.[3–6] Relapse at distant sites is thought to be a result of occult micrometastatic disease, undetected at the time of preoperative staging.

Eradication of early metastatic disease by chemotherapy may theoretically translate into a decreased incidence of recurrence in distant sites, and thereby improve survival. This chemotherapy can be administered before (neoadjuvant or induction) or after (postoperative or adjuvant) surgery. Several randomized trials and metaanalyses have recently demonstrated an overall survival benefit with adjuvant platinum-based chemotherapy in early stage NSCLC.[7–9] These results have lead to the adoption of surgery and adjuvant chemotherapy as the new standard of care in selected patients.[10] This chapter will focus on the administration of chemotherapy prior to surgery as an alternate approach to adjuvant chemotherapy in early stage resectable NSCLC.

## RATIONALE FOR NEOADJUVANT CHEMOTHERAPY

The term *neoadjuvant chemotherapy* was coined by Frei[11] to refer to the specific strategy of using a drug treatment at the earliest

time possible. Neoadjuvant chemotherapy has several potential advantages over immediate surgery and adjuvant therapy. The most important is the systemic treatment of occult microscopic metastatic disease at the earliest possible time, with an improved progression-free and overall survival as compared to the local treatment only. The former is thought to be the result of a better control of the cytokines released by the wound repair, the latter by an improved sterilization of the occult metastases. Besides its potential systemic effects, chemotherapy induces cytotoxic effects at the level of the primary tumor, resulting in clinical and even pathological remissions. A reduction in the primary tumor mass may theoretically lead to less extensive surgery and possibly renders borderline unresectable lesions resectable (e.g., by downstaging of involved mediastinal lymph nodes). Another potential advantage of neoadjuvant chemotherapy is its better compliance. Only 45% to 60% of the patients are able to complete the adjuvant chemotherapy without dose reductions or delays, whereas the induction chemotherapy was shown to be administrated in more than 80% of the patients in most phase II induction trials.[12] Other potential advantages include the in vivo assessment of tumor chemosensitivity, a lower risk of developing drug resistance, and the selection of responsive patients, as patients with disease progression on chemotherapy will most likely not benefit from surgery.

The potential disadvantages of neoadjuvant chemotherapy include a delay in potentially curative surgery, less accurate staging—as the pathological staging is confounded by the induction treatment—and increased surgical morbidity and mortality after chemotherapy with decrease in quality of life. Lastly, a benefit of neoadjuvant chemotherapy is well established for the treatment of invasive bladder cancer and endothoracic esophageal cancer.[13,14]

## EARLY STUDIES

Enthusiasm for the use of neoadjuvant chemotherapy for treating early stage NSCLC was generated by positive survival results from two small randomized studies in patients with

stage IIIA. Roth et al.[15] randomized patients with potentially resectable clinical stage IIIA NSCLC between perioperative chemotherapy followed by surgery and a control arm of surgery alone. Patients allocated to chemotherapy were to receive three cycles of chemotherapy with cyclophosphamide, etoposide, and cisplatin before surgery; an additional three cycles were given after surgery to patients with preoperative radiographic response. Following an interim analysis, the trial was closed after 60 patients had been accrued because of a clinically meaningful survival benefit in favor of the induction chemotherapy arm. Long-term follow-up of this trial, after a median time from randomization of 82 months, confirmed the beneficial effect of induction chemotherapy. Median and 5-year survival rates were 21 months and 36% versus 14 months and 15% for surgery alone.[16]

In a similar randomized trial conducted by Rosell et al.,[17] clinical stage I to IIIA NSCLC patients were randomized to immediate surgery or surgery preceded by three cycles of mitomycin, ifosfamide, and cisplatin chemotherapy. Both treatment groups received postoperative mediastinal radiation therapy to 50 Gy. Interim analysis after 24 months follow-up with 60 eligible patients showed a significant difference in survival favoring induction chemotherapy and enrollment was stopped. Reassessment with 7-year follow-up found median and 5-year survival rates of 22 months and 17% in the chemotherapy arm compared to 10 months and 0% in the surgery-alone arm.[18] The outcome of patients treated with immediate surgery was, however, disappointingly low.

Pass et al.[19] randomized 27 patients between surgical resection either preceded by cisplatin–etoposide chemotherapy or followed by radiotherapy and observed median survival rates of 29 versus 16 months. The results of this trial are, however, difficult to interpret because of the asymmetry in randomization. Four other small randomized series did not observe a difference in outcome between an approach with or without preoperative chemotherapy.[20–23]

These earlier trials have a number of weaknesses in their design: (a) a variable use of adjuvant chemotherapy and radiotherapy; (b) the use of first- and second-generation drugs, of which some have been associated with a detrimental effect on survival[24]; and (c) the use of the 1986 staging classification, in which stage III is even more heterogenous than in the present one.[25]

In 2001, the results of a French phase III randomized trial of induction mitomycin, ifosfamide, cisplatin chemotherapy in resectable stages IB, II, and IIIA were reported.[26] Three hundred fifty-five eligible patients were randomized to surgery alone or combined modality therapy consisting of two cycles of chemotherapy followed by surgery. Responding patients (radiographically or pathologically) received two additional cycles of adjuvant chemotherapy. The arms were well balanced for patient characteristics with the exception that less clinical N2-assigned patients were assigned to the surgery-only arm (28% vs. 40%; $p = 0.65$). A nonsignificant excess of postoperative morbidity in the chemotherapy arm was seen (24/167 vs. 22/171). Postoperative mortality was 6.7% in the chemotherapy arm and 4.5% in the surgery arm ($p = 0.38$). Median

survival was improved by 11 months (37 vs. 26 months) and at 4 years, there was an 8.6% increase in survival in the chemotherapy arm, but this did not achieve statistical significance. In a subset analysis, the benefit of chemotherapy was confined to patients with N0 and N1 disease with a relative risk of death of 0.68 ($p = 0.027$). After a nonsignificant excess of deaths in the combined modality arm during the treatment period, the effect of induction chemotherapy was favorable on survival. No difference was seen in local recurrence rates. A significant decrease in distant metastases was observed, favoring the chemotherapy arm with a relative risk of 0.54 ($p = 0.01$). Follow-up data on this trial, when minimal follow-up exceeded 60 months, showed that the 3- to 5-year survival differences were stable around 10% ($p = 0.04$ at 3 years and $p = 0.06$ at 5 years).[27] Statistically significant benefits in the N0–1 subgroup were confirmed with 5-year survival rates of 49% compared to 34% in the N2 subgroup ($p = 0.02$)

## SURGICAL MORBIDITY AND MORTALITY AFTER INDUCTION THERAPY

The use of preoperative chemotherapy may increase surgical complication rates. Several large retrospective series have addressed this issue. Siegenthaler et al.[28] reported data from 335 patients undergoing lobectomy or greater resection for NSCLC, of whom 76 received induction chemotherapy. The use of preoperative chemotherapy did not significantly affect morbidity or mortality overall, based on clinical stage, postoperative stage, or extent of resection. No significant differences in overall or subset mortality or morbidity, including pneumonia, acute respiratory distress syndrome, reintubation, tracheostomy, wound complication, or length of hospitalization, were seen.

Four hundred and seventy patients treated with induction chemotherapy and surgery from 1993 through 1999 at Memorial Sloan-Kettering Cancer Center were reviewed.[29] Univariate and multivariate methods for logistic regression model were used to identify predictors of adverse events. Overall, a surgical mortality rate of 3.8% was observed, which compared favorably to other primary surgery studies. Total morbidity and major complication rates were 38% and 27%, similar to previous primary surgery studies. The authors concluded that overall morbidity rates were not significantly affected by the use of induction therapy. They did find an operative mortality rate of 24% for patients undergoing right pneumonectomy following induction therapy. This number was higher than previous mortality rates seen in trials wherein patients did not have induction therapy. The authors recommended that right pneumonectomy after induction therapy be performed very selectively and only when no alternative resection is possible.

A third French series reviewed 114 patients who underwent thoracotomy following induction chemotherapy.[30] In this series, there was only one death following pneumonectomy in 55 patients. Overall morbidity rate was 29%, similar to other surgical series. The authors concluded that preoperative chemotherapy did not increase postoperative morbidity and mortality.

The conclusion from these series is that induction chemotherapy is likely to be a feasible and safe procedure, not impacting on complication and hospitalization rates, with the possible exception of right-sided pneumonectomy.

## RECENT EVIDENCE

The feasibility and safety of preoperative chemotherapy using third-generation drugs in early stage NSCLC, classified according to the 1997 staging classification, was prospectively established in the Bimodality Lung Oncology Team (BLOT) trial.[31] This phase II trial enrolled two sequential cohorts of patients with clinical stage IB, II, and IIIA patients. Clinical staging was defined by computed tomography (CT) imaging, and all patients were required to undergo mediastinoscopy. Positron emission tomography (PET) imaging was not routinely performed in this study. Patients with mediastinoscopy proven N2 disease or superior sulcus tumors were excluded from this trial. Patients were treated with paclitaxel and carboplatin before and after surgery (number of cycles in cohort I: 2 pre and 3 post; cohort 2: 3 pre and 4 post). For the two cohorts combined, the radiographic response rate was 51%, complete resection rate was 86%, and pathologic complete response rate was 5%. Three- and five-year survival rates were 61% and 45%, respectively, and comparable with historical series.[2,27] There were no significant differences in patient characteristics or outcome between the two cohorts. A detailed analysis of the radiological and pathological responses showed a lack of correlation between both, with 50% of, patients who were found to have equivalent or more extensive disease at surgery, having major chemotherapy responses. Two postoperative deaths occurred. A total of 96% of patients received the planned preoperative chemotherapy versus 45% receiving postoperative chemotherapy.

At least five randomized trials have since explored the issue of neoadjuvant chemotherapy. A common feature of these trials is that they all have been confronted with accrual problems, leading in some studies to their early closure, when the results of randomized trials showing a benefit of adjuvant chemotherapy were published. Table 54.1 details the patient, tumor and treatment characteristics of the two trials whose mature results are available.

The Southwest Oncology Group trial S9900 was a phase III randomized study comparing induction paclitaxel/carboplatin chemotherapy for three cycles followed by surgery to surgery alone in clinical stage IB, II, and IIIA NSCLC (excluding superior sulcus and N2 disease). Mediastinoscopy was performed whenever the mediastinal lymph node size exceeded 1 cm. PET imaging was not required. As such, the study built on the previously mentioned BLOT data and called for 600 patients to detect a 33% increase in median survival or 10% increase in 5-year survival. The rationale for the trial was to assess whether preoperative chemotherapy with paclitaxel and carboplatin for three cycles improves survival compared to surgery alone in previously untreated patients with clinical stage IB, II, and selected IIIA NSCLC and to compare operative mortality and other toxicities in the two study arms. Other specific aims included the evaluation of response rates (confirmed and unconfirmed, complete and partial) and the toxicities associated with the combination of paclitaxel and carboplatin.

This trial prematurely closed in June of 2004, when new evidence demonstrated the superiority of adjuvant chemotherapy over surgery alone, making continued accrual to the control arm of S9900 untenable. At the time of study closure, 336 of the planned 600 eligible patients had been enrolled representing one of the largest preoperative randomized trials in early stage NSCLC. Preoperative chemotherapy was well tolerated with 79% of patients receiving all three cycles. Objective responses were documented in 41% and 7% had progressive disease. Seven postoperative deaths were seen in the chemotherapy arm versus four deaths in the surgery-alone arm. With a median follow-up of 53 months, median and 5-year survival rates were 75 versus 46 months, and 50% versus 43% for the chemotherapy/surgery and surgery-alone arms, respectively. Although the use of chemotherapy was associated with a 19% reduction in the risk of death (hazard ratio [HR] = 0.81; $p = 0.19$), this difference did not achieve statistical significance. Progression-free survival trended in favor of neoadjuvant chemotherapy, with a median of 33 months vs. a median of 21 months for immediate surgery ($p = 0.07$; Fig. 54.1). Results have been presented in abstract form only to date.[32] Patient characteristics were well balanced between the two groups.

In the European Intergroup trial MRC-LU 22 EORTC-08012 NVALT-2, 519 patients with resectable early stage NSCLC were randomized to either surgery alone or three cycles of platinum-based chemotherapy followed by surgery. Choice of chemotherapy regimen was at investigator's choice, as was the intensity of preoperative staging, resulting in only one fourth of the patients being staged with mediastinoscopy and/or PET scan. Their characteristics were equally well balanced between both arms. This trial was also prematurely closed for slowing accrual and its results reported.[33] Of the patients randomized to chemotherapy, 75% completed three cycles of chemotherapy, 49% had radiographic response, and 81% had complete resection. Seventy-nine percent of patients on the control arm had a complete resection. With a median follow-up of 41 months, median and 5-year survival rates were 54 versus 55 months, and 44% versus 45% for the chemotherapy/surgery and surgery-alone arms, respectively. A peculiar finding is the inaccuracy of clinical staging, whereas 18% of the patients who were resected without neoadjuvant chemotherapy actually had a lower pathological than clinical stage, and 41% were likewise "upstaged." Patient's quality of life seemed not to suffer from the use of chemotherapy and the delayed resection.

Besides their low power and accrual, both trials have two further weaknesses in common: the survival in both control arms treated with immediate surgery is better than initially

**TABLE 54.1** Summary Characteristics of Two Randomized Trials Comparing Neoadjuvant Chemotherapy to Immediate Surgery

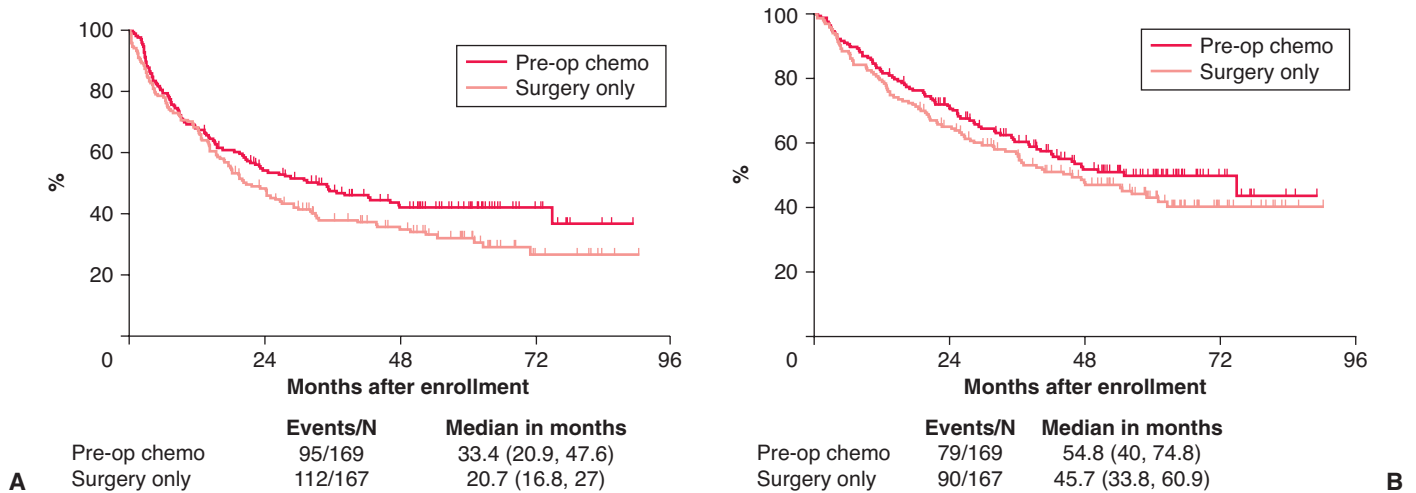

**FIGURE 54.1** Surgery alone (*bottom line*) or surgery plus preoperative paclitaxel/carboplatin chemotherapy (*top line*) in early stage NSCLC. **A:** Progression-free survival. **B:** Overall survival. (From Pisters KM, E. Vallieres E, Bunn PA, et al. S9900: Surgery alone or surgery plus induction (ind) paclitaxel/carboplatin [PC] chemotherapy in early stage non-small cell lung cancer [NSCLC]: Follow-up on a phase III trial. *J Clin Oncol* 2007;25[18S]:7520.)

estimated, compounding the underpowering caused by the early closure of these trials, and stage I (clinical or pathological) accounted for more than 50% of the enrollment to both trials. The accumulated evidence in the adjuvant setting has not found a statistically significant survival benefit for postoperative chemotherapy in stage I disease.[9] The implication of this finding in the neoadjuvant setting might imply that a possible benefit for higher stages was diluted.

Mature result of three more trials are awaited. In the European chest trial, prematurely closed in August 2004, 270 patients with stages 1B to IIIA (T3N1) NSCLC were randomized to either surgery alone (141) or three cycles of cisplatin and gemcitabine (129) followed by surgery.[34] Eighty-six percent of the patients in the chemotherapy arm received all three cycles. The response rate was 35% (complete response [CR] = 3%; partial response [PR] = 32%) and 6% of the patients progressed through chemotherapy. A total of 97% of the patients in the surgery group received surgery, whereas 85% went onto surgery in the chemotherapy group. Causes for no surgery included patient refusal, progression, and lost to follow-up. There was a significant difference in progression-free survival favoring the chemotherapy group (HR = 0.71; CI, 0.50 to 0.98; $p = 0.011$). The benefit was greatest for the IIB and IIIA groups. Overall survival favored the chemotherapy group (HR = 0.63; 95% CI, 0.42 to 0.89; $p = 0.005$). The benefit was again greatest for the IIB and IIIA groups.

Three more European randomized trials comparing surgery with or without neoadjuvant chemotherapy have recently been presented as abstracts, with contradictory results. A Spanish trial found no outcome difference at 5 years,[35] a Scandinavian an HR of 0.89,[36] and an Italian an HR of 0.63 at 3 years,[37] both in favor of neoadjuvant chemotherapy.

# SYSTEMATIC REVIEWS AND METAANALYSES

Two systematic reviews from published summary data of randomized chemotherapy trials in early stage NSCLC have been published.[8,37] These metaanalyses should be interpreted with caution, as they were not based on individual patient data (IPD), but on data extracted from abstracts and manuscripts. An IPD metaanalysis is considered vastly superior to one based on abstracted or pooled data, as it allows verification of randomization and patient data, updates the data, and is highly reliable. Drawbacks to the IPD metaanalysis are its increased cost and length of time required. Furthermore, most literature-based systematic reviews appear to be good proxy's of their ensuing IPD metaanalysis. The metaanalysis by Berghmans et al.[9] reported six randomized trials, including 590 patients, published between 1990 and 2003. The overall fixed-effect HR on survival was 0.69 (95% CI, 0.57 to 0.84), in favor of the addition of neoadjuvant chemotherapy to surgery. A less extreme result was seen in the publication by Burdett et al.[38] Data from seven randomized trials (published between 1990 and 2005), including 988 patients were combined in a systematic review and metaanalysis. Preoperative chemotherapy improved survival with an HR of 0.82 (95% CI, 0.69 to 0.97), equivalent to an absolute benefit of 6% at 5 years. They, furthermore, found an incremental benefit by stage (stage IA = +4%; stage IB = 6%; stage II to III = +7%) but did not observe any interaction between the kind of platinum-containing regimen or the kind of adjuvant treatment (chemotherapy or radiotherapy). The exploratory nature of these subgroup analyses warrants an IPD approach, which is ongoing. Gilligan et al.[33] added the mature results of the European Intergroup trial to the previous metaanalysis and observed a shift of the HR to

|  | Number of patients | | | |
|---|---|---|---|---|

**FIGURE 54.2**    Hazard ratio plot for overall survival. Each individual trial is represented by a *square*, the center of which denotes the hazard ratio for that trial. The extremities of the *horizontal bars* denote the 99% CIs and the *inner bars* mark the 95% CIs. The size of the *square* is directly proportional to the amount of information in the trial. The *filled diamond* at the bottom of the plot gives an overall hazard ratio for the combined results of all trials. The center of the *diamond* denotes the hazard ratio for all trials and the extremities the 95% CIs. Trials are ordered chronologically by the age of the trial, with the oldest listed first. *95% CI*, 95% confidence intervals; *CT*, chemotherapy; *df*, degree of freedom; *HR*, hazard ratio; *S*, surgery. (Adapted from Gilligan D, Nicolson M, Smith I, et al. Preoperative chemotherapy in patients with resectable non-small cell lung cancer: results of the MRC LU22/NVALT 2/EORTC 08012 multicentre randomised trial and update of systematic review. *Lancet* 2007;369:1929–1937.)

0.87 (95% CI, 0.76 to 1.01), with loss of the significance of the improvement in outcome (Fig. 54.2, Table 54.2).

## CONCLUSION

Do the observed results of neoadjuvant therapy in NSCLC match with the expectations?

The available outcome data trend in favor of neoadjuvant therapy, but the majority of individual trials did not find a statistically significant benefit. This can be a result of the underpowering of the individual studies or contamination of the outcome by the use of adjuvant therapy in some

of them. The data of both systematic reviews, on the other hand, show an overall effect that is significantly in favor of neoadjuvant treatment. The size of the observed effect is comparable to the one described in a similar metaanalysis of adjuvant chemotherapy[9] (Table 54.2). One must keep in mind that both patient populations are different, as only selected patients are offered adjuvant chemotherapy, after pathological staging. The lack of clinicopathological correlation observed in the BLOT and European Intergroup trial illustrates the heterogeneity of patients enrolled on neoadjuvant trials.

As the standard of care in resected NSCLC has since shifted to the selective use of adjuvant chemotherapy, the focus for further research might be redirected toward comparing neoadjuvant and adjuvant chemotherapy. It is, however, dubious whether this issue will ever be adequately addressed, as large number of patients will have to be included in such an undertaking. A randomized trial addressing this issue was recently closed secondary to poor patient accrual. The introduction of novel biological adjuvant approaches and the renewed interest for postoperative radiotherapy will confound and interfere with the results of any strategy aiming at the sole use of chemotherapy.

Neoadjuvant chemotherapy results in a clinical downstaging in approximately 40% to 60% of the patients and

| **TABLE 54.2** | **Metaanalysis of Outcome of Perioperative Platinum-Based Chemotherapy in NSCLC** | |
|---|---|---|
| **Hazard Ratios (95% Confidence Intervals)** | **Adjuvant Chemotherapy** | **Neoadjuvant Chemotherapy** |
| Early evidence[8] | 0.86 (0.80–0.92) | 0.66 (0.48–0.93) |
| Recent evidence | 0.89 (0.82–0.96)[9] | 0.88 (0.76–1.01)[33] |

a pathological complete response rate in 5% to 10%. As expected, compliance is better with neoadjuvant chemotherapy compared to adjuvant treatment: more than 70% of the patients are able to complete all three cycles of neoadjuvant chemotherapy, whereas the full planned adjuvant chemotherapy could only be administrated in 45% to 60% of patients. Compliance with adjuvant chemotherapy may improve in the future now that it has proven effective in prolonging survival.

The feasibility and safety of preoperative chemotherapy has been established in several trials. Surgical concerns regarding neoadjuvant chemotherapy can be eased, as it does not result in an increased length of hospital stay or a significantly increased rate of perioperative complications, when compared to immediate surgery. One possible exception to this is increased mortality seen in patients undergoing right pneumonectomy following induction therapy. Induction chemotherapy also does not negatively influence patient's quality of life.

With the present status of knowledge, neoadjuvant regimens should be platinum-based, and at least three cycles of chemotherapy should be administered. As in advanced NSCLC, a two-drug combination of platinum and a third-generation drug seems preferable. The role of nonplatinum-containing regimens has not been explored up to now and remains an area of future research.

In conclusion, the current data favor the use of adjuvant (postoperative) chemotherapy in patients with resectable NSCLC. The neoadjuvant trials lend further support to the role of systemic therapy in operable lung cancer patients, but the data for its use is not as strong as it is in adjuvant therapy. At this time, preoperative therapy should not be offered outside of a clinical trial.

# Preoperative Chemotherapy/Radiation Therapy for Early Stage and Locally Advanced Non–Small Cell Lung Carcinoma

Surgery remains the cornerstone of management for patients with non–small cell lung cancer (NSCLC). Unfortunately, at the time of initial diagnosis, approximately half of all patients have localized disease and less than a third are candidates for surgical exploration. Despite complete resection, 5-year survival rates are disappointing, ranging from 73% for T1N0 disease to 24% for patients with T1–3N2 based on the proposed International Association of the Study of Lung Cancer staging recommendations (Table 55.1).[1] The ability of a patient to undergo a surgical resection of their lung cancer is associated with an improved survival, but this is the result of many factors. Despite complete resection, many patients develop local and distant recurrence and die as a result of uncontrolled lung cancer.

Efforts at improving survival for patients with resectable NSCLC, as well as those with potentially resectable, more advanced local disease, examined the use of chemotherapy or radiation in the postoperative (adjuvant) or preoperative (neoadjuvant or induction) settings. Postoperative therapy is discussed in Chapter 53. This chapter will focus on the use of chemotherapy and/or radiation in the preoperative setting. In approaching this topic, the reader must understand that this is one of the most controversial topics in the management of potentially resectable NSCLC. Some of the more contentious inquiries include: (a) whether it is justified to consider induction therapy in patients who, at presentation, can have a definitive (R0) resection of all disease; (b) whether a surgical resection should ever be performed after combined modality treatment in stage IIIA/B disease; (c) what (if any) pretreatment patient characteristics help determine the optimal method of local control; (d) what prescription for the timing of the local and systemic therapy best maximizes treatment effect with a minimum of complications; and (e) what specific cytotoxic chemotherapy combinations should be used. For patients with locally advanced disease, the current standard of care is concurrent chemotherapy and radiotherapy (chemoRT), and the long-term survival results in reported randomized phase III trials are between 8% and 15%. The limitations of this approach include persistent local disease, which is reported to be as high as 83% after treatment with chemotherapy and full-dose RT, and very high distant failure rates, primarily in the brain. Moreover, persistence of local disease after completion of treatment portends an especially poor prognosis, not only as a result of the local effects of the uncontrolled tumor but also hypothetically as a potential source of metastatic seeding. Those advocating a surgical removal of residual disease hypothesize that this method for local control could render a proportion of these patients disease free.

The pros and cons of how to orchestrate chemotherapy, RT, and surgery for locally advanced lung cancer revolve around the optimization of dose intensity, toxicity, and efficacy. Patients have better tolerance of adjunctive therapies prior to thoracotomy, resulting in improved delivery of planned doses of chemotherapy and RT. The ability to actually monitor the sensitivity of the tumor to the therapy at a time when micrometastatic disease may be lowest, while also cytoreducing the local tumor burden (possibly leading to improved resectability and a potential for less pneumonectomies) are appealing hypotheses for an induction strategy. Arguments against a neoadjuvant approach revolve around the impact of the therapy on the presurgical, nutritional, and immunological status of the patient, possibly leading to a delay of definitive surgery, early tumor progression, technically challenging surgery (especially if RT is incorporated in the induction program) and poor postoperative healing.

The most significant argument against the use of preoperative chemotherapy may be that the benefit associated with chemotherapy use in NSCLC has been rather extensively demonstrated in the postoperative setting.[2–4] This benefit appears to increase with more advanced disease. The investigations into adjuvant chemotherapy were based on a metaanalysis suggesting a potential benefit.[5] With more trials of preoperative chemotherapy having been completed over time, similar analyses have recently been performed, with results suggesting a possible survival benefit.[6–8] Given the heterogeneous populations that represent the patients with lung cancer clinically, some patients will benefit more from adjuvant therapy, whereas other patients may benefit more from induction therapy.

# INDUCTION THERAPY FOR LOCALLY ADVANCED LUNG CANCER (STAGES IIIA AND IIIB)

## First-Generation Induction Trials

**Radiation Therapy as the Sole Induction Modality** The initial trials of preoperative RT from the 1950s to the early 1970s were conducted without the benefit of modern staging technologies[9–12] and before effective cytotoxic chemotherapies for NSCLC existed. Pathologic complete responses (pCRs) were reported in up to 27% of patients, but operative morbidity rates rose with RT doses greater than 40 Gy. A large randomized study published in 1975, however, found no difference in overall survival (OS),[12] and a subsequent study from the Lung Cancer Study Group (LCSG 881)[13] for patients with pathologic stage IIIA (N2) disease given 44 Gy before surgery had disappointing results, with only one pCr and a median survival of 12 months. The last randomized trial that used RT alone as induction treatment was Cancer and Leukemia Group B (CALGB 9134).[14] This trial closed early because of poor accrual, and long-term results were not encouraging. Thus, based on more recent studies, RT is no longer recommended as the sole induction modality prior to surgery.

**Early Phase II Studies of Induction Chemotherapy with or without Radiotherapy** In the 1980s, a series of phase II induction trials of first-generation cisplatin-based chemotherapy were performed with or without sequential RT prior to surgery.[15–19] These were small trials with staging heterogeneity, and broad variability in both the amount of low- versus high-volume disease and in the percentage of biopsy-proven N2 disease. Three trials employed the CAP regimen (cyclophosphamide, doxorubicin, and low-dose cisplatin), whereas two studies used cisplatin plus etoposide-based preoperative chemotherapy. The study designs and outcomes of these trials are outlined in Table 55.2.[15–19] Response rates (RR) from the induction therapy were 39% to 82%, resection rates (percent of original number accrued) were 14% to 88%, and the survivals were highly variable. Staging and volume of tumor differences within these trials preclude conclusions about efficacy or comparisons across trials; however, these pivotal studies demonstrated the general safety of surgery after induction therapy and in some instances, provided intriguing survival data.

Therefore, larger, second-generation trials were designed that enrolled more restricted stage subsets, and required, in most instances, pathologic documentation of nodal disease. The following sections review the major categories of second-generation studies and long-term survival from selected trials.

## Second-Generation Phase II Studies of Induction Chemotherapy as the Sole Induction Modality

Five phase II second-generation studies of induction therapy tested preoperative chemotherapy. These trials are described in Table 55.3.[13,20–25] Although all studies required pathologic documentation of N2 disease, tumors with a wide range of disease bulk were accrued. The LCSG 881 trial was a two-arm phase II randomized trial, in which one arm was assigned preoperative chemotherapy and the other received preoperative RT.[13] The results were reported for the entire group of patients and not separately for each treatment arm. Four of the studies utilized preoperative vinblastine and cisplatin with or without mitomycin C (MVP, VP [etoposide + cisplatinum]), and the fifth trial tested continuous infusion cisplatin and 5-fluorouracil (5-FU) with leucovorin rescue. The RT was variably given (intraoperative, postoperative, or not at all), and information on why RT was either given or withheld was not provided in detail for some of the studies. Thus, lack of concordance on the disease bulk and RT utilization variables makes comparison of results among the studies difficult.

Resection rates (based on the entire denominator) were 51% to 68%. Postoperative mortality ranged from 0% to 18%. The causes of death were predominantly pulmonary or

cardiopulmonary. Pulmonary complications attributable to mitomycin C in the Memorial Sloan-Kettering study, including the three lethal ones, all occurred after the cumulative dose of 24 mg/m$^2$. The studies that did not use mitomycin C had lower perioperative death rates. pCR rates ranged from 0% to 15%. Postoperative RT did not provide additional benefit in the Memorial Sloan-Kettering study ($p = 0.24$); however, the selection of patients receiving RT was based on unfavorable response to neoadjuvant chemotherapy, not by randomized assignment. In the Dana-Farber study, all mediastinal downstaging to N0 or N1 occurred in patients with low-volume disease. The CALGB study noted that persistent N2 disease following induction chemotherapy is unfavorable. Although there was no correlation between radiographic response to the induction regimen and pathological downstaging at the time of surgery, patients with a pCR in N2 nodes were felt to potentially benefit from surgical resection. Survival outcomes were highly variable, with median survival ranging from 12 to 21 months, because of differences in the study eligibility and design, as reviewed previously. In the Dana-Farber study and CALGB trial 8935, 15% and 41% of first relapses occurred in the brain, respectively.

## Second-Generation Phase II Studies of Induction Chemoradiotherapy before Surgery

**Trial Designs and Results** The other major category of second-generation induction studies utilized concurrent chemoRT induction therapy in which the RT began on day 1 of the chemotherapy. These phase II trials are described in Table 55.4.[26–30] The RT varied in schedule (continuous to split course) and in total dose (30 to 59 Gy, single fractionation). All induction chemotherapy was cisplatin-based, with the addition of either etoposide, 5-FU, vinblastine, or some combination of these drugs. The treatment prescribed after surgical resection was not uniform among these five studies. There was no therapy after surgery in the Rush-Presbyterian and LCSG 852 trials; two cycles of additional chemotherapy plus 14 Gy of RT were given in the Southwest Oncology Group (SWOG) 8805 study (if residual disease in chest or mediastinum); and one cycle of chemotherapy plus 30 Gy of RT was used in the CALGB trial (all patients). The Tufts investigators initially gave etoposide plus cisplatin postoperatively, but later in the trial allowed use of the carboplatin plus paclitaxel regimen.

CALGB, Cancer and Leukemia Group B; Carbo, carboplatin; E, etoposide; F, 5-fluorouracil; Gy, gray; LCSG, Lung Cancer Study Group; NS, not stated; P, cisplatin; SWOG, Southwest Oncology Group; T, paclitaxel; V, vinblastine.

Eligibility criteria for the five second-generation chemoRT induction trials were more varied than for the studies of induction chemotherapy alone. Biopsy documentation of N2 disease or T4 status was required only in the SWOG, LCSG, and CALGB trials, and the SWOG trial was unique in this regard because pathologic proof of N2, T3, or N3 disease was mandated. A broad range of stage subsets were included across trials, so that stage IIIA (N2) accounted for 47% to 87% of patients per trial. Two studies included T3N0 or T3N1 (21% and 20% in the Rush-Presbyterian and CALGB studies, respectively), whereas all patients with stage IIIA disease in the SWOG 8805, LCSG 852, and Tufts trials had N2 nodal involvement. The stage IIIB subsets of T4 and/or N3 were allowed in all trials except the CALGB study and accounted for 6% to 53% of patients per trial. The SWOG 8805 and Tufts trials were designed for bulky disease, whereas the others allowed a mix of minimal and bulky presentations.

Response or "response plus stable" (one study) rates were 56% to 92%, and 52% to 76% of the total number of patients accrued to each study had a complete resection at thoracotomy. Twenty-six of the thirty patients with stable disease as their "best" response to induction chemoRT underwent a complete resection of tumor in the SWOG 8805 trial.[26] The pCR rates were 16%, 21%, and 27% in the LCSG, SWOG, and Rush-Presbyterian trials, respectively.[26,27,30] An additional 37% had rare microscopic foci of tumor cells as the sole residual disease in the SWOG trial. It was demonstrated that postinduction assessment of nonresponse by computed tomography (CT) scan is often misleading because 46% of the 26 patients with resectable stable disease in the SWOG study had pCR or only rare microscopic foci.[26]

The operative mortalities were predominantly pulmonary related, as observed in the induction chemotherapy trials. The cause of death often resembled the adult respiratory distress syndrome (ARDS) to be considered in more detail in the morbidity and mortality section of this chapter. The Tufts trial was unique in that postoperative ARDS was not observed, despite the high total dose of induction RT.[28] A rigid protocol to minimize fluids, transfusions, and the fraction of inspired oxygen (Fi02) was employed in this study. The Tufts trial also utilized a higher dose of preoperative RT, a prescription similar to those used for standard concurrent chemoRT without surgery. Thus, most of the allowable dose of RT was given upfront without a break. In the other trials, truncation of the RT occurred at around 45 to 50 Gy to plan for the surgery. Thus, patients with residual disease or unresectable disease could only receive full-dose RT via an interruption of several to many weeks, depending on time to recovery from surgery.

The median survival for the two studies that excluded T3N0–1 tumors and required pathologic staging were 15 and 13 months.[26,30] In contrast, the other three trials included this better prognostic subset and did not require biopsy proof of the T and N substages. For these studies, the median survivals were 22, 16, and 20 months.[27–29] Patterns of first recurrence in the SWOG 8805 trial were 11% (locoregional only) and 61% (distant alone).[26] There was no difference in the sites of

relapse between those patients with negative mediastinal nodes at the time of operation (but originally positive) versus those who had persistent involvement of the mediastinal nodes. A significant number of the distant first relapses (and in many cases, the only relapse or the sole cause of mortality) occurred in the brain.[26] The LCSG investigators noted that in patients who had complete resection, 28% of first recurrence sites were in the brain, in contrast to only 7% in patients who did not undergo surgery. In patients who experienced a recurrence in the brain, in almost one third that was the sole site of recurrence. Similar findings were noted by the SWOG 8805 study. The CALGB protocol called for prophylactic cranial irradiation (PCI) in patients with nonsquamous histologies who completed all the treatment, but about one third of eligible patients did not receive it. None of 13 patients who received PCI developed brain metastases, compared to 1 out of 7 who were eligible but did not receive it. The Tufts investigators also reported a very high rate of isolated brain metastases, all of which occurred within the first 32 months of follow-up.[28]

## The Stage IIIB Subgroup in Second-Generation (and Subsequent) Studies of Chemoradiotherapy Induction Trials

From a subset of these second-generation chemoRT trials, data are available regarding the role of induction therapy followed by surgery in selected stage IIIB subsets. The LCSG 852 trial and the Rush-Presbyterian study included 13% "minimal T4" and 6% "selected T4" lesions (clinically staged), respectively.[27,30] Separate survival data for this subset were not provided. Of note, two groups of investigators had reported equivalence in outcome of clinical stage IIIA and IIIB disease in combined modality trials with no surgery.[31,32] However, these authors suggested that the clinical T4N0 subset may have a better outcome than the other subsets and perhaps should be removed from the IIIB category, just as the T3N0 subset had been reassigned to stage IIB instead of its former designation of IIIA.[33] Based on this observation in chemoRT-alone trials, the SWOG 8805 study was designed prospectively to include a sufficient sample of the stage IIIB subgroup to allow independent assessment of outcome.

The SWOG 8805 trial was unique among the other chemoRT trials in that it included stage IIIB disease. Pathologic documentation of T4 or N3 disease was required and outcome was analyzed separately for this subset.[26,34] The Tufts investigators also reported outcome separately for the IIIB group, but the staging requirements were radiographic rather than pathologic.[28] The resection rates in these two studies for stage IIIA(N2) were 76% and 76%, and 63% and 50% for stage IIIB, respectively.

The median, 2- and 3-year survivals were identical for the IIIA (N2) versus the IIIB group in the SWOG 8805 study (27%, 24%).[26] This phenomenon was not seen in the Tufts trial where the 3-year survivals were 73% and 32% for the clinical IIIA (N2) and IIIB subsets, respectively, possibly because of the aforementioned staging requirements leading to inaccuracies. Of note, in the SWOG 8805 study, the T4N0–1 subset had an outcome identical to the T1N2 substage and

achieved a 2-year survival of 64%. This substage variable was the only independent predictor of favorable outcome from the time of registration to the study in a multivariate analysis.[26] Exploratory survival analyses were conducted within the N3 subset of the SWOG trial, of which 27 patients were accrued. The 2-year survival for the contralateral nodal N3 subgroup was zero, whereas it was 35% for the supraclavicular N3 subset. However, the resection rate in this latter group was only 39%. An update of SWOG 8805 provided 6-year survival statistics: IIIA (N2), 20%; T4N0–1, 49%; and N2 or N3, 18%.[35]

A follow-up trial to SWOG 8805 for pathologic stage IIIB disease was conducted by the SWOG (SWOG 9019). Identical induction chemoRT was utilized as in SWOG 8805, but no surgery was given; instead, the RT was continued without a break to 61 Gy and two additional cycles of EP were given.[36] The OS in this study was identical to that observed for the stage IIIB group in SWOG 8805. This suggested that in an identically staged patient population, chemoRT with definitive-dose RT may achieve the same benefit as surgical resection after induction chemoRT (and lower RT total dose). However, in the SWOG 9019 trial (chemoRT alone), the 2-year survival was only 33% for the T4N0–1 subset, compared to 64% in 2-year and 49% in 6-year survival in the surgical study, SWOG 8805.[35,36] This historical comparison of these two consecutive trials in pathologically staged IIIB disease suggests *that surgery for stage IIIB tumors might be beneficial only in the select substage of T4N0–1.*

Based on these results, the Spanish Lung Cancer Group performed a phase II trial of induction chemotherapy with a cisplatin-based triplet follow by surgery for stage IIIA N2 and selected stage IIIB (T4N0–1).[37] A total of 136 patients were entered onto the study; the clinical RR in 129 assessable patients was 56%. Completely resected stage IIIA and IIIB patients (68.9% of those eligible for surgery) had an impressive median survival time of 48.5 months, with a 5-year survival rate of 41.4%. For completely resected stage IIIB patients, median survival time was 60.6 months, and 5-year survival rate was 53.2%. In the absence of mediastinal lymph nodes, median survival time for these patients was not reached, and 5-year survival rate was 57%. Still, a prospective randomized study is needed to validate these findings.

Additional studies have commented on the role of induction therapy for stage IIIB disease. Grunenwald et al.[38] prospectively studied 40 patients with stage IIIB disease, of whom 30 had T4 disease and 18, N3. Five patients had T4N0 tumors and one had T4N1. All patients underwent pretreatment surgical staging. Induction treatment consisted of 5-FU, cisplatin, and vinblastine for two cycles. A total of 42 Gy of external RT was given split in two 21 Gy courses, 1.5 Gy bid, with 10 days of rest between the courses. Patients who responded to the induction regimen underwent thoracotomy. A clinical response was obtained in 73% of patients and in 60% resection was performed. The resection was complete in all but one patient who underwent thoracotomy. Four patients (10%) had complete pathological response and 30% had complete mediastinal clearance. There were five treatment-related deaths and seven

additional patients suffered serious morbidity. Median survival was 15 months and 5-year OS was 19%. Thirty percent of overall patient number had locoregional relapse and 50% had distant relapse. Pathological mediastinal nodal downstaging was the only significant favorable prognostic factor in a multivariate analysis (5-year survival 42% for postinduction N0/N1 vs. 12 % for postinduction N2/N3 for resected patients). All long-term survivors had persistent viable tumor cells in the primary tumor but six of seven were postinduction N0–1.

Pitz et al.[39] treated patients with stage IIIB NSCLC with neoadjuvant gemcitabine and cisplatin without RT, followed by surgery in responding patients. There was an RR of 66%, resection rate of 44%, and perioperative mortality of 2.4%. Median survival for all patients was 15.1 months and 3-year survival was 15%. The investigators found no difference in outcome between T4N0 and N2/N3 subsets. However, only patients with a response after induction chemotherapy were considered for surgical resection.

These trials highlight that the T4N0/N1 substage as a group does particularly well with trimodality therapy.

## Second-Generation Induction Trials: Long-Term Survival and Predictors of Outcome

**Mature Survival Data** Long-term survival data were reported in several of the trials of induction chemotherapy and induction chemoRT (Table 55.5). Several of the trials suggest that a plateau emerges on the tails of the survival curves, as 5- to 7-year survival of 17% to 34% were reported. Despite differences in methodology and patient populations, the long-term outcomes were encouraging and provided support for subsequent phase III trials.

**Factors that Predict Favorable Outcome** The seven phase II trials of induction chemotherapy or chemoRT depicted in Table 55.5 also analyzed predictors of long-term survival. Favorable outcome predictors included postinduction pCR, complete resection, T3N0 or T3N1 disease, T4N0 or N1 disease, and pathologic clearance of initial N2 or N3 involvement (nodal downstaging). The significance of these predictive factors varied across trials, but all factors were not uniformly assessed in each study. Nevertheless, in most trials, a factor related to the *efficacy* of the induction therapy was important. It was suggested that the inclusion of RT in the induction removes the possible importance of pCR as a predictor observed in chemotherapy-only induction programs. However, the Memorial Sloan-Kettering Cancer Center trial of MVP alone did not report statistical significance to pCR.[24,40] Response to induction therapy was not an important predictive factor in some trials, most likely because of the mandate in those studies to resect disease even if "stable" was the best response.[26] This observation underscores the inability of standard CT scanning to detect those patients with major postinduction responses.

The SWOG 8805 trial analysis showed that nodal downstaging was an independent favorable prognostic impact of intermediate (2- to 3-year) survival is of interest, and was the

only significant factor in a multivariate model that included complete resection rate, pCR, and multiple other factors.[26] This variable was also the most important univariate discriminant of 6-year survival, although complete resection emerged as a long-term survival predictor as well.[35] The survivals 3 and 6 years after thoracotomy for patients with uninvolved nodes at surgery were 41% and 33%, respectively, versus only 11% and 11% if there was persistent mediastinal disease. Unfortunately, the prognostic impact of nodal downstaging was not assessed in multivariate models for any other study with second-generation therapy.

Implications of the nodal downstaging observation are that lack of residual disease in the mediastinum may be a surrogate marker for eradication of distant chemotherapy-sensitive micrometastases, implying that these patients may be the optimal candidates for additional postoperative chemotherapy. Conversely, persistent N2 or N3 disease may predict the presence of distant resistant disease. Thus, one wonders whether surgery is necessary for those cases with nodal downstaging, or are these patients the best candidates for maximal local control with surgery? If postinduction mediastinal status is clearly of prognostic value, then there would be a critical role for a second mediastinal assessment after induction, even though, in some cases, this would be technically difficult. How to assess the mediastinum after induction therapy remains an enigma, and the role of positron emission tomography (PET) scanning in this regard as well as the use of new bronchoscopic techniques are discussed in Chapters 27 and 28.

### Third-Generation Phase II Studies of Induction Chemotherapy plus Concurrent Hyperfractionated Radiotherapy

Four phase II induction trials used platinum-based chemotherapy and hyperfractionated RT either with a planned break or with radiation intensification by delivering it in an accelerated fashion. These trials are summarized in Table 55.6. The Massachusetts General Hospital (MGH) study enrolled 42 patients with histologically confirmed N2 disease to a preoperative regimen consisting of split course, hyperfractionated RT concurrent with chemotherapy.[41] The volume of mediastinal disease among patients was mixed in this study with 33% of patients having mediastinal lymph nodes smaller than 1 cm on a pretreatment CT, and 19% having lymph nodes that were greater than 2 cm. Twelve gray of postoperative RT was given for either complete response or microscopic disease only, and 18 Gy for residual disease or positive margins, concurrent with chemotherapy.

The West German Cancer Center (WGCC) study used three cycles of induction chemotherapy, followed by continuous hyperfractionated accelerated RT concurrent with chemotherapy.[42–44] Patients eligible for enrollment had to have either surgically unresectable disease, or more than one ipsilateral mediastinal lymph node involved, or positive contralateral mediastinal lymph nodes. This study mandated repeat mediastinoscopy at the completion of induction treatment. Only those patients whose mediastinal tumor burden was downstaged (defined as a negative mediastinal biopsy or only one positive lymph node) were offered surgical resection. Thus, not all patients with stable disease were mandated to proceed to thoracotomy, and the patients who did not undergo resection of residual disease were given additional RT to a total of 60 Gy. These investigators reported a high incidence of isolated brain relapse and introduced PCI in the third year of the study. The PCI dose was 30 Gy in 2 Gy fractions over 3 weeks, starting 1 day after the last chemotherapy administration.

The German Lung Cancer Cooperative Group (GLCCG) trial accrued 54 patients to a regimen that consisted of two cycles of induction chemotherapy, followed by hyperfractionated accelerated RT concurrent with chemotherapy, followed by resection.[45] Eligibility criteria included either biopsy-proven N2 disease or clinical T4 or N3 disease. Patients who had a tumor

response or stable disease were eligible for surgery. Patients who did not have complete resection received additional 16 Gy of RT.

The Cleveland Clinic trial enrolled 105 patients with pathologically proven IIIA (n = 78) or IIIB (n = 27) NSCLC to a study of accelerated multimodality therapy, consisting of hyperfractionated RT with concurrent chemotherapy (paclitaxel and cisplatin) followed by resection.[46] All patients then underwent postoperative chemoradiation.

The results of these trials are presented in Table 55.6. Treatment-related mortality was 7%, 6%, 9%, and 2% and postoperative mortality 5%, 7%, 8%, and 1% (of patients who underwent thoracotomy) in the MGH, WGCC, GLCCG, Cleveland Clinic trials, respectively. The main perioperative complication seen in both WGCC and GLCCG trials was bronchial stump insufficiency, most often after right-sided resections. After both groups started reinforcing bronchial stumps with tissue later in each trial, the incidence of this problem dropped to zero.

A complete resection with negative margins was accomplished in 81% of all patients in the MGH trial. The median survival was 25 months and OS was 66%, 37%, and 37% at 2, 3, and 5 years, respectively. Of interest, the preoperative size of mediastinal nodes (≤1 vs. >1 cm) did not influence the survival, but the sample size was very small. Four patients had pCR, three of whom showed only a partial response on postinduction CT. Five-year survival was 79% if the nodes were downstaged to N0.

Sixty-four percent of patients entered on the WGCC study were eligible for surgery after the induction regimen, and 53% had complete resection with negative margins. A total of 24 (26%) had complete pathological response. Among 29 patients with radiographically stable disease after the induction treatment, about a third was completely resected and 3 had pathological complete response. Median survival was 20 and 18 months and 3-year survival were 36% and 31% for stages IIIA and IIIB, respectively (no statistical difference). No differences were observed for the different TNM categories and T (T1/T2 vs. T3/T4) and N (N0/N1 vs. N2/N3) subgroups. The complete resection rates were 60% for IIIA and 45% for IIIB. Of eight patients with T4N0–1, six were able to have a complete resection. PCI markedly reduced the incidence of brain relapse, but the difference in median survival (26 months with PCI and 20 months without) did not reach statistical significance, possibly because the follow-up period for the first group was shorter.

A complete resection with negative margins was achieved in 63% of patients enrolled on the GLCCG trial. Over a half of these exhibited a major histological response, defined as necrosis or fibrosis of more than 90% of tumor cells. Seven (13%) had pathological complete response. Preoperative assessment of response (complete/partial) did not correlate with the degree of tumor regression. Approximately 25% of patients who relapsed had only a local recurrence, whereas 35% had a distant-only relapse. The median survival for the whole group was 20 months, with 2- and 3-year survival of 40% and 30%,

respectively. Median survivals for stages IIIA and IIIB (25 vs. 17 months) showed no statistical significance, as did 2- and 3-year survivals (52% and 35% vs. 30% and 26%).

In the Cleveland Clinic trial, all patients completed induction therapy in 12 days (100%). Ninety-eight patients (93%) were operative candidates. Among the seven inoperable cases, four patients had locoregional progression, two had new distant metastatic disease, and one was considered medically unfit for surgery. Eighty-three patients (79%) underwent curative resection. There were no clinically determined complete responses, probably because of the brief interval between induction therapy and reassessment. A total of 62% of patients had a measurable partial response, defined as a more than 50% reduction in the sum of the crossed diameters of measurable tumor. The 5-year survival for all patients from commencement of therapy was 30%; for the 81 patients who completed multimodality, the 5-year survival was 39%.

The MGH study and the Cleveland Clinic study had higher resection rates and OS than the two German studies but also enrolled patients with less advanced disease. The two German trials had similar patient populations, treatment, and outcome. The authors of those studies credit the accelerated radiation schedule for the fact that many of their patients with advanced, high-volume disease were able to undergo resection. However, second-generation trials with concurrent chemoRT in patients with high-volume tumor burdens (described previously, e.g., SWOG 8805) also achieved high resection rates.

# COMPLETED RANDOMIZED TRIALS OF SURGERY ALONE VERSUS INDUCTION THERAPY FOLLOWED BY SURGERY IN MIXED-STAGE, RESECTABLE DISEASE

As mentioned briefly earlier in this chapter, four small randomized studies and three large phase III trial of induction chemotherapy for NSCLC were conducted for patients with a surgery-alone arm as the control. These trials are summarized in Table 55.7.[6,47–55] Although surgery alone (with or without some RT) was deemed acceptable for the control arms of these trials, the eligibility criteria regarding degree of homogeneity in the T and N subsets, volume of disease and mandate for pathologic staging varied among the studies. Patients with more advanced disease were enrolled in the National Cancer Institute (NCI) and Japan Clinical Oncology Group (JCOG) trials.[53–54] The NCI trial was the most homogeneous in the stage subsets accrued. However, neither the MD Anderson nor the Spanish studies required microscopic N2 disease and mediastinal node biopsy was not mandated if the CT scan was negative.[47,48,51,52] In fact, in the surgical control arm of the MD Anderson trial, 40% of cases were actually stage IIIB or IV at time of operation. Thus, the treatment groups of the small MD Anderson and Spanish studies had heterogeneous stage subset distributions. The same stage mix issues exist in the large French Thoracic Cooperative Group (FTCG) trial reported by Depierre et al.,[49]

**TABLE 55.7    Reported Phase III Trials of Surgery with or without Induction Therapy Resectable NSCLC**

with some imbalance of stage subsets between the two arms ($p = 0.07$). Furthermore, clinical staging alone was accepted and documentation of N2 status was not required in the FTCG study. The largest of the induction trials was actually a successful collaboration between Medical Research Council (MRC), Dutch Society of Pulmonologist (NVALT), and European Organisation for Research and Treatment of Cancer (EORTC) known as the LU22 trial.[6] In the LU22 trial, 519 patients were randomized between immediate surgery or an induction regimen. The majority of these patients were early stage disease (stage I = 61%, stage II = 31%, and stage III = 7%). N2 status was not documented; for the patients treated with surgery alone, 41% were upstaged by pathological finding. In contrast, both the Scandinavian trial[55] and SWOG 9900[50] required documentation that the mediastinum was not involved prior to enrollment.

The induction chemotherapy regimens for these trials were platinum-based and were also variably given after surgery, depending on the study design. Some of the trials utilized RT if N2 involvement was demonstrated. For the trials that utilized RT, it was employed either postoperatively in the nonchemotherapy arm only of one trial or postoperatively for all patients. Although the use of RT is different in a few trials, several other trials did investigate a question of "pure" induction chemotherapy followed by surgery versus surgery alone.

Most of these trials closed before the target accrual goal was met. The MD Anderson and Spanish studies were stopped early because of large survival differences by data monitoring committees. The others closed because of slow accrual or the inappropriateness of a surgery-alone control arm based on postoperative chemotherapy data. The NCI investigators found no statistical difference between the two arms, but the

*p* value decreased with longer follow-up to 0.11 in favor of the chemotherapy arm.[53] There were differences in recurrence patterns by arm in the NCI trial in that less distant but more local disease was observed in the induction chemotherapy group. In the JCOG trial,[54] both arms had survival comparable to the surgery-alone arm of the NCI study. However, both of these trials were small in number with very heterogeneous populations.

Two small randomized trials were stopped early because of strongly positive results in favor of the induction chemotherapy arms. With additional follow-up of the MD Anderson trial cohort (median follow-up, 81 months), 32% of patients were alive in the induction chemotherapy group versus 16% in the surgery-alone arm (*p* = 0.06).[48,51] The *p* value became significant if only deaths caused by cancer were considered. The update of the Spanish trial has revealed that no patients survived in the surgery group, whereas 16% were long-term survivors in the induction chemotherapy arm.[47,52]

These MD Anderson and Spanish trials generated extensive discussion and debate. The consensus was that these results were provocative but not definitive. There were many aspects of the design and outcome of the studies that clearly called for larger, confirmatory trials in more homogeneously staged subsets subsequently conducted or are ongoing. The major concern was the marked substage heterogeneity within these two trials. It is not clear if early stopping rules for these very small trials accounted for the strong potential influence of even slight substage or molecular prognostic factor imbalances between the two arms. Minor shifts of these factors between arms would have a major impact on the survival differences because of the small sample sizes. Furthermore, the surgical control arms fared poorly, possibly a result of substage imbalances. There were a large number of patients with unexpected stage IIIB/IV disease at time of surgery in the control arm of the MD Anderson trial. The Spanish trial control arm had 37% patients with N0 or N1 disease, but this arm contained more tumors with k-ras mutations and aneuploid DNA, both potential adverse prognostic factors. Small differences in unstratified prognostic factors such as k-ras could potentially affect the results.

These results prompted the initiation of a larger trial, the FTCG trial that enrolled patients with stage IB to IIIA disease.[49] All patients were judged to have resectable disease before any induction treatment. Staging was clinical (radiographic), and presurgery mediastinoscopy was not required. An excess of patients with N2 disease was accrued to the chemotherapy arm (12%), but the difference was not statistically significant (*p* = 0.065). Complete resection rate was 92% in the induction chemotherapy arm, and 86% in surgery-alone arm. Postoperative RT to 60 Gy was delivered for pathologic T3 or N2 status, or if the resection was incomplete. A total of 41% of patients in surgery alone arm and 23% in induction chemotherapy arm received postoperative RT. The 1-, 2-, 3-, and 4-year survivals were 77%, 71%, 59%, and 44%, respectively, in the induction chemotherapy arm and 73%, 52%, 41%, and 35% in the surgery-alone arm. The difference did not reach statistical significance (*p* = 0.15). Stage-adjusted relative risk of death was 0.80 in the chemotherapy arm (*p* = 0.089). In a subset analysis, there was a benefit to induction for patients with N0–1 disease (RR = 0.68; *p* = 0.027), but not for patients with N2 (RR = 1.04; *p* = 0.85). There was excess risk of deaths within the first 5 months after the surgery in the induction chemotherapy arm (RR = 1.32; *p* = 0.37), but the curves crossed at 5 months and the RR in the induction chemotherapy arm decreased to 0.74 after these first 5 months. There was a nonsignificant excess of mortality (10% vs. 5%) in the induction chemotherapy arm, consisting of pneumonia, emphysema, fistula, and pulmonary embolism. Induction chemotherapy reduced the risk of distant relapse (RR = 0.54; *p* = 0.01). Locoregional relapses were not significantly different between the treatment arms.

An additional three trials have been reported involving induction chemotherapy. All three are very similar in that they asked a primary induction chemotherapy question in patients with low burden of disease, of which two trials documented lack of N2 involvement. Also, all three failed to meet their accrual goal. Both the Scandinavian trial and SWOG 9900 utilize an induction paradigm of three cycles of carboplatin/paclitaxel. LU22 allowed three cycles of a platinum-based doublet. Collectively, these trials showed that chemotherapy was tolerable and resulted in a radiographic response in 70% to 80%. Still the resection rates were very good, ranging in the 70%'s for the Scandinavian trial and LU22 to the 90%'s for SWOG 9900. Induction chemotherapy consistently resulted in a slightly higher but nonsignificant resection rate. Lastly, induction chemotherapy in these three trials resulted in improved trends for both OS and disease-free survival.

Recently, several of the phase III trials have been analyzed as part of a metaanalysis.[7,8] The results suggest that, overall, some patients do benefit from induction chemotherapy. In light of the positive evidence in support of adjuvant chemotherapy, it is likely that some future clinical trials will ask the question, which is better, adjuvant or induction chemotherapy? Still, a more thoughtful question might be, which patients benefit from induction chemotherapy and which patients benefit from adjuvant chemotherapy?

## RADIOTHERAPY AS A COMPONENT OF THE INDUCTION REGIMEN

There is debate regarding the role of RT in multimodality induction regimens. Proponents hypothesize that RT increases the rate of downstaging and resectability and plays a role in sterilizing microscopic mediastinal disease that cannot be completely removed during the surgery. Still, nodal downstaging is likely an important predictor of long-term survival. In a retrospective analysis from the University of Toronto, Uy et al.[56] showed that chemoradiation before pulmonary resection in carefully selected patients with surgically resectable stage IIIA (N2) NSCLC can lead to improved overall and disease-free survival.

Whether RT is needed as part of an induction regimen for patients with microscopic N2 disease remains an unanswered question. The only randomized trial to date that addressed the necessity of RT in an induction regimen for high-volume IIIA disease was that of Fleck et al.,[57] conducted in Brazil and reported only in abstract format. Ninety-six patients with either clinically bulky or biopsy-proven stage IIIA(N2) and T4 IIIB disease were randomized between chemoRT followed by surgery versus chemotherapy alone followed by surgery. Two programs commonly employed at the time were compared, cisplatin, and 5-FU plus RT versus the MVP regimen. At the 1994 abstract presentation, survival was significantly better in the chemoRT arm. More neutropenia and neurologic toxicity were observed in the MVP arm, whereas there was a higher rate of mucositis in the chemoRT group. Updated results were provided during a 1997 meeting presentation but are not published at this writing. The 5-year survival was 31% in the chemoRT arm but was only 15% in the MVP arm ($p = 0.05$). However, this study enrolled mixed volume disease with some, but not all, cases pathologically staged.

It is generally agreed that to definitively determine the worth of induction RT, additional studies are needed in a homogeneously staged population, probably with minimally bulky or microscopically involved mediastinal nodes, who receive identical induction chemotherapy on both arms. Moreover, controversy exists regarding the optimal timing of RT with respect to chemotherapy and surgery, as well as the dose of RT. An RT dose prescription of 40 to 45 Gy is generally used in induction regimens because it is efficacious but does not result in excessive perioperative and postoperative morbidity. Somewhat higher rates of postoperative complications were reported in trials that used higher doses of RT, especially in association with pneumonectomy.[58–60] One exception is the Tufts study that did not report any deaths after a neoadjuvant regimen that included 59.4 Gy of RT.[28] The optimal sequence of RT relative to surgery is also an unresolved issue. Patients with large, locally advanced tumors will likely have improved respectability when preoperative RT synergizes with chemotherapy, and there is a greater chance of receiving the entire planned RT dose when it is given preoperatively. Nevertheless, postoperative RT can be given to a higher dose, which may be important in patients for whom a complete resection is not possible. With chemoRT induction protocols, eligibility for surgical resection must be determined before fibrosis sets in, usually 6 to 8 weeks after the completion of the induction with "noncurative" RT doses. This break in therapy, especially for the patients with unresectable disease, may be associated with a detriment in survival.[61,62] This reassessment "break" time must be put in context when considering that many patients receiving postresection RT do not complete the planned treatment.[25]

The schedule of RT in trimodality programs also remains undefined. The hyperfractionated accelerated schedule intensifies the effect of RT, which may be important in locally advanced tumors. This schedule has been well tolerated and has not been associated with excessive rate of perioperative complications in three prospective phase II trials.[41,42,63] A recently completed phase III German trial built upon the phase II results randomized patients with stage IIIA disease after three cycles of cisplatin/etoposide to either hyperfractionated RT (45 Gy = $2 \times 1.5$ Gy/day) with concurrent carboplatin/vindesine, then surgery and, if no or R1/2 resection, additional preoperative hyperfractionated radiotherapy (hfRT; 24 Gy = $2 \times 1.5$ Gy/day) or surgery and postoperative RT (54 Gy or, if no or R1/2 resection, 68.4 Gy = 1.8 Gy/day).[64,65] Because both of the arms included RT, this trial does not test whether RT is necessary for improved survival. Regardless of therapy, the 3-year rate for OS and progression-free survival were 25% and 18% ($p =$ ns). Treatment-related mortality was approximately 5% for both treatment arms. As mentioned, the timing and fraction of the RT as well as the chemotherapy drugs differed between the arms of this trial. A critique of this study includes its low resection rates, suboptimal chemotherapy, and a design that did not contain a control arm with any RT.[66] When published, this trial will also provide important information on the impact of RT on the pathologic RR, nodal downstaging, morbidity, and resectability.

## PHASE III TRIALS OF CHEMORADIOTHERAPY WITH OR WITHOUT SURGERY

Several prospective, randomized trials involving trimodality therapy have been conducted in stage III NSCLC, and all but one closed early without reaching the planned accrual target. They are summarized in Table 55.8. A small NCI Canada study[67] that investigated the efficacy of induction chemotherapy followed by surgery versus RT alone was halted after a CALGB randomized trial showed the superiority of combined chemoRT over RT alone as definitive treatment of stage III NSCLC.[68] A CALGB trial[14] compared induction chemotherapy versus induction RT but closed early because of poor accrual. There was no difference in survival between the arms (median 24 months in RT induction vs. 18 months in chemotherapy induction; $p = 0.46$).

The Radiation Therapy Oncology Group (RTOG) 8901 study attempted to define the role of surgery by comparing whether definitive chemoRT alone to induction chemoRT followed by surgery. The original accrual goal was 244 patients, but the trial closed early because of poor accrual of only 73 patients, revealing no differences in median survival (19.4 vs. 17.4 months) or in 1-, 2-, or 4-year survival (70% vs. 66%, 48% vs. 34%, 22% vs. 22%, respectively).[69] Although patient accrual to this trial made its results inconclusive, several observations are notable. In this trial, histologic confirmation of N2 disease in the surgical and nonsurgical arms eliminated the usual biases from clinical staging. In this setting, local control and survival were essentially equal between the surgical and RT arms. The 3- and 5-year survival rates of nonsurgical therapy were comparable to published surgical trials of N2 disease.

The North American Intergroup trial 0139, chaired by RTOG, is the largest phase III trial to date that addressed the

**TABLE 55.8    Reported Phase III Induction Trials of Chemotherapy for NSCLC**

| Investigators | Stage Subset | Question | Study Design | N | Outcome Comment | | | |

CALGB, Cancer and Leukemia Group B; INT, North American Intergroup; M, mitomycin C; E, etoposide; NSCLC, non–small cell lung cancer; OS, overall survival; P, cisplatin; PFS, progression-free survival; RT, radiotherapy; RTOG, Radiation Therapy Oncology Group; S, surgery; V, vinblastine.

potential value of surgery in stage IIIA (N2) NSCLC.[71,72] The entry criteria for this study included T1-3 primary tumor, pathologically confirmed N2 disease, feasible resection from a surgical standpoint, and medical ability to undergo resection. Patients were stratified by performance status, T1 to T2 versus T3, and whether contralateral mediastinal nodes required biopsy or not (mandated if nodes visible on CT scan), and randomized between the trimodality versus the bimodality arm. The induction regimen was identical in both arms: 45 Gy of external RT given in once-daily fraction, concurrent with day 1 of induction chemotherapy, which was cisplatin, 50 mg/m$^2$ on days 1, 8, 29, 36 and etoposide, 50 mg/m$^2$ days 1 to 5 and 29 to 33. Patients were reevaluated by a CT scan 2 to 4 weeks after completion of the induction regimen in the surgical arm, and in the RT arm, a week before completion of treatment. Those patients with no progression proceeded with their assigned treatment. In the surgical arm, the treatment consisted of resection of all known disease and mediastinal nodal sampling. In the RT arm, the RT continued to 61 Gy without a break. In both arms, consolidation chemotherapy (two cycles of cisplatin and etoposide) was given to all patients. The study initially was designed to accrue 510 patients, but the Data Safety and Monitoring Board recommended closure at 429 patients because of sufficient events based on the slower than anticipated accrual. The second interim results were presented at the ASCO 2005 meeting.[71] At a median follow-up for all patients of 22.5 months (range: 0.9 to 125.1 months) and 69.3 months (range: 6.2 to 125.1 months) for patients still alive, 396 patients were analyzable. Induction treatment was delivered as per the protocol equally in both arms. In the surgical arm,

164 (81.2%) underwent thoracotomy. A complete resection was accomplished in 144 patients (71.3%), incomplete resection in 11 (5.4%), and no resection in 9 (4.5%). There were 18% pathologic complete responses (T0N0) and 46% with pathologic nodal clearance. The chemoRT toxicity was similar in both arms, with the exception of grades 3 and 4 esophagitis, which was more common in the chemoRT alone arm (23% vs. 10%; $p = 0.0006$). Consolidation chemotherapy was not administered to 44% of patients undergoing surgery and 25% of those not having undergone surgery ($p < 0.0001$), reiterating the difficulty of delivering chemotherapy after "definitive" surgical treatment for lung cancer. Conversely, RT was delivered according to protocol in 79% on the chemoRT arm versus 96% on the surgery arm ($p < 0.0001$). Four patients (2.1%) in chemoRT arm and 16 (7.9%) patients in chemoRT-surgery arm died from treatment-related toxicity. In the latter group, 10 of these deaths were caused by postoperative complications. All but two postoperative deaths followed a pneumonectomy (especially right sided), and the most frequent cause of death was ARDS.

Median progression-free survival was 12.8 and 10.5 months in the chemoRT-surgery arm and chemoRT arm, respectively. Five-year progression free survival was 22.4% in chemoRT-surgery arm versus 11.1% in chemoRT arm (log-rank $p = 0.017$). The median OS was 23.6 versus 22.2 months and the 5-year survival was 27.2% versus 20.3% in the chemoRT-surgery and chemoRT arms, respectively (log-rank $p = 0.51$). The OS curves cross over and begin to separate at 22 months. In 5 years, there was a 7% absolute survival benefit in the surgical arm, but the confidence intervals (CI) are wide and overlap. More patients died of treatment

complications in the surgical arm, but more are alive without progression in the same treatment arm. Sites of relapse were also analyzed: 10% of patients in chemoRT-surgery arm had locoregional relapse only versus 22% in the chemoRT arm ($p = 0.002$). Relapse in the primary site was seven times more common in the nonsurgical arm. Brain was common site of first relapse in both arms (11% vs. 15 % in the chemoRT and chemoRT-surgery arm, respectively; $p = 0.29$). Pretreatment factors predictive of favorable outcome were female sex, less than 5% weight loss, and number of N2 stations positive. Age, Karnofsky performance status (KPS), T stage, lactate dehydrogenase (LDH), and histology did not reach statistical significance. After the induction treatment, patients who achieved complete response in the mediastinal nodes had median survival of 34 months and 5-year survival of about 41%, regardless of the response in the primary tumor. For the patients who achieved a T0N0 (pCR), the median survival was 40 months and the 5-year survival was 42%. Thus sterilization of the mediastinum can have significant prognostic importance.

The influence of type of resection on the results of this trial was performed in an unplanned, exploratory matching analysis. OS was significantly improved on the surgical arm if a lobectomy was performed compared to the matched cohort in the chemoRT arm. Median survivals were 33.6 versus 21.7 months, log-rank $p = 0.002$, with 5-year survival of 36.1% versus 17.8%. There was a nonsignificant trend toward worse survival for the pneumonectomy group versus a matched cohort in the chemoRT arm with median survivals of 18.9 versus 29.4 months, 3-year survival of 36.3% versus 45.0%, and 5-year survival of 21.9% versus 23.6%, respectively.

The authors of this study concluded that trimodality therapy increased the 5-year progression-free survival with a trend for increased 5-year OS and that N0 status at surgery significantly predicted a greater survival. Nevertheless, the trimodality approach was not optimal when a pneumonectomy was required because of high mortality risk. Thus, conventional wisdom for trimodality therapy in locally advanced IIIA disease dictates that surgical resection after chemoRT should only be considered for fit patients if a lobectomy is feasible.

## PHASE II TRIALS OF INDUCTION REGIMENS THAT INCORPORATED THIRD-GENERATION CHEMOTHERAPY AGENTS

Third-generation chemotherapy agents were recently tested in phase II induction therapy protocols in stage III disease, similar to those reviewed earlier in this chapter for stage I, II, and selected early stage III presentations. Selected studies with larger numbers of patients are presented later (Table 55.9), but any comparisons among studies as well as conclusions regarding an improvement over second-generation induction programs are premature. In fact, studies with newer agents and concurrent RT as induction were often problematic with respect to excessive toxicity. The Swiss Group for Clinical Cancer Research (SAKK) enrolled 90 potentially operable stage IIIA patients with biopsy-proven ipsilateral mediastinal nodal involvement.[73,74] The induction regimen consisted of cisplatin 40 mg/m$^2$ on days 1 to 2 plus docetaxel 85 mg/m$^2$ on day 1 for three cycles. In all, 75 patients underwent tumor resection after three cycles of chemotherapy, with positive resection margin in 16% of patients. Interestingly, the median overall cisplatin dose-intensity in patients with negative

resection margin was higher than that in patients with positive margin (96 vs. 80 mg/m$^2$/cycle; $p = 0.034$). Perioperative morbidity and mortality were low (17% and 3%, respectively). Complete pathological response was seen in 19% of resected patients. No postoperative chemotherapy was given and 33 patients (44%) received postoperative RT, with median total dose 60 Gy (range, 22 to 70). Of these, 23 patients were treated per protocol (i.e., for a positive margin and/or involvement of the upper lymph node). Nine patients who were due to receive postoperative RT did not actually receive this treatment.

After a median observation time of 5 years, the median OS was 35 months and the median event free survival was 15 months. Of 47 patients who died, 42 were caused by lung cancer. The median time to death caused by tumor was 43 months. At 3 years after initiation of trial therapy (a follow-up time that all patients reached), 27 patients (36%) were alive and free of disease.

Univariate analysis assessing the impact of baseline patient and tumor characteristics identified only multilevel involvement of mediastinal lymph nodes as a poor prognostic factor for OS. Among surgery characteristics, only complete resection was significantly associated with better OS and event-free survival. All aspects of chemotherapy activity (clinical response, pathological response, mediastinal downstaging, and clearance of the uppermost mediastinal lymph node) were significantly associated with improved OS and event-free survival. Pathological response (percentage of necrosis and fibrosis) was the most important feature of the chemotherapy activity on the primary tumor. Similar associations were seen when patients who died from non-NSCLC causes were censored. The prognostic impacts of complete tumor resection, mediastinal downstaging, and pathological response on OS and event-free survival were confirmed in multivariate analyses.

In another recent trial, three preoperative cycles of gemcitabine, paclitaxel, and cisplatin were delivered to 49 patients biopsy-documented N2 disease patients.[75] Patients with at least stable disease after the induction regimen underwent attempted surgical resection. Patients whose disease did not respond received RT alone, and the patients whose disease responded but did not undergo thoracotomy received three more cycles of the same chemotherapy followed by RT. Postoperative RT was delivered for patients with persistent N2 disease or incomplete resection. There was one death during the induction. An RR of 73.5% based on radiographic criteria was recorded, and a complete resection was performed in 55% of patients. Mediastinal nodal disease clearance occurred in 35% of cases, and complete pathological response in 16%. Median and progression-free survival were 23 and 18 months, respectively, and the brain was the most common metastatic site (16%).

The Italian Lung Cancer Project (ILCP) completed a phase II trial in 129 unresectable, locally advanced stage IIIA and IIIB NSCLC patients.[76] The induction regimen consisted of four cycles of gemcitabine 1000 mg/m$^2$ on days 1 and 8, and cisplatin 70 mg/m$^2$ on day 2. The RR was 80%, but the resectability rate was only 29%. There was no perioperative mortality and minimal morbidity. Postoperative RT was given for

positive mediastinal lymph nodes and was continued to 60 Gy if the disease was unresectable. The median progression-free survival was 11 months and median survival was 20 months.

The EORTC 08941 was a phase III trial in clinical stage IIIA (N2) disease where all patients received induction chemotherapy with either cisplatin- (100 mg/m$^2$) or carboplatin- (400 mg/m$^2$) based chemotherapy and then where randomly assigned to surgery or radiation if at least a partial response was achieved.[77] This study closed to accrual on December 2002, with a total of 333 patients randomly assigned, and final results were recently reported (to be discussed shortly). Several phase II trials were embedded within this larger phase III trial as feasibility studies of three third-generation chemotherapy regimens.

The first study was EORTC 08955.[78] Gemcitabine 1000 mg/m$^2$ on days 1, 8, and 15 and cisplatin 100 mg/m$^2$ on day 2, were given every 4 weeks for three cycles. A total of 47 patients were enrolled, of whom 33 (70.2%) had objective responses, and 17 patients underwent thoracotomy, of whom 71% had complete resections. The second embedded pilot study (EORTC 08958) tested carboplatin (area under the curve [AUC] 6) and paclitaxel (200 mg/m$^2$) every 21 days for three cycles.[79] Fifty-two patients were accrued, of whom thirty-three (64%) had objective responses; twelve underwent surgery, two of these patients had mediastinal nodal clearance. In the third phase II trial (EORTC 08984),[80] cisplatin (40 mg/m$^2$ days 1 and 2) and docetaxel (85 mg/m$^2$ day 1) were given every 3 weeks for three cycles before surgery. Forty-six patients were enrolled, with eighteen (39%) patients who had objective responses. None of these embedded phase II studies planned to report survival outcomes, but instead established feasibility and efficacy for preoperative third-generation chemotherapy.

As mentioned, the parent phase III trial, EORTC 08941, was recently published in the literature.[77] Induction chemotherapy resulted in an RR of 61% (95% CI, 57% to 65%) among the 579 eligible patients. Only patients who demonstrated at least a "minor" response were subsequently randomized; a total of 167 patients were allocated to resection and 165 to RT. Thus this trial selected the "best of the best" patients for analysis. Of the 154 (92%) patients who underwent surgery, 14% had an exploratory thoracotomy, 50% a radical resection, 42% a pathologic downstaging, and 5% a pathologic complete response; 4% died after surgery. Among the 154 (93%) irradiated patients, overall compliance to the RT prescription was 55%, and grade 3 and 4 acute and late esophageal and pulmonary toxic effects occurred in 4% and 7%; one patient died of radiation pneumonitis. Median and 5-year OS for patients randomly assigned to resection versus RT were 16.4 versus 17.5 months and 15.7% versus 14%, respectively (hazard ratio = 1.06; 95% CI, 0.84 to 1.35). Rates of progression-free survival were also similar in both groups. The results maybe partially explained by the high number of pneumonectomies, especially because postoperative RT was administered to 62 (40%) patients in the surgery arm. This trial will be thoroughly parsed by surgeons, radiation oncologists, and medical oncologists alike to asses how each specialty's contribution might be improved and the negative aspects minimized.[81]

# TREATMENT-RELATED MORBIDITY AND MORTALITY IN COMBINED MODALITY INDUCTION TRIALS

The morbidity from combined modality therapy that includes surgery is not insignificant. It is often difficult to attribute a particular toxicity to just one modality because the entire "package" affects patient tolerance and the treatment-related mortality. All combined modality induction programs were tested in the "fittest" patients who were fully ambulatory and had general medical conditions that permitted the rigors of this therapy. Eligibility criteria were of necessity quite strict in these trials. It may be dangerous to offer this type of treatment outside of a clinical trial, especially to patients who have a poor performance status and/or major comorbidities, because the literature will underestimate the extent of morbidity and mortality in this group. Clinical trials designed for the large group of patients ineligible for these aggressive approaches are needed. But for patients who match the eligibility criteria of published studies, the literature provides some information on the expected morbidity and mortality during induction therapy, the postoperative period, the late or posterior chemotherapy, or RT, and after all treatment is completed.

## Morbidity/Mortality during Induction Therapy

The most common toxicity reported among all trials during the presurgery induction phase is myelosuppression from chemotherapy. This is usually short-lived and, in most studies, did not result in admissions for neutropenic fever. Other drug-specific side effects such as nausea and emesis, diarrhea, mucositis, and cisplatin-related malaise are variably reported. In fact, nausea and emesis are now quite infrequent compared to the rates reported in the initial trials because of the expanded number of compounds effective against this toxicity. Esophagitis is more often observed after induction chemoRT than chemotherapy alone, although severe events occurred in less than 10% of patients in most series with single fractionation RT.[26–30] The two-third generation trials with hyperfractionated RT reported severe esophagitis rates of 6% and 14%.[41,42] In a report phase I to II high-dose concurrent chemoRT protocol from the University of Maryland, patients with stage IIA or IIB were treated with induction concurrent carboplatin (area under the plasma concentration–time curve 1), vinorelbine (5 to 15 mg/m$^2$), and hyperfractionated RT (69.6 Gy) followed by consolidation chemotherapy (carboplatin area under the plasma concentration–time curve 6, vinorelbine 25 mg/m$^2$, docetaxel 75 mg/m$^2$) or surgery (n = 19) plus consolidation chemotherapy.[82] A low pretherapy body mass index and percentage of esophagus volume treated to >50 Gy were significantly associated with acute grade 2 or worse esophagitis.

Pneumonitis during induction therapy is quite rare, except that the risk of septic deaths from postobstructive pneumonia may be greater with the MVP regimen in one large series.[20,21] Overall, most second-generation induction regimens were fully

managed in an outpatient setting. A significant proportion of patients who enter induction therapy with symptoms related to bulk disease in the chest report a gradual improvement in sense of well-being and performance status as treatment is ongoing. However, formal quality-of-life (QOL) studies have not been conducted for this group of patients.

In the previously mentioned GLCCG study,[64] after receiving induction therapy, patients were randomized to preoperative versus postoperative RT. The fractionation as well as the concomitant chemotherapy differed between the arms. Interestingly, grades 3 and 4 esophagitis was more frequent with preoperative RT (19% vs. 3%; $p = 0.0001$), whereas the incidence of pneumonitis grades 3 and 4 was higher with postoperative RT (1% vs. 6%; $p = 0.004$). QOL was assessed throughout therapy using the EORTC QLQ-C30 and EORTC QLQ-LC.[83] Of 126 eligible patients, 54 completed treatment. For patients in both treatment arms, physical functioning decreased, whereas dyspnea, fatigue, and pain increased from beginning to the end of treatment. For self-assessed QOL, no statistically significant effect was found in or between the two treatment arms. The combined modality approach with preoperative chemoRT proved to be feasible in treating locally advanced NSCLC patients without decreasing their subjective QOL.

## Mortality/Morbidity during the 30-Day Postoperative Time Period

Despite the wealth of clinical trials that follow algorithms that lead to eventual exploration and resection after induction therapy, there is no consensus as to what constitutes expected or acceptable postinduction surgical morbidity and mortality. This lack of consensus is caused by the marked heterogeneity of induction regimens (as reviewed in preceding sections); the lack of consistency across trials in the adequate reporting of surgical complications; different criteria for preoperative eligibility regarding pulmonary function, comorbidities, and conditioning; and variable experience of the surgeon in dealing with postinduction surgical scenarios at the time of thoracotomy and in providing the required supportive care during the postoperative time period.

Several publications document the risk of pulmonary resection in the noninduction situation. The modern 30-day mortality for pneumonectomy is 3% to 6.2%, and the mortality of a standard lobectomy is 1% to 2%.[84–86] Surgical issues, in association with neoadjuvant therapy, have been reviewed.[87] It is generally agreed that postinduction resections usually pose a greater technical challenge and require more vigilance in postoperative care. More recent data suggest the possibility that the potential adverse effect of induction chemotherapy on postoperative mortality may have been over estimated.[88] Specific recommendations for patients undergoing postinduction resection include restriction of intravenous fluids perioperatively, reinforcing bronchial stumps with tissue, pain control via epidural/paravertebral catheter, early use of broad-spectrum antibiotics, aggressive pulmonary toilet, and monitoring/prevention of supraventricular tachycardia.

Acute surgical morbidities appear to be similar regardless of the type of induction, unless RT is given and too much time is allowed to elapse so that extensive fibrosis is encountered.

Fibrotic reaction from RT may obliterate resection planes. To minimize the effect of fibrotic reaction, surgery should be performed within 4 to 6 weeks after completion of induction regimen. Whether drugs that rarely cause pulmonary reactions during induction therapy increase the rates of these types of postoperative complications is not clear.

Pulmonary complications and deaths because of pulmonary causes during the postoperative time period are the greatest concern after induction therapy and collectively rates are probably greater than reported in the literature after surgery alone. In particular, events such as extensive pneumonitis, usually culture-negative, ARDS, and bronchopleural fistula have a high mortality in the postoperative period. Pulmonary morbidity and mortality rates are often quoted to be greater after induction regimens with chemoRT than after induction chemotherapy alone. However, a careful review of all the literature available discloses great variability. Postoperative mortality rates from 3.1% to 17% were reported after MVP- or VP-containing induction chemotherapy (including some cases of ARDS), from 4% to 15% after second-generation induction chemoRT, and 5% to 7% after induction chemoRT with hyperfractionation.

The specific type of mortal postoperative event may differ according to whether RT was included with induction chemotherapy or not although this issue is not fully resolved. For example, complicated stump insufficiency was the most common cause of postoperative death in the WGCC experience with twice-daily RT in the induction,[42] whereas ARDS may be the most common cause of postoperative deaths after single fractionation chemoRT in multiple series. The presence of RT in the induction regimen, however, may not be the sole explanation for greater pulmonary-related mortality, especially ARDS, after certain induction regimens. For the most part, many of the patients treated with concurrent chemoRT induction approaches had advanced, central disease that required a pneumonectomy after induction. Pulmonary-related postoperative mortality rates are expected to be much higher in this population with advanced disease.[26,27] So far, there has been no difference in overall postoperative mortality rates compared to the surgery-alone control arms in trials with induction chemotherapy for early, more minimal bulk disease.[47,48,51–53]

Serious pulmonary complications in the postoperative period clearly result from a combination of causes in addition to the type of induction therapy.[59,89–91] Although higher doses of RT than 45 Gy have been implicated,[59] the occurrence of ARDS in trials with no induction RT and the lack of an excess rate of ARDS in other trials with higher-dose RT or altered fraction RT[28,41,42] underscore that the tolerance of lymphatic sump disruption and postpneumonectomy shunts is variable after both induction chemotherapy and induction chemoRT. The type of complication may also vary based on schedule of the RT, with perhaps more events of serious stump insufficiency but less ARDS after hyperfractionated versus single-fraction RT. Moreover, stump problems can usually be eliminated when the surgeons incorporate a bronchial stump protection protocol for all patients.

## Morbidity/Mortality after the Postoperative Time Period

Many induction program algorithms recommend additional chemotherapy with or without RT after the patient has recovered from surgery. Usually, the spectrum of toxicities from posterior chemotherapy is similar to those observed during induction[26] although it may be more difficult to complete a boost dose of RT.[25] Patients are at greater risk for pneumonitis, either from prior RT or because of infectious causes, beyond the postoperative period, especially if the prior surgery was a pneumonectomy. Data on this issue is rarely reported in the induction therapy literature.[26] Prompt attention to symptoms of infection with broad-spectrum antibiotic coverage is critical to minimize the risk of mortality.

The other major morbidity experienced by many patients after induction therapy followed by surgery is a posttreatment constitutional syndrome. This consists of a constellation of symptoms including thoracotomy pain, malaise, anorexia, and poor pulmonary reserve. This syndrome probably occurs at a greater frequency than with radiation or surgery alone, but its rate is grossly underreported.[26] It often resolves within a year after treatment although its lingering presence is clearly discouraging to the patient and caregiver. Prospective QOL analyses and active rehabilitation protocols for this population are needed. Patients also continue to experience problems from their comorbid diseases long after treatment is completed, especially cardiovascular disease and noncancer pulmonary events. Competing cause of death reporting is rare, and often death certificates attribute cause to "lung cancer" even when the disease has never recurred. This was documented in the SWOG 8805 trial. Although cancer accounted for 64% of all deaths, 20% were caused by various other causes such as late pneumonia long after the end of treatment, myocardial infarction, pulmonary embolus, cerebrovascular accidents, trauma, ulcer, or second primaries.[26]

## Strategies to Reduce Radiotherapy-Related Morbidity

Induction RT likely helps improve resection rates, especially in locally advanced tumors, but at the same time, contributes to surgical morbidity and mortality. Two well-recognized morbid effects of RT are radiation pneumonitis (usually occurring within 6 months from completion of radiation) and late fibrosis. These complications are likely to be more devastating in patients who undergo a lobectomy or pneumonectomy. The occurrence of clinical radiation pneumonitis has been correlated with the volume of lung receiving over 20 Gy (V20).[92] Although there has been significant literature investigating correlation of lung volume and dose to predict pneumonitis, a V20 less than 30% to 35% is standard in most treatment plans.[93] However, impairment of diffusion capacity and perfusion can and do occur at lower doses.[94–97] By fitting patient data into a mathematical model, Gopal et al.[94] suggested a sharp loss in local diffusing capacity of the lung for carbon monoxide (DLCO) occurring with radiation doses above 13 Gy. These data suggest that it is prudent to limit the volume of lung receiving even low-dose radiation.

There are several strategies that can be used to limit the radiation effect on the normal lung; however, none have been studied in the context of a trimodality approach. Technical improvements in the application of thoracic radiation therapy for lung cancer, particularly with the integration of CT-based treatment planning, have greatly improved our ability to identify tumors and, relevant to this report, to delineate normal tissues. Three-dimensional conformal RT technique can ensure adequate radiation dose to the tumor and areas of risk and limit the irradiation of the healthy tissue. Limiting the mediastinal target volume to only those areas positive on PET scan will reduce the volume of irradiated lung and should be considered for future studies. Irradiation of contralateral uninvolved lung should be avoided to the maximum extent possible, especially in patients who are likely to require pneumonectomy. Ideally, the irradiated volume should include as little lung outside the area destined to be resected as possible. Also of note, the main source of death from intercurrent disease associated specifically with the postoperative use of RT is heart disease mortality.[98] A recent population-based study suggested that postoperative-associated heart disease mortality has decreased over time, particularly for patients who have tumors located where heart irradiation is more likely to occur.[99] Thus, it would appear that our ability has improved to deliver RT to the operative patient with minimal damage to the normal tissues.

## WORLDWIDE PHASE III TRIALS: ONGOING AND PLANNED

The EORTC has just completed accrual to a phase III trial (EORTC 08941) of induction chemotherapy followed by either RT or surgery.[53] The trial enrolled patients with stage IIIA (N2) NSCLC, considered unresectable pretreatment with positive N2 nodal biopsy or ipsilateral vocal cord or diaphragm paralysis. Patients were given any combination chemotherapy regimen that contained cisplatin at 100 mg/m$^2$ or carboplatin at 400 mg/m$^2$. Upon completion, patients were reassessed for response, and those achieving either complete or partial response are randomized to either radical RT or surgical resection. Postoperative RT was given either for positive surgical margins of persistent N2 disease at surgery. This trial was opened in 1994 and first survival results are anticipated soon.

The German/French consortium has opened a new phase III trial based on encouraging pilot data of a novel trimodality regimen (see Chapter 56). Patients with advanced stage III disease (two or more N2 levels involved, large-volume N2 disease, selected IIIB subsets) are treated with induction cisplatin plus paclitaxel followed by (if no progression) hyperfractionated RT plus concurrent cisplatin plus vinorelbine. Upon restaging, patients with operable disease are randomized to either surgical resection or to a boost chemoRT program of cisplatin plus vinorelbine plus single daily fraction RT to 75 Gy.

A phase III Nordic trial is ongoing for patients with biopsy-proven N2 disease. The randomization is to either carboplatin plus paclitaxel for three cycles followed by RT to 60 Gy (single daily fraction) or to the same induction therapy followed by surgical resection and then followed by RT to 60 Gy (single daily fraction).

Other studies are planned to examine the role of RT in the induction regimen in patients with low-volume N2 disease that is proven by biopsy and with resectable primary tumors. A SAKK trial prescribes phase III trial is designed to give three cycles of cisplatin plus docetaxel, followed by restaging. If a response or stable disease occurs, patients will be randomized to either surgical resection or to daily RT (with a novel hyperfractionated imbedded boost) followed then by surgical resection. The North American Intergroup (RTOG0412/S0332) planed to also test induction cisplatin and docetaxel, but the randomization will be to concurrent daily RT or not. Both arms then receive surgical resection, followed by additional chemotherapy in all patients. Unfortunately, this trial closed early as a result of poor accrual.

## CONCLUSION

Despite reported results of multiple clinical trials reviewed herein, the debate regarding combined modality therapy that involves surgery continues, and it must be concluded that there is no consensus whether neoadjuvant chemotherapy for early stage NSCLC results in improved survival or whether chemoRT in high-volume, advanced stage III NSCLC should be followed by surgical resection. In 2003, a consensus statement from the International Association for the Study of Lung Cancer (IASLC) reaffirmed surgical resection alone and chemoradiation alone as standards of care for early and locally advanced NSCLC, respectively.[100] However, the National Comprehensive Cancer Network's (NCCN) current clinical practice guidelines recommends either induction chemotherapy with or without radiation therapy, followed by surgery for patients with T1 to T2, N2-positive disease, or definitive chemoradiation.[101] For patients with T3N2 disease, the treatment recommended by the NCCN is chemoradiation, although no prospective trial specifically addresses this issue.

However, critical data emerged since these consensus recommendations were published and recent Evidence-based Clinical Practice Guidelines from the American College of Chest Physicians suggest considering induction therapy only in the context of a clinical trial.[102–104] Furthermore, the recent Cancer Care Ontario and American Society of Clinical Oncology recommend adjuvant for selected stage IB and all stage IIA to IIIA NSCLC. Some impact will be felt on the ability to complete large trials in stage I and II disease designed to test the role of induction chemotherapy. That is, the surgery-alone arms are now substandard therapy, which suggests that what remains to test is whether the chemotherapy is best given in an induction setting or as postoperative adjuvant therapy. For patients with patients with high-volume, mediastinal nodal positive disease, chemotherapy alone as induction may be problematic, since the complete resection rates are generally lower when the tumor burden is higher. The first report of the large North American Intergroup trial 0139

showed that surgical resection in this group of patients after induction chemoRT increases disease-free survival, but at the cost of increased noncancer mortality, ultimately resulting in same OS.[71] Longer follow-up will be necessary to determine whether this advantage in disease-free survival will translate into an OS improvement. Hence, until more data are available, trimodality treatment should not be routinely offered to this patient population outside a clinical trial without a detailed, informed discussion of risks and benefits. However, for patients with T4N0/1 disease, data collectively suggest that surgical resection markedly improves the long-term outcome for this subgroup, with 5-year survival of almost 50%. A phase III trial to validate these observations ideally should be done, but most likely will not be feasible. Thus, routine use of a published trimodality program in this uncommon subset appears to be reasonable as a present standard of care. However, as we develop a greater appreciation for the molecular mechanisms responsible for response and resistance to the various therapeutic options, we will be able to utilize molecular markers identifying which patients will benefit from induction versus adjuvant therapy. Such will also detail which agents to use and their sequence with respect to surgery. Paradigms investigating such will hopefully form the basis of the next generation of clinical trials.

# Stage IIIB Non–Small Cell Lung Cancer

Radiation therapy approaches remain the cornerstone of management for patients with stage IIIB advanced non–small cell lung cancer (NSCLC). Radiation therapy alone, however, is today only rarely given as a single treatment modality. Historically, combined modality trials have demonstrated that induction chemotherapy prior to radiation already improves long-term results by improvement of systemic control.[1,2] Progress has been made significantly with concurrent application of platinum-based chemotherapy to radiation treatment. This concurrent chemoradiotherapy strategy significantly increases local control and thus long-term results. At this time point, a concurrent chemoradiotherapy strategy—whenever possible—represents the standard of care for a large number of patients in this stage.[3] Platinum-based combinations have emerged as typical partners of radiation, but adequate coverage of systemic risks of the patients has to be taken into account. Different strategies have either tried to give consolidation chemotherapy following a combined chemoradiation protocol. An alternate possibility looks at an induction chemotherapy strategy followed by the definitive concurrent chemoradiation protocol. The optimal combination strategy has not yet been established so far. The reader will learn to evaluate different multimodality regimens regarding their local and systemic efficiency. At the end of this chapter, the reader should in concert with the other chapters dealing with radiotherapy delivery and application be able to (a) learn that the patient population subsumed under the IIIB stage grouping represents a very heterogeneous patient group; (b) define the different risk factors of the individual patients including their local, locoregional, and systemic risks; (c) identify the small group of patients in whom surgery still represents a valuable strategy to include in this disease subset (e.g., T4N0 to N1); (d) group comorbidity profiles of the patients concerning their impact and relevance on the choice of the treatment protocol; (e) be critically aware of the results with typical chemoradiation protocols based on either cisplatinum combinations as well as carboplatinum combinations; (f) know about the differences of radiation delivery protocols including different dosing schedules as well as dose fractionation issues; (g) learn that new ways to improve this treatment design include a possible integration of molecular-targeted agents into this setting of definitive chemoradiation; (h) identify the toxicity profiles of typical definitive chemoradiation protocols both concerning their acute toxicities as well as possible late toxicities and their proper management; and (i) lead the interdisciplinary discussion in the individual patient based on his existing risks and define the aims of a multidisciplinary treatment strategy, including systemic treatments (medical oncology), radiation therapy, and surgery in selected cases. This knowledge of the possible pros and cons of individual treatment approaches will help to critically discuss these issues with the patient and finally, following this open discussion, generate an individualized treatment strategy for each patient. At the end of this chapter, the reader will also learn possible future innovative strategies to optimize the therapeutic management of patients with stage IIIB NSCLC.

## HETEROGENEITY OF PATIENTS WITH STAGE IIIB NSCLC

The International Staging System includes into stage IIIB disease different patient groups with T4 tumors as well as involvement of contralateral mediastinal nodes at the N3 position.[4] Permutations of these factors lead to different TN groupings—from T4N0 to T1N3 or even more unfavorable T4N3 categories. Recently, the proposals by the International Association for the Study of Lung Cancer (IASLC) staging committee have regrouped ipsilateral pulmonary metastases outside the involved lobe as stage T4 disease and ipsilateral pulmonary metastases inside the primarily involved lobe as T3 disease[5] (see Chapter 30). Pleural effusion and pleural metastases are now considered to be M1 disease, thus reflecting the already known separation of this group outside of any combined modality approach including radiation therapy. The newly proposed stage groupings (especially the T4 subsets) have, so far, not been implemented into the clinical trials

performed with multimodality treatment in NSCLC. Future trials for patients with stage IIIB should keep this in mind and should carefully give the individual subsets included into their patient selection. The T factor represents a very different number of clinical situations with important implications on possible surgical measures. T4 disease can include potentially resectable situations as involvement of the main carina, parts of the atrium, one or two segments of trachea, vertebral body, superior vena cava infiltration, or involvement of central parts of the pulmonary artery. Other subsets include those with esophageal, thoracic aorta, or extensive cardiac involvement. These represent definitively irresectable subsets. Even in the very few potentially resectable T4 indications, surgery is today usually performed within a clearly defined multimodality setting, taking care of the increased systemic risks of these patients. Besides the stage groupings and subsets, different other prognostic factors should be recognized for these patients, but some of them are not well defined yet (Table 56.1).[6] These include histopathology (e.g., neuroendocrine, rare histopathological subsets) or tumor differentiation (G3 vs. G1), serum lactate dehydrogenase (LDH) as an unspecific marker of tumor burden, gender (female vs. male), performance status (0,1 vs. 2), pretreatment weight loss, and patient age. Besides prognostic factors, major comorbidities have to be taken into account for development of individual treatment plans. These include pulmonary function and significant pulmonary diseases (e.g., chronic obstructive pulmonary disease [COPD], emphysema, pulmonary hypertension), cardiovascular diseases (e.g., myocardial infarction, myocardial insufficiency), cardiovascular diseases (e.g., cerebral infarction), peripheral vascular problems, or other major organ dysfunctions (renal insufficiency, hepatic insufficiency, etc.). With most patients with lung cancer being at the age older than 60 years, these factors represent significant influences for the decision making in the individual patient. A valid denominator to make the comorbidity profiles of the patients objectively measurable are different Geriatric Assessment Scores in clinical use such as the

Charlson Comorbidity Index.[7] Thus, a significant heterogeneity of the patient population with stage IIIB is the natural consequence. Besides impact on potential operability of patients, comparable criteria exist concerning eligibility to intensive, definitive chemoradiation protocols, and administration of effective platinum-based chemotherapy regimen. With chemotherapy, radiotherapy, and (rarely) surgery being the major partners in multimodality treatment approaches, significant experience with handling of these modalities requires multidisciplinary treatment groups based on medical oncologists, pulmonologists, and radiation oncologists together with dedicated lung cancer surgeons. With increasing experience in the dedicated treatment center, toxicities and adverse effects of treatment can be significantly reduced, last but not the least from learning effects over time.

## Impact of Diagnostic Investigations to Define Different Subsets and Risk Groups in Stage IIIB

The small subset of patients with stage IIIB in whom surgery is being considered (T4N0) is typically staged extensively including thoracic computed tomography (CT) scans with vascular imaging studies based on adequate contrast media bolus-tracking techniques. Recently, positron emission tomography (PET) scanning has become an important addendum to the staging investigations, mainly for ruling out systemic metastases as well as mediastinal lymph node involvement.[8] Cervical, parasternal, or extended mediastinocopy are typically performed to rule out extensive mediastinal lymph node involvement (N2, N3) that represents a major adverse prognostic factor in this patient group.[9] It can be used to verify positive findings from PET studies, and sometimes thoracoscopic techniques may be added to clarify unequivocal findings from imaging investigations. Recently, endoscopic ultrasound techniques (EUS) or endobronchial ultrasound techniques (EBUS) have become an interesting alternative to extend initial staging investigations to pathologic staging of solid tumors and mediastinal and hilar lymph nodes based on fine-needle biopsies guided by ultrasound.[10] However, these patients with intensive, surgically or endoscopically based staging investigations still represent a very selective and small subset of the population with stage IIIB. If definitive chemoradiation protocols with curative intent are planned, mostly imaging investigations only are performed including CT studies. This also holds true for most clinical phase II trials or phase III studies of multimodality treatment (chemoradiation) that will be mentioned and discussed later. Recently, PET and PET-CT investigations have been included into initial staging for a better definition of the treatment fields in three-dimensional (3D) radiotherapy treatment planning.[11] Functional PET imaging studies may also be used for identifying response to multimodality treatment on induction protocols but with limited impact once radiation therapy is included into the protocol.[12] Inflammatory and stromal response to radiation treatment significantly hamper interpretation of these investigations, especially during the postradiotherapy inflammatory pneumonitis phase. It is not yet clear, whether repeated EUS- or

EBUS-guided biopsies during or following multimodality protocols may help to identify selected high-risk treatment groups or low-risk patient groups with improved prognosis following multimodality treatment. Furthermore, some investigators have proposed redo-mediastinoscopy following induction protocols to select patients with upfront involvement of the mediastinal nodes properly for definitive local treatment following their response to initial treatment.[13,14]

## Surgical Indications in Selected Stage IIIB NSCLC Patients as Part of Multimodality Protocols

Biologically, patients with T4N0 stage of NSCLC represent a small but selective subgroup of patients in this stage with more locally invasive tumors and probably, a lower risk of distant metastases. This may be the background for improved results with extensive surgical approaches that have been reported within several small phase II trials in this setting. Here, we will only give the selection criteria typically used in some of the reported trials. Following extensive surgical staging that has excluded mediastinal lymph node involvement, the final aim is complete resection, which can be achieved by extensive surgical procedures including simple and intrapericardial pneumonectomies, sleeve pneumonectomies, bilobectomies, pericardectomies, cardiosurgical techniques for the left atrium, plastic vascular surgical techniques involving the pulmonary artery, its branches and superior vena cava, carinal resections, resections of one to two tracheal rings, or vertebral body resections. Long-term survival has been reported in all of these

subgroups. Unfortunately, most of these clinical trials have not employed chemotherapeutic integration within induction or adjuvant treatment protocols. Some of the multimodality trials that have looked at induction chemotherapy and radiotherapy protocols also had T4N0 patients among their patient selection (Table 56.2) (Fig. 56.1). The largest ones are probably the Southwest Oncology Group (SWOG) 8805 study,[15] the West German Cancer Center trial,[16] an Italian study,[17] and a Spanish study.[18] They tested definitive surgery following chemotherapy or complex chemoradiation induction protocols. In the SWOG 8805 study, 19 patients were included with T4N0 to N1 tumors.[15] A subset analysis showed that this group had an excellent median survival of 28 months. The West German Cancer Center Study included 10 patients with T4N0 to N1 treated with induction chemotherapy followed by chemoradiotherapy and definitive surgery.[16] The median survival of this selected subgroup of patients was found to be 26.5 months with a 5-year survival rate of 37.5%. An Italian study looked at an induction chemotherapy only protocol of two cycles of cisplatinum-based chemotherapy in 43 patients with T4 disease, but this included patients with N0 as well as N1 and N2 nodal status.[17] Four-year survival rates of this selected T4 group were 19.5%, proving that long-term survival is possible with aggressive induction and surgical strategies among these patient groups. In the phase II 9901 trial of the Spanish Lung Cancer Group, selected stage IIIA-N2 and T4N0–N1 tumors were included. Patients were treated by induction chemotherapy only, followed by surgical resection.[18] Overall response rate

**FIGURE 56.1** T4 disease with multimodality treatment including surgery. CT and PET/CT images of a patient with pathologically proven T4 disease at parasternal mediastinoscopy/thoracoscopy prior to induction treatment **(A)** and following an induction therapy **(B)** with induction chemotherapy (three cycles cisplatin and paclitaxel) followed by induction chemoradiotherapy (one cycle cisplatin and vinorelbine) with 45 Gy hyperfractionated accelerated radiotherapy (2 × 1.5 Gy bid). (See color plate.)

was 56%. In the 67 patients with stage IIIB disease, complete resection was obtained in 29 patients (43.3%). Overall median survival time for T4N0 to N1 tumors was 16.8 months. For completely resected T4N0 to N1 patients, an impressive 5-year survival rate of 53.2% was obtained.

However, surgical intervention in T4N0 tumors with necessarily extended resections has significantly increased morbidity and mortality (>5%) rates if compared with simple lobectomies. Data on surgical management in selected N3 patients are even fewer (Table 56.2; Fig. 56.2). The SWOG
**FIGURE 56.2** N3 disease with multimodality treatment including surgery. PET/CT images of a patient with mediastinoscopically proven N3 disease prior to induction treatment **(A)** and following an induction treatment **(B)** with chemotherapy (three cycles cisplatin and paclitaxel) followed by induction chemoradiotherapy (one cycle cisplatin and vinorelbine) with 45 Gy hyperfractionated accelerated radiotherapy (2 × 1.5 Gy bid). (See color plate.)

8805 included 27 patients with N3 disease in their induction chemoradiation trial, and the 2-year survival rate was 35% in the subgroup with supraclavicular N3 nodes but 0% in those with contralateral mediastinal nodes.[15] The West German Cancer Center Group reported a larger series of 32 patients with N3 disease and found a median survival of 20 months with a 5-year survival rate of 28%.[19] The Group in Paris aggressively treated 18 patients with N3 disease with induction chemoradiation followed by surgery and noticed a 17% 5-year survival rate. The surgical technique in this trial was a midline sternolaparotomy approach.[20] The Cleveland Clinics Group treated 20 patients with proven N3 disease with an induction chemoradiation protocol including cisplatin, paclitaxel, and 30- to 33-Gy radiation.[21] The 2-year survival rate to be observed was 15% in an early analysis. Typically, extended resections had to be performed, and in some trials contralateral mediastinal exploration was part of the operative procedure, whereas following complex chemoradiation protocols others did not explore the contralateral mediastinum at the time of thoracotomy. Surgical morbidity and mortality in all reported trials was increased compared with earlier disease stages. This has been the strongest argument against surgery in this setting, and it is generally accepted that this extensive surgery in the IIIB subset should be strictly performed in experienced hands in dedicated thoracic surgical centers. Furthermore, the number of patients treated in these trials was usually very small and also selective; therefore, a final evaluation of this concept is not possible. As no randomized trials are available, it is not clear whether the inclusion of surgery gives any benefit compared with definitive chemoradiation protocols that also have reported long-term survival outcomes in these stages.[22]

### Historical Results of Radiation Therapy as Single Modality in Stage IIIB

Those patient subsets with stage IIIB without pleural effusion or contralateral hilar lymph node involvement historically represented the group of patients primarily treated with radiation therapy alone in the 1980s and 1990s without any surgical intervention being possible. This local and locoregional approach already achieved a 5% to 7% long-term survival rate in selected patient populations.[1,2] Radiation doses included were typically between 50 and 60 Gy over a 5 to 6 weeks' application period. Over the years, with progress in radiation therapy delivery (electrons/photons with linear accelerators vs. Cobalt sources) and treatment planning (from two-dimensional planning with two or three treatment fields to 3D treatment planning based on CT studies), some benefit could be achieved with better efficacy versus toxicity profiles of the protocols (e.g., dermatological toxicity, radiation pneumonitis, cardiac toxicities, esophageal toxicities). The strongest argument against a single treatment modality in these locally far advanced stage IIIB patients comes from their relapse pattern. Within different clinical trials, between 40% and 70% of patients developed systemic relapses (systemic metastases to liver, bone, brain, adrenals, etc.), following the local modality only approach (surgery or radiation).[1,2] This has been a major argument to introduce systemic treatment components such as chemotherapy into this setting.

### Biological Rationale of Combining Chemotherapy Sequentially with Radiotherapy in Lung Cancer

Both chemotherapy and radiotherapy can theoretically have an effect on different tumor cell clones.[23] Although radiotherapy exerts its effect on local and locoregional disease, chemotherapy may add significant effects on systemic micrometastases, besides a further activity on the primary tumor and its nodal involvement. Theoretically, this effect is most pronounced when both modalities are given separately in a sequential schedule as both modalities can be delivered without major dose and dose intensity compromises. The latter usually derive from overlapping or interacting toxicities once the modalities are combined at one time. These arguments have been the background for several clinical trials in stage III NSCLC patients

looking at the sequential administration of chemotherapy and radiotherapy for stage III disease where IIIB patients were predominantly included.

## Sequential Approaches of Chemotherapy and Radiotherapy in Comparison with Radiation Alone

Four prospective randomized clinical trials have looked at the sequential addition of induction chemotherapy to standard fractionated radiotherapy in stage III NSCLC (Table 56.3). All trials were multicenter trials and were performed on an intent-to-treat basis with upfront randomization. All four trials used cisplatinum-based combinations as induction therapy in the experimental arm and full cumulative radiotherapy doses between 56 and 65 Gy.

The Cancer and Leukemia Group B (CALGB) 8433 study compared a standard fractionated radiotherapy protocol of 60 Gy in 6 weeks or an experimental arm with cisplatin and vinblastine combination chemotherapy for two cycles as induction (Table 56.3).[24] Patient selection included patients with good performance status and clinically staged IIIA and IIIB disease, usually low bulk lymph node involvement, and minimal weight loss. One hundred and fifty-five patients were randomized and there was a significant benefit in overall survival with 3-year survival rates of 24% versus 6% and 5-year survival rates of 17% versus 6% in favor of the induction arm ($p = 0.012$). Median survival was 13.7 months in the combined modality versus 9.6 months in the radiation only arm. Also, locoregional control was significantly improved with administration of the induction chemotherapy. No stratification was made for stage IIIB versus IIIA in this trial. The trial was prematurely closed based on positive findings at the first planned interim analysis and generated a first strong signal for the combined modality approach to stage III NSCLC patients.

Based on the positive results of this trial, a subsequent North American Intergroup trial—initially Radiation Therapy Oncology Group (RTOG) trial 8808—tested the same induction therapy of two cycles of cisplatin and vinblastine induction followed by radiation therapy of the same 60 Gy against the radiation only arm.[25] A third randomization arm of 69.9 Gy given in hyperfractionated application schedule (2 times 1.2 Gy bid) was added looking at a novel fractionation schedule of single-modality radiation therapy in this setting. No induction therapy was added in this intensified radiotherapy arm. With comparable inclusion criteria, this prospective randomized trial could confirm the benefit of induction chemotherapy followed by radiotherapy in this setting with a median survival of 17 months in the combined modality arm versus 11 months in the radiotherapy-alone arm ($p = 0.04$). However, 5-year survival rates were only marginally improved of 8% with the combination versus 5% in the radiotherapy-alone arm. No significant benefit was derived from the hyperfractionated radiotherapy application in the third arm. Critical voices following the publication of this trial argued that the low–single-fraction dosing of 1.2 Gy may be suboptimal, and one of the reasons for this failure to improve radiotherapy technique with this application schema.

The third study was performed in France as a multicenter randomized trial under the leadership of the Institute Gustave Roussy.[26] Three hundred and thirty-two patients were prospectively randomized to receive a rather uncommon induction chemotherapy protocol based on cisplatin and vindesine in combination with cyclophosphamide and lomustine (VCPC)—a combination chemotherapy protocol developed and popular in France at that time—followed by 65-Gy standard fractionated radiotherapy. The standard arm was based on 65-Gy single-modality radiation treatment alone. An important and unique addendum to the trial were predefined bronchoscopic

reinvestigations looking at the local control induced in the two treatment arms. There was a significant improvement in overall survival with 3-year survival rates of 13% with induction therapy versus 4% in the standard arm, and a 5-year survival rate of 6% versus 3% in the radiotherapy-alone arm ($p <0.02$). Local control based on the findings at bronchoscopy was only 15% in the radiotherapy-alone arm with 85% of the patients still having persistent vital tumor. The benefit observed in this study was mainly derived from an increase of systemic control in the induction chemotherapy arm.

The fourth trial in this setting was a Nordic trial looking at induction therapy with cisplatin and etoposide followed by 56 Gy of a split-dose radiation therapy versus a "standard" radiation-alone arm with the same 56-Gy split-dose protocol.[27] Three hundred and twenty-seven patients were randomized to the two treatment arms, and an increase in locoregional control was observed in the induction arm (4-year local failure-free survival rate of 7% vs. 3% in the radiotherapy-alone arm; $p = 0.07$). The difference showed a trend of improvement with the chemotherapy induction, but the benefit was not statistically significant. With overall 5-year survival rates being 3% in the induction arm and 1.4% in the radiotherapy-alone arm, no significant benefit for overall survival could be observed in this trial, either. It can only be speculated that the patient selection of this trial probably allowed a significant heterogeneity that may be responsible for the negative finding in this study.

Taken together the results of all four trials, induction chemotherapy prior to definitive radiotherapy resulted in a small but measurable benefit for overall and long-term survival in patients with stage III NSCLC. Critical commentaries should mention that in all four trials, the radiation protocols were far from being optimal concerning modern conformal radiation treatment planning standards. Also, the split-course radiotherapy application is biologically inferior and has been abandoned in the last years. Cumulative doses of 65 Gy are today accepted as standard treatment; therefore, only the French study fulfilled this rigid criterion. Cisplatinum-based chemotherapy application was still a problem at the time of performance of the first three trials. Modern antiemetic combinations represent a significant improvement for patients' compliance to these intensive protocols. Radiotherapy treatment planning was not uniformly optimally based on CT scans and 3D planning, therefore leading to higher esophagitis rates within these studies.

A unique motif of all four trials was the cisplatinum-based induction chemotherapy combination. In light of the findings for adjuvant chemotherapy, it can be argued that two cycles of chemotherapy may have been suboptimal for the systemic efficacy on micrometastases in this setting; however, cisplatinum-based protocols are currently also the major choice for effective adjuvant chemotherapy in earlier disease stages.

When transferring the presented data to the stage IIIB NSCLC population, it can be concluded that cisplatin-based induction chemotherapy may generate a small but significantly long-term survival benefit based on the systemic efficacy of the combination chemotherapy and the high risk of systemic

relapse in these patient subsets. Unfortunately, a further significant risk lies in the development of brain metastases in this patient group.[28,29] Chemotherapy does not reduce the brain recurrence rate of these patient populations what can be derived from the large RTOG database.[30] Other interventions (such as prophylactic cranial irradiation) should cover those competing risks if proven effective in the future.

## Biologic Rationale of Concurrent Chemoradiotherapy in Lung Cancer

Radiation therapy and cytotoxic chemotherapy theoretically can target different cellular pathways (e.g., DNA-damage, DNA-repair, apoptotic pathways, signal-transduction pathways), and thus may exert their major effects on different tumor cell populations. A concurrent application might lead to additive or even supraadditive effects on growing tumors.[31] Concurrent chemotherapy to radiotherapy may prevent the development of radiotherapy-resistant tumor cell clones. Radiotherapy exerts its effect on the local and locoregional tumor. Chemotherapy not only exerts its effect locoregionally but on distant micrometastases (outside the brain) as well. By the effect of this so called spatial cooperation, the combination of both may lead to an increased overall effect of the simultaneous combination.[32] These arguments have served as the major drivers of concurrent chemotherapy and radiotherapy protocols in locally advanced NSCLC. From other solid tumors, it is well-known that cisplatin alone already serves as a significant enhancer of radiation therapy effects. Within recent years, concurrent chemoradiotherapy protocols have gradually emerged as standard treatment approaches for different locally advanced solid tumors (e.g., esophageal cancer, cervical cancer, head and neck cancer).

## Concurrent Application of Chemotherapy and Radiotherapy: Single–Agent Cisplatinum

Overall, four prospective randomized trials have looked at the concurrent application of single-agent cisplatinum together with radiotherapy (Table 56.4). All trials tested different schedules of cisplatinum and included patients with locally far advanced stage III disease.

A prospectively randomized multicenter Italian study randomized 173 patients to either 45-Gy standard fractionated radiotherapy and concurrent daily cisplatinum treatment versus radiation treatment alone.[33] Median survival results as well as 3-year survival rates were not significantly different between both arms. Esophageal toxicity was more pronounced in the combined modality arm. The strongest criticism to this study would include that the radiation dose of 45 Gy cannot be considered an optimal and effective radiation dose today.

The most important and influential multicenter trial was performed within the European Organization for Research and Treatment of Cancer (EORTC) and was based on a split-course radiation protocol up to 55 Gy.[34] In two arms, either weekly cisplatin or daily cisplatin were added and compared with a radiation-only comparator arm. The concurrent application of daily cisplatin led to a significant improvement of locoregional control as well as overall survival if compared with radiation

alone. 2-y-Locoregional disease-free survival was 31% in the concurrent daily cisplatin arm versus 19% with radiation alone. The 3-year survival rate was 16% in the concurrent arm versus 2% in the radiation therapy–only arm ($p = 0.009$). The cisplatinum weekly arm showed an improvement in locoregional control and overall survival, but the data did not reach statistical significance. The combination of concurrent cisplatinum to radiotherapy showed an increase in toxicity in both arms, mainly esophageal and hematologic toxicities. No major treatment-related deaths were noticed in this landmark trial that could establish the significant effect of single-agent cisplatin as an effective radiation enhancer in NSCLC.

Only recently, a randomized Turkish study in 176 patients could substantiate a significant benefit of single-agent cisplatin given concurrently for 5 days per cycle with 64-Gy conventionally fractionated radiotherapy versus the same radiotherapy alone.[35] This study showed a significant benefit for concurrent cisplatin with 3-year survival rates of 10% of the combined modality arm versus 2% for single-modality treatment ($p = 0.0002$). Moreover, the locoregional control was significantly improved with concurrent cisplatinum with 25% 3-year locoregional progression-free survival versus 0% in the radiation-alone arm. With the adequate radiation doses of 64 Gy and with modern CT-guided treatment planning, this study clearly underlines the single-agent activity of cisplatin in this combined modality setting.

A negative trial came from the Hoosier Oncology Group (HOG) concerning this issue.[36] The group randomized 240

patients to either three weekly 70 mg/m$^2$ cisplatinum given concurrently with adequate 60- to 65-Gy radiotherapy versus radiotherapy alone. Although the 5-year survival rate was increased with 5% in the concurrent cisplatinum arm versus 2% in the radiotherapy-alone arm, this difference did not show statistical significance ($p = 0.35$). Locoregional control was also not different between both arms. The rather poor results in both arms may give a hint that the patient selection of this study was probably more unfavorable than the one chosen in the other studies (concerning performance status and weight loss). Nevertheless, this study clearly represents a negative trial for concurrent chemoradiotherapy based on cisplatin. It is not clear whether the three weekly application of a lower dose of cisplatin (70 mg/m$^2$) may be the major factor for these negative findings.

Taken together all trial results with single-agent cisplatinum, we can conclude that cisplatin alone given either in five daily applications per cycle (days 1 to 5) or as daily low-dose application has a significant radiation-enhancing effect, leading to a clinical benefit in local control. This benefit for local control translates into a significant overall survival benefit. With the systemic effect of single-agent cisplatinum on micrometastases being rather questionable, these results have prompted trials looking at an increased dose density of cytotoxic chemotherapy, giving combined chemotherapy protocols of cisplatinum doublets that will be discussed later in this chapter.

**Trials of Concurrent Chemotherapy and Radiotherapy: Single-Agent Carboplatin** With the platinum derivative carboplatinum being very popular in North America, it should be kept in mind that single-agent clinical data of carboplatin given concurrently to radiation are all negative, so far (Table 56.4).

A Dutch study randomized 160 patients to concurrent daily carboplatin with 60-Gy standard fractionated radiotherapy versus single-modality radiotherapy alone.[37] Two-year locoregional progression-free survival was inferior in the concurrent arm with 35% versus 38% in the radiotherapy-alone arm. Two-year overall survival rates were decreased with the carboplatinum application versus single-modality radiotherapy (20% vs. 28%). Both results, however, were not statistically significant, but the toxicity (especially esophagitis) was increased by the combined modality protocol.

The CALGB randomized 120 patients to either weekly carboplatinum given concurrently to 60-Gy standard fractionated radiotherapy or the same radiation alone.[38] Both arms were given an induction two cycles cisplatinum and vinblastine protocol. Although this study does not represent a completely fair test for concurrent carboplatinum, it is remarkable to note that no significant difference in either locoregional control nor in overall survival could be observed between the two arms. Currently, we have to state that there is no clinical evidence that the application of single-agent carboplatinum given concurrently to radiotherapy has any radiation-enhancing capacity. Together with the missing data on adjuvant chemotherapy efficacy of carboplatinum as well as data from the metaanalysis in the palliative setting of reduced efficacy of carboplatin versus cisplatin, these data could lead to a rather critical sight of carboplatin-based regimen in the curative setting of combined modality for stage III NSCLC.[39,40]

**Trials of Concurrent versus Sequential Chemotherapy and Radiotherapy: Chemotherapy Combinations** The benefit of induction chemotherapy added to definitive radiation is primarily based on increased systemic control with impact on systemic micrometastases outside the brain. The impact of concurrent application of chemotherapy to radiation is predominantly related to an increase in locoregional control that translates into an overall survival benefit. Therefore, several randomized clinical trials have compared these two strategies in stage III NSCLC (Table 56.5).

The West Japan Lung Cancer Group (WJLCG) randomized 314 patients to two cycles of a second-generation chemotherapy protocol consisting of mitomycin, vindesine, and cisplatinum (MVP) as induction followed by a definitive split-dose radiation protocol of 56-Gy conventionally fractionated radiotherapy in the sequential arm.[41] This was compared with the same two cycles of MVP chemotherapy giving concurrently with the same split-dose radiation of 56 Gy. This study substantiated a significant benefit in overall survival with a median survival of 16.5 months in the concurrent arm and 13.3 months in the sequential arm ($p = 0.04$). The 5-year survival rates were 16.9% in the concurrent versus 8.9% in the sequential arm, meaning nearly a doubling of long-term survivors in the concurrent treatment arm. Locoregional progression-free survival was significantly increased by the concurrent application of MVP to radiation in comparison with the sequential administration. Thus, the concurrent application in this trial led to an increase in local control that translated into a significant increase in overall survival.

bid, twice daily; BROCAT-G, Bronchial Carcinoma Taxol Group; Carb, carboplatin; cc, concurrent; cons, consolidation; E, etoposide; ind, induction; M, mitomycin; NA, not applicable; NR, not reported; orE, oral etoposide; P, cisplatin; Pac, paclitaxel; RT, radiotherapy; RTOG, Radiotherapy Oncology Group; GLOT-GFPC, Groupe Lyon-Saint-Etienne d'Oncologie Thoracique–Groupe Français de Pneumo-Cancérologie NPC 95-01; SplC, split course; S, survival; V, vindesine; Vbl, vinblastine; Vrb, vinorelbine; WJLCG, West Japan Lung Cancer Group.

The second landmark trial of concurrent chemotherapy versus sequential chemotherapy was the RTOG 9410 trial.[42] This study randomized 611 patients to three different treatment arms. The standard comparator arm was two cycles of cisplatin and vinblastine followed sequentially by 60-Gy conventionally fractionated radiotherapy. The first experimental arm was the same two cycles of cisplatin and vinblastine given concurrently to 60-Gy radiation. The third arm was based on an RTOG pilot trial and used cisplatin and oral etoposide giving concurrently with 69.9-Gy hyperfractionated accelerated radiotherapy (HART) (1.2 Gy bid). The final results of this trial indicated that the concurrent chemotherapy arm with standard fractionated radiotherapy gave significantly improved survival results. The 4-year survival rate was 21% in the concurrent arm versus 12% in the sequential arm ($p = 0.05$). The hyperfractionated radiotherapy arm showed intermediate results but no significant difference to the standard comparator arm.

Both studies together, the WJLCG and the RTOG trial had a significant impact on the combined modality treatment of locally advanced stage III NSCLC. Two further prospectively randomized trials have been reported that should deserve attention here.

The German BROCAT study group randomized 219 patients to induction carboplatin and paclitaxel followed by single agent weekly paclitaxel given concurrently to 60-Gy conventionally fractionated radiotherapy.[43] The standard comparator arm was based on carboplatin and paclitaxel induction chemotherapy followed by sequential radiation therapy of 60 Gy. This trial did only show a trend of survival improvement (18.7 vs. 14.7 months; $p = 0.09$). Median time to progression significantly favored the concurrent approach (11.3 vs. 6.3 months; $p < 0.001$). However, based on these study results, single-agent weekly paclitaxel cannot be considered the standard of care for concurrent chemoradiotherapy protocols.

The fourth study was the French GLOT-GFPC study group protocol NPC 95-01.[44] The French cooperative group randomized 205 patients to cisplatin and vinorelbine given as induction therapy for three cycles followed by conventionally fractionated 66-Gy radiotherapy as the standard arm. The experimental arm used a concurrent chemotherapy of two cycles cisplatin and etoposide with the same 66-Gy radiotherapy and two cycles of cisplatin and vinorelbine consolidation treatment. The study showed an increase in median survival (16.3 vs. 14.5 months) as well as 3- and 4-year survival rates (25% vs. 19%; 21% vs. 14%; $p = 0.24$) with the concurrent chemotherapy application. This study could only substantiate a trend toward better survival and long-term survival but, overall noteworthy, showed increased treatment-related deaths in both study arms (10 vs. 6 patients) that may set a note of caution to the patient selection based on comorbidity profiles of patients in this study.

Taken together, the whole accumulated dataset on concurrent versus sequential chemotherapy to radiotherapy in stage III NSCLC, the benefit of the concurrent application of combination chemotherapy seems to be moderate but clinically meaningful and significant. Especially the long-term survival rates are nearly doubled by these combined modality protocols.

The toxicity profiles of the two approaches are different with significant increase in hematologic and esophageal toxicities with concurrent chemoradiation protocols. However, these toxicities are self-limiting and, therefore, concurrent chemoradiotherapy protocols have become a standard of care for most patients with good performance status, especially in the stage IIIB subset of locally advanced NSCLC.

### Toxicity Profiles of Concurrent Chemoradiation Protocols

The analysis of the prospectively randomized trials in stage III NSCLC revealed a significant increase in treatment-related toxicities within concurrent chemoradiation protocols.[41–44] However, these toxicities were uniformly self-limiting. The increased hematologic toxicities with more neutropenia and thrombocytopenia did uniformly not lead to an increased infection rate or an increase in bleeding episodes. The increased esophagitis rate did not lead to significantly increased fistula or late stenosis of the esophagus. Especially with modern CT-guided conformal radiotherapy planning techniques, the rates of esophagitis in the concurrent chemoradiation protocols could be further reduced and no longer represent a significant toxicity issue. Comparable to this, the initially increased pneumonitis rate with concurrent chemoradiation in cases with larger treatment fields could be significantly reduced by the new 3D-conformal treatment planning techniques with a possible significant reduction of the V20 based on more individualized treatment plans.

However, comorbidity profiles still represent an issue in the clinical decision making for patients to put on concurrent chemoradiation protocols. Age is usually not a limit on its own, a subgroup analysis of a large North American RTOG trial 94-10 showed the greatest benefit in the subgroup of patients older than 70 years of age.[45] However, significant pulmonary comorbidities resulting in reduced forced expiratory volume in 1 second ($FEV_1$) or reduction of diffusing capacity of the lung for carbon monoxide ($D_LCO$) values should lead to careful evaluation of the patients to be treated with aggressive chemoradiotherapy protocols.[46] Cardiovascular impairments should be taken into account especially in large left lower-lobe tumors with a significant part of the myocardium to be included in the treatment fields. Again, with more advanced techniques of radiation treatment planning, significantly more patients can be individually planned for combined modality approaches. It is likely, that especially with PET-CT functional imaging technology now available, in the future even more patients can be put on more conformal and restricted radiation fields within definitive high-dose chemoradiation treatments.

### The Consolidation Chemotherapy Issue to Improve Systemic Control

The general perception has been that two cycles of concurrent chemotherapy given concurrently to radiation therapy may not be enough systemic treatment for existing micrometastases in far locally advanced stage III tumors with significant systemic risks. This may especially hold true for patients with stage IIIB NSCLC. The pilot study was the SWOG 9405 trial looking at a surgically staged IIIB patient

| TABLE 56.6 | Prospective Multicenter Trials of Concurrent Radiotherapy and Chemotherapy Plus Consolidation Chemotherapy | | | | | | |

population put on a definitive concurrent chemoradiation protocol (Table 56.6).[22] Following this study and the report of the results of the North American Intergroup trial 0139 that accrued patients in stage IIIA (N2) disease, a postoperative application of two cycles of consolidation cisplatin and etoposide had become a typical consolidation protocol after concurrent chemoradiation with two cycles of cisplatin and etoposide.[47] However, postoperative application of chemotherapy in the phase of beginning postradiation pneumonitis has eventually turned out as a difficult task. Even in the Intergroup trial, only 75% of the patients received the planned postchemoradiation consolidation. This has triggered consolidation protocols that are easier to administer. The SWOG piloted the introduction of consolidation single-agent docetaxel for three cycles following definitive chemoradiation with cisplatin and etoposide for two cycles administered concurrently to radiation (SWOG 9504).[48] The patient selection was similar to a prior chemoradiation protocol using the same chemoradiation protocol with two cycles of cisplatinum and etoposide as consolidation (SWOG 8808). Only patients with pathologic IIIB disease were included into that trial. The trial was carried out in the cooperative group multicenter setting and in 83 patients showed a median survival of 26 months, which was a major improvement in comparison with the predecessor cisplatinum and etoposide consolidation trial. The logical step following these favorable results was to carry out a multicenter prospective randomized trial. This was carried out by the Hosier Oncology group, and the final survival results of that trial have been presented at ASCO 2007.[49] The trial randomized 250 patients with stages IIIA and IIIB NSCLC to either two cycles of cisplatin and etoposide given concurrently to 63-Gy conventionally fractionated radiotherapy followed by three cycles of single-agent docetaxel consolidation versus the same chemoradiation protocol without any consolidation treatment. The final survival data showed a median overall survival of 21.5 months with consolidation docetaxel versus 24.1 months with chemoradiation alone and 3-year survival rates of 27.2%

versus 27.6% in both arms, respectively. The toxicity profile significantly favored the arm without docetaxel consolidation as a significant number of treatment-related deaths was observed, probably due to the administration of docetaxel in the typical time phase of radiation-induced pneumonitis but also due to serious infections. Thus, the widely adopted consolidation docetaxel strategy in North America cannot be supported any longer in stage IIIB NSCLC management.

### Induction Chemotherapy to Improve Systemic Control Prior to Definitive Chemoradiation

Other groups have looked at further induction chemotherapy for systemic treatment to be added prior to definitive concurrent chemoradiation protocols (Table 56.7). The first group to pilot such a strategy was the CALGB in their prospectively randomized phase II study looking at cisplatinum-based combinations with newer drugs such as paclitaxel, gemcitabine, and vinorelbine.[50] Two cycles of the combination chemotherapy were given as induction treatment, and then two cycles of the same combination with some dose reductions of the newer drugs were given concurrently to 66-Gy conventionally fractionated radiotherapy. One hundred and seventy-five patients were randomized to receive either cisplatin and paclitaxel, cisplatin and gemcitabine, or cisplatin and vinorelbine combination chemotherapy in this setting. Overall survival rates at 3 years were not different with 19%, 28%, and 23%, respectively. The toxicity profile of the combination protocols in this trial favored the cisplatin and vinorelbine arm. Thus, either cisplatin and vinca alkaloid or cisplatin and etoposide combinations have currently the largest evidence to be combined within definitive chemoradiation protocols.

Another randomized trial has been presented at ASCO 2007 from the French Cooperative GLOT group.[51] They randomized an upfront chemoradiation arm of two cycles of cisplatin and vinorelbine to 65-Gy conventionally fractionated radiotherapy, followed by three cycles of cisplatin and paclitaxel

versus an induction chemotherapy arm of three cycles of cisplatin and paclitaxel, followed by the concurrent chemoradiotherapy based on cisplatin and vinorelbine. Although not planned as a phase III trial, this study observed somehow better survival outcome in the induction therapy arm with cisplatin and paclitaxel. Because of the small number of patients in this study (n = 201), overall survival results are not conclusive and should be interpreted with caution.

The CALGB in their follow-up trial to the randomized phase II based on cisplatinum protocols investigated a carboplatinum combination with paclitaxel.[52] They randomized 366 patients to either upfront weekly concurrent carboplatin and paclitaxel together with 66-Gy standard fractionated radiation versus an induction protocol of two cycles of carboplatin and paclitaxel followed by the same concurrent chemoradiation with weekly carboplatin and paclitaxel. The induction arm did better with 3-year survival rates of 24% versus 18% in the upfront chemoradiation arm although only a trend was reached statistically with a *p* value of 0.1. However, both arms still fared poorly in comparison to their earlier studies and to other multicenter chemoradiation trials results. It could as well

be, and it was subsequently speculated that the patient population was too negatively selected within this study including patients with significant weight loss, and thus, changing to a prognostically more unfavorable patient subgroup.

Thus, with these existing conflicting results, induction chemotherapy has not yet emerged as a standard of care for patients with stage IIIB NSCLC. Differently to experience in head and neck cancer trials, induction protocols in NSCLC may only show significantly high enough activity in a defined proportion of the patient population. Adequate results have, so far, only been achieved with cisplatinum-based combinations. Carboplatin-based protocols and especially weekly low-dose chemotherapy may not be appropriate in the curative setting of aggressive multimodality treatment protocols. Future testing of aggressive induction strategies based on newer and more active chemotherapy protocols as well as the introduction of molecular targeted drugs such as epidermal growth factor receptor (EGFR) drugs (e.g., cetuximab) may be necessary to achieve more downsizing and downstaging of tumors prior to the definitive chemoradiation protocol aiming predominantly at locoregional control of the tumor.

## Higher Radiation Doses or Alternative Fractionation following Induction Therapy Protocols

The CALGB has piloted a more aggressive protocol based on an induction chemotherapy strategy followed by a dose-escalated conformal radiation therapy up to 74 Gy in stage III NSCLC patients.[53] The trial was a randomized phase II protocol including 67 patients (Table 56.7). The patients were randomized to an induction protocol of either carboplatin and paclitaxel (Arm A) or carboplatin and gemcitabine (Arm B). Arm A received a concurrent application of further carboplatin and paclitaxel given to 74-Gy conventionally fractionated high-dose conformal radiotherapy. Arm B received biweekly gemcitabine concurrently to high-dose radiotherapy of 74 Gy. Arm B had to be closed early because of high grade 4 and 5 toxicities observed. Arm A reached its predefined end point with a median survival of 18 months in the selected patient subset. This protocol is currently being tested in a randomized trial of CALGB versus a standard-dose chemoradiation protocol. A further phase I trial within CALGB has been looking at an innovative chemotherapeutic induction regimen of carboplatin and paclitaxel combined with bevacizumab as well as erlotinib followed by a definitive high-dose radiation protocol to 74 Gy together with weekly carboplatin and paclitaxel[54] (Table 56.8). Final efficacy and toxicity results have to be awaited for further interpretation of this aggressive strategy.

Eastern Cooperative Oncology Group (ECOG) has piloted a more aggressive accelerated radiation fractionation schedule with the HART protocol (Table 56.7).[55] Accelerated fractionation has a strong radiobiological rationale to support it as time for radiation-induced damage repair is significantly shortened by giving several daily fractions of treatment and reducing the overall treatment duration. ECOG randomized 112 patients with stage III NSCLC following induction chemotherapy with carboplatin and paclitaxel to either conventionally fractionated radiotherapy with 64 Gy or an accelerated radiotherapy fractionation of 57.6 Gy given in three daily fractions with an overall treatment duration of 2.5 weeks. Although the patient number of this study was too small and the study had to close early because of poor patient accrual, the accelerated fractionation arm had a 3-year survival rate of 24% versus 18% in the conventionally fractionated treatment arm. There was a trend for improved survival results with the accelerated radiotherapy but because of the small number of patients randomized, this study has no conclusive results concerning the overall efficacy of such an intensive radiation therapy approach.

## Future Directions Including the Introduction of Molecular-Targeted Agents into this Setting

Besides the aforementioned phase I trial in CALGB, first experience has been reported looking at an EGFR tyrosine kinase inhibitor maintenance treatment in the setting of stage IIIB NSCLC following definitive chemoradiation and consolidation docetaxel.[56] This large randomized trial included stage III NSCLC patients without disease progression under treatment with chemoradiation and consolidation docetaxel (Table 56.8). The patients were then randomized to either maintenance treatment with gefitinib or placebo. The trial accrued 572 eligible patients and was able to randomize 243 patients to either maintenance gefitinib or placebo. More than half of the patient population was initially found to be in stage IIIB NSCLC. Needless to say, this treatment was given to unselected patients concerning their molecular signal transduction and mutational EGFR status. The trial had to be closed down because the first interim analysis presented an inferior survival result in the arm randomized to maintenance gefitinib (median survival 35 months with maintenance placebo vs. 23 months with

maintenance gefitinib). It is still not clear whether these unfavorable results are based on a significant selection bias between the arms or related to an imbalance of major prognostic factors or if this study gives a hint that EGFR inhibitors could be deleterious in unselected patient populations such as the one chosen in this trial.

Recently, very positive data have been presented with the combination of chemotherapy together with cetuximab in the first-line treatment of advanced NSCLC.[57] In head and neck cancer, very positive data have been reported with single-agent cetuximab as a radiation sensitizer within a large randomized phase III trial.[58] The survival benefit observed in that trial was found to be 10% at 5 years, comparable with the range of benefit achieved with cisplatin-based chemotherapy when given concurrently to radiotherapy in the same setting (8% at 5 years, results of the metaanalysis).[59] Based on these encouraging results, the RTOG has performed a pilot phase II trial of concurrent chemoradiotherapy based on a weekly carboplatin and paclitaxel protocol combined with weekly cetuximab treatment, a 63-Gy upfront conventionally fractionated radiotherapy followed by consolidation single-agent cetuximab, followed by two further cycles of carboplatin and paclitaxel together with cetuximab (Table 56.8)[60] The preliminary data of this trial for 93 patients entered have been presented at ASCO 2007 and with longer follow up at ASCO 2008. The combination was found to be feasible with moderate acute and late toxicities. Nearly half of the patient population was initially found to have stage IIIB disease. Preliminary efficacy data showed encouraging survival results in this patient cohort. The group is currently planning to perform a large randomized phase III trial with the same regimen looking at the impact of cetuximab administration in this setting.

Further, pilot trials are currently performed with VEGF-acting drugs such as bevacizumab in the combined modality approach to stage III patients (see also previous discussion). When introducing new molecular-targeted agents into the setting of chemoradiation protocols, interaction with radiation as well as amelioration of radiation induced pneumonitis have to be carefully monitored.[61] Both acute as well as late effects should be screened and well documented. Thus, the development of future progress within this combined modality setting will be time consuming and slowly.

## CONCLUSION

For most patients with stage IIIB NSCLC, a combination of chemotherapy with radiotherapy remains the most optimal treatment strategy with a curative intent. Nevertheless, it should be kept in mind that IIIB disease in itself represents a very heterogeneous group of patients spanning from T4N0 tumors with less biologic aggressiveness to metastasize on one hand, to T1N3 disease on the other hand with small primary tumors that have a striking tendency to metastasize early into mediastinal nodes as well as to promote micrometastatic spread. Furthermore, even T4 disease represents several subsets of patients, including those with potentially resectable T4 tumors

involving the carina, the distal trachea, the superior vena cava, the left atrium, and a vertebral body. In contrast to that, other T4 subsets include patients definitely found to be unresectable such as T4 tumors invading the thoracic aorta, the esophagus, the pulmonary artery main stem, and the myocardium. The new IASLC staging system will recognize prognostic differences observed within the large database for T4 tumors and will regroup prior M1 pulmonary satellite nodes in ipsilateral lobes outside the primarily involved lobe as T4 disease. Comparable to this, pleural effusion and pleural metastasis found at thoracotomy or thoracoscopy will be regrouped into the M1a disease category. Satellite nodules in the same lobe as the primary will be regrouped as T3 disease because they present a subgroup with a more favorable long-term prognosis. Several groups have reported selected patient cohorts with definitive surgical treatment in stage IIIB. However, these trials usually had small patient numbers, represent selective patients subsets, and patients were usually treated within combined modality protocols including chemotherapy-positive/negative radiotherapy prior to definitive surgery. The T4N0 subset of IIIB may represent a specific group of patients with favorable outcome when put on multimodality protocols. Some data have also been reported on surgery in further patient groups, including N3 disease in contralateral mediastinal and even supraclavicular nodes. The overall value of surgery in this setting is not established, and patients should be preferably included into prospective trials if surgery is to be included within the combined modality approach.

On the whole and looking at the broader patient population, concurrent chemoradiotherapy protocols as definitive treatment with curative intent have achieved the best results, so far. The largest experience has been reported with cisplatin-based combinations—either cisplatin and etoposide or cisplatin and vinorelbine given concurrently with conventionally fractionated radiotherapy protocols up to 63- or 66-Gy cumulative doses. Based on the single-agent data of cisplatin and carboplatin from early randomized chemoradiation trials, cisplatin may be preferred to carboplatin as the backbone of concurrent chemotherapy in this setting. Induction chemotherapy prior to sequential radiotherapy has proven to be superior to radiation therapy alone with an improvement in long-term survivors. Concurrent chemotherapy to radiotherapy has achieved a significant increase in local control, and thus in overall survival. This strategy has become the preferred approach to patients with stage IIIB NSCLC in recent years. The broadest evidence of chemoradiation protocols comes from the IIIA disease setting with cisplatin and etoposide given for two cycles of concurrent chemotherapy to radiotherapy. Typically, two cycles of cisplatin and etoposide are added as consolidation chemotherapy. Consolidation with single-agent docetaxel has shown encouraging results in a multicenter phase II trial. These favorable results could not be confirmed in the HOG randomized phase III comparison where consolidation docetaxel did not result in a survival improvement but rather led to increased morbidities and an increase in treatment-related deaths. Whether induction chemotherapy based on cisplatin combinations—as piloted in the

CALGB study—will further improve the results by an impact on systemic micrometastases and downsizing and downstaging effects on the primary tumor is not yet known. However, it is clear that systemic metastases remain the major issue for a significant number of patients in this disease stage. The search for molecular-targeted drugs that may further enhance the chemoradiation strategy has recently begun. EGFR-acting drugs have already been tested within pilot phase II trials, and the first randomized trial looking at maintenance strategy with these drugs has already been reported. Whether this innovative approach can be applied to unselected patient populations or will have to be introduced within previously well-defined patients' subsets based on signal transduction studies is not yet known. Unfortunately, another significant competing risk of these patients' subgroups lies in the development of brain metastases. Chemotherapy has no effect to reduce these brain relapses prophylactically. Prophylactic cranial irradiation seems to be the natural intervention in high-risk populations, but data on survival impact from randomized trials are missing, so far.

# Prophylactic Cranial Irradiation in Non–Small Cell Lung Cancer

Brain metastases in patients with non-small cell lung cancer (NSCLC) are a devastating problem with profound impact on survival and quality of life. Historically, the incidence of brain metastases has been underreported. Generally, brain metastases are not diagnosed until they are symptomatic. Asymptomatic metastases frequently go unrecognized. This is clinically inconsequential for patients who die from uncontrolled extracranial disease. However, with improvements in systemic therapy and locoregional therapy, more patients with localized disease are being cured and patients with metastatic, incurable disease, are living longer. Consequently, brain metastases have taken on greater clinical significance. Management of the brain after diagnosis of brain metastases has taken on increasing importance and is being intensively studied. However, preventative treatments for brain metastases are infrequently employed in clinical practice, and only recently is prophylactic cranial irradiation (PCI) for NSCLC being reevaluated in clinical studies.

## RISK OF BRAIN METASTASES

The high incidence of brain metastases in lung cancer can be partially explained by normal physiology. Fifteen percent of blood flow from the left heart goes directly to the brain. Lung cancer cells have direct access to the left side of the heart via the pulmonary veins. Cancer cells from other organs must pass through the pulmonary capillaries or be shunted from the right to left side of the heart before gaining access to the brain.

Cancer cells require complex capabilities of extravasation, evasion of the immune detection system, and establishing new blood vessels in the process of establishing brain metastases. This process is detailed in an excellent review article published by Gavrilovic and Posner.[1] Cells undergo genetic changes to allow for uncontrolled growth, angiogenesis, and intravasation into blood vessels. Cells must then survive circulation and reach the organ in question where the right biochemical environment is necessary for proliferation and development of metastases. Cancer cells destined to become brain metastases are caught in the CNS capillaries and then proliferate through the vessels into the brain parenchyma. Here, the blood-brain barrier protects them from many systemic cancer therapies. There is a variable period of dormancy during which time, genetic changes take place, enabling cells to proliferate and become clinically significant metastases. This period of protected dormancy explains why we see delayed brain metastases in patients with effectively treated lung cancer and why as treatment is improving and survival is lengthening, the rate of brain failures is increasing.

The incidence of brain metastases in patients with locally advanced non–small cell lung cancer (LA-NSCLC) varies between 13% and 54%.[2–11] From various reports, a range from 18% to 52% of patients have a solitary brain lesion.[11–15] The risk of brain failure has been related to disease stage,[10] disease bulk,[16] histology,[10,17–19] length of survival from diagnosis,[20] female gender,[21] age <60 years,[12,16,22] type of therapy,[10,17,23] and serum lactate dehydrogenase.[21]

**Histology**    The incidence of brain metastases is higher with adenocarcinoma and large cell carcinoma than with squamous cell carcinoma.[17–19,24] Consequently, some studies evaluating PCI for NSCLC have included only patients with nonsquamous histologies.[5,7] Although a trend toward increased incidence of brain metastases in patients with adenocarcinoma is observed in most studies, not all studies have shown a significant correlation.[4,8,10,11,16,21,25]

**Extent of Mediastinal Disease**    Ceresoli et al.[16] reported borderline significance of bulky mediastinal disease (nodes >2 cm) and the incidence of brain disease by multiple regression analysis. Robnett et al.[10] reported 2-year actuarial incidence of brain metastases of 36% with stage IIIB disease and 29% with Stage II/IIIA disease ($p < 0.04$). Wang et al.[25a] conducted a more extensive analysis of impact of nodal disease on brain failures in 223 patients treated surgically with stage IIIA/B disease. Brain metastases were greater in patients with more lymph nodes and more nodal regions involved.

**Age** Ceresoli et al.[16] evaluated risk factors for brain metastases in 112 patients with LA-NSCLC. In multivariate analysis, age younger than 60 years was associated with an increased risk of brain metastases (31% vs. 9%; $p = 0.03$). In a series reported by Carolan et al.,[12] 25.6% of patients younger than age 60 failed first in the brain compared with 11.4% of patients older than 60 ($p = 0.022$). In a review of four Southwest Oncology Group (SWOG)[22] studies, patients age 50 and younger were at increased risk for developing brain metastases with a hazard ratio of 1.8 ($p = 0.046$). Other series have not shown an increased risk of brain metastases with young age.[10,13]

**Time to Brain Failure** Most brain metastases occur within 2 years of diagnosis.[10–13,16,20,22] Median time to relapse in the brain is 5.7 to 11.7 months.[10,12,13,16,20] Earlier relapse is associated with younger age (<60),[12,16,22] bulky disease (>2 cm),[16] and nonsquamous histology.[12,22]

**Duration of Survival** The addition of chemotherapy to local regional therapy for LA-NSCLC has improved survival. Systemic therapy decreases the risk of visceral metastases[17,18,26,27] but has limited impact on brain metastases.[17,18,27] In fact, as survival lengthens the risk of brain, metastasis increases. Review of Radiation Therapy Oncology Group (RTOG) and single-institution data has shown that longer survival for patients with LA-NSCLC treated with radiation alone[20,24] or radiation and chemotherapy[18] is associated with an increased incidence of brain metastases.

Review of 1415 patients treated on radiation therapy alone and 350 patients treated on radiation and chemotherapy on RTOG studies demonstrated a significant decrease in distant metastases with the addition of chemotherapy (41% vs. 19%; $p < 0.001$). Brain metastases were not altered by chemotherapy (17% vs. 12%).[18]

Andre et al.[17] reported the patterns of relapse in 81 patients with clinical N2 disease treated with preoperative chemotherapy to 186 comparable patients treated with primary surgery. Survival at 2 and 5 years was 35% and 17% for preoperative chemotherapy and 26% and 8% for primary surgery. Preoperative chemotherapy was associated with a better prognosis in multivariate analysis ($p = 0.001$). Additionally, patients treated with chemotherapy had a lower rate of visceral metastases (28% vs. 38%; $p < 0.05$) and a higher rate of brain metastases (32% vs. 18%; $p < 0.05$). The observation that neoadjuvant chemotherapy (or chemoradiotherapy) is associated with an increased risk of brain metastasis is bolstered by reports from Philadelphia and San Francisco.[10,13] An explanation might be that as local and system disease are better controlled, and the untreated risk site, the brain, becomes a dominant site of failure.

Recursive partitioning analysis (RPA) of RTOG studies employing radiation therapy alone showed that patients in the RPA group with the longest survival had the highest incidence of brain metastases.[20] Median survival for class I and II was 12.6 and 8.3 months, and class III and IV was 6.2 and 3.3 months. First failure in the brain was significantly higher in class I (18%) compared with class III (9%) and IV (6%) ($p = 0.0004$ and 0.03, respectively).

Recently, several studies employing multimodality therapy for LA-NSCLC have reported excellent median and 3-year survival rates of 20 to 43 months and 34% to 37%.[4,11–13,16,23,28] These studies reported the brain to be a common site of failure. Overall brain failure rates were 22% to 55%, and rates of brain as first site of relapse were 16% to 43%. Studies with lower median survival (3 to 17 months) and 3-year overall survival (5% to 27%) report a lower incidence of brain metastases, suggesting that the later brain relapse in the longer-surviving patients occurs in a sanctuary site. Overall rates of brain failure are 6% to 21%, and rates of brain as first site of failure are 9% to 19% (Table 57.1).[3,10,20,29,30]

**Locoregional and Systemic Therapy** Studies have shown an association between timing of local therapy incidence of brain metastases. Robnett et al.[10] reported a near doubling of the 2-year actuarial risk of brain metastases of 39% in patients treated with sequential chemotherapy and radiation compared with 20% for patients treated with concurrent chemotherapy and radiation. Mamon et al.[23] reported results of patients treated preoperatively with chemotherapy or concurrent chemotherapy and radiation. Decreased risk of brain metastases was associated with preoperative +/− postoperative radiation versus postoperative radiation therapy only ($p = 0.062$), use of taxane-based chemotherapy ($p = 0.044$), and conversion to N0 status ($p = 0.025$). Conversely, Furuse et al.[31] reported a higher rate of brain failures in patients treated with concurrent chemotherapy and radiation compared with patients treated sequentially, (19% vs. 9%; $p = 0.018$). The higher rate of brain metastases may be explained by longer survival in the concurrently treated patients (16.5 vs. 13.3 months; $p = 0.04$). Byhardt et al.[32] reviewed the outcome in 461 patients treated on five RTOG studies and found no association between the incidence of brain metastases as first failure and sequential versus concurrent chemotherapy and radiation. Median survival for concurrent regimens was 16.3 and 15.8 months and for sequential therapy 13.6 months ($p = 0.47$).

## MANAGEMENT OF THE BRAIN IN NON–SMALL CELL LUNG CANCER

There is not a standard of care for addressing brain micrometastases after successful therapy for LA-NSCLC. Most clinicians will perform routine physical examination with imaging of the brain only upon development of signs or symptoms of brain failure. The National Comprehensive Cancer Network (NCCN) guidelines for follow-up of lung cancer include physical exam, chest x-ray, and thoracic computed tomography (CT) scans at regularly defined intervals. CT or magnetic resonance imaging (MRI) screening for brain metastases is not included as standard management. Although some investigators have evaluated and/or endorse routine neuropsychological

assessment and CT or MRI screening for early detection of brain metastases,[11,13,15] others have begun to use PCI as part of multimodality therapy regimens[3–5,9,33] or suggested the urgent need for further investigation of PCI.[4,10,12,17,18,21–23]

## Standard Follow-up

Prognosis of patients with brain metastases is poor. Median survival ranges between 3 and 7 months.[34–37] Most information regarding outcomes of patients with brain metastases consists of reports on symptomatic patients with varying controls or lack of control of the primary and systemic disease sites, age, gender, and performance status.

There seem to be subgroups of patients that have a relatively favorable prognosis. Recursive partitioning analysis of RTOG brain metastases trials (61% of patient had lung cancer) identified three prognostic groups.[37] RPA class I patients have Karnofsky Performance Score (KPS) ≥70, age <65 years, control of primary tumor, and no extracranial metastases. Class III patients include all patients with KPS <70. Class II includes all others. Median survival for class I to III is 7.1, 4.2, and 3.3 months. Other studies have confirmed the value of RPA-derived prognostic classes.[38,39] Unfortunately, the most favorable subsets of patients represent a minority of cases. Only 20% of patients were RPA class I in RTOG studies treating brain metastases. Nieder et al.[38] retrospectively reviewed 532 consecutive patients at a single institution treated for brain metastases, and only 3% were RPA class I.

Brain metastases studies with the most favorable results (median survival between 10 and 16 months) include patients with favorable prognostic factors that have been treated for overt brain disease with either surgery[40–43] or radiosurgery,[44,45] with or without whole-brain irradiation. Survival has been associated with high performance status,[44,45] female gender, absence of active systemic disease, long duration from lung cancer diagnosis to development of brain metastases,[44] solitary versus 2 to 3 lesions, and favorable histologic status.[45]

Long-term survival and possible cure has been reported in patients with control of extracranial disease who are treated surgically for brain metastases.[46–48] Overall 5-year survival for carefully selected patients with resected solitary brain metastases as high as 20% to 30%.[49] There are case reports of patients surviving more than 10 years.[46,50,51] Unfortunately, patients with brain metastases rarely have potentially curable disease.

## Routine Brain Imaging

Early detection of brain metastases allows for intervention prior to debilitating neurological symptoms. Additionally, brain metastases are more likely to be amenable to aggressive therapy with radiosurgery or resection, when tumor burden is low. Theoretically, even if disease is multifocal and not appropriate for localized therapy, smaller lesions are more likely to have a meaningful response to standard doses of whole-brain irradiation. Yokoi et al.[15] evaluated the potential benefits of MRI and CT to detect brain metastases in patients with stage I to IIIB NSCLC treated surgically. Disease was detected prior to development of neurological symptoms in 76% of patients diagnosed with brain metastases. Median survival for patients with asymptomatic brain metastases was 25 months, whereas overall median survival was only 10 months.[15]

ChT, chemotherapy; NA, not available; NSCLC, non–small cell lung cancer; PCI, prophylactic cranial irradiation; RT, radiotherapy; S, surgery.

**Prophylactic Cranial Irradiation**    Four prospective randomized trials[6–8,25] and several retrospective studies[3–5,9,51,52] have shown that prophylactic cranial irradiation decreases the incidence or delays the onset of brain failures in LA-NSCLC (Tables 57.2 and 57.3). Effective doses of PCI included 2 Gy per fraction to 20, 30, and 36 Gy and 3 Gy per fraction to 30 Gy. These studies were not powered to show a survival advantage nor did they thoroughly evaluate quality of life or neurological function.

**Prospective Studies**    In the early 1980s, RTOG conducted a prospective randomized study[7] comparing PCI (30 Gy in 10 fractions) and chest radiation with chest radiation alone for patients with inoperable or unresectable T1-4N1-3M0 and resected T1-3N2-3M0 nonsquamous NSCLC. Development of symptomatic brain metastases was delayed by PCI. Overall incidence of brain metastases was not significantly decreased. In a small subgroup of patients with prior complete surgical resection, PCI decreased the incidence of brain metastases from 25% to 0% ($p = 0.06$). Most patients in this study did not live long enough to develop brain failure. Median survival in this study was only 8 months because of ineffective therapy and relatively poor prognostic factors. Also, ineffectiveness of locoregional therapy and lack of systemic therapy resulted in a high incidence of locoregional and distant failures that likely were sources of secondary seeding of the brain after PCI was delivered.

ChT, chemotherapy; NA, not available; NSCLC, non–small cell lung cancer; PCI; prophylactic cranial irradiation; RT, radiotherapy.

The Veterans Administration Lung Group[6] conducted a trial that included patients with LA-NSCLC who were not candidates for curative resection and who had no evidence of distant metastases. Patients were randomized to receive whole-brain irradiation (20 Gy in 10 fractions) or no brain treatment and to receive one of two regimes of thoracic irradiation. PCI decreased the incidence of brain metastases from 13% to 6% ($p = 0.038$) in all non–small cell histologies and from 29% to 0% in adenocarcinoma ($p = 0.04$). There was no difference in median survival with PCI.

Umsawasdi et al.[8] reported results of patients with LA-NSCLC treated with combined chemotherapy and radiation therapy and randomized to PCI (30 Gy in 10 fractions) or no PCI. PCI significantly decreased the incidence of brain metastases from 27% to 4% ($p = 0.002$). PCI also increased the brain metastasis-free interval. No survival benefit was observed for the treated group. Beneficial effects of PCI by multivariate analysis favored patients with squamous histology, women, patients with good performance status, weight loss less than 6%, stage III disease, or no prior therapy.

Pottgen et al.[25] randomized 106 patients with stage IIIA NSCLC to either surgery followed by postoperative thoracic radiation therapy or neoadjuvant chemotherapy followed by concurrent chemotherapy and radiation, surgery, and PCI to 30 Gy in 15 fractions. PCI reduced the actuarial rate of brain metastases at 2 and 5 years from 22% to 7.8% and 34.7% to 7.8%, respectively ($p = 0.01$).

**Retrospective Reviews** Six nonrandomized multimodality studies for patients with LA-NSCLC have demonstrated the potential benefits of PCI.[3–5,9,33,52] In the most notable of these studies, 75 patients with stage IIIA/B NSCLC were treated with induction chemotherapy, preoperative radiochemotherapy, and surgery. PCI was introduced after the first half of the study because of a high incidence of brain relapses. Patients treated during the second half of the study were offered PCI (30 Gy in 15 fractions). PCI reduced the rate of brain metastases as the first site of relapse from 30% to 8% at 4 years ($p = 0.005$) and the rate of overall brain relapse from 54% to 13% ($p < 0.0001$).[4]

Skarin et al.[9] treated 41 patients with stage III NSCLC with chemotherapy and radiation followed by surgery. A total of 14% of patients treated with PCI (36 Gy in 18 fractions) developed brain metastases compared with 27% of patients not treated with PCI.[9] SWOG performed a phase II study with neutron chest radiotherapy sandwiched between four cycles of chemotherapy.[3] PCI was administered concurrently with chest irradiation (30 Gy in 10 fractions or 36 Gy in 18 fractions). There was no clinical or radiological evidence of brain metastases in patients who completed PCI. In another phase II SWOG study, patients with stage IIIA NSCLC were treated with chemoradiotherapy and optional PCI (36 Gy in 18 fractions) followed by surgery.[33] A total of 2 out of 18 (11%) patients treated with PCI and 24 of 108 patients (22%) not treated with PCI developed brain metastases. In a phase II Cancer and Leukemia Group B (CALGB) trial, patients with

large cell or adenocarcinoma received 30 Gy in 15 fractions to the brain and neoadjuvant chemoradiation and resection for LA-NSCLC. No brain relapse was observed among the 13 patients who received PCI.[5]

**Toxicity** There is limited information regarding the impact of PCI on quality of life and cognitive functioning. PCI toxicity data is derived mainly from SCLC. Early data suggest significant toxicity associated with PCI. The highest rates of toxicity have been reported when PCI is given concurrently with chemotherapy or when given at high dose per fraction.[53] More recent data has shown that PCI toxicity is acceptable.

Two randomized controlled trials of PCI in patients with SCLC[54,55] have examined cognitive functioning as an outcome, one of which also examined quality of life (QOL).[55] Arriagada et al.[54] randomized 300 patients with SCLC in complete remission to PCI versus observation. No statistically significant differences were noted between the PCI and observation groups in the relative risks of 2-year cumulative incidence of neuropsychological changes. Gregor et al.[55] prospectively evaluated PCI in 314 patients, 136 of these patients (84 PCI, 52 control) were included in an evaluation of quality of life, cognitive functioning, anxiety, and depression at 6 and 12 months. In the PCI and control groups, there was impairment of cognitive function and QOL before PCI with additional impairment at 6 and 12 months. There were no consistent differences between the two groups and no evidence over 1 year of major impairment attributed to PCI.

Retrospective reviews also suggest that PCI does not negatively impact cognitive function and QOL.[56,57] Tai et al.[56] assessed quality-adjusted survival utilizing the QTWiST (quality time without symptoms and toxicity) methodology in 98 patients in complete remission from SCLC who did or did not receive PCI. They reported a significant difference in the mean QTWiST survival between the two groups, favoring the PCI patients ($p < 0.01$). Van Oosterhout et al.[57] evaluated patients with SCLC with neurological function, neuropsychological function, and CT or MRI of the brain. Patients were treated with chemotherapy alone, sequential chemotherapy and PCI, or concurrent or sandwiched chemotherapy and PCI. Although PCI groups had more white matter abnormalities, there was no statistical evidence for additional neurotoxicity of PCI.

It has been suggested that neuropsychological abnormalities associated with SCLC may be secondary to the disease itself (paraneoplasia), systemic therapy,[58] or emotional distress and deteriorated physical condition.[57] Because of potential paraneoplastic effects and different therapy for NSCLC relative to SCLC, definite conclusions regarding tolerance of PCI for NSCLC can only be drawn from prospective studies with serial longitudinal neuropsychological testing of patients with NSCLC treated with and without PCI. Comorbid diseases and their medications need to be kept in mind as potential culprits as well.

Late cognitive deficits with the use of PCI for patients with NSCLC have not been detected, partially because of lack of intensive neuropsychological testing and limited survival. Stuschke et al.[4] studied neuropsychological function and brain MRI in patients with LA-NSCLC after PCI. T2-weighted MRI revealed white matter abnormalities of higher grade in patients who received PCI than in those who did not. Two of the nine patients treated with PCI and none of the four patients not treated with PCI had grade 4/4 white matter abnormalities. There was a trend toward impaired neuropsychological functioning in patients with higher-degree white matter abnormalities. Impairments in attention and visual memory in long-term survivors was seen in both PCI and non-PCI patient groups.

Pottgen et al.[25] performed a battery of neuropsychological tests for attention, memory, associative learning, and information processing in 11 long-term survivors of stage IIIA NSCLC treated surgically.[25] Five patients were treated with chemotherapy, thoracic radiation, surgery, and PCI (30 Gy in 15 fractions); the other six patients were treated with surgery and thoracic radiation. There was no difference in any of the neuropsychological testing between patients with and without PCI. A slightly reduced neurocognitive performance in comparison with age-matched normal population was found for patients in both treatment groups. Ten patients (five from each group) had MRIs of the brain. Leukencephalopathy grade 1 was found in one patient who did not receive PCI and three patients who received PCI.

RTOG recently closed phase III study evaluating PCI for patients with LA-NSCLC. Three hundred and fifty-nine patients were enrolled in the study. Patients without progressive locoregional or distant disease were eligible after completing definitive locoregional therapy for stage IIIA/B NSCLC. Patients were stratified by histology (squamous vs. nonsquamous), therapy (surgery vs. no surgery), and stage (IIIA vs. IIIB), and randomized to PCI (2 Gy per fraction to 30 Gy) or observation. Both groups completed neuropsychological and QOL testing prior to PCI and at regular posttherapy or enrollment intervals. The target accrual for this study was 1058 patients. The study was closed prematurely because of slow accrual. Despite early closure, this study will provide important information regarding the neuropsychological effects of PCI and the impact of PCI on the incidence of brain failures.

## CONCLUSION

Neurological compromise, degradation of QOL, and death in the event of brain metastases are almost certain. The benefit of early detection with prompt intervention or prevention of symptomatic brain metastases in patients with LA-NSCLC may have significant impact on QOL and/or overall survival.

PCI is not standard of care for NSCLC even though there is sufficient evidence to support its effectiveness in decreasing brain failure rates. This is caused by incomplete data regarding toxicity and lack of evidence showing a survival advantage.

Patients with NSCLC treated for potential cure with the highest risk of brain metastases (age ≤60 years, good performance status, treatment with multimodality therapy, particularly therapy including surgery) at a minimum should be followed closely for brain failure during the first 12 to 24 months after completing therapy with detailed history and physical examination. Physicians should have a low threshold for scanning the brain and/or schedule regular scans of the brain.

CHAPTER

# 58

# Chemotherapy for Small Cell Lung Cancer

Small cell lung cancer (SCLC) accounts for 13% of all lung cancer cases diagnosed each year in the United States.[1] A slow decline in the incidence of SCLC has been observed over the last 3 decades because of refined cigarette filters and a decrease in the number of cigarette smokers.[1] At the time of presentation, two thirds of patients will have disseminated disease, making systemic chemotherapy the cornerstone of treatment. SCLC is exquisitely sensitive to chemotherapy. Sixty to eighty percent of patients with SCLC achieve an objective response with combination chemotherapy, but despite these high response rates, the median survival (MS) is 16 to 22 months for patients with limited-stage disease (LS-SCLC) and 9 to 11 months for patients with extensive-stage disease (ES-SCLC). Although this survival time seems dismal, considerable progress has been made. A recent analysis of the SEER (Surveillance, Epidemiologic, and End Results) database revealed a modest but significant survival improvement with current therapies.[1] In 1973, the 2-year survival rate for ES-SCLC was 1.5% compared to 4.6% in the year 2000, whereas the 5-year survival rate for LS-SCLC increased from 4.9% to 10% during a similar time period.

## SINGLE-AGENT CHEMOTHERAPY

The chemosensitivity of SCLC was first identified 50 years ago, with the recognition that methyl-bis-$\beta$-chloroethylamine hydrochloride could cause tumor regression in more than 50% of patients.[2] Older, active agents include nitrogen mustard, doxorubicin, methotrexate, ifosfamide, etoposide, teniposide, vincristine, vindesine, nitroureas, cisplatin, and its analog carboplatin.[3] In the 1990s, six new agents were discovered to have activity against SCLC: paclitaxel, docetaxel, topotecan, irinotecan, vinorelbine, and gemcitabine in untreated and or previously treated patients (Table 58.1).[3–34] This decade, two additional cytotoxic agents have been evaluated (Table 58.1). Pemetrexed, a multitargeted antifolate, an approved agent for the second-line treatment of advanced non–small cell lung cancer (NSCLC), showed no meaningful activity in previously treated SCLC patients in two small studies.[27,28] However, pemetrexed was well tolerated and further evaluation focused on combinations with cisplatin and carboplatin. A randomized phase II trial evaluated the use of cisplatin or carboplatin plus pemetrexed in previously untreated ES-SCLC in 78 patients. Median survival time (MST) for cisplatin/pemetrexed was 7.6 months, with a 1-year survivorship of 33.4% and a response rate of 35% (95% confidence interval [CI], 20.6% to 51.7%). The MST for carboplatin/pemetrexed was 10.4 months, with a 1-year survivorship of 39% and a response rate of 39.5% (95% CI, 24.0 to 56.6). Median time to progression (TTP) for cisplatin/pemetrexed was 4.9 months and for carboplatin/pemetrexed was 4.5 months. Grade 3 and 4 hematologic toxicities included neutropenia (15.8% vs. 20.0%) and thrombocytopenia (13.2% vs. 22.9%) in the cisplatin/pemetrexed and carboplatin/pemetrexed treatment groups, respectively. These data compare favorably with other regimens for ES-SCLC.[36]

An open-label phase III worldwide direct comparison of pemetrexed and carboplatin with the standard first-line etoposide and carboplatin chemotherapy in ES-SCLC is planned to enroll 1820 patients in 23 countries.[37]

Amirubicin, a topoisomerase II inhibitor, has produced impressive responses in both untreated and treated SCLC.[29–34] The promising efficacy and/or tolerability of these drugs have led to their investigation in first-line combination regimens as well as their continued evaluation in the salvage setting.

## COMBINATION CHEMOTHERAPY

In the 1970s, randomized trials clearly demonstrated the superiority of combination chemotherapy over single-agent therapy. Furthermore, they showed that simultaneous administration of multiple agents was more efficacious than the sequential administration of the same agents.[35,38] Cyclophosphamide-based regimens were commonly used to treat SCLC, including CAV (cyclophosphamide, doxorubicin, and vincristine); CAE or CDE

[a] Weekly schedule.

[b] Survival for all patients.

MS, median survival; NR, not reported; R, refractory/resistant relapse; RR, response rate; S, sensitive relapse.

(cyclophosphamide, doxorubicin, and etoposide); and CEV (cyclophosphamide, etoposide, vincristine) until the introduction of cisplatin. Subsequently, randomized trials with the PE (cisplatin and etoposide) regimen were shown to be equally as effective as CAV and less toxic.[39–41] A metaanalysis of 36 trials demonstrated that regimens containing cisplatin and/or etoposide offered a significant survival advantage to patients with SCLC.[42]

Thus, PE became the preferred regimen for treating ES-SCLC yielding objective response rates (ORR) of 65% to 85% with 10% to 20% complete response (CR) rates and an MS of 8 to 10 months.[39–41] Full dose (FD) PE can also be combined with thoracic radiotherapy. In LS-SCLC PE plus twice-daily thoracic radiotherapy is the documented standard regimen when feasible producing an 87% ORR with a 56% CR rate, an MS of

23 months and a 5-year survival rate of 44%.[42] Carboplatin is frequently substituted for cisplatin because of its more favorable toxicity profile. One small randomized trial comparing PE to CE (carboplatin and etoposide) in LS and ES patients showed similar efficacy but CE was significantly less toxic.[43]

**Novel Chemotherapy**    Years lapsed before the discovery of the newer cytotoxic agents described in Table 58.1. For the first time, an abundance of new agents were available to study and a renewed enthusiasm at the opportunity of improving survival for SCLC patients emerged. A wealth of phase I and II trials with

novel combinations were launched. Table 58.2 summarized the results from those promising combinations that were evaluated in phase III trials.[44–55] Most provocative were the results from the Japanese trial comparing cisplatin and irinotecan (PI) to PE. This trial was halted prematurely after an interim analysis showed a survival benefit for PI.[44] One hundred fifty-four patients were randomized to receive four cycles of etoposide 100 mg/m$^2$ on days 1, 2, and 3 with cisplatin 80 mg/m$^2$ on day 1 every 3 weeks or four cycles of PI, irinotecan 60 mg/m$^2$ on days 1, 8, and 15 with cisplatin 60 mg/m$^2$ on day 1. Patients treated with PI had a significantly better overall response rate, MS and 1-year survival rate as

compared to those treated with PE (84.4% vs. 67.5% [$p = 0.02$]; 12.8 vs. 9.4 months; 58.4% vs. 37.7% [$p = 0.002$]), respectively. The PI combination was associated with a higher rate of grades 3 and 4 diarrhea ($p = 0.01$), whereas the PE combination was associated with a higher rate of myelosuppression ($p = 0.0001$). A confirmatory trial using the identical schema by the Southwest Oncology Group (SWOG trial) failed to show a benefit for PI.[45] In this large 651-patient trial, all efficacy parameters were very similar except that there was a trend toward improved progression-free survival (PFS) time for PI at 5.7 versus 5.2 months for PE ($p = 0.07$). Grade 3 or 4 neutropenia and thrombocytopenia were higher in the PE arm, whereas grade 3 or 4 nausea/vomiting and diarrhea were higher in the PI arm. The toxic death rates were low, 4% for PI and 5% for PE. A phase III superiority trial comparing a novel dose and schedule of the PI regimen (irinotecan 65 mg/m² with cisplatin 30 mg/m² both given on days 1 and 8) to standard PE produced similar survival times for both arms.[46] Two large phase III trial with topotecan, either oral or intravenous (IV) plus cisplatin were compared PE.[47,48] No survival benefit was observed with the experimental topotecan regimen over standard PE. The IV topotecan regimen did show a significantly higher ORR that translated into a prolonged PFS time of 7 versus 6 months for PE ($p = 0.004$). A European study reported superior survival for irinotecan plus carboplatin over an oral etoposide and carboplatin combination; however, survival in both arms was less than 9 months.[49] Drug doses and schedules were unconventional and lower than other regimens with irinotecan 175 mg/m² and carboplatin (area under the curve [AUC] = 4) administered on day 1 and in the standard arm, the etoposide was administered at 120 mg/m² orally days 1 to 5 with carboplatin (AUC = 4 on day 1). In contrast, a carboplatin-based doublet with paclitaxel failed to meet its primary end point of improving PFS when compared to CDE.[50] Most disappointing was the recent failure of the novel regimen of pemetrexed and carboplatin (Pem/C). In a previous randomized phase II study of pemetrexed plus cisplatin or carboplatin, the carboplatin arm produced an MS of 10.4 months and was well tolerated.[36] The GALES (Global Analysis of Pemetrexed in SCLC Extensive Stage) was designed to show noninferiority of pemetrexed (500 mg/m²) plus carboplatin (AUC = 5) as

compared to etoposide and carboplatin (EC). With 733 randomized patients, the study was terminated prematurely when the predefined PFS futility end point showed *inferiority* of the experimental arm.[51] The median PFS time was 3.68 months for Pem/C and 5.32 months for EC ($p < 0.0001$). ORR also favored EC at 41% compared to 25% ($p = 0.01$). The preliminary overall survival (OS) time was 7.3 months for Pem/C and 9.6 months for EC. Significant neutropenia and more febrile neutropenia were seen in the EC arm. In contrast, deaths on therapy or within 30 days were higher for the pemetrexed arm 16% versus 10% ($p = 0.032$) and the toxic death rates were 1.4% versus 0 ($p = 0.028$), respectively. However, the causes of death were atypical and variable.

The favorable toxicity profiles of new agents led several investigators to explore the possibility of integrating them into an active doublet (Table 58.2). Three randomized trials showed that paclitaxel-containing triplets did not result in superior survival compared to traditional doublets; furthermore, they were associated with increased toxicity.[53–55] A four-drug regimen has also been evaluated. While building upon a doublet with newer agents was not successful, in a French study, cyclophosphamide and 4'-epidoxorubicin were added to PE, the PCDE regimen, and showed a significant improvement in the CR rate (13% vs. 21%; $p = 0.02$) and OS (9.3 vs. 10.5 months; $p = 0.0067$) for PCDE over PE.[55] PCDE, however, was associated with significantly higher hematologic toxicity (22% of patients had documented infections compared with 8% in the PE arm; $p = 0.0038$). Toxic death rates were similar, 9% for PCDE and 5.5% for PE.

In summary, overall, no major breakthroughs have been seen with newer chemotherapy agents in the first-line setting and currently, platinum plus etoposide remains the standard of care for the treatment of SCLC.

Alternative chemotherapy strategies focus on modifications of the doses and schedules of established regimens, including dose intensification, alternating non–cross-resistant chemotherapy and prolonged treatment duration. Table 58.3 summarizes recent trial results employing these different approaches.

**Dose Intensification** Dose intensity is defined as the dose per square meter per week. Dose intensification can be

accomplished by either increasing the dose or shortening the interval between doses (dose density). Preclinical tumor models have illustrated that one of the simplest methods to overcoming drug resistance was drug dose escalation.[56] In the late 1970s, Cohen et al.[57] randomized patients to receive standard dosages of cyclophosphamide, methotrexate, and lomustine or a higher dose of cyclophosphamide and lomustine and a standard methotrexate dose. Hande et al.[58] randomized patients with ED SCLC to high dose or low dose methotrexate with leucovorin rescue in combination with cyclophosphamide, doxorubicin, and vincristine alternating with cycles of VP-16, vincristine, and hexamethylmelamine (negative study). They observed both a higher overall response rate and prolonged survival in the high-dose chemotherapy group. Long-term survivors were observed only among those patients given high-dose chemotherapy. These studies spawned a series of seven randomized trials comparing high dose to conventional dose chemotherapy in LS- and ES-SCLC patients.[59–65] Most of these trials were conducted in the 1980s and did not show a clinical benefit. The Spanish Lung Cancer Group recently reexamined this question (Table 58.3).[64] They compared high-dose epirubicin at 100 mg/m$^2$ plus cisplatin 100 mg/m$^2$ administered on day 1 to standard PE (cisplatin 100 mg/m$^2$, day 1 and etoposide 100 mg/m$^2$, days 1 to 3) in 402 SCLC patients. Efficacy results were similar between the two arms. For LS patients, one study published in 1989 showed a superior 2-year survival rate of 43% when the dose of cisplatin and cyclophosamide was increased by 20% in the first cycle of a PCDE regimen versus 23% for standard PCDE.[65]

Dose dense regimens have shown mixed results. CODE, an intense weekly regimen of cisplatin 25 mg/m$^2$ for 9 consecutive weeks; vincristine 1 mg/m$^2$ on even weeks for 9 weeks; with doxorubicin 40 mg/m$^2$ and etoposide 80 mg/m$^2$ days 1 to 3 on odd weeks for 9 weeks, reported an impressive 2-year survival rate of 30% in 48 patients with ES-SCLC.[66] Importantly, the investigators were able to administer close to the intended FDs of all four agents, thereby increasing the dose intensity by twofold. The National Cancer Institute of Canada Clinical Trials Group (NCIC-CTG) in collaboration with SWOG conducted a phase III trial comparing the promising CODE regimen to conventional alternating CAV/PE in patients with ES-SCLC.[67] Response rates were higher in the CODE arm, but there was no difference in PFS or OS. Although rates of neutropenia and fever were similar, toxic deaths occurred in 9 of 110 patients receiving CODE compared to only 1 of 109 patients given CAV/PE ($p = 0.42$). Given the high toxic death rate and similar efficacy, CODE was not recommended and the trial was closed prematurely. The Japanese subsequently demonstrated that the addition of granulocyte colony-stimulating factor (G-CSF) to CODE increased the mean total dose intensity received, reduced neutropenia and febrile neutropenia, and significantly prolonged survival (59 vs. 32 weeks; $p = 0.0004$).[68] This led to a phase III trial comparing CODE + G-CSF versus CAV/PE.[69] The response rate was significantly higher for CODE but, once again, no survival advantage was observed. The toxic death rate with CODE + G-CSF was low with only four reported cases.

Seven additional phase III trials incorporating a dose dense strategy with or without colony-stimulating factors have been conducted in Europe.[70–77] One trial showed a survival advantage for the dose dense arm. This trial performed by the British Medical Research Council (MRC) randomized 403 patients to receive CAE in 2 or 3 weekly schedules.[74] In this trial, a 34% escalation in dose density was achieved. Although the response rates in the two arms were similar, there was a significant improvement in the CR rate (40% vs. 28%; $p = 0.02$) that translated into a 2-year survival benefit (13% vs. 8%; $p = 0.04$). Subgroup analysis showed that the survival advantage in patients with extensive disease was as large as for limited disease patients. Other subset analyses in LS patients have shown opposing results. Steward et al.[73] showed a significant survival benefit for dose intensification, whereas Ardizzoni et al.[76] showed an inferior survival for the intensified regimen.

A possible explanation for the failure of the prior trials is that the dose intensity was insufficient to produce a survival benefit. To definitively answer the dose intensification question, studies emerged employing stem cell rescue that could allow for a 200% to 300% dose escalation. Multiple, small studies have shown this approach to be feasible. Early studies focused on patients who had achieved a response with conventional cytotoxic therapy who then received high-dose consolidation with stem cell rescue. A randomized trial testing this late-intensification strategy was reported by Humblet et al.[77] One hundred one patients received standard induction chemotherapy and forty-five chemotherapy-sensitive patients were randomized to receive one additional cycle with high-dose cyclophosphamide, carmustine (BCNU), and etoposide or conventional doses of the same drugs. In this highly selected group of patients, the median OS was 68 weeks for the high-dose arm compared to 55 weeks for the conventional therapy ($p = 0.13$).

The improved safety and feasibility of peripheral blood stem cells (PBSC) transplantation has largely replaced autologous marrow transplants. The Japanese reported promising results from a phase II study of high-dose ICE (ifosfamide, carboplatin, and etoposide) with autologous PBSC transplantation in 18 patients with LD-SCLC after concurrent, hyperfractionated chemoradiotherapy.[78] The CR was 61% and the MST was 36.4 months. One toxic death was reported. A randomized trial based on these results is ongoing.

Three randomized trials using high-dose ICE chemotherapy with peripheral blood rescue as first-line treatment for SCLC have been reported.[79–81] The largest trial with 318 predominantly LS-SCLC patients compared six cycles of a dose dense (every 14 days) ICE regimen followed by G-CSF mobilized whole blood hematopoietic progenitors, to six cycles of the standard every 28-day ICE regimen.[79] Despite doubling of the median dose intensity with the dose dense regimen (182% vs. 88%, respectively), the MST and the 2-year survival rates were comparable, 14.4 months and 22% versus 13.9 months and 19%, respectively. In contrast, an identical study by Buchholz et al.[80] was halted after 70 patients were enrolled. They reported a favorable MS of 30.3 months ($p = 0.001$), a 2-year survival rate of 55%, and TTP of 15 months ($p = 0.0001$)

for the dose intense arm versus an MS of 18.5 months, 2-year survival rate of 39%, and TTP of 11 months for the standard dose arm in this small single institution study. The European Group for Blood and Marrow Transplant conducted a similar study.[81] The study closed after 140 of the planned 340 patients were enrolled because of poor accrual. The median dose intensity for the high-dose arm was 293%, but this did not translate into a survival benefit with a MST of 18.1 months and a 3-year survival rate of 18% versus 14.4 months and 19%, respectively, for the standard ICE arm. None of the subgroups benefited from high-dose ICE.

Overall, the majority of trials employing a dose intensification strategy did not produce a survival advantage over standard therapy for patients with ES-SCLC and were typically associated with greater toxicity. This approach should be abandoned in extensive disease. In LS-SCLC, the optimal drug doses remain unclear with several studies suggesting a possible benefit. Continued evaluation of dose intensity in this curative setting is reasonable.

### Alternating Non–Cross-Resistant Chemotherapy Regimens

To achieve maximal antitumor effects using multiple active agents, they should be administered simultaneously at their optimal single-agent dose. However, because drug toxicities often overlap, strict adherence to this approach is often not possible in the clinical setting. In the 1980s, Goldie et al.[82] suggested that alternating two non–cross-resistant chemotherapy regimens of relatively comparable efficacy potentially could minimize the development of drug resistance while avoiding excessive host toxicity.[83] This strategy was particularly appealing for SCLC because both CAV and PE are highly active against SCLC and contain agents from divergent drug classes. Three randomized phase III trials were performed comparing CAV to CAV alternating with PE.[39,40,84] The United States and Japanese studies observed similar efficacy between the study arms, whereas the NCIC-CTG reported superior efficacy for the alternating regimen with an overall response rate of 80% versus 63% ($p < 0.002$) and a survival time of 9.6 versus 8.0 months ($p = 0.03$). Investigators at NCIC-CTG went on to test this approach in patients with limited disease SCLC.[84] Patients were randomized between two induction regimens either alternating CAV/PE or sequential therapy with three cycles of CAV followed by three cycles of PE. Chemotherapy was followed by radiotherapy in responding patients. No significant differences in therapeutic outcomes were observed between the two study groups. SWOG conducted a similar study and found no advantage for the alternating CAV/PE regimen over the EVAC (etoposide, vincristine, adraimycin, and cyclophosphamide) regimen in LS patients.[85]

The EORTC reported a trial testing two relatively non–cross-resistant regimens: CDE and VIMP (vincristine, carboplatin, ifosfamide, mesna).[86] Patients with ES-SCLC were randomly assigned to receive a maximum of five courses of CDE or an alternating regimen consisting of CDE in cycles 1, 3, and 5 and VIMP in cycles 2 and 4. The trial accrued only 148 of its 360 planned patients. The MS was 7.6 in the standard arm and 8.7 months in the alternating arm ($p = 0.243$).

Although no survival benefit for the alternating drug hypothesis was demonstrated, the emergence of newer active agents in the treatment of SCLC justified revisiting this strategy. The North Central Cancer Treatment Group (NCCTG) conducted a trial of PE alternating with topotecan and paclitaxel.[87] The overall response rate was 77% including 4 CRs in 44 evaluable patients. The MS was 10.5 months with 1- and 2-year survival rate of 37% and 12%, respectively. This alternating regimen was associated with high rates of grades 3 and 4 neutropenia (95%) despite the use of filgrastim in cycles 2, 4, and 6. The Hellenic Oncology Research Group treated 36 previously untreated patients with ES-SCLC with PE alternating with topotecan.[88] The overall response rate was 64% with 14% of patients achieving a CR. Grades 3 and 4 neutropenia occurred in 39% of patients during the PE cycles and in 55% after the topotecan treatment. This limited data incorporating newer chemotherapy agents into an alternating strategy was disappointing. Taken together, alternating newer and/or older cytotoxic agents to overcome drug resistance is unsuccessful and should not be pursued.

### Treatment Duration and Maintenance Therapy

The ideal number of chemotherapy cycles for SCLC has not been defined; however, four to six cycles is considered the standard based on the randomized trials presented previously. Clinical trials specifically designed to investigate the role of prolonged treatment using a consolidation or maintenance approach have been performed for decades. Three of 14 trials produced positive results.[89–91] All three trials were initiated in 1982. Two trials in LS-SCLC patients gave two to four cycles of PE consolidation to responding patients after induction CAV with or without thoracic radiotherapy.[89,90] The remaining trial randomized nonprogressors with LS or ES disease to four additional cycles of CEV or observation.[91] Although this trial showed that four cycles of CEV was inferior, a second randomization to salvage chemotherapy versus symptomatic care upon disease progression revealed that the subset of patients who received eight cycles of CEV with or without salvage therapy did no better than patients who received four cycles of CEV and salvage therapy at the time of relapse. The role of consolidation and/or maintenance therapy with a newer agent, topotecan, in ES-SCLC patients was evaluated by Eastern Cooperative Oncology Group (ECOG).[92] Two hundred twenty-three nonprogressing patients were randomized to receive four cycles of topotecan or observation. PFS from the date of randomization was significantly better with topotecan compared with observation (3.6 vs. 2.3 months; $p < 0.001$) but OS from randomization was not significantly different between the two arms (8.9 vs. 9.3 months; $p = 0.43$). Thus, it does not appear that there is a role for consolidation and/or maintenance therapy in SCLC. A 2007 metaanalysis of the 14 randomized trials suggests otherwise.[93] The odds ratios for 1- and 2-year OS rates were both 0.67 ($p < 0.001$) favoring prolonged treatment. Significant odds ratios for the 1- and 2-year PFS rates also support the role for consolidation and/or maintenance treatment. These results should be interpreted with caution, however, because they are not based on individual patient data, the studies were highly variable in their designs and most of the trials employed outdated

regimens. In general, chemotherapy after four to six cycles of a combination regimen is not warranted. Further evaluation of this strategy should turn to molecularly targeted agents.

## SECOND-LINE CHEMOTHERAPY

Despite a high response rate, the majority of patients will progress. If these patients are left untreated, survival is about 2 to 3 months. For patients who receive second-line treatment, tumor stabilization and shrinkage may occur but rarely do patients live longer than 6 months. Predictors of response to second-line therapy are dependent on the interval between cessation of initial therapy and the detection of recurrence and the responsiveness to previous induction chemotherapy. Three disease categories exist: (a) sensitive relapse denotes a relapse greater than 3 months after the last treatment; (b) resistant relapse develops in less than 3 months of the last treatment; and (c) refractory relapse signifying no response to front-line treatment or progressing on therapy. The Ottawa Hospital Regional Cancer Center reviewed the records of all ES-SCLC patients from 1999 to 2003 and showed that of the 192 patients completing first-line therapy, only 32% received second-line treatment.[94] Patients receiving salvage therapy, who tended to be younger and healthier, lived longer from the time of relapse (5.2 months as compared to 1.5 months) than did patient who did not receive treatment. A survival benefit was seen regardless of the timing of the relapse and patients receiving additional therapy. In the multivariate analyses, second-line therapy was an independent predictor of survival.

Prior to the mid-1990s, PE was a reasonable choice in CAV failures. A phase III SWOG trial randomly assigned 103 good- and poor-risk relapsed patients to PE or BTOC (BCNU, thiotepa, vincristine, and cyclophosphamide).[95] Good-risk patients achieved a 27% remission rate with an MS of 35 weeks with PE versus 27% remission rate and a 10-week survival time for BTOC. Poor-risk patients in both arms had an unfavorable 9% response rate and MSTs of 10 to 12 weeks. Conversely, CAV was shown to be inactive in PE failures.[96]

Single-agent activity of newer agents evaluated in relapsed SCLC is listed in Table 58.1. Topotecan emerged as a leading candidate to pursue in phase III trials (Table 58.4). In the first study, 211 patients who relapsed more than 60 days after completion of induction therapy were randomized to receive topotecan (1.5 mg/m$^2$/day, days 1 to 5 q 21 days) or conventional CAV.[97] The overall response rates and MSs were not statistically different between the two arms: 24.3% versus 18.3% and 25 versus 24.7 weeks, respectively. Dyspnea, fatigue, anorexia, hoarseness, and daily activity significantly improved with topotecan. Grades 3 and 4 anemia and thrombocytopenia were greater in the topotecan arm but there were no differences in nonhematological toxicities. Topotecan was subsequently approved for second-line treatment in patients with sensitive relapse based on symptom control. An oral formulation of topotecan was developed for patient convenience. To evaluate its efficacy, 141 relapsed patients were randomized to receive oral topotecan (2.3 mg/m$^2$/day × 5 days) plus best supportive care (BSC) versus BSC every 21 days.[98] Oral topotecan was superior to BSC with a MST of 25.9 weeks compared to 13.9 weeks for BSC ($p = 0.01$). Importantly, a survival advantage was recognized in patients who had relapsed less than as well as greater than 60 days from the end of their previous therapy. The most common toxicities with oral topotecan were hematological. Grades 3 and 4 neutropenia occurred in 61%, thrombocytopenia (38%) and anemia (25%), of patients. Subsequently, oral topotecan was compared to IV topotecan in sensitive relapsed patients (defined as relapse >90 days after chemotherapy).[99] A total of 153 patients received oral topotecan (2.3 mg/m$^2$/day, days 1 to 5 q 21 days) and 151 patients received standard doses of IV topotecan (1.5 mg/m$^2$ /day, days 1 to 5 q 21 days). The response rate, MS, and 1-year survival for the oral agent were 18.3%, 33 weeks and 33%, respectively, compared to 21.9%, 35 weeks and 29%, respectively, for the IV administration. The incidence of grade 4 neutropenia was 47% with oral topotecan versus 64% with the IV formulation. The quality-of-life analysis was comparable between the arms. Oral topotecan was approved by the Food and Drug Administration (FDA) for the treatment of both sensitive and resistant/refractory patients.

In the past 2 years, there has been renewed enthusiasm for chemotherapy because of the interesting results generated with amirubicin (Table 58.1). Two multicentered phase II trials of single-agent amirubicin in relapsed SCLC have been conducted in Japan. The first study included 16 patients who relapsed in less than 60 days (refractory group) and 44 patients who relapsed greater than 60 days (sensitive group) to receive amirubicin 40 mg/m$^2$ for 3 days every 3 weeks.[29] The overall response rate in the refractory group was 50% (95% CI, 25% to 75%) and it was 52% (95% CI, 37% to 58%) in the sensitive group. The OS and 1-year survival rates were 10.3 months and 40%, respectively, in the refractory group and 11.6 months and 46%, respectively, in the sensitive group. The median number of cycles was four. Grade 3 or 4 neutropenia was 83% with a febrile neutropenia rate of 5%. No toxic deaths occurred. In a second study, 34 relapsed patients (10 relapsed in less than 60 days and 24 relapsed beyond 60 days) received amirubicin at 45 mg/m$^2$ for 3 days every 3 weeks.[30] With a median of four cycles, the response rates for the refractory patients was 60% (95% CI, 23% to 97% ) and 53% (95% CI, 35% to 70%) for the sensitive patients. MSTs were 6.8 and 10.4 months, respectively. Grade 3 or 4 neutropenia was common, occurring in 71% of patients. Grade 3 or 4 febrile neutropenia developed in 35% of patients and one toxic death from pneumonia was reported. These data suggest that amirubicin is highly active but produces significant neutropenia although toxic deaths were rare. A randomized phase II trial comparing response rate between amirubicin to topotecan followed. Sixty patients received amirubicin (40 mg/m$^2$, days 1 to 3) or topotecan (1 mg/m$^2$, days 1 to 5, IV) every 3 weeks.[32] The ORR was 38% (53% in sensitive and 17% in refractory patients) for amirubicin and 13% (21% in sensitive and 0 in refractory patients) for topotecan. Overall median PFS was 3.5 versus 2.2 months, respectively. Survival was similar at 8.1 months for amirubicin and 8.4 months for topotecan. Amirubicin produced more grade 3 and 4 neutropenia 97% (vs. 87%) that resulted in more febrile neutropenia 14% (vs. 3%). There was one reported toxic death on amirubicin. Thrombocytopenia and anemia were more frequent with topotecan, 40% and 30% compared to 28% and 21% for amirubicin. In the United States, a randomized study to evaluate the response rate of amirubicin compared to topotecan has been completed in sensitive relapsed patients.[31] Seventy-six patients were randomized in a 2:1 fashion to receive the same dose of amirubicin or topotecan at 1.5 mg/m$^2$ IV, days 1 to 5 every 3 weeks. The ORR for the amirubicin arm was 34% as compared to 1% ($p <0.004$). The median PFS time was 4.6 months for amirubicin and 3.5 months for topotecan. At this time, the survival data are immature. In this study, there was more significant neutropenia in the topotecan arm 61% as compared to 45% with amirubicin that was most likely caused by the higher dose of topotecan used. Importantly, there was no evidence of anthracycline-induced cardiotoxicity. An international phase III trial of amirubicin versus topotecan is ongoing. Data from a U.S. phase II study in refractory or resistant patients progressing with 90 days has also been recently reported.[33] Seventy-five

patients received amirubicin at 40 mg/m$^2$, days 1 to 3 every 3 weeks. The ORR was 17.4% with one patient achieving a CR. The median PFS time was 3.2 months and OS is pending. Grades 3 and 4 neutropenia was seen in 49% of patients and no cardiac toxicity was observed.

Exploratory studies with a two-drug combination in this salvage setting have not generated promising data that would warrant phase III testing. Although it is reasonable to continue to evaluate doublets, balancing efficacy and toxicity is challenging.

Finally, two small case series totaling 18 patients reported that 10 patients who relapsed >10 months from the end of therapy had durable responses to their original regimen.[100,101] Reinduction with the original treatment regimen should be entertained in patients with prolonged time to relapse.

To summarize, topotecan IV or oral represents a modest advance for the treatment of relapsed SCLC. However, other agents are frequently used.[102,103] Amirubicin has produced impressive results in both sensitive and resistant/refractory patients, but its ultimate role awaits the results from phase III trials. Given the poor outcome of these patients, they should be encouraged to participate in clinical trials with novel therapeutic agents.

## BIOLOGICAL THERAPY

The current understanding of the molecular biology of SCLC is detailed in Chapter 5. In this section, a comprehensive review of the targeted therapies evaluated in SCLC based on a biological rationale is provided.

**Tyrosine Kinase Inhibitors** A hallmark of SCLC is its multiple neuropeptide autocrine growth loops. Numerous studies have demonstrated that these growth loops are a dominant mitogenic stimulus for SCLC.[104] Antagonists to neuropeptides have undergone clinical testing, but drug delivery issues and the heterogeneity of neuropeptides and their receptors have hampered their continued development. Meanwhile, other signaling pathways emerged as potential targets. Enthusiasm for imatinib, a small molecule tyrosine kinase inhibitor (TKI) against c-kit, surfaced when C-kit expression was demonstrated in 50% to 70% of SCLC cell lines tested.[105–108] Moreover, imatinib-treated cell lines resulted in apoptosis and cytostasis.[109] Despite preclinical evidence of activity, imatinib failed to show antitumor activity in clinical trials either as a single agent or in combination with chemotherapy as shown in Table 58.5.[110–113] The first study involving 19 chemonaive or sensitive relapsed patients did not produce any objective responses.[110] The low number of tumors with c-kit expression was thought to be the explanation for the lack of efficacy. A second study in 29 relapsed patients with c-kit expressing tumors, however, also failed to demonstrate responses.[111] One study to determine if imatinib with chemotherapy would be effacious showed results similar to chemotherapy alone. Irinotecan and carboplatin plus imatinib in 68 untreated

BCG, bacillus Calmette-Guérin; bid, twice a day; ID, intradermal; NA, not applicable; NR, not reported; po, oral; qd, once a day; R, refractory/resistant relapse; S, sensitive relapse; SCLC, small cell lung cancer; U, untreated.

ES-SCLC patients induced a response rate of 67%, median PFS of 5.4 months, and median OS of 8.4 months.[112] It is now believed that imatinib ineffectiveness is caused by c-kit activity being a result of an autocrine or paracrine growth loop rather than the presences of an activating mutation in the receptor as seen in gastrointestinal stromal tumors.[113]

Unlike NSCLC, the epidermal growth factor receptor (EGFR) pathway plays a minimal role in the malignant process of SCLC. Nonetheless, the Hoosier Oncology Group postulated that the EGFR signaling network may be activated through other mechanisms and conducted a phase II trial (Table 58.5).[114] Twelve patients with chemosensitive and seven patients with chemorefractory disease received gefitinib. The best response was stable disease in 2 patients and 17 patients had progressive disease. The median TTP was 50 days and the 1-year survival was 21%. Inhibitors of downstream signals of the tyrosine kinase receptors including RAS and c-MYC have been unsuccessful.[115,116]

**Matrix Metalloproteinase Inhibitors**    The matrix metalloproteinases (MMPs) are a family of degradative enzymes associated with tumor cell invasion of the basement membrane and stroma, blood vessel penetration, angiogenesis, and metastasis.[117] MMP expression in SCLC was found to be as high as 89% in one study and increased expression of certain MMPs[3,11,14] were associated with shorter survival.[118] Two MMP inhibitors have been studied in SCLC as displayed in Table 58.5. The oral agent marimastat was compared to placebo in a study of 555 patients with SCLC who had responded to first-line therapy.[119] No survival benefit was seen with marimastat. Musculoskeletal toxicity was a significant problem. A second smaller but identical trial in 350 SCLC patients was also negative.[120] A large trial comparing BAY12-9566 to placebo in 700 patients with lung cancer who had responded to induction chemotherapy was halted early because of negative interim results.[121] Of the 327 SCLC patients enrolled, the TTP was 3.2 months in the BAY12-9566 group versus 5.3 months for the placebo group ($p$ = 0.05). The incidence of adverse events was higher in the patients on the BAY 12-9566 arm.

**Immunotherapy**    In the early 1980s, interferons demonstrated antitumor activity and presented a novel approach to cancer therapy including SCLC. Several trials with interferons were launched, but most failed to show a favorable impact,

and were toxic.[122–125] A popular strategy today is evaluating tumor vaccines. SCLC expresses numerous gangliosides such as fucosyl GM1, polysialic acid, GM2, GD2, and GD3 that are not expressed on most normal tissue making and ideal for a vaccine approach.[126] The anti-idiotypic antibody (BEC-2) mimicking GD3 was evaluated in an international phase III trial.[127] Five hundred fifteen LS-SCLC patients responding to definitive treatment were randomized to BEC2 or observation. No impact on survival was seen with the vaccine. The PFS was 6.6 months for the observation arm and 5.7 months for the vaccine arm. MS was 16.3 and 14.3 months, respectively. Other vaccines in clinical testing target the fucosyl-GM1 ganglioside (Fuc-GM1) and polysialic acid (polySA) a component of the neural cell adhesion molecule (NCAM).[128,129]

A study conducted in United Kingdom explored an alternative immunologic strategy using SRL172, a suspension of heat killed *Mycobacterium vaccae* that works as a potent immunological adjuvant when given in combination with autologous cells in animal models. In a phase III trial with standard chemotherapy, survival times were similar between the two groups, however, symptom improvement favored the vaccine Table 58.5.[130,131]

Novel immunological strategies included immunologically targeted toxins such as BB 10901, a humanized murine monoclonal antibody (huN-901) that binds to CD56 conjugated to the tubulin toxin maytansinoid cytotoxin DM1 and the use of dendritic cells transduced with full-length wild-type p53 gene delivered via an adenoviral.[132,133]

**Apoptotic Modulators**  The most extensively studied apoptosis modulator in SCLC is bcl-2. Overexpression of bcl-2 has been reported in 69% to 90% of SCLC.[134,135] In vitro studies using SCLC cell lines have demonstrated antisense sequences against bcl-2 induces apoptosis and enhances cytotoxicity of chemotherapeutic agents.[136–138] Oblimersen (G3139, Genasense), an antisense oligonucleotide, was shown to suppress the anti-apoptotic protein bcl-2. Encouraging early clinical work lead to a randomized phase II of CE plus or minus oblimersen described in Table 58.6.[139] The addition of oblimersen did not improve efficacy over CE alone. This agent has been abandoned, but other novel small molecule bcl-2 inhibitors are being explored.[140]

Exisulind is an apoptotic inhibitor whose mechanism of action is independent of p53, bcl-2, or cell cycle arrest.[141] This oral derivative, from the cyclooxygenase inhibitor sulindac, produces its apoptotic effect by inhibiting cyclic guanosine monophosphate (cGMP) phosphodiesterases, which, in turn, increases levels of protein kinase G and activate the apoptotic cascade.[142] Synergistic cytotoxicity was observed with exisulind plus several cytotoxic agents used to treat SCLC.[143] Interestingly, synergy was seen in cell lines that overexpress MDR (multiple drug resistance)-associated protein.[144] In untreated ES-SCLC, a phase I study of CE with exisulind (125 to 250 mg po [orally] bid [twice daily]) showed that the combination was well tolerated and lead the Cancer and Leukemia Group B (CALGB) to conduct a phase II study administering exisulind at 250 mg bid with CE.[145] This trial involving 43 patients did not meet its primary survival end point of 60% of patients surviving greater than 12 months (Table 58.6). The median PFS was 6.7 months and the median OS was 10.5 months.

The ubiquitin-proteosome pathway is essential for the degradation of intracellular proteins. In particular, proteosome 26S inhibition limits the breakdown of inhibitor IB disrupting the nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathway leading to apoptosis.[146] Bortezomib (PS341) is a potent inhibitor of the 26S proteosome.[147] SWOG conducted a phase II trial of bortezomib in 56 relapsed patients.[148] One platinum refractory patient had a confirmed response and two patients had stable disease (Table 58.6). None of the platinum-sensitive patients responded. The median PFS was 1 month and the OS was 3 months.

**Cell Cycle Regulators**  CCI-779, a structural ester of sirolimus, forms a complex with FK506-binding protein (FKBP), which then inhibits mammalian target of rapamycin (mTOR). Inhibition of mTOR blocks the translation of several key proteins that regulate the G-1 phase of the cell cycle resulting in cytostasis.[149] ECOG evaluated CCI-779 as

a maintenance agent in 86 nonprogressing patients after induction chemotherapy (Table 58.6).[150] The median PFS was 1.9 months for the 25-mg dose level and 2.5 months for 250-mg dose level with MS of 6.6 and 9.5 months, respectively. The MS for all 85 patients was 8 months. No major toxicities were observed.

**Angiogenesis Inhibitors** It is well established that angiogenesis is necessary for tumor growth and metastases. Pathological studies in resected SCLC specimens revealed that high microvessel count and vascular endothelial growth factor (VEGF) expression were associated with decreased survival.[151–153] Furthermore, VEGF expression was shown to be an independent poor prognostic factor in one study.[151] The first angiogenesis inhibitor tested in SCLC was thalidomide. Thalidomide is an old agent with multiple well-defined mechanisms of action, including inhibition of antiangiogenesis. Its oral availability, tolerable toxicity profile, and easy access made it a readily available to evaluate. In Europe, a phase III double-blind, placebo-controlled study of maintenance thalidomide versus observation was stopped prematurely because of poor accrual. In 119 responding patients with ES-SCLC, no significant survival benefit was seen with thalidomide although the MS was 11.7 months for the thalidomide group compared to 8.7 months for the placebo group (Table 58.7).[154] Prolonged disease progression was noted in performance status (PS) 1 to 2 patients receiving thalidomide (hazard ratio [HR] = 0.54; $p$ = 0.02). Based on the hint of superior survival seen in the French study, the London Lung Cancer Study Group conducted a phase III randomized, double-blind, placebo-controlled of etoposide/carboplatin with or without thalidomide in 724 patients. Survival times were essentially identical as displayed in Table 58.7.[155] The MS was 10.5 months for placebo and 10.2 months for thalidomide. There was higher incidence of thrombotic events in the thalidomide arm 18% versus 11% in placebo arm.

Bevacizumab humanized monoclonal antibody to VEGF inhibits neoangiogenesis and normalizes tumor vasculature. In NSCLC, an ECOG study showing that the combination of bevacizumab with paclitaxel and carboplatin significantly improved response rate, PFS, and OS compared with chemotherapy alone generated enthusiasm for testing bevacizumab in SCLC.[156] CALBG combined bevacizumab with irinotecan and cisplatin in 72 chemotherapy naive SCLC patients. As described in Table 58.7, the response rate was 71%, median PFS was 7.1 months, and MS was 11 months.[157] This study failed to meet its primary end point of a 12.8-month MS. A similar study by ECOG testing bevacizumab with etoposide and cisplatin followed by bevacizumab successfully met its goal of 6-month PFS rate greater than 33% (Table 58.7). In 64 patients, they reported a 6-month PFS of 35%, ORR of 69%, a median PFS of 4.7 months, and an MS of 11.1 months.[158] Preliminary results of a phase II trial of irinotecan, carboplatin, and bevacizumab in 34 patients showed a 78% response rate.[159] Bevacizumab has also been explored in LS-SCLC. A phase II study administering irinotecan plus carboplatin and

bid, twice a day; IV, intravenous; NA, not applicable; NR, not reported; po, oral; qd, once a day; R, refractory/resistant relapse; S, sensitive relapse; SCLC, small cell lung cancer.

concurrent radiation followed by bevacizumab maintenance showed a 2-year PFS rate of 70% and 53% and a 1- and 2-year OS rate of 38% and 29% in 60 patients. The MS was 17.5 months.[160] Since this preliminary report, a tracheoesophageal fistula occurred in one patient. In a follow-up study integrating bevacizumab with concurrent chemoradiotherapy, two additional tracheoesophageal fistulas were seen and the study was terminated with 29 of the planned 50 patients enrolled.[161]

Oral angiokinases inhibitors have been piloted. SWOG studied sorafenib, a TKI of RAF and VEGFR in 83 relapsed patients.[162] Four patients (4%) achieved a partial response and 25 patients (32%) had stable disease. The median PFS was 2 months for all patients. The MS was 7 months in the sensitive relapsed group and 5 months in refractory group. Sunitinib and cediranib are also being investigated in SCLC.

Vandetanib, an oral VEGFR and EGFR TKI has been studied in a by the NCIC-CTG. They examined maintenance vandetanib versus placebo in 107 patients with LD- and ES-SCLC after initial chemotherapy response (Table 58.7).[163] No difference in OS or PFS was seen between the groups. Median PFS for vandetanib and placebo were 2.7 and 2.8 months, respectively (HR = 1.01). OS for vandetanib was 10.6 versus 11.9 months for placebo (HR = 1.43). In planned subgroup analyses, a significant interaction was noted in patients with LS disease who received vandetanib. These patients had a longer OS (HR = 0.45; one-sided $p$ = .07) and extensive-stage vandetanib patients had a shorter survival compared with placebo (HR = 2.27; one-sided $p$ = 0.996). In summary, targeted therapy for SCLC has not demonstrated the success we anticipated but it is vital that we continue the search. We remain confident that as we unravel the complex biology of SCLC, we will develop effective treatments.

## SCLC IN THE ELDERLY

Elderly patients with cancer represent a growing population. The SEER database recently published their statistics on the clinical presentation and outcomes for lung cancer patients diagnosed during 1988 to 2003.[164] A total of 47% of lung cancer cases occurred in patients 70 years old or older with 14% of cases diagnosed in patients 80 years or older. Similar age distributions are seen worldwide.[165,166] Specifically looking at SCLC, the SEER analysis showed that 61% of patients were ≥70 years old at diagnosis.[164] The relative 5-year survival rate for SCLC was significantly worse for elderly patients versus younger patients ($p$ <0.0001) and had not changed over the 15 years studied. For the time period between 1998 and 2003, the 5-year survival rate was 6.5% for patients younger than 70 years old, 3.4% for patients age 70 to 79, and 2.4% for patients 80 years or older.

Retrospective reviews to identify prognostic factors in SCLC have shown variable results concerning age. The largest experience to date was conducted by Albain et al.[167] who examined the SWOG database in 1990. An analysis of 2580 patients enrolled on six SWOG studies of which approximately

10% were elderly revealed that patients older than the age of 70 had a significant HR death of 1.5 ($p$ ≤0.0001) for LS patients and an HR of 1.3 ($p$ = 0.006) for ES disease. In contrast, a smaller study reported a year later on 614 LS and ES patients in the University of Toronto clinical trial database revealed that age older than 70 was not a significant predictor of a poorer outcome.[168] In LS patients, a metaanalysis published by Pignon et al.[169] in 1992 examined 2140 patients from 13 randomized trials that were designed to determine the role of thoracic radiotherapy combined with chemotherapy versus chemotherapy alone. The relative risk of death in patients older than the age of 70 receiving combination therapy was 1.07 as compared to elderly patients receiving just chemotherapy. Since this metaanalysis, a review of two NCIC-CTG trials, BR.3 and BR.6, involving 618 LS patients that received the same chemotherapy regimen, revealed no difference in survival between patients younger or older than 70 years,[170] although a significantly higher proportion of elderly patients failed to complete all planned chemotherapy cycles. In the United States Intergroup study comparing once-daily to twice-daily radiation in limited SCLC, survival of younger than 70-year-old patients compared to younger patients was of borderline significance in favor of younger patients ($p$ = 0.051).[171] Taken together, these studies suggest that age alone is a poor indicator of a patients overall health status.

Nonetheless, increased age has been perceived as a strong rationale for the use of less aggressive therapies or no therapy for fear of increased toxicity. The literature on this topic is conflicting with retrospective reviews reporting that increased age is associated with a heightened risk of chemotherapy-related morbidity and mortality.[172–175] Other studies show that despite toxicity and dose reductions elderly patient do receive a survival benefit with chemotherapy and/or radiotherapy over no treatment.[176–179] A recent review from the Royal Marsden investigated the survival outcome in 322 elderly SCLC patients older than the age of 70 treated with chemotherapy from 1982 to 2003.[180] Patients treated between 1995 and 2003 had a better MS of 43 weeks and a 1-year survival of 37% compared to 25 weeks and 14%, respectively, for patients treated from 1982 to 1994 ($p$ <0.001). Patients who received platinum combination had a statistically superior survival ($p$ <0.001) versus those who received single agents or another combination. There was no survival difference between a cisplatin versus a carboplatin regimen. A 2005 analysis of the 54 elderly patients with LS disease who participated in NCCTG phase III trial of PE plus twice-a-day or once-a-day thoracic radiation revealed that although the elderly patients were sicker and developed more toxicity, survival was not different from their younger counterparts.[181]

Modern phase III trials have been reporting outcomes in elderly patients in the primary manuscript. In the CALGB study of PE versus PET in ES-SCLC, 19% of the patients enrolled were age 70 years or older.[54] A significantly worse survival outcome was reported for patients 70 years or older with an MST of 8.6 months compared to 10.5 months for younger patients ($p$ = 0.0008). No additional information was

provided regarding treatment group or toxic deaths among the elderly to further understand this finding. An international phase III trial of oral topotecan plus cisplatin (TC) versus PE in ES patients reported half of the patients enrolled were age 65 years or older and had a similar survival time to younger patients.[48] The MS was 39.9 weeks (TC) and 42.9 weeks (PE) for patients younger than 65 years compared to 38 and 36 weeks, respectively, for older patients. Variable survival results have also been demonstrated in prospective phase II studies making it difficult to meaningfully understand the risk: benefit ratio of chemotherapy in the elderly.[182–189]

To formally address the question of dose, Ardizzoni et al.[190] randomized SCLC patients 70 years old or older to four cycles of cisplatin 25 mg/m$^2$, days 1 to 2 with etoposide 60 mg/m$^2$ IV, days 1 to 3 every 3 weeks, the attenuated dose (AD) regimen (n = 28) or to cisplatin 40 mg/m$^2$, days 1 to 2 plus etoposide 100 mg/m$^2$ IV, days 1 to 3 with prophylactic G-CSF, the FD regimen (n = 67). As shown in Table 58.8, the response rate was 39% in the AD arm versus 68% in the FD arm with 1-year survival rates of 18% and 39%, respectively. There was no grade 3 or 4 myelotoxicity in the AD group and 10% in the FD group. There was one toxic death in the FD arm. The median number of cycles was four in both groups with 75% in the AD group and 72% in the FD group completing all planned cycles. The Japanese conducted a phase III trial designed to test if near FDs of carboplatin and etoposide (CE) was superior to their standard regimen for elderly patients of a split dose of PE (SPE). Elderly patients were defined as patients ≥70 years old or older with a PS of 0 to 2. Patients younger than 70 years old with a PS of three were allowed to participate.[191] A total of 220 ES patients

were entered onto the study with 110 patients receiving carboplatin (AUC = 5 on day 1) and etoposide 80 mg/m$^2$, IV on days 1 to 3 every 3 to 4 weeks for four cycles and 109 patients receiving cisplatin 25 mg/m$^2$, days 1 to 3 with etoposide 80 mg/m$^2$ IV, days 1 to 3 every 3 to 4 weeks for four cycles (Table 58.8). G-CSF was recommended in both arms. Ninety-two percent of the patients met the elderly criteria and eight percent were poor risk. ORR were identical in both arms at 73%. MS for the CE arm was 10.6 months with a 1-year survival rate of 41% as compared to 9.9 months and 35%, respectively, for the SPE arm. Both arms reported very high grades 3 and 4 neutropenia rates of 95% for CE and 90% for SPE. Treatment-related deaths were four, three in the CE arm and one in the SPE arm. The only significant difference in toxicity was the higher rate of grades 3 and 4 thrombocytopenia at 56% for CE and 16% for SPE (p = 0.01). The authors concluded that either regimen was a reasonable treatment option. A phase III trial of CE versus amirubicin in the elderly is ongoing

In LS-SCLC patients, Jeremic et al.[192] administered accelerated hyperfractioned radiotherapy, 1.5 Gy twice a day to a total dose of 45 Gy over 3 weeks concurrently with carboplatin and oral etoposide. No further chemotherapy was given. They treated 77 patients aged 70 to 77 years. Of note, 12 patients had a Karnofsky PS of only 60% or 70%, and 18 patients had weight loss of more than 5% of body weight. The patients tolerated treatment remarkably well with only 2.8% grade 3 esophagitis, 8.3% grade 3 leukopenia, and 4.2% grade 3 infection. Despite the abbreviated chemotherapy treatment, the overall response rate was 75%, and survival rates were promising (74%, 1 year; 32%, 2 years; 19%, 3 years). In a trial of similar

design, Murray et al.[193] gave two cycles of chemotherapy (CAV followed by EP) and radiation consisting of either 20 Gy in 5 fractions or 30 Gy in 10 fractions concurrently with EP to the frail elderly (older than 70 years) as well as to younger patients who had significant comorbidity or who refused standard chemotherapy.[191] Although 14 of the 55 patients were less than 70 years of age, the remainders were elderly, with 22 patients older than 75 and 4 patients were older than age 80. Three patients died of treatment-related complications, although two of these deaths were acute cardiac events that may have had other causes in this elderly or infirm patient cohort. Other toxicities were no different from expected. The overall response rate was 89%, and MS was 12.5 months with 28% and 18% of patients alive at 2 and 5 years, respectively. These pilot studies suggest that when combined with early concurrent thoracic irradiation, chemotherapy may be further abbreviated to as few as two cycles without compromising efficacy in elderly or infirm patients. This approach deserves further study.

In summary, the optimal chemotherapy for elderly patients with SCLC is not known. We have learned that chronological age alone is a misleading clinical characteristic to base a treatment decision. Physiological age determined by comorbidities and PS provides a clearer framework for guiding treatment decisions. Categories such as "fit" elderly (≥70 years and PS 0 to 1) and "frail" elderly (≥70 years and PS 2 to 4) are emerging as beneficial terms both the clinical and research setting. Despite the limited data, we are encouraged that a subset of elderly patients can achieve a survival benefit with acceptable toxicity. As the elderly population continues to grow, it is critical that we develop solid evidence-based treatment plans. We must embrace clinical research in this population.

## TREATMENT OF POOR PERFORMANCE STATUS PATIENTS

PS is universally recognized as an independent prognostic factor and typically correlates with the extent of tumor burden. Thus, PS 2 patients are unduly challenging. These patients are perceived to be poor candidates for treatment, ineligible for clinical trials and have short life spans, making any research difficult. Lilenbaum et al.[194] recently determined the prevalence of poor PS in lung cancer patient by examining two large quality-of-life databases. A PS of 2 to 4 was noted in 34% of patients. This high percentage of patients with a poor PS magnifies the need to conduct specific research in this population. In SCLC, several retrospective studies from large databases confirm the shorten survival associated with a poor PS.[167,168,195] The CALGB reviewed their SCLC experience from 1972 to 1986.[195] Five trials with a total of 1745 patients were conducted in either LS or ES disease. PS of 2 to 3 accounted for 11% to 27% of patients in the 3 LS studies and 31% to 42% in the three ES studies. Overall, PS was a highly significant predictor of survival in all stages of SCLC. A more current analysis examined pretreatment PS in five large trials of topotecan conducted in chemotherapy sensitive recurrent SCLC.[196]

A total of 479 patients were enrolled in these studies and 98 patients (20%) had a PS of 2. The median OS for patients by PS were 38.3 weeks for PS = 0, 25.4 weeks for PS = 1, and 16 weeks for PS = 2.

Despite poor survival rates in PS 2 patients, they have routinely been eligible for phase III SCLC trials in contrast to NSCLC trials that typically exclude them. Clinical experience rather than clinical evidence has taught us that selective patients, whose poor PS is attributed to tumor burden, have an opportunity of responding to treatment that can result in meaningful symptom palliation, improved PS and prolonged survival versus the alternative of a rapid demise with no therapy. Determining the appropriate PS 2 patients to enter a PS 0 to 2 trial is perplexing because most trials are designed for PS 0 to 1 patients. This could account for why only 10% of untreated PS 2 patients enroll in phase III trials. In the previously treated trials, 20% of patients were deemed PS 2. To determine if PS patients derive benefit from treatment, a retrospective review of seven trials examined whether PS 2 patients converted to PS of 0 to 1 with salvage topotecan.[197] Of the 152 PS 2 patients, 21% experienced PS improvement and this was associated with a higher response rate and a prolonged survival. Unfortunately, this information is not available for untreated patients.

PS is also an indicator of tolerance to therapy. However, in the CALGB metaanalysis reported previously, poor PS was not a predictor of increased risk for hematological toxicity.[195] Tolerance to therapy is highly dependent on the intensity of the treatment, regardless of PS, but is dramatically decreased with increasing dose intensity in the poor PS group. The MRC Lung Cancer Working Party randomized 310 poor PS patients to a control arm consisting of four drugs: etoposide, cyclophosphamide, methotrexate, and vincristine (ECMV) or to a less intense two-drug regimen of etoposide and vincristine (EV).[198] There was no difference in symptom palliation, response rates or survival times between the two groups. Grade 2 or greater hematological toxicity and mucositis were worse with the four-drug regimen. Thirty-seven patients died during cycle one of ECMV versus nine patients treated with EV. No data is available from recent randomized phase III trials in untreated patients but the topotecan review showed no difference in grades 3 and 4 leukopenia, neutropenia, or thrombocytopenia between PS 0 to 1 patients and PS 2 patients, however, grades 3 and 4 anemia was significantly worse in PS 2 patients ($p = 0.009$).[196] Whatever the treatment regimen, added caution is advised for PS 2 patients.

In the 1990s, the oral formulation of etoposide was thought to be ideal for poor PS patients, leading to two randomized studies. The first study shown in Table 58.8 randomized previously untreated patients with a PS of 2 to 4 to oral etoposide 50 mg orally twice a day for 10 days (N = 171 patients) or standard chemotherapy with PE or CAV (N = 168 patients).[199] The primary end point was palliation of symptoms at 3 months. The trial was stopped early by the data safety and monitoring board because of an inferior result with oral etoposide. Palliation was similar in both arms 41% versus 46%, respectively. Survival was lower in the oral etoposide arm, 130 days versus 183 days for

CAV ($p = 0.03$). Grade 2 or greater hematological toxicity was low in both arms, 21% for etoposide and 26% for CAV. The second trial listed in Table 58.8 by the London Lung Cancer Group enrolled patients younger than the age of 75 with a PS of 2 to 3 or patients older than the age of 75 with any PS to receive oral etoposide 100 mg orally for 5 days (N = 75) or CAV alternating with PE (N = 80).[200] They hypothesized that oral etoposide would produce a similar survival but with improved quality of life. Again, this study was stopped prematurely because of a significantly inferior survival in the oral etoposide arm. The MS was 4.8 months with a 1-year survival rate of 9.8% for oral etoposide as compared to 5.9 months and 19.3% for CAV/PE ($p < 0.05$). Grade 3 and 4 toxicities were infrequent and similar between the arms except there was more nausea and vomiting in the IV arm. The recently reported Japanese phase III trial in elderly and poor-risk patients that is described previously in the elderly section was essentially a fit elderly trial with only 40 elderly PS 2 patients. It was noteworthy that the 18 poor-risk patients defined as <70 years old and a PS of 3 had an MS of 7 months.[191]

Poor PS patients with SCLC are common. To treat or not to treat is a frequent dilemma that relies on physician judgment more so than clinical data. Given the exceptionally short survival of untreated patients, poor PS patients whose disease is the cause of a declining PS may be offered therapy because standard platinum-based chemotherapy is well tolerated and efficacious. Meanwhile, specific research in poor PS patients is gaining momentum.

## CONCLUSION

Chemotherapy undeniably produces a survival benefit for patients with SCLC. Four to six cycles of a platinum doublet or an anthracycline-based combination should be offered to patients including the elderly and PS 2 patient. Unfortunately, SCLC is rarely cured except in patients with LS disease receiving bimodality therapy. Over the past 20 years, no major survival benefit has occurred with various old and new cytotoxic chemotherapy agents, regimens, and schedules. Evaluations of numerous biologically targeted agents have also been ineffective. Nonetheless, we have learned invaluable lessons that have shaped our future research strategies. We predict that continued insight into the biology of SCLC will guide us in discovering novel chemotherapeutic and targeted therapies that will translate into prolonged remissions and higher cure rates for all patients with this disease.

# Multimodality Therapy for Limited-Stage Small Cell Lung Cancer: Combining Chemotherapy and Radiotherapy

## INTRODUCTION

The disappearance of a large malignant mass is a dramatic phenomenon in medicine. Experienced lung cancer oncologists agree that it is easy to make the chest radiograph or computed tomography (CT) scan of a patient with locally advanced small cell lung cancer (SCLC) look much better with chemotherapy and thoracic irradiation. However, it is definitely more challenging to eliminate the last clonogenic cell in the neoplasm to prevent the development of an incurable relapse. The treatment of limited-stage SCLC requires us to combine chemotherapy and radiotherapy in the most effective way to increase the proportion of long-term survivors.

The incidence of SCLC, which accounts for about 12% to 15% of all lung cancers, is decreasing in developed countries most likely because of changes in the composition of cigarettes and patterns of tobacco consumption.[1] The declining incidence of SCLC parallels a stalling in the pace of research in this cancer as reflected by the number of abstracts submitted to the American Society of Clinical Oncology annual meetings and the International Association for the Study of Lung Cancer world conferences.[2] In contrast, the amount of research for non–small cell lung cancer (NSCLC) has increased dramatically. The slow pace of SCLC investigation is unfortunate and puzzling because the proportion of estimated deaths from this disease is about 4% of all cancer mortality and similar to ovarian cancer, leukemia, and non-Hodgkin lymphoma.[3]

## STAGING

SCLC may be staged by either the Veterans Administration Lung Study Group (VASLG)[4] system or the tumor, node, metastasis (TNM) classification.[5] The VASLG system categorizes the stage of SCLC as either limited (LSCLC) or extensive (ESCLC). This system has persisted for SCLC because of its simplicity, reliable prognostic value, and practical utility.[6–8] LSCLC is defined as tumor confined to one hemithorax and the regional lymph nodes, whereas extensive-stage disease (ESCLC) is defined as disease beyond these bounds. The original definition of limited disease was a tumor volume that could be encompassed by a "reasonable" radiotherapy treatment plan. Because long-term survival is uncommon (7% to 9%) when chemotherapy alone is used to treat LSCLC,[9,10] the reasonable radiotherapy port rule continues to be of practical importance in the design of combined modality therapy.

Although the term reasonable lacks precision, the adoption of this criterion internationally has broad acceptance in operational definition of limited disease. There continues to be support for moving to the TNM system, but this has not been widely adopted. Using simple staging techniques, the University of Toronto Lung Oncology Group[8] identified a subgroup of patients with "very limited" SCLC without mediastinal node involvement who had a significantly better prognosis and a 5-year survival of 18% with sequential chemotherapy followed by thoracic irradiation used between 1976 and 1985. The 5-year survival for patients with evidence of involved mediastinal nodes was 6%. Only 2% survived 5 years when there was pneumonic consolidation, atelectasis, pleural effusion, or involved supraclavicular nodes. Such distinctions may be addressed by application of the TNM staging system. Until 2007, the TNM system had been reported only in small surgical series. At the *12th World Conference on Lung Cancer*, the International Association for the Study of Lung Cancer Staging Committee presented an analysis of 8088 patients.[5] Survival outcome was superior in patients without mediastinal or supraclavicular nodal involvement. Patients with pleural effusion regardless of the cytology have an intermediate prognosis between limited and extensive-stage disease. The median survival of stage IIIA/IIIB (12.1/11.1 months) and the 5-year survival (10% to 12%) reported in this data set are lower than what has been reported for state-of-the-art treatment described in this chapter. It remains to be seen whether adoption of the TNM system will improve the investigation and management of LSCLC. New and ongoing studies of SCLC treatment should report both the VASLG as well as the TNM system.

A legitimate question in a disease, such as SCLC with early widespread dissemination, is the clinical necessity of multiple staging investigations. Because chemotherapy is recommended for all fit patients, to expedite treatment, most clinicians perform a minimum number of staging procedures, rather than the wider range recommended in clinical trials. This approach might be appropriate if the management were initial treatment with multiple chemotherapy cycles followed by consolidative thoracic irradiation. On the other hand, if patients with true LSCLC are better treated by concurrent and early chemoradiotherapy, careful staging is imperative to properly categorize intent (curative vs. palliative) and determine the treatment program.[2] LSCLC patients have curative potential, which justifies the complexity and toxicity of integrated thoracic irradiation and combination chemotherapy. Without appropriate staging, patients with undetected widespread disease will be subjected to unnecessary toxicity and unrealistic hope. Despite modern technology, the stage of some patients will be equivocal, so clinicians must use their judgment.

Complete evaluation of a patient with newly diagnosed SCLC consists of a history and physical examination, pathology confirmation, CT of the chest and abdomen to include the whole liver and adrenal glands, bone scan, and brain CT with contrast or MRI examination. Additionally, a complete blood count (CBC), electrolytes, blood urea nitrogen (BUN), creatinine, albumin, and liver function tests should be performed at baseline. Bone marrow biopsy has a low yield[11] if other tests are negative, but may be considered in patients with leukoerythroblastic features, low platelet count or a very high lactate dehydrogenase. After such a workup, the proportion of patients with LSCLC is approximately 40%.[1]

The utility of positron emission tomography (PET) in SCLC has been reported in several small studies[12–14] that have mainly used PET rather than PET/CT technology. The evidence suggests that PET added to conventional staging improves the sensitivity in detecting extracranial disease in 10% to 15% of cases, but the confidence intervals on the estimates of staging accuracy are wide because the studies are small. The information required to be confident that PET results should be used to guide therapy for LSCLC will not be available in the foreseeable future. It would be informative if a large cohort of patients with LSCLC as determined by conventional procedures also underwent a PET scan. This cohort should be treated with state-of-the-art combined modality therapy regardless of the PET result. The crucial information would not be that those with extensive SCLC according to the PET scan result have a worse outcome; this would be expected.[10] The important outcome would be to demonstrate that patients with ESCLC by PET scan, but LSCLC by conventional procedures were not curable by standard treatment. It would be inappropriate for a PET scan result to deny patients with potentially curable SCLC a combined modality protocol, even if the chance for cure was decreased. On the other hand, it would be useful to know if patients with ESCLC detected by PET scan alone had an equivalent chance of long-term survival as those defined by conventional staging procedures. Whether PET imaging is useful in guiding thoracic radiotherapy planning should be evaluated in prospective clinical trials. Until this information is available, the routine use of PET scanning to guide therapy for SCLC cannot be recommended.

Although the limited- versus extensive-stage system was created for practical purposes, it also suggests important biological and clinical characteristics of the disease. When SCLC is overtly metastatic (ESCLC), an underlying biological aggressiveness in the tumor may exist that transcends the importance of the simple physical distribution of cancer cells within the body. Potentially curable LSCLC may fundamentally differ from incurable ESCLC; however, the categorical boundary may be fluid. Obliteration of the stem cells at the root cause of this disease justify early aggressive combined local management. Cure evaporates once resistant to chemotherapy stem cells establish themselves outside the primary site. Time may be of the essence when attempting to cure SCLC.

Therapeutic endeavors address concentrations of locoregional bulk of disease in LSCLC, and a subclinical metastatic population in widely distributed sites. Normal healthy tissues vary in their tolerance of therapeutic interventions, just as tumor populations vary in their susceptibility to anticancer agents. These clinical considerations and the biological factors underlying them have led directly to modern concepts of multiple-modality therapy for this disease. Although a small fraction of SCLC patients will benefit from surgery when they present with a solitary pulmonary lesion without involvement of the mediastinum, integrated chemotherapy with radiotherapy to the chest and brain offers the most realistic chance for symptom abatement, extension of median survival, and long-term survival.

## THE EVOLUTION OF COMBINED MODALITY THERAPY

The legacy of treatment for LSCLC can be described by a series of treatment paradigms.[15] The sequence of development of these paradigms was determined by incremental steps grounded in controlled clinical trials of crucial issues of therapy and consensus by lung cancer investigators. They provide a useful insight into how our understanding of cancer biology and treatments has evolved over the last 3 decades.

### Paradigm 1: Surgery as Standard Treatment
World Wars I and II profoundly influenced on the upsurge of lung cancer. The availability of tobacco products and permissive attitude toward tobacco consumption during both wars were associated with a large increase in smoking among servicemen. In addition, the prevalence of smoking among women increased greatly during the 1940s.

Surgical treatment of penetrating wounds to the chest during World War II produced major advances in thoracic surgery, and the cadre of expert chest surgeons trained during the war had to contend with the increasing numbers of lung cancers among veterans in the 1950s and 1960s.[16,17] In the

immediate post–World War II era, surgery was the only truly effective treatment for patients with all types of lung cancer, including SCLC.

## Paradigm 2: Thoracic Irradiation Better than Surgery

The epithelial origin of SCLC was described in 1926,[18] and the separation of this virulent pathologic subtype on morphologic grounds was established in 1959.[19] From the earliest reports,[20] impressive regressions of SCLC induced by radiotherapy suggested an integral role of this modality in the definitive management of this disease.

In a trial conducted in the 1960s, the median survival of surgically unresectable LSCLC patients randomized to supportive care alone was 12 weeks.[21] Another randomized trial comparing surgery alone with thoracic irradiation alone for patients with SCLC was carried out by the Medical Research Council in the United Kingdom.[22,23] Eligibility criteria included (a) SCLC on bronchial biopsy; (b) no evidence of extrathoracic metastasis; (c) the tumor was regarded as operable on clinical examination and chest radiograph; (d) the patient was considered fit enough for resection; and (e) the patient was considered fit enough for radical radiotherapy. Although this study was conducted in an era before the availability of modern staging techniques, the intrathoracic extent of tumor was probably less than in most contemporary LSCLC trials. Of the 144 patients included in the main analysis, 71 were allocated to surgery and 73 to radical megavoltage radiotherapy. A complete resection of all visible growth was performed in 48% of the surgical group, all of whom had a pneumonectomy. A total of 34% were unresectable, and 18% had no operation because of preoperative deterioration or refusal of surgery. In the radiotherapy group, 85% had radical thoracic irradiation, 11% had palliative radiotherapy, and 4% had no radiotherapy because of deterioration or refusal. The median survival was 28.5 weeks for surgery and 43 weeks for radiotherapy ($p = 0.04$). Five-year survival was 1% for the surgical arm (the sole survivor refused surgery and was given radiotherapy) and 4% for radiotherapy. Outcome for both groups was poor, but treatment feasibility, toxicity, and survival all favored thoracic irradiation. The standard of treatment for LSCLC shifted from surgery to thoracic irradiation. The main aim was to give patients relief of local symptoms until their death from metastatic disease.

## Paradigm 3: Thoracic Irradiation with Adjuvant Chemotherapy

The systemic nature of SCLC was emphasized by the rapid tempo of systemic relapse and low probability of long-term survival in patients with apparently localized disease given definitive local therapy alone. In a classic study[24] of 19 patients undergoing potentially curative surgical resection who died of noncancer-related causes within 30 days of surgery, 13 were found to have persistent disease at autopsy. Moreover, distant metastases were present in 12 of the 13 cases. Although not all patients with LSCLC have subclinical metastatic disease, the actual proportion is so high that we assume that there are metastases and treat accordingly. The success of chemotherapy for leukemia and lymphoma was in its infancy,

but already the vision of cure by systemic treatment stimulated clinical research into using such an approach for SCLC.

A major step in the systemic treatment of SCLC was reported in 1969. This randomized study compared alkylating agents at several dose schedules with an inert compound in about 2000 patients with lung cancer at a group of Veterans Administration hospitals.[4] The antitumor effects of chemotherapy were analyzed according to cell type, and improvement in survival was the sole criterion of drug activity. The 4-month median survival for patients with SCLC treated with high intermittent doses of cyclophosphamide compared with 1.5 months for patients given placebo ($p = 0.0005$). Documentation of a survival improvement with chemotherapy for patients with lung cancer was a notable development in cancer medicine, and cyclophosphamide became the cornerstone in SCLC chemotherapy regimens for decades. The credibility of cyclophosphamide efficacy in the treatment of SCLC was augmented by randomized trials that showed prolonged survival for that agent as adjuvant chemotherapy compared with no further treatment after surgical resection.[17] Curiously, the lack of survival benefit for cyclophosphamide and other alkylating agents in the treatment of NSCLC in these and other lung cancer trials[17,25–30] did not prevent them from being incorporated into combination chemotherapy regimens for this disease over the next 20 years.

The perceptive observations of Watson and Berg[20] suggested thoracic irradiation coupled with chemotherapy as a model for treatment of SCLC. This hypothesis was first tested in a randomized trial by Bergsagel et al.[31] from Toronto. Patients with nonresectable lung cancer confined to the central area of the thorax were randomly assigned treatment with radiotherapy to the primary lesion and mediastinum or radiotherapy plus two schedules of intermittent intravenous cyclophosphamide. One third of 123 patients in the study had SCLC and both progression-free survival (29 vs. 16 weeks) and overall survival (42 vs. 21 weeks) were significantly superior for patients receiving combined modality therapy.

Two other randomized trials[32,33] showed significantly superior survival for thoracic irradiation and adjuvant chemotherapy when compared with radiotherapy alone. The median survival for patients with LSCLC treated by radiotherapy alone was consistently about 5 to 6 months. Two additional randomized controlled trials[34,35] showed some advantage for combined modality therapy, but the survival differences between the groups were not statistically significant, probably because many patients in the radiotherapy arms received chemotherapy at the time of disease progression.

The paradox that a local modality had a role in a disease dominated by systemic spread had been established. The issues of integration such as what drugs, what timing, what volume to irradiate, and what dose were not clear enough to formulate and endure today.

## Paradigm 4: Combination Chemotherapy with Adjuvant Thoracic Irradiation

The success of combination chemotherapy in leukemia and lymphoma and the recognition of SCLC as a type of lung cancer with marked

chemosensitivity spurred investigation of multidrug regimens. The first study of combination chemotherapy for lung cancer was published in 1972 by Hansen et al.,[36] using a regimen that included cyclophosphamide, methotrexate, dactinomycin, and vincristine. All eight patients with SCLC subtype responded; combination chemotherapy for SCLC was off to a promising start. High response rates for cyclophosphamide and vincristine were reported by Eagan et al.[37] and Holoye and Samuels.[38] By combining cyclophosphamide, doxorubicin, vincristine (CAV), and bleomycin, Einhorn et al.[39] produced not only high response rates in SCLC, but complete responses were seen in 20% of cases. Bleomycin was discarded because of pulmonary toxicity, especially when combined with thoracic irradiation,[40] and the CAV regimen persists to this day as a standard regimen for SCLC. A cardinal feature of drug selection was individual agent activity in SCLC, nonoverlapping toxicity of each of the agents in the combination, and the holy grail of synergy.

By using the principle of combination chemotherapy[41] and incorporating new, more active agents, the search for a regimen with a high complete response rate for SCLC was intense during the 1970s. Combination chemotherapy was shown to be better than single-agent chemotherapy in three early randomized trials,[42–44] but a superior regimen did not emerge. Nevertheless, in the early 1970s, a change in philosophy occurred; with the observed high response rates, multiagent chemotherapy became the primary therapy in LSCLC and thoracic irradiation was positioned as an adjuvant or "consolidative" treatment after initial numbers of cycles of systemic therapy.[45]

Treatment regimens giving aggressive combination chemotherapy *without* thoracic irradiation[46] appeared to yield survival results similar to combined modality therapy. Median survival was in the range of 12 to 15 months, and projected long-term survival was usually in the range of 10%, whether radiotherapy was administered or not. However, aggressive combined modality therapy was also associated with more toxicity, and the selection of only patients fit enough to receive this more demanding treatment in nonrandomized reports may have biased results against chemotherapy alone. Many investigators began to speculate that radiotherapy might not be necessary at all in LSCLC.

This debate persisted throughout the 1980s,[45,47] and many randomized trials were performed in an attempt to settle this vexing issue.[48–50] It was not until 1992 that two metaanalyses[9,10] demonstrated a modest improvement in survival rates in those patients given thoracic radiotherapy in addition to chemotherapy. The survival benefit becomes evident at about 15 months after the start of treatment and persists beyond 5 years. At 3 years, 8.9% of the chemotherapy-only group was alive compared with 14.3% of the combined modality group. The analysis of local control showed a 2-year local failure rate of 23% for irradiated patients versus 48% for non-irradiated patients ($p = 0.0001$). These benefits were obtained at the cost of an increase in treatment-related deaths of 1%. However, none of the trials in these metaanalyses employed

initial cisplatin etoposide chemotherapy, which is now the acknowledged international standard.

The addition of thoracic irradiation to chemotherapy for LSCLC has, for several theoretical reasons, the potential to improve outcomes. Its mechanism of action is different from chemotherapeutic agents so the potential exists for additive or even synergistic damage to the tumor. This capacity to eradicate the most populous, and hence most dangerous concentration of tumor cells, improves the probability of controlling local disease that may evolve more resistant progeny and metastasize systemically

## Paradigm 5: Integrated Early Concurrent Chemotherapy and Radiotherapy

The strategy to destroy as many cancer cells as possible in the shortest period of time using early concurrent chemoradiation has several theoretical advantages.

### Decreased Probability of Metastatic Events

Experimental work by Hill et al.[51] indicate that tumor cells mutate spontaneously and randomly to acquire metastatic potential. Moreover, once tumors reach a critical size or volume, metastatic phenotypes are generated "explosively," so the cumulative probability of the existence of metastases and the number of metastases increases in proportion to elapsed time. The best way to decrease metastatic events is to quickly eliminate as much tumor as possible.

### Lower Probability of Chemotherapy Resistance

A large body of experimental and clinical data exists that support the observation that variability exists for chemosensitivity within tumor cell populations.[52] Moreover, tumor cells display a capacity to be resistant to many drugs concurrently.[53] The biologic basis of this evolution of resistance originates during tumor growth from mutations in the cancer genome.[54] The development of resistant mutants is a random process, and the probability of their appearance increases with time in proportion to the total number of cell divisions the neoplastic burden has undergone. The best way to minimize the probability of chemotherapy resistance is to eliminate as many cancer cells as possible in the shortest time.

### Lower Probability of Resistance to Radiotherapy

The probability of mutation to intrinsic radiotherapy resistance[55] or acquired radioresistance as a consequence of enhanced DNA repair efficiency secondary to previous chemotherapy[56] should be minimized by the early deployment of both modalities.

### Diminished Accelerated Repopulation

Accelerated repopulation of tumors undergoing radiotherapy has been proposed[57] to explain the clinical observation that regimens with extended duration of therapy often require increased radiation dosages to achieve an isoeffective result.[58] Accelerated tumor growth has been reported after surgery[59] and chemotherapy[60] in animal models. Accelerated repopulation will decrease local control, and also, the increased mitotic activity within

a larger residual tumor may result in an increased probability of metastatic events and the development drug and radiation resistance. Rapid destruction of tumor by early integration of chemoradiation should minimize the amount of tumor capable of repopulation.

Although theoretically attractive, the practical implementation of early chemoradiation initially proved challenging. In 1976, investigators from the Radiation Oncology Branch of the National Cancer Institute in Bethesda, Maryland performed an exploratory study that tested the limits of toxicity.[61–65] Although the protocol was influenced by the successful model of combined modality therapy for childhood lymphocytic leukemia,[66] the vigor of therapy was unprecedented in solid tumor protocols. It involved initial simultaneous irradiation to the brain, primary tumor, and mediastinum and aggressive concurrent chemotherapy (cyclophosphamide 1.5 g/m$^2$, doxorubicin 40 mg/m$^2$, and vincristine 2 mg). The drugs were repeated as soon as the leukocytes increased to $3.5 \times 10^9$/L. All therapy was complete in 3 to 4 months.

The toxicity of this regimen was formidable. Radiation pneumonitis occurred in 38%, and a combination of pneumonitis and neutropenic sepsis was fatal in 24%. Severe esophagitis requiring nasogastric or parenteral nutrition occurred in 14%, and permanent strictures were observed.[62] Additionally, a previously undescribed neurologic syndrome of somnolence, poor attention span, recent memory loss, and action tremor was seen. The symptoms became evident within 2 to 4 months of starting treatment and were reversible within 4 months of onset.

The first reported survival results for patients with LSCLC treated in this manner were spectacular with 100% complete remissions and projected 80% long-term survival.[61] With longer follow-up, the survival rates dwindled and this trial was criticized for generation of false optimism by preliminary data reporting and unacceptably severe toxicity. Nevertheless, the mature results, which demonstrated an 80% complete remission rate and 25% survival at 4 years, were provocative and unprecedented.[65] Although the response result was noteworthy, 13% died without evidence of tumor at autopsy; it is speculative whether the survival rate could have been higher had modern supportive care been available or whether the toxicity of the approach was unacceptable. In an analysis of treatment factors contributing to long-term survival, it was concluded that concurrent chemotherapy and radiotherapy achieved better local tumor control than sequential therapy.[65] These data infer that if the duration of concurrent therapy is prolonged longer than 3 weeks, the enhanced survival and local tumor effect were lost in a flood of treatment-induced toxicity.[55]

It was evident that the combined chemoradiation model could not progress unless chemotherapy and radiotherapy could be compatible and integrated in a manner such that extreme toxicities did not compromise delivery of either modality. Sequential regimens giving thoracic irradiation during a gap in chemotherapy[67] (the "sandwich" technique) were less toxic but efficacy was not improved, possibly because the interruption of the cadence of chemotherapy allowed tumor regrowth in nonirradiated sites. The results of a phase II study of a less

aggressive CAV regimen[68] with concurrent thoracic irradiation led to a large randomized trial comparing simultaneous chemoradiation with CAV chemotherapy alone. However, a significant survival benefit was not observed[69] and excessive toxicity impaired drug delivery. Another controlled trial of CAV alone versus a split course of thoracic irradiation delivered in three phases between CAV pulses demonstrated a survival benefit for combined modality therapy.[50] However, gastrointestinal and hematologic toxicity continued to be problematic. The severity of morbidity to normal tissue from the interaction of doxorubicin and radiotherapy has limited the utility of these approaches. Concurrent thoracic irradiation with chemotherapy containing cyclophosphamide, methotrexate, and lomustine was superior to chemotherapy given alone,[48] with higher rates of remission and prolonged survival in patients with LSCLC, but the benefit was offset by unacceptable pulmonary toxicity. Similarly, concurrent cyclophosphamide, etoposide, and vincristine and radiotherapy have demonstrated superiority to chemotherapy alone, but unacceptable chemotherapy attenuation from myelosuppression was associated with combined therapy.[49]

Then the development of cisplatin and etoposide in the late 1970s at Memorial Sloan-Kettering[70] as a potent combination for SCLC allowed the next step forward. Cisplatin produces no pneumonitis, esophagitis or stomatitis, and little myelosuppression at normal doses. Etoposide at standard doses has myelosuppression as its only serious side effect. More importantly, although cisplatin has some weak radiosensitizing properties,[71] normal tissue toxicity from concurrent cisplatin and irradiation is not nearly so severe as with doxorubicin, nitrosoureas, methotrexate, or cyclophosphamide. Additionally, neither cisplatin nor etoposide have been implicated in "radiation recall"[62] toxicity.

Therefore, an important development in the evolution of therapy for LSCLC occurred when cisplatin and etoposide was integrated with thoracic irradiation. Thoracic radiotherapy and cisplatin etoposide could be used concurrently and at full doses of each modality. Pilot studies were independently performed at the British Columbia Cancer Agency[72,73] and by investigators associated with the Southwest Oncology Group.[74] From the first report[72] in 1984, it was clear that cisplatin etoposide chemotherapy and thoracic irradiation could be administered concurrently with manageable toxicity and little compromise in drug or radiation delivery at full dosage.

The National Cancer Institute of Canada (NCIC) explored the integration of chemotherapy and thoracic irradiation in a phase III randomized controlled trial and demonstrated that early concurrent cisplatin etoposide and thoracic irradiation was superior to delayed thoracic irradiation given concurrently with cisplatin etoposide.[75] A delay of as little as 12 weeks in the administration of thoracic irradiation for patients with LSCLC resulted in an approximate 50% decrease in the probability of 5-year survival from 22% to 13%. The benchmark 5-year survival rate for LSCLC shifted from about 10% to about 20%.

Other randomized trials[32,49,76–79] of thoracic irradiation timing have been reported (see Table 59.1), but not all support

**TABLE 59.1** **Trials Comparing Early and Late Radiotherapy for LSCLC**

| | | Dose / Volume | Start Time | | Patients | | Median (mos) | | 5-Year (%) | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | Early | Late | Early | Late | Early | Late | Early | Late | |
| 1. | CALGB[49,131] | CEVA for up to 18 mos | 40 Gy/20 F to GTV, hilum, med, bilat SCF then 10 Gy/5F to GTV only | week 1 | week 9 | 125 | 145 | 13.04 | 14.54 | 6.6 | 12.8 | NS |
| 2. | Aarhus[76] | CAV/EP (RT given with EP) total of 8 chemo cycles | 40 Gy/20# APPA as split course to GTV, hilum, med., SCF only if involved. Dose increased to 45 Gy/22 F later in trial | week 1 and 3 | week 18 and 23 | 99 | 100 | 10.7 | 12.9 | 10 | 10 | NS |
| 3. | Helenic[93] | Carbo/E. total 6 cycles | 30 Gy/20 F(1.5 Gy bid) APPA to GTV, hilum, med., SCF only if involved then 15 Gy/10 F bid with oblique fields to GTV only | week 1 | week 9 | 42 | 39 | 17.5 | 17 | 22 | 13 | NS |
| 4. | London[79] | CAV/EP. total 6 cycles | 40 Gy/15 F GTV, hilum, med., SCF only if involved. APPA with block to keep cord dose <35 Gy | week 3 | week 15 | 159 | 166 | 13.5 | 15.1 | NA | NA | NS |
| 5. | NCIC[80] | CAV/EP. total 6 cycles | 40 Gy/15 F GTV, hilum, med., SCF only if involved. APPA with block to keep cord dose <35 Gy | week 3 | week 15 | 155 | 153 | 21.2 | 16 | 22 | 13 | 0.013 |
| 6. | Yugoslavian[77] | Carbo/EP –daily carbo/E during RT and an additional 4 cycles of EP | 36 Gy/24 F (1.5 Gy bid) APPA to GTV, hilum, med., SCF only if involved. Then 18 Gy/12 F using oblique fields with limits to dose to esophagus. | week 1 | week 6 | 52 | 51 | 34 | 26 | 30 | 15 | 0.027 |
| 7. | JCOG[78] | EP total 4 cycles | 45 Gy/30 F (1.5 Gy bid) GTV, hilum, SCF only if involved. | week 1 | week 15 | 114 | 114 | 27.2 | 19.7 | 30 | 15 | NS |

A, Doxorubicin; APPA, anterior posterior radiation fields; bid, twice daily; C, Cyclophosphamide; CALGB, Cancer and Leukemia Group B; Carbo, Carboplatin; E, Etoposide; GTV, gross tumor volume; NCIC, National Cancer Institute of Canada; JCOG, Japan Clinical Oncology Group; LSCLC, limited-stage small cell lung cancer; med., mediastinum; NS, not specified; P, Cisplatin; RT, radiotherapy; SCF, supra-clavicular fossa; V, Vincristine.

the superiority of early chemoradiation. These negative trials[49,76,79] consistently have long-term survival rates in both arms of only 10% to 15%, whereas the early chemoradiation arms of the positive studies[77,78,80] report long-term survival rates of 20% to 26%. The reason why some randomized trials do not support the superiority of early chemoradiation may be explained by the use of the inferior cyclophosphamide-based chemotherapy,[49,81] failure to deliver chemotherapy with thoracic irradiation,[76] and attenuation of chemotherapy delivery subsequent to the radiotherapy.[49,76,79] To obtain the survival benefit of early concurrent chemoradiation, it is important to deliver the chemotherapy at full dose and in a timely manner.[69] Despite the variable quality of the randomized clinical trials, metaanalyses of randomized trials comparing early versus delayed thoracic irradiation in LSCLC consistently show superiority of early thoracic irradiation.[82,83]

Accelerated repopulation of surviving clonagens[57,84,85] during protracted (greater than 3 weeks) thoracic irradiation is a plausible hypothesis for the decreased effectiveness of treatment in LSCLC. This was a key concept in a landmark clinical trial reported by Turrisi et al.[86] This phase III randomized trial compared 45 Gy in 5 weeks with an accelerated fractionation regimen of 45 Gy in 3 weeks using twice-daily radiotherapy treatment with cycle 1, cisplatin etoposide chemotherapy. The 5-year survival rate of 26% for accelerated fractionated radiotherapy was clearly superior to conventional fractionation (16%). This is the only controlled trial that has ever demonstrated superior survival when one thoracic irradiation schedule is compared with another in LSCLC.

To further test the hypothesis that initial treatment triggers accelerated repopulation, De Ruysscher et al.[87] calculated the start of any treatment to end of radiation therapy (SER) for the study arms of four of the randomized trials of LSCLC.[65,67,68,77] Corrections for the different schedules were made by calculating the equivalent radiation dose ($EQD_{2T}$); this attempts to account for different total radiotherapy doses, fraction size, and overall treatment time. A shorter SER was found to be associated with better long-term survival, such that a survival decrement of approximately 1.8% per week occurred when SER was extended beyond 3 weeks. A major implication of the analysis of De Ruysscher et al. is that repopulation of clonogenic tumor cells caused by neoadjuvant chemotherapy inhibits the effectiveness of subsequent radiotherapy and contributes to treatment failure in LSCLC. Altogether, multiple lines of evidence support the importance of accelerated repopulation in LSCLC and provide a consistent radiobiological framework for investigation and treatment of this disease.

Research has focused on new drugs and systemic management, and to date, no further comparative trials have been conducted comparing other schedules with the Intergroup method, which sets the gold standard for long-term survival.

Technical radiotherapy has undergone a sea change since the design and conduct of this trial, but some have been dissuaded by the higher frequency of esophagitis, despite the universal reversibility and no reports of permanent stricture.

Also some publicly funded healthcare systems have found the delivery of twice-daily treatment impractical.

## Paradigm 6: The Addition of Prophylactic Cranial Irradiation

Despite the success of the integration of chemotherapy and thoracic radiotherapy, patients frequently relapse in the brain. Clinical intracerebral relapses are observed in 50% to 60% of patients, and even more are detected at autopsy. The concept is that chemotherapy could eliminate systemic disease, radiotherapy, the primary and bulky thoracic sites, thereby leaving the brain as a sanctuary site for relapse. Most chemotherapeutic agents cannot cross an intact blood-brain barrier, and even those that do (lomustine, procarbazine), do not prevent intracranial relapses. The challenge was therefore to devise a radiotherapy schedule that eradicates microscopic intracerebral disease without damage normal brain tissues. The success of prophylactic cranial irradiation (PCI) in leukemia suggested that such an approach might also be useful in SCLC and was first investigated by the National Cancer Institute–Veteran Affairs (NCI–VA) lung group in the early 1970s.[88]

For decades, PCI had advocates and adversaries, and the issues of timing, dose, and even need for its use were debated. For a time, anecdotal reports cautioned about late effects and warned that the few survivors had more potential harm than benefit from this tactic. This controversy was at its height during the time of the intergroup study accrual, and although mandated, not all cases received PCI after complete response, and compliance with the policy was not monitored a study end point. In a metaanalysis, Auperin et al.[89] confirmed the hypothesis that low doses of radiotherapy administered to patients without detectable CNS involvement might eradicate occult metastatic disease for some patients and improve the outcome in LSCLC. The incidence of brain metastases in patients who did not receive PCI was 57.6%, a 3 years in contrast to 33.3% in the treated group ($p < 0.001$). Three-year survival in the control group was 15.3% versus 20.7% in the treated group.

However, the timing, dose (total and per fraction), and criteria about specific population characteristics were not clear. The principal outstanding question, the relative frequency of late neurocognitive effects, remains open. One of the largest trials examining the role of PCI following completion of chemotherapy also included prospective assessment of neurocognitive function. This study suggested that there were no significant differences in functioning with up to 3 years of follow-up, and late effects were seen in fewer than 10% of those receiving PCI or observation.[90] Therefore, it is routine practice to deliver PCI with a dose of 25 to 30 Gy in 10 to 15 fractions on completion of chemotherapy to all patients who have responded to chemoradiation.

Currently, the research focus on both sides of the Atlantic is in determining whether higher doses (36 Gy in 18 fractions) produce better survival and local control than lower dose (25 Gy in 10 fractions). The European study has completed accrual, but recruitment continues in the North American study.

Whether or not PCI has a role in ESCLC has also been investigated. There was debate as to whether or not these patients would succumb to extracranial disease without deriving any survival or local control benefit. The European Organisation for Research and Treatment of Cancer (EORTC) recently published a study[91] involving 284 patients proving a survival advantage at 1 year and 75% reduction in the rate of intracranial relapse. Patients entered into this study merely had to respond to four to six cycles of chemotherapy, and three quarters of patients had local and systemic disease evident. Critics of the study note that fewer than 30% had imaging of the brain prior to randomization; however, this does not explain why the treatment arm should prove to be superior. Importantly, quality of life was not adversely affected, and no late neurocognitive effects were reported despite using large dose per fraction (3 to 4 Gy) in more than 75% of patients, with 20 Gy in 5 fractions being the predominant regimen. However, fewer than 10% survived more than 2 years, the time when late effects may begin to emerge and become important.

Overall, over the past 25 years, progress in the paradigm of integrated chemotherapy and radiotherapy has been most evident with innovations of radiotherapy. Future research in this disease should focus on optimizing radiotherapy and identifying key aspects of the molecular biology of SCLC, which may lead to more effective systemic therapy.

## THORACIC RADIOTHERAPY VOLUME AND DOSE

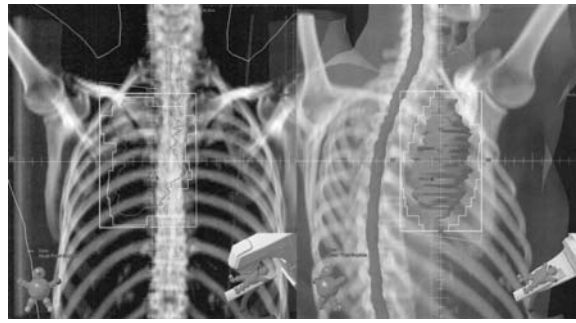
The role of thoracic radiotherapy in improving survival and local control has been confirmed, but exactly which tissues need to be irradiated has yet to be elucidated. In the older studies of chemoirradiation, such as the study of Perez et al.,[34] volume irradiated included the gross tumor volume (GTV), ipsilateral hilum, bilateral mediastinum, and both supraclavicular fossae. In contrast, in the most recently published studies, a reduced volume has been employed. Table 59.1 illustrates the wide variation in volume and techniques used.

Only one randomized clinical trial, performed by Southwest Oncology Group (SWOG),[92] has ever examined the issue of radiotherapy volume. In this, patients with a partial response or stable disease after four cycles of chemotherapy were randomized to radiotherapy based on either the prechemotherapy or postchemotherapy disease. No appreciable differences were detected in either overall survival or recurrence patterns between the two arms.

The idea of using either a shrinking volume technique, such as that used in the Hellenic study[93] or a very reduced volume treating just gross disease, is very attractive; it would minimize toxicity and potentially allow dose escalation of both radiotherapy and chemotherapy. Some information on which tissues should be treated may be obtained from retrospective studies looking at patterns of local failure. Tada et al.[94] analyzed the patterns of recurrence in 117 patients treated between 1986 and 1993. There appeared to be more marginal relapses in the upper mediastinum and supraclavicular fossae in those patients with N2 and N3 disease, although the number of patients was small. The authors suggested that the upper border of the treatment volume should be extended in patients with N2 or N3 disease. The relapse patterns following surgery of early stage SCLC suggest that radiotherapy volumes could be safely reduced in those patients presenting with N0 or N1 disease.

The three main potential toxicities of thoracic radiotherapy in LSCLC are esophagitis, pneumonitis, and radiation myelopathy. For both the esophagus and the lungs, the risk of toxicity is dependent not only on dose, but also on the volume of tissue irradiated. Although there has been very little analysis of this risk in SCLC, there are increasing data on these in NSCLC. The risk of pneumonitis can be predicted by either the percentage volume of lung receiving over a threshold dose, for example 20 Gy (V20),[95] or the mean lung dose[96]; however, it should be noted that these data are based on the use of radiation alone. A study from Japan[97] demonstrated that the "safe" percentage of lung receiving greater than 20 Gy drops from 32% with radiotherapy alone[95] to 25% in the presence of platinum-based chemotherapy. Similarly, the risk of esophageal toxicity is volume dependent.[98]

The question is how to reduce the volume of these critical tissues while adequately treating the target volume? In the early studies of chemoradiation in LSCLC, anterior–posterior (APPA) fields were employed, which minimize the dose to the lungs, but such an approach may result in overdosage to the spinal cord. To reduce the dose to the latter, in several studies, for example in the National Cancer Institute of Canada study,[75] a posterior block was inserted for part of the treatment. This patently underdoses the mediastinal lymph nodes. In later studies, lateral or oblique fields were employed, but lateral fields resulted in excessive pulmonary toxicity.[99] Therefore, a two-phase cone-done technique, or more recently, in single phase involved-field only approach has been used. In a recent phase II study, the radiotherapy volume encompassed just the primary and all lymph nodes greater than 1 cm in short axis[100] and treatment delivered with a single-phase three-dimensional conformal technique. Few local recurrences were observed. Such an approach enables dose escalation without excessive normal tissue toxicity, however, this method has not been formally compared with wide-field treatment in a clinical trial. An example of modern dose–volume planning for LSCLC is seen in Figure 59.1.

Although concurrent thoracic radiotherapy improves outcomes for patients with LSCLC, the local relapse rate remains high; with around 30% of patients experiencing an isolated in-field relapse[101] and 20% both in-field and distant relapse. In view of this, many of the ongoing studies are looking at the feasibility of escalation of the radiation dose. Because of practical difficulties of administering twice-daily radiotherapy, many radiation oncologists continue to use once-daily radiotherapy, but the optimal dose has not been established. Doses of as high as 70 Gy have now been used safely,[102] but whether or not the increased total dose can overcome the potential detrimental


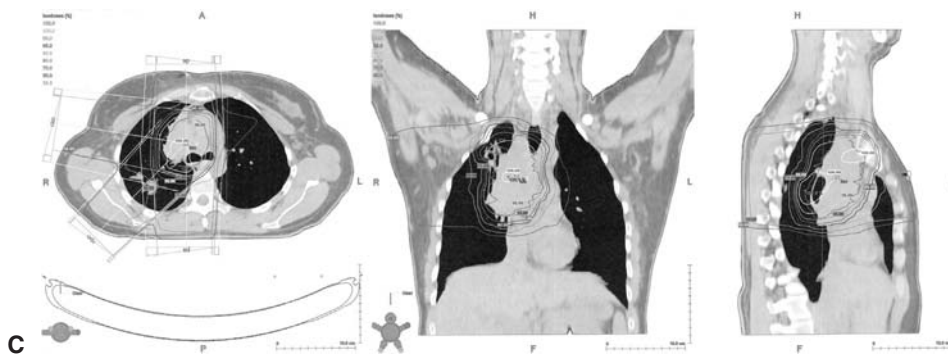


**FIGURE 59.1** **A:** Anterior and oblique digital reconstructed radiograph (DRR). The **left panel** shows anterior port with saw-toothed edges of a multileaf collimator portal, with the physician-defined target outlined in red. The **right panel** displays an oblique portal in red-pink color wash, demonstrating the facility of avoiding the spinal cord. **B:** Dose-volume histogram (DVH): note the uniform dose coverage to the defined target (tumor) by the red line; the marked reduction in dose to the esophagus dose (*orange*) showing about 50% dose to only two thirds of the esophageal volume, and the relatively lesser volumes of total lung irradiated. **C:** Dose distribution: these show isodose distributions in the (**left**) axial, (**middle**) coronal, and (**right**) sagittal plane. This patient was treated with four wedged fields for the entirety of the course without interruption and demonstrated a complete response by the second cycle of chemotherapy despite presenting with superior vena cava syndrome. (See color plate.)

| Structure | Coverage [%] / [%] | Volume [cm³] | Min [%] | Max [%] | Mean [%] | Modal [%] | Median [%] | STD |
|---|---|---|---|---|---|---|---|---|
| CTV | 100.0 / 99.9 | 248.8 | 88.0 | 101.4 | 99.0 | 99.8 | 99.3 | 1.36 |
| Esophagus | 100.0 / 99.4 | 28.9 | 4.0 | 99.1 | 53.9 | 97.8 | 69.2 | 36.98 |
| Spinal Cord | 100.0 / 98.5 | 48.8 | 0.0 | 70.3 | 18.3 | 0.0 | 4.7 | 23.84 |
| Total lung | 100.0 / 100.0 | 3620.5 | 0.6 | 101.4 | 25.9 | 2.3 | 15.2 | 27.79 |

impact of increased overall treatment time is unknown. A trial comparing 45 Gy in 30 fractions over 3 weeks with 66 Gy in 33 fractions over 6.5 weeks is proposed.

## CHEMOTHERAPY FOR LSCLC

Multiagent chemotherapy is superior to single-agent therapy in most cancers, when treatment is given with curative intent.[41] For more than 2 decades, LSCLC has been most commonly treated with a two-drug chemotherapy regimen consisting of cisplatin and etoposide (PE).[103] Cisplatin is the preferred agent in the potentially curable LSCLC patient population,[104] but substitution of carboplatin for cisplatin in patients intolerant to cisplatin is reasonable. The widely recommended practice of administration of thoracic irradiation concurrently with the first or second cycle of chemotherapy has reinforced the adoption of PE.[105] In contrast, for many years, it was common in Europe to use induction chemotherapy regimens with regimens that included alkylating agents and anthracyclines, with thoracic irradiation delivered sequentially in a consolidative fashion.[106] However, this practice has changed since Sundstrom et al.[81] demonstrated the superiority of PE therapy when compared with a regimen including cyclophosphamide, epirubicin, and vincristine. The superiority of PE was clear in LSCLC but not significant in ESCLC.

Because LSCLC is potentially curable, incremental improvements in the power of chemotherapy may be more easily detected in this setting compared with the palliative ESCLC group. In addition to the example by Sundstrøm et al.,[81] Reck et al.[107] showed a small but statistically significant improvement in survival for paclitaxel, etoposide, and carboplatin compared with carboplatin, etoposide, and vincristine in LSCLC but not ESCLC. Similarly, Thatcher et al.[108] showed better outcome for doxorubicin, cyclophosphamide, and etoposide at 2-week intervals (with granulocyte-colony stimulating factor [G-CSF]) compared with conventional every 3-week therapy in a population of predominately LSCLC. Taken together, these randomized trials of LSCLC patients with good prognostic factors suggest that chemotherapy innovations can result in modest survival improvements in LSCLC. However, the increased toxicity of three-drug protocols or dose-dense regimens is problematic with concurrent thoracic irradiation. When chemotherapy is manipulated by adding additional cytotoxic agents or dose intensification, the fidelity of both modalities of treatment is impaired by increased hematological and nonhematologic toxicity. Several new chemotherapy approaches using these themes have been evaluated in combined modality pilot studies,[100,109–115] but none have a therapeutic index sufficiently promising to be taken forward to phase III trials.

It has not yet been demonstrated that analogues of existing drugs have advantages over the parent compounds in controlled trials of LSCLC. The topoisomerase I inhibitors have been extensively investigated in SCLC. In a study of ESCLC patients, Noda et al.[116] showed that irinotecan and cisplatin was superior

to the PE regimen (median survival [MS], 12.8 vs. 9.4 months [$p = 0.002$]). One phase III North American trial[117] using a different schedule of irinotecan and cisplatin has failed to confirm improved survival compared with PE in ESCLC and another larger study duplicating the Japanese regimen has yet to be reported. Irinotecan is difficult to combine with concurrent thoracic irradiation. The Japanese Clinical Oncology Group (JCOG) has incorporated irinotecan into a pilot study in LSCLC.[118] Because of toxicity concerns associated with initial concurrent irinotecan and intensive thoracic irradiation (1.5 Gy bid × 30 treatments over a period of 3 weeks), JCOG administered initial concurrent chemoradiation with the PE regimen and delivered the irinotecan plus cisplatin regimen in three additional cycles after radiotherapy beginning on day 29. In a phase II study of 31 patients, there were no cases of interstitial pneumonitis and no treatment-related deaths. The 1-year survival was 79% and median survival was 20.4 months. A randomized trial comparing this regimen with standard PE combined with the same initial concurrent accelerated radiotherapy is now completed and should be reported soon by JCOG.

Clinical trials of other agents including amrubicin and pemetrexed are in progress. The combination of pemetrexed and platinum may be of special interest because phase I data demonstrate that it can be combined with thoracic irradiation without an increase in normal tissue toxicity or compromise in delivery of drug or radiotherapy.[119] To date, molecularly targeted therapy has had no proven impact on the prognosis of patients with either ESCLC or LSCLC.

The demographic patterns of patients diagnosed with LSCLC are not conducive to increasingly toxic combined modality protocols. Gaspar et al.[120] examined a National Cancer Data Base including four patient cohorts diagnosed with LSCLC in 1985 (N = 2123), 1990 (N = 6279), 1995 (N = 7815), and 2000 (N = 2123). The proportion of patients aged ≥70 years increased significantly over time, from 31.6% in 1985 to 44.9% in 2000 ($p = 0.001$). Moreover, SCLC patients are generally physiologically aged beyond their chronological years, at least in part from heavy smoking. This analysis identified the continued need for the evaluation of new treatments in this group of patients, but more aggressive chemotherapy in combined modality protocols is unlikely to enhance the therapeutic index. In 2008, the demonstrated safety, reliable delivery, and efficacy of standard doses of PE with initial concurrent thoracic irradiation for LSCLC has not been seriously challenged.

## FUTURE RESEARCH OF CHEMORADIATION IN LSCLC

Lung cancer investigators must decide how much change in long-term survival is important enough to warrant a clinical trial large enough to prove it. Most would probably agree that an increase in the cure rate of 10% is worthwhile. What about 5%? Many would reply affirmatively. For a disease this common, a true increase in the cure rate of 5% would save many

| TABLE 59.2 | Total Sample Size Required for Two-Arm Phase III Trials as a Function of Overall Survival Rate and Improvement in Overall Survival Rate | | |
|---|---|---|---|
| **Survival Rate (%)** | **Total Sample Size Required for Improvement in Survival Rate** | | |
| **Control Arm** | **5%** | **10%** | **15%** |
| 10 | 1290 | 394 | 134 |
| 15 | 1894 | 544 | 208 |
| 20 | 2444 | 676 | 328 |
| 25 | 2926 | 788 | 374 |

Sample size needed to have a *p* value of 0.05 and power of 0.90 to detect the difference; although additional allowance should be made for ineligibility, loss to follow-up, and late events.

patients. What about less than 5%? Probably not. Table 59.2 gives the sample sizes for clinical trials where clinical parameters are in the range of those likely to be seen in LSCLC trials in the future. Examination of this table shows that only a few of the trials in LSCLC have been adequately powered to detect a significant difference. Although most trials are small, metaanalyses have been able to demonstrate value in the use of radiation. A substantial improvement from a succession of small advances seems realistic. The rationale for the creation of large intergroup trials is particularly strong in LSCLC where modest therapeutic advance seems possible.

Issues in LSCLC that require further examination in randomized clinical trials include the controversies associated with irradiation volumes and the resolution of the relative importance of the start of treatment until the end of radiotherapy (SER) versus total dose. Currently, there are only four published randomized trials examining volume, dose, or fractionation issues in LSCLC.[86,92,101,121] The only study yielding a positive result administered thoracic irradiation initially and concurrently with thoracic irradiation.[86] The remaining studies,[92,101,121] which have given thoracic irradiation after a series of induction chemotherapy cycles, have failed to show any impact on survival.

Several trials are underdevelopment, primarily examining the impact of radiotherapy dose and overall treatment time. The largest of these is CONVERT, which hopes to randomize just under 600 patients to either the Intergroup regimen of 45 Gy in 30 fractions over 3 weeks or 66 Gy in 33 fractions over 6.5 weeks both delivered concurrent with cisplatin etoposide. This moves the concurrent chemotherapy to overlap with cycle 2 in the accelerated arm, but it also overlaps with cycles 2 and 3 in the protracted arm. Dose and time are different, and there is potential for administration of chemotherapy intensity to also be different between the arms. It should address the question of benefit of compressed radiotherapy versus extended radiotherapy, and the magnitude of difference. Prophylactic cranial irradiation will be provided in this trial, as it was irregularly administered in the intergroup study.

Over the last decade, there has been a revolution in the management of epithelial cancers with initial concurrent chemoradiation demonstrating an improvement in long-term survival. In squamous head and neck cancer,[122] anal cancer,[123] esophageal cancer,[124] cervical cancer,[125,126] brain cancer,[127] and NSCLC,[128–130] synchronous chemoirradiation is now the standard of care. For many years, some of these tumor types were managed with neoadjuvant chemotherapy prior to radiotherapy. However, initial synchronous chemoradiation has consistently proven to be superior to sequential treatment. Taken together, the increase in the proportion of long-term survivors from initial chemoradiation for this diverse array of notoriously difficult malignancies is one of the most important and understated advances in cancer medicine over the past 20 years.

Although the randomized trials of timing of thoracic irradiation have not been consistent in showing an optimal way to integrate chemotherapy and radiotherapy for LSCLC, a substantial and growing body of clinical trial data supports the initial concurrent chemoradiation model as the optimal management approach for locally advanced cancers in general. It is improbable that the therapeutic principles governing management of LSCLC would be different from other epithelial cancers. Dissonance with this harmony is found only when induction therapy and alkylator-based systemic therapy finds its way into treatment regimens. One of the attributes of cisplatin etoposide is the ability to use it in full doses concurrent with full dose, uncompromised radiotherapy.

Investigation of new drugs with molecular-targeted mechanisms generates considerable excitement. However, there is no evidence at this time that such therapies will replace conventional thoracic irradiation and chemotherapy. Indeed, new drugs are most likely to prosper when combined with an optimally integrated chemoradiation package. Because advances in the treatment of LSCLC over the past 20 years have largely been associated with innovations of radiotherapy, molecularly targeted therapy should focus on enhancement of radiotherapy as well as systemic therapy. Because accelerated repopulation is a major mechanism of treatment failure in cancer medicine, the molecular basis of this phenomenon must be elucidated. It seems probable that the mechanism will involve hypoxia targets, growth factors, and their receptors. Investigators should

consider adding drugs that block accelerated repopulation to periods of maximal tumor regenerative activity in combined modality protocols.

# Prophylactic Cranial Irradiation in Small Cell Lung Cancer

Small cell lung cancer (SCLC) has several features that distinguish it from other tumor types of lung cancer: the risk of early hematogenous dissemination, its marked radiosensibility and chemosensibility but also its particular propensity to disseminate in the brain. Even if chemotherapy is the cornerstone treatment in both limited and extensive disease, thoracic radiotherapy and prophylactic cranial irradiation (PCI) should be part of the therapeutic strategy in a subset of patients with limited disease (LD) as shown in two metaanalyses.[1,2] PCI should be considered among patients with extensive disease who respond to treatment.[2,3] In the past years, there has been improvement of both systemic and local control so that about two thirds of these patients, mainly those with LD, treated with aggressive induction therapy combining multidrug chemotherapy and thoracic radiation therapy will be put in complete remission. However, there is a high risk of relapse, so that only 15% to 25% of complete responders will be long-term survivors. Brain failures, for instance, have become a significant cause of relapse as the risk of developing brain metastases increases with length of survival to a cumulative risk that can be as high as 80%.[4,5] PCI has been developed as a strategy to prevent dissemination to the uninvolved brain, where systemic agents do not cross the blood-brain barrier effectively.[6] Thus, several studies have been undertaken that proved PCI would significantly reduce the incidence of a central nervous system (CNS) relapse compared with patients who did not receive PCI. However, in spite of the positive results of several retrospective and prospective studies, the utility of PCI has been a controversial issue for several years because of the lack of improvement in survival in individual trials and a possible risk of neurotoxicity and cognitive deficits in long-term survivors.[7–10] Since the publication of a metaanalysis on PCI in SCLC complete responders, showing the benefit of PCI not only in terms of brain control but also in terms of survival, PCI is now considered by most clinicians as standard treatment.[2]

Because brain metastases are frequent and difficult to treat, accompanied by distressing and sometimes life-threatening symptoms, prophylactic treatment seems a good alternative. At the time of initial diagnosis, up to 24% of patients may have brain metastases if magnetic resonance imaging (MRI) is used as initial workup.[5,6,11] Brain metastases may occur in 50% to 80% of 2-year survivors; in patients who achieve a complete response, the incidence of cerebral metastasis as sole site of initial relapse varies between 14% and 45% at 2 years.[12–14] Historically, chemotherapeutic agents have had a limited role in the treatment of cerebral metastases because of the inability of cytostatic drugs to cross the blood-brain barrier, situated in the endothelium of cerebral microvessels. However, more recent studies have reported efficacy of chemotherapy alone, with response rates on brain metastases ranging from 40% to 76%.[15–18] Chemotherapy-administered postradiation could also be more effective by abrogation of the blood-brain barrier[19]; however, that may also increase toxicity as well. Radiation therapy has remained the most widely accepted treatment modality for brain metastases with improvement of neurological symptoms in 56% to 92% of patients.[5,20–23] However, even if the symptomatic relief is of some benefit, quality of life (QOL) after overt brain metastasis is poor, and overall survival after development of brain metastases is low with median survival times ranging from 1.5 to 4.5 months.[21,23–27]

## STUDIES EVALUATING PROPHYLACTIC CRANIAL IRRADIATION

PCI has been used irregularly in the past 20 years, but since the metaanalysis, it has been accepted more generally, that PCI would delay the symptomatic cerebral metastases and would reduce the lifetime risk of brain relapse by 30% to 50%.[4,5] Several randomized trials listed on Table 60.1 have been published showing a significant twofold to threefold decrease in brain metastases incidence in the PCI arm compared to the control arm.[24,28–36] However, they included a very heterogeneous patient population: patients who failed to achieve a complete remission, patients with limited and extensive disease, patients who had concomitant chemotherapy and different PCI doses and fractionations, which can explain the differences observed

*Out of 172 patients evaluated and analyzed, only 29 patients achieving CR were randomized.

CR, PCI given when patients are in complete remission; D1, PCI given on the first day of induction treatment; LD, limited disease; NS, not specified; PCI, prophylactic cranial irradiation.

in brain failure reduction. None of these randomized studies could show an impact on the survival rate. However, in 1983, Rosen et al.[12] were the first one to report than PCI could have an impact on survival in a subgroup of patients and since then, several retrospective studies have suggested that PCI could not only reduce brain failure rates but also improve survival in complete responders to induction treatment.[37,38] Subsequently, only patients with complete remission were included in randomized trials. In these more recent trials listed in Table 60.2, the rates of brain failures seem higher than in older trials probably because

they are reported as actuarial and not as crude brain metastasis rates.[13,39–42] The overall 2-year actuarial brain failure rates are 40% and 67%, respectively, in the trial reported by Arriagada et al.,[13] 30% and 54% in the trial reported by Gregor et al.[39] Even if there was a trend in favor of PCI, none of these more recent randomized trials were large enough to confirm statistically the survival benefit suggested in retrospective studies.[12,37,38,43]

Current randomized trials have included patients with both limited and extensive disease, usually complete responders. Thus, as anticipated, more patients with LD comprise these

CR, PCI given when patients are in complete remission; D1, PCI given on the first day of induction treatment; LD, limited disease; NS, not specified; PCI, prophylactic cranial irradiation; SR, survival rate.

studies. The surprising recent EORTC trial addressed the question of PCI exclusively among 286 patients with documented extensive disease having responded to four to six cycles of chemotherapy and with residual local and systemic disease in nearly three quarters of the randomized patients.[3] Patients did not undergo brain imaging before randomization if they were not symptomatic, but were screened for predefined key symptoms of brain metastases. The primary end point was the time to symptomatic brain metastases. The results reported in 2007 strongly support PCI; the authors conclude that it should be part of standard care, not only among complete responders, but also extended to all responders. The majority of patients (61%) received a dose of 20 Gy in five fractions. The cumulative risk of brain metastases at 1 year is 14.6% in PCI group, whereas it is 40.4% in the control group (hazard ratio [HR] = 0.27; $p$ <0.001). Furthermore, irradiated patients also had significantly (HR = 0.68; $p$ = 0.003) longer overall survival (median survival of 6.7 months and survival rate at 1 year of 27.1%) than those in the control group (median survival of 5.4 months; survival rate at 1 year of 13.3%). The difference in survival may be explained also by the fact that patients with extracranial progression were more often treated than those in the control group.

## PROPHYLACTIC CRANIAL IRRADIATION METAANALYSES

The metaanalysis, which collected individual data from seven trials including a total of 987 patients randomized from 1977 to 1995, compared PCI to observation without PCI in patients with SCLC in complete remission with the primary end point of overall survival.[2] The determination of complete remission varied in each trial: a simple chest radiograph in many trials, whereas others mandated a chest computed tomography (CT) scan, and another trial required both a negative bronchoscopy and chest CT scan. The majority of patients were men (about 75%) and with a good performance status (97%). Most patients (86%) had LD, but 140 patients (14%) had extensive disease. The results have shown that PCI led to a 16% reduction in the mortality rate corresponding to 5.4% increase in the 3-year survival rate (from 15.3% observed in the control group to 20.7%). Therefore, PCI not only decreases, significantly, the risk of developing brain metastases (from 58.6% to 33.3% at 3 years) as proven in other individual trials, but also improves overall survival and disease-free survival.[2] The magnitude of the survival benefit is similar and parallels that achieved with the use of thoracic radiotherapy in patients with LD.[1,2] The Cochrane library published, in 2000, this same metaanalysis and included more tables and figures corresponding to all the subgroup (age, performance status, extent of initial disease, type of induction therapy, and time between the initiation of induction therapy and randomization) and indirect analyses (total dose of irradiation) that were performed.[44]

In 2001, Meert et al.[45] published a systematic review of the literature, including 12 published trials (1547 patients) that randomly assigned patients to receive PCI or not. Whereas the metaanalysis, based on individual data of Aupérin et al.,

included only trials addressing the question of PCI in complete responders, out of the 12 selected trials by Meert et al., 5 included exclusively complete responders, 5 included patients where PCI was eventually administered at initiation of chemotherapy and 2 included patients given PCI as consolidation treatment whatever the response status. PCI decreases significantly brain metastases incidence. PCI improved survival significantly only among complete responders. When all studies were considered, there was no significant difference. The authors conclude that PCI can only be recommended in complete responders documented by a workup including brain CT scan; several studies did not require a radiological workup before entering the study.

Although the dose–response relationships for PCI in SCLC may predict the optimal treatment schedule, no total dose or fractionation scheme has been established as optimal, and there are no adequate prospective studies to evaluate the effects of total dose and/or fraction size in PCI. In most studies, the prescribed PCI dose lies between 24 and 30 Gy with fraction sizes varying between 2 and 3 Gy. Even if some studies have reported results with one fraction of 8 Gy, large fractions in PCI should be avoided among patients with LD because of late neurotoxicity.[39,46] Among patients with extensive disease, the established dose may be 20 Gy in five fractions of 4 Gy, as reported in the Slotman trial. The short median survival for such patients is only 9 months,[3,47] making the concern about late effects caused by larger fraction negligible. Only one randomized trial has directly addressed the issue of PCI dose.[39] The first part of this trial was a three-arm comparison, with two PCI dosages (24 Gy and 36 Gy) being compared to no PCI, and the higher dose was more effective in reducing the risk of brain metastasis. A trend for a dose response was also observed in the study of Work et al.,[43] which did not address the question of PCI dose, where the 5-year incidence of CNS recurrences was 15% after 33 Gy and 23% after 25 Gy (non significant [NS]).

Most importantly, a marked trend for a dose–response relationship was observed in the metaanalysis.[2] The effect of PCI on brain metastases seemed to increase with the total PCI dose when 4 dose groups (8 Gy, 24 to 25 Gy, 30 Gy, 36 to 40 Gy) were analyzed. Hence, the relative risk of developing brain metastasis as compared to the control group was respectively 24% in the 8-Gy group, 48% in the 24- to 25-Gy group, 68% in the 30-Gy group, and 73% in the 36- to 40-Gy group, but the effect on survival did not differ significantly according to the dose. A dose–response relationship was also found in a recent review that collected data from 12 nonrandomized studies and 12 randomized studies comparing brain relapse rates with and without PCI.[48] The dose–response curve was almost linear within the dose range of 20 to 35 Gy. As the selection of an optimal dose for PCI that would lead to further decrease brain metastasis incidence with minimal toxicity was one of the challenges raised by the metaanalysis, an international intergroup trial addressing the question of dose effect for the prevention of metastases in patients with limited disease who achieved a complete response was undertaken.[49] It compared a standard dose of 25 Gy in ten fractions to a higher dose of 36 Gy (36 Gy/18 fractions or 36 Gy in 24 twice-daily fractions). Toxicities and treatment delivery were not different between the two arms.[50]

Patients who received a higher PCI dose (36 Gy) had a non-significant decrease in brain metastases (BM) compared to patients who received the standard dose: the BM two-year rate was 29% in the standard dose group and 23% in the high dose group (HR = 0.80; 95% CI, 0.57–1.11; $p$ = 0.18).[51] Overall survival was unexpectedly worse among patients in the higher dose PCI group (HR for death: 1.2 [1.00, 1.44]). Thus the standard PCI dose to be given in SCLC LD should 25 Gy.

We surmise from retrospective studies and reports of late effects that the dose per fraction should be less than or equal to 3 Gy[13] because of the risk of late radiation effects. The use of twice-daily treatments with a smaller dose per fraction and an interval between fractions of at least 6 hours could decrease the risk of late toxicity. A phase II trial has suggested recently that hyperfractionated PCI (30 to 36 Gy given in twice-daily 1.5-Gy fractions) was acutely well tolerated and effective PCI schedule.[52] This dose schedule is being tested in a phase II/III randomized study led by the Radiation Therapy Oncology Group (RTOG 0212).

The optimal timing for PCI in limited stage SCLC has also not been firmly determined. Even if PCI should be administered quite early so as to avoid reseeding of the brain, it has been recommended that it should be administered following documentation of complete remission, after 2 to 4 months but before 6 months from start of chemotherapy.[53] Only one small and rather old trial has directly addressed the issue of PCI optimal timing but was not conclusive.[32] PCI was either administered during the first week (early PCI group), or during the seventh week (late PCI group), and there was no difference in the incidence of brain metastases (7% in both groups).[32] However, the metaanalysis addressed the question of optimal timing in a subgroup analysis, and there was a trend ($p$ = 0.01) toward a greater effect of PCI on the incidence of brain metastasis in patients randomized within 4 months after start of induction treatment than in those randomized later.[2] The study of Suwinski et al.[48] has also made a provocative analysis of PCI dose response according to its timing. They have asserted that the delay between initiation of induction treatment and the start of PCI introduces a 20 Gy threshold in the dose–response curve that seems to be linear otherwise. Considering only studies where PCI was initiated less than 60 days after the first day of induction treatment, there was nearly a linear relationship between the given dose in 2-Gy fractions equivalent and the percentage reduction in total brain relapse rates within the range of 8 to 30 Gy. In the studies where PCI was initiated later, it looked as if higher doses were necessary to obtain the same prophylactic effect. Thus, by increasing the delay between induction treatment and PCI, one possibly increases the burden or the resistance of metastatic disease to the brain.

## NEUROTOXICITY AND QUALITY OF LIFE

The concerns of severe late neurotoxicity (NT) and detrimental impact on the quality of life (QOL) of patients undergoing PCI for patients with predominantly LD-SCLC have been anecdotally reported but never seriously studied prospectively.[7–10,14,25]

Most analyses are marred by too few patients follow-up for too short of time periods,[52,54–56] too few patients at risk,[41,57–61] or did not present the incidence of NT[40] to permit any adequate quantitative assessment. Moreover, most of these reports are retrospective in nature and lack baseline neurological or neuropsychological evaluations.[10,57–59]

In addition, before any real determinations on the impact of PCI on neurological and cognitive functioning can be made, pre-PCI, and prospective follow-up neuropsychometric testing establish the incidence and frequency of late effects.[62] This latter concept has been incorporated into the phase II/III prospectively randomized RTOG 0212 trial. In fact, one recent report[63] has presented a "decision-analytic model" that could potentially incorporate the future results of RTOG 0212 to determine the optimal use of PCI for patients with LD-SCLC who achieve a complete response to chemotherapy by comparing patient survival with the incidence and degree of NT. Finally, by applying a cost-effectiveness QOL model[64] (along with adding patient-derived QOL information not used by its original investigators) to the long-term results from RTOG 0212 when available will further serve to determine the most appropriate dose fractionation schedule (conventional daily vs. hyperfractionated twice-daily PCI) in the context of the impact of the financial cost on the QOL-adjusted survival for this group of patients.

Several factors have been implicated in increasing the risk for long-term NT, namely, age older than 60 years,[65] a daily fraction size >3 Gy per fraction,[14,25,65–67] and concomitant administration of chemotherapy during PCI.[13,39,65,66,68–71] In fact, one published database found that the actuarial risk of severe or worse brain toxicity was 2% at 2-year and 10% at 5-year posttreatment and only occurred in those who received daily fraction sizes of PCI of at least 3 Gy.[25]

Despite the fact that most drugs used for chemotherapy in SCLC do not cross the blood-brain barrier, it has been suggested that repeated high doses of cisplatin may lead to excessive levels in the brain that have been implicated in the development of "chemo brain," which is characterized by abnormal changes in perception, memory, attention, and executive functioning.[72] The neurotoxicities from cisplatin parallel those resulting from inorganic salts and other heavy metals. Furthermore, these adverse NT from cisplatin-containing chemotherapy may require up to 8 months before full recovery is seen.

Importantly, many patients with SCLC have defined neurological and cognitive impairments at diagnosis and prior to the PCI.[13,39,71,73–79] These may be a result of comorbid conditions, the effects of chemotherapy on the brain, paraneoplastic syndrome, aging, an immunologic dysfunction, or even microscopic cranial metastases leading to frontal–subcortical cognitive abnormalities.

The timing from the conclusion of brain irradiation to the appearance of NT generally indicates the type and severity of the injury has previously been described[80] and is outlined in Table 60.3. The signs and symptoms of acute injury from PCI are generally modest and include alopecia, headache, and self-limiting changes in hearing, appetite, and taste along with easy patient.[65] The acute and early delayed

| TABLE 60.3 | Classification of Radiation Injury Based on Temporal Relation to Radiation Treatment | |
|---|---|---|
| Type of Injury | Timing in Relation to Radiation | Prognosis |
| Acute injury | During or just after completion of radiation therapy | Good. |
| Early delayed injury | A few weeks (up to about 12 wks after completion of radiation treatment) | Usually good. |
| Late injury | A few months to several yrs after radiation | Guarded. Usually irreversible. May be relentlessly progressive, with a tendency to recur after surgical resection in some patients. |

From Giglio P, Gilbert MR. Cerebral radiation necrosis. *Neurologist* 2003 Jul;9(4): 180–188, with permission.

brain injuries are largely reversible with supportive therapy (including steroid administration) and are characterized by accumulation of edema from damaged, leaky capillaries. Acute brain changes are generally not imageable, whereas early delayed injury is seen as hypodense regions on CT scans and as increased signal intensity on fluid-attenuated inversion recovery (FLAIR) and T2-weighted MRI scans.[81]

The delayed and late clinical manifestations of brain injury include "gradual intellectual decline, short-term memory loss, fatigue, and personality change."[65] The most common finding is cognitive impairment,[81] whereas the most common symptom is memory loss[66,82] that is further supported by an animal model study.[83] Pathologically, there is damage to blood vessels that can lead to irreversible ischemic necrosis of white matter and demyelination along with fibrinoid necrosis of blood vessel walls.

There have been only a few prospectively randomized studies with limited 2-year follow-up data that have attempted to evaluate the impact of PCI (with concurrent chemotherapy) on cognitive functioning and other QOL markers[13,39] for patients with SCLC. The French PCI trial[13] employed a neuropsychological assessment performed by a neurologist and showed that there were no significant differences in those receiving PCI versus those in the nonirradiated control group with respect to the end point of 2-year cumulative incidence of neuropsychological changes (Table 60.4). The trial from the United Kingdom[39] suggested that those patients receiving PCI were no more likely than those randomized to no PCI to have abnormalities in either cognitive functioning or QOL indicators attributed directly to the use of radiation.

To ameliorate the long-term effects of PCI on neurocognitive functioning in patients with SCLC, there have been some attempts to modulate the brain damage by either altering the fractionation schedule or by using drugs (such as erythropoietin, warfarin, or a glutamate antagonist) or hyperbaric oxygen therapy.[84] Although not completely understood, there is a very dynamic interaction of vascular and neuronal damage with subsequent inflammation, cytokine production, and increase in the concentration of reactive oxygen and nitrogen species and excitatory amino acids in the brain. Obviously, the most important strategy is to ultimately ascertain how to prevent the onset of permanent brain damage that can result from the delivery of PCI.

## CONCLUSION

Several studies in the past 20 years have reported a lower incidence of brain metastases with PCI, thereby reducing the risk of the associated morbidity and social consequences of

RR, relative risk.

brain failure. If recent trials have shown that brain metastases could be really prevented and not just delayed with PCI in complete responders, the metaanalysis has now demonstrated that PCI leads to a 5.4% increase in the 3-year survival rate (from 15.3% observed in the control group to 20.7%). This benefit on overall survival among patients with LD can be added up to the effect of thoracic radiotherapy, which has about the same value.

Among patients with extensive disease, a recent EORTC trial has shown that indications of PCI should be enlarged to all responders, as the 1-year rate of symptomatic metastases is decreased from 40.4% to 14.6%, with a significant impact on survival.

The selection of an optimal dose for PCI that would lead to further decrease brain metastasis incidence with minimal toxicity is one of the challenges raised by the metaanalysis as well the ideal timing of PCI. An international trial addressing the question of dose effect for the prevention of metastases in patients with LD who achieved a complete response has been completed. It compares a standard dose of 25 Gy in 10 fractions to a higher dose of 36 Gy (36 Gy/18 fractions or 36 Gy in 24 twice-daily fractions).[53] So as to evaluate whether dose escalation results in higher cerebral control rates and a possible over added neurological toxicity, all patients have a baseline radiological evaluation as well as a QOL and clinical evaluation at baseline before PCI, 6 months after PCI then yearly. A phase II/III RTOG trial is still ongoing, comparing conventional fractionation (36 Gy in 18 fractions) to hyperfractionated accelerated radiotherapy (36 Gy in 24 twice-daily fractions). All patients will have a neurocognitive assessment in their follow-up.

Even if there are questions left concerning the optimal dose and fractionation of PCI as well as the optimal timing, there is level 1 evidence that PCI is effective. It should now be considered as part of the standard treatment of patients with SCLC in complete remission. For patients with extensive disease, it should be considered for all responders.

# Endoscopic Ablational Therapies and Stenting

According to the American Cancer Society, there will be 215,020 new cases of lung cancer in 2008. This is the leading cause of cancer-related death in both men and women.[1] Most patients with lung cancer will have advanced disease, and of these, a certain percentage will have an endobronchial component requiring some form of intervention. These patients may present with acute respiratory distress, worsening dyspnea, hemoptysis, or with pneumonitis resulting from endoluminal obstruction. Significant improvement in quality of life can be achieved if the airway obstruction is relieved.

In terms of lung cancer statistics as well as 5-year survival, the outcomes have not changed significantly over the past 10 years. Nevertheless, patients can be palliated with endobronchial obstruction and hemoptysis more efficiently and in a more durable fashion, because the treatment modalities and options have improved. Some of these are ablational, and all require some form of bronchoscopy whether flexible or rigid. These therapies include, for example, laser therapy cautery, rigid bronchoscopy, argon plasma coagulation, cryotherapy, photodynamic therapy (PDT), and stenting.[2]

Unfortunately, an almost equal percentage of patients that are diagnosed with locally advanced lung cancer present with metastatic disease, and of these, 20% will have an endobronchial component compounding their symptoms. Extrinsic or intrinsic luminal compromise eventually causes acute or chronic respiratory failure, and many patients will present with symptoms of hemoptysis, postobstruction pneumonia, or dyspnea.[3]

Palliation of bronchial obstruction frequently involves the use of a stent. "Stent" refers to a British dentist, Charles R. Stent, who created a mold for edentulous patients and since then has carried his name to describe any device that maintains the integrity of a hollow tubular structure. Originally, these stents were used in the gastrointestinal tract and in the vascular system and subsequently were applied to the airway. There are basically two types of stents: *metal* and *silicone*. Although they have essential differences with regard to their design and properties, they can both be used to palliate malignant central airway obstruction (CAO).

Currently, airway stents are either made of self-expanding metal for more permanent use or silicone if a temporary solution is needed. Complications of these stents include airway fracture with insertion or perforation (early or late), bleeding, granulation or tumor ingrowth, infection, migration, obstruction, as well as a small risk of death. There are no large randomized clinical trials to examine the utility of stent use in the patient with lung cancer. Limited case series from multiple institutions support the use of stenting techniques to help palliate these patients. Moreover, the palliation of symptoms by stenting is almost immediate in most cases and offers short-term improvement in quality of life, with little or no effect on long-term and overall prognosis. Additionally, recent data supporting the use of therapeutic bronchoscopy in patients with non–small cell lung cancer can achieve not only palliation of their symptoms but also potential lung-sparing surgery.

## HISTORICAL OVERVIEW

Although many techniques to treat and palliate CAO exist, the most current technique of rigid bronchoscopy with and without endobronchial laser was perfected in the early 1980s by Dumon et al.[4] The key to this technique was the provision of superior airway control and the versatility of performing most endobronchial procedures. Subsequent to Dumon et al.'s experience, there have been multiple series with large number of cases that demonstrate the efficacy of this modality. These include Cavaliere et al.[5,6] in 1988 who published their experience with 1396 applications of rigid bronchoscopy with laser in 1000 patients, in 1994 with 2253 applications in 1585 patients, and in 1996 with 2610 treatments in 1838 patients. Venuta et al.[7] published their series in 2002 with 273 patients with a goal of palliation or as a bridge to surgery. Most recently in 2006, Moghissi et al.[8] published their data over a 21-year experience with 2235 treatments in 1159 patients. Their review implies that laser therapy of lung cancer still plays an important role in the palliation of inoperable cancer.[8]

Rigid bronchoscopy has withstood the test of time and with the combined use of either laser, cautery or just forceps alone remains the preferred modality with most airway interventionalists when dealing with CAO. Refinements in the protocol have, in some instances, led to improvement of results over laser and rigid bronchoscopy, and the use of electrocautery in the airway may be more cost-effective and readily available. Cautery can be easily delivered through the working channel of a specially designed therapeutic scope with a larger working channel. In a recent review of interventional techniques to treat malignant obstruction of the large airways, the authors imply that electrocautery is likely to replace laser as the preferred tool in these cases.[9]

*Silicone stents* have evolved over time from their initial description by Montgomery[10] in 1965. The *Montgomery* tube is a silicone T tube placed through a tracheal stoma for the relief of subglottic tracheal stenosis or to support a reconstructed tracheal anastomosis (Fig. 61.1).[10] Subsequently, the T tube was modified by Cooper et al.[11] and by Duvall and Bauer[12] in order to be placed endoscopically. Westaby et al.[13] also modified the T tube into a bifurcating T-Y stent that could be pulled through a stoma.

Dumon[14] in 1990 published his data on silicone stents with good results for airway obstruction. Typically, this stent has studs that are molded to the exterior to prevent migration and is deployed through rigid bronchoscopy. The *Dumon* silicone Y stent can be used for bilateral mainstem pathology as well as for tumors of the carina.

The most recent silicone stent that has been popularized by Boston Scientific is known as the *Polyflex Airway Stent* (Fig. 61.2A) This is a fully covered polyester silicone mesh that has its own delivery system with a loading basket and a pushing rod to facilitate deployment through a rigid bronchoscope. This can be used for all types of CAO regardless of etiology and has the obvious advantage of being removable. As with all silicone stents, mucus impaction and migration are the most common complications related to their use. Migration can be minimized with the airway Polyflex as long as the stent is appropriately sized with a tendency toward a larger diameter stent.

The *Dynamic* (Y) stent (Fig. 61.2B) is a removable airway stent made of silicone and has metal rings to resemble the cartilage of the trachea anteriorly. Also, it has a softer plastic posterior membrane that moves with respiration and resembles

that of the membranous trachea. Because of this design, it moves dynamically with each phase of the respiratory cycle. Placement requires use of special forceps also called Freitag forceps and can be positioned directly through the cords or with a special laryngoscope. A video laryngoscope may be helpful to visualize the cords to facilitate placement. This is indicated for CAO involving the carina, proximal mainstem, as well mid-to-distal tracheal pathology.[15] More proximal lesions require a T-Y Montgomery tube with a tracheal stoma.

*Metal stents* are also used to palliate malignant CAO. These stents can be deployed through flexible bronchoscopy, a guide wire, and fluoroscopy. Their sizes vary according to the desired length and diameter, and the stents are usually contained within a deployment system, which is released by pulling of a string that unravels and deploys the stent. Most of these stents have markers and can be visualized under fluoroscopic guidance.

## EARLY METAL AIRWAY STENTS

The *Gianturco stent* was one of the first stainless steel metal stents with a zigzag loop design.[16–18] This model is made of 0.018 inch stainless steel monofilaments into a double-zigzag design and is introduced via 12 French Teflon sheath. *Palmaz* was next to follow, which was positioned by balloon expansion and conformed to the airway. This feature prevents the stent from opening to a diameter larger than that of the given airway obstruction.[16] These stents are rarely used in clinical practice in the United States today. *Wallstent* is a self-expandable super alloy stent that expands to a preset diameter and is mostly used in Europe.[17,18] It is composed of 20 surgical steel monofilaments of 100-$\mu$m diameter braided into a cylindrical tube. It is mounted on a 7 to 9 French delivery catheter and a rolling membrane that serves to protect the device.

## NEXT GENERATION METAL AIRWAY STENTS

*Ultraflex* (Boston Scientific) stents are made of single-strand nitinol.[19] Nitinol is a memory metal and has the advantage of conforming to the irregularities of the airway (Fig. 61.3). This is a self-expanding stent that is contained within a flexible

deployment system and unravels with the pulling of a thread. The deployment system can be passed over a guidewire that has been previously placed with a flexible bronchoscope or through an endotracheal tube. This obviously has the benefit of easy deployment and can be visualized under fluoroscopic control. The Ultraflex stent has upper and lower markers for accurate positioning across the obstruction. In addition to the noncovered version, this stent comes with a polyurethane cover that spans its length except for 1 cm on each end to allow for granulation and prevent migration. In a recent publication on Ultraflex stents, it demonstrates a low-complication rate and effective use in complex malignant airway stenoses with marked asymmetry or irregularity, angulation, or changing diameters.[20]

Included within the next generation of airway stent is the *Aero Pulmonary stent* by Alveolus company. This stent contains characteristics of metal and silicone stents. It has a biologically inert cover and can be removed if necessary. This stent can be deployed with either flexible or rigid bronchoscopy and can be repositioned after deployment.

## INDICATIONS FOR STENTING

The goal of airway stenting is to improve upon a specific symptom that the patient demonstrates. This is usually caused by

**FIGURE 61.3** Ultraflex covered. (Courtesy of Boston Scientific, Natick MA.)

alteration of the flow of air through the trachea or bronchi because of the luminal decrease of at least 60% to 70%. These symptoms are usually acute or chronic dyspnea and hemoptysis. The decrease in luminal diameter can be either extrinsic or intrinsic with the same end result of airway compromise. The indication for stenting in most cases will be unresectable primary lung cancer, and thus, the most common cause of malignant CAO,[21] followed by secondary involvement of the airway by esophageal and thyroid cancer.[21] Wood et al.[21] have reported that 42% of patients in their series had extrinsic compression from lung cancer and 27% had endobronchial tumor. Of the patients who had extrinsic compression, the most common cause was lung cancer, followed by mediastinal, thyroid, esophageal cancer, mesothelioma, metastatic lesions from kidney, thyroid, sarcoma, breast, and others.[21] Less common indications for airway stenting include either primary or metastatic laryngeal cancer, lymphoma, myeloma, or lymphadenopathy of any etiology.

## ABLATIONAL THERAPIES

Ablational therapies act in a complementary role and are often necessary for purposes of debridement prior to stenting. As detailed by Santos et al.,[22] laser, PDT, cryotherapy, cautery, and brachytherapy in combination with stenting often produce a more favorable outcome than stenting alone.

**Rigid Bronchoscopy**    This is, by far, the most effective means to address any airway problem. It can be used to core out the tumor, dilate the airway stricture, and provide superior airway control. It is a tool that most thoracic surgeons are familiar with, and it can provide the means by which the flexible scope is passed for more distal visualization, adjustments of stent position, or for airway balloon dilation (Fig. 61.4). Essentially, any therapy can be used with rigid bronchoscopy including laser, cautery, argon plasma coagulation, PDT, cryotherapy, or, more recently, use of the microdebrider.[23] Rigid bronchoscopy has changed little over the years, is most popular with surgical groups in North America for the endoscopic relief of airway obstruction, and in the most recent literature, appears to be the preferred technique for airway management and stent deployment.[21]

**Electrocautery and Argon Plasma Coagulation**
The use of electrical current is commonly used in the operating room during most surgical procedures. The use of cautery
**FIGURE 61.4    A:** Right upper sleeve bronchoplasty with anastomotic stricture. **B:** Balloon dilation of the stricture. **C:** Polyflex airway stent placement. **D:** Airway remodeling after stent was removed 3 months late.

in the airway was described by Gilfoy in 1932.[24] More recently, cautery forceps have been modified to be passed through the large channel of a flexible bronchoscope. They have grasping capability and can cauterize the tissue providing tumor necrosis and hemostasis simultaneously. *Argon plasma* coagulators are a noncontact form of electrocoagulation and have also been used for obtaining cauterization within the airway and surface bleeding. Its utility in the open surgical field has been validated for liver, splenic, or chest wall bleeding, and the device can also be delivered through the bronchoscope to treat tumors "around the corner" or at an acute angle.[25]

**Laser Therapy**    The use of laser in the airway is well documented. It can be delivered through the flexible or rigid bronchoscope. The most commonly used laser is the Nd:YAG 1064 nm and can achieve tissue penetration up to 10 mm. The largest series to date with regard to the use of laser therapy are by Dumon et al.,[4] Cavaliere et al.,[5,6] and Venuta et al.[7] All of these studies confirm the definite improvement, and thus palliation, of symptoms with a high degree of success (90% to 100%).

**Photodynamic Therapy**    PDT is a modality that uses a photosensitizer intravenously administered 48 to 72 prior to treatment, which is selectively taken up by the tumor tissue

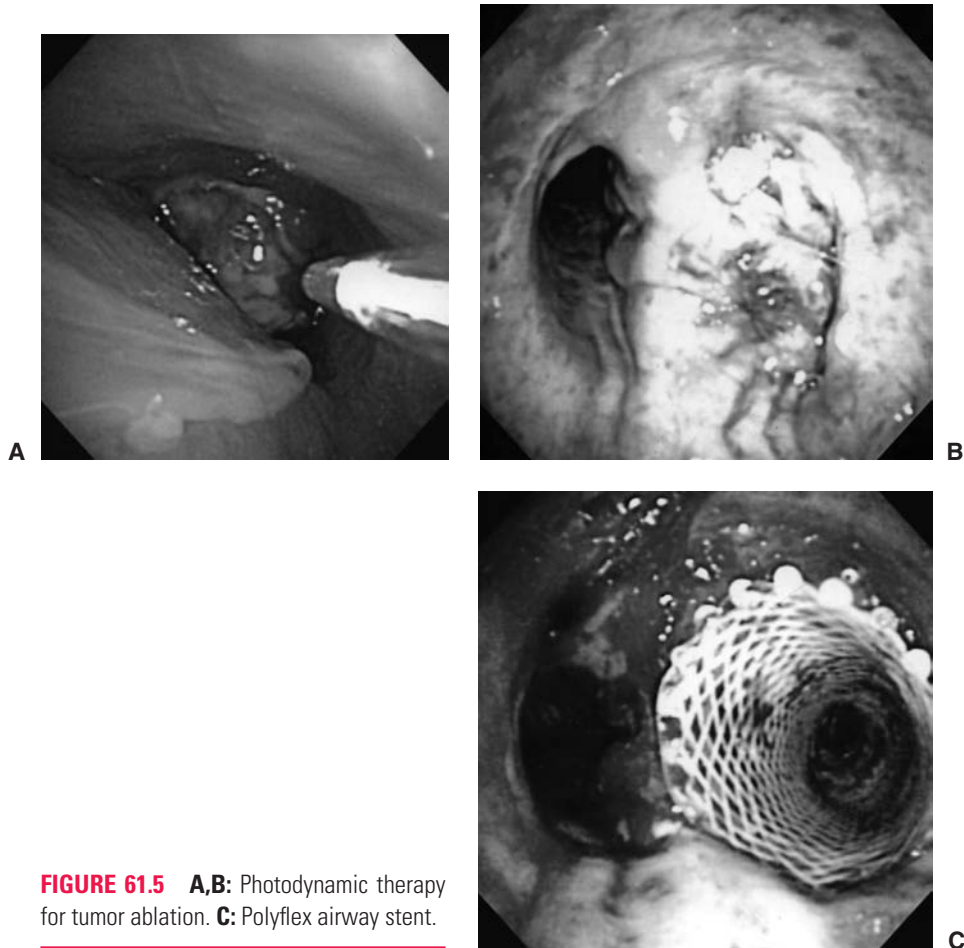
(Fig. 61.5). Monochromatic light that matches the activation wavelength of the photosensitizer (Photofrin Axcam pharmaceutical) is illuminated onto the tumor, and a chemical reaction occurs with the release of oxygen free radicals and subsequent vascular collapse of the tumor. This creates tumor necrosis and can be used for superficial lesions as well as bulky tumors. Repeat bronchoscopy is usually necessary to "clean up" the airway. This is a well-documented treatment modality and has been reported by Moghissi et al.[26–28] in 1997, 1999, and most recently 2004. In all of these reviews, it is clear that this therapy cannot only palliate patients with advanced stage disease but also potentially treat early lesions. In the most recent analysis by Moghissi,[28] a review of 24 articles (1153 patients) in the world literature was provided. He concluded that bronchoscopic PDT is a safe and effective therapeutic method for the palliation of advanced lung cancer. Others have also reported their experience with favorable outcomes for the use of PDT. A recent review from Roswell Park Cancer Institute concludes that PDT is an effective tool for the palliation of endobronchial cancers that obstruct the central airways.[29] Also in another review by Chen et al.[30] from the University of Pittsburgh concluded that PDT is effective in the palliation of lung cancer. In certain situations, it might be possible to treat an endobronchial tumor with photodynamic therapy


**FIGURE 61.5**    **A,B:** Photodynamic therapy for tumor ablation. **C:** Polyflex airway stent.

and then follow with surgical treatment. Recently, a case report by DeArmond et al.[31] demonstrates the combined use of photodynamic therapy and thoracoscopic sleeve lobectomy.

**Cryotherapy** *Cryotherapy* is a technique that uses repeated freeze–thaw cycles to achieve tumor necrosis through extreme cold. The method utilizes temperatures in the −80° to −160°C range and thus causes cell death by intracellular and extracellular crystallization and microthrombosis.[32] This can be delivered through flexible or rigid bronchoscopy and can be used to successfully palliate endobronchial cancers. This is a safe technique but has the major disadvantage of having delayed effects. The largest series to date was by Maiwand and Homasson[33] in 1995, which reported 622 cases with reasonable improvement in dyspnea and hemoptysis. More recently, Noppen et al.[32] in 2001 achieved 80% airway patency rates in their study. Asimakopoulos et al.[34] in 2005 reported on the use of cryotherapy in a comparative analysis between groups of patients receiving a single dose of cryotherapy versus multiple doses over a 5-year period. The group concluded that cryotherapy is a safe method of palliation of endobronchial malignancies causing airway obstruction.

**Brachytherapy** *Brachytherapy* is typically performed through a transnasal approach, and the most common method is by an after-loading technique using Iridium 192. A thin polyethylene catheter is first positioned, and the radiation source is loaded later.[35] One of the largest series was by Macha et al.[36] in 1995 with 365 patients with administration of high dose rate (500 cGy at 10 mm × 3 or 4 fractions) with a 66% palliation rate. Celebioglu et al.[37] in 2001 reported 95 patients at the high dose rate (750 to 1000 cGy at 10 mm × 2 or 3 weekly fractions) with significant improvement in palliation of symptoms. A recent analysis looks at high-dose endobronchial brachytherapy and concludes that it is effective in palliating lung cancer but is associated with a risk of fatal hemoptysis.[38]

## PALLIATION OF LUNG CANCER

There are no randomized clinical trials comparing metal versus silicone stents to compare the degree of palliation of lung cancer or comparisons of stents with other therapies possibly because of the ethical dilemma that is created by such life-threatening conditions.[22,39] On the other hand, what does exist are series from various institutions in the United States and abroad that provide their experience and their preferences. The common goal in all cases is palliation of hemoptysis or respiratory failure.

There are several large series of stenting for malignant CAO. All of these studies share one thing in common, that is, stenting can improve upon, and thus palliate, the symptoms caused by airway compromise. Survival is limited for this group and can be measured in terms of months (3 to 4 months) on average.

One of the largest series to date is from Dumon et al.[40] in 1999, which reported their results with 1574 stents in 1054 patients. This was a multicenter European study, which also included stenting for benign strictures as well as for malignant CAO and reported good resolution of airway patency with minimal complications. The three most common complications in this series were migration (9.5%), granulomas (7.9%), and mucus impaction (3.6%). The average length of stent placement was 4 months.

Miyazawa et al.'s study[41] on the use of 54 Ultraflex stents in 34 patients, stratified the patients based on dyspnea scores 1 to 4 and showed that after deployment of the stent, patients immediately improved with regard to their dyspnea. Most patients were downgraded from their initial scores of 3 and 4 to 0, 1, and 2. Their conclusions were that the patients were significantly palliated in terms of dyspnea, which contributed to improved quality of life.

Sadd et al.[42] analyzed their 6-year experience with 112 self-expanding metal stents (Wallstent and Ultraflex Boston Scientific) in 82 patients. The majority of patients had dyspnea (80%), and 16 patients were on ventilators. Of the 16 patients on ventilators, 14 were able to be extubated and there were no deaths. The most common complications included infections (15.9%), obstructive granulomas (14.6%), and migration (4.7%). The median follow-up duration was 42 days with a range of 1 to 672 days.

Wood et al.[21] placed 309 stents in 143 patients, 67% of which were for malignant airway obstruction. A total of 87% of the stents were molded silicone rubber (Hood Laboratories Penbroke, MA), and 13% were metal stents. Of the 96 patients with malignant CAO, 88 (92%) had received previous radiation or chemotherapy or both, and 14% had previous surgery for lung, esophageal, or thyroid cancer. In addition, 68% of the patients had additional procedures (laser, core-out, dilation, brachytherapy, photodynamic therapy) to prepare for or as an adjunct to stenting. Ninety-five percent of the patients noted significant improvement of their symptoms. In this study, 45 of the 53 patients with malignant disease (85%) maintained airway palliation for follow-up periods of 1 to 13 months, (mean, 4 months) with 28% requiring further bronchoscopic interventions.

Shin et al.[43] evaluated the safety and effectiveness of covered retrievable expandable nitinol stents in 35 patients with malignant tracheobronchial strictures with the intent of palliation. In this study, dyspnea was assessed according to the Hugh-Jones classification.[43] Average survival was 9.62 weeks (2 days to 26 weeks). The authors concluded that stent placement is safe, effective, and improvement was noted in terms of dyspnea with improved quality of life.

Lemaire et al.[2] reviewed their outcomes with tracheobronchial stents in 172 patients. In this group, 225 stents total were placed. A total of 172 stents were placed in 142 patients for malignant disease. The study sought to assess the short-term (<30days) and intermediate (>30days) risks and benefits of tracheobronchial stenting. The complications related to stent placement included tumor ingrowth (n = 9),

excessive granulation tissue (n = 7), stent migration (n = 5), and restenosis related to extrinsic compression (n = 2). Five of the complications occurred in the first 30 days, whereas the rest occurred later on. The latter complications were mostly related to excessive granulation tissue and tumor ingrowth. Median survival after stenting is 3.4 months with a 1-year survival of 15%. The authors concluded that the stents offer minimally invasive therapy for patients with unresectable malignant CAO with an acceptable risk of complications at short and intermediate time points.[2]

Chin et al.,[44] in a recent review article on stenting, provides a detailed analysis of the different types of stents and the indications. In this analysis, once again the end point was symptomatic relief and improvement in quality of life.

## CONCLUSION

Stenting appears to be an accepted method to palliate patients that are dying from lung cancer. Often, these patients have very limited survival, creating the dilemma of whether to do anything at all. As long as patency of the airway can be achieved, patients will have symptomatic improvement within their last year of life. In a recent review from the Netherlands,[45] where euthanasia is legal, stenting is performed with improvement in quality of life. After the patients died, their general practitioners (GPs) were given a questionnaire to determine whether the stent was helpful. In 58% of the cases, the GPs thought that stent placement should always be considered as part of the treatment of terminal cancer patients with imminent suffocation. Regardless of the specific design, stents provide palliation for patients with malignant airway disease.

# Management of Malignant Pleural Effusion

Malignant pleural effusions (MPEs) are a common complication of advanced cancer. There are estimated to be greater than 150,000 cases of MPE each year in the United States, and approximately half of all patients with metastatic cancer will develop an MPE. Lung cancer and breast cancer account for over 75% of malignant effusions.[1] For most patients with MPE, cure is no longer an option and, for many, life expectancy is short. MPEs are clinically important because they cause significant symptoms that can severely impact the quality of life for patients with advanced cancer.

Common symptoms that result from an MPE include dyspnea, orthopnea, cough, and chest pain. Dyspnea is, by far, the most common presenting symptom and is seen in 96% of patients.[2] The mechanical impact of the pleural fluid on the diaphragm, chest wall, and compressed lung all contribute significantly to dyspnea, but may not be the only cause. Dyspnea in a patient with advanced lung cancer is very common. The majority of lung cancer patients will have dyspnea at some point during their illness and MPE is just one cause. Underlying poor lung function, parenchymal replacement by tumor, endobronchial obstruction, postobstructive pneumonia, and toxicity from treatment can also contribute to dyspnea in patients with advanced lung cancer (see Chapter 23). In a dyspneic patient with advanced lung cancer, evaluation is made for potentially correctable causes of dyspnea such as MPEs because these can be frequently palliated. It is also important to recognize the potential for multifactorial etiology for dyspnea and to note that removal of all the pleural fluid may not provide complete relief of symptoms.

Cough is another common problem in patients with advanced lung cancer, and the list of possible causes for cough is similar to that for dyspnea. Large pleural effusions are a treatable cause for cough, and lung cancer patients with cough should be evaluated for effusion and treated prior to attempting other palliative alternatives.

## MALIGNANT EFFUSIONS IN NON–SMALL CELL LUNG CANCER

Malignant effusions occur in 7% to 15% of all lung cancer patients. Patients with non–small cell lung cancer (NSCLC) and associated malignant effusions are not considered to be curable, but have been classified as cT4M0, stage IIIB. These were frequently referred to as "wet IIIB" and treated in a manner very similar to stage IV disease. The International Association for the Study of Lung Cancer (IASLC) recently reviewed the current TMN staging for lung cancer and recommended several revisions (see Chapter 30).[3] One of the most significant of these revisions was to place pleural dissemination of disease, either by pleural effusion or pleural nodularity without evidence of other metastatic disease into an M1a classification, making it stage IV disease.[4] IASLC reviewed over 100,000 patients worldwide treated for primary NSCLC. Patients with pleural dissemination and without other metastatic disease (n = 488) had a median overall survival of 8 versus 13 months for other cT4M0 patients.[4] The 1- and 5-year survival patients with pleural dissemination were 36% and 2%. This was consistently worse than other T4M0 cases (where they were previously classified), but consistently better than cases with distant metastases where median survival is 4 to 7 months, hence, the new M1a classification.

## PATHOGENESIS

A pleural effusion seen in association with a known lung cancer can be either malignant or paramalignant in nature. A malignant effusion is the result of direct pleural dissemination of disease. Paramalignant effusions are not a result of direct pleural involvement with tumor but are related to the primary tumor.[5] Examples of paramalignant effusions include chylothorax secondary to thoracic duct obstruction, postobstructive pneumonia from an obstructing tumor with an associated
**FIGURE 62.1**   A schematic representation of pleural space, which demonstrates main patterns of fluid production and clearance. In the normal pleural space, the parietal pleural is the primary site of fluid production and absorption. In the setting of MPE, production and clearance of fluid can be abnormal on both the parietal and visceral surface, and obstruction of chest wall lymphatics play a significant role in fluid accumulation.

parapneumonic effusion, and an effusion secondary to hypoalbuminemia from cancer cachexia.

The pleural space is a moist "potential space." Effusions occur because of an imbalance in the normal equilibrium between production and clearance of fluid in that space. Anything that results in increased fluid formation or decrease in absorption will result in an effusion (Fig. 62.1). Changes in the oncotic fluid gradient from hypoalbuminemia secondary to cancer cachexia or in the hydrostatic fluid gradient from heart failure will alter the normal forces of filtration in the intercostal and bronchial microvasculature and result in a transudative effusion. Increased capillary permeability from disease processes that directly involve the pleura itself lead exudative effusions with leakage of both proteins and fluid into the pleural space. Effusions that result from tumor implants on the pleural surface will frequently also have abundant tumor cells in the pleural fluid. Effusion caused by lung cancer, breast cancer, and mesothelioma have been noted to have elevated levels of vascular endothelial growth factor (VEGF) in the pleural tissue and fluid. VEGF is a potent inflammatory mediator as well as an important mediator of vascular permeability and angiogenesis. Elevated VEGF levels secondary to pleural tumor involvement results in an increased capillary permeability and increased fluid production from the pleural surface.[6,7]

The most common mechanism for the formation of an MPE is decreased drainage of pleural fluid as a result of blockage of chest wall lymphatics.[8] Blockage anywhere along the lymphatic tract, from the stomata on the surface of the parietal pleura to the mediastinal nodes can result in accumulation of pleural fluid. The development of MPEs in lung cancer are more closely related to involvement of mediastinal lymph nodes than to direct pleural involvement by disease.[9]

## DIAGNOSIS OF MALIGNANT PLEURAL EFFUSION

Following a careful history and physical examination, the workup for a suspected MPE proceeds through a series of diagnostic test that typically includes a chest x-ray, chest computer tomography (CT) scan, thoracentesis, pleural fluid analysis, and pleural biopsy. Many lung cancer patients will develop an effusion late in the course of their disease, but for some patients, the appearance of an effusion is their first evidence of malignancy. In patients with unilateral effusion of unknown etiology or bilateral effusions and no evidence of heart failure, diagnostic workup is recommended.

## RADIOGRAPHIC IMAGING

Posterior–anterior (PA) and lateral chest x-ray can detect as little as 50 cc of fluid in the pleural space with blunting of the posterior costophrenic recess on lateral view and approximately 200 cc of fluid will cause blunting of the lateral recess on the PA view.[10] Decubitus films can detect 100 cc of free-flowing effusion.[11] Larger effusions produce a meniscus sign along the lateral chest wall and very large effusions will completely

opacify ("white out") the pleural space. Massive effusions can cause inversion of the diaphragm and a shift of the mediastinum to the contralateral side.

Chest CT scan with contrast has become the imaging modality of choice for better definition and visualization of a suspected MPE. CT findings characteristic of an MPE include circumferential pleural thickening, nodularity, involvement of mediastinal pleural, and evidence of a primary pulmonary tumor. Diagnostic sensitivity of these findings range from 88% to 100% and specificity from 22% to 56%.[12,13] Histologic confirmation is necessary, despite a convincing image on CT scan.

Magnetic resonance imaging (MRI) provides excellent imaging of soft tissues and can provide useful information on chest wall and diaphragmatic invasion. MRI is highly sensitive for the detection of even very small pleural effusions and, with triple pulse technology, can differentiate transudative from exudative effusions, but CT scan remains the diagnostic exam of choice.

The experience with positron emission technology (PET) for the diagnosis of MPE is limited to date. In a series of 98 patients evaluated for suspected MPE, PET demonstrated sensitivity of 96.8% and specificity of 88.5% for the detection of malignancy.[14] False-positive exams occurred in patients with inflammatory pleural disease, such as parapneumonic effusion. Of note, talc pleurodesis causes pleural thickening and increased activity on PET that can mimic the appearance of pleural involvement by malignancy.[15]

## DIAGNOSTIC THORACENTESIS AND PLEURAL FLUID ANALYSIS

Patient who presents with a new pleural effusion should undergo diagnostic thoracentesis to establish transudative or exudative nature of the fluid, perform cytological evaluation, and determine the ability of the underlying lung to reexpand.

Observation without thoracentesis is only recommended for patients with a well-recognized cause for the effusion, such as chronic heart failure or recent pneumonia. There are no absolute contraindications to thoracentesis; relative contraindications include small-sized effusions, bleeding disorders, anticoagulation, and mechanical ventilation. Complications associated with thoracentesis include pneumothorax, hemothorax, infection, and hemoptysis. Thoracentesis has traditionally been performed as a "blind" procedure where the needle is placed based on standard positioning and the appearance of fluid on radiographic imaging. Several studies have indicated that ultrasound guidance can assist even experienced physicians in selecting appropriate puncture site.[14,16–18]

The gross appearance of pleural fluid at thoracentesis can be suggestive of an MPE, if it is hemorrhagic or opalescent. Half of all hemorrhagic effusions are malignant and 11% of MPEs are bloody in nature.[19] The majority (90% to 97%) of MPEs are exudative, but malignancy is not the only cause of an exudative effusion. Inflammatory causes are also common, because anything that increases capillary permeability in the pleural space will result in leakage of both fluid and protein into the pleural space. Although, the presence of an unexplained exudative effusion is worrisome for malignancy, the absence of transudative properties does not rule out a malignant etiology.[20] Exudative properties are most commonly defined on the basis of the Light's criteria, which is outlined in Table 62.1. Overall diagnostic accuracy of Light's criteria is 93%.[21]

Pleural fluid from thoracentesis should be evaluated for lactate dehydrogenase (LDH), total protein, pH, glucose, and cell count. LDH and total protein are components of Light's criteria for determination of exudate versus transudate. Low glucose and pH are common in pleural space infections but are also seen in up to 30% of MPEs and can be prognostic with regard to palliation of effusion and overall survival.[22,23] The diagnostic yield from the cytological examination of fluid from thoracentesis is variable, ranging from

| **TABLE 62.1** | **Criteria for Establishment of Exudative Pleural Effusion** | | |
|---|---|---|---|
| **Light's Criteria** | **Abbreviated Light's Criteria** | **Two-Criteria Pleural Fluid Rule without Blood Test** | **Three-Criteria Pleural Fluid Rule without Blood Test** |
| Pleural fluid-to-serum LDH ratio >0.6 or | — | — | — |
| Pleural fluid LDH >67% of normal serum LDH upper limit or | Pleural fluid LDH >67% of normal serum LDH upper limit or | Pleural fluid LDH >67% of normal serum LDH upper limit or | Pleural fluid LDH >67% of normal serum LDH upper limit or |
| Pleural fluid-to-serum protein ratio >0.5 | Pleural fluid-to-serum protein ratio >0.5 | — | — |
| | | Pleural fluid cholesterol >450 mg/L | Pleural fluid cholesterol >450 mg/L or Pleural fluid protein >30 mg/L |

62% to 90%.[24–29] Increasing the volume of pleural fluid sent for cytological evaluation does not increase the sensitivity.[28] If a diagnosis is not made by initial thoracentesis, a second drainage can be attempted with approximately a 25% increase in yield, but the increase in yield drops dramatically after two attempts.[30] Repeated diagnostic aspirations beyond two are not recommended because of low diagnostic yield and increasing risk for infection and loculation. Closed pleural biopsy with an Abrams or Cope needle is often attempted when initial cytology is negative. Although the diagnostic yield from closed biopsy when combined with cytology can be as high as 80%,[31] it has very small diagnostic yield in cases where the initial cytological evaluation was negative.[26] Therefore, if two consecutive percutaneous drainages provide no diagnosis, thoracoscopy is recommended. Video-assisted thoracoscopic surgery (VATS) allows for wide examination of the pleural space and for large visually directed pleural biopsies. Diagnostic sensitivity for VATS procedures is reported at greater than 90% with specificity of 100% and perioperative mortality is less than 0.5%.[32,33]

The addition of tumor marker evaluation to the analysis of pleural fluid has been investigated. Carcinoembryonic antigen (CEA), carbohydrate antigen 15-3 (CA 15-3), cytokeratin 19, and cancer antigen 125 (CA-125) analysis can all be performed, but their diagnostic value remains limited.[34] No single marker has sufficient specificity to add to routine practice. In cases of NSCLC, epidermal growth factor receptor (EGFR) analysis of MPE is proving useful. EGFR mutations can be detected from cells in MPEs, helping to identify a group of patients likely to benefit from EGFR-targeted therapies.[35] DNA methylation analysis appears to carry significant diagnostic value in MPEs. Brock et al.[36] detected DNA methylation in 59% of MPEs but in none of the benign effusions evaluated. The addition of methylation studies to standard cytological evaluation increases both the sensitivity and the negative predictive value compared to cytology alone.[29,36]

## TREATMENT

The goal of treatment in a patient with a malignant effusion from lung cancer or other tumors is palliation of symptoms. MPEs occur in a diverse patient population with variable life expectancies. A small percentage of patients are robust and will have life expectancies of months to years, whereas many patients are frail with advanced disease and significant cancer-related comorbidity with life expectancy of only days to weeks. It is important to appropriately tailor therapy to the best needs of the individual patient. Successful palliation of an MPE is judged by long-term relief of symptoms related to the effusion and no evidence of reaccumulation of fluid on chest radiograph until death. Removal of the effusion, improvement in symptoms, and prevention of reaccumulation do not signify a cure or prolong expected survival from the underlying malignancy, but inappropriate management of an MPE can shorten expected survival by compromising respiratory function.

The two most common treatment options currently used for MPE are pleurodesis or the insertion of a chronic indwelling tunneled pleural catheter. There are numerous other treatment options from noninvasive approaches such as observation or repeated thoracentesis, to the very aggressive procedures such as pleurectomy. The use of systemic chemotherapy has limited use in palliation form MPE except in small cell lung cancer, where many patients will respond to chemotherapy with resolution of their effusion and associated dyspnea.[37] Similarly, MPEs rarely respond to mediastinal radiation except in the case of some lymphomas where the effusion is a result of obstruction of mediastinal lymphatics that can be relieved following radiation.[38]

**Observation**    Observation alone is recommended for those patients who are asymptomatic from their effusion or in the small number of patients (<2%) in whom there is no fluid reaccumulation following thoracentesis.[1,39] Observation and supportive care are also reasonable options for those patients who are very frail and whose life expectancy is in days. Supportive care in this situation also includes the use of opioids and oxygen therapy to ease the anxiety associated with dyspnea.[40]

**Serial Thoracentesis**    Thoracentesis is very effective at acutely alleviating symptoms associated with MPE and has an important role in the diagnosis and planning treatment, but it has limited value as therapeutic approach. From 98% to 100% of MPE associated with lung cancer will reoccur within the first month of the initial thoracentesis.[1,39] Serial thoracentesis usually need to be performed frequently with an interval dependent on the rate of fluid accumulation. Repeated thoracentesis can lead to pneumothorax, fluid loculation, and empyema. This approach is only recommended in patients whose life expectancy is days to weeks, those who are too frail for pleurodesis or insertion of a chronic indwelling tunneled pleural catheter, or in the very rare patient with a very slowly reaccumulating effusion.

**Chest Tube Drainage Alone**    The most common use of chest tube drainage for MPE is to provide apposition of the parietal and visceral pleural surfaces for subsequent pleurodesis. Prior to the introduction chronic indwelling tunneled pleural catheters, chronic chest tubes were frequently used for palliation of patients with MPE refractory to pleurodesis. Chronic chest tubes were used in patients with trapped lungs, where pleurodesis is not an option.(Fig. 62.2) Formerly, traditional large-bore tubes were used almost exclusively, because it was believed that they were less likely to clot and obstruct, but a series of trials in the 1990s indicated small-bore tubes (10 to 14 Fr) were as efficacious as larger tubes, and significantly more comfortable.[41,42]

**Pleurodesis**    Pleurodesis is the most commonly performed procedure for the management of symptomatic MPEs. Pleurodesis is not appropriate management for all patients with an MPE. Prior to undertaking pleurodesis, one must consider if
**FIGURE 62.2**  Chest radiographs demonstrating a patient with large right pleural effusion before (**A**) and after (**B**) large-volume drainage. The postdrainage film demonstrates classic appearance of "trapped lung" where the distribution of air in the pleural space corresponds to the previous distribution of pleural fluid.

the patient is a suitable candidate. In some histologies, specifically small cell lung cancer, MPEs respond to systemic therapy. These patients typically benefit from initial thoracentesis, but the effusion can then be followed as a measure of response to therapy. For other patients, the MPE is not the main source of dyspnea, and the removal of fluid from the pleural space does not improve their symptoms. Experts advise against pleurodesis only for patients with life expectancies less than 2 to 3 months to justify the cost, risk, and discomfort of the procedure. In other patients, the underlying lung has become trapped by long-standing fluid or excessive tumor on the lung surface (Fig. 62.2), and without apposition of the pleural surfaces, pleurodesis is not possible.

The goal of pleurodesis is to create fibrosis of the pleural space that obliterates the space, either by chemical or mechanical means. The most common methods employ chemical sclerosants or irritants, which achieve pleural symphysis through an inflammatory process. After complete drainage of the effusion, the sclerosants are usually instilled into the pleural space either at the bedside via a chest tube or in the operating room during thoracoscopy (VATS). For a pleurodesis to be successful, the lung needs to be completely expanded so that the pleural surfaces are in direct apposition. Incomplete drainage and undisrupted loculations decrease the success rate of pleurodesis. Pleural fluid glucose concentration <60 mg/dL, LDH concentration >600 U/L, and pH <7.30 are all predictive of lower success rate of pleurodesis.[22,23] The overall complete response rate to chemical pleurodesis is 64%.[5,43] Over the past 20 years, a large number of different sclerosing agents have been used, and some of the most frequently used are included in Table 62.2 with their relative rates of success and recommended doses.

The ideal sclerosant for pleurodesis remains controversial. The most commonly used agents today are talc, bleomycin, and doxycycline. The exact mechanism of how pleurodesis is established is not entirely clear, but it is related to the release of proinflammatory mediators that promote fibrosis.[44] Chest pain, atelectasis, pneumonia, fever, dysrhythmia, empyema, and respiratory failure have all been reported with talc pleurodesis.[45–47] Hypoxemia and respiratory failure following talc pleurodesis are more dependent on the particle size of the talc than on the dose or the route of administration.[47,48]

**TABLE 62.2  Sclerosing Agents for Pleurodesis**

| Sclerosing Agent | Success Rates | Standard Dose |
|---|---|---|
| Talc[45,55,65–67] | 70%–100% | 2.55–10 mg |
| Nitrogen mustard[68,69] | 27%–95% | 0.4 mg/kg |
| Tetracycline[69,70] | 70% | 20 mg/kg in 50 mL NaCl 0.9% |
| Doxycyclin[71,72] | 60%–80% | 500 mg in 30 mL NaCl 0.9% |
| Bleomycin[73–75] | 64%–84% | 60 U in 100 mL NaCl 0.9% (1 U/kg) |
| Quinacrine[76–78] | 64%–100% | 500 mg |
| Corynebacterium parvum[79–82] | 65%–92% | 3.5–14 mg |
| OK-43[83,84] | 73%–79% | |

Respiratory failure is more common with talc preparations, which have a mean particle size less than 15 $\mu$m.[49] Smaller talc particles have the ability to move from the pleural space into pulmonary vascular bed and initiate systemic inflammation. This phenomenon has been demonstrated in both animal and human models.[50,51] Talc preparations carry vary significantly in particle size,[52] which may explain some of the large discrepancy between rates of respiratory failure following talc pleurodesis reported by different institutions.[45,53] It is now recommended that only size-calibrated talc with a mean particle size greater than 20 $\mu$m and no particle less than 10 $\mu$m be used.

Two main pleurodesis techniques have emerged, VATS pleurodesis and bedside pleurodesis via chest tube. The VATS and bedside procedures differ in several aspects, which can have an affect on their success rate. First, VATS procedures allow for more complete drainage of the effusion prior to pleurodesis. Small loculation and flimsy adhesions can be broken down to completely free the lung within the pleural space. Second, VATS also provides a more complete evaluation of the pleural space and better determination of whether or not the lung is trapped. Small- to moderate-sized areas where the lung does not approximate the chest wall are better seen at VATS than on chest radiograph, and these spaces decrease the success of pleurodesis and may alter treatment choices when recognized. Third, the distribution of sclerosants over the entire pleural space has the potential to be more complete in a VATS procedure than via installation at the bedside because of the ability to disrupt loose adhesions. VATS also allows for visually directed biopsies in those patients with a suspected MPE and no diagnosis. Perioperative mortality needs to be considered but is reported at less than 1%.[32,33] There are also several advantages to bedside pleurodesis over a VATS procedure. It can be performed quickly and easily by a single person. It does not require the use of sedation or general anesthesia or the availability of an operating room. So, as with other aspects of the management of MPE, the decision between a bedside or VATS pleurodesis is often individualized to each clinical scenario, with the priority being the quickest and safest way to palliate the patient with the shortest time in hospital.

In clinical practice, there appears to be little consensus on the optimal pleurodesis strategy. Numerous clinical trials on the topic of pleurodesis have been performed, but their results are very difficult to interpret because of the small number of patients, short life expectancy of the study population, numerous histologies investigated, numerous sclerosing agents employed, and multiple approaches undertaken. Two large metaanalyses have recently been published on the topic pleurodesis for palliation of MPE, and an overview of these analyses is outlined in Table 62.3. The first is authored by Shaw and Agarwal[54] from the Cochrane Collaboration. They identified 36 randomized control trials with 1499 subjects

| No. RCTs evaluated | 36 | 46 |
| Total no. of pts | 1499 | 2053 |
| Findings re: sclerosing agents | * Talc most efficacious with **RR of nonrecurrence of effusion of 1.34** (95% CI, 1.16–1.55) compared to bleomycin, tetracycline, mustine, or drainage alone (6 studies, 186 pts) | * Talc is *not* more efficacious than other agents with **RR of recurrence of 0.65 (95% CI, 0.34–1.20)** compared to bleomycin, **RR of recurrence of 0.50 (95% CI, 0.06–4.42)** compared to tetracycline, and **RR of recurrence of 0.21 (95% CI, 0.05–0.87)** compared to mustine (9 studies, 341 pts) |
| Findings re: pleurodesis technique | * VATS pleurodesis with talc more efficacious with **RR of nonrecurrence of effusion of 1.19 (95% CI, 1.04–1.36)** compared to bedside talc pleurodesis (2 studies, 112 pts)<br><br>* VATS pleurodesis with any agent was more efficacious with **RR of nonrecurrence of 1.68** (95% CI, 1.35–2.10) compared to bedside pleurodesis (5 studies, 145 pts) | * VATS pleurodesis with talc was more efficacious with **RR of recurrence of 0.21** (95% CI, 0.05–0.93) compared to bedside talc pleurodesis. (2 studies, 112 pts)<br><br>* VATS pleurodesis with tetracycline was ***not*** more efficacious with **RR of recurrence of 1.05** (95% CI, 0.57–1.94) compared to bedside tetracycline pleurodesis (1 study) |

CI, confidence interval; pts, patients; RCT, randomized controlled trial; RR, relative risk; VATS, video-assisted thoracoscopic surgery.

over the 22-year period between 1980 and 2002 and focused on a comparison of the most commonly used sclerosants, talc, bleomycin, and tetracycline and on a comparison of the most common methods of installation, VATS versus bedside. The analysis determined that the relative risk (RR) for success favored talc over bleomycin (RR = 1.23; 95% confidence interval [CI], 1.00 to 1.50) or tetracycline (RR = 1.32; 95% CI, 1.01 to 1.72). Bleomycin and tetracycline were found to be equally effective (RR = 1.03; 95% CI, 0.89 to 1.20). In the six trials that reported mortality, there was no statistically significant difference in the RR for mortality between talc and bleomycin (RR = 1.39; 95% CI, 0.84 to 2.30) or tetracycline (RR = 2.26; 95% CI, 0.95 to 5.39). In a comparison of VATS and bedside installation of various sclerosants, they found the RR of success favored VATS (RR = 1.68; 95% CI, 1.35 to 2.10), but noted the confounding effects of multiple sclerosing agents being compared. The second metaanalysis, from a British group, Tan et al.[55] identified 46 randomized control trials over a similar time period. They found a trend favoring talc over other sclerosing agents, but no statistically conclusive evidence supporting the use of one sclerosing agent over another. They identified only two trials comparing VATS to bedside procedures with the same agent. Although these trials found VATS procedures were associated with fewer recurrences, they did not feel that this was strong enough evidence to recommend VATS over bedside procedures. The recommendation rendered from the analysis was that the decision be made according to such factors as the overall health of the patient, the need for a biopsy and the delay required to get the patient to the operating room. In an evidence-based review by the American College of Chest Physicians (ACCP), they report the overall success rates for palliation of MPE with talc pleurodesis is >90%, but make no recommendations on VATS versus bedside use.[40]

### Chronic Indwelling Pleural Catheter
The introduction of the Pleurx catheter (Cardinal Health, Dublin, OH) has had a significant impact on the management of MPEs.

The Pleurx is small-bore, chronic indwelling, tunneled silicone catheter for use in the pleural space. It is designed for intermittent outpatient drainage for the relief of symptoms associated with pleural effusion. The catheter has a fenestrated end that is placed in the pleural space, a velcro cuff that is placed in a tunnel under the subcutaneous tissues, and an externalized end with a one-way valve that requires canalization for drainage (Fig. 62.3A). The Pleurx can be inserted percutaneously using the Seldinger technique or at the time of a VATS procedure. The catheter can be attached to a pleurovac for continuous in-hospital drainage, but in general, it is designed for outpatient use. The externalized end of the catheter is capped and placed under a dressing on the patient's chest wall for the majority of the time. It is intermittently undressed and attached to a vacuum bottle (Fig. 62.3B) for evacuation of pleural fluid. Drainage kits with vacuum bottles (600 or 1000 mL) and all necessary dressing supplies are individually packaged and delivered to the patient's home. The catheter and drainage procedure are intended for use by family members, rather than healthcare professionals. The ease of catheter placement and drainage, low complication rates, increased patient comfort, decreased need for hospitalization, and decreased cost have made these catheters the overwhelming treatment of choice for patients with a trapped lung or who those who have failed pleurodesis.[56–59] It is also advocated by many as first-line treatment of MPEs.[56,57,59,60] It has equivalent efficacy to pleurodesis and have decreased the length of hospitalization and decreased costs associated with the palliation of MPEs.[57] In select patients and in select centers, Pleurx catheters are inserted in the outpatient setting.[57] From 40% to 58% of patients managed with a chronic indwelling pleural catheter achieve pleurodesis within 2 to 6 weeks of insertion without the use of any sclerosing agents.[56,59,61] Sclerosants can also be inserted through the catheter if spontaneous pleurodesis is not achieved after several weeks of drainage. Removal following sclerosis is simple and typically performed with local anesthetic in an outpatient setting.
**FIGURE 62.3** The Pleurx (Cardinal Health, Dublin, OH) catheter system. **A:** Silicone tunneled, indwelling catheter. The fenestrated end is inserted into pleural space, cuff is placed in subcutaneous tissues, and capped end is externalized. **B:** The drainage system is inserted into one-way valve on externalized end of catheter, and is available as 600- and 1000-mL size.

**Pleuroperitoneal Shunt**   Prior to the introduction of the Pleurx catheter, indwelling pleuroperitoneal shunting was the management of choice for refractory or recurrent MPEs that could not be controlled by pleurodesis.[62,63] The shunts are typically placed in the operating room, with one end of the silicone catheter placed in the pleural space and the other tunneled into the abdomen and with a one-way pump between the two ends placed over the costal margin in the subcutaneous tissues. Each compression of the pump transports approximately 1.5 mL of fluid; patients are asked to compress the pump 5 to 10 times at least four times each day, but may be required to pump it >100 times per day for high-volume effusions. Complications hamper the utility of these catheters in approximately 15% of users, the most common issue being occlusion secondary to fibrinous material in the pumping mechanism.[64]

**Pleurectomy**   Total parietal pleurectomy has nearly 100% success rate for the control of MPEs, but it does so at a high cost in terms of morbidity, mortality, and hospital stay. The majority of patients with MPE have limited life expectancy and therefore, other less invasive palliative options should be used.

## CONCLUSION

Malignant pleural effusions are a common clinical condition in patients with end-stage lung cancer and other malignancies. Therapy is directed at palliation of symptoms rather than cure, but inappropriate management can decrease survival and severely impact quality of life. Prior to therapeutic intervention, a careful assessment of the effusion and the pleural space is combined with an evaluation of the patient's functional capacity and prognosis. Therapeutic options are then individualized to the patient's unique needs. Pleurodesis with talc or other sclerosants or insertion of a chronic indwelling tunneled pleural catheter are the most frequent modalities currently used for control of symptoms.

# Management of Overt Central Nervous System Metastases: Brain and Spinal Cord

Brain metastasis is very common in cancer, with an annual incidence in the United States of approximately 170,000 to 200,000. The rising incidence of brain metastasis is most likely from a combination of increasing survival from recent advances in systemic therapy, and a greater availability and use of magnetic resonance imaging (MRI). The most common primary site is the lung (50%) followed by breast (15%). The average age at presentation is approximately 60 years, and the median survival is usually less than 1 year. Metastatic brain tumors outnumber primary brain tumors by almost a factor of 10 to 1, with autopsy series demonstrating a 10% to 30% incidence rate for all patients with a diagnosis of cancer.[1,2]

## CLINICAL PRESENTATION, DIAGNOSIS, AND PROGNOSIS

Most patients present with significant neurologic signs and symptoms (Table 63.1).[3] Although differential diagnoses such as an abscess or a stroke must be considered, new-onset neurologic symptoms in a known cancer patient should always be presumed to be from brain metastasis until proven otherwise.

MRI has become the gold standard for imaging of the central nervous system in cancer patients.[4] Given its ability to image in multiple orientations and sequences, as well as having superior resolution and accuracy, it has replaced the older computed tomography (CT). MRI will frequently pick up smaller lesions not seen on CT scans, which can have a significant effect on the patient's prognosis and treatment course. Full systemic workup (e.g., positron emission tomography [PET] and CT) should be promptly initiated if brain metastasis is the presenting event. The incidence of unknown primaries may subsequently decrease with the increasing popularity of integrated PET/CT scans.

Performance status and extracranial disease status have consistently been shown to impact prognosis. Gaspar et al.[5] reported on the Radiation Oncology Therapy Group (RTOG) the experience of 1200 patients, which is summarized in Table 63.2.

This analysis revealed three recursive partitioning analysis (RPA) classes, with the RPA class I (Karnofsky performance score [KPS] ≥70, controlled primary, age <65 years, brain metastasis only), II (not meeting requirements of classes I or III), and III (KPS <70) having median survivals of 7.1, 4.2, and 2.3 months, respectively.

## CORTICOSTEROIDS

In symptomatic patients, the initial therapy should promptly start with corticosteroids (e.g., dexamethasone or methylprednisolone), which effectively improve edema and neurologic deficits in approximately two thirds of patients.[6] The only randomized trial on the dosage question was reported by Vecht et al.[7] This trial included two successive groups of patients. The first group (n = 47) evaluated 8 versus 16 mg/day initial dexamethasone doses, with tapering schedules over 4 weeks. The second group (n = 49) evaluated 4 versus 16 mg/day of initial dexamethasone, with continuation of these doses for 28 days before tapering. The patients were scheduled for whole-brain radiotherapy (WBRT) and concurrent ranitidine. All arms had similar KPS improvements at 7 days (54% to 70%) and 28 days (50% to 81%). The study concludes that 4 mg/day of dexamethasone (with a taper over 4 weeks) is the preferable regimen.

However, one should be cautious in interpreting the results of this study. Patients in the 4-mg/day arm had to have the medication reinstituted at a higher rate than the patients in the 8- or 16-mg/day arms. Furthermore, the arm with the greatest improvement in the KPS was the 16-mg/day arm when this was tapered over 4 weeks, compared with any of the other arms. It can be argued that higher KPS improvement arose from the maximal anti-inflammatory effects of the initial higher doses, with the 4-week taper minimizing the late toxicity associated with corticosteroids.

A reasonable corticosteroid regimen in patients with brain metastases is a 10-mg intravenous (IV) or oral bolus, followed

by a 4 to 6 mg every 6 to 8 hours of dexamethasone equivalent dose (with a concurrent proton pump inhibitor), before this is tapered in a clinically cautious manner. In asymptomatic patients with little peritumoral edema or mass effect, initial corticosteroids may be reserved until the first sign of neurologic symptoms.

## WHOLE-BRAIN RADIOTHERAPY

WBRT continues to be the standard of care in patients with brain metastasis. In general, WBRT should be given soon after the diagnosis of multiple brain metastases. There has never been any evidence to suggest that delaying systemic chemotherapy for WBRT compromises overall survival (OS), especially when one considers that progression in the brain frequently leads directly to the death of the patient.

Multiple randomized studies have been performed to determine the optimum dose and fractionation of WBRT. Table 63.3 summarizes selected randomized studies on WBRT fractionation.[8–11] OS has not improved appreciably over the last 25 to 30 years. Typically, the radiographic and clinical response rates range from 50% to 75%. A total of 30 Gy in 10 fractions continues to be the standard for most patients. In chemotherapy refractory, RPA class III patients, a shorter fractionation scheme (e.g., 20 Gy in 5 fractions) should be considered. However, short fractionation schemes should be avoided in chemotherapy-naive patients with brain metastasis as the presenting event in the cancer diagnosis. The natural disease course of such patients can be frequently unpredictable, so they may live sufficiently long enough to experience late radiation toxicity posed by such short fractionation schedules.[12]

## SURGICAL RESECTION

Surgical resection can provide immediate relief of the tumor mass effect, whereas WBRT typically takes several days to work. Radiobiologically, 30 Gy in 10 fractions to a solid tumor (excluding radiosensitive tumors) is not adequate to achieve long-term tumor control. This issue is especially germane because historically, up to one half of all patients died from neurologic causes after being treated with WBRT alone.

There have now been three phase III trials testing the hypothesis that surgical resection to single brain metastasis is potentially beneficial. All three trials were on patients with a single lesion, which is defined as the presence of only one lesion in the brain regardless of the extracranial disease status, whereas a solitary lesion is defined as the presence of the CNS metastasis as the only site of the metastatic disease burden. Table 63.4 summarizes the three trials.[13–15] The studies by Patchell et al.[13] (KPS ≥70) and Noordijk et al.[14] (World Health Organization grade ≤2) included patients with better performance status compared with the Mintz et al.'s[15] study (KPS ≥50) that mainly contributed to the differences in the survival outcomes between the studies. The results of these studies suggest that surgical resection should be reserved for lesions causing life-threatening complications or those with good performance status (i.e., KPS ≥70).

## RADIOSURGERY BOOST TRIALS

Radiosurgery provides an alternative to conventional surgery. The three randomized trials of surgical resection were performed before the widespread availability of stereotactic radiosurgery (SRS). Although no randomized trials have been performed comparing surgery with SRS, SRS appears to provide similar local control rates (in the order of 80% to 90% only when combined with WBRT). Unless the tumor causes significant edema and mass effect, with consequent hydrocephalus or herniation requiring urgent surgical intervention, SRS can serve as a noninvasive option. Frequently, a patient may not be a craniotomy

candidate because of tumor location in eloquent areas or existing medical contraindications. Although two of the three conventional surgery trials have shown a survival benefit in single brain metastasis, there have been no randomized trials addressing multiple lesions and the retrospective data available are contradictory. For SRS, there have been three randomized trials assessing the efficacy of SRS in the treatment of multiple metastases.[16–18] Key findings of the three trials are summarized in Table 63.5.

The first randomized trial was reported by Kondziolka et al.,[16] but this study was stopped early at a planned interim analysis of 60% patient accrual because the authors reported to have found a large difference in the primary end point of local control in favor of SRS (92% vs. 0%; $p = 0.0016$). Unfortunately, the study used nonstandard end points to measure recurrence, defining it as any increase in the lesion size on MRI rather than the more usual 25% increase in product of the diameter. Furthermore, no attempt was

made to control for corticosteroid use, radiation changes, or other factors that might produce small fluctuations in the lesion size on MRI. Therefore, this study is difficult to interpret.

The second trial was reported by Chougule et al.,[17] and the results are only available in abstract form.[17] This three arms trial randomized patients to treatment with SRS alone with Gamma Knife, SRS plus WBRT, or WBRT alone. This trial suffers from several serious methodological problems. Although the authors conclude that the survival times among the treatment arms were similar and that patients treated with SRS experienced superior local control and fewer brain metastases, no *p* values are reported. Furthermore, 51 of the patients had surgical resection for at least one symptomatic brain metastasis prior to entry into the study, and no attempt was made to stratify for previous surgery. The inclusion of the surgically resected patients effectively made this a six-arm trial and, therefore, the size of this trial was not large enough to support a meaningful analysis. Finally, the radiation doses used in the SRS arms cannot be considered conventional because the peripheral dose was not individualized based on the tumor size or volume. Thus, this study has not been interpretable.

The third study, RTOG 95-08, was reported by Andrews et al.[18] The primary end point was OS, which was not statistically different between the WBRT plus SRS and WBRT-alone arms (6.5 and 5.7 months, respectively; $p = 0.1356$), although SRS boost favored the survival in the subgroup (planned analysis) of patients with single metastasis. For secondary end points, the local control and performance measures were higher in the SRS boost arm, but this did not translate into a lower death rate from neurologic progression. Multiple, unplanned subgroup analyses were made, and an OS benefit with the SRS boost was found in several subgroups that included patients with RPA class 1, tumor size $\geq$2 cm, and non–small cell lung cancer (NSCLC) or metastatic squamous histology from any site. Unfortunately, these subset analyses were not planned or prespecified, and the *p* values needed for significance should have been adjusted for inflation of the type I error. When this was done, none of these subgroup analyses showed a positive benefit for SRS.[19] On the other hand, this trial did demonstrate that SRS is associated with lower edema and corticosteroid use, countering a commonly held notion that SRS actually increases the edema risk. However, with regard to the major end points for multiple metastases, this study should be considered a negative trial.

Although SRS boost is indicated (from RTOG 95-08 and from the extrapolation of surgical resection data) in patients with a single metastasis, it is difficult to justify its routine use in patients with multiple metastases in the light of the equivocal phase III SRS boost trials.

## POSTOPERATIVE WHOLE-BRAIN RADIOTHERAPY

A controversy in the treatment of brain metastasis is the routine use of postoperative or post–SRS WBRT. In a multi-institutional retrospective SRS study, Sneed et al.[20] argue for the omission of upfront WBRT because this does not compromise OS. Unfortunately, only an OS analysis was performed, and no local control or retreatment data were given. In an earlier study by the same group of investigators, patients who were initially treated with SRS alone without WBRT experienced worse freedom from new brain metastasis and overall brain freedom from progression despite the imbalance of the prognostic factors that favored the SRS-alone group, although the OS was not different.[21] Because of the equivalency of OS, many have advocated withholding upfront WBRT. They often use repeat SRS for the failures, which can be very expensive. Furthermore, brain failure can lead to unacceptable consequences. For example, Regine et al.[22] reported on 36 patients with planned observation after initial SRS alone. Even with close follow-up with exams and high-resolution MRIs, 47% of patients experienced brain failure, with 71% and 59% experiencing symptomatic relapse and neurologic deficits, respectively.

The omission of upfront WBRT may have even more serious consequences for patients with more radioresistant tumors such as renal cell carcinoma (RCC). The SRS dose given is typically limited by tumor size and volume, and not by whether the patient received additional dose with WBRT. Therefore, a patient treated with WBRT plus SRS receives much higher tumor dose than SRS alone. It is then not a surprise that an Eastern Cooperative Oncology Group phase II study, which evaluated SRS alone in radioresistant tumors (RCC, melanoma, sarcoma), demonstrated very disappointing results,[23] reporting a 6-month total brain failure rate of 48.3%. The authors correctly conclude that routine avoidance of WBRT should be approached judiciously.

Fortunately, there have been two phase III trials that have assessed the use of postoperative WBRT (Table 63.6). Patchell et al.[24] demonstrated that surgical resection without WBRT led to a failure rate at the original site and the entire brain of 46% and 70%, respectively. More importantly, 44% of the patients in the surgery-alone arm died as a result of neurological sequalae from the brain failure. The results of this study have been frequently misinterpreted in the literature. Some have justified the withholding of upfront WBRT based on the fact that this study demonstrated equivalent survival. In fact, this study was designed with brain tumor recurrence rate as the primary end point and not OS. To show an OS difference, this trial needed to enroll over 2000 patients. The study met its primary end point and confirmed the importance of postoperative WBRT in preventing brain failure and death from neurologic causes.

Results of the JROSG 99-1 trial by Aoyoma et al.[25] demonstrated similar benefits of WBRT. In this phase III trial of 1 to 4 lesions, the SRS-only arm experienced worse 6-month freedom from new brain metastasis ($p = 0.003$) and 1-year local control ($p = 0.019$). Most importantly, the average duration until deterioration of mini-mental state examination (MMSE) was 16.5 months in the WBRT+SRS arm versus 7.6 months in the SRS-alone group ($p = 0.05$).[26] The main drawback of this study was the designation of OS as the primary end point.[26a,26b] There is very little evidence that adjuvant WBRT after surgery is likely to improve OS. However, this study did demonstrate the importance of WBRT in decreasing brain failure, corroborating the findings of the study by Patchell et al.[24]

These two phase III trials provide sufficient level I evidence. Adjuvant WBRT, therefore, should be considered the standard of care after local therapy with surgical resection or SRS.

## REPEAT WHOLE-BRAIN RADIOTHERAPY

Occasionally, patients fail in the brain with multiple lesions after initial WBRT. Repeat WBRT should strongly be considered. Wong et al.[27] reported on a series of 86 patients who underwent repeat WBRT. The median dose for the first course was 30 Gy, whereas the median dose for the second course was 20 Gy. A total of 70% experienced neurologic improvement, with 27% experiencing complete neurological resolution, whereas 43% had partial improvement with repeat WBRT. Retreatment dose of >20 Gy was associated with a significantly longer survival. Only one patient experienced dementia thought to be caused by radiation.

Repeat WBRT is relatively safe because most patients have limited survival with recurrent or progressive brain metastases after initial WBRT. A minimum of 20 in 1.8 to 2 Gy fractions should be given.

## CONCURRENT RADIOSENSITIZERS

Although most patients ultimately succumb to the systemic progression, a significant percent will die from neurologic progression. Multiple randomized trials (Table 63.7) of concomitant radiosensitizers have been performed in an attempt to optimize brain control.[28–37] Most studies have included various primary histologies, although some series [30–32] only included patients with NSCLC. The results from these three studies do not suggest that patients with multiple brain metastases from NSCLC behave differently from other primaries. Unfortunately, no

trial has demonstrated a survival advantage although a few have demonstrated an increased response rate. The two trials with temozolomide showed promise. Temozolomide is an oral alkylating agent with excellent central nervous system penetration. However, the findings of these two relatively small trials need to be confirmed in a larger trial.

# SYNCHRONOUS, SOLITARY BRAIN METASTASIS FROM NON–SMALL CELL LUNG CANCER

It appears that synchronous, solitary brain metastasis (SSBM) from NSCLC may represent a distinct subgroup of patients that may have a more favorable prognosis compared with other metastatic disease patients. With aggressive brain treatment with SRS or surgery and adequate management of the chest, the 5-year OS for this limited number of patients ranges from 8% to 21%, which is line with stage III patients.[38–41]

Flannery et al.[41] reported a median survival of 18 months for the entire cohort of patients with SSBM from NSCLC. All patients received definitive therapy of SSBM with Gamma Knife SRS. The 1-, 2-, and 5-year actuarial OS rates were 71.3%, 34.1%, and 21%, respectively. For patients who underwent definitive thoracic therapy, the median survival was 26.4 months compared with 13.1 months for those who had nondefinitive therapy, and the 5-year actuarial OS was 34.6% versus 0% ($p < 0.0001$). Median survival was significantly longer for patients with a KPS ≥90 versus KPS <90 (27.8 vs. 13.1 months; $p < 0.0001$). The prognostic factors significant

on multivariate analysis for OS were definitive thoracic therapy ($p = 0.020$) and KPS ($p = 0.001$). A potential problem of this study is that no patient had histologic proof of the SSBM because all patients received SRS. However, these results corroborated findings from an earlier study, in which a 5-year survival of 21% was reported after resection of the SSBM and surgery of the thoracic tumor.[39]

Table 63.8 summarizes the published literature demonstrating the potential for long-term survival in this unique group. Therefore, effort should be made to definitively treat the thoracic disease and SSBM. A common treatment paradigm is to start with a course of WBRT, followed sequentially by definitive thoracic therapy, SRS boost, and adjuvant chemotherapy. Alternatively, upfront SRS or craniotomy can be for the SSBM, followed sequentially by definitive thoracic therapy, WBRT, and adjuvant chemotherapy. However, the exact sequence or mode of local brain (i.e., SRS or craniotomy) or thoracic therapy (i.e., surgery or chemoradiation) must be individualized based on intracranial and thoracic disease burden, as well as presence of symptoms and performance status.

**Leptomeningeal Carcinomatosis**  Leptomeningeal carcinomatosis (LCM) is a rare complication of lung cancer that portends a poor prognosis. Of patients with LCM, the frequency of lung cancer (22% to 36%) is only exceeded by breast cancer (27% to 50%). It occurs in approximately 1% to 6% of patients with lung cancer, and it is most commonly involved by adenocarcinoma (50% to 56%), followed by squamous cell carcinoma (26% to 36%), and small cell carcinoma (SCLC) (13% to 14%).[42–46]

Most patients present with signs and symptoms. According to the review by Gleissner and Chamberlain,[42] spinal symptoms (>60%) are the most common, followed by cerebral (50%) and cranial nerve symptoms (40%). Contrast-enhanced MRI is the radiographic modality of choice. The entire neuraxis must be imaged if LCM is clinically suspected in a patient with a known malignancy. Most patients the MRI will reveal leptomeningeal enhancement that are frequently associated with cranial nerve enhancement and gross tumor deposits. Although Collie et al.[47] found that all 25 patients with solid tumors exhibited abnormal Gadolinium-enhanced MRI, Straathof et al.[48] found the MRI to have a

diagnostic sensitivity and specificity of LCM of 76% and 77%, respectively.

If MRI is equivocal, then cerebrospinal fluid (CSF) should be obtained if safe. Multiple samples may need to be obtained because the initial yield of a lumbar tap may be only 50%.[42] Neurosurgery must be consulted to evaluate the need for (a) shunting if hydrocephalus is suspected, and (b) placement of Rickham or Ommaya reservoirs for possible intrathecal (IT) chemotherapy. Chamberlain et al.,[42,43] argue that CSF flow studies should be performed with indium-111 or technetium-99, because up to one half of patients have abnormal CSF flow from gross tumor deposits that may disrupt adequate IT chemotherapy delivery. However, flow studies are not performed by many centers because gross tumor nodules, most likely to cause flow disruption and not effectively treated by IT chemotherapy, are treated with radiation anyway. Thus, CSF flow studies typically do not change the overall management of patients with LCM who require treatment decisions to be made in an expedient manner.

There is no consensus on the optimal management of patients with LCM. This is mainly from the lack of large published experiences, limited number of randomized trials, nonuniform treatment regimens in single-institution experiences, and inclusion of various primary tumor histologies in the clinical trials. However, most would agree that an aggressive treatment with radiation (either WBRT or focal spinal radiation to symptomatic sites) and IT chemotherapy is indicated in patients with good performance status.[49] In the largest published experience to date on LCM from SCLC (n = 36), the dismal median survival of 1.3 months is a direct result of only 14 patients being offered some kind of therapy (n = 9 for radiation; n = 5 for chemotherapy).[50] In contrast, Chamberlain et al.,[51] in the largest series of patients with LCM from NSCLC (n = 32), treated all patients prospectively with radiotherapy followed by IT chemotherapy. The median survival for the entire cohort was 5 months, whereas patients with normal CSF flow had a significantly longer median survival compared with patients with interrupted CSF flow (6 vs. 4 months; $p < 0.05$). This suggests that an aggressive multimodal approach can extend survival times that are comparable to patients with multiple brain parenchymal metastases.

All of the randomized clinical trials on patients what LCM from solid tumors have included IT methotrexate (MTX)-based regimens (Table 63.9).[52–56] The only trial that compared IT versus non-IT (i.e., systemic) chemotherapy was reported by Boogerd et al.[56] However, this negative trial only included patients with breast primaries. Glantz et al.[54] reported that IT DepoCyt led to a greater median time to neurological progression (8 vs. 4 weeks; $p = 0.007$), although the OS was not statistically different. The only positive trial reported to date has been by Kim et al.[55] in which patients randomized to IT methotrexate, cytosine arabinoside, and hydrocortisone had a significantly longer survival than those randomized to IT methotrexate alone (18.2 vs. 10.4 weeks; $p = 0.029$). Patients with adenocarcinoma of the lung in the multiagent arm had a significant longer survival (23.9 vs. 10.4 weeks; $p = 0.038$). Multiple other agents have been studied, but none have demonstrated significant responses.

There is extensive evidence that focal radiation, such as WBRT or spinal radiation, provides added benefit to IT chemotherapy. This is particularly true in patients with bulky meningeal disease because IT chemotherapy only penetrates 2 to 3 mm. In the randomized IT chemotherapy trial reported by Hitchins et al.,[52] patients who received concurrent CNS radiation had a higher response rate compared with those who did not (73% vs. 35%; $p < 0.05$). Likewise, in the randomized trial reported by Kim et al.,[55] those who received concurrent CNS radiation had a significant higher neurological response rate (81.5% vs. 50.0%; $p = 0.014$). There is a concern that concurrent radiation and IT chemotherapy could potentially increase toxicity. However, most patients do not survive long enough to clinically manifest the late neurological toxicity.

### Causes of Neurocognitive Decline in Brain Tumor Patients

Historically, brain radiation has been frequently cited as the major cause of neurocognitive decline in cancer patients. One of the most misinterpreted studies on this issue is that reported by DeAngelis et al.[12] In this study, an 11% risk of radiation-induced dementia was reported in patients undergoing WBRT for brain metastasis. A thorough analysis revealed that the 11% figure was very misleading. Of the 47 patients who survived 1 year after WBRT, 5 patients (11%) developed severe dementia. When these five patients are examined, all were treated in a fashion that would significantly increase the risk of late radiation toxicity (i.e., large daily fractions and concurrent radiosensitizer). Three patients received 5 and 6 Gy daily fractions, while a fourth patient received 6 Gy fractions with concurrent Adriamycin. Only one patient received what is considered a standard radiation fractionation scheme (i.e., 30 Gy in 10 fractions), but this patient received a concurrent experimental radiosensitizer (lonidamine). No patient

who received the standard 30 Gy in 10 fractions WBRT alone experienced dementia.

The accuracy of the 11% dementia rate is further questioned by faulty statistical interpretation. Even though the study included 232 in the initial analysis, it only examined 47 patients who survived at least 1 year. The principles of conditional probability dictate that the 11% risk is accurate only if a patient survives 1 year, which is significantly longer than most reported series. Therefore, a radiation-induced dementia risk of 2% (5/232) would have been more accurate because this would reflect the true probability ab initio for patients presenting with brain metastasis. Indeed, in a separate study of a larger cohort, DeAngelis et al.[57] estimate the true risk of radiation-induced dementia to be only 1.9% to 5.2% for all patients presenting with brain metastasis. This small risk of dementia is not high enough to warrant withholding potentially lifesaving WBRT.

Many have argued that the increased local control with adjuvant WBRT does not translate into a survival benefit, and that performing repeat SRS or deferring WBRT for recurrences are reasonable approaches. However, WBRT may actually improve neurocognition in a significant number of patients, and that brain recurrence or progression is associated with decrease in neurocognitive function. In a neurocognitive analysis of an RTOG study, Regine et al.[58] demonstrated that approximately one third of patients treated with WBRT experienced improvement in MMSE; most importantly, those who had uncontrolled brain metastases had an average decrement of six points on the MMSE. In the North Central Cancer Treatment Group experience of 701 high-grade glioma patients, Taylor et al.[59] found similar results for those who experienced tumor progression.

Most of the studies that employed MMSE did not utilize sophisticated neurocognitive testing. It is possible that subtle neurocognitive dysfunction may indeed result from WBRT. Recent studies that have used sophisticated neurocognitive testing are clearly demonstrating that the brain tumor (presence, recurrence, and progression) has the greatest effect on neurocognitive decline. In the large phase III motexafin gadolinium study, a thorough neurocognitive battery of tests examined memory recall, memory recognition, memory delayed recalled, verbal fluency, pegboard hand coordinate, and executive function.[60] This neurocognitive correlative analysis study demonstrated that 21% to 65% of patients had impaired functioning at baseline before treatment with WBRT. Furthermore, patients who progressed in the brain after treatment experienced significantly worse scores in all of these individual tests.

There is now sufficient evidence that other factors, such as anticonvulsants, benzodiazepines, opioids, chemotherapy, craniotomy and, most importantly, the brain tumor, contribute significantly to the neurocognitive decline of patients with brain tumor.[61–67]

**Anticonvulsants**   Patients frequently present to the oncologist already started on prophylactic anticonvulsants. This represents one of the most preventable causes of neurocognitive decline in brain tumor patients. Anticonvulsants are clearly

known to impact negatively on quality of life and neurocognition in healthy volunteers.[66,67] This detrimental effect may be even more pronounced in brain tumor patients. In a study of 156 patients with low-grade glioma (85% experiencing a seizure), Klein et al.[63] correlated seizure burden with quality of life and neurocognitive function. This study convincingly demonstrates the significant correlation between the increase in the number anticonvulsants (even with lack of seizures) with the decrease in quality of life and neurocognitive function.

Indeed, based on four negative randomized trials, the American Academy of Neurology recommends that prophylactic anticonvulsants not be initiated in newly diagnosed brain tumor patients who have not experienced a seizure.[68] It is safe to taper a patient off of anticonvulsants provided that the patient has not experienced a seizure.

## SPINAL CORD COMPRESSION

In the United States, more than 20,000 cases of metastatic spinal cord compression (MSCC) are diagnosed annually, and it is estimated to develop in approximately 5% to 14% of all cancer patients.[69,70] MSCC is a devastating complication of cancer. It is considered a true medical emergency, and immediate intervention is required. Even with aggressive therapy, results can often be unsatisfactory. Although most patients with MSCC have limited survival, up to one third will survive beyond 1 year.[71] Therefore, aggressive therapy should always be considered to preserve or improve the quality of life.

**Pathophysiology**   MSCC develops primarily in one of three ways: (a) continued growth and expansion of vertebral bone metastasis into the epidural space; (b) neural foramina extension by a paraspinal mass; and (c) destruction of vertebral cortical bone, causing vertebral body collapse with displacement of bony fragments into the epidural space. Although complex, the most significant damage caused by MSCC appears to be vascular in nature. Epidural tumor extension causes epidural venous plexus compression, which leads to edema of the spinal cord. This increase in vascular permeability and edema cause increased pressure on the small arterioles. Capillary blood flow diminishes as the disease progresses, leading to white matter ischemia. Prolonged ischemia eventually results in white matter infarction and permanent cord damage.[72]

**Clinical Presentation, Diagnosis, and Prognosis**
Most patients have a cancer diagnosis history. Fuller et al.,[73] in a review of over 1000 patients with MSCC, reported in the literature that the most common tumor type was breast cancer (29%), followed by lung cancer (17%), and prostate cancer (14%). This reflects the high natural incidence of these tumors. New-onset back pain in cancer patients needs to be taken seriously and worked up. Even without a prior cancer diagnosis, MSCC should be suspected in anyone who presents with progressively worsening back pain, incontinence, or paraplegia, especially in the high-risk population such as long-time smokers. The most

common level of the MSCC involvement is in the thoracic spine (59% to 78%), followed by lumbar, (16% to 33%) and cervical spine (4% to 15%), whereas multiple levels are involved in up to one half of the patients.[73–75] Back pain is the most common presenting symptom (88% to 96%), followed by weakness (76% to 86%), sensory deficits (51% to 80%), and autonomic dysfunction (40% to 64%).[74,76–78]

MRI is the standard modality for imaging of the spine. It has a very high sensitivity (93%), specificity (97%), and accuracy (95%) in diagnosing MSCC.[79] Because patients can have synchronous, multifocal MSCC, an MRI of the entire spine with and without contrast should be promptly performed in anyone suspected of having MSCC.[80] High-resolution CT scan or CT myelogram of the spine should be performed for those with contraindications to MRI.

Prognostic factors predicting survival are generally similar to patients with brain metastasis as discussed previously. In terms of predicting ambulatory outcome, one of the most important factors is the rapidity of symptom onset. Other important prognostic factors include favorable histology (e.g., multiple myeloma, germ cell tumors, small cell carcinoma) and pretherapy ambulatory function.[81] In a prospective study of 98 patients with MSCC reported by Rades et al.,[82] the single strongest predictor for ambulatory status after therapy on multivariate analysis was time to development of motor deficits before radiation ($p < 0.001$) from the start of any symptoms. This cohort was separated into three groups according to the time to motors deficits before radiation therapy: 1 to 7 days (group A), 8 to 14 days (group B), and >14 days (group C). The ambulatory rates for groups A, B, and C were 35%, 55%, and 86% ($p < 0.001$), respectively. The symptom improvement rates for groups A, B, and C were 10%, 29%, and 86% ($p = 0.026$), respectively. The other significant factor on the multivariate analysis for posttherapy ambulatory status was favorable histology ($p = 0.005$), and there was a trend regarding pretherapy ambulatory status ($p = 0.076$). Acute, rapid deterioration is predictive of irreversible spinal cord infarction. Only 10% of the patients in group A had symptom improvement; therefore, prompt diagnosis and treatment of MSCC is crucial.

**Corticosteroids**  Corticosteroids must be started as soon as possible in anyone suspected of having MSCC even before radiographic diagnosis, because this can be rapidly discontinued with a negative diagnosis. They effectively decrease cord edema, and they serve as an effective bridge to definitive treatment. Although multiple retrospective studies have demonstrated its clinical efficacy, Sorensen et al.[83] reported the only randomized controlled study (n = 57) on the utility of high-dose corticosteroids before definitive radiotherapy in MSCC from solid tumors. The treatment arm consisted of 96 mg of IV bolus of dexamethasone followed by 96 mg oral (PO) per day for 3 days and a 10-day taper versus no therapy. This study demonstrated 3- and 6-month ambulatory rates of 81% versus 63% and 59% versus 33% ($p < 0.05$), respectively, in favor of high-dose dexamethasone.

The optimal maintenance dose of corticosteroids is unknown. Vecht et al.[84] reported the only randomized study (n = 37) comparing corticosteroid doses in patients with MSCC, but this study only evaluated the IV loading dose. It compared IV loading doses of 10 versus 100 mg, followed in both arms by the same oral regimen of 16 mg/day. Both arms demonstrated significant reductions in pain from baseline ($p < 0.001$); however, there was no difference between the two arms with respect to pain reduction, ambulation, or bladder function.

Very high doses of corticosteroids are associated with significant side effects. Sorensen et al.[83] reported in the phase III study an 11% incidence of serious side effects for patients in the treatment arm, whereas Heimdal et al.[85] reported a 14.3% incidence of serious gastrointestinal side effects in 28 consecutive patients treated with 96 mg of IV dexamethasone per day. The toxicities in the study of Heimdal et al. included one fatal ulcer hemorrhage, one rectal bleeding, and two bowel perforations. Subsequently, the dexamethasone dose was decreased to 16 mg/day for the next 38 consecutive patients, and there was no incidence of serious side effects ($p < 0.05$). Most importantly, the ambulatory rates were not different between the two dexamethasone doses.

Based on these data, a loading of 10 mg of IV dexamethasone followed by a maintenance dose of 4 to 6 mg every 6 to 8 hours should be sufficient before being tapered judiciously. Patients can be safely switched to oral steroids after 24 to 48 hours because there is good oral bioavailability of corticosteroids. Furthermore, patients should be started on a proton pump inhibitor for gastrointestinal bleeding prophylaxis. Although here has been no randomized trial utilizing proton pump inhibitors in patients receiving corticosteroids, there have been multiple phase III studies demonstrating the protective effects of these agents against peptic ulcers in patients receiving chronic nonsteroidal anti-inflammatory drugs.[86] Nonsteroidal anti-inflammatory drugs and corticosteroids both cause gastrointestinal mucosal injury by decreasing mucosal protective prostaglandin levels. Therefore, it is not an unreasonable extrapolation to assume that proton pump inhibitors provide a similar mucosal protective effect with corticosteroids, especially considering that the morbidity of gastrointestinal toxicity can be life threatening.

**Radiotherapy**  Palliative radiotherapy has long been the standard of care in the treatment of patients with MSCC. Although a total of 30 Gy in 10 fractions is most frequently employed fractionation schedule, multiple fractionation schemes have been reported, which undoubtedly reflects the heterogeneity in the patient population and tumor histology.[87] In one of the largest studies to date, Rades et al.[88] reported a retrospective series of 1304 patients with MSCC.[8] The patients were separated into five schedules: 8 Gy × 1 in 1 day (n = 261, group 1), 4 Gy × 5 in 1 week (n = 279, group 2), 3 Gy × 10 in 2 weeks (n = 274, group 3), 2.5 Gy × 15 in 3 weeks (n = 233, group 4), and 2 Gy × 20 in 4 weeks (n = 257, group 5). All of the groups had similar posttreatment ambulatory rates (63% to 74%) and motor

function improvements (26% to 31%). However, in-field recurrence rates were much lower for the protracted schedules. The 2-year in-field recurrence rates for groups 1, 2, 3, 4, and 5 were 24%, 26%, 14%, 9%, and 7% ($p$ <0.001). They recommend that a single fraction of 8 Gy should be used in MSCC patients with limited survival expectations, and that 30 Gy in 10 fractions should be used for all other patients.

Although there is no large series of MSCC from small cell lung cancer, Rades et al.[89] have reported the largest series to date of patients with MSCC from NSCLC (n = 252). In this retrospective study, the short-course radiotherapy group (8 Gy × 1, 4 Gy × 5) and the same functional outcome as long-course radiotherapy group (3 Gy × 10, 2.5 Gy × 15, 2 Gy × 20); therefore, 8 Gy × 1 was recommended.

Maranzano et al.[90] have reported the only randomized trial on radiation schedule for patients with MSCC. They compared two hypofractionation schemes, a short course (8 Gy × 1 followed by 6-day break then 8 Gy × 1; 16 Gy total in 1 week) versus a split course (5 Gy × 3 followed by 4-day break and then additional 3 Gy × 5; 30 Gy total in 2 weeks). The study concludes that the treatment with short versus split courses of radiation therapy resulted in similar back pain relief (56% vs. 59%), ambulatory maintenance (68% vs. 71%), and good bladder function (90% vs. 89%) rates. Therefore, they recommend that an 8 Gy × 2 regimen should be used for patients with MSCC. Serious problems inherent to this study have been recognized; therefore, readers should be cautious before implementing the the recommendations by Maranzano et al.[91] Although the response rates may seem impressive, when one limits the definition of response to regaining motor function and sphincter control, the rates of success decrease to 29% and 14%, respectively. Confounding variables included having patients with favorable histology, excellent performance status, and the use of nonstandard, large fraction sizes in both arms. It is entirely conceivable that the 5% who progressed to paraplegia without in-field recurrence may have suffered from late radiation-induced toxicity, even if not scored as late toxicity by the authors.

For patients with MSCC secondary to solid tumors, 30 Gy in 10 fractions is considered the standard of care. Shorter fractionation schedules, such as 8 Gy × 1 or 4 Gy × 5, should only be reserved for those with clear evidence of progressive disease, refractory to systemic therapy. Furthermore, these short schedules should be avoided in newly diagnosed, chemotherapy-naive patients because the clinical course can be quite variable and unpredictable. Chemotherapy may be considered in select, newly diagnosed patients with excellent neurologic status and very chemosensitive tumors (e.g., multiple myeloma, germ cell tumors), but this is still considered outside the accepted standard. If the patient is found to have unresectable/inoperable tumor, and otherwise has good performance status, oligometastatic disease, and controlled primary disease, then consideration should be made to escalate the dose beyond 30 Gy because this will not be sufficient to achieve long-term gross tumor control. Special techniques such as image-guided, intensity-modulated radiation therapy (IGRT/IMRT) or stereotactic body radiation

therapy (SBRT) should be considered. However, the routine use of IMRT or SBRT cannot be universally recommended because the technology is expensive, and it has yet to show definite benefit over conventional delivery of radiation in a patient population that has a median survival of 6 months or less.

**Caution against Short, Hypofractionated Radiotherapy** A common mistake made by those who advocate a short hypofractionated regimen (e.g., 8 Gy × 1, 8 Gy × 2, or 4 Gy × 5) for the spine is equating the safety and equivalency of these abbreviated schedules in bone and lung metastases studies as a justification for the safety of such regimens in MSCC. It is well recognized that the retreatment rates are higher with single fraction schemes versus conventional schedules in bone metastases.[92] The consequence of progression in the bone despite prior radiotherapy (i.e., 8 Gy × 1) is an increase in pain, which leads to an increased need for pain medications and usually reirradiation. By contrast, the consequences of MSCC progression despite prior radiotherapy are an increase in pain, paralysis, and incontinence, which usually contributes significantly to the direct demise of the patient.

The predominant mechanism of cord injury by both MSCC and radiation-induced myelopathy (RIM) is vascular damage leading to ischemia.[93] There are many studies that have established the vascular effects of high fraction dose. Dose response to single dose of SRS for arteriovenous malformation obliteration starts at doses as low as 8 Gy and as soon as 6 months or earlier.[94] It is possible that a compressed cord has a lower threshold for RIM when a short, hypofractionated schedule of radiation therapy is used. This two-hit phenomenon (i.e., physical and radiation-induced vascular insults) is not considered by those who advocate a short, hypofractionated regimen. Chow et al.[95] demonstrated that oncologists are not accurate at all in predicting survival times. As systemic therapy improves for patients with metastatic disease, our ability to predict survival will undoubtedly become less accurate. Therefore, these abbreviated schedules should be routinely avoided unless the patient is chemotherapy refractory, and has convincing evidence of progressive systemic disease with limited expected survival.

**Surgery** Radiation for nonradiosensitive tumors typically takes several days to have an effect and does not stabilize the spine, whereas surgery allows for immediate cord decompression and provides an opportunity to stabilize the spine intraoperatively. For years, surgery was abandoned when several retrospective studies and one, small randomized study showed no benefit to surgery over radiation alone. Young et al.[96] randomized 29 patients with MSCC to decompressive laminectomy followed by radiation versus radiation alone. Although this trial showed no benefit to surgery in terms of pain relief, ambulation, or sphincter function, it is difficult to draw any conclusion because of the small sample size. All of these studies used posterior laminectomy in conjunction with radiotherapy; however, most of the lesions in MSCC involve the anterior portion of the vertebral body.[69] Therefore, a laminectomy

does not effectively relieve the compression and may actually worsen the stability of the spine.

Recently, several authors have advocated the use of direct surgical decompression, tumor debulking, and spinal stabilization via instrumentation to improve on the results from radiation alone. Patchell et al.[97] reported the first phase III randomized trial testing the efficacy of direct decompressive surgery in patients with MSCC. Table 63.10 summarizes the key findings of this study. It compared radiation alone (standard 30 Gy in 10 fractions) versus decompressive and stabilization surgery within 24 hours of diagnosis followed by the same radiotherapy (within 2 weeks of surgery). The trial was terminated early at interim analysis when early stopping rules were met regarding the primary end point of ambulation after treatment. This study definitively demonstrated an advantage to surgery for every end point at statistically significant levels. For nonambulatory patients, the combined treatment patients had a significant higher chance of regaining the ability to walk after therapy. Maintenance of continence, maintenance of American Spinal Cord Injury (ASIA) and Frankel scores

(measures of spinal function after injury), median OS, and median mean daily dexamethasone and morphine equivalent doses all favored the surgery arm.

If operable, patients should undergo surgical decompression and stabilization followed by radiotherapy. Even for radiosensitive tumors, surgery can often stabilize the spine. Therefore, all patients with MSCC should be evaluated by a surgeon. Effective multidisciplinary teamwork is critical to the rapid evaluation and management of patients with MSCC.

## INTRAMEDULLARY SPINAL CORD METASTASIS

Intramedullary spinal cord metastasis (ISCM) is rare, representing only 1% of all intramedullary tumors. According to a review by Kalayci et al.[98] ISCM is more commonly secondary to a lung primary (54%), followed by breast cancer (11%), renal cell carcinoma (9%), and melanoma (8%), in contrast to patients with MSCC. Although back pain is common in

ASIA, American Spinal Injury Association.

>90% of MSCC patients, back or neck pain was seen in only 38% with ISCM. However, high sensory deficits (79%), sphincter dysfunction (60%), and weakness (91%) are more common in ISCM. The most striking difference between ISCM and MSCC is the high incidence of synchronous brain metastasis (41%) in patients presenting with ISCM. This is not surprising when one considers the route of spread and the high incidence of lung primaries in patients with ISCM.[98,99]

The treatment of ISCM should be approached very similarly to MSCC, except for the role of surgery. Most surgeons are reluctant to operate in ISCM because surgery carries a high morbidity rate and most patients have widely metastatic disease at the time of ISCM diagnosis. Indeed, the Kalayci et al.[98] indicated that only 32 cases of surgery in ISCM have ever been reported. An MRI of the brain should be obtained because of the high incidence of synchronous brain metastasis. High-dose corticosteroids as well as radiation therapy should be promptly initiated. With therapy, the expected median survival and neurological improvement rate are 7 months and 66%, respectively.

# Thymoma and Thymic Carcinoma

Thymoma and thymic carcinoma represent the most common malignancies found in the anterior mediastinum. Thymomas can also rarely originate in the thyroid, lung, or pleural spaces, presumably arising from ectopic vestigial remnants of thymic tissue. According to Surveillance, Epidemiologic, and End Results (SEER) data accumulated between 1973 and 1998 from nine states within the United States, the overall incidence of thymoma was of 0.15 cases per 100,000 person-years.[1]

Epithelial disorders of the thymus exhibit a wide spectrum of histologic features and clinical behavior. Thymic hyperplasia displays an invariably benign behavior, whereas thymomas demonstrate variable degrees of local invasiveness and some have distant metastatic potential. At the other extreme are thymic carcinomas, which exhibit cytological features of carcinoma, including nuclear enlargement, pleomorphism, and hyperchromasia. These often present in advanced clinical stages.

## ETIOLOGY AND PATHOGENESIS

The thymus is a spongelike scaffolding of epithelial cells soaked with T lymphocytes. It reaches its maximum development at puberty, weighing approximately 40 g, and undergoes involution and atrophy with aging. The dynamic microenvironment of the thymus contributes to the maturation of T lymphocytes, a process that depends on signals provided by the thymic stroma.[2] Stromal elements include epithelial cells, macrophages, dendritic cells, fibroblasts, and matrix molecules. The topographical separation of the thymus in cortical and medullary portions reflects the functional progression of this maturation process. This is relevant to thymoma, as tumors may show histologic evidence of cortical and medullary differentiation.

Causative factors for the development of thymomas have not been identified, although Epstein-Barr virus (EBV) has been associated with cases of lymphoepithelioma-like thymic carcinoma.[3]

Several immunohistochemical studies have examined the expression of apoptosis-related proteins, such as bcl-2 and p53, in thymomas.[4–6] Bcl-2 expression is notable in medullary or spindle-cell thymoma (World Health Organization [WHO] type A, see discussion that follows). The p53 gene is found to be overexpressed by immunohistochemistry (IHC) in a subset of thymomas, whereas the majority of thymic carcinoma cases are overexpressors of p53.[6,7] However, on polymerase chain reaction (PCR) testing, very few cases have p53 mutations.

Genetic abnormalities, most commonly described as loss of heterozygosity (LOH), are seen throughout all thymoma subtypes. The long arm of chromosome 6 is usually involved, especially region 6q23.3 to 25.3.[8,9] Other consistent abnormalities include chromosomes 3, 5, 7, 8, 13, and 17. These are rarely seen in WHO type A thymomas. Correlation of these findings with the invasive potential of thymomas has been proposed,[10–12] but no definitive link is available to date. Another study has shown an increased incidence of aneuploidy in thymic epithelial tumors with advancing stage.[13]

The expression of two tyrosine kinase receptors, epithelial growth factor receptor (EGFR) and c-KIT ligand, have been examined in a relatively large number of malignant thymic tumors. EGFR and c-KIT appear to be preferentially expressed in thymoma and thymic carcinoma, respectively.[14–17] Although the significance of this observation is unclear, the differential staining pattern of these markers is of potential diagnostic use in distinguishing these tumors.

The maturation process of T lymphocytes frequently becomes abnormal in patients with thymomas.[18,19] Irregularities include impairment of CD4+ T-cell development, decreased interferon-gamma–induced human leukocyte antigen-DR (HLA-DR) expression on cultured thymoma epithelial cells, and lower levels of major histocompatibility complex (MHC) class II antigen expression.[20] Peripheral blood lymphocytosis is commonly observed, with an increased proportion of CD45RA+CD8+ T cells as opposed to an apparent decrease in the CD4 cell population that may reverse after thymectomy.[21]

## PATHOLOGY

Thymoma is a neoplasm arising from thymic epithelial cells. Classification of thymic epithelial tumors has been confused by a plethora of subtyping schemes.[22] (Table 64.1) The difficulty in the histopathologic classification of thymomas is twofold. First, thymomas have a spectrum of appearances, ranging from lymphocyte-rich tumors in which the neoplastic epithelial cells are difficult to discern without the aid of IHC, to lymphoid-deplete tumors that approach the appearance of undifferentiated carcinoma. Second, histologic examination correlates poorly with clinical behavior.

A standard classification, based on the relative proportions of epithelial cells and lymphocytes, subdivided thymomas into predominately lymphocytic, epithelial, mixed, and spindle-cell types.[23] Although simple in concept and reproducible in

application, this scheme lacked the clinical relevance and ontogenetic considerations that the later schemes attempted to provide. Levine and Rosai[24] divided thymic epithelial tumors into thymoma, noninvasive and invasive types, and thymic carcinoma, the latter discernible by its frankly malignant cytology. Marino and Müller-Hermelink (MM-H)[25] stressed ontogenic considerations and subtyped thymomas according to the appearance of the neoplastic epithelial cells (i.e., cortical vs. medullary types). Additional descriptions of well-differentiated thymic carcinoma followed, which suggested a spectrum of tumors ranging from thymoma to unequivocal carcinoma.[26] Suster and Moran,[27] in an effort at simplication, proposed the distinction of thymic neoplasms based on the degree of differentiation: thymoma (well-differentiated type), atypical thymomas (moderately differentiated type), and thymic carcinomas (poorly differentiated type).[27]

The most recent classification, from the WHO Committee for the Classification of Thymic Epithelial Tumors,[28] incorporates features from both the traditional and MM-H classifications. It is the classification that is currently advocated in an effort to standardize thymoma classification. The WHO scheme divides thymoma into types A, B, and C, as well as mixed forms (i.e., type AB). Type A represents spindle-cell or medullary thymoma, an indolent tumor with little propensity for aggressive behavior. Type B is further subdivided into types B-1, B-2, B-3. Type B-1 tumors are lymphocyte rich and may resemble the normal thymus, with areas of medullary differentiation. In type B-2 tumors, neoplastic epithelial cells are more numerous with larger nuclei and more prominent nuclei. Type B-3 tumors have a predominance of epithelial cells and include tumors that previous authors have called well-differentiated thymic carcinoma and atypical thymoma. These tumors lack the cytologic atypia that warrants a diagnosis of thymic carcinoma. Type C thymoma represents thymic carcinoma; various cell types are encountered, with lymphoepithelioma-like carcinoma being the most common. These are high-grade tumors that are histologically reminiscent of their namesake, lymphoepithelial carcinoma of the nasopharynx. Other cell types include squamous cell carcinoma, small cell or neuroendocrine carcinoma, anaplastic or undifferentiated carcinoma, sarcomatoid carcinoma, adenosquamous carcinoma, and clear cell carcinoma. Although most carcinomas are high-grade malignancies, a few low-grade variants carry a more favorable prognosis and include well-differentiated squamous carcinoma, low-grade mucoepidermoid carcinoma, and basaloid carcinoma. Thus, grading thymic carcinomas into low- and high-grade types is of prognostic utility.[26] The WHO classification has come into criticism.[29,30]

Because the histology of thymic carcinomas is "non-organotypic" (i.e., their appearance provides no recognition of their origin from the thymus), it may be difficult to unequivocally assign the organ of origin when evaluating tumors involving the region of the thymus.[31–36] No immunohistochemical profile is unique to thymic carcinoma, although CD5 expression is reportedly increased.[33,35] The specificity of CD5 for thymic carcinoma relative to other differential diagnostic considerations is unclear and in our experience, CD5

staining is too inconsistent to be of clinical utility. Especially when pathology reveals squamous cell carcinoma, small cell carcinoma, and clear cell carcinoma, another primary malignancy should be excluded before the definitive diagnosis of thymic carcinoma.[37]

Nonepithelial tumors arising in the thymus are not considered in the tumor classifications mentioned previously, including thymic carcinoid tumors, germ cell tumors, hematopoietic malignancies, sarcomas, and benign mesenchymal neoplasms. Thymic carcinoid tumors are much more pernicious than their pulmonary counterparts and have been linked to multiple endocrine neoplasia in up to a quarter of the cases.[38]

## CLINICAL FEATURES

**Presentation**    In a recent SEER database study, the mean age at presentation of thymomas and thymic carcinomas was reported as 56 years, with the incidence increasing up to the age of 77, when it neared 0.5 cases per 100,000.[1] Eleven percent of cases occurred prior to 35 years of age. The incidence was slightly higher in men compared to women (0.16 vs. 0.13 per 100,000) and in blacks compared to whites (0.20 vs. 0.12 per 100,000).

The thymus is located adjacent to the pericardium and the great vessels of the chest and is limited by the neck superiorly. Thymomas encompass 20% of all mediastinal masses and 45% of anterior mediastinal tumors. Nonmalignant masses in the anterior mediastinum to be considered in the differential diagnosis include aneurysms, granulomas, pericardial and esophageal cysts, and Morgagni hernias. Other malignant masses of the anterior mediastinum include lymphoma (20%), parathyroid and thyroid tumors (15%), germ cell tumors (15%), and neurogenic and mesenchymal neoplasms.

Thymomas often present as a mediastinal mass, which may cause local symptoms (chest pains, dyspnea, hemoptysis, dysphonia, Horner syndrome, and superior vena cava compression). Alternatively, in approximately one third of patients may present with a paraneoplastic syndrome, such as myasthenia gravis (MG) or pure red cell aplasia (PRCA). Finally, one third of patients may present with a mediastinal mass incidentally discovered on radiographic imaging.

**Paraneoplastic Syndromes**    Approximately 40% of thymoma patients have a paraneoplastic syndrome (Table 64.2), and there is a lower incidence among thymic carcinoma cases. The precise correlation of paraneoplastic phenomena with deranged intratumoral T-cell maturation has not been established.

MG is the most common paraneoplastic syndrome.[39,40] The acetylcholine receptor (AChR) is transiently found on the surface of myoid cells in the thymus in patients with thymic hyperplasia, and is considered to be the stimulus for autoimmunity and generation of anti-AChR antibodies that lead to MG.[41] Interestingly, in thymoma specimens, myoid cells were not detected, although cytoplasmic AChR epitopes were seen.[42] Expression of the AChR P3A$^-$ $\alpha$-subunit gene also

| Sjögren syndrome | |

correlated with MG in patients with thymoma.[43] Ströbel et al.[44] demonstrated a higher production of intratumorous naive CD4+ T cells in thymoma patients with MG compared to thymoma without MG.

Thymoma is believed to be present in 10% of established MG cases, whereas 30% to 50% of patients with thymoma eventually develop clinical MG. Of note, MG is rarely associated with thymic carcinoma or WHO subtypes A or AB. In the study of Okumura et al.,[45] which excluded thymic carcinoma cases, 69% of MG cases had thymomas of B subtype (Table 64.3), and 80% were of B subtype in the series of Evoli et al.[46] Some studies suggest that HLA A24 and B8 are predictive for the presence of thymoma in patients with MG.[47]

Anti-titin antibodies represent one type of antiskeletal muscle antibodies that is frequently present in patients with thymoma or late-onset MG. One study revealed a sensitivity of 68% for presence of thymoma in newly diagnosed MG patients.[48] However, anti-titin antibodies have not been found to be helpful in predicting thymoma recurrences.[49]

Acquired PRCA occurs in approximately 5% of patients with thymoma,[50] and approximately 10% of patients with this syndrome harbor a thymoma.[51] PRCA is suspected in the presence of isolated anemia and a low reticulocyte count and is confirmed with a bone marrow examination. Alternative diagnoses such as myelodysplastic syndromes, underlying chronic lymphocytic leukemia, and parvovirus (erythrovirus) B19 infection need to be entertained. The etiology of PRCA in the setting of a thymoma has not been definitely established, although mouse and in vitro studies suggested the presence of a possible erythropoiesis inhibitor.[52] A T cell-mediated process has also been proposed.[53–55]

Hypogammaglobulinemia (Good syndrome) also occurs in patients with thymic epithelial malignancies[56,57] and is frequently associated with recurrent sinopulmonary infections. Good syndrome leads to severe manifestations in less than 5% of cases. Cytomegalovirus infections (colitis, retinitis) have been reported.[58] Masci et al.[59] demonstrated the presence of an oligoclonal population of CD8+ T cells in the bone marrow of five patients with thymoma-associated hypogammaglobulinemia. Lymphopenia has also been reported[56] and frequently coexists with hypogammaglobulinemia.

Second neoplasms were found to occur with increased incidence (up to 28%) in patients who had a history of thymoma according to several reports.[1,60,61] The most common was colorectal, and reasons for this association are largely unknown. The recent SEER review, however, could not definitely establish an increased incidence of malignancies other than B-cell non-Hodgkin lymphomas (4.7-fold increased incidence, persisting up to 10 years after thymoma diagnosis) and soft tissue sarcomas.[1]

**Diagnostic Evaluation**   The diagnosis of thymomas is established by a core needle biopsy computed tomography (CT) guidance, mediastinoscopy with biopsy, or open or video-assisted thoracotomy. Fine needle aspiration (FNA) may reveal the diagnosis in a subset of cases,[62] but are error prone in 5% to 10% of cases (usually confused with lymphoma).[63] There is a possibility that only lymphoid material, rather than epithelial cells, will be present.[64] Flow cytometry and T-cell receptor rearrangement studies[65] may be helpful in assessing the possibility of lymphocyte clonality. FNA also does not allow assessment of capsular invasion. In ancillary testing, a careful and often history-directed immunohistochemical panel (see previous discussion under "Pathology") can assist in the differentiation between lymphoid neoplasms, non–small cell lung cancer (thyroid transcription factor-1 [TTF-1] positive in approximately 60% to 70% of cases), thyroid, and germ cell tumors. Given the fact that thymomas are relatively uncommon, and that alternative diagnoses carry important treatment implications (such as germ-cell tumor, lung cancer, or lymphoma), pathology specimens are best reviewed by individuals and at institutions with experience in the evaluation of mediastinal neoplasms.

Especially when the mediastinal mass is described as a poorly differentiated malignancy, it is important to confirm and be sure of the diagnosis. Aspects of importance in the history include the age and gender of the patient, the amount of tobacco exposure, and a careful search for paraneoplastic syndromes. In the physical exam, a thorough lymph node exam should be performed, especially when it is not clear if the mediastinal mass is originating from the anterior or posterior mediastinum. Thymomas and germ cell tumors generally may present with or supraclavicular adenopathy; bilateral or peripheral lymphadenopathy should lead one to suspect lymphoma. In patients with undiagnosed masses or poorly differentiated malignancies, serum $\alpha$-fetoprotein (AFP) and human chorionic gonadotropin (HCG) levels should be obtained. Imaging studies can be helpful when showing pleural-based metastases that are typical of thymic malignancies. Lastly, chromosomal evaluation with the presence of isochromosome 12p with fluorescence in-situ hybridization (FISH) would lead to a diagnosis of germ cell tumors.

When there is a high clinical suspicion for thymoma, based on an encapsulated mediastinal mass on chest CT scans, no evidence of metastases and normal serum AFP and HCG levels, then definitive resection can be planned without biopsies being obtained. The direct surgical procedure without a previous biopsy avoids the concern of tumor seeding, which has been raised by some authors.

The pattern of spread may be helpful in distinguishing from other malignancies. Thymomas characteristically spread to pleural surfaces. Although uncommon, liver, bone, kidney, and brain metastases may also occur. In the face of metastatic pleural implants on CT scans, representative percutaneous ultrasound or CT-guided core biopsies can be obtained to establish the diagnosis.

Thymomas often express somatostatin receptors. Although indium-labeled octreotide scans lack diagnostic specificity, they are frequently positive in thymomas[66–68] and are helpful when considering treatment with octreotide. Indium-labeled octreotide can be helpful in distinguishing a thymoma from thymic hyperplasia.

Kubota et al.[69] examined the role of positron emission tomography (PET) scans in 22 patients with anterior mediastinal masses. It was found that both noninvasive thymomas

and invasive thymomas can demonstrate increased uptake, although the invasive subtypes and thymic carcinomas appeared to have higher standard uptake values (SUV). Another study did not find significant differences in $^{18}$F-fluorodeoxyglucose PET uptake between patients with invasive and noninvasive thymomas.[70] The use of PET scans in the evaluation and management of thymomas remains investigational at this time.

**Staging**    In 1981, Masaoka et al.[71] published a clinical staging system based on the degree of invasion of thymomas (Table 64.4). This classification has been validated and established 5-year overall survivals of 92.6%, 85.7%, 69.6%, and 50% for stages I, II, III, and IV, respectively. These data support the indolent nature of this disease even for many patients with advanced disease. Of note, patients with subtotal

**TABLE 64.4    Staging of Thymomas**

**Masaoka Clinical Stage**

| | |
|---|---|
| Stage I: | Macroscopically completely encapsulated and microscopically no capsular invasion |
| Stage II: | Macroscopic invasion into surrounding fatty tissue or mediastinal pleura, or microscopic invasion into capsule |
| Stage III: | Macroscopic invasion into neighboring organs (i.e., pericardium, great vessels, or lung) |
| Stage IVa: | Pleural or pericardial dissemination |
| Stage IVb: | Lymphogenous or hematogenous metastasis |

**GETT Postoperative Staging System**

| Stage | Description |
|---|---|
| I-A | Encapsulated tumor, totally resected |
| I-B | Macroscopically encapsulated tumor, totally resected, but the surgeon suspects mediastinal adhesions and potential capsular invasion |
| II | Invasive tumor, totally resected |
| III-A | Invasive tumor, subtotally resected |
| III-B | Invasive tumor, biopsy only |
| IV-A | Supraclavicular metastasis or distant pleural implant |
| IV-B | Distant metastasis |

**TNM Classification and Staging**

**T factor:**

T1: Macroscopically completely encapsulated and microscopically no capsular invasion

T2: Macroscopically adhesion or invasion into surrounding fatty tissue or mediastinal pleura, or microscopic invasion into capsule

T3: Invasion into neighboring organs, such as pericardium, great vessels, and lung

T4: Pleural or pericardial dissemination

**N factor:**

N0: No lymph node metastasis

N1: Metastasis to anterior mediastinal lymph nodes

N2: Metastasis to intrathoracic lymph nodes except anterior mediastinal lymph nodes

N3: Metastasis to extrathoracic lymph nodes

**M factor:**

M0: No hematogenous metastasis

M1: Hematogenous metastasis

**Stage:**

| | | | |
|---|---|---|---|
| Stage I | T1 | N0 | M0 |
| Stage II | T2 | N0 | M0 |
| Stage III | T3 | N0 | M0 |
| Stage IVa | T4 | N0 | M0 |
| Stage IVb | Any T | N1,2,3 | M0 |
| | Any T | Any N | M1 |

resections received radiation therapy (RT) postoperatively in that series.

Another system, from the French Groupe d'Etudes des Tumeurs Thymiques (GETT), was proposed in 1991,[72] and is based on pathological postoperative staging (Table 64.4). Although generally felt to be equivalent to the Masaoka stage in terms of prognosis,[73] the GETT system (when compared with Masaoka) downstages invasion into neighboring organs, if complete resection was achieved. Additionally, in the Masaoka classification, microscopic invasion through the capsule was found to have prognostic significance. Microscopic invasion is not taken into account in the GETT classification. These slight differences have some implication regarding prognosis. For instance, Masaoka stage II-GETT stage I patients tend to have a better disease-free survival than the Masaoka stage II-GETT stage II patients. The current TNM staging greatly reflects the original Masaoka system[74] (Table 64.4).

One study evaluated the correlation of computer tomography with the ability to predict capsular invasion.[75] Invasive thymomas were more likely to have lobulated or irregular contours than noninvasive thymomas, as well as a higher prevalence of low attenuation areas and foci of calcification within the tumor than noninvasive thymomas. However, the findings are unlikely to be of enough specificity to substitute for pathological staging during thymectomy.

## PROGNOSTIC FACTORS

Interpretation of the current literature regarding the factors affecting individual prognosis in thymic malignancies is difficult. Studies that investigate prognostic determinants have been hindered by the use of different histologic classifications and by their retrospective nature, which potentially introduces selection biases into results. Furthermore, treatment differences among series, including the extent and expertise of the surgical resection, further confound prognostic associations.

**FIGURE 64.1** Thymoma-specific survival according to WHO classification.

Nonetheless, three factors consistently emerge to shape prognosis: stage of disease, completeness of resection, and tumor histology.[75–77] Histological classifications were found to be independent predictors of survival or relapse in some studies[45,78–80] (Fig. 64.1) Close correlation is seen between the pathological classifications of MM-H[81,82] and WHO[45] and the Masaoka clinical staging system (Table 64.5). The prognostic significance of tumor histology seemed to be greater with low stage disease in another study.[83] Medullary or spindle-cell thymomas (WHO type A) typically present as low-stage tumors and carry the most favorable prognosis. High-stage tumors are more likely to be cortical-type thymomas (WHO type B) or thymic carcinoma (WHO type C).[84]

Other poor prognostic indicators include recurrence, unresectable tumor (Fig. 64.2), symptoms at presentation, and invasion of great vessels, which, however, was not an independent factor for thymoma-related mortality[85] (Fig. 64.3). Some data suggests that molecular markers such as high p53, low p27, and low p21 expressions may be associated with adverse outcomes.[86]

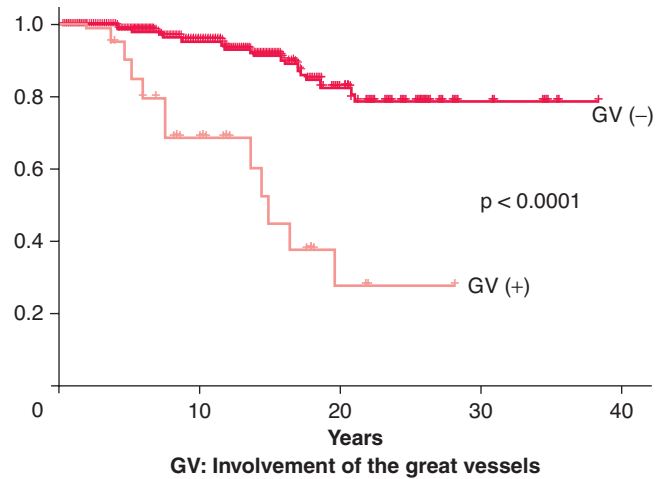
**FIGURE 64.2**  Thymoma-specific survival according to completeness of resection.

**FIGURE 64.3**  Thymoma-specific survival according to involvement of great vessels.

The significance of staging becomes less clear with thymic carcinoma, which carries a poor long-term outcome. In one study, 65% of patients were alive at 5 years and only innominate vessel invasion was an independent prognostic factor.[87] Other authors have associated improved survival with encapsulated tumors, a lobular growth pattern, low mitotic activity, and low histologic grade.[88]

In most recent series, MG has not been associated with overall survival differences.[87,89] These data refute early reports that indicated an increased risk of surgery in these patients. Maggi et al.[90] analyzed the outcome of 662 patients who underwent thymectomies for MG in Italy prior to 1989. The postoperative mortality was 4.9% in patients with MG and concurrent thymomas. With current MG preoperative and perioperative management, this risk appears to have decreased; indeed, a few series have associated the presence of MG with improved overall survival, possibly because of an earlier diagnosis of the thymoma.[80,92] Evoli et al.[46] retrospectively evaluated 207 patients with MG and thymoma who underwent thymectomies. One hundred and fifteen patients had invasive thymomas at surgery. Eighteen patients (15%) with invasive disease experienced recurrences.

## TREATMENT

**Clinically Localized Disease**  Surgical resection is the recommended treatment for early stage thymic epithelial malignancies, as determined after a clinical and radiographic assessment (e.g., a CT scan of the chest with intravascular contrast).[91–94] Those patients with complete resection fare better than similarly staged patients with incomplete disease.[95] Resection of pericardial surfaces or parietal pleural surfaces as well as lung tissue is often required, especially in stages II and III. Although phrenic nerve involvement may have an adverse effect on postoperative pulmonary function, as a solitary


finding, it is not a contraindication for surgery. Less commonly, surgical extirpation may require removal of great veins such as the innominate or superior vena cava (see "locally advanced thymomas" section). The completeness of the surgical resection is considered one of the main prognostic determinants of survival. If an intraoperative determination is made that complete resection is impossible, debulking may have some value based on retrospective data (see discussion that follows),[73] although in recent years, the tendency has been to employ neoadjuvant chemotherapy to facilitate a subsequent complete resection.

Several surgical approaches to accomplish a thymectomy have been described,[96–101] including minimally invasive techniques, but long-term results related to thymoma rates of recurrence are still not available. Complete removal of thymic tissue is typically recommended in MG cases, whereas encapsulated thymomas may need a smaller exploration of the mediastinal contents. Masaoka initially described three approaches for thymectomy: transsternal simple, transcervical simple, and extended thymectomy.[96] Chen et al.[97] advocated thymectomy by anterosuperior cervicomediastinal exenteration. A reversed-T upper mini-sternotomy was proposed by Grandjean et al.[98] with an extended thymectomy for complete removal of thymic tissue, reporting good cosmetic results. Icard et al.[99] published on resection of anterior mediastinal tumors through a mini-sternotomy, and Kaiser[100] used video-assisted techniques in several patients with encapsulated thymoma, especially when combined with a transcervical approach to achieve total thymectomy. Although the results of minimally invasive surgical approaches are being explored, most would consider a complete sternotomy approach standard to accomplish wide mediastinal dissection including total thymectomy in the surgical treatment of thymoma. Finally, Takeo et al.[101] used a sternum-elevating method that provides a wide field of vision between the sternum and the heart and recommended this technique for mostly low-stage thymomas.

Re-resections for isolated recurrences were shown to be feasible.[102] Regnard et al. reviewed their experience in

28 patients with recurrences confined to the thorax. Nineteen patients were able to have complete re-resections, and only three had a subsequent recurrence. The overall 10-year actuarial survival was 43%. However, because many thymomas have an indolent natural history, the impact of re-resections on survival is uncertain.

Radiographic evidence of a recurrent mediastinal density is not always a synonym of recurrent thymoma. In young adults, hyperplasia of benign thymic tissue may be seen after an incomplete resection of the thymus, or especially after chemotherapy for germ cell tumors and lymphomas.

## Adjuvant Radiation Therapy after Surgery

**Thymoma** The evidence for benefit of adjuvant RT in the postoperative setting is retrospective and based on several series from different institutions.[73,76,95,103–116] These series included patients with variable Masaoka stages, variable degrees of completeness of the surgical resection, as well as different radiation fields and doses.[117]

In general, there appears to be no role for RT for completely resected stage I thymomas (absence of microscopic invasion). In several series, the long-term relapse-free survival for stage I patients who did not receive RT is close to 100%.[118] Nevertheless, a 20% recurrence rate has been described for stage I patients with peritumoral adherences found at surgery,[118] whereas patients who received RT in this situation had no recurrences.[73,118,119] The importance of this finding, and the exact definition of peritumoral adherences across different institutions, remains unclear.

Approximately 30% of patients with Masaoka stages II and III who undergo complete surgical resection alone will recur. The use of adjuvant RT in this scenario remains controversial. Adjuvant RT proponents make note of retrospective series in which mediastinal recurrence rates appear to be lower with adjuvant radiation. For instance, in the series of Curran Jr. et al.,[105] there was a 5% recurrence rate in irradiated patients in comparison to 28% without radiotherapy. Alternatively, in a series of 49 completely resected stage II patients from Massachusetts General Hospital, 14 of whom received adjuvant RT, there were no cases of local or distant recurrences in 10 years with or without RT.[120]

Other studies also support the concept that postoperative radiation may not have an impact on completely resected, margin-negative disease. In one of the largest retrospective series reported to date, the outcomes of 1320 patients treated in Japan were evaluated.[95] Adjuvant RT was found not to be of value in preventing local recurrences in patients with completely resected stage II and III thymomas, and the prognosis of completely resected patients receiving adjuvant radiation was not improved compared to no adjuvant RT. However, the latter group was composed of very few patients, because most received adjuvant radiation in this series. Similarly, Singhal et al.[121] found no advantage for postoperative radiation in 40 patients with completely resected stage II thymomas, of which 20 received RT.

The chance of recurrence increases with stage, even for completely resected patients. Ogawa et al.[103] described a 10% overall recurrence rate for stage II patients who received RT, and 44% for similarly treated stage III patients. Haniuda et al.[106] noted an 18.8% recurrence rate in stage II irradiated patients, and a 25% recurrence rate for stage III patients with prior radiation. The majority of recurrences occurred in patients with evidence of microscopic invasion of the mediastinal pleura or pericardium. However, most of these recurrences occurred in the pleura and outside the radiation field. In patients receiving postoperative RT with a mediastinal field with boost, the prognostic value of pathological pleural invasion at surgery in predicting future pleural relapses was also noted.[122]

Most patients in these older series were treated with less sophisticated radiotherapy simulation techniques than available today, and prior to the availability of high-resolution CT scans. This might have resulted in clinical understaging, with more advanced disease patients being referred to surgery, compared to today. In the absence of definitive data, the decision regarding adjuvant RT is made individually based on clinical stage, histological aggressiveness of the primary tumor, and the ability to tolerate RT-related potential complications, such as pulmonary fibrosis.

Different fields have been recommended including whole mediastinum or involved field.[103] Most commonly adjuvant RT fields consist of the entire mediastinum and part of adjacent lung as delineated by surgical clips, or alternatively, based on the preoperative CT scan. One of the major risk factors for radiation-induced pneumonitis appears to be the volume of normal lung encompassed by the 20-Gy isodose line. In an effort to minimize this risk, dose–volume histograms should be created and fields should be selected to achieve the lowest volume of lung in the high-dose regions. Generally, doses of 45 to 50 Gy in 1.8 to 2.0 Gy fractions are used, although no prospective dose-finding studies have been done. Doses greater than 60 Gy did not result in improvements in local control.[123] Lastly, prophylactic pleural and pulmonary adjuvant RT has been deemed feasible in one series but is not widely employed.[124]

**Thymic Carcinoma** Most patients with thymic carcinomas have locally advanced disease at presentation. In one series, the experience of surgery followed by radiation was reviewed specifically in patients with thymic carcinomas.[125] Seventy-five percent of patients who had a complete resection remained alive with follow-up times ranging from 44 to 193 months. The role of combined modality therapy in such patients lacks sufficient prospective data at this time.[126–128]

**Radiotherapy following Incomplete Resections** Patients with incomplete resections or positive margins are generally recommended to undergo adjuvant radiation for disease control. Some series report that the outcome of patients with incomplete resections who receive RT can be similar to completely resected patients.[76] Curran Jr. et al.[105] noted a relapse-free survival of 21% following incomplete resections, and at least three series showed no significant outcome differences between subtotal resection and biopsy only.[104,105,129]

However, several adjuvant radiation studies note a worse long-term outcome for patients who have a biopsy only, compared to debulking surgery.[73,95,125] Mornex et al.[111] reported a series of 90 patients with stages III or IV thymomas who underwent surgery with incomplete resections: 31 had subtotal resections and 55 had biopsy only. This was followed by radiotherapy (median dose 50 Gy), including chemotherapy in 59 patients. Sixty-six percent of patients were free of disease after a median follow-up of 8.5 years. These authors also performed a multivariate analysis[73] in 149 patients who had thymectomies and inferior overall survival was related to the presence of mediastinal compression at diagnosis, absence of chemotherapy, biopsy only as the surgical procedure, and young age.

The aforementioned series include patients treated over the last 2 decades. At present, as a result of improved preoperative imaging and the use of neoadjuvant chemotherapy in locally advanced cases, the role of upfront surgical debulking followed by radiation has diminished.

**Locally Advanced Thymomas**    The term "locally advanced disease" is variably defined in thymomas. For purposes of treatment, when the tumor appears to be unresectable after a thoracic surgeon's evaluation, or resectable only at the cost of great morbidity (extensive resections of lung tissue, great vessel involvement requiring vascular grafts, or need for large pericardial resections), then a combined modality approach with the use of neoadjuvant chemotherapy should be considered. Selected centers have experience with resections of great vessels and superior vena cava and reconstruction in the locally advanced situation.[130–133] Other centers have performed extensive surgical procedures for thymomas involving the pleura, followed by intrapleural chemohyperthermia,[134,135] but this cannot be widely recommended.

An intergroup study utilized cisplatin, doxorubicin, and cyclophosphamide (PAC regimen) followed by definitive RT to the mediastinum (total dose 54 Gy), in patients with limited-stage unresectable thymoma.[136] Out of 23 evaluable patients who had a histologic diagnosis of unresectable thymoma (or thymic carcinoma in 2 patients), 5 complete remissions and 11 partial remissions were seen with chemotherapy (69.6% overall response rate). Five patients had further tumor regression after RT, including four who did not have an objective response to PAC. Median time-to-treatment failure was 93.2 months (range, 1 to 110) with a 5-year overall survival of 52.5%.

The approach of neoadjuvant chemotherapy in locally advanced cases, followed by surgery, depending on the response to chemotherapy, has been well described in the literature. Neoadjuvant ADOC (Adriamycin, cisplatin, vincristine, and cyclophosphamide) was found to have activity in the locally advanced situation.[137] In 16 patients treated in one institution over a 7-year period, an 81% response rate was seen and 9 patients became eventually resectable. Four of these patients survived for more than 5 years. Macchiarini et al.[138] conducted a phase II trial with neoadjuvant cisplatin, epirubicin, and etoposide in seven patients with histologically confirmed stage IIIa

thymomas. Four patients were able to undergo a complete resection and two had pathological complete remissions. Finally, a recent phase II study performed at MD Anderson Cancer Center used a modified PAC plus prednisone regimen in 22 patients.[139] Seventy-seven percent of patients had "major" responses and 21 patients underwent surgical resection. Four patients had greater than 80% tumor necrosis on pathological review. Nineteen patients received RT following surgery. The estimated 7-year overall survival was 79%.

Neoadjuvant radiotherapy is not commonly employed, but might improve the complete surgical resection rate.[114] A retrospective study of 12 patients with invasion of great vessels in the mediastinum used a mean preoperative dose of 18.3 Gy.[140] Complete surgical excision was possible in 9 cases, and 10 cases also received postoperative RT. In another series, it was noted that histologic changes (downgrading or necrosis) were seen in thymoma but not thymic carcinoma.[141]

A retrospective series of 10 patients with stage III and IV patients utilized RT plus cisplatin and etoposide. Four patients had a partial response.[142] Ultimately, complete resection of the tumor is the primary goal of therapy.

**Advanced Disease**    Chemotherapy is commonly employed for patients with metastatic disease, or patients who progress after local therapies, such as surgery or radiation to the mediastinum. Several chemotherapy agents have demonstrated activity in thymic epithelial malignancies[143,144] (Table 64.6).

One of the first prospective phase II studies in previously treated and untreated thymoma used cisplatin 50 mg/m$^2$ every 3 weeks.[145] Two partial remissions were seen in 20 treated patients.

| **TABLE 64.6** | **Chemotherapy Regimens Studied in Advanced Thymomas and Thymic Carcinomas** |
|---|---|
| **Phase II trials** | |
| Cisplatin (single agent) | |
| Ifosfamide (single agent) | |
| Cisplatin, doxorubicin, and cyclophosphamide (PAC) | |
| Cisplatin and etoposide | |
| Cisplatin, etoposide, and ifosfamide (thymoma VIP) | |
| High-dose carboplatin and etoposide | |

| 5-fluorouracil and leucovorin | |
| Prednisone | |
| Capecitabine | |
| **Ongoing trials** | |
| Carboplatin and paclitaxel | |
| Gefitinib | |

The first prospective, intergroup study using combination therapy in previously untreated patients with advanced thymoma or thymic carcinoma evaluated cisplatin 50 mg/m$^2$, doxorubicin 50 mg/m$^2$, and cyclophosphamide 500 mg/m$^2$ every 3 weeks (PAC regimen) for a maximum of eight cycles.[146] An overall response rate of 50% was seen, including 3 of 29 patients with clinical complete remissions.

The European Organization for the Treatment and Research of Cancer (EORTC) performed a trial evaluating etoposide and cisplatin in patients with recurrent or metastatic disease.[147] Sixteen patients were enrolled; five complete and four partial remissions were observed. Ifosfamide as a single agent was also studied in patients with stage III or IV disease at a dose of 1.5 g/m$^2$ daily for 5 days.[148] Out of 15 patients, 5 had complete responses, with the duration of complete response ranging between 25 and 87 months.

To capitalize upon the EORTC observation and the single-agent activity seen with ifosfamide, a subsequent intergroup trial evaluated the use of etoposide 75 mg/m$^2$, ifosfamide 1.2 g/m$^2$, and cisplatin 20 mg/m$^2$ (VIP thymoma regimen), all agents given daily for 4 days every 3 weeks.[149] No complete responses were seen, although 32% of patients had partial responses. The median survival was 31 months, with median response duration of 11.9 months. The 2-year overall survival was 70%.

A phase II study with the carboplatin plus paclitaxel combination conducted by the Eastern Cooperative Oncology Group (ECOG) in previously untreated patients demonstrated an approximate 30% response rate in patients with thymoma (n = 25) and thymic carcinoma (n = 21).

In all these trials, the proportion of patients that were reported as having stable disease after chemotherapy is approximately 40%, with a variable follow-up time between 2 and 5 years. Although these results are affected by selection biases typical of phase II studies, they constitute further evidence that thymomas often behave as an indolent disease. Definitive phase III trials are lacking and are difficult to be performed in this rare disease. Retrospective analysis, however, suggests this response rates and progression-free survival are improved with anthracycline-based regimens.

**Thymic Carcinoma**   The efficacy of chemotherapy regimens in patients with thymic carcinoma is difficult to assess, because the number of patients included in the studies described previously was often in the single digits. A regimen consisting of cisplatin, doxorubicin, vincristine, and cyclophosphamide (ADOC) was evaluated retrospectively in patients with thymic carcinoma.[150] In fact, two patients had small cell carcinoma, four had squamous cell carcinoma, and two had undifferentiated carcinoma. The significance of the described response rate of 75% is unclear given the different pathologies. Two of four patients treated with PAC had objective response in the original ECOG series. In the previously mentioned intergroup study using VIP,[149] eight patients had thymic carcinoma, of which two had partial responses. The 2-year overall survival was 50% for thymic carcinoma patients. The largest prospective trial involving thymic carcinoma, as previously mentioned, incorporated paclitaxel and carboplatin. A 24% response rate was seen. In sum, this data suggest a similarly broad range of activity in thymic carcinoma compared to thymoma, but modestly reduced response rates unlike thymoma. Long-term survival for unresectable disease is uncommon.

**Salvage Therapy**   A phase II study with high-dose carboplatin and etoposide followed by peripheral blood stem cell rescue given in a tandem fashion was also performed at Indiana University in patients with relapsed thymoma or thymic carcinoma.[151] Five patients were enrolled, and three remained alive beyond 2 years, but none remained disease free.

Case reports describe occasional activity of infusional 5-fluorouracil and leucovorin.[152] Some patients can have partial responses or stable disease with the use of prednisone.[153] Radiographic responses may be related to suppression of the lymphocytic component of the thymoma without true antineoplastic activity, which can be of value in ameliorating severe local compressive symptoms (such as compression of the superior vena cava) in patients who have failed to respond to chemotherapy.

Because thymomas exhibits high affinity to octreotide by radionuclide scanning, this agent was examined in advanced or recurrent disease in a phase II study.[154] Thirty-six evaluable patients with pathologically proven thymic epithelial malignancies and positive uptake on indium-labeled octreotide scans received octreotide 0.5 mg subcutaneously three times daily for a maximum of 1 year. In patients with stable disease by CT scans, after 8 weeks, prednisone 0.6 mg/kg daily was added. Octreotide alone had a 12.5% response and in the combination phase of the study, an additional 17.5% of patients responded. The exact role of prednisone in this study, as compared to a delayed effect (beyond 8 weeks) of octreotide in this patient population, remains unclear. Another phase II trial using octreotide 1.5 mg daily subcutaneously with prednisone 0.6 mg/kg/day for 3 months followed by 0.2 mg/kg/day maintenance in 16 patients showed a median survival of 15 months with a 31% response rate.[155] Octreotide has also been used in the management of red cell aplasia (see discussion that follows). A phase II study of subcutaneous recombinant interleukin 2 has been performed in patients with relapsed or refractory thymomas. No objective responses were seen.[156] A phase II study is exploring the use of gefitinib in patient's refractory to chemotherapy.

Other trials that have been conducted demonstrated minimal activity to the targeted tyrosine kinase inhibitors, gefitinib[157] and erlotinib (plus bevacizumab).[158] Though a case report for imatinib demonstrated a brief partial response to imatinib in a patient with a thymic carcinoma,[159] none of 10 patients with C-kit and/or platelet-derived growth factor receptor (PDGFR)-positive (by IHC) thymic carcinoma responded to imatinib.[160] Dasatinib produced a partial response in a patient with advanced thymoma.[161] Pemetrexed was

found to have approximately 22% response rate in 27 previously treated patients with thymoma or thymic carcinoma.[162] Palliative radiation is an option in patients who do not experience symptomatic improvement with chemotherapy, and are suffering from chest discomfort, superior vena cava obstruction, or lung atelectasis. Significant responses can be achieved at standard doses of 30 Gy in 300 Gy fractions. RT is also used in the management of bony metastases. Solitary brain metastases can be addressed with excision followed by whole-brain radiation therapy (WBRT), in similar fashion to other malignancies, or with WBRT alone for multiple metastases.

## Management of Paraneoplastic Syndromes

Thymectomy is a frequently utilized procedure in the management of MG, and a thymoma is found in approximately 10% of cases. Transient worsening of MG symptoms after thymectomy has been observed.[46,163] The expectation of MG improvement after thymectomy is higher with thymic hyperplasia than in the presence of a thymoma, even if it is completely resected. A retrospective Italian study evaluated 500 patients with MG without thymoma, who had a 37.9% improvement in the symptoms of MG after thymectomy, whereas 162 MG patients with thymoma who were subjected to the same surgery had a remission rate in MG symptoms of 15.7%, improvement in 60.3%, and unchanged or worse in 3.7%.[91] The remission rate was higher with mild symptoms and when the tumor was encapsulated. Evoli et al.[46] studied 207 patients who had MG and underwent a thymectomy for thymoma. After a median follow-up of 8.25 years, only 17 patients (8%) were asymptomatic and off immunosuppression for MG.

In patients with advanced or metastatic thymoma and MG, management of the latter is generally not different from MG in the absence of a thymic epithelial malignancy, and often involves pyridostigmine and immunosuppression with steroids or azathioprine. For patients with recurrent myasthenic crises and metastatic thymomas, treatment of the underlying thymoma with chemotherapy occasionally improves symptoms of MG, and the presence of a recurrent myasthenic crisis is not always a synonym of progression of the thymoma. Furthermore, the use of chemotherapy agents in patients on chronic immunosuppression needs to be approached with caution because of the risks of infectious complications.

PRCA related to thymomas is usually initially managed with thymectomy, and a return of normal erythropoesis within 4 to 8 weeks was reported in 6 of 17 patients in a retrospective review.[164] However, PRCA may sometimes recur or even appear after the surgical procedure.[50] For nonresponders or nonsurgical candidates, additional options include further treatment of the thymoma with combined modality approaches, immunosuppression or octreotide.[165] Octreotide has rarely been shown to precipitate a flare of autoimmune phenomena with potentially serious complications.[166] Intravenous immunoglobulin can be effective in a few patients.[167] Anecdotal reports using plasmapheresis for PRCA have been described.[168]

**Recommended Algorithm** Summarizing the role of different treatment modalities, our recommendations for localized or locally advanced thymomas are as follows (Fig. 64.4):

- Cases that on initial radiographic assessment appear to be encapsulated, or even locally advanced, should be evaluated by a thoracic surgeon with experience in resection of mediastinal masses. For anterior mediastinal masses that appear encapsulated on CT scans (meaning a high pretest probability of thymoma), immediate resection without need for biopsy can be advocated. When the diagnosis is in doubt (such as adenopathy suggestive of lymphoma) or there is possible metastatic disease, a core biopsy is obtained. Patients with elevated β-hCG and/or AFP strongly support the diagnosis of germ cell cancer. Consideration should be given to biopsy potential metastatic sites before treatment decisions, such as pleural implants on CT scan, which are very suggestive of metastatic disease.
- For localized unresectable or bulky poorly resectable thymomas, our current approach consists of neoadjuvant chemotherapy, usually PAC. If a response is seen after two cycles and there is no prohibitive toxicity, we recommend an additional two cycles to be given. Upon restaging, consideration should be given to resection followed by consideration of postoperative RT. In patients who remain unresectable, immediate RT after chemotherapy is employed.

No prospective studies have evaluated the adequacy of different follow-up protocols for thymoma. For thymomas that have been resected, as intrathoracic recurrence is most common and repeat surgery for isolated areas of recurrence has resulted in long-term cure, we recommend chest CT scans every 3 months for 1 year, every 4 months for the 2nd year of follow-up, every 6 months for 1 year, and then annual chest radiographs, with office visits once a year.

# Malignant Mesothelioma

Malignant mesothelioma (MM) is an aggressive malignant tumor of the pleura and other serosal surfaces, such as the peritoneal and occasionally other serosal surfaces. It was considered a rare disease until 50 years ago, but has increased dramatically in incidence since that time. This increase is caused by the widespread use of asbestos fibers in the postwar industrial period.

We will summarize the main features of the disease and provide an update of recent developments, focusing on new approaches to therapy for this otherwise treatment-resistant problem.

## EPIDEMIOLOGY

In 1960, Wagner et al.[1] reported an association between asbestos and both pleural and peritoneal MM in a South African case series. Since then, many reports supporting the relationship between occupational or environmental exposure to asbestos and the subsequent development of MM have been published.[2,3]

That initial study identified risks from both direct occupational exposure and brief or indirect exposure to asbestos.[4] If asbestos exposure occurs at a young age, then the lifetime risk of development of MM is higher than in someone whose exposure occurs at a later age.

Around 80% of individuals with MM have an identifiable exposure to asbestos. Therefore, in around 20% of cases, there is no obvious exposure to asbestos and examination of the lung mineral fiber content shows that in many of these subjects there is a lower lung fiber burden than seen in subjects with asbestosis.[5] MM may occur after brief and indirect exposure to asbestos. MM patients generally, though, have markedly increased lung fiber burdens when compared with a reference population.

Asbestos fiber dimensions and type play an important role in the development of MM, with longer and thinner asbestos fibers more likely to cause MM than shorter and wider fibers because they can penetrate the lungs (see discussion that follows). The critical fiber dimensions appear to be less than 0.25 mm in diameter and greater than 5 mm in length to produce MM, and, although the risk of developing MM from exposure to chrysotile fibers is lower than that from amphibole fibers, large amounts of chrysotile can cause MM, possibly because of contaminating tremolite fibers.[6] A potential role for SV40 is also described (see discussion that follows).

## PATHOGENESIS

### Mesothelial Tissues

Mesothelial tissues include all those that line the cavities that were derived from the embryonic mesodermal coelomic cavity. The tissue develops as a continuous epithelial layer, which covers the pleura, the pericardium, and the peritoneal cavity. A single layer of mesothelial cells rests on a basement membrane. Their rate of division is slow, but increases in response to inflammatory damage.[7]

### Etiological Agents

#### Asbestos

Asbestos types include *serpentines*, which are short and curved, such as chrysotile; and *amphiboles*, which are long and needlelike, such as crocidolite. Not all of the different forms have had widespread commercial use—in fact, 90% of industrial asbestos is chrysotile. The mining and use of asbestos is now in decline because of the related pulmonary conditions such as pleural plaques, diffuse pleural thickening, asbestos-related pleural effusions, lung cancer, and MM.[8,9]

Mesothelial cells have been shown to be 10 times more sensitive than bronchial epithelial cells to the direct cytotoxic effects of asbestos fibers.[10] The fibers cause iron-catalyzed generation of reactive oxygen metabolites, which can have a direct toxic effect, causing DNA mutations and strand chromosomal breaks[11,12] leading to cellular apoptosis.[13] The end result is malignant transformation.

#### SV40

The double-stranded DNA virus SV40 has been suggested as a possible factor in the development of MM.[14]

Carbone et al.[15] found SV40-like sequences in 60% of frozen MM specimens using polymerase chain reaction (PCR).[16] SV40 is dependent on its host for the enzymes of replication except for the large T antigen (TAG). When the virus infects a cell, the TAG is transcribed from the viral genome. TAG binds to the specific SV40 origin of replication, pulling apart the DNA strand, allowing viral DNA synthesis. In this way, the virus is able to bypass the normal cellular controls on replication, and will even do so in quiescent cells. TAG binds to both p53 and the retinoblastoma protein (pRb), with inactivation of these cell cycle checkpoints.

It is presumed that SV40 was introduced into humans as a result of the Salk polio vaccines used in the 1950s, because up to 30% of vaccines used were contaminated by SV40 as a result of culturing the poliovirus in rhesus monkey kidney cells.

Several other studies have confirmed Carbone's findings, with the proportion of cases ranging from 44% to 86% of MMs tested. Dissenting groups include that of Strickler et al.[17] who examined MM tissue from 50 patients with two separate primer sets and did not detect any SV40 sequences. This group also undertook a retrospective cohort study comparing those people who were likely to have received contaminated polio virus against those who did not and found no increase in the incidence of several cancers, including mesothelioma.[18]

SV40 sequences present in MM tissue samples retain the ability to inactivate both p53[19] and pRb,[20] enabling a tumor to survive and progress. Clearly, SV40 is not essential for the development of MM, because many cases do not express TAG sequences. Further investigations and more accurate molecular and proteomic reagents are required to determine more clearly how SV40 fits into the pathogenesis of MM.

**Other Agents**   Several other possible agents have been proposed to cause MM. These include thoracic radiotherapy, intrapleural thorium dioxide, and other silicates, including erionite and zeolite. The numbers of cases attributed to radiation exposure are very small. A genetic predisposition has also been suggested, but numbers are small and coexposure is difficult to exclude. There is no known association between smoking and MM.[21]

## MOLECULAR LESIONS

A single mesothelial cell likely develops a genetic mutation that enables it to proliferate and overcome negative growth-stimulatory signals. A multistep accumulation of further mutations to cells occurs, producing the hallmarks of malignancy, namely autocrine growth, invasion, and the ability to metastasize.[22] This whole process takes many years. These alterations include oncogene activation or mutation, loss of tumor suppressor genes, and autocrine or paracrine secretion of growth factors. In MM, considerable new information is available regarding candidate factors, but no clear single pathogenic pathway has been found.

**Chromosomal Abnormalities**   Asbestos is known to induce chromosomal mutations. Cytogenic studies have shown many karyotypic changes,[23] and a wide range of complex and heterogeneous chromosomal abnormalities have been described. Chromosomal gains have been found to be as frequent as losses, such as loss of 4, 22, 9p and 3p, and gain of 7, 5, and 20.[24] The mean chromosomal number has also been shown to correlate with survival in patients with MM. Those patients with a normal chromosome number and no clonal abnormalities had the longest survival.[25]

There are some alterations that are of particular interest in terms of pathogenesis. Monosomy 22 correlates with mutations in the neurofibromatosis type 2 (*NF2*) gene.[26] The loss of at least one locus in 1p (nearly all in 1p22) was found in 74% of examined specimens[27]; 42% to 62.5% of MM cases have been found to have loss of heterozygosity of one or more loci on chromosome 3p, the location of a gene for cellular senescence on chromosome 1 and a tumor suppressor gene located on chromosome 3. Polysomy of chromosome 7 is common and is a negative prognostic feature.[28] The loci for the two potentially relevant growth regulators epidermal growth factor receptor (EGFR) and the platelet-derived growth factor A chain (PDGF-A) are both present on this chromosome. Deletions of 9p,[29] the location of the gene for p16ink4 are also common, as are allelic losses in 6q in four discrete locations.

**Oncogenes**   The oncogenes c-*fos* and c-*jun* have been implicated in animal models, with the levels of both c-*fos* and c-*jun* mRNA upregulated when rat pleural mesothelial cells are exposed to asbestos.[30] Wild-type K-Ras was found in all 20 MM cell lines examined.[31] c-Myc immunocytochemical expression is common,[32] but c-*myc* is not amplified in murine MM cell lines.[33]

**Tumor Suppressor Genes**   For a tumor to grow, it is necessary that normal cellular processes for inhibiting growth and for detection of damage be impaired. Tumor suppressor genes do this, so loss of a tumor suppressor gene enables an altered cell to continue through the cell cycle unchecked.[34] Alterations in *p53* have been found in 75% of murine MM cell lines[35] but wild-type p53 was normally expressed in most human MM cell lines[36] and primary tumors.[37]

The retinoblastoma protein pRb prevents progression of a damaged cell into S phase, but its level of expression in human MM cell lines has been shown to be normal.[38]

The product of the *CDKN2* gene, p16ink4, was found to be abnormally expressed in 12 of 12 primary MMs and 15 of 15 MM cell lines.[39] As p16ink4 normally inhibits phosphorylation of pRb, its loss would permit progress through the cell cycle. Deletions of the portion of chromosome 9 containing *CDKN2A*, but not *CDKN2B*, were also found in MM cell lines.[40] P16 has previously been found to be deleted in 85% of MM cell lines but only 22% of primary tumors.[41]

Seventy-two percent of primary MMs have also been found to have codeletions of *p15* and *p16*.[42] P16/CDKNA2 was homozygously deleted in 59 out of 80 human tumors.[43] Patients with intact p16 had a significant survival advantage.[44]

The *NF2* gene was found to be mutated in 41% of MM cell lines examined by Sekido et al.[45] and 53% of cell lines examined by Bianchi et al.,[46] and confirmed to be present in the primary tumor.

The Wilms' tumor gene (*WT1*) is expressed in normal mesothelium. WT1 proteins control the transcription of genes such as those for PDGF-A, insulin-like growth factor (IGF)-II,[47] transforming growth factor (TGF),[48] and the IGF-I receptor (IGF-IR),[49] which have been described as potential autocrine growth factors in MM. No inverse correlation was found between expression of WT1 and IGF-II or PDGF-A.[50] A further study using mutational screening found no significant changes to WT1, and no correlation between WT1 immunostaining and EGFR or IGF-IR levels.[51]

## GLOBAL TRANSCRIPTIONAL PROFILING IN MALIGNANT MESOTHELIOMA

Various global transcription profiling "microarray" strategies have been used in MM with various aims: to understand the genetics and biology of MM, to identify genes that may help diagnosis, for determining prognosis, and to identify potential targets for new therapies.

Studies using human MM patient samples have shown activation of pathways common to the development of many cancer types, including the IGF-1, p38 mitogen-activated protein kinase (MAPK), Wnt/$\beta$-catenin and integrin pathways.[52,53]

Diagnostic strategies for distinguishing MM from lung adenocarcinoma based on gene expression profiling of cytology samples have been described.[54,55]

Some studies have concentrated on finding gene "signatures" that can be used to predict prognostic indicators for MM.[56–59] However, clinical prognostication based on gene expression profiling is not superior to clinical parameters such as age, epithelial histology, lymph node status, and tumor stage.[60]

## IMMUNOBIOLOGY

There is some evidence in MM that specific immune responses are initiated against the tumor during the course of the disease.[60] A lack of tumor-infiltrating lymphocytes (TILs), as with many other tumors, has been attributed either to a lack of tumor antigens or to the secretion of immunosuppressive cytokines.

Recent work has suggested that an immune response is generated in a significant proportion (28%) of MM patients[61] using patient sera and a panel of human MM cell lines as in Western blot analysis. The titre increased with the progression of the disease and the MM-reactive antibodies were of the immunoglobulin G (IgG) class, indicative of immunoglobulin class switching, and hence the involvement, of CD4 "help." This may lead to identification of tumor-associated antigens (TAAs) and potential vaccination strategies.

This malignancy may be susceptible to immunotherapy. Intralesional therapy with granulocyte–macrophage colony-stimulating factor (GM-CSF) induced a partial response with intense lymphocytic infiltration in biopsy samples.[62] Gene therapy involving the use of gene encoding cytokines has provided some encouraging results in animal models, but limited success in patients.[63]

MMs have to secrete several cytokines known to modulate immune responses, including TGF-$\beta$ and interleukin 6 (IL-6).[64,65] The role of these molecules in MM has not been fully investigated in humans.

Human and murine lines all express class I molecules and thus can still be targets for the immune response.

## ANIMAL MODELS

Spontaneous mesotheliomas have not been described in mice and occur very rarely in rats. Natural and synthetic fibers, chemicals, and metals, however, can induce pleural and peritoneal mesotheliomas in rodents.[66] Inoculation of hamsters with SV40 virus causes pleural mesotheliomas.[67] Mouse mesotheliomas are comparable to the human disease with respect to latency, growth patterns, and molecular lesions.[68] These tumors have been used to study the immunobiology of MM[69] and to evaluate chemotherapies, immunotherapies, and other therapies.[70–72]

Genetically modified transgenic mouse mesothelioma models have been developed. These models will be used for testing of drug therapies and study of the biology of the disease. Heterozygous p53 +/− knockout mice have a longer life span, and 76% of these mice had developed asbestos-induced mesothelioma, compared with 32% wild-type mice, at 44 weeks after asbestos exposure.[73]

*Nf2* +/− knockout mice exposed to asbestos develop mesothelioma more rapidly and at a higher incidence than wild-type littermates.[74,75] These tumors recapitulate the most common molecular features of human MM.[76]

A novel transgenic mouse model uses MexTAg, which directs SV40 Tag expression to the mesothelial compartment using the mesothelin promoter.[77] When MexTAg mice are injected with asbestos, all of the animals develop MM and the disease occurs much more rapidly than in wild-type mice. This model is suitable to examine the efficacy of preventative and therapeutic drugs and also to investigate the molecular events occurring at the early stages of MM development.

**Applications to Therapy** Interventions that target factors such as TGF-$\beta$ may be very effective from two aspects: first, by altering the growth cycle and, second, by permitting an immune response to be generated. When TGF-$\beta$ was reduced by inhibiting translation of these proteins using antisense DNA technology, tumor growth was inhibited but not blocked completely—these effects were lost on cessation of treatment. Such approaches are worthy of further investigation—possibly in combination with other treatments.

## PATHOLOGY

There are several reasons for securing the diagnosis early in the course of the disease. Accurate classification is nowadays considered very important because of differences in the (natural) course of disease between MM and other tumors, and even between different subgroups of MM. The response to therapy can significantly influence both the response rate and survival time and will influence the results of single-arm phase II studies. In the last 2 decades, financial reimbursement programs have been initiated in many developed countries. Over and above a history of occupational asbestos exposure, this has also led to a greater demand for a definitive diagnosis.

In general, cytological examination of pleural effusion can accurately diagnose MM but cannot differentiate between mixed forms and epithelial type of MM. However, the accuracy of cytological diagnosis depends on the experience of the pathologist and the antibodies chosen.[78] Fine-needle biopsies are recommended for the diagnosis of MM in some cases but are associated with low sensitivity (around 30%). Despite an increase in incidence of MM, the frequency is still relatively low. Thus, many local pathologists will have relatively little experience with this tumor, which often poses a diagnostic challenge, even to experienced pathologists. This is caused by the combination of highly variable histological features, often only low-grade nuclear changes and the need to identify invasion for definitive diagnosis. The diagnostic material presented to the pathologist is often inadequate, and the inexperienced pathologist may struggle to attempt a diagnosis when the safer option is to ask for better samples.

Such problems in diagnosis have resulted in the foundation of so-called national and international mesothelioma panels. Their task is to optimize the diagnostics of pleural tumors, to give recommendations on further diagnostic requirements, to check reproducibility of tests that require stringent methodological procedures, and to validate newly reported immunohistochemical staining methods regarding sensitivity and specificity for use in routine diagnostic practice. Furthermore,
these panels have been approved as official legal organs in financial reimbursement cases in many countries.

In patients presenting with pleural masses, large or multiple histological biopsies are preferred for diagnostic staining procedures.

MM can be differentiated into four subgroups including the epithelioid subtype ($\pm$ 50% of cases), the biphasic subtype (20% to 25%), the sarcomatoid subtype ($\pm$ 20%) and the desmoplastic subtype (1% to 5%). Older literature has clearly identified that diagnosis of the biphasic subtype is positively correlated with the number of biopsies taken during thoracoscopy or thoracotomy. In many pleural diseases, the mesothelial lining responds with a hyperplastic reaction, which might resemble MM (Fig. 65.1).[79] One of the key features in diagnosing true cases of MM is, therefore, evidence of invasion of the underlying tissue layers (Fig. 65.2).[80] This diagnosis cannot easily be made on small biopsies and cannot be assessed at all on cytology. Indeed, this is why many cytopathologists will not offer a definitive diagnosis; cytological diagnosis of MPM is presumptive at most centers.[81]

The collected material can be stained for many different markers. A combination of both "positive" and "negative" mesothelial markers should be used, taking into account the likely differential diagnosis in each case. To date, in Europe, it is advised that the diagnosis be made when the staining results include at least two positive markers (nuclear markers such as anticalretinin and anti-WT1, the membrane marker anti-epithelial membrane antigen [EMA], and cytoplasmic markers anti-CK5/6, antiD2-40 [podoplanin], antimesothelin) and two negative markers (anti-Ber-EP4, a membrane marker; antithyroid transcription factor-1 (TTF-1), a nuclear marker; monoclonal anti-carcinoembryonic antigen (CEA), anti-B72-3, anti-MOC-31 (antibody against epithelial glycoprotein 2), antiestrogen receptor/-progesterone receptor (ER/PR), anti-EMA–cytoplasmic staining, selections based on likely differential diagnosis) (level of evidence 1A).[82] The positive mesothelial markers

**FIGURE 65.1**    Reactive mesothelium. Superficial biopsy of the parietal pleura. There is no sign of infiltration, and a reactive mesothelial proliferation is the preferred diagnosis. (See color plate.)

**FIGURE 65.2**    Deep biopsy showing invasion indicating MM. Deep biopsy from the parietal pleura in the same patient. Tumor cells show infiltration of the muscular layer and fat. The diagnosis of mesothelioma can now be confirmed. (See color plate.)

stain best in epithelioid tumor and are much less reliable in sarcomatoid tumor. The positive markers support the mesothelial nature of the cells but do NOT indicate their malignancy. The differential diagnosis of MM[83] consists in general of:

- Primary adenocarcinomas of the lung involving the pleura
- Metastatic disease from extrathoracic sites
- Diffuse pleural sarcomas
  - epithelioid hemangioendothelioma
  - synovial sarcoma
  - leiomyosarcoma
- Desmoplastic small round-cell tumor
- Ewing sarcoma
- Solitary fibrous tumors
- Pleural thymoma

## CLINICAL PRESENTATION AND COURSE

Patients with pleural MM classically present with chest pain, dyspnea, cough, weight loss, fatigue, and sometimes fever or night sweats. Symptoms can persist for months or longer prior to diagnosis. Peritoneal MM patients present with increasing abdominal girth, abdominal pain or discomfort, constipation, anorexia, and occasionally an umbilical hernia. The most common presentation for a pericardial MM is death, because most are diagnosed postmortem. Other symptoms of a pericardial MM include dyspnea, fever, night sweats, congestive heart failure, constructive pericarditis, pericardial effusion, pericardial tamponade, and myocardial infarction. Tunica vaginalis MMs usually present with a unilateral testicular mass.

For the patient with pleural MM, the physical exam is often unrevealing except for dullness to percussion, reduced air entry on auscultation, or asymmetric chest excursion. The disease tends to remain localized to the hemithorax until late in its course. The most common sites of metastases are to the mediastinal and hilar lymph nodes, contralateral pleura, lung, and peritoneal cavity. Metastases to liver, bone, and brain, although rare, can occur. Extensive local progression usually results in death, either from respiratory or cardiac failure.

MM is a heterogenous disease with a variable clinical course dependent upon several key prognostic factors. Using multivariate analysis, the Cancer and Leukemia Group B (CALGB) identified pleural involvement, high levels of lactate dehydrogenase, poor performance status, chest pain, thrombocytosis, nonepithelial histology, and age older than 75 years as poor prognostic factors. The CALGB defined six distinct prognostic groups, whose median survival ranged from 1.4 to 13.9 months.[84] The prognostic scoring index developed by the European Organization for Research and Treatment of Cancer (EORTC) determined that poor performance status, probable diagnosis of MM, leukocytosis, male gender, and sarcomatoid subtype are indicators of poor prognosis. The EORTC classified patients into good- or poor-prognostic groups; good-prognosis patients had a 1-year survival of 40%, compared with only 12% for patients in the poor-prognosis group.[85] The EORTC prognostic score has been independently validated.[86] In addition, measures of health-related quality of life (HRQOL), specifically pain and loss of appetite, may be independent prognostic factors in patients with advanced disease.[87]

## IMAGING

The clinical manifestations of MM are usually nonspecific and insidious, but when complaints persist, a chest x-ray is performed to determine the additional diagnostic steps. Besides the presence of a unilateral pleural mass, chest x-rays can detect effusions and pleural plaques with/without calcifications. The presence of calcified plaques on the diaphragm indicates a probable exposure to asbestos in the past. Shrinkage of the afflicted hemithorax is compatible with more advanced cases of MM and can explain complaints of severe pain.

**CT Scanning** *CT scanning* is considered to be the most important method of radiological evaluation. It is not only useful to determine the extent of the disease but can also narrow the differential diagnosis. Signs of liver and adrenal metastases are unusual in MM and are only seen in very advanced cases. The following are other signs that point to the direction of MM:

1. soft tissue masses encasing the diaphragm, including the absence of a fat plane between the inferior surface of the diaphragm and adjacent abdominal organs
2. pleural tumor which may extend into the subcutaneous tissues at the site of a previous biopsy or thoracoscopy after weeks to months
3. the presence of pericardial effusion or nodular pericardial thickening
4. the possible involvement of mediastinal lymph nodes
5. shrinkage of the involved site

The diagnosis cannot be made based on the radiological appearance, nor can it be used alone for reliable staging. CT scanning will show the location and size of pleural and interlobular masses, allowing these lesions to be used as target lesions.

CT scanning is currently the method of choice for evaluation of response measurement in MM treatment and is used for follow-up after (combined modality) therapy. The accuracy of the CT scan to identify tumor-positive mediastinal lymph nodes is limited. Schouwink et al.[88] performed a prospective study where preoperative CT scanning was compared with cervical mediastinoscopy and found a diagnostic accuracy of 67% for CT scanning and 93% for mediastinoscopy.

**MRI Scanning** *MRI scanning* has limited value in the diagnosis and staging of MM. It can be used when transdiaphragmal growth or involvement of major vessels or nerve plexus is suspected. Heelan et al.[89] compared the accuracy of CT with MRI scanning for staging purposes. CT scan accuracy was identical to MRI for the detection of lymph nodes but superior in determining chest wall invasion.

**PET Scanning** Recently, the value of SUV (standard uptake values) in PET scanning has been identified as a new factor for both staging and prognosis purposes and validation studies are underway. Flores et al.[90] investigated the sensitivity of PET scanning in 63 patients with different histology types of MM. He found that PET scanning was positive in all cases, showed a high false-positive rate for detection of mediastinal lymph nodes but identified an occasional, unsuspected, distant metastasis.

Erasmus et al.[91] correlated the staging of PET/CT scanning in 24 patients. In seven cases, there was an understaging and in two cases, over staging of the T stage. For the N status, 35% were understaged and 29% overstaged. Flores et al.[90] correlated the SUV value with survival in 137 patients. He observed an inverse relationship between higher SUV values and survival when a cutoff value of 10 was used.

PET scanning as an evaluation tool was tested by Ceresoli et al.[92] in a group of 20 patients who received two courses of chemotherapy. Responders were defined as having at least a 25% reduction in SUV. In the group of responders (8) the median overall survival was 14 months, whereas in the nonresponding group (12), this was 7 months. The use of PET scanning is considered unreliable when patients have had a (chemical) pleurodesis. The resulting reactive pleuritis will lead to a high-glucose uptake and leads to false-positive PET scan results. This can be positive up to 3 months after the procedure.

It is clear that PET/CT scanning contributes to the diagnosis and response evaluation of MM, but validation studies still have to be performed.

**Biomarkers** Measurement of tumor markers in effusions may provide a complementary tool to aid in effusion diagnosis. Although differential levels of CEA, cancer antigen (CA) 15.3, CA72.4, CA19.9, CA549, neuron-specific enolase, or cytokine fragment 19 (CYFRA 21-1) differentiate malignant from benign effusions,[93,94] there is less data available for the differential diagnosis of MM from other cancers. Elevated CA15-3 levels have been reported in MM[94–96] and in one study as being able to differentiate between MM and bronchial cancer.[96] Higher levels of hyaluronic acid have been reported in effusions from MM patients compared with those with other malignant disease; however, the difference was too small for diagnostic purposes.[97] Mesothelin levels in effusions above 20 nM are highly suggestive of malignancy, particularly of MM; at this cutoff value, the assay had a sensitivity of 77% for nonsarcomatoid MM, and a specificity of 98% relative to nonmalignant effusions and 86% relative to non-MM malignancies (Fig. 65.3).[98] Mesothelin levels in the blood have been shown to be useful in diagnosis plus monitoring disease progress/regression.[98]

Elevated mesothelin levels are seen in some effusions before a definitive cytological and/or histological diagnosis can be made.

## DIAGNOSTIC PROCESS

All patients who present with relevant symptoms should be considered for diagnostic procedures to obtain a diagnosis

**FIGURE 65.3** Elevated mesothelin levels in MM effusions. Mesothelin concentrations in pleural effusions were determined by enzyme-linked immunosorbent assay (ELISA) and individual patient values are plotted on the graph. Effusions were defined as being transudate or exudate in nature and as being benign or resulting as a consequence of malignancy.

without performing unnecessary or expensive tests. After confirmation of the diagnosis, patients can be informed about the treatment options and prognosis and supported with financial reimbursement programs. In general, patients can be divided into two groups: those where only the diagnosis is required and palliation is the primary option versus those where an experimental, multimodality treatment is proposed. The choice will depend on factors of performance of the patient, prognostic factors, comorbidities, and motivation.

A minimal approach should consist of a detailed history, physical examination, general blood examination, and tapping of pleural fluid in case of shortness of breath with cytological examination, plus serum and effusion mesothelin levels.

For patients with bad prognostic signs, this approach is often sufficient for further management. For patients who are in good general condition, and who are considered candidates for chemotherapy, additional examinations must be performed. These include more invasive tests to obtain material for histological diagnosis with immunohistochemistry and subtyping. CT scanning and more extensive lab testing is required for optimal choice of therapy and to evaluate the response to therapy. Imaging studies should be recent (<4 weeks) when invasive procedures are planned. In the event that there are signs of distant metastases, the diagnostic workup should be limited to confirming the M1 status and to avoid further invasive or expensive examinations.

For patients who are considered candidates for experimental therapies such as multimodality treatment, including extrapleural pneumonectomy (EPP), extensive staging procedures are required.

In these cases, the patient must be discussed in a multidisciplinary team meeting, have localized disease, and adequate pulmonary, cardiac, and renal function. Furthermore, a pulmonologist and cardiologist must assess the postpneumonectomy function of heart and lungs.

In the workup, most centers perform a cervical mediastinoscopy to exclude patients with lymph node involvement. Recently, EUS (endoesophageal ultrasound) and EBUS (endobronchial ultrasound) have been introduced in the evaluation of the mediastinum.[99] Most lymph nodes in the mediastinum can now be assessed by these endoscopic means and can replace the cervical mediastinoscopy.[100] In addition, EUS/EBUS can identify direct involvement of the esophagus or trachea by the tumor.

## PROGNOSTIC FACTORS

Prognostic factors are clinical or biological characteristics of a patient or tumor that have an impact on the outcome of the disease, regardless of the choice of treatment. Prognostic factors are used in all kinds of diseases to select patients for certain therapies and to be informed about the course of the disease. They are generally identified by multivariate analysis of outcome in untreated patients and classify patients into prognostic groups and are especially important when noncomparative studies (such as single-arm phase II trials) are performed, and choices for large phase III studies must be made.

To identify prognostic factors for survival in MM, the EORTC analyzed data from patients who were included in their trials.

From large multicenter studies, several prognostic factors have been identified and validated.[101] In the Surveillance, Epidemiology and End Results (SEER) Program, the outcomes for 1475 patients with histologically confirmed MM have been analyzed. The most important prognostic factors identified were age, gender, tumor stage, treatment, and geographic area of residence. Factors such as performance status, stage, and weight loss are generally found in other kinds of tumors and relate to the detrimental effect of a tumor on the general well-being of the host. Other factors such as thrombocyte count, leukocytosis, pathological subtype, and stage have been identified as prognostic factors but have not been confirmed in other studies. Nonepithelioid subtype is consistently associated with a poorer prognosis, even in nonsurgical series. Of the numerous biological factors studied, low hemoglobin level, high LDH, high white blood cell, and high thrombocyte count are generally associated with a poor prognosis. The prognostic factors have led to prognostic scoring systems, which have been prospectively validated: the CALGB and the EORTC prognostic scoring system.[84,85] Based on the results of a large randomized chemotherapy trial, the latter scoring system has been adapted.

## STAGING

Staging should describe the anatomical extent of a tumor to convey information to others without doubt. Staging systems classify tumors according to the extent of the primary tumor (T), lymph node involvement (N), and hematogenous dissemination (M). The most important reason for staging is to select patients who are considered candidates for multimodality therapy, and for the ability to compare studies.[102] Clinicians need a system to guide their clinical decisions. What they would really like is to predict a tumor's biological behavior and group patients accordingly. Unfortunately, the ability to do this is limited.

In MM, there have been at least five different staging systems, all with their limitations.

The first staging system was developed by Butchart et al.[103] and was easy to use. This system gave a general impression of the prognosis of the patient, but failed to properly select patients for the more recently developed multimodality treatments. Staging itself is often based on a surgical procedure and therefore has limitations, especially when applied to an elderly population, with significant comorbidities and limited treatment desires being the most important reasons.

The main drawback of the classification systems was the inaccuracy in describing the T and N extent using the available imaging techniques. Because of this, there was a need for a new robust and uniform clinical staging system that could be prospectively validated, was TNM-based, and included the existing surgical–pathological staging systems accepted by international experts. The International Mesothelioma Interest Group (IMIG), therefore, developed a TNM-based staging system in 1995 based on the lung cancer staging system, which is now used in most studies.[104] Despite this structural approach, there are still questions that need to be answered, and there is a clear need for reevaluation of the staging system in MM.

Some of these questions are related to the site of origin of MM and raise questions about the true location of N1 and N2 stations in this pleural disease. Primary lymph node stations of a pleural disease might be mediastinal (numbers 2, 3, 4, 7, 8, or 9) or intrathoracic instead of intrapulmonary (numbers 10 to 12) according to the anatomic relations. Their relevance for stage grouping and effect on survival therefore remain unclear. In addition, there is no effect of tumor load on T status although anatomic extension is well described. The International Association for the Study of Lung Cancer (IASLC) and IMIG are therefore planning to update this system and to improve its prognostic value.

## TREATMENT

MM is an almost uniformly fatal disease that is not usually curable with surgery, chemotherapy, or radiotherapy. Treatment options are the same as for other malignancies (i.e., surgery, radiotherapy, chemotherapy, immunotherapy, gene therapy, supportive care, or combination therapy) utilizing some or all of the said treatments. However, in MM, it is often difficult to quantify the location and extent of disease. Also, many patients are older and often have underlying illness that makes them unfit for aggressive treatment. Few large prospective clinical trials have been published, and clinicians rely on retrospective clinical trials with small numbers of patients.

In 1988, the *Journal of Clinical Oncology* published an article with a remarkably nihilistic title, "Malignant mesothelioma, a disease unaffected by current therapeutic maneuvers."[105] In a series of 262 patients, there was no difference in survival between patients who received no treatment at all and those who were treated with chemotherapy, radiation, or surgical resection. Fortunately, in the ensuing years, we have made considerable strides in surgical and radiation techniques, and active chemotherapeutic agents have been developed. Such nihilism is no longer justifiable regarding the treatment of MM.

## SURGERY

The role of surgical resection in the management of MM is quite controversial. Although the principal aim of resection is maximal cytoreduction, surgery alone cannot eradicate all residual microscopic disease. No recent published trials compare surgery with other treatments. Some authors therefore conclude that the primary reason for the promising results reported in some surgical series is patient selection.[106] Retrospective data, however, have demonstrated that surgical resection in a multimodality setting is associated with an improved survival.[107]

The optimal surgical procedure, EPP or pleurectomy/decortication (P/D), is also a matter of extensive debate. For many surgeons, the procedure of choice is dependent on the extent of a patient's disease, comorbid medical illnesses, and the subsequent modalities of treatment that are planned.[108]

Pleurectomy with decortication removes the visceral and parietal pleura, leaving the lung in place. Operative mortality, about 1% to 2% at most centers, is low. Some surgeons prefer this approach for early stage patients, to spare the lung and reduce morbidity, whereas others reserve P/D only for those individuals who lack the cardiopulmonary reserve to tolerate a pneumonectomy.[109]

The more extensive EPP is an en bloc resection of the lung, visceral and parietal pleura, pericardium, and hemidiaphragm. It is the only procedure that can be performed when a thick rind obliterates the pleural space. It is also easier, safer, and more effective to perform adjuvant radiation therapy when the lung is no longer in place.[110,111] Early series reported operative mortality rates of up to 30%. Today, in experienced high-volume centers, the operative mortality rate is only about 3%, whereas major and minor complications occur in 60% of patients.[112]

A recent analysis of 663 consecutive patients resected from 1990 to 2006 at three tertiary referral centers reported no statistically significant difference in survival by procedure for any stage.[108] The operative mortality, as expected, was higher for EPP (7%) than for P/D (4%). Five-year overall survival was 12%. Local recurrences predominated in patients who underwent P/D (65%), whereas distant recurrences (66%) were more common in patients treated with EPP. Superior survival was associated with earlier stage, epithelial histology, P/D, multimodality therapy, and female gender in univariate analysis. Controlling for stage, sex, pathologic subtype, and

multimodality therapy, EPP yielded a hazard ratio of 1.4 for survival compared with P/D.[108]

The Mesothelioma and Radical Surgery (MARS) trial in the United Kingdom may help to determine the role of EPP in MM. In this ongoing study, 670 patients are randomized to induction chemotherapy followed by either EPP and adjuvant radiation, or no surgery.[106]

## RADIATION THERAPY

The administration of radiation therapy (RT) for MM is quite challenging because of the large treatment volumes required, the radiation sensitivity of the surrounding organs, and the technical difficulty of treating multiple pleural surfaces.

MM has the potential to seed along the tracts of biopsies, chest tubes, thoracoscopy trocars, and surgical incisions, producing uncomfortable subcutaneous nodules. For many years, adjuvant RT was standard after such instrumentation, based on a 40-patient study in which 21 Gy administered in three fractions decreased local recurrence from 40% to 0%.[113] Subsequent randomized studies have not supported the routine administration of adjuvant radiation in this setting.[114]

Radiation for this disease is principally employed after resection. The use of radiation following P/D is particularly problematic given the significant risk of fibrosis of the underlying lung, in addition to the poor local control achievable at safe doses. In one of the largest retrospective series, 1-year local control was only 42%, and median survival was only 13.5 months among 123 patients who underwent P/D followed by adjuvant external beam RT.[110]

In contrast, high-dose hemithoracic radiation has been shown to significantly decrease the risk of local recurrence following EPP. In a phase II study at Memorial Sloan-Kettering Cancer Center, only 7 of 54 patients who received EPP followed by 54-Gy hemithoracic radiation had any locoregional recurrences. Median survival was 33.8 months for patients with stages I and II disease, but only 10 months for more advanced tumors.[111]

Intensity-modulated radiation therapy (IMRT) can further enhance local control following EPP. In the largest series, from MD Anderson Cancer Center, locoregional recurrences developed in only 13% of the 63 patients who underwent EPP followed by 45-Gy IMRT. It is noteworthy that only 5% of recurrences occurred in the irradiated field.[115] Unfortunately, this approach has been complicated by a substantial risk of toxicity to the contralateral lung, which has resulted in fatal pneumonitis.[116]

## MULTIMODALITY THERAPY

Chemotherapy has been integrated into multimodality treatment studies before, during, and after surgery. In the largest series incorporating adjuvant chemotherapy, from Brigham and Women's Hospital, 183 patients received EPP, radiation,

and adjuvant chemotherapy. Median survival was 19 months, and 5-year survival was 15%. The 31 patients with the best outcome had epithelial histology, no extrapleural lymph node metastases, and negative margins. This subset had a median survival of 51 months, and a 5-year survival of 46%.[117] These investigators have also pioneered the evaluation of hyperthermic intraoperative chemotherapy, an approach that remains experimental.[118]

Neoadjuvant chemotherapy is more commonly used in the current generation of trials. This has consisted of three or four cycles of a gemcitabine- or pemetrexed-containing platinum doublet, followed by surgery, and in some studies, radiation. In a multicenter study from Switzerland, 74% of the 61 patients who received three cycles of gemcitabine plus cisplatin were able to undergo an EPP; their median survival was 23 months.[119] In a multicenter American trial, 77 patients received four cycles of neoadjuvant pemetrexed and cisplatin. Radiographic partial responses were reported in 33% of evaluable patients, and 61% underwent an EPP. Median overall survival was only 16.6 months.[120]

## SYSTEMIC THERAPY

Systemic therapy is the sole treatment option for most MM patients, for whom advanced age, medical comorbidities, non-epithelial histology, and locally advanced disease will preclude surgery. Cytotoxic drugs with activity in this disease include carboplatin, cisplatin, doxorubicin, epirubicin, gemcitabine, pemetrexed, raltitrexed, vinflunine, and vinorelbine.[121–129] The addition of cisplatin to the antifolates pemetrexed or raltitrexed increases survival.[130,131] The addition of cisplatin to epirubicin, gemcitabine, irinotecan, pemetrexed, raltitrexed, or vinorelbine increases the response rate (Fig. 65.4).[130–135] Quality of life can be improved by gemcitabine, pemetrexed, and vinorelbine.[129,130,133]

The anthracyclines were once considered the most active drugs for this disease. Early trials reported response rates of up to 44% for doxorubicin. However, the largest series, a retrospective review of 51 patients treated by the Eastern Cooperative Oncology Group, documented a response rate of only 14%.[123] The EORTC observed a response rate of 15% and a median survival of 40 weeks in a phase II trial of epirubicin.[124] Although cardiac protectants and several liposomal formulations have been employed to potentially diminish the cardiac toxicity of the anthracyclines, these approaches are even less effective.[136,137]

Several recent trials have evaluated the activity of epirubicin plus cisplatin or gemcitabine. None of these combinations are significantly more active than gemcitabine or antifolate platinum doublets, and none will be developed further. In a phase II trial of epirubicin plus cisplatin in 69 patients, the European Lung Cancer Working Party achieved a 19% response rate and a median survival of 13.3 months.[122] An Italian group reported a response rate of 14% and a 32% 1-year survival in 28 patients treated with epirubicin plus gemcitabine,[138] whereas the North Central Cancer Treatment Group observed moderately severe toxicity and response rates of only 13% and 7% respectively, for high- and low-dose regimens using this combination.[139]

A metaanalysis of 83 mesothelioma clinical trials published from 1965 to 2001 determined that the most active cytotoxic agent in this disease is cisplatin.[122] Single-agent cisplatin has been employed as the control arm of several clinical trials[130,131]; it is otherwise not used alone for this disease. Similar activity has been reported for carboplatin.[121] Oxaliplatin has not been tested as a single agent for MM, although it has been evaluated in combination with gemcitabine, raltitrexed, and vinorelbine.[140–142]

The antifolates are currently regarded as the most active class of cytotoxic drugs against MM. High-dose methotrexate produced a response rate of 37% and a median survival of 11 months in a 60-patient study.[143] Edatrexate produced a 25% response rate with significant toxicity in a phase II CALGB trial; leucovorin decreased both response and toxicity.[144] Although very active in MM cell lines and xenografts, no

**FIGURE 65.4** CT scan showing tumor shrinkage with gemcitabine plus cisplatin. Patient exhibited advanced histologically confirmed MM **(A)**, which shrank by >50% following therapy with systemic gemcitabine plus cisplatin **(B)**.

objective responses were observed in a recent phase II trial of the antifolate pralatrexate.[145]

The antifolate pemetrexed inhibits thymidylate synthase, dihydrofolate reductase, and glycinamide ribonucleotide formyltransferase. Like other drugs of this class, pemetrexed principally crosses the cell membrane via the reduced folate carrier. A high-affinity cell membrane transporter specific for pemetrexed has also been described in mesothelioma cell lines.[146]

A 64-patient phase II trial of single-agent pemetrexed yielded a response rate of 14% and a median survival of 10.7 months.[126] The pivotal study of pemetrexed in MM was a single-blind, placebo-controlled phase III trial, which randomized 456 patients to pemetrexed, 500 mg/m$^2$ every 21 days and cisplatin 75 mg/m$^2$, or placebo and cisplatin.[130] Patients treated with pemetrexed plus cisplatin had a superior survival (12.1 vs. 9.3 months; $p = 0.020$), a longer time to progression (5.7 vs. 3.9 months; $p = 0.001$) and a higher response rate (41% vs. 17%; $p < 0.001$) than those who received single-agent cisplatin. Combination treatment also resulted in significant improvements in pulmonary function, quality of life, and symptoms including dyspnea and pain.

To decrease the risk of severe pemetrexed toxicities, after the first 117 patients enrolled in this trial, all subsequent patients were given vitamin supplementation with dietary doses of folic acid and vitamin B$_{12}$. This improved response rates and survival in both arms of the study. In preclinical models, there is a significant decrement in pemetrexed activity when extracellular folate levels increase above the physiological range. This has led some investigators to suggest that folate supplementation be limited to the lowest recommended level that provides protection from toxicity, about 400 $\mu$g daily.[147]

Because cisplatin may be poorly tolerated in elderly or frail individuals, carboplatin is often substituted. Response rates (26% and 22%) and 1-year survival (63% and 64%) were very similar for patients treated with pemetrexed and cisplatin or carboplatin, respectively, in the International Expanded Access Program.[148] A phase II trial of pemetrexed given with carboplatin (area under the curve [AUC] 5) achieved a median overall survival of 12.7 months and a median time to progression of 6.5 months in 102 patients. The response rate, however, was only 19%.[149] A 76-patient phase II trial of the same regimen yielded a response rate of 25%, a median time to progression of 8 months, and a median survival of 14 months.[150] Despite greater hematologic toxicity, elderly patients in these two trials experienced similar outcomes as younger individuals.[151]

A 250-patient randomized trial from the EORTC and the National Cancer Institute of Canada that compared raltitrexed plus cisplatin with single-agent cisplatin demonstrated that pemetrexed is not the only antifolate with phase III activity in mesothelioma.[131] Patients who received raltitrexed and cisplatin had a longer survival (11.2 vs. 8.8 months; $p = 0.048$), a superior time to progression (5.3 vs. 4.0 months; $p = 0.058$), and a higher response rate (24% vs. 14%; $p = 0.06$) than those who received cisplatin alone. Vitamin supplementation was not given. This agent is not being developed further for MM.

Although it produces few responses as a single agent,[152] gemcitabine has considerable activity when combined with a platinum. A retrospective British-Canadian series actually observed no difference in overall survival between platinum doublets of pemetrexed and gemcitabine.[153] Response rates for the combination of gemcitabine plus cisplatin were quite variable, however, and have ranged between 12% and 48%. This is thought to reflect heterogeneity in patient selection and inconsistencies in disease measurement between trials, rather than slight differences in the dose and schedule of these drugs.[125] In the initial 21-patient, single-center Australian study, gemcitabine 1000 mg/m$^2$ was given on days 1, 8, and 15, and cisplatin 100 mg/m$^2$ on day 1 every 28 days. The partial response rate was 48%, median survival was 9.4 months, and 90% of the responding patients experienced an improvement in symptoms.[154] The same investigators employed the same regimen in a 52-patient multicenter trial, and observed a partial response rate of 33% and a median survival of 11.2 months.[133]

Other active gemcitabine-platinum doublets include gemcitabine plus carboplatin, which produced a 26% response rate, a median survival of 15.1 months, and an improvement in pain, weight, and dyspnea[155]; and gemcitabine plus oxaliplatin, which, in a 20-patient study, achieved a response rate of 40%, a median time to progression of 7 months, and a median survival of 13 months.[140] The combination of gemcitabine plus pemetrexed has been studied in a 108-patient phase II trial that tested two different schedules. Median survival, 8.1 and 10.1 months for the two cohorts, respectively, was similar to single-agent pemetrexed, but the toxicity was greater.[156]

A 29-patient phase II trial of vinorelbine achieved a response rate of 24% and a median survival of 10.6 months. Pulmonary symptoms decreased in 48% of the patients.[129] The addition of oxaliplatin significantly increased toxicity, but did not enhance the response, which remained at 23%.[134] The addition of cisplatin to vinorelbine in 54 patients produced a 30% response rate, a median survival of 16.8 months, and a 1-year survival of 61%.[135] Another vinca alkaloid with activity in MM is vinflunine, which demonstrated a response rate of 14%, a median survival of 10.8 months, and modest toxicity in a 67-patient phase II trial.[128] This agent is not currently being developed for this disease.

The Medical Research Council and British Thoracic Society recently reported the results of the MS01 trial, which randomized 409 patients to active symptom control (ASC) or ASC plus either vinorelbine or mitomycin-vinblastine-cisplatin (MVP). Because of lower-than-expected accrual, the chemotherapy arms were analyzed together. There was a minimal survival advantage for chemotherapy (8.5 vs. 7.6 months) that was not statistically significant (HR = 0.89; $p = 0.08$). An exploratory analysis reported an improvement in survival for the vinorelbine-treated patients (median survival, 9.5 months) compared with ASC (HR = 0.80; $p = 0.08$), but there was no survival benefit for MVP (HR = 0.99; $p = 0.95$).[157]

## NOVEL AGENTS

Although cytotoxic chemotherapy has definite activity in MM, the modest results achieved with this approach have led many

investigators to evaluate more novel agents for this disease. Recent studies suggest that several of these agents may have promising activity.

Early clinical trials of the targeted agents were resoundingly negative, however. Although preclinical studies in MM suggested an autocrine growth-stimulatory effect of PDGF, response rates were 0% in all four studies of the PDGF receptor tyrosine kinase inhibitor imatinib.[158] The EGFR is highly overexpressed in MM, but activating mutations of EGFR are quite rare.[159] Thus, it should not be surprising that minimal activity was reported for phase II trials of gefitinib and erlotinib.[160,161]

In preclinical models, agents that target vascular endothelial growth factor (VEGF) inhibit the growth of MM. In MM patients, elevated serum VEGF correlates inversely with survival. Several VEGF inhibitors, including AZD2171, bevacizumab, sorafenib, SU5416, sunitinib, tetrathiomolybdate, thalidomide, and vatalanib have been studied in MM patients; their activity is quite modest.[158] Vatalanib, an inhibitor of VEGF and PDGF receptor tyrosine kinases, produced a response rate of 11% and a median survival of 10 months in a 47-patient phase II trial.[162] Likely reflecting patient selection in a two-cohort phase II trial, median survival in chemonaive patients who received the multikinase inhibitor sorafenib was 5.2 months, compared with 14.3 months for previously treated patients.[163] An Australian study of sunitinib, an inhibitor of the VEGFR-1, -2, and -3 tyrosine kinases, demonstrated a response rate of 15% by CT scan and 30% by CT/PET.[164] Thalidomide produced stable disease for 6 months or more in 28% of 40 patients in a phase II trial in The Netherlands.[165] Thus, the ongoing Nederlandse Vereniging van Artsen voor Longziekten en Tuberculose (NVALT) 5 maintenance study randomizes patients to thalidomide or observation after pemetrexed-based treatment.

A 108-patient, double-blind, placebo-controlled randomized phase II trial at the University of Chicago assessed the addition of the anti-VEGF monoclonal antibody bevacizumab to gemcitabine plus cisplatin. The primary end point, progression-free survival, was 6.9 months for the bevacizumab arm and 6.0 months for placebo. Median overall survival was 15.6 versus 14.7 months, for bevacizumab and placebo, respectively. Neither difference was statistically significant. Elevated baseline plasma VEGF levels correlated with briefer progression-free and overall survival.[166] Despite these negative results, several phase II trials of pemetrexed, bevacizumab plus a platin continue to accrue.

Suberoylanilide hydroxamic acid (SAHA) is an oral agent that inhibits class I and II histone deacetylases. Two unconfirmed partial responses occurred in 13 MM patients included in a phase I trial of SAHA. Responding patients also experienced a decrease in tumor pain and dyspnea. These preliminary data formed the rationale for an ongoing, international, double-blind, placebo-controlled randomized phase III trial of SAHA versus placebo in 660 previously treated patients who have received no more than two prior chemotherapy regimens. The primary end point is overall survival.[167,168]

In preclinical mesothelioma models, the proteasome inhibitor bortezomib abrogates the activity of nuclear factor kappa B (NFκB), induces apoptosis, and inhibits cell growth.[169]

Two ongoing European trials are evaluating bortezomib in MM patients: the EORTC is studying it first line in combination with cisplatin, and an Irish group is testing single-agent bortezomib in previously treated patients.

Ranpirnase, a ribonuclease derived from the leopard frog, is thought to disrupt protein translation, resulting in apoptosis. A 5% response rate and a median survival of 6 months were reported in a phase II trial in 105 previously treated patients.[170] A 154-patient phase III trial that compared ranpirnase with doxorubicin produced a similar survival for both arms of the study. Subset analysis of 105 patients suggested that patients with a better prognosis might benefit from ranpirnase. These data were presented in abstract form in 2000 and have never been published.[171] A phase IIIB trial of doxorubicin given with or without ranpirnase has recently completed accrual.

Mesothelin, a cell surface glycoprotein expressed on normal mesothelium, is another potential therapeutic target. Preclinical models demonstrate activity for SS1P, a recombinant immunotoxin, morphotek antibody 9 (MORAb-009), a monoclonal antibody, and live-attenuated listeria monocytogenes expressing human mesothelin (CRS-207), a live-attenuated listeria vector that encodes human mesothelin. These agents are synergistic with cytotoxic chemotherapy. A phase I study of CRS-207 is ongoing, and phase II trials of pemetrexed/cisplatin with SS1P or MORAb-009 have recently been initiated.[172–175]

## FUTURE DIRECTIONS

The key strategies to improve outcomes for this disease and to reduce the enormous compensation burden facing many countries (estimated to total over U.S.$ 300 billion) include:

- Early diagnosis
- Improved therapy
- Prevention of disease

*Early diagnosis* will require a blood or urine test that detects the early stages of disease in most cases with high specificity. Serum mesothelin detects only about 15% of patients prior to diagnosis, so better markers are needed. These might be discovered by mass spectrometry methods, immunochemistry, or microarray studies.

The attraction is that MM remains localized to cavities for most of the course of the disease, and early detection should lead to cures.

*Improved therapy* will probably require multimodality approaches that are firmly based on a scientific understanding of the biology of the disease and the basis for responses to therapy. It has been encouraging to find chemotherapies that actually work in this disease, and there is a lot of excitement in the field that such therapies can be combined with novel approaches, such as immunotherapy, for improved outcomes.

*Prevention of disease* is the "holy grail" of asbestos-induced cancers. Most patients are aware of their asbestos exposure, and would love to be able to take something that will reduce their risk, in the same way that lipid-lowering agents reduce the risk of cardiovascular disease. Retinoic acid was looking like it was

such an agent, but recent analysis of the longer-term data does not support its use.

Other preventative strategies will be based on animal studies. Cohort studies proving the efficacy of such agents will be limited by the lack of cohorts in which the incidence of MM is sufficiently high to enable the results to be accurate. Immunization strategies are being studied but are also difficult.

Progress in this field has been rapid, however, and this is in part caused by the enormous level of international cooperation that has occurred, largely via the peak body, the International Mesothelioma Interest Group. Also, effective national cooperatives have been developed, such as the National Center for Asbestos Related Diseases in Australia. Creative collaboration between scientists, clinicians, epidemiologists and funding bodies should see cures occurring within the next decade.

# Management of Mediastinal Tumors Not of Thymic Origin

The *mediastinum* is the term used to describe the contents of the thorax between the pleural cavities. It is an anatomical region defined by the lungs laterally, the diaphragm inferiorly, the thoracic inlet superiorly, the sternum anteriorly, and the vertebral column posteriorly. It is densely populated with vital structures including, but not limited to, the heart and great vessels as well as the trachea and the esophagus. It has been described as the "third space" of the thorax or "the space between spaces."[1]

Tumors of the mediastinum may originate from the normal anatomic structures of the region or from adjacent tissues. They may be primary or metastatic and they encompass a wide variety of histologies. This discussion will focus on mediastinal masses in adults.

## COMPARTMENTS

There are numerous classification systems for the compartments of the mediastinum in the surgical and radiological literature. Perhaps the simplest and most clinically relevant system is that proposed by Shields,[2] which subdivides the mediastinum into three anatomic compartments: the anterior, middle (or visceral), and the paravertebral sulci laterally. These compartments are readily depicted on a lateral view of the chest (Fig. 66.1).

The anterior compartment contains the thymus gland, lymph nodes, connective tissue, and fat. It may also contain displaced parathyroid glands or ectopic thyroid tissue. The visceral (or middle) compartment contains the heart and great vessels within the pericardium, the esophagus, trachea, and portions of the mainstem bronchi, the thoracic duct, and numerous lymph nodes and nerves (vagus and phrenic). The paravertebral sulci (posterior compartment) contain the proximal portions of the intercostal nerves, arteries, and veins, as well as the sympathetic trunk.

The clinical relevance of the model lies in the differential diagnoses of masses in each compartment (Table 66.1).[3]

## SIGNS AND SYMPTOMS

Approximately 50% of mediastinal masses in the adult population are found in asymptomatic patients.[4] Increased use of screening and surveillance CT scans and chest radiographs will likely raise the proportion of asymptomatic masses. In adults, the anterior mediastinum is the most common location for tumors.

Symptoms depend on the size and location of the mass. Malignant lesions are more likely to be symptomatic.[5] Although many symptoms are caused by local compression or invasion of adjacent structures, systemic symptoms associated with specific tumor types may also be present.[3]

Respiratory symptoms of cough, dyspnea, stridor, and hemoptysis are among the most common. Local invasion of pleura or chest wall may result in chest pain, which is often pleuritic in nature. Chest pain may also mimic angina. Other symptoms and signs resulting from local invasion or compression of structures includes dysphagia (esophagus), hoarseness (recurrent laryngeal nerve), superior vena cava (SVC) syndrome, Horner's syndrome (stellate ganglion), and cardiac tamponade (pericardium).

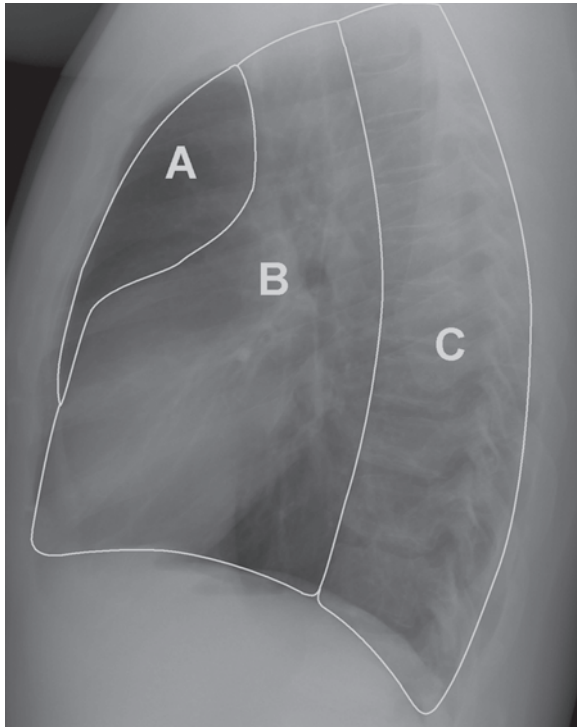
Generalized symptoms associated with malignancies such as fever, chills, and weight loss also need to be considered. Symptoms and signs associated with specific endocrine tumors may also be present (Tables 66.2 and 66.3). Signs and symptoms of hypercalcemia may be associated with parathyroid adenomas. The classical association of myasthenia gravis with an anterior mediastinal mass is almost pathognomonic of thymoma (not considered in this chapter). The presence of "café-au-lait" spots and a posterior mass is similarly suggestive of von Recklinghausen neurofibromatosis. Physical examination should include testicular assessment if a germ cell tumor (GCT) is suspected.[6]


**FIGURE 66.1** Mediastinal compartments diagram. Used with permission.)

## IMAGING

**Radiology** Although most patients will have a lateral and posteroanterior (PA) chest radiograph during their first examination, almost all patients will subsequently have a computed tomography (CT) scan. It is routine for computerized tomograms of the chest to image the area between the lung apices to the base of the adrenal glands. When mediastinal pathology is suspected, intravenous contrast should be used as it helps with lesion detection and definition. CT gives valuable information as to the density of the mass (cystic or solid) as well as its relationship to adjacent anatomic structures (Fig. 66.2).[7]

Magnetic resonance imaging (MRI) is somewhat limited in evaluation of the thorax because of its sensitivity to motion artifact (from cardiac and respiratory movements) and poor imaging quality of lung parenchyma. In imaging of mediastinal masses, its greatest utility lies in its assessment of specific areas where CT may fall short. These may include cases where the patient is unable to tolerate contrast for CT. The most common indication for magnetic resonance (MR) is in assessment of masses in the paravertebral sulci or posterior compartment. MR is useful if there is a "dumbbell" component to

HD, Hodgkin disease; RBC, red blood cell.

a neurogenic tumor (i.e., if the tumor has extended into the spinal canal). MR can give information as to the longitudinal extent of the involvement of the spinal canal.[8]

Ultrasound has limited use in the evaluation of mediastinal pathology. It is primarily used for localization during percutaneous biopsies.

**Positron Emission Tomography** Positron emission tomography (PET) has become an increasingly important tool in the investigation of malignancies throughout the body. This is true of mediastinal pathology as well (Fig. 66.3). Most centers will routinely perform PET with $^{18}$F-fluorodeoxyglucose (FDG) in the evaluation of suspected non–small cell lung cancers (NSCLC) or esophageal cancers. PET also plays an important role in the evaluation of lymphoma. In both Hodgkin's and non-Hodgkin's lymphoma (NHL), PET has been found to be an accurate and cost-effective method of staging disease as well as monitoring responses to therapy and assessing recurrence.[9]

The use of PET in the indeterminate mediastinal masses has not been well defined and requires further study. In one Japanese study, increased FDG uptake correlated with an increased likelihood of malignancy.[10]

**Other Nuclear Imaging Techniques** Octreotide, a somatostatin analogue, has been used in the evaluation of some suspected mediastinal pathology. It has an affinity for

**FIGURE 66.2** Sarcoma of anterior mediastinum.

**FIGURE 66.3** PET scan of anterior mediastinal mass.

neuoroendocrine neoplasms such as pheochromocytomas, medullary carcinomas of the thyroid, carcinoid tumors, small cell lung cancer, and some lymphomas.[11]

Other nuclear imaging techniques may be relevant in the evaluation of other specific diagnoses. For example, parathyroid sestamibi scans can be used in the search for ectopic mediastinal parathyroid tissue or scintigraphy with an iodine isotope can be used for suspected mediastinal goiters. Gallium scanning plays a role in the staging of lymphoma.[11]

## TUMOR MARKERS

Certain serum markers are relevant in mediastinal pathology. Antiacetylcholine receptor antibodies (Anti-AChR) may be elevated in thymic tumors.[12] Other tumor markers should be tested for in patients with anterior mediastinal masses that may be GCTs. Human chorionic gonadotropin beta ($\beta$-hCG) and $\alpha$-fetoprotein (AFP) are useful in the diagnosis of nonseminomatous germ cell tumor (NSGCT). Lactate dehydrogenase (LDH) levels should also be drawn as they may be elevated in patients with lymphoma.[13] In addition to helping with diagnoses, these markers can be used in monitoring the progression of disease or the response to therapy.

## BIOPSY

Biopsy of mediastinal masses should be performed if, after other investigations, the diagnosis remains unclear. It is specifically indicated if excisional biopsy of the mass is not warranted (e.g., in lymphoma). There are several techniques that can be employed to obtain tissue diagnoses of mediastinal masses. The selection of biopsy method depends not only on the location of the mass, but also on the suspected diagnosis. In particular, the diagnosis of lymphoma often requires a substantially greater mass of tissue to allow adequate subtyping. Furthermore, it cannot often be made on the grounds of a fine needle aspiration (FNA) and often requires an amount of tissue only obtainable by more invasive procedures.[4]

A similar caveat is important to consider in the evaluation of GCTs with FNA. Most GCTs have multiple elements and some pathologists feel that multiple tissue sections need to be evaluated, which can only be performed with larger volumes of tissue, which are obtained by open techniques.

Cervical mediastinoscopy is a well-established and safe technique that can give large volumes of biopsied tissue material through a 2-cm incision above the suprasternal notch. It is used to obtain tissue in the visceral compartment, particularly the paratracheal and subcarinal regions. Anterior mediastinotomy is a procedure performed through a small incision in the second intercostal space parasternally, which affords excellent access to almost all anterior mediastinal masses. Both of these procedures are associated with few complications and can provide large volumes of tissue. When combined, almost any mass in the anterior mediastinum or visceral compartment can be

accessed. They are performed under general anesthesia and are often done as day cases.

With increasing expertise in the use of thoracoscopic techniques, many thoracic surgeons find that video-assisted thoracic surgery (VATS) enables easier access to any part of the mediastinum with the added benefit of being able to completely excise smaller masses. VATS usually requires general anesthesia and is usually performed through one to three 1-cm incisions for biopsies depending on the anatomic area being sampled.

The recent advent of endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS) have enabled clinicians to obtain tissue from previously difficult to access areas in a minimally invasive fashion. Both EUS (through the esophagus) and EBUS (through the trachea or bronchi) can provide aspirates and core needle biopsies of masses and lymph nodes in the mediastinum. EUS is well suited to biopsy areas adjacent to the esophagus including subcarinal regions, the aortopulmonary window, and particularly the inferior mediastinum (an area inaccessible to mediastinoscopy). In addition to accessing areas accessible by mediastinoscopy (paratracheal), EBUS can access areas distal to the mainstem bronchi (i.e., at the pulmonary hila).

## CLINICAL PRESENTATION

**Anterior Mediastinal Mass**   The most common causes of anterior mediastinal masses in adults are thymic neoplasms, lymphomas, and germ cell neoplasms. Thymic neoplasms are not dealt with in this chapter.

**Germ Cell Tumors**   Mediastinal GCTs arise from primitive germ cells that have failed to migrate during embryonic development. They often present in young adulthood and represent 15% of anterior mediastinal masses in adults.[14] Malignant GCTs are more common in men (>90%). Histologically, GCTs can be subdivided into three broad categories: benign teratomas, seminomas, and NSGCTs.[15]

**Benign Teratomas**   Benign or mature teratomas represent the greatest proportion of mediastinal GCTs and consist of tissue from at least two of the three primitive germ layers. Ectodermal tissues (hair, skin, teeth) predominate with some mesodermal components (fat, cartilage, bone) and less often endodermal tissues (respiratory or intestinal epithelium). Most patients are asymptomatic although symptoms can be caused by local compression. Teratomas containing digestive enzymes can rupture into bronchi, lung, or pericardium. Malignant transformation is rare but possible.[16] Benign teratomas have normal serum markers. Complete surgical excision is the treatment of choice.

**Seminomas**   Seminomas occur in men in their 20s to 40s and can present with symptoms of chest pain, cough, dyspnea, fever, weight loss, and may be associated with SVC syndrome. Some patients present with gynecomastia. They can

reach extremely large diameters before causing symptoms dependent on location. On imaging, they are bulky, lobulated, homogenous masses. Serum $\beta$-hCG may be mildly elevated. Patients with pure seminomas should never have an elevated serum AFP; its presence implies the presence of yolk sac tumor and embryonal cell carcinoma in the primary or in a metastatic site.

Seminomas are radiosensitive tumors and radiation is often the primary treatment modality. For small masses, radiation alone may be administered. For larger masses, combined chemoradiotherapy with cisplatin and etoposide regimens is used. If a residual mass remains posttreatment, most clinicians would advocate observation if the mass is less than 3 cm or surgical excision if the mass is greater than 3 cm.[17]

## Nonseminomatous Germ Cell Tumors

The term *nonseminomatous germ cell tumor* comprises several histologically distinct tumor types including yolk sac carcinoma, embryonal carcinoma, choriocarcinoma, and mixed tumor histology.

Several hematologic malignancies may occur in conjunction with mediastinal NSGCTs, such as acute megakaryocytic leukemia, myelodysplastic syndrome, refractory thrombocytopenia, refractory anemia with excess blasts, malignant histiocytosis, and systemic mastocytosis. In approximately 80% of NSGCTs, AFP is elevated. $\beta$-hCG is elevated in approximately 30% to 35% of patients and may lead to gynecomastia in young male patients. Either tumor marker may be elevated alone or together in any particular patient.[18,19] The presence of any nonseminomatous element (i.e., elevated AFP), even in a tumor that is predominantly seminomatous by histology, is classified as an NSGCT and treated as such.

Although treatment can be initiated based on positive tumor marker results, histological diagnosis is recommended. There is a pathologic discrepancy of 6% between histology and FNA, and difficulty may arise in differentiating GCTs from poorly differentiated carcinoma.[20] Core needle biopsy should be performed when possible and, if surgical biopsy is warranted, an anterior mediastinotomy, (Chamberlain procedure) is usually the procedure of choice. In diagnostic dilemmas, tissue should be sent for genetic analysis, specifically abnormalities of the short arm of chromosome 12, which is a consistent finding in GCTs and rarely observed in other tumors. Chemotherapy is the mainstay of initial treatment, and surgery should be viewed as an adjuvant to chemotherapy. Four cycles of bleomycin, etoposide, and cisplatin (BEP) is the current standard.[21,22] A rapid decline of tumor marker levels with platinum-based chemotherapy treatment is associated with improved response rates and overall survival.[23] Chemotherapy is also indicated postsurgical resection when viable tumor is present in the resected specimen.

After initial treatment with chemotherapy, a patient with tumor marker normalization and a persistent mass on CT is the most favorable candidate for surgical resection. Patients demonstrating a residual mass on CT and persistently elevated tumor markers have been treated with salvage chemotherapy in the past in an effort to obtain normal tumor marker levels prior to surgery. This approach, however, has not improved outcome,[22] and current practice at some centers is to recommend surgery after initial chemotherapy (regardless of persistently elevated tumor markers), in an attempt to achieve complete surgical resection. If patients are to undergo salvage chemotherapy preoperatively, this should be performed in a clinical trial setting. In rare circumstances, postchemotherapy patients will demonstrate elevated tumor marker levels but no residual mass on CT. Surgery is not recommended in these patients. Instead, they should be followed by serial CT scans.

## SURGICAL APPROACH

Median sternotomy is the most common approach for small, centrally located tumors in the anterior mediastinum. The patient is placed in the supine position with both arms tucked to the sides, which allows exposure to the right or left hemithoraces, the lung hila, and mediastinal vascular structures. However, exposure to the posterior aspects of the lung is suboptimal and visualization of the left lower lobe is limited.

A hemiclamshell incision is our preferred approach for large tumors arising in the anterior mediastinum and extending significantly into either the right or left hemithorax. The exposure is a combined upper median sternotomy and anterior thoracotomy (Fig. 66.4).[24] The patient is placed in the supine position, the side of the anterior thoracotomy extension is elevated 30 degrees with a longitudinal roll placed beneath the scapula, and arms are tucked at the sides. Exposure is facilitated by collapse of the ipsilateral lung, allowing for anatomical lung resection if necessary. Once the involved lung is divided, optimal exposure to the posterolateral aspect of the tumor is obtained, thereby allowing complete assessment of adjacent vascular structures and phrenic nerve.

If a large tumor extends into the neck area, an extension along the anterior border of the sternocleidomastoid provides excellent exposure, especially if dissection of the vascular structures is required. This provides excellent exposure of the carotid and jugular vessels (Fig. 66.5).[25]

On rare occasions, resection of the subclavian vessels is necessary with mediastinal GCTs. If required, extending the top of the sternotomy along the superior portion of the clavicle allows adequate control of the vessels. This can be described as a "trap door" incision. In addition, the excision of the medial one third of the clavicle may provide added exposure (Fig. 66.6).

A series of 32 patients who underwent postchemotherapy surgical resection of mediastinal GCTs has been published.[26] Histologic analysis revealed viable tumor in 66%, teratoma in 22%, and necrosis in 12% of the specimens. Viable tumor included embryonal carcinoma, choriocarcinoma, yolk sac carcinoma, seminoma, and teratoma with malignant transformation to non-germ cell histology (e.g., sarcoma). Because teratoma and residual tumor were found in the majority of resected patients, we maintain an aggressive approach to surgical resection

of potentially involved adjacent structures. The Kaplan-Meier curve showing the survival of the 32 patients who underwent postchemotherapy surgery is shown in (Fig. 66.7).

## LYMPHOMA

Primary mediastinal lymphoma is a rare form of the disease and constitutes approximately 10% of mediastinal lymphomas. Generally, lymphoma presents in the anterior mediastinum and is part of more widespread disease. The majority

**FIGURE 66.7** Kaplan-Meier survival curve for 32 patients who underwent postchemotherapy surgery. (From Vuky J, Bains M, Bacik J, et al. Role of postchemotherapy adjunctive surgery in the management of patients with nonseminoma arising from the mediastinum. *J Clin Oncol* 2001;19:682–688. Used with permission.)

(50% to 70%) of lymphomas in the mediastinum are Hodgkin disease (HD).[27]

The majority of lymphoma patients are symptomatic and may have local symptoms and/or systemic (B grade) symptoms including fever, night sweats, and weight loss. Common local signs and symptoms include cough, dyspnea, chest pain, and SVC syndrome.[28]

Management of lymphoma depends on accurate tissue diagnosis and staging. Generally, FNA is not adequate for the diagnosis and subtyping of lymphoma, and often larger samples of tissue are required (e.g., from mediastinoscopy or VATS procedures).[28] As mentioned previously, the role of PET in the staging of lymphoma is increasingly important.

The presence of Reed-Sternberg cells is pathognomonic for HD with a classical immunohistochemical profile of CD15 and CD30 biomarker positivity.[29] The Ann-Arbor Staging system is used (see Table 66.4).[30] Early stage HD, defined as stages 1 and 2, is generally treated with combined chemotherapy and radiation with cure rates as high as 90%. Late stage (3 and 4) HD is treated with chemotherapy alone.[31]

Among NHLs, lymphoblastic lymphoma and large B-cell lymphoma are the most common subtypes found in the mediastinum. Large samples of tissue are mandatory as flow cytometry and cytogenetic testing are often required for a definitive diagnosis. Lymphoblastic lymphoma is generally a very aggressive disease and in addition to common symptoms, patients may present with SVC syndrome, cardiac tamponade, or airway obstruction. Treatment consists primarily of chemotherapy, but bone marrow transplant is also employed. Patients with primary mediastinal B-cell lymphomas are also treated

primarily with chemotherapy although some centers use involved field radiation as well.[31]

## VISCERAL (MIDDLE) COMPARTMENT MASSES

The most common masses in the visceral compartment relate to lymphadenopathy near the tracheobronchial tree. Barring that, the remaining masses in the compartment are generally benign and cystic in nature.

**Bronchogenic Cysts**    Bronchogenic cysts are the most common cysts found in the mediastinum. They arise embryologically from respiratory epithelium, hence, they can be found anywhere along the path of lung development. It is thought that respiratory buds that break off early in development will end up in the mediastinum, whereas if they break off later they will end up in the lung parenchyma.[32] Although many mediastinal bronchogenic cysts are found in asymptomatic patients, the majority of them do progress to symptomatic stages. Symptoms, when they arise, are a result of compression of local structures and can range from cough and dyspnea to dysphagia and SVC syndrome. Because of the propensity for progression to a symptomatic state and the potential for infection of the cyst, surgical excision is recommended. Bronchogenic cysts can almost always be resected by VATS techniques. There are also reports of excision by mediastinoscopy.[33]

**Enterogenous Cysts**    Similar to bronchogenic cysts, enterogenous cysts are of foregut origin and include esophageal duplication cysts. They can cause symptoms from compression and can also spontaneously hemorrhage and rupture into the esophagus or tracheobronchial tree. They also have the potential to get infected. Complete surgical excision via VATS is recommended (Fig. 66.8).[34]

**FIGURE 66.8**    CT pericardial cyst.

**FIGURE 66.9**    Esophageal duplication.

**Pericardial Cysts**    The most common location for pericardial cysts is in the right cardiophrenic angle (Fig. 66.9). They are generally asymptomatic and often found on routine radiography for other purposes. Excision is recommended if the patient is symptomatic as cysts can grow to large proportions rarely causing compression and hemodynamic compromise.[29]

## PARAVERTEBRAL (POSTERIOR MEDIASTINAL) TUMORS

**Neurogenic Tumors**    Most tumors in this region are neurogenic in origin and arise from the intercostal nerve rami or sympathetic chain (Fig. 66.10). The majority (80% to 90%) are benign, slow growing, and asymptomatic. In adults, the most common tumors are nerve sheath tumors (schwannomas and neurofibromas).[35] Schwannomas are usually firm and encapsulated, whereas neurofibromas are nonencapsulated and soft. Approximately 30% of neurofibromas are associated with von Recklinghausen's disease.[36] Nerve sheath tumors are often spherically shaped on imaging and can be associated with erosion and destruction ribs and vertebral bodies. Ten percent of these tumors have intraspinal extension (dumbbell tumors) through the vertebral foramen.[37]

If intraspinal extension is suspected, MRI should be performed to characterize the extent of longitudinal involvement. Preoperative angiography should be performed if major spinal arteries are at risk. Resection of dumbbell tumors is often performed in conjunction with neurosurgeons and requires meticulous preoperative planning.[38] Simple nerve sheath tumors should be resected by VATS or thoracotomy if the former method is not feasible.

Malignant nerve sheath tumors are often symptomatic and may present with pain and neurological deficits. They
**FIGURE 66.10**    CT paraverterbal mass.

are associated with sarcomatous degeneration in 5% of cases. Complete excision is the treatment of choice. Unresectable tumors may benefit from chemotherapy and radiation.[37]

## CONCLUSION

Mediastinal masses in adults are a challenging problem for the clinician. The anatomic location of the mass will often give substantial clues as to the precise etiology. Surgical excision is indicated in many cases, but tissue confirmation is required if there is doubt about the diagnosis. Specifically, anterior mediastinal masses that may be lymphomas or malignant GCTs should have histological confirmation as nonsurgical therapies form the mainstay of treatment. A multidisciplinary approach in these situations is invaluable.

# The Spectrum of Carcinoid Tumors

Lung carcinoids had been classified as "bronchial adenomas," which included other bronchial tumors with benign behavior. Subsequently, lung carcinoids were included in a group of heterogeneous tumors with relatively benign behavior except for a small subgroup with more aggressive clinical course and atypical histologic features. The difference between typical and atypical carcinoid was better described in 1944.[1] Years later, in 1972, Arrigoni et al.[2] proposed the histologic criteria to distinguish these tumors. This proposal along with others had never been accepted. However, in 1999, World Health Organization (WHO) defined better the classification based on strict criteria from Travis et al.[3,4] These criteria have been widely accepted and described carcinoids as well-differentiated neuroendocrine malignant tumors. Typical and atypical carcinoids were classified as two distinctive tumors with different histologic features, different clinical course, and different prognosis.[3,5] In the latest 2004 WHO classification, neuroendocrine tumors involving the lung include a spectrum of clinicopathologic entities ranging from hyperplastic neuroendocrine cell lesions (carcinoid tumorlets and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia [DIPNECH]) to typical and atypical carcinoids with indolent and slightly aggressive behavior to high-grade aggressive small cell lung cancer (SCLC) and large cell neuroendocrine tumors.[6]

## EPIDEMIOLOGY

Lung carcinoids account for 85% of all bronchial gland tumors. Lung carcinoids are rare, malignant neuroendocrine tumors that comprise approximately 2% of primary resected lung tumors.[7,8] Of all carcinoid tumors, approximately 25% are located in the respiratory tract.[7] The annual incidence is approximately 2.3 to 2.8 cases per 1 million population.[8] The ratio of women to men is 1.6:1.[8] This is in contrast with bronchogenic carcinoma in which men still dominate. Information from the U. S. Surveillance Epidemiology and End Results (SEER) database has shown that the annual rates of bronchial

carcinoids among white men and women per 100,000 population between 1992 and 1999 were 0.52 and 0.89, respectively, and 0.39 and 0.57, respectively, for black men and women.[9–11] Patients with pulmonary carcinoid tumors are, on average, 10 years younger than patients with bronchogenic carcinoma.[12] The prevalence of smoking is similar to the general population in patients with typical carcinoid and is twice as high in patients with atypical carcinoid.[8,13] Familial pulmonary carcinoids, although rare, are found and are associated with the syndrome of multiple endocrine neoplasia type I.[7,14,15] There is also a report of familial pulmonary carcinoid that is not associated with multiple endocrine neoplasia type I syndrome.[7] Rarely, combined tumors of carcinoid and adenocarcinoma have been reported.[16,17] Carcinoid tumors in children are extremely rare.[18,19] However, bronchial carcinoids are the commonest primary lung neoplasms in late adolescence.[10] Carcinoid tumors allocated peripherally, or with size more than 3 to 5 cm in diameter, are more likely to be atypical carcinoids. In addition, these patients are usually older than 55 years old and current or former smokers.[20]

## CLINICAL PRESENTATION

Pulmonary carcinoids produce symptoms as a result of their location within the tracheobronchial tree. Cough, hemoptysis, or recurrent pneumonia are common symptoms. Unilateral wheezing resulting from a bronchial carcinoid has been described.[12,21] Some of these patients have been misdiagnosed as having asthma. These symptoms are common in tumors that arise in the proximal airways. In peripheral lesions, 19% to 39% of patients are asymptomatic, and these are generally discovered as incidental findings on plain chest radiography.[22,23] Thoracic carcinoid tumors are the commonest cause of ectopic adrenocorticotropic hormone (ACTH) production in patients with Cushing syndrome.[12,24–32] Acromegaly is also a rare manifestation of carcinoid tumors. This is caused by the ectopic production of growth hormone–releasing hormone (GHRH).

Bronchial carcinoids are the commonest cause of extrapituitary GHRH secretion.[33–37] These tumors behave more aggressively.[38] Carcinoid syndrome is relatively uncommon in pulmonary carcinoids. Symptoms such as flushing, sweating, or diarrhea occur in 5% to 10% of patients and are reported mainly in those with bronchial tumors larger than 5 cm or in those with tumors metastasized to the liver. Long-term sequelae of prolonged elevated hormone levels such as serotonin include venous telangiectasias, right-side valvular heart disease, and fibrosis in the retroperitoneum and other sites. Pulmonary carcinoids produce lesser quantities of serotonin than do midgut carcinoids. For the uncommon case of carcinoid syndrome, urinary excretion of 5-hydroxy-indole acetic acid (5-HIAA) may be elevated but, certainly, much less than in a case of midgut carcinoid. Measurement of urinary serotonin levels may be of value.[39] Very rarely, biopsy of a bronchial carcinoid may induce a carcinoid crisis, which is an acute carcinoid syndrome. Extreme flushing, changes in blood pressure, bronchoconstriction, and confusion are the commonest symptoms. This is caused by massive systemic release of bioactive substances. Although, this syndrome is extremely rare, prophylactic administration of octreotide is of value.[40,41]

## DIAGNOSIS

The commonest findings on chest radiograph include a hilar tumor not necessarily accompanied by atelectasis or a peripheral lesion in 25% of cases, which is more often atypical carcinoid.[24,42,43] There are several classifications regarding the location of carcinoids. One widely accepted definition of a centrally located mass is one that is visible at the time of bronchoscopy. Tumors that are not visualized at bronchoscopy are considered to be peripherally located.[12] Computed tomography (CT) scan is very useful because it provides a good resolution of tumor extent, location, and the presence or absence of mediastinal lymphadenopathy. The tumor frequently looks like a mixture of intraluminal and extraluminal component. The tumor may have lobular or irregular borders, calcifications, and marked enhancement by contrast-enhanced CT because of the rich vascularity. Cavitation of the tumor is rare, and pleural effusion is unusual. CT scan is useful for the detection of hilar or mediastinal lymphadenopathy, although the predictive value is low.[44–46] Magnetic resonance imaging (MRI) may be useful to differentiate a small peripheral carcinoid nodule with high-contrast enhancement from pulmonary vessels. MRI is also useful in detecting liver metastasis.[47] Carcinoid tumors generally demonstrate a low level of uptake of $^{18}$F-fluorodeoxyglucose as measured by positron emission tomography (PET). Therefore, patients with carcinoid tumors are more likely to have a negative PET scan,[48–54] immunoscintigraphy by In-111 octreotide based on the expression of somatostatin receptors is a promising diagnostic tool, although negative results cannot exclude carcinoid tumors.[7,46,55–57] Checking for serotonin (HIAA) levels whenever a carcinoid tumor is suspected in the absence of carcinoid syndrome is not recommended.[12] Definite diagnosis

of carcinoid tumors is made by bronchoscopy, thoracotomy, and biopsy. The bronchoscopic appearance of centrally located tumors include a rather smooth, polypoid endobronchial mass with brownish or red color. Histologic diagnosis of biopsies is accurate in 54% to 100% of patients.[12] Bronchial carcinoids are vascular tumors, and in spite of that, the incidence of serious bleeding during bronchoscopic biopsy is very low.[58,59] The diagnostic yield of fine-needle aspiration, brushing, washing, or expectorated sputum remains low in the range of 4% to 63%, possibly because the normal bronchial mucosa that covers the tumor remains intact.[60–62] This is an additional reason why preoperative diagnosis is many times difficult. Furthermore, it is difficult to differentiate precisely typical from atypical carcinoids preoperatively. This is reported to occur in less than 20% of cases.[12] Also, frozen section examination during surgery differentiates carcinoid tumors from carcinomas in 26% to 40% of cases.[12] Staging pulmonary carcinoid tumors is similar to that of other lung neoplasms. Typical carcinoid usually present as stage I, whereas more than 50% of atypical carcinoids present with II or III (Table 67.1). Certainly, the prognostic value of staging system in carcinoid tumor is limited, mainly, in typical ones because the long-term survival is not usually affected by the presence or absence of hilar or mediastinal lymphadenopathy.[12,63–65] Bronchial carcinoids have generally low serotonin content, and occasionally secrete bioactive amines. Therefore, elevated plasma or urinary hormone levels are rarely detected, and only a few develop clinical paraneoplastic syndrome from peptide secretion. However, measurement of serum levels of chromogranin A (CGA) can be a useful marker to follow disease activity and response to treatment in advanced or metastatic disease.[66,67]

## HISTOLOGY AND MOLECULAR BIOLOGY

Bronchial carcinoids belong to the group of neuroendocrine tumors, which is composed of four main types: typical carcinoid, atypical carcinoid, small cell lung carcinoma, and large cell neuroendocrine carcinoma. These four types of tumors are part of a biologic continuum from the relatively indolent typical carcinoid to a more clinically aggressive atypical carcinoid,
**FIGURE 67.1** Typical carcinoid: endobronchial tumor of the upper lobe of the left lung in a 35-year-old woman. small cell lung carcinoma, and large cell neuroendocrine carcinoma.[68,69] Bronchial carcinoids are characterized by different biologic behavior. Despite their different biologic behavior, these tumors share certain morphologic and biochemical characteristics (i.e., the capacity to synthesize neuropeptides as well as the presence of neuroendocrine granules in the cytoplasm, which can be visualized by electron microscopy).[6] Pulmonary carcinoid tumors are thought to originate from a specialized bronchial cell, the so called kulchitsky cell, which belongs to a diffuse system of neoroendocrine cells. These tumors have been referred to as amine precursor uptake and decarboxylation (APUD) or apudomas.[6] Typical carcinoid tumors are composed of bland cells containing round-to-oval nuclei with finely dispersed chromatin and small nucleoli. The cells
are mostly polygonal in shape, mitotic figures are scarce and necrosis is absent.[6] (Fig. 67.1) Typical carcinoids located peripherally usually have a spindle cell growth pattern, and most of them have foci of diffuse DIPNECH and/or tumorlets in the adjacent lung parenchyma, which does not seem to alter prognosis (Fig. 67.2). Atypical carcinoids include all of the above plus the fact that mitotic figures are more numerous and foci of necrosis are present (Fig. 67.3). It is likely that atypical carcinoids derive from progression of typical carcinoids, which derive from a precursor lesion-identified DIPNECH.[70,71] Most carcinoids can be diagnosed on routine light microscopy. Immunohistochemical diagnosis of secreted and cytoplasmic products such as synaptophysin, neuron-specific enolase, and chromogranin has replaced silver staining as the best method to confirm neuroendocrine differentiation. Carcinoid tumors with the rare exemption of atypical carcinoids do not express thyroid transcription factor-1 (TTF-1).[72] The differentiation between typical and atypical carcinoid tumors is based mainly on the mitotic count. The typical carcinoids have less than two mitoses per square millimeter of viable tumor in 10 high-power fields and lack necrosis. Atypical carcinoids have more than 2 to 10 mitoses per square millimeter in 10 high-power fields or have foci of necrosis or both (Table 67.2). The necrosis is more

or less punctuate.[6] There is an inconsistent correlation between "atypical" histology in carcinoid tumors and DNA aneuploidy. Although aneuploidy seems to be more common in atypical tumors, abnormal DNA content does not provide additional prognostic information.[73] Molecular biologic changes may be useful as an adjunctive tool to differentiate typical and atypical carcinoids. E-cadherin impairment expression has been correlated with extensive disease in typical and atypical carcinoids.[74] Tumor suppressor genes, P53, retinoblastoma gene, P16, and P19 show an increase in frequency of alteration and inactivation in atypical carcinoid compared with the typical one.[75–78] Also, proliferation rates assessed by MIB-1 and Ki-67 are higher in atypical carcinoids.[7,22,23] Angiogenesis has not been found to be a useful marker as well as C-erbB-2 protein, which is not expressed.[66,79–82] K-ras-2 analysis showed no evidence of point mutational changes in either typical or atypical carcinoid.[78] On the contrary, multiple endocrine neoplasia type I gene activation appears to be a specific genetic marker in atypical carcinoid.[7] Human acute homologue-1 (ASH-1), a transcription factor that plays a crucial role in neuronal endocrine determination and differentiation, is expressed at high levels in SCLC and non–small cell lung cancer (NSCLC) with neuroendocrine feature. It is absent in typical carcinoids although it is expressed in atypical carcinoids[83] (Table 67.3).

**Biologic Behavior**   Physicians who take care of patients with pulmonary carcinoids must be familiar with the biologic behavior of these tumors specifically to differentiate between typical and atypical carcinoids, because these subtypes behave in a different manner. Atypical carcinoid tumors are more aggressive than typical carcinoid tumors (Table 67.4). Atypical carcinoid tumors metastasize not only more commonly to regional lymph nodes but also systematically. The overall 5-year survival rates of resected patients found to have atypical carcinoids range between 40% to 69% versus 87% to 100% for typical carcinoid tumors.[12] After resection, atypical carcinoids recur more commonly. Also, atypical tumors are more advanced in stage on presentation. Both typical and atypical carcinoid tumors can metastasize to regional lymph nodes N1, N2, and N3. The overall incidence of lymph node metastases is greater in patients who have atypical carcinoid tumors and involve more often N2 and mediastinal nodes.[7,12] Distant metastases are most commonly found in liver, bones, adrenals, brain, and soft tissues.[7,12] In a retrospective study by Rea et al.[84] with 252 patients with bronchial carcinoid tumors, the 10-year survival following surgery was 93% and 64% for typical and atypical carcinoids, respectively. In the same study, the overall 5-, 10-, and 15-year survival rate was 90%, 83%, and 77%.[84] The prognostic impact of nodal involvement for typical bronchial carcinoid tumors is controversial. There are reports with worse outcome,[22,85] whereas in other studies there are no differences.[65,86] In contrast, in atypical bronchial carcinoids, in most series there is an adverse influence of nodal metastases on prognosis.[13,22,64,87–90]

## TREATMENT

Preoperative histologic diagnosis is extremely helpful, in particular when distinguishing between typical and atypical carcinoid tumors. This, in addition to the staging with the assistance of CT and scintigraphy with In-111 octreotide, will determine the strategic plan for the treatment.[91–93]

**Localized Disease**   Surgery offers the only chance of cure and is the treatment of choice[7,12,13,94] (Table 67.5). In patients with central typical carcinoid tumors, bronchial sleeve resection or sleeve lobectomy should be considered. Local recurrence is rare, and survival is excellent. In peripherally located typical carcinoid tumors, segmentectomy for patients with inadequate pulmonary function tests is indicated. Otherwise, lobectomy is preferable to secure the minimal risk of recurrence. The primary goal is the removal of all tumor. The secondary goal is to preserve as much lung parenchyma as possible.[95–97] In case

AC, atypical carcinoid; TC, typical carcinoid.

of endobronchial localization of typical carcinoids, broncho-plastic parenchyma-sparing surgery is the standard surgical procedure.[98] Endobronchial resection or partial resection with laser can be used to clear infection in distal lung parenchyma or in patients not fit to undergo surgical resection. In selected patients in whom there is no extraluminal component identified on chest CT, endobronchial approach may remove the tumor completely. Certainly in these cases, radiographic and endoscopic surveillance is extremely important.[12] In all other cases, this technique fails because of the high rate of recurrence caused by extraluminal extention of the tumor. Intraoperative lymph node evaluation should always be performed in all patients with typical carcinoid tumors. Metastases to hilar or mediastinal lymph nodes found on frozen section should lead to a complete lymph node dissection. Mediastinoscopy is performed for the same indications as they would be for NSCLC.[12] Patients with atypical carcinoid tumors, in whom local recurrence is highly possible, should have a more extensive surgical approach such as lobectomy or pneumonectomy associated with lymph node dissection. Bronchial margins should be negative and should be checked intraoperatively. Surgical margin as small as 5 mm is considered adequate because carcinoids do not spread submucosally.[95–97] Incomplete resection is associated with negative prognosis. In cases in which preoperative or intraoperative diagnosis of carcinoid cannot be made, then the rules of NSCLC resection must be followed.[12,99]

### Adjuvant Chemotherapy

There are no guidelines regarding adjuvant treatment for pulmonary carcinoid tumors. The 5- and 10-year survival rates of typical carcinoids with or without regional lymph node involvement does not justify adjuvant treatment with either chemotherapy or radiotherapy.[97,99] A very small study with adjuvant radiotherapy including typical and atypical carcinoids with N2 lymph nodes metastasis failed to show benefit.[100] Other studies also failed to show benefit for adjuvant RT or chemotherapy.[65] On the contrary, atypical pulmonary carcinoid tumors have a poorer 5- and 10-year survival and, although there are no randomized trials, adjuvant treatment should be administered. Therefore, patients with resected atypical carcinoid tumors, regardless of lymph node status, should receive adjuvant chemotherapy like those patients with SCLC.[101–105]

### Locoregional Unresectable Disease

Although, there are no studies for this group of patients, a combination of chemotherapy and radiotherapy in a similar manner like SCLC is adviced. Certainly, this approach is mainly palliative and not curative. The possible advantage of double-modality versus single-modality treatment is not clear.[101,106]

### Metastatic Disease

The percentage of patients who develop metastases varies between 5% and 70%.[107,108] Metastases may occur late, even decades after the initial diagnosis. Treatment for metastatic disease includes chemotherapy, interferons, radionucleotides, somatostatin analogs, combinations of the above, liver embolization, liver resection, and liver transplantation as well as radiofrequency ablation. However, because of the rarity of the tumor, the lack of good prospectively designed studies, information, and experience are very much limited. Combination chemotherapies include platinum-based and streptozotocin-based regimens. In a recent report from Uppsala, Sweden, cisplatin-etoposide was given in eight patients.[108] Two patients with typical carcinoids responded for 6 and 8 months respectively, whereas one patient with atypical carcinoid had stable disease for 7 months. For the remaining five patients, the disease progressed. Patients with carcinoid syndrome responded less frequently to this combination than patients without this syndrome. There was no correlation between response to treatment and Ki-67 expression.[108] In seven patients who received the combination streptozotocin-fluorouracil, only one had stable disease for 8 months. All other patients progressed. Streptozotocin-doxorubicin was administered in two patients, both of whom achieved radiologically stable disease at 8 and 10 months, respectively.[108] Paclitaxel as single agent or in combination with doxorubicin was given in four patients with stable disease as the best response for several months.[108] It is interesting that patients with neuroendocrine tumors in other organs such as the pancreas have a better response rate compared with pulmonary carcinoids. Even the combination of cisplatin-etoposide, which is very effective in SCLC or in aggressive atypical carcinoids of other organs, has limited efficacy in carcinoids of the lung, including the atypical ones.[109] In the study by Granberg et al.,[108] interferon-$\alpha$ alone or in combination with other biotherapies was evaluated. In 27 patients, interferon-$\alpha$ as single agent or in combination with octreotide was given.

Of these patients, 21 progressed radiologically and biochemically. In four patients, the disease was stable for a median of 15 months. There was no difference in the type of response among patients with or without carcinoid syndrome, and neither could a correlation be found between responses and any of the immunohistochemical analysis including Ki-67 expression. There was no difference in objective response or survival between patients who received interferon-$\alpha$ alone and in combination with octreotide. In this group of patients, 16 had carcinoid syndrome and seven achieved symptomatic relief.[108] In four patients, somatostatin analogs were given as a single agent, resulting in progressive disease in all four patients. One patient benefited from relief of carcinoid syndrome.[108] In addition to interferon-$\alpha$, interferon-$\gamma$ has been given with disappointing results and increased toxicity.[108] Targeted radiotherapy with In-111 octreotide and I-131 metaiodobenzoguanidine (MIBG) has been administered in a limited number of patients with metastatic pulmonary carcinoid tumors as second- or third-line treatment without any results.[108] Certainly, there are rare reported cases with long-term survival.[110] Hepatic artery embolization with gel foam has been undertaken in a few patients with symptomatic disease. Embolization has been performed once or more in one or both liver lobes. Transient stabilization and clinical benefit has been occasionally observed. This technique is applied to those symptomatic patients who are not candidates for surgery. Liver resection has a role to play for the treatment of selected patients with limited volume metastatic disease. With this approach, symptoms are relieved, life prolongation may be expected but certainly it is not curative. Hepatic resection is indicated only in the absence of widespread bilobular disease, compromised liver function, or extensive extrahepatic disease. Simultaneous resection of liver metastasis and the primary tumor is indicated either if the primary site is causing symptoms or both sites are amenable to potentially curative resection. Liver transplantation is considered investigational approach, and patients with isolated liver metastasis are candidates for this procedure. Radiofrequency ablation or cryoablation are other alternative options. These procedures are useful only in small-size lesions. Radiation therapy is a useful palliative treatment for pain relief in bone metastasis. Novel therapeutic approaches include targeted radiotherapy, inhibitors of angiogenesis (bevacizumab), and small molecule tyrosine kinase inhibitors (sunitinib), as well as Imatinib.[111–113] Some mammalian target of rapamycin (mTOR) inhibitors have shown promising activity in neuroendocrine tumors.[114] All of these novel agents are considered investigational. Bronchial carcinoids are rare tumors, and therefore, data for the activity of novel agents is very limited.

**Carcinoid Syndrome**  Patients with the carcinoid syndrome require therapies for the different components of the syndrome. Mild diarrhea can be controlled by codeine phosphate, whereas more severe diarrhea will require somatostatin analog. Asthma can be treated with theophylline or the beta-2-adrenergic agonist albuteral.[115,116] For patients with severe flushing, the main treatment is octreotide.[115] Most

of the patients will be relieved initially, but higher doses of the octreotide will be necessary later on. Radiographic evidence of regression of the disease following octreotide is very rare in spite of the symptomatic improvement. The depot form of octreotide is the usual way for chronic treatment. Another somatostatin analog is lanreotide and appears to have similar efficacy as octreotide.[117] The long-acting preparation is given at a dose of 20 to 30 mg intramuscularly once every 14 days. Octreotide is well tolerated. However, about 30% of patients develop mild abdominal discomfort, nausea, bloating loose stools, fat malabsorption, and cholesterol gallstones.[118] Interferon-alpha (IFN-$\alpha$) has induced biochemical responses up to 40% to 50% of patients. It is not proven if combination of IFN-$\alpha$ and octreotide is superior to either agent alone. For carcinoid crisis, which may be fatal, intensive treatment is required. The blood pressure must be supported by plasma infusion and a continuous intravenous drip of octreotide at a rate of 50 to 150 $\mu$g/hour can be used.[40,41] Cyproheptadine, a serotonin antagonist, can be used in refractory diarrhea as well as in patients who develop anorexia and cachexia.[119]

## CONCLUSION

Bronchial carcinoids are rare tumors and are characterized by neuroendocrine differentiation and indolent clinical course. Histologic differentiation between typical and atypical carcinoids is mandatory because of their different biologic behaviour and prognosis. Typical carcinoids rarely metastasize and have an excellent prognosis even with involvement of regional lymph nodes. Atypical carcinoids commonly metastasize especially in cases of mediastinal lymph node involvement. Most patients with centrally located tumors have symptoms from the mass, such as cough, dyspnea, wheezing, hemoptysis, whereas patients with peripheral lesions are mostly asymptomatic. CT is the most useful radiographic test, and the diagnosis is confirmed either by bronchoscopic biopsy or by transthoracic needle aspiration. Surgery is the only treatment for cure. Surgical resection with a complete mediastinal lymph node dissection is the treatment of choice. The surgical technique aims to the removal of the whole tumor with negative margins and preservation of lung parenchyma. In same selected patients, endobronchial resection is feasible. Adjuvant chemotherapy and/or radiotherapy is indicated in resected atypical carcinoid tumors. For localized unresectable disease, combination of chemotherapy and radiotherapy should be considered. In metastatic disease, the treatment is only palliative. In isolated liver metastasis, surgical resection is recommended. Liver transplantion is still experimental. Liver chemoembolization has a role to play in symptomatic patients. Radiofrequency and cryoablation are used in small liver lesions. Radiation therapy is useful only in bone metastasis for pain relief. Chemotherapy is moderately effective. The combination cisplatin-etoposide is preferred in atypical carcinoids, whereas streptozotocin-fluorouracil regimen is given mainly to typical carcinoid tumors. In symptomatic patients,

Somatostatin analogs or interferon-$\alpha$ or the combination of both is indicated. In cases of bulky symptomatic disease, the combination of chemotherapy, somatostatin analogs and interferon-$\alpha$ might help. Targeted radiotherapy, angiogenesis inhibitors, and small molecule tyrosine kinase inhibitors are under investigation.
