Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or an infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the healthcare provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: http://www.lww.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 AM to 6 PM, EST.

*This book is dedicated to our families. There are no substitutes
for their patience, encouragement, love, and support.*

*To Helen, Ally, and Eric Pass*

*To Beverly and Mary-Michael Johnson
for their unwavering support and love*

*To Kazel Carbone, Daniel, Elizabeth,
Beatrice, and Anna Carbone*

*To Lynn, Laura, and Leslie Minna*

*To Silvia and to the memory of my parents,
Rosa and Luigi Scagliotti*

*To Kathy, Richard, Casey, Harmon, Katie,
Carolyn, and mostly, little Emilia Turrisi*

*The inspiration for this endeavor, as always, came from our patients,
students, and residents as well as from our colleagues and mentors.
These sources of incredible wisdom and diversity force us to grapple
with our limitations and help us to recognize
how we can best utilize our strengths.*

# CONTENTS

I

t is truly amazing how things can change in 4 years. Speculation about the use of molecular strategies has become reality in such a short time. The whole approach to the management of lung cancer at presentation and recurrence has changed. Genomic and proteomic profiles, dismissed as fishing expeditions in earlier times, are now used in validation studies, not only as prognostic, but also as predictive markers. Who would have thought that a rebirth of the idea of minimalist surgery involving sublobar resections for the management of primary lung cancer would become one of the prime questions for the disease, and that we are actually planning and performing trials, which compare surgical resection to stereotactic radiation therapy? Adjuvant studies for lung cancer have matured, and the use of preoperative therapy remains as controversial as ever. We now have to be precise in our histologic classifications of non–small cell lung cancer in order to define best treatment strategies and to avoid therapeutic complications. Finally, for the first time since 1987, a new internationally based staging system involving more than 100,000 individuals is ready for prime time and will serve as the foundation for future editions, which may incorporate clinical, pathologic, as well as molecular parameters.

This fourth edition of *Principles and Practice of Lung Cancer* is meant to serve as a foundation. Although we attempt to keep up with the newest concepts in all aspects of the disease, it is pretty clear that with the pace of discovery as it is, it will not have every detail available to the reader. The book is meant to educate about new concepts and point the reader to other sources of knowledge—including the web, journals, CME courses, and conferences—to expand on the basics presented in the book. The editors have realized also that the complexity of the disease is not geographically limited. Lung cancer is an international problem, and the book, therefore, has become an international production with the addition of Dr. Giorgio V. Scagliotti as an international editor. *Principles and Practice of Lung Cancer* has now officially become an international reference text as the textbook of the International Association for the Study of Lung Cancer (IASLC). We want this book to be available for readers in all parts of the world, just as the IASLC has attempted to bring together all international disciplines that are attempting to decrease the lethality of the disease. Just as we added mesothelioma and thymoma with the last edition, the editors felt that we should expand into other areas of thoracic malignancies, including mediastinal and carcinoid tumors.

The editors are again indebted to our publishing colleagues who helped produce this edition. Particular thanks are due to Keith Donnellan, Emilie Moyer, and Gil Rafanan for keeping things organized and on track, to Angela Panetta for marketing expertise, and to Senior Executive Editor Jonathan W. Pine, Jr.

**Alex A. Adjei, MD, PhD, FACP**

Professor and Chairman
Department of Medicine
Katherine Anne Gioia Chair in Cancer Medicine
Roswell Park Cancer Institute
Buffalo, New York

**Naveed Alam, MD, FRCSC**

Lecturer
Department of Surgery
University of Melbourne
Consultant Thoracic Surgeon
Department of Surgery
St. Vincent's Hospital
Melbourne, Australia

**Kathy S. Albain, MD**

Professor
Medicine, Hematology/Oncology
Loyola University Health System
Maywood, Illinois

**Nasser K. Altorki, MD**

Professor
Department of Cardiothoracic Surgery
Weill Cornell Medical College
Attending Surgeon
Department of Cardiothoracic Surgery
New York Presbyterian Hospital
New York, New York

**Christopher I. Amos, PhD**

Professor
Department of Epidemiology
The University of Texas MD Anderson Cancer Center
Houston, Texas

**Hisao Asamura, MD**

Chief
Division of Thoracic Surgery
National Cancer Center Hospital
Tokyo, Japan

**Paul Baas, MD**

Head
Department of Thoracic Oncology
The Netherlands Cancer Institute
Amsterdam, The Netherlands

**Joan E. Bailey-Wilson, PhD**

Senior Investigator and Co-Branch Chief
Inherited Disease Research Branch
National Human Genome Research Institute
National Institutes of Health
Baltimore, Maryland

**Jair Bar, MD, PhD**

Clinical Fellow
Division of Medical Oncology
The Ottawa Hospital Cancer Center
Ottawa, Canada

**José Belderbos, MD, PhD**

Radiation Oncologist
Department of Radiation Oncology
The Netherlands Cancer Institute–Antoni van Leeuwenhoek
    Hospital (NKI–AVL)
Amsterdam, The Netherlands

**Søren M. Bentzen, PhD, DSc**

Professor
Departments of Human Oncology, Medical Physics, and
    Biostatistics and Medical Informatics
School of Medicine and Public Health
University of Wisconsin
Director of Research and Education
Department of Human Oncology
Paul P. Carbone Comprehensive Cancer Center
Madison, Wisconsin

**Costas Bizekis, MD**

Assistant Professor
Department of Cardiothoracic Surgery
New York University
Attending Surgeon
Director of Esophageal Surgery
Department of Cardiothoracic Surgery
New York University Langone Medical Center
New York, New York

**Naama R. Bogot, MD**

Clinical Lecturer
Division of Cardiothoracic Radiology
Department of Radiology
University of Michigan Health System
Ann Arbor, Michigan

**Julie R. Brahmer, MD, MSc**

Assistant Professor
Department of Oncology
The Sidney Kimmel Comprehensive Cancer Center
Johns Hopkins University School of Medicine
Baltimore, Maryland

New York, New York

**FIGURE 6.1** SKY of a primary lung adenocarcinoma showing numerous numerical and structural chromosome changes. The classified image with the pseudocolors is shown in **(A)** and the inverted DAPI image is shown in **(B)**. The specimen was near triploid, with extra copies of chromosomes 1, 10, 12, 19, and 20 and deletions of segments of chromosomes 1, 4, 5, 6, and 11. Translocations were found involving chromosomes 1 and 13, 1 and 17, 3 and 20, 5 and 19, 5 and X, 6 and 22, 7, 15, and X, 18 and 21, 16 and 22, and 18 and 21. Two very small marker chromosomes were found carrying chromosome 2 sequences.

**FIGURE 6.2** **A:** SKY of the non–small cell lung cancer cell line Calu 3 showing multiple abnormalities and two copies of abnormal chromosome 17, derivatives from the translocations between chromosomes 17 and 2 and chromosomes 17 and 12. In addition, the chromosome 17 material identified by SKY in the long arm (q-arm) of these derivative chromosomes was larger than expected if that arm was normal. **B:** FISH analyses with a probe set including ERBB2 and CEP 17 sequences demonstrated that there was ERBB2 gene amplification in both derivatives (indicated by the *arrows*). In the FISH assays, ERBB2 probe is highlighted by *red color* and CEP 17 by *green color*.

**FIGURE 6.3** FISH of sections of non–small cell lung cancer with *CDKN2*-CEP9 **(A)**, *FHIT*-CEP3 **(B)**, *EGFR*-CEP7 **(C)** and *KRAS*-CEP12 **(D)** probe sets. Hybridization spots with the gene probes fluoresce in *red color* and with the centromere control probes fluoresce in *green color*. All the CEP probes and the *EGFR* probe are commercially available (Abbott Molecular). Probes for the genes *CDKN2*, *FHIT*, and *KRAS* were developed using BAC clones from the RP11 library. Panels **A** and **B** show loss of the gene sequences, respectively *CDKN2* and *FHIT*, compared with the controls used. Arrows indicate one of the nuclei with loss. Panels **C** and **D** show gene amplification, for *EGFR* and *KRAS*, respectively. It is noticeable that the clusters of *EGFR* signals are much more tightly packed than the clusters of *KRAS* signals. Arrows indicate one nucleus displaying gene amplification in each panel.

**FIGURE 6.4** SKY of a bronchial epithelium cell from a heavy smoking individual showing deletion of the short arm of chromosome 3, with breakpoint at 3p21.1. **A:** Inverted DAPI image. **B:** Karyotype, including both the inverted DAPI and the classified images.

**FIGURE 13.2** Noninvasive imaging reveals individual variation in mice treated with conditionally replicating oncolytic adenoviruses (CRAds). Examples of treatment results in mice treated with Ad5-Δ24RGD. The labels at left indicate the day of imaging, and each mouse is identified with a number. Mice *1*, *7*, and *12* had progressive disease; mice *5*, *9*, and *11* had stable disease; and mice *6*, *8*, and *10* achieved tumor response. (From Sarkioja M, Kanerva A, Salo J, et al. Noninvasive imaging for evaluation of the systemic delivery of capsid-modified adenoviruses in an orthotopic model of advanced lung cancer. *Cancer* 2006;107:1578–1588.)

**FIGURE 13.3** Increased survival and reduced tumor development in KrasLA2 mice crossed with integrin $\alpha$1-null mice. **A:** KrasLA2 mice crossed with the integrin $\alpha$1-null mice (KrasLA2/$\alpha$1KO) showed significantly increased survival compared to KrasLA2 mice crossed with integrin $\alpha$1 wild-type mice (KrasLA2/$\alpha$1WT). **B:** Top: Photograph of the lungs of KrasLA2/$\alpha$1WT and KrasLA2/$\alpha$1KO male mice sacrificed 120 days after birth. *Scale bar,* 5 mm. Bottom: Hematoxylin and eosin staining of lungs of KrasLA2/$\alpha$1WT and KrasLA2/$\alpha$1KO mice. Magnification, $\times$200. **C,D:** KrasLA2/$\alpha$1WT and KrasLA2/$\alpha$1KO mice were sacrificed 120 days after birth and tumor number (**C**) and size (**D**) were evaluated. The number of tumors visible on the lung surface was evaluated and expressed as average number of tumors per lung (**C**). Tumor diameter was measured with a caliper in 170 tumors from KrasLA2/$\alpha$1WT and 102 tumors from KrasLA2/$\alpha$1KO mice, and tumors were divided into three groups as indicated (**D**). (Data from Macias-Perez I, Borza C, Chen X, et al. Loss of integrin alpha1beta1 ameliorates Kras-induced lung cancer. *Cancer Res* 2008;68(15):6127–6135.)

**FIGURE 18.1** Squamous cell carcinoma. **A:** A syncytial cluster and rare single cells with high nuclear:cytoplasmic ratios and irregular nuclear borders (Diff-Quik, 40$\times$). **B:** Orangeophilic cells present as clusters and singly with hyperchromatic nuclei and relatively low nuclear:cytoplasmic ratios; anucleate squames are also present (Papanicolaou stain, 20$\times$). **C:** Cell block with intercellular bridges and keratinizing cells (cell block, hematoxylin and eosin [H&E], 40$\times$). **D:** Polygonal-, spindle-, and bizarre-shaped squamous cells (Papanicolaou stain, 40$\times$).

**FIGURE 18.2** Squamous cell carcinoma. **A:** Atypical tadpole-shaped cell with hyperchromatic nucleus (Papanicolaou stain, ThinPrep, 40$\times$) **B:** Marked acute inflammation and necrotic debris associated with squamous cells. *Inset:* malignant cells are also present (Papanicolaou stain, ThinPrep, 40$\times$ [*inset* 60$\times$]).

**FIGURE 18.3** Adenocarcinoma. **A:** Monolayer sheets of relatively monotonous epithelial cells with pale chromatin and no significant nuclear overlap suggestive of BAC features (Papanicolaou stain, 20×). **B:** Two-dimensional sheet with bland nuclei containing pinpoint nucleoli and nuclear grooves often associated with BAC differentiation (Papanicolaou stain, 60×). **C:** Acinar formation (Diff-Quik, 20×). **D:** Fibrovascular cores surrounded by epithelial cells suggestive of papillary features (Diff-Quik, 10×). **E:** Epithelial cells enveloping delicate core in carcinoma with papillary architecture (Diff-Quik, 60×). **F:** Columnar cells line a fibrovascular core consistent with papillary features (cell block, H&E section, 20×).

**FIGURE 18.4** Adenocarcinoma. **A:** Three-dimensional cluster with nuclear pleomorphism, conspicuous nucleoli, and vacuolated cytoplasm (Papanicolaou stain, ThinPrep 60×). **B:** Cluster of epithelial cells with fine chromatin, inconspicuous nucleoli, intranuclear grooves, and inclusion (Papanicolaou stain, 60×). **C:** Adenocarcinoma with mucin: abundant mucin with scattered clusters of epithelial cells (Diff-Quik, 4×). **D:** Adenocarcinoma with mucin: malignant epithelial cells with conspicuous nucleoli and relatively abundant cytoplasm associated with mucin. *Inset:* Cells have vacuolated cytoplasm and nuclear membrane irregularities (Diff-Quik, 40×; *inset:* Papanicolaou stain 60×).

**FIGURE 18.5** Typical carcinoid. **A:** Arborizing capillary network associated with monomorphic, loosely cohesive epithelial cells (touch prep, Diff-Quik, 20×). **B:** Loosely cohesive monotonous cells with eccentric nuclei and *plasmacytoid* features (touch prep, Diff-Quik, 40×). **C:** Bland cells with speckled chromatin (touch prep, H&E, 60×). **D:** Carcinoid with hyalinized stroma (cell block, H&E, 40×). **E,F:** Spindle cell carcinoid (Diff-Quik and Papanicolaou stains, 100×).

**FIGURE 18.6** Atypical carcinoid. **A:** Epithelial cells with mild pleomorphism (Diff-Quik, 60×). **B:** Loose cell clusters with speckled chromatin and rare mitotic figure (touch prep, H&E, 60×).

**FIGURE 18.7** Small cell carcinoma. **A:** Clusters and single cells with scant cytoplasm and focal nuclear molding (Diff-Quik, 40×). **B:** Small cell carcinoma with rosettes, nuclear molding, and crush/smearing artifact (Diff-Quik, 40×). **C:** Small cell carcinoma with a dirty background and scattered apoptotic cells (Diff-Quik, 60×). **D:** Cells with high nuclear:cytoplasmic ratios, fine chromatin, and inconspicuous nucleoli (Papanicolaou stain, 60×) **E:** Eosinophilic necrotic areas and malignant small cells (cell block, H&E, 40×) **F:** Rare cell clusters and scattered single cells in small cell carcinoma mimicking lymphoma (ThinPrep, Papanicolaou stain, 60×).

**FIGURE 18.8** **A:** Granuloma: enlarged spindle-shaped and epithelioid histiocytes (Diff-Quik, 40×). **B,C:** Granuloma with atypia. **B:** Atypical spindle-shaped and epithelioid histiocytes in clusters. *Inset:* areas with streaming pattern associated with reactive changes (Papanicolaou stain, bronchial brush, 40×; *inset* 40×). **C:** Histological section from same case demonstrating histiocytes and giant cells without evidence of malignancy (H&E, 40×). **D–F:** Aspergillus with atypical squamous cells. **D:** Sheet of atypical squamous cells in an inflammatory/dirty background. *Inset:* high magnification of rare single cells with dense cytoplasm and high nuclear: cytoplasmic ratio (Diff-Quik, 10×; *inset* 40×). **E:** Atypical cells with dense cytoplasm and high nuclear:cytoplasmic ratios associated with rare fungal form and neutrophils. *Inset:* silver stain demonstrating fungal organisms. (ThinPrep, Papanicolaou stain, 60×; *inset:* Gomori methanamine stain, 40×) **F:** Histological section demonstrating atypical squamous cells and intraluminal necrotic debris (H&E, 40×)

**FIGURE 18.9** Therapy-related changes. **A:** Markedly atypical cells (post-chemotherapy and stem cell transplant) (Diff-Quik- 20×). **B:** Cytomegaly with prominent nucleoli and relatively preserved nuclear:cytoplasmic ratios in an inflammatory background (postchemotherapy and stem cell transplant) (Diff-Quik, 60×). **C:** Atypical cells in cohesive cluster with vague *streaming pattern* without significant population of single atypical cells (postchemotherapy and stem cell transplant) (Papanicolaou stain, 60×). **D:** Multinucleated cell with prominent nucleoli and cytoplasmic vacuolization (postchemotherapy and stem cell transplant) (Papanicolaou stain, 60×).

**FIGURE 19.1** White-light (*left*) and autofluorescence bronchoscopy (*right*) images of a carcinoma in situ (CIS) lesion in the left main bronchus. No abnormality was seen under white-light examination. Under fluorescence imaging, the CIS lesion as an area of decreased fluorescence.
**FIGURE 19.2** Real-time dual simultaneous imaging of digital video autofluorescence bronchoscope images (SAFE 3000, Pentax, Japan). Previous biopsy site over right upper lobe carina with small scarring on conventional image (*left*), abnormal but nonsuspicious digital autofluorescence (*center*), and hybrid image to enhance contrast of the localization (*right*) with histology normal biopsy.

**FIGURE 20.1** Hierarchical clustering of genes commonly perturbed by smoking across intrathoracic and extrathoracic airway epithelium. **A:** Supervised hierarchical clustering of the expression of 45 genes induced by smoking in the bronchial airway that are present in both the nasal and buccal "leading edge subsets" in samples from smokers and nonsmokers. These represent genes upregulated by smoking in bronchial, nasal, and buccal epithelium. **B:** Supervised hierarchical clustering of the expression of 50 genes repressed by smoking in the bronchial airway that are present in the nasal leading edge subset in samples from smokers and nonsmokers. High expression (*red*), average expression (*white*), low expression (*blue*). (From Sridhar S, Schembri F, Zeskind J, et al. Smoking-induced gene expression changes in the bronchial airway are reflected in nasal and buccal epithelium. *BMC Genomics* 2008;9:259.)

**FIGURE 22.1** Dysplastic squamous cells in sputum. **A:** Mild dysplasia on the right consists of small rounded red cell with condensed nucleus and low N/C ratio. **B:** Moderately dysplastic orangophilic cell with large irregular nucleus and visible nucleolus. **C:** Carcinoma with large nucleus, high N/C ratio, and visible nucleolus. Large cell appears to be ingesting smaller one.

**FIGURE 22.2** Chronological sequences of cellular and molecular changes that may occur during central airway carcinogenesis. Although this sequence is rarely observed in a single individual, these changes are well described in the high-risk population and the sequence provides a useful way to conceptualize multistep carcinogenesis in the lung. At the cellular level, the earliest smoking-related changes may consist of mucous gland hyperplasia (shown), basal cell hyperplasia, or squamous metaplasia, which are not recognizably premalignant changes. The earliest cellular abnormalities that suggest premalignancy are squamous dysplastic changes that may range from mild-to-severe carcinoma in situ. The appearance of stromal invasion marks progression to fully established malignancy.

**FIGURE 22.3** Premalignant changes in the bronchial epithelium. Mucociliary cells are converted to squamous cells and may elicit and angiogenic stromal response shown at low magnification (**top**) and high magnification (**bottom**). Nuclear irregularity with clearly visible nucleoli is present in the cells surrounding the vascular loop in the lower frame.

**FIGURE 22.5** Chromosomal heterogeneity and instability. The high degree of chromosomal instability in lung carcinoma is reflected in numerous structural abnormalities that are visible through chromosomal imaging methods. Shown here is a spectral karyotype of a large cell undifferentiated carcinoma (H&E section). The SKY pseudocolor image of the karyotype provides a color code for each chromosome. In this figure, extra chromosomes 1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 12, 18, 19, 20, and 22 are visible. A reciprocal translocation, several nonreciprocal translocations, deletions, and marker chromosomes are also present. *FISH*, fluorescence in situ hybridization; *H&E*, hematoxylin and eosin; *SKY*, spectral karyotyping.

**FIGURE 22.6** Various morphological appearances of squamous carcinoma. Cytological examination reveals bright orange, irregularly cells with conspicuous nucleolus. Histology of squamous cancers visible in both biopsy and resection specimens are characterized by irregular nests of cells, often with central KP. Early stage resected tumors are frequently ulcerated as indicated by the area of mucosal roughening and erythema (*arrow*). The ulcer overlies white invasive tumor tissue that surrounds a black anthrocotic LN. *KP*, keratin pearl; *LN*, lymph node.

**FIGURE 22.7** Large cell undifferentiated lung carcinoma exhibits no differentiating features and is composed of large cells with coarsely clumped nuclei and prominent nucleoli. Mitoses are abundant.

**FIGURE 22.8** SCLC as found on cytology, histology, and IHC. On the upper left are clusters of small cells with scant cytoplasm, nuclear molding (*arrow*), and finely granular nuclei with inconspicuous nucleoli. Macrophage (*Mac*) provides size comparison. The frame on the upper right shows the histology of SCLC with closely packed cells with scanting cytoplasm with streaming nuclei. NCAM and TTF-1 stains are strongly positive along plasma membranes and in the nuclei. *Mac*, macrophage; *NCAM*, neural cell adhesion molecule; *TTF-1*, thyroid transcription factor-1.

**FIGURE 22.9** Histological comparison of various forms of neuroendocrine tumor of the lung. On the left is a classical carcinoid tumor with a ribbonlike pattern of growth. The central image shows more sheetlike tumor growth with occasional mitotic figures (see text). This tumor type also is defined by the presence of focal areas of necrosis. The figure on the right shows the high level of mitotic activity (*arrows*) and areas of necrosis that characterize LCNEC. *LCNEC*, large cell neuroendocrine carcinoma.

**FIGURE 22.10** Atypical adenomatous hyperplasia. On the left is a low magnification view showing the small overall size of the lesion. At higher magnification (*right*), a single layer of cuboidal cells covers the alveolar septae with minimal associated inflammation.

**FIGURE 22.11** Histology of various forms of BAC, BAC mixed with invasive carcinoma, and pure invasive carcinoma. **A:** Small nonmucinous BAC at low magnification without evidence of stromal invasion. **B:** High magnification of **A** shows lepidic spread of well-differentiated malignant pneumocytes along alveolar septae. **C:** Pink acellular mucus fills the alveoli of this mucinous BAC photographed at low magnification. **D:** At higher magnification of **C**, mucous vacuoles are present in apex of columnar cells lining alveoli. **E:** In this invasive adenocarcinoma, there is fibrosis at the center of a tumor that exhibits extension of tumor cells. **F:** High magnification of this tumor (**E**) reveals a sclerotic response to tumor cells with pink fibers aligned parallel to the elongated fibroblastic nuclei.

**FIGURE 22.12** Cytology of adenocarcinoma showing Papanicolaou-stained cluster of adenocarcinoma cells. These are large cells with high N/C ratio and prominent nucleoli (dark circular structure in nucleus [Nucl]). Under the microscope, the cell cluster has a three-dimensional structure and a mucus vacuole (Muc) is present at one margin of the cluster. *MC* indicates smaller mucociliary cell.

**FIGURE 22.14** Immunohistochemical stains of two morphologically similar BAC. Both tumors strongly express EGFR but on the upper tumor sufficient levels of HER-2/*neu* to be visible in immunostains. Activation of intracellular signaling through the mitogen-activated protein (MAP) kinase pathway as reflected in phosphorylated MAPK (pMAPk) immunostaining levels is strongest in the lower tumor. *BAC*, bronchioloalveolar carcinoma; *EGFR*, epidermal growth factor receptor; *H&E*, hematoxylin and eosin; *pMAPk*, phosphorylated MAPK.

**FIGURE 22.13** Immunohistochemical staining patterns for several biomarkers reported to be of diagnostic and prognostic significance in adenocarcinoma (see text). **A:** TTF-1, nuclear staining; **B:** CEA, cytoplasmic staining; **C:** p27, nuclear staining; **D:** p53; strong nuclear staining (mutant pattern); **E:** COX-2, cytoplasmic staining; **F:** MIB-1 (Ki67); nuclear staining.

**FIGURE 22.15** Histological sections showing similarity between epithelial type mesothelioma and adenocarcinoma.
**FIGURE 27.4** Transaxial **(A)** and coronal **(B)** PET images with a right lung tumor and accompanying adenopathy, either in the right hilar or mediastinal station. On CT, there is a suspect LN **(C)**, on integrated PET/CT, right paratracheal adenopathy is confirmed **(D)**.

**FIGURE 27.6** Patient with limited disease SCLC on conventional staging, with unexpected lesion in the left thigh on PET **(A,B)**, and on accompanying CT and PET/CT images **(C,D)**. Biopsy confirmed subcutaneous SCLC metastasis.

**FIGURE 27.5** PET/CT in a patient with squamous cell carcinoma of the left upper lobe. FDG uptake is present in the primary tumor and an adjacent hilar LN **(A,B)**. PET also shows a focal hot spot suspected for N2 disease in level 2L **(A,C** *arrow*). PET/CT fusion images project the hot spot in brown fat tissue **(D,E)**. At thoracotomy with LN, dissection confirmed the absence of mediastinal involvement (pT2N1).
**FIGURE 27.7** Right upper lobe large cell carcinoma **(A)** with right hilar and paratracheal adenopathy **(B)**, both clearly FDG avid on PET/CT fusion images. After induction chemotherapy, a major decrease in the metabolic activity of the primary tumor **(C)** and absence of FDG uptake in the mediastinum **(D)** is noted. Patient underwent complete resection, pT1N0.

**FIGURE 27.10** Patient with left upper lobe adenocarcinoma (not shown) and abnormal left adrenal gland on CT **(A)**, PET **(B)**, and fusion image **(C)**. Needle aspiration biopsy revealed normal cortical adrenal tissue **(D)**. No change in the adrenal gland during follow-up postlobectomy.

**FIGURE 27.8** Patient with a squamous cell carcinoma in the left hilum (cT3N3) with atelectasis of the left upper lobe resulting in a shift of heart and mediastinum **(A,B)**. For a better discrimination of atelectasis and tumor, PET/CT was performed to optimize radiation treatment planning **(C,D)**.

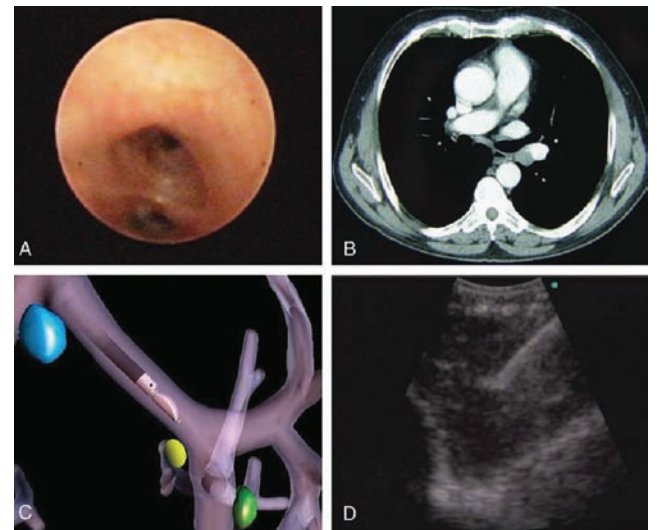

**FIGURE 28.3** **A:** Intraluminal view of the carina left upper and lower lobe. **B:** CT image of node station 10 L. **C:** Position of the bronchoscope. **D:** EBUS image of the puncture procedure, the needle is visible. (Photo courtesy of Felix Herth.)

**FIGURE 28.4** Optical coherence tomography (OCT) of an intraluminal squamous cell cancer in the tracheal wall. **A:** Bronchoscopic image showing nodular tumor (*T*) and normal tracheal wall (*W*). **B:** OCT showing tumor (*T*) infiltrating beyond the cartilage. **C:** Normal OCT. (From Tsuboi M, Hayashi A, Ikeda N, et al. Optical coherence tomography in the diagnosis of bronchial lesions. *Lung Cancer* 2005;49:387–394; courtesy of N. Ikeda, Mita Hospital, Japan.)

**FIGURE 40.1** Views from a planning CT scan. Note the flat tabletop used for radiation therapy imaging, the absence of the patient's arms as they are above their head to avoid being radiated during treatment, and the foam mold surrounding the patient to assist with immobilization. The gross tumor volume (*red*) and planning target volume (*pink*) are shown.

**FIGURE 40.3** Dose-limiting normal tissues to avoid and/or limit radiation dose. Target volume delineation is performed on the entire 3D (or 4D) data set. Right lung: *blue*; left lung: *green*; heart: *pink*; esophagus: *green*; spinal cord: *brown*; main airways: *yellow*. The target volumes can be seen in Figure 40.1.

**FIGURE 40.4** PET images overlaid on the CT scan from a treatment planning PET-CT simulation session. For radiation oncology, a critical step is the delineation of the tumor boundaries that are necessary for determining the shape of the radiation treatment beams.

**FIGURE 40.5** The beam arrangement for an intensity-modulated radiotherapy (IMRT) treatment of lung cancer.

**FIGURE 40.6** The dose distribution for an intensity-modulated radiotherapy (IMRT) treatment of lung cancer.

**FIGURE 42.1** Treatment portals (*in yellow*) for an anterior field used in elective nodal irradiation **(A)** and involved-field radiotherapy **(B)** in the same patient. Uninvolved nodal regions, including the contralateral upper mediastinum, are routinely treated with the first approach, leading to higher doses to the contralateral lung and esophagus.

**FIGURE 42.2** Planning target volumes (*red*) and corresponding treatment portals (*yellow*) for a patient with stage III NSCLC. **(A)** is derived from a single 3DCT scan with the addition of standard planning margins,[98] **(B)** is an internal target volume (ITV) encompassing all motion observed on 4DCT scan acquired during quiet respiration, and **(C)** is the ITV from motion in three phases at end inspiration for audio-coached gated radiotherapy. The amount of right lung tissue outside the portal is maximal with approach **C**.

**FIGURE 43.1** Typical beam arrangement for SBRT for primary early stage lung cancer. Ten nonopposing and noncoplanar beams coming from various incident directions converge on the demarcated tumor target.

**FIGURE 43.2** Dose–volume histogram for an optimized dosimetry plan using the beam arrangements from Figure 43.1. The *red line* is for the PTV, the *yellow* for the proximal bronchial tree, the *green* for the spinal cord, the *dark blue* for the esophagus, the *purple* for the heart, the *orange* for the total lung minus GTV, and the *light blue* for the proximal trachea.

**FIGURE 44.13** Radiation pneumonitis: local dose versus [18F]2-fluoro-2-deoxyglucose (FDG) uptake response in irradiated lung.[14] Radiation dose and FDG positron emission tomography (PET) response are illustrated for examples of high (case 1) and low (case 2) response. Case 1: **(A)** isodose distribution for patient with esophageal cancer shown overlaying single transaxial section from treatment planning computed tomography (CT scan; **(B)** corresponding restaging FDG–PET scan (high response), after image registration, shown overlaying transaxial treatment planning CT scan. The pulmonary region with high FDG uptake is indicated by horizontal arrows. Case 2: **(C)** isodose distribution shown overlaying transaxial section from treatment planning CT scan; **(D)** corresponding restaging FDG–PET scan shown overlaying transaxial treatment planning CT scan. The pulmonary region of high dose and its corresponding PET region are indicated by diagonal arrows. These two cases represent the range of FDG uptake response found in all 36 cases evaluated.[14] (From Guerrero T, Johnson V, Hart J, et al. Radiation pneumonitis: local dose versus [18F]-fluorodeoxyglucose uptake response in irradiated lung. *Int J Radiat Oncol Biol Phys* 2007 Jul 15;68[4]:1030–1035.)

A

**FIGURE 56.1** T4 disease with multimodality treatment including surgery. CT and PET/CT images of a patient with pathologically proven T4 disease at parasternal mediastinoscopy/thoracoscopy prior to induction treatment **(A)** and following an induction therapy **(B)** with induction chemotherapy (three cycles cisplatin and paclitaxel) followed by induction chemoradiotherapy (one cycle cisplatin and vinorelbine) with 45 Gy hyperfractionated accelerated radiotherapy (2 × 1.5 Gy bid). *(continued)*
**FIGURE 56.2** N3 disease with multimodality treatment including surgery. PET/CT images of a patient with mediastinoscopically proven N3 disease prior to induction treatment **(A)** and following an induction treatment **(B)** with chemotherapy (three cycles cisplatin and paclitaxel) followed by induction chemoradiotherapy (one cycle cisplatin and vinorelbine) with 45 Gy hyperfractionated accelerated radiotherapy (2 $\times$ 1.5 Gy bid).

| Structure | Coverage [%] / [%] | Volume [cm³] | Min [%] | Max [%] | Mean [%] | Modal [%] | Median [%] | STD |
|---|---|---|---|---|---|---|---|---|
| CTV | 100.0 / 99.9 | 248.8 | 88.0 | 101.4 | 99.0 | 99.8 | 99.3 | 1.36 |
| Esophagus | 100.0 / 99.4 | 28.9 | 4.0 | 99.1 | 53.9 | 97.8 | 69.2 | 36.98 |
| Spinal Cord | 100.0 / 98.5 | 48.8 | 0.0 | 70.3 | 18.3 | 0.0 | 4.7 | 23.84 |
| Total lung | 100.0 / 100.0 | 3620.5 | 0.6 | 101.4 | 25.9 | 2.3 | 15.2 | 27.79 |

**FIGURE 59.1** **A:** Anterior and oblique digital reconstructed radiograph (DRR). The **left panel** shows anterior port with saw-toothed edges of a multileaf collimator portal, with the physician-defined target outlined *in red*. The **right panel** displays an oblique portal *in red-pink* color wash, demonstrating the facility of avoiding the spinal cord. **B:** Dose-volume histogram (DVH): note the uniform dose coverage to the defined target (tumor) by the *red line*; the marked reduction in dose to the esophagus dose (*orange*) showing about 50% dose to only two thirds the esophageal volume, and the relatively lesser volumes of total lung irradiated. **C:** Dose distribution: these show isodose distributions in the (**left**) axial, (**middle**) coronal, and (**right**) sagittal plane. This patient was treated with four wedged fields for the entirety of the course without interruption and demonstrated a complete response by the second cycle of chemotherapy despite presenting with superior vena cava syndrome.

**FIGURE 65.1** Reactive mesothelium. Superficial biopsy of the parietal pleura. There is no sign of infiltration, and a reactive mesothelial proliferation is the preferred diagnosis.

**FIGURE 65.2** Deep biopsy showing invasion indicating MM. Deep biopsy from the parietal pleura in the same patient. Tumor cells show infiltration of the muscular layer and fat. The diagnosis of mesothelioma can now be confirmed.

**FIGURE 67.1** Typical carcinoid: endobronchial tumor of the upper lobe of the left lung in a 35-year-old woman. Well-differentiated neuroendocrine tumor without atypia, necrosis, or mitosis (hematoxylin and eosin [H&E] ×40). # Lung Cancer Epidemiology

# The Etiology and Epidemiology of Lung Cancer

Lung cancer is the leading cause of cancer mortality in men and women in the United States, accounting for an estimated 161,840 deaths in 2008. Whereas lung cancer accounted for only 3% of all cancer deaths in women in 1950, in the year 2008 it accounted for an estimated 28% of cancer deaths. In 1990, the average annual mortality rate per 100,000 (standardized to the U.S. 2000 population) was 90.6 in men and 37.6 in women compared to 70.3 in men and 40.9 in women in 2004. Lung cancer incidence in men peaked in the 1980s and subsequently decreased after 1992 by 2.3% per year; mortality decreased 1.8% per year after having peaked around 1990. The age-adjusted lung cancer death rates in the United States surpassed those of breast cancer in white women in 1986 and in black women in 1990. It was estimated that in the year 2008, 30,550 more women will die of lung cancer (71,030) than of breast cancer (40,480).[1]

The incidence patterns, because of persistently poor survival rates, closely parallel the mortality rates. From 1992 to 2000, the average annual age-adjusted lung cancer incidence per 100,000 in men was 82.4, which was exceeded only by prostate cancer (180.6); the average annual lung cancer incidence in women was 49.4, which was second to that of breast cancer (132.5). In 2008, it was estimated that there were 215,020 new lung cancer cases diagnosed in the United States, and approximately 1.35 million cases were diagnosed worldwide with 1.18 million deaths in 2002.[2]

Lung cancer incidence and mortality patterns follow, after a latency interval of 20 or more years, the temporal patterns of cigarette smoking. In older men in the United States, lung cancer has displaced coronary heart disease as the leading cause of excess mortality among smokers. The risk of dying from lung cancer is associated with age of initiation and duration of cigarette smoking, and with the number and tar concentration of cigarettes smoked each day or as a regular pattern. The cumulative probability of lung cancer in the general population for individuals up to 74 years of age is 10% to 15% in those who smoke one or more packs of cigarettes per day. Exposure to other environmental and occupational respiratory carcinogens may be interactive with cigarette smoking and may influence trends of lung cancer incidence and mortality.[3]

## DESCRIPTIVE EPIDEMIOLOGY

**Age and Gender**   Whereas lung cancer incidence in men in the United States declined after peaking in the mid-1980s, the pattern in women differed significantly. In women, lung cancer incidence more than doubled between 1975 and 2000. Age-adjusted incidence in women increased on average by 4.1% per year between 1973 and 1990, but from 1990 to 2000, the average annual increase was only 0.2% (Fig. 1.1).

Among men and women, the rates declined in the past 10 years particularly among those younger than the age of 60 but continued to increase among those older than the age of 70. Only 5% to 10% of lung cancer cases are diagnosed in individuals younger than 50 years of age. Epidemiologic studies of lung cancer in young adults emphasize the predominance of adenocarcinomas and the importance of a positive family history. The current smoking prevalence and magnitude of estimates of relative risk (RR) caused by the average intensity and duration of smoking in women in the United States appear to be converging on the patterns in similarly exposed and aged men. Among whites, the male to female age-standardized lung cancer incidence ratio of rates is about 1:6, or 60% higher in men.[4,5]

Compared with women, men generally began smoking cigarettes at an earlier age, smoked more cigarettes per day and for a longer duration, inhaled more deeply, and consumed cigarettes with higher tar content. With increasing prevalence and duration of tobacco smoking in women after World War II, lung cancer mortality increased substantially in North America and Western Europe.

Several case-control studies have suggested that female smokers have a higher RR of lung cancer than male smokers, after adjusting for age and average daily intensity of smoking
**FIGURE 1.1** Annual age-adjusted cancer incidence rates for selected cancers by sex, United States, 1975 to 2004. Rates are age-adjusted to the 2000 U.S. standard population and adjusted for delays in reporting. Source: Surveillance, Epidemiology, and End Results (SEER) Program (http://www.seer.cancer.gov). Cancer statistics, 2008. *CA Cancer J Clin* 2008;58:71–96.)

exposure.[6–8] The case-control design and the method of estimation of odds ratios in women may have been susceptible to recall bias, underreporting of amount smoked by the cases, and differences in baseline confounding risk factors for lung cancer between male and female nonsmoking controls (e.g., occupational risk factors, nutritional risk factors, unmeasured exposure to environmental tobacco smoke, history of non-neoplastic lung diseases, etc.). Prospective studies are required to derive unconfounded incidence measures of absolute or attributable risk that may be compared in smoking and nonsmoking men and women. In an analysis of former and current smokers in the Nurses' Health Study of women and the Health Professionals Follow-up Study in men, Bain et al.[9] reported that the hazard ratio in women ever smokers compared with men was 1.11 (95% confidence interval, 0.95 to 1.31). The analytic model controlled for the number of cigarettes smoked per day, age at starting smoking, and time since stopping smoking. Freedman et al.[10] compared the age-standardized incidence rates of lung cancer in men and women participating in the National Institutes of Health American Association of Retired Persons (AARP) cohort. In current smokers, in a model adjusted for lifetime smoking exposure, the hazard ratio was 0.9 (95% confidence interval, 0.8 to 1.0) for women compared with men. Both studies concluded that women were not more susceptible than men to the carcinogenic effects of cigarette smoking. Future studies should continue to monitor lung cancer incidence in women and men who have never smoked.

## Race and Ethnicity

In the United States, the risk of lung cancer in black men has been about 50% higher than that in white men in the past 10 to 15 years, but the annual rate of decline after 1990 in black men (–2.5%) was about equal to that in white men (–2.3%) (Table 1.1). Among black men, lung cancer mortality was the second leading cause of death, ranking below coronary heart disease. The excess mortality from lung cancer among black men, compared with white men, was greatest for the age interval of 35 to 64 years. Cohorts of white men born before 1900 had higher (50%) age-specific rates than black men; however, this pattern reversed after 1915.

In the United States from 1975 to 1990, the age-adjusted lung cancer incidence in black women was 10% to 20% higher than that in white women; in the past 10 years, the average annual rate in black women (39.3 per 100,000) was slightly less than that in white women (40.9 per 100,000). After 1990, the incidence rates have continued to increase at an average annual rate of 0.7% to 0.8% for black and white women.

The Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute enables a comparison

of risks among various racial and ethnic groups in the United States (Table 1.2). The lowest age-adjusted lung cancer incidence rates in men and women, 50% to 70% of the rates among non-Hispanic whites, were registered for Native Americans, Hispanics, and Asian-Pacific Islanders; the highest rates were reported in blacks, native Hawaiians, and non-Hispanic whites. The ratio of male to female incidence rates reflected elevated risks in men that were 2.5 to 3.5 times the rates in women from the various racial and ethnic groups. Although the age-adjusted lung cancer incidence rates varied substantially by ethnicity, the percentage of all cancer deaths attributed to lung cancer in men and women combined was as high in Native Americans (27.7%) as in African Americans (26.1%). Lung cancer is the leading cause of cancer mortality among Hispanic men and the second leading cause among Hispanic women.

It is generally assumed that the differences in rates of lung cancer can be partially explained by different lifetime patterns of cigarette smoking. Compared with non-Hispanic white men, a higher percentage of non-Hispanic blacks were current smokers, smoked cigarettes with greater yield of tar and nicotine, and preferred to smoke mentholated cigarettes, which may stimulate deeper inhalation of cigarette smoke. However, in surveys of current smokers, black men were reported to smoke fewer cigarettes per day than white men. Molecular and biochemical studies, when controlling for differences in smoking habits, described higher serum cotinine levels and 4-aminobiphenyl-hemoglobin adduct levels in black smokers when compared with white smokers, suggesting that there may also be differences in susceptibility between blacks and whites as expressed in the metabolism of tobacco smoke.[11–14]

**Socioeconomic Status** Various studies have reported an inverse association between lung cancer mortality and socioeconomic status (Table 1.3). A twofold gradient in mortality was observed between low and high social class, as measured by occupation, income, or education. Smoking patterns accounted for part of the differential risk by social class, with smoking prevalence increased among blue-collar workers and among those with lower levels of education. Socioeconomic status may also serve as a surrogate measure for other risk factors such as occupation, diet, and ambient air pollutants, and may influence the quality, access, and utilization of healthcare services.[15,16]

**International Patterns** Global lung cancer incidence is increasing at a rate of 0.5% per year, and as a consequence, lung cancer is the leading cause of cancer incidence and mortality in European countries, accounting for about 21% of all cancer cases in men.[17–20] In less industrialized, developing countries, the proportion of all cancer deaths attributed to lung cancer is about 15%. In most parts of the world, rates were higher in urban than in rural areas and two to six times higher in men than in women. The areas with the highest incidence and mortality were in Eastern Europe, North America, Australia and New Zealand, and South America. The rates in China, Japan, and Southeast Asia were moderately high, whereas the lowest rates were observed in southern Asia, and in India and Pakistan, as well as in most countries in sub-Saharan Africa. Worldwide, in the year 2000, it was estimated that 47% to 52% of men and 10% to 12% of women smoked tobacco. In the United States, 25% of non-Hispanic white men and 23% of non-Hispanic white women were smoking tobacco. The prevalence of smoking men and women, the

types of cigarettes and amounts smoked, ages at initiation and duration of smoking exposure, and proportions of heavy smokers in the population, were important determinants of geocultural variations in lung cancer incidence. Recent trends in lung cancer mortality in men exhibited declining rates in all European countries except in France, Greece, Portugal, and Spain. Cigarette smoking in China has followed a pattern similar to that among adults in the United States although the significant pattern of increase, particularly among men, occurred 40 years later. Of the Chinese deaths attributed to tobacco, 15% were due to lung cancer and 45% to chronic obstructive lung disease. The relatively elevated rates of adenocarcinoma of the lung among Chinese women in China and Singapore were attributed to exposures to smoking tobacco and to environmental pollutants other than smoking tobacco (e.g., fossil fuel combustion products and cooking oils in the home).[21,22]

## LIFESTYLE AND ENVIRONMENTAL RISK FACTORS

**Tobacco**    The causal relationship between tobacco smoking and lung cancer was established by epidemiologic studies conducted in the 1950s and 1960s. The complexity of tobacco smoke, with over 3000 different chemicals, has made it difficult to identify the contribution of more than 50 putative carcinogenic agents. The carcinogens in tobacco smoke include the polynuclear aromatic hydrocarbons (PAHs), N-nitrosamines, aromatic amines, other organic (e.g., benzene, acrylonitrile) and inorganic (e.g., arsenic, acetaldehyde) compounds, and polonium-210. The composition of the smoke depends on the ambient conditions of smoking, the blend of tobacco leaf, filtration, additives, and paper wrapping. Tobacco smoke produced by the tobaccos in pipes and cigars is both harsher and more alkaline than that produced by cigarettes. Most of the compounds in tobacco are produced in an oxygen-deficient, hydrogen-rich environment, arising from pyrolysis

and distillation, in the region immediately behind the burning tip of the cigarette. The nicotine concentration is addictive and toxic but not carcinogenic.[23,24]

As mainstream cigarette smoke emerges from the cigarette, it has approximately $10^9$ to $10^{10}$ particles per mL. The aerodynamic diameters of the particles, ranging in size from 0.1 to 1.0 $\mu$m, determine the sites of deposition in the airways and alveolar regions of the lung. The fraction of smoke retained varies markedly with the pattern of inhalation. The chemical analysis of tobacco smoke is separated into particulate or "tar," and gaseous phases. Filter tips of cellulose acetate remove volatile nitrosamines and phenols selectively. The neutral fraction of the particulate phase contains potentially important tumor initiators such as the PAHs.[25]

In 1964, the first surgeon general's report on smoking summarized existing evidence and declared cigarette smoking to be the major cause of lung cancer among American men.[26] In the ensuing 30 years, epidemiologic studies have established that there were increasing risks in women and underscored the relationships with onset, duration, intensity, and cessation of smoking. Prospective studies demonstrated a rising trend in lung cancer death rates with increasing average amounts smoked per day in current smokers. The initial emphasis of epidemiologic studies of lung cancer and smoking was on men who, in almost all countries, began smoking earlier, consumed greater quantities of tobacco, and exhibited higher RRs than women.[27–29]

In the past 20 years, the prevalence of cigarette smoking in many countries, including the United States, has increased significantly among women; concomitantly, changes in smoking practices have been accompanied by increasing relative and attributable risks for lung cancer.[30–32] In a follow-up study of approximately 600,000 women conducted in 1980s by the American Cancer Society, the RR of dying of lung cancer in current smokers was 12.7; for those who smoked 30 or more cigarettes per day, the RR was increased 22.3 times compared with the never-smoker. In 1985, cigarette smoking accounted for an estimated 82% of lung cancer deaths, or 31,600 deaths.[33] The International

Agency for Research on Cancer (IARC) estimated that the smoking-attributable fraction of lung cancer deaths occurring in the United States and in England and Wales was 92% in men and 78% in women.[25] In 2001, the U.S. Health Interview Survey estimated that 46.2 million adults were current smokers and that 44.7 million adults were former smokers. Current smoking prevalence was highest among persons aged 18 to 24 years (26.9%), and among those aged 25 to 44 years (25.8%), and lowest among those aged older than 65 years (10.1%). From 2000 to 2001, current smoking prevalence, for the first time, was similar in non-Hispanic white (25.4%) and black (27.7%) men; in contrast, the prevalence in non-Hispanic black women (17.9%) was less than that in non-Hispanic white women (22.8%).[32]

Lower tar content and the use of filters are factors that may result in reduced lung cancer risks in those who smoke. In the earlier American Cancer Society (ACS) Twenty-five–State Study, men who smoked low-tar (<22 mg) cigarettes experienced 20% lower risk of dying of lung cancer when compared with men who continued to smoke high-tar cigarettes. The excess lung cancer risk for current smokers was directly proportional to the estimated milligrams of tar consumed daily. In the more recent ACS Fifty-State Study, Garfinkel and Stellman concluded that doubling the cigarette tar yield would result in a 40% increase in the RR of dying of lung cancer, independently of the amount smoked or depth of inhalation. The Federal Trade Commission estimated that the current average sales-weighted tar content of cigarettes manufactured in the United States was about 12 to 13 mg of tar per cigarette, compared with nearly 40 mg in the early 1950s. Lifelong filter cigarette smokers have experienced 20% to 40% lower risk of lung cancer than lifelong nonfilter smokers, after adjusting for differences in the amount smoked. Presumably, larger reductions in risk have not been observed because of alternations in smoking behavior in response to low-nicotine yield of manufactured cigarettes. Namely, it has been shown that in maintaining addiction, the smoker will inhale larger volumes of mainstream smoke and at more frequent intervals.[34-37]

Although these studies suggested that switching to filtered or low-tar cigarettes may modestly reduce the risk of lung cancer, the more significant reduction in risk would be derived from cessation of smoking. Whereas approximately 25% of smoking adults in the United States continue to smoke, an additional 40% to 50% have become former smokers. The RR of lung cancer among ex-smokers decreases significantly after 5 years of smoking cessation. In the initial 1 to 4 years after quitting smoking, however, the RR of lung cancer among ex-smokers may appear to be higher than among current smokers, presumably because a proportion of individuals may have stopped smoking because of illness or premonitory symptoms of lung cancer.[38,39]

It has been suggested that the risk of lung cancer in former smokers will approximate but never equal that of lifelong nonsmokers. The baseline risk of lung cancer in lifelong nonsmokers increases in relation to age raised to the fourth or fifth power. In the British Physicians Study, Doll and Peto[38] showed that the incidence of lung cancer in cigarette smokers increased approximately in proportion to the fourth power of duration of

smoking, and was multiplicative with the previously described exponential increase with age among never-smokers. The percentage reduction in risk after quitting depended on the prior duration and average amount smoked each day, being more readily demonstrable among lighter smokers and smokers of lesser duration or those who quit at a younger age. Lung cancer results from a multistep process in which persistent genetic lesions accumulate at specific chromosomal loci. Most current or former smokers, in contrast to never-smokers, exhibit loss of heterozygosity at multiple allelic sites (e.g., 3p14, 9p21, p16, p53) in both normal and metaplastic or dysplastic bronchial epithelium.[40,41]

Pipe and cigar smoking have been linked to lung cancer, particularly squamous cell and small cell carcinomas, but the estimated RRs, compared with people who never smoked, who are assigned an RR of 1.0, were considerably lower than the risks reported among cigarette smokers; the risks among exclusively pipe or cigar smokers in the United States or Europe have been estimated to range from 2.0 to 9.0. In countries such as Sweden, Switzerland, and Holland, where pipe or cigar smoking was nearly as common as cigarette smoking, the RRs of lung cancer, when controlling for cumulative exposure levels, were equally high for all forms of smoked tobacco. Differences in the manner in which pipes and cigars were smoked in different countries, (i.e., depth of inhalation or average daily or cumulative amount smoked) may provide an explanation for differences in the estimated risks. Cigars are products made of tobacco, wrapped in tobacco leaves rather than in paper. Cigars smoked in Europe weigh 2 to 8 g and are similar to American "small cigars." Cigarillos are smaller than cigars weighing 1.5 to 3 g and are described as "little cigars" in the United States. Risks of lung cancer also varied with the type of tobacco used. Dark tobaccos were associated with greater risk of lung cancer than light tobaccos, and with formation of higher levels of 4-aminobiphenyl-hemoglobin adducts.[42-45]

**Environmental Tobacco Smoke** Environmental tobacco smoke (ETS) is comprised of sidestream smoke (about 80% released from burning tobacco in between puffs), and from the exhaled smoke (about 20% of the smoke). The smoke that the smoker inhales is known as mainstream smoke. Other minor contributors to ETS include the smoke that escapes during puffing from the burning cone, and gaseous components that diffuse through the cigarette paper. These components are diluted by the ambient air and when inhaled, in particular by nonsmokers, are referred to as "passive" or "involuntary" smoking. ETS contains various toxic agents, including mutagens and carcinogens, which, for some chemicals (e.g., nitrosamines, 4-aminobiphenyl, benzo[a]pyrene), have been measured at higher concentrations than in mainstream smoke. Estimates of ETS exposure, based on serum or urinary measurements of cotinine, the metabolite of nicotine, suggest that involuntary smokers absorb about 0.5% to 1% of the nicotine that active smokers absorb, or smoke the equivalent of about one-half cigarette a day. Studies of 4-aminobiphenyl-hemoglobin adduct levels indicate that passive smokers have approximately 14% of the concentration of active smokers.[46]

Many scientific consensus committees have concluded that exposure to ETS causes lung cancer in humans. Table 1.4 lists the RRs of lung cancer among nonsmoking women based on a review of epidemiologic studies in various countries, which have evaluated dose–response trends.[47–64] The risks increased with amounts smoked by husbands, with about 30% to 150% increases in RR experienced in general among those women most heavily exposed. A weighted analysis of 37 published epidemiological studies resulted in the conclusion that there was an elevated risk of 24% (95% confidence interval [CI], 13% to 36%) among nonsmoking wives of *smoking* husbands, when compared with nonsmoking wives of *nonsmoking* husbands. Workplace exposures to ETS are measured with less precision than spousal exposures; however, some studies have suggested that there is a dose–response relationship when combining workplace and spousal sources of ETS. It has been suggested that when using biological markers of nicotine exposure in studies of ETS and lung cancer, about 5% of female respondents, who were in fact smokers, may have reported that they were nonsmokers. Correcting for this bias, however, would result in an adjusted RR in nonsmoking women who were living with smokers of about 1.15 to 1.20. The report of the National Research Council concluded that about 20% of lung cancers occurring in nonsmoking women and men, or 3000 cases per year, may be attributable to exposure to ETS; in the context of lung cancer cases diagnosed each year in smokers and nonsmokers, 2% to 3% may be attributable to ETS.[65,66]

**Air Pollution**   Pollutants in the urban air other than from tobacco have been investigated as potential causal agents in the epidemic rise of lung cancer in industrialized nations. The products of fossil fuel combustion, principally polycyclic hydrocarbons, have been of particular concern. Other sources of ambient air pollution have been motor vehicle and diesel engine exhausts, power plants, and industrial and residential emissions. The ratio of urban to rural age-adjusted lung cancer mortality rates in many industrialized nations have varied between 1.1 and 2.0. It has been suggested that the net attributable risk effect of protracted exposure to urban air pollutants in men with average smoking habits would be 10 cases of lung cancer per 100,000 per year. In most countries, however, a major fraction (i.e., 80% or greater) would be attributable to cigarette smoking, and the independent association with urban residence, or the "urban factor," could not be assessed without controlling for the confounding effect of differences in smoking practices, or exposures to environmental tobacco smoke, between urban and rural residents. In addition, the urban factor has yet to be defined, but is undoubtedly a complex mixture of interacting chemical compounds and elements that vary by geographic area and over time. Exposure to combustion-source ambient air pollution has been associated with declining pulmonary function, increased rates of hospitalization for respiratory illnesses, and increased rates of cardiopulmonary diseases mortality.[67–69]

Evidence in support of the potential association of air pollution with lung cancer may be provided by occupational studies of workers exposed to combustion products from fos-

sil fuels. Workers exposed to emissions from retort coal gas plants manifested smoking-adjusted RR of lung cancer that was approximately twice that in unexposed workers. Roofers exposed to coal tar fumes while working outdoors had an approximately 50% increase in lung cancer risk after 20 years of exposure, and 150% increase after 40 years.[70,71]

Benzo(a)pyrene has been used as a surrogate index of ambient urban air exposure produced by fossil fuel combustion and correlated with lung cancer mortality rates. However, putative carcinogenic agents present in ambient urban air may include inorganic particles or fibers (e.g., arsenic, asbestos, chromium, nickel, uranium); radionuclides (e.g., $^{210}$Pb, $^{212}$Pb, $^{222}$Ra); and organic gaseous and particulate combustion products (e.g., dimethylnitrosamine, benzene, benzo[a]pyrene, 1,2-benzanthracene). In a longitudinal study by the ACS, age-, occupational-, and smoking-standardized rates for lung cancer were computed according to residence. Minimal differences in mortality were observed between urban and rural residential areas, or among cities categorized by indices of pollution.[72] The World Health Organization (WHO) IARC has declared diesel engine exhaust a "probable carcinogen." In studies of railroad workers exposed to diesel exhaust, Garshick et al. described a 40% increase in the smoking-adjusted RR of lung cancer.[73,74]

In a rural area in Yunan Province, China, an excess risk of lung cancer among men and women was attributed to indoor pollution because of burning soft, "smoky" coal in unvented firepits inside the home. Replacing the firepits with stoves vented with chimneys was reported to reduce lung cancer incidence by about 40% to 45%.[75] In Shanghai, the elevated risk of lung cancer was hypothesized to be a result of prolonged exposure to oil vapors, particularly from rapeseed oil that was used in high-temperature wok cooking. Condensates of the volatile emissions from rapeseed and soybean oil have been found to be mutagenic. In urban Shenyang in northeastern China, indoor pollution from coal-burning heating devices gave rise to an age-, education-, and tobacco smoking-adjusted RR of 2.3 for lung cancer in the highest exposure group.[76–78]

**Indoor Radon**    Radon ($^{222}$Ra), with a half-life of 3.8 days, is an inert, radioactive, colorless, and odorless gas at usual environmental temperatures that can percolate through the earth's crust and accumulate in residential dwellings. At sufficiently high concentrations, radon and its $\alpha$-particle–emitting decay products, polonium-214 and polonium-218, have been shown to cause lung cancer in cigarette smoking and nonsmoking uranium, tin, and iron-ore miners. These observations have been replicated by conducting experimental studies in rats.[79] Indoor radon exposure accounts for about 50% to 80% of the total radiation received on average in the United States. It has been estimated, based on extrapolations from high-risk miner studies, that indoor radon may cause between 6000 and 36,000 lung cancer deaths per year in the United States. Joint exposures to tobacco smoke and radon gas have been interpreted to yield risks of lung cancer that were greater than linear and additive and approximated multiplicative or log linear effects.[80–82]

Case-control studies of lung cancer have been conducted in various countries based on estimated lifetime exposures to residential radon and tobacco smoke. Axelson et al.[83] noted an increased risk of lung cancer among persons living in stone compared to wood houses in Sweden. In a later study by Pershagen et al.,[84] it was concluded that the smoking-adjusted risk of lung cancer increased in relation to the cumulative and time-weighted exposure to radon. The RR was 1.3 (95% CI, 1.1 to 1.6) for average radon concentrations, over a period of about 30 years, of 3.8 to 10.8 pCi per liter; for exposure in excess of 10.8 pCi/L, the RR was 1.8 (95% CI, 1.1 to 2.9). Moreover, there was evidence that the joint effect of radon exposure and tobacco smoking was multiplicative rather than additive. In a study conducted in New Jersey, the risk of lung cancer was increased more than twofold among women living in homes with radon levels exceeding 4 pCi/L.[85] However, in a case-control study of women who were recently diagnosed with lung cancer in China, no association was demonstrated between increasing residential radon exposure and lung cancer; 20% of the yearlong radon measurements exceeded 4 pCi/L, the level above which remedial action is recommended in the United States.[86] Conclusions that were similar to those from the study in China were presented based on a study by Létourneau et al.[87] in Canada. Thus, although radon and its $\alpha$-particle–emitting decay products are classified as a human lung carcinogen, there has been uncertainty expressed about whether or to what extent residential radon exposure levels contributed to the lung cancer burden and how accurate were predictions based on extrapolations from studies of underground miners. Epidemiologic studies of indoor radon in the United States must be interpreted with caution because of limitations in estimating lifetime exposures based on current exposure measurements. Exposure reconstruction is complicated because persons reside in many homes throughout life, and the time actually spent in each home may be only approximated. Average prior residential exposure levels were generally low, exceeding remedial action levels in 5% of United States homes. Extrapolated RR estimates of less than 1.2, which was associated with average residential exposures, would have been potentially confounded by effects of active and environmental tobacco smoke inhalation. Notwithstanding these caveats, recent publications were supportive of risks of lung cancer associated with residential radon exposure that were consistent with extrapolations of risk using underground mining-based models.[88,89]

**Occupational Respiratory Carcinogens**    Although smoking is the major cause of lung cancer, other respiratory tract carcinogens have been identified, or are suspect, and may enhance the carcinogenic effects of tobacco smoke. Notable among these independent determinants of lung cancer are chemical and physical agents that have been identified in the workplace. An example of an occupational lung cancer was described in central Europe in the latter part of the 19th century in underground metal miners. The likely cause of what was described historically as "mountain disease" has been attributed to

the miners' inhalation of radon and $\alpha$-emitting radon daughters. At that time, lung cancer was a rare disease, and the prevalence of cigarette smoking was low. Other occupational agents classified as group 1 carcinogens by the IARC include inorganic arsenic, asbestos, bis(chloromethyl)ether, chromium (hexavalent), nickel and nickel compounds, polycyclic aromatic compounds (PAHs), radon, and vinyl chloride (Table 1.5). Group 2A probable carcinogens included acrylonitrile, beryllium, cadmium, formaldehyde, acetaldehyde, synthetic fibers, silica, and welding fumes. Currently, occupational exposures have been estimated to account for 5% to 15% of lung cancers occurring among men and women of different cultures and nations.[90]

**Asbestos**   The association between asbestos exposure and lung cancer has been established by epidemiological and animal experimental studies. It has been estimated that since the beginning of World War II, up to 8 million persons in the United States have been exposed to asbestos in the workplace. In the United States, more than 90% of the production and consumption of asbestos is represented by the serpentine or curly form of fiber known as chrysotile ("white asbestos"). The bronchopulmonary neoplasms of various cell types induced by asbestos tend to originate peripherally and in the lower lobes, accompanied frequently by the fibrosis of asbestosis.[91–93]

Asbestos is a general term used to describe a variety of naturally occurring hydrated silicates that produce mineral fibers upon mechanical processing. In addition to the serpentine group, there are the amphiboles, a larger family of straight, needlelike fibers that includes anthophyllite, tremolite, and amosite ("brown asbestos"), and crocidolite ("blue asbestos"). Most mesotheliomas are associated with exposure to crocidolite asbestos. Because of unique physical and chemical properties, such as noncombustibility, withstanding temperatures of over 5000°C, resistance to acids, high tensile strength, and use in thermal and acoustic insulation, asbestos has had wide applications in commercial products. Such products include textiles, cement, paper, wicks, ropes, floor and roofing tiles, water pipes, wallboard, fireproof clothing, gaskets, brake linings, etc.[94]

Various morphologic, biochemical, and molecular techniques have been utilized to document events that might be associated with asbestos toxicity at the cellular level. Prolonged exposure to asbestos results in the accumulation of macrophages and inflammatory cells in the alveoli, which is accompanied by the release of oxygen free radicals, the peroxidation of cell membranes, and damage to DNA and other macromolecules. Asbestos fibers that cross the alveolar epithelium may be translocated to the pleura by macrophages. The shape, length, and persistence of fibers may be important in eliciting cellular responses intrinsic to carcinogenesis. Longer, rodlike fibers (i.e., >5 to 10 $\mu$m in length and <0.25 $\mu$m in diameter) appear to be more cytotoxic than shorter, coarse fibers. Electrostatic charge on the fiber surface may enhance deposition in lung tissue, and the surface biochemistry may also impact the inflammatory response. Experimentally, in tracheobronchial epithelial culture systems, asbestos exhibits the characteristics of a tumor promoter; chronic exposure to asbestos, subsequent to the introduction of subcarcinogenic amounts

of dimethyl benzanthracene (DMBA), has resulted in increased DNA synthesis, basal cell hyperplasia, squamous metaplasia, and squamous cell carcinoma. In the induction of mesotheliomas and pleural sarcomas, asbestos is a complete carcinogen.

The risk of lung carcinoma in cigarette smokers has been examined in several asbestos-exposed populations. In 1968, Selikoff et al.[93] reported on the effects of combined exposures to cigarette smoking and asbestos in insulation workers; the RR for lung cancer significantly exceeded the level of risk expected if each exposure were to have acted only independently (noninteractively). The synergy resulting from combined exposures to tobacco and asbestos has been demonstrated in asbestos factory workers, Quebec miners and millers, amosite asbestos factory workers, and Finnish anthophyllite miners and millers. Although most studies have concluded that the RRs were close to multiplicative, as in exposures to smoking and radon combined, a study among Canadian chrysotile miners and millers concluded that the effect of each agent was independent and additive. Various sources have concluded that asbestos exposure, in the absence of tobacco smoking, increases the risk of both squamous cell carcinoma and adenocarcinoma of the lung. It is assumed in risk assessment models that the dose–response relationship may be linear or exponential, and without an apparent threshold. On the assumption of synergy between asbestos exposure and tobacco smoking, it has been emphasized that it is especially important for asbestos-exposed persons to quit smoking as a cost-effective preventive measure.[95]

Mesothelioma has a protracted latency period averaging 35 to 40 years. Unlike carcinoma of the lung, smoking does not contribute to the development of mesothelioma in asbestos workers. Statistics on the incidence and mortality of mesothelioma are not reported routinely because of problems in histopathologic classification of mesothelial cell hyperplasia and malignant neoplasia and the distinction from metastatic sarcomas or adenocarcinomas. A combination of histochemistry, immunocytochemistry, and electron microscopy may be necessary to achieve a precise and valid diagnosis. In the SEER program consisting of various state, county and metropolitan population-based cancer registries that cover currently about 14% of the total U.S. population, the average annual age-adjusted incidence of mesothelioma (per 100,000 population) in white men nearly doubled from 1978 to 1992 (from 1.3 to 2.5), whereas the rates among white women remained stable at about 0.4. Rates in men aged 75 to 84 years increased from 6.3 to 18.2. In developed countries, approximately one mesothelioma case occurs concurrently with 100 lung carcinoma cases. The rates in nonwhites were too low to yield reliable estimates during this period of time. As reported in other countries, pleural exceeded peritoneal mesotheliomas by a ratio of 9:1 in men and 3:1 in women. The incidence rates appeared to have peaked among those born around 1910 and have declined among cohorts born subsequently.[96]

There are well-documented areas of elevated incidence of mesothelioma, such as the coastal area of Virginia, San Francisco-Oakland, Hawaii, and Seattle in the United States; England and Wales; and Japan, where there were shipbuilding centers; among women in areas where, during World War II,

| TABLE 1.5 | Chemicals and Industrial Processes Associated with Human Lung Cancer* | | |
|-----------|-----------|-----------|-----------|
| **Agent** | **Human Target Organs** | **Epidemiology** | **Toxicology** |
| Arsenic | Lung<br>Skin<br>Urinary tract | Over 95% of arsenic produced in the United States is byproduct of copper, lead, zinc, and tin ore smelting. Excess lung cancer reported in association with use and production of inorganic trivalent arsenic-containing pesticides. Dose–response trends have been validated by measuring concentrations in air and urine. In a review of published studies, combined relative risk reported as 3.69 (95% CI, 3.06–4.46).[170]<br><br>Joint action with tobacco smoking appears to be more than additive and less than multiplicative. Latency of 10–35 years. | No satisfactory animal model. In tissue culture systems: Chromosomal aberrations, inhibition of DNA repair, and increased sister chromatid exchanges.<br>The current OSHA standard for airborne inorganic arsenic is 10 $\mu$g/m$^3$. |
| Asbestos | Lung<br>Mesothelium or serosa of pleura, pericardium, and peritoneum<br>GI tract<br>Larynx | Various workers in asbestos industries at increased risk: miners, millers, textile, insulation, shipyard, cement. Average latency period of 25–30 years for carcinoma of lung. Length of interval varies with type of fiber, exposure intensity and duration, host factors. Dose–response relationship that is approximately linear in form across mid to upper levels of exposure. Relative risk of lung cancer appears to decrease following cessation of exposure.<br><br>Synergistic relationship with cigarette smoking, which is more than additive and close to multiplicative. Asbestos exposure in the United States accounts for approximately 5% of lung cancer deaths in men. | Asbestos minerals are divided into:<br>a) the amphiboles, including amosite, crocidolite, anthophyllite, and tremolite;<br>b) serpentine class, which is represented by chrysotile.<br>All types of commercial asbestos fibers are carcinogenic in mice, rats, hamsters, and rabbits; after inhalation, or intrapleural and intraperitoneal administration, cancers of the lung and bronchus, and/or mesotheliomas have been induced.<br>The current OSHA standard is 0.1 fibers per mL for fibers greater than 5 $\mu$m in length. |
| BCME and CMME | Lung | Used in manufacture of ion-exchange resins, polymers, plastics. Tumor cell type was primarily (85%) small cell (oat-cell) carcinoma.<br><br>Changes in industrial process from open-kettle to closed hermetically isolated systems in 1971 have markedly reduced exposure and were accompanied by declining risk of lung cancer. Increasing risk with increasing intensity and duration of exposure. | Highly carcinogenic in rodents by inhalation, skin application, or subcutaneous injection. BCME is a more potent carcinogen than CMME. |
| Chromium and compounds | Lung<br>Nasal and paranasal sinuses | Used in metal alloys, electroplating, lithography magnetic tapes, paint pigments, cement, rubber, photoengraving, composition floor covering, and as oxidant in synthesis of organic chemicals.<br><br>Excess risk, threefold and higher, was demonstrated for all cell types of lung cancer in the chromate-producing industry, producers of chromate paints, and chromate plating workers, particularly from 1930–1945. Risks in other occupational settings, with lower intensity exposures, have not been consistently or substantially increased. | Epidemiologic and experimental data implicate hexavalent and not trivalent chromium compounds.<br>The OSHA standard for chromic acid and hexavalent chromates is 0.1 mg/m$^3$. |
| Nickel and compounds | Lung<br>Nasal and paranasal sinuses<br>Larynx | Used in electroplating, manufacturing of stainless steel and other alloys, ceramics, storage batteries, electric circuits, petroleum refining, and oil hydrogenation. | Animal studies indicate that nickel compounds can produce local sarcomas by injection, and pulmonary tumors by inhalation and intratracheal instillation. |

**TABLE 1.5    Chemicals and Industrial Processes Associated with Human Lung Cancer\* (continued)**

| Agent | Human Target Organs | Epidemiology | Toxicology |
|---|---|---|---|
| | | Risk associated with earliest stage of refining, involving heavy exposure to dust from relatively crude ore. | Several forms of nickel may be carcinogenic, and include oxides, sulfites, and soluble nickel. |
| | | In some nickel refineries, high levels of PAHs, arsenic, or other agents may have contributed to increased risks. In mining for nickel, workers may be exposed to asbestos. | The OHSA standard is 0.1 mg/m$^3$ for soluble compounds, and 1 mg/m$^3$ for nickel metal and insoluble nickel compounds. |
| PAHs | Lung Skin and scrotum Urinary bladder | These chemicals may result from ferrochromium production and smelting of nickel-containing ores; aluminum production, iron and steel founding, coke production, and coal gasification; coal tars, coal tar pitches, untreated mineral oils; soot from combustion and diesel engine exhausts. | PAHs result from pyrolysis or incomplete combustion of organic compounds. |
| | | In relation to coke oven emissions, risk of lung cancer highest in workers on the topside of coke ovens. Among the most heavily exposed, lifetime risk could reach 40%. | Benzo(a)pyrene-DNA adducts, a marker of PAH exposure, have been detected in the blood samples of coke oven workers. |
| | | Combined relative risk, based on six studies, of 1.31 (95% CI, 1.13–1.44) for diesel-exposed workers.[171] | Diesel exhaust, the particulate phase, has been demonstrated to be a lung carcinogen in animals. |
| Radon | Lung | Increased risks of lung cancer have been observed among underground miners in North America, Europe, and Asia, and quantitatively related to the inhalation of radon daughter products. | Dose of high-LET alpha particles to individual cells will vary with respiratory dynamics, thickness of the epithelial cell and overlapping mucous layers, and the clearance rate of absorbed radioactive particles. |
| | | Although small cell cancers predominate, all cell types are affected. | |
| | | Radiation and cigarette smoking are interactive with relative risks somewhat less than multiplicative. | Cellular DNA damage depends on the type of radiation, amount of energy deposited per volume of tissue, the rate at which the energy is deposited, and the time over which a given dose is accumulated. |
| | | Exposure levels in miners associated with elevated risks generally exceeded 100 working-level months (about 0.5 Gy). | |
| | | Linear nonthreshold dose response. For the same cumulative dose, prolonged exposures at low dose rates appear more hazardous than shorter exposures at higher dose rates. | |
| Vinyl chloride | Liver (angiosarcoma) Lung Brain Lymphoreticular | Principal use is in production of plastics, packaging materials, and vinyl asbestos floor tiles. | Inhalation of vinyl chloride monomer and polyvinyl chloride in experimental animals causes pulmonary fibrosis and adenomas, skin appendage tumors, and osteochondromas. |
| | | A review of 12 cohort studies of men employed at synthetic plastics or polyvinyl chloride polymerization plants reported SMRs for lung cancer indicating an overall observed to expected lung cancer ratio of 1:12 (95% CI, 1.0–1.2).[172] | |

\*Agents are those classified as known carcinogens (group 1) by the International Agency for Research on Cancer.

BCME, Bis(chloromethyl) ether; CMME, chloromethyl methyl ether; GI, gastrointestinal; LET, linear energy transfer; OSHA, Occupational Safety and Health Administration; PAHs, Polycyclic aromatic hydrocarbons; SMR, standardized mortality ratios.

gas masks with asbestos filters were manufactured; or in South Africa, where excess mesothelioma incidence was concentrated in mining districts. Mesotheliomas may result from neighborhood or environmental (nonoccupational) exposures to asbestos industries and from household contact with asbestos dust, primarily through the laundering of work clothing.[97–101]

All types of asbestos have the potential for causing mesothelioma, although the risks in humans are two to four times more significant for amphibole fibers, such as crocidolite and amosite, than for the serpentine fibers of chrysotile. The mechanisms of induction appear related to the physical properties of fiber size and dimension. The amphibole straight rodlike fibers can more readily be transported or penetrate to peripheral segments of the lung. The pathogenesis in mesothelial cells is accompanied by induced proto-oncogene expression and the formation of oxygen radical species.

The association between the physical structure of asbestos fibers and carcinogenicity has raised concerns regarding possible hazards of other fibers, whether natural or synthetic. Inorganic synthetic vitreous substances derived from glass, rock, slag, or clay are used primarily in the manufacture of thermal and acoustic insulation materials. Intrapleural injection of such fibers is associated with mesothelioma or sarcoma of the pleura of laboratory animals. In 1987, the WHO declared that glass wool, rock wool, slag wool, and ceramic fibers were to be classified as 2B agents, namely, agents possibly carcinogenic to humans. This category is generally used for agents for which there is limited evidence in humans and where there is the absence of sufficient evidence in experimental animals. Epidemiologic studies of the association of occupational exposures to synthetic vitreous fibers and the risk of lung cancer have not shown a consistent pattern of risk in relation to duration of employment, average intensity and cumulative exposure dose levels, or latency interval. Further, many of the studies have not controlled adequately for confounding by cigarette smoking habits or exposure to other workplace respiratory carcinogens.[102–108]

**Nutrition: Antioxidants and Fat**    Epidemiologic studies have provided evidence about the nature of dietary deficiencies and excesses that have influenced the risk of lung cancer. The most consistent association, gathered from case-control and cohort studies, was that increased consumption of fresh vegetables and fruits lowered the risk in men and women, in current or former smokers, or particularly among never-smokers, and for all histologic types. The higher levels of consumption, when compared with the lowest reference level, tended to be associated with 40% to 50% reduction in the smoking-, age-, and gender-adjusted RR of lung cancer of various cell types. Various antioxidants were considered as putative chemopreventive nutrients, but a major focus has been on the provitamin A carotenoids, particularly $\beta$-carotene. Some investigators have reported that $\beta$-carotene was most protective in current or heavy smokers, whereas others have found that $\beta$-carotene or carotenoids were most protective in former smokers or in nonsmokers.[109–113] In a population-based case-control study of lung cancer in nonsmokers conducted in New York State,

Holick et al.[114] concluded that the increased consumption of raw (not cooked) fruits and vegetables was associated with a significantly reduced risk for lung cancer. Dietary $\beta$-carotene (odds ratio = 0.70; 95% CI, 0.50 to 0.99), but not dietary retinol (vitamin A), was significantly associated with risk reduction for lung cancer in nonsmoking men and women.

By the mid-1980s, large-scale randomized clinical trials of $\beta$-carotene, $\beta$-carotene plus retinol, or $\beta$-carotene and/or vitamin E were initiated in subjects at increased risk of lung cancer. The $\alpha$-tocopherol/$\beta$-carotene trial (ATBC) in Finland was a primary prevention trial among over 29,000 male smokers of 50 to 69 years of age. The 2 × 2 factorial design evaluated 20-mg $\beta$-carotene and/or 50-IU $\alpha$-tocopherol (vitamin E) daily for 6.5 years. These doses represented a fivefold excess over the median intake of $\alpha$-tocopherol and a 10-fold excess over the median intake of $\beta$-carotene in the general population. When compared with placebo groups, supplementation with vitamin E did not alter lung cancer incidence; however, participants receiving $\beta$-carotene alone or in combination with $\alpha$-tocopherol had significantly higher lung cancer incidence (RR = 1.18; 95% CI, 1.03 to 1.36). The excess lung cancer incidence was demonstrable after the initial 18 months. The randomized design and analysis controlled for cigarette smoking history.[115]

The Carotene and Retinol Efficacy Trial (CARET) was a multicenter randomized trial to test whether oral administration of the combination of $\beta$-carotene (30 mg/day) and retinyl palmitate (25,000 IU/day) would decrease lung cancer incidence in high-risk populations of female smokers and male smokers and/or exposed asbestos workers. In the treatment group, when compared with the placebo group, the RR, after an average follow-up of 4 years, of death from lung cancer was 1.46 (95% CI, 1.07 to 2.00). The RRs were elevated in current smokers.[116,117] After 12 years of follow-up in the placebo arm of CARET, a significant protective effect was observed with total fruit or cruciferous vegetable consumption. The RR for highest versus lowest quintile of total fruit consumption in the placebo arm was 0.56 (95% CI, 0.39 to 0.81); for cruciferous vegetables, the RR was 0.68 (95% CI, 0.45 to 1.04).[118]

The Physicians' Health Study was a long-term randomized trial organized to test the effect of aspirin on cardiovascular disease incidence. $\beta$-Carotene (50 mg) was added in a 2 × 2 factorial design. In this healthy male population with 11% current cigarette smokers, and after an average follow-up of 12.5 years, the investigators concluded that the intervention did not reduce or increase the incidence of lung cancer (RR = 0.93).[119,120]

It is disconcerting and challenging to reflect about the lack of demonstrable benefit or even an adverse outcome of increased risk of lung cancer in smoking men and women participating in various chemoprevention clinical trials. The results of these clinical trials would appear to contradict the epidemiologic observational studies. $\beta$-Carotene is only one of many carotenoids ingested in vegetables and fruits and, under conditions of increased oxidative stress as in exposure to cigarette smoke or asbestos, $\beta$-carotene can be oxidized to an epoxide or reactive electrophilic derivative that would be mitogenic rather than inhibitory of cell proliferation. Handelman et al.[121]

exposed human plasma to the gas phase of cigarette smoke and observed oxidative disruption of carotenoids and $\alpha$-tocopherol. In addition to carotenoids, fresh fruits and vegetables contain other micronutrients including vitamin C, folic acid, flavones, isoflavonoids (e.g., soy products), protease inhibitors, thiocyanates, and indoles (e.g., indole-3-carbinol in *Brassica* vegetables). Methyl-deficient diets result from low consumption of fruits and vegetables (folate) and of poultry, fish, and dairy products (methionine). Folic acid, methionine, and choline are interrelated in methyl group metabolism. Selective growth and transformation of cells can result from DNA hypomethylation and overexpression of proto-oncogenes or hypermethylation of CpG islands in promoter regions that may attenuate the expression of tumor suppressor genes. In the cohort study of health professionals by Feskanich et al.,[122] both fruits and vegetables, consumed with regular frequency were protective for lung cancer in women and men who never smoked (RR = 0.63; 95% CI, 0.35 to 1.12). In the study by Shen et al.,[123] the association with folate was most apparent among former heavy smokers.

Various chemopreventive mechanisms of action by micronutrients and nonnutritive phytochemicals in fruits and vegetables have been suggested by in vitro and animal feeding experimental studies. Chemoprevention refers to the use of natural or synthetic agents to reverse, prevent, or delay the progression of preneoplastic or preinvasive neoplastic disease. The complex interrelated mechanisms by which substances in vegetables and fruits may inhibit carcinogenesis include regulation of cell differentiation, "quenching" or "trapping" of oxygen or hydroxyl free radicals, preventing the formation of electrophilic metabolites from precursor compounds by inhibiting the enzymatic activation pathway (e.g., cytochrome P450) or by inducing the detoxification pathway (e.g., glutathione S-transferase [GST]), enhancing DNA methylation, inhibiting the expression of oncogenes, and stimulating immune function.[124]

Lung cancer mortality is significantly positively correlated in various countries with per capita fat availability and consumption. An increased risk of lung cancer has been reported in association with high dietary intake of foods rich in fat and cholesterol, or with elevated indices of abdominal adiposity. However, the positive association of dietary cholesterol and lung cancer risk has not been reflected in studies of serum cholesterol levels. Shekelle et al.[125] have hypothesized that a low, not elevated, serum cholesterol is predictive of increased risk of lung cancer, particularly in the subgroup of the population with low intake of $\beta$-carotene. Studies of the effects of dietary cholesterol and total and saturated fat have attempted to control for the confounding effects of gender, smoking status, and total intake of energy, fruits, vegetables, and carotenoids. In the study by Alavanja et al.[126] in female smokers in Missouri, a significant association was noted between intake of saturated fat and lung cancer. Despite the positive association with dietary fat, lung cancer risk was not associated with increasing body mass; indeed, several studies have described elevated risks in subgroups in the lowest categories of body mass index, which were not explained by confounding from cigarette smoking.[127,128] Although the potential association of specific

histologic types of lung cancer with body fat distribution should be investigated further as suggested by Olson et al.,[129] the considerable inconsistencies in the associations with cholesterol and fat do not suggest that dietary fat intake has a major etiologic role.

## Nonneoplastic Lung Diseases: Chronic Inflammation, Chronic Obstructive Pulmonary Disease, and Pulmonary Fibrosis

Lung cancer risk has been reported to be increased among persons with a history of tuberculosis, pulmonary fibrosis as in silicosis, or chronic bronchitis and emphysema. An increased risk of lung cancer following the diagnosis of tuberculosis has been reported in cohort and case-control studies. For example, in a population-based case-control study of lung cancer that was conducted in Shanghai, Zheng et al.[130] reported that the age-, sex-, and smoking-adjusted odds ratio or RR of lung cancer was increased by 50% (95% CI, 1.2 to 1.8) among all survivors of tuberculosis, and by 100% among those diagnosed with tuberculosis within the previous 20 years. Among men, prior infection was reported by 26% of the cases and by 20% of the controls. The RR of lung cancer was higher for adenocarcinoma than for squamous or oat-cell carcinoma, and the locations of the granulomatous fibrotic lesions were highly correlated with that of the lung cancers. Based on the estimation of RR and the proportion of the population in Shanghai exposed to pulmonary tuberculosis, 9% of lung cancer cases were attributed to prior infection. In a case-control study by Hinds et al.,[131] the RR of lung cancer in never-smoking women in Hawaii with prior tuberculosis was increased significantly (OR = 8.2; 95% CI, 1.3 to 54.4).

The IARC has classified silica as a "probable" lung carcinogen (2A). Inhalation of silica causes both lung fibrosis and cancer in rats, but fibrosis in the absence of cancer has been observed in mice. For workers exposed to crystalline silica, with clinical indication of pneumoconiosis, as reported in 12 cohort and 3 case-control studies, the combined RR of lung cancer was 1.33 (95% CI, 1.12 to 1.45).[132] In a metaanalysis of lung cancer mortality among patients with silicosis, Smith et al.[133] reported a pooled estimated RR of 2.2 (95% CI, 2.1 to 2.4). RRs have been elevated in workers with increased exposure to silica dust that is incurred in mining and quarrying, and in the granite, ceramics and glass, and foundry industries. In underground mining, exposure to silicon dioxide or crystalline silica may be confounded by exposure to radon and its $\alpha$-particle progeny, diesel fumes, asbestos, and other occupational carcinogens, and/or to tobacco smoke. Increased risk appears to vary with the severity of pulmonary fibrosis or with clinical signs of obstructive lung disease that accompanies chronic silicosis. The excess risk of lung cancer reported in previous studies has persisted after adjusting for smoking or has not been associated with excess risks for other smoking-related cancers, as in the upper digestive or urinary tract organs.[134]

Cigarette smoking may result in COPD and/or emphysema, and/or lung cancer. In the early 1960s, Passey[135] hypothesized that it was the irritating properties of tobacco smoke, resulting in chronic bronchitis and inflammatory destruction of lung tissue, which was of pathogenic significance in the causal pathway of lung cancer, rather than any direct action by volatile

and particulate carcinogens in tobacco smoke. The experiments of Kuschner,[136] however, suggested an alternative explanation; namely that bronchial and bronchiolar inflammation, accompanied by reactive proliferation, squamous metaplasia, and dysplasia in basal epithelial cells, provided a cocarcinogenic mechanism for neoplastic cell transformation upon exposure to polycyclic aromatic hydrocarbons. Continued smoking in association with COPD, when accompanied by moderate or marked cytological atypia in exfoliated cells in the sputum, was significantly predictive of lung cancer in the Colorado Cancer Center Sputum Screening Cohort Study.[137]

Although cigarette smoking is the predominant cause of COPD, with an estimated attributable (etiologic) risk fraction exceeding 80% in smoking affected individuals, perhaps only 10% to 15% of current smokers will eventually develop clinically significant sequelae of productive cough, exertional dyspnea, and cardiovascular disease.[138,139] There are at least 10 cohort studies indicating that chronic obstructive airway disease is an independent predictor of lung cancer risk, and numerous studies reporting an increased risk of lung cancer among adults with asthma (Table 1.6).[140–149]

Chronic cigarette smoking retards mucociliary clearance of foreign particulates and respiratory tract secretions, evokes an inflammatory response accompanied by fibrosis and thickening in the membranous and respiratory bronchioles, and causes mucus gland hypertrophy, hyperplasia, and dysplasia in the proximal airways.[150] The manifestations of COPD signal the extent of bronchopulmonary structural and functional damage arising from the interaction of sustained exposure to toxic products of tobacco combustion and host susceptibility. In this context, COPD is both a biomarker of both exposure dose level and tissue susceptibility. A more controversial issue would be that of how COPD impacts the development of lung cancer. A conceptual model is proposed that incorporates the potential cocarcinogenic effects of chronic obstructive inflammatory disease in the causal pathway of cigarette smoke and lung cancer. The molecular events in the natural history of lung cancer comprise multiple genetic mutations that are determinants of neoplastic transformation and tumor progression, and the elaboration of autocrine growth factors that influence the clonal behavior and morphologic features of neoplastic cells. Chronic inflammation in the proximal and distal bronchial airways is an important cause of obstructive symptoms and provides the dynamic setting for oxidative stress and the formation of free radicals that accompany the reparative proliferative response. Increased proliferation kinetics and the interaction of hydroxyl radicals with DNA augment the likelihood of DNA structural and transcriptional errors.

## GENE–ENVIRONMENT INTERACTIONS

Both genetic and environmental factors affect lung cancer risks, but the molecular pathophysiology of gene–environment interactions is complex. The genes influencing cancer susceptibility may consist of heterogeneous alleles at one locus or a combination of alleles at multiple loci. In a study of familial aggregation of lung cancer, Tokuhata and Lilienfeld[151] reported a significantly increased risk of lung cancer mortality among nonsmoking relatives of lung cancer cases when compared with nonsmoking relatives of age-, race-, and sex-matched controls. Kreuzer et al.[5] concluded that lung cancer in a first-degree relative was associated with a 2.6-fold increase in risk of lung cancer in cases diagnosed in patients younger than 50 years of age. A similar pattern of familial aggregation limited to probands with lung cancer diagnosed at a younger age than the median age in the general population was reported by Bromen et al.[152] In a segregation analysis involving 337 high-risk families with lung cancer, Sellers et al.[153] described a pattern of autosomal codominant inheritance, and hypothesized that segregation at the putative gene locus would account for 69% of the lung cancer cases diagnosed in persons up to age 50 years. Samet et al.[154] concluded that the personal risk of lung cancer was increased more than fivefold if at least one parent had lung cancer. In a study of families of women with lung cancer, an odds ratio gradient was noted: never-smoker with a positive family history (5.7), smoker with a negative family history (15.1), and smoker with a positive family history (30.0).[155] Familial aggregation of lung cancer may be attributed to shared exposures to tobacco smoking or other environmental and/or heritable determinants. On the assumption that a lung cancer susceptibility gene with a frequency of 0.3 to 0.5 would increase the risk of lung cancer in carriers, then an autosomal recessive model of inheritance would predict that siblings of cases would manifest a twofold to fourfold increased RR of lung cancer.[156]

Multiple inherited and acquired mechanisms of susceptibility to lung cancer have been proposed. Individual susceptibility to tobacco-induced lung cancer may be dependent on competitive gene–enzyme interactions that affect activation or detoxification of procarcinogens and levels of DNA adduct formation, or on the integrity of endogenous mechanisms for repairing lesions in DNA.[157] Nicotine is converted to cotinine in a two-step enzymatic process for which the rate-limiting step is the drug-metabolizing enzyme, cytochrome P450, a genetically polymorphic enzyme. Glucuronyl transferase enzymes conjugate and inactivate carcinogenic compounds, including 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), the tobacco-specific methylnitrosamino metabolite, a potent procarcinogen in tobacco smoke. In a case-control study by Nakachi et al.[158] in which they assessed DNA polymorphisms in the cytochrome P4501A1 gene in relationship to squamous cell lung carcinoma, persons with the susceptible genotype had a RR of 7.31 after adjusting for cigarette smoking history. DNA polymorphisms in the cytochrome P450 gene (CYP1A1), or aromatic hydrocarbon hydroxylase, which is responsible for the metabolic activation of benzo(a)pyrene and other polyaromatic hydrocarbons, may represent a locus of a susceptibility gene for lung cancer. Increased activity of CYP1A1 has been demonstrated in lung cancer cells when compared with normal tissue in the same patient, suggesting that dysregulation of the gene may occur in carcinogenesis. However, no association between lung cancer and CYP1A1

**TABLE 1.6    Review of Cohort Studies of Chronic Obstructive Pulmonary Disease and Lung Cancer**

| Author | Sources of Exposed and Nonexposed | Person-Years and Interval of Follow-up | Index of Risk | Age, Smoking-Adjusted Relative Risk (95% CI) | Commentary |
|---|---|---|---|---|---|
| Peto et al.[140] | 2718 British men 25–64 years of age identified in random surveys conducted in 1954–1961. | 20–25 years of follow-up. | Maximal value for: $FEV_1 \div$ standing height$^3$ (Ht$^3$) chronic phlegm production by questionnaire. | When index of airway obstruction exceeded 2 SD below average (108 men) risk of lung cancer mortality increased, 1.3. Mucus hypersecretion was predictive of 40% increased risk of lung cancer, after adjustment for $FEV_1$/Ht$^3$. | Mucus hypersecretion was not predictive of COPD mortality, but was correlated with lung cancer mortality. |
| Skillrud et al.[141] | 93 men, 20 women, 45–59 years of age from rural area of SE Minnesota; 123 controls treated for fractures, dental extractions; Matched on age, sex, occupation, smoking history. | 1973–1974 until 1984. | % predicted $FEV_1$ ≤70% compared with $FEV_1$ ≥85%. | 10-year cumulative probability in men: 0.108/0.025 = 4.32 (0.93, 19.99). | No lung cancer cases in women. |
| Tockman et al.[142] | Screening and early detection for lung cancer clinical trial at John Hopkins: 3728 white men, 45 years and older, who smoked at least 1 pack of cigarettes per day. Intermittent positive-pressure breathing trial (IPPB), 667 white men, 30–74 years of age, with COPD. | Lung cancer screening: 4436 pack-years or <2 years IPPB trial: 2001 pack-year or 3 years followed. | $FEV_1 > 60\%$ of predicted value compared with ≤60%. $FEV_1$/FVC ≤60% chronic cough and shortness of breath. | Lung cancer screening trial: 2.72 (0.98, 7.55) IPPB trial: 4.85. | Presence of symptoms of chronic cough or shortness of breath did not contribute significantly to lung cancer risk after adjustment for $FEV_1$ % predicted. |
| Tenkanen et al.[143] | Three urban and three rural areas in Finland; 4452 men, selected by sampling birth cohorts, 1898–1902, 1903–1907, 1908–1917, from electoral lists. | Follow-up period, 1964–1980. | Phlegm, all day for at least 3 months each year. Shortness of breath when walking. Wheezing. | Phlegm = 1.9 ($p < 0.001$) Shortness of breath = 1.6 ($0.05 < p < 0.10$) controlling for other symptoms, smoking, age Severe wheezing alone was not associated with significant increase in risk of lung cancer. | Significant lung cancer risk was associated with severe level of phlegm production, even after controlling for smoking, shortness of breath, and wheezing. |

| TABLE 1.6 | Review of Cohort Studies of Chronic Obstructive Pulmonary Disease and Lung Cancer *(continued)* | | | | |
|---|---|---|---|---|---|
| **Author** | **Sources of Exposed and Nonexposed** | **Person-Years and Interval of Follow-up** | **Index of Risk** | **Age, Smoking-Adjusted Relative Risk (95% CI)** | **Commentary** |
| Kuller et al.[144] | Cigarette-smoking men (N = 8194) participating in the Multiple Risk Factor Intervention Trial. Of the above, 6075 (75%) had satisfactory pulmonary function measurements. Aged 35–57 years of age at entry. | Average follow-up, 10.5 years (1973–1984); However, the $FEV_1$ measurements were obtained at year 3, thus allowing for 0.5 years of follow-up. | $FEV_1$ levels distributed into quintiles. For example, lowest quintile included ≤2670 mL, highest quintile, ≥3749 mL. | $FEV_1$ (lowest) ÷ $FEV_1$ (highest) = 3.57 (0.94, 12.5) Proportional hazards model was compatible with 40% reduction in risk with increase in $FEV_1$ of 1000 mL. | Production of phlegm for >3 months in a year was a significant predictor of lung cancer, after adjusting for age, smoking, and $FEV_1$. There was no relation between baseline shortness of breath and subsequent lung cancer mortality. |
| Lange et al.[145] | Population-based sample of 7573 women and 6373 men who were participants in the Copenhagen City Heart Study. | Average follow-up period of about 10 years. | % predicted $FEV_1$, $FEV_1$/FVC%, chronic phlegm (3 months each year for >1 year). | Cox regression model controlling for age, sex, cigarette smoking. % predicted $FEV_1$: 40–79 = 2.1 (1.3, 3.4) <40 = 3.9 (2.2, 7.2) $FEV_1$ ÷ FVC <0.6 = 2.6 | |
| Vestbo et al.[146] | Random sample (6.6%) of all men (N = 876), 46–69 years of age, living in city in Denmark, 1973. | 1974–1985, 12,134 pack-years Cancer incidence was based on the Danish Cancer Registry. | Chronic phlegm (lasting ≥3 months), cough, or shortness of breath. $FEV_1$ per liter, under the expected $FEV_1$ given the height. Chronic bronchitis (defined as cough and phlegm lasting ≥3 months for ≥2 years). | Cox regression model using age as the underlying time scale: $FEV_1$ = 2.1 (1.3, 3.4) cough = 2.5 (1.3, 5.0) dyspnea = 2.2 (1.0, 4.9) phlegm = 1.2 (0.5, 3.0) chronic bronchitis = 0.8 (0.3, 2.7) | Regression coefficients did not differ between women and men. Among subjects who reported chronic phlegm at enrollment, only 54% reported it on reexamination 5 years later. Dyspnea was significant predictor of COPD and overall mortality. |
| Nomura et al.[147] | 6317 Japanese-American men residing on Hawaiian island of Oahu, who were 45–68 years of age at entry. | 19-year follow-up survey subsequent to examination in 1965–1968. | % predicted $FEV_1$, quartile distribution. Highest quartile category (>103.5%) was baseline in estimating relative risk. | Lowest quartile % predicted $FEV_1$ = 2.1 (1.3, 3.5) (<84.5%) | Only 2% of the cohort had % predicted $FEV_1$ of <60%. The data suggested that subjects with % predicted $FEV_1$ below 94.5%, after controlling for age and smoking, were at increased risk of lung cancer (95% CI, 1.3–4.1). |

| TABLE 1.6 | Review of Cohort Studies of Chronic Obstructive Pulmonary Disease and Lung Cancer *(continued)* | | | | |
|-----------|------------------------------------------------|--------------------------------------|---------------|--------------------------------------------|-------------|
| **Author** | **Sources of Exposed and Nonexposed** | **Person-Years and Interval of Follow-up** | **Index of Risk** | **Age, Smoking-Adjusted Relative Risk (95% CI)** | **Commentary** |
| Islam and Schottenfeld[148] | 2099 women and 1857 men, 25 years of age or older when first examined from 1962–1965 in Tecumseh, Michigan. | Minimum of 15 years of follow-up. | Lung cancer incidence in relation to baseline ventilatory lung function and cigarette smoking status; average annual decline in $FEV_1$ (mL/yr); Cox proportional hazards regression model with % predicted $FEV_1$. | Among smoking men and women, those in lowest quartile % $FEV_1$ were at 2.7 times the risk of lung cancer compared with highest quartile. With each 10% decrease in % $FEV_1$, the risk of lung cancer increased 1.17 times, after controlling for age, sex, and cigarette smoking intensity. | Rapidly declining ventilatory function in conjunction with persistent symptoms of chronic bronchitis in current smokers is predictive of increased risk of lung cancer. |
| Hole et al.[149] | 7058 men and 8353 women, aged 45–64 years at baseline screening 1972–1976, as part of a general population study in Renfrew and Paisley, Scotland. | 25-year prospective study with 36,270 pack-years in men and 42,907 pack-years in women. | $FEV_1$ relative to the predicted value, in relation to cause-specific mortality, adjusted for age, sex, social class, cigarette smoking. Cox proportional hazards regression model, with hazard ratios relative to highest quintile of $FEV_1$. | Hazard ratios for lung cancer in subjects in the lowest quintile of $FEV_1$ distribution: Men: 2.53 (1.69, 3.79) Women: 4.37 (1.84, 10.42) | Significant trends were observed among lifetime never-smokers with impaired $FEV_1$ for ischemic heart disease, stroke, and lung cancer. The gradients of risk of dying for a nonsmoker with a low % $FEV_1$ were similar to the relative risks for heavy smokers but with high quintile levels of pulmonary expiratory function. |

polymorphisms was reported in studies in Finland conducted by Hirvonen and coworkers.[159,160]

The genetically controlled ability to metabolize the antihypertensive agent debrisoquine has been linked to the risk of lung cancer. The P450 gene (CYP2D6) that regulates debrisoquine metabolism appears to influence the metabolism of nicotine to cotinine and metabolic activation of NNK, which is a potent carcinogen in experimental animals. Those who are extensive metabolizers in the hydroxylation of a 10-mg test dose of debrisoquine, a dominant trait affecting up to 90% of the U.S. white population, have been characterized as being at increased risk of lung cancer. Caporaso et al.[161] had initially estimated the smoking-adjusted RR to be increased sixfold, but more recently, studies have suggested more modest increases that are twofold or have

failed to demonstrate an association using either the debrisoquine metabolic phenotype or polymerase chain reaction assays for detecting the genotype.[162] Various phase II detoxification systems serve to modulate risk in relation to cumulative levels of exposure to chemical metabolites. GST alleles encode a family of enzymes that catalyze the conjugation of electrophilic substrates.[163,164]

Inherited genetic traits can influence an individual's smoking addictive behavior. The candidate genes affecting smoking behavior include the dopamine receptors, dopamine and serotonin transporter alleles, and the cytochrome P450 alleles (e.g., CYP2A6). These genetic factors collectively influence binding and metabolism of nicotine and other neurotransmitters.[165] Several case-control studies have suggested that subjects with deficiency of the GST-$\mu$ isoenzyme or the GSTM1 null genotype,

may have a 10% to 60% increase in lung cancer risk. Metabolites of constituents of cigarette smoke, including polycyclic aromatic hydrocarbons, aryl amines, and nitrosamines are potential substrates for GSTM1. Some studies have also evaluated potential interactions between CYP1A1 and GSTM1 genotypes.[166] Studies in Japan have reported that subjects with the combined GSTM1 null genotype and CYP1A1 polymorphisms were at increased risk.[167] The risk appears to be greater than additive in cigarette smokers with homozygous deletions of GSTM1 and CYP1A1 polymorphisms. Alexandrov et al.[168] noted that with both variant genes, the concentration levels of benzo(a)pyrene diol epoxide adducts of DNA were increased in lung parenchyma.

It is now clear that human tumors result from a complex sequence of mutational events. The bronchial epithelium of sustained smokers progresses from squamous metaplasia, to dysplasia, to invasive carcinoma, which is accompanied by progressive genomic instability. Many of the genetic defects that have been described in somatic cells of lung neoplasms are acquired during adult life and are related to exposures to environmental carcinogens. Some genetic events, however, are inherited and are present in all somatic cells. Mechanistic interactions of genes and exogenous agents may result from environmental agents altering the expression of genes involved in the regulation of the cell cycle, intercellular signaling, cell cycle arrest, and apoptosis. Susceptibility genes, in addition, include those concerned with the fidelity of DNA repair, DNA replication, and genomic stability. Individuals with combinations of alleles that dysfunctionally controlled enzyme systems regulating activation or detoxification pathways may be at increased risk of lung cancer when exposed to even low dose levels of tobacco smoke or other mutagens. However, the validity and efficiency of screening for carcinogenic metabolites in predicting human lung cancer risk is questionable in the context of a population. Strategic targeting of phenotypic or genotypic testing as a cancer control measure in high-risk families, in conjunction with behavioral counseling, may be more cost-effective. In a cohort study of monozygotic and dizygotic twin pairs followed in the National Academy of Sciences/National Research Council Twin Registry, it was concluded that inherited predisposition was not demonstrable in relationship to smoking-induced lung cancer diagnosed in men older than 50 years.[169] If one were to assume that 50% of lung cancer deaths before the age of 50 result from genetic predispositions, this would represent only 5% of lung cancer deaths.

# The Tobacco Epidemic

Tobacco has a fascinating history. Tobacco is native only to the Americas and its scientific names include *Nicotiana rustica* and *Nicotiana tabacum*.[1] Tobacco was first experienced by Europeans when Columbus discovered the Americas in 1492 when they saw natives smoking "a kind of plant" while exploring what is now Cuba. The first two Europeans to see this smoking, Rodrigo de Jerez and interpreter Luis de Torres, even tried it themselves, becoming the first Europeans to experience tobacco.[1] Tobacco was brought back to the European countries where it rapidly spread in usage. Reportedly within 3 months after Columbus returned to Spain, the two Europeans to first experience tobacco were perpetual users of the plant. Quite quickly, the addictive nature of tobacco was noted by the Spanish, which was a novel experience for Europeans—this habitual use was felt to be un-Christian, and therefore declared a "sin."[1]

However, there was no turning back. Tobacco rapidly became a cash crop, with the product flowing from the New World to support the growing number of users in the Old World. Jamestown, much to the dismay of King James, was able to become solvent as a result of tobacco production from 1610 to 1620.[2] When King James could no longer prevent Jamestown from shipping tobacco, he placed the first New World tax—on tobacco![2] In many places in the new colonies, tobacco was used as a form of currency.[2] Tobacco cultivation spread throughout many of the colonies, and with the patent of the new Bonsack machine in 1881, which more efficiently mechanized production, the manufacturing of cigarettes began.[2] With the increasing widespread marketing of cigarettes, the death toll also began to increase.

Globally, in high-income countries, tobacco is the major causative agent for three of the top five causes of death for 2005: heart disease, stroke, lung cancer, lower respiratory infections, and chronic obstructive pulmonary disease (COPD).[3] It is predicted that by 2030, 8.3 million people globally will die from tobacco-induced disease, and tobacco will be responsible for 10% of all deaths globally.[4] Smokers will lose on average 10 years of life and 50% of people who smoke will die of a tobacco-related disease.[5] At present, globally there are a total of 848,132 lung cancer deaths in men (age-standardized rate [ASR]: 31.2) and 330,786 deaths in women (ASR: 10.3).[6] Overall, lung cancer is the number one cause of cancer deaths, accounting for 17.6% of the total number of deaths. Lung cancer is the leading cause of cancer death in men worldwide; however, the picture is a little more complicated with either breast or lung cancer being the number one cause of cancer deaths in women. The relationship of breast to lung cancer deaths often reflects the prevalence of smoking among women. Figure 2.1 illustrates the age-standardized incidence of lung cancer for regions around the world, which reflects the regions' historical use of tobacco.[6]

The tobacco epidemic is rapidly changing around the world, and it varies from country to country, mostly according to the state of economic development. Figure 2.2 illustrates the Lopez curve of the tobacco epidemic.[7] This model was developed from the 100-plus year history of smoking, particularly in the developed world. As demonstrated in Figure 2.2, a few decades after the peak in smoking prevalence, a country experiences a peak in lung cancer deaths. This model is even more powerful when gender is considered. When comparing gender-related prevalence and rate of deaths, the tobacco epidemic may then be divided into four stages. Stage I is one of quite low male and female prevalence of smoking and few smoking-related deaths. Many low-income countries, such as in sub-Saharan Africa, are in this stage. Stage II consists of a rapid rise in the number of male smokers to its peak, a start in the rise in female smokers, an upswing in the number of male deaths, but still few deaths in women. In stage III, the prevalence of male smoking begins to decline, female smoking is still increasing, and the rate of smoking-attributed male deaths is at its peak (around 30% of all deaths) with the rates for women beginning to sharply increase. In stage IV, female smoking peaks and then declines as male smoking continues
**FIGURE 2.1** Age-standardized incidence of lung cancer for regions around the world. Data shown per 100,000 by sex. (From Parkin DM, Bray F, Ferlay J, et al. Global cancer statistics, 2002. *CA Cancer J Clin* 2005;55:74–108.)

to decline and smoking-attributable death for men and women decreases. Countries such as the United States and United Kingdom would be characteristic of stage IV, where the rates of female smoking–attributable deaths are just reaching their peaks, while the males rates have already started their decline.

**FIGURE 2.2** Stages of the tobacco epidemic—the Lopez Descriptive Model. (From Lopez AD, Collishaw NE, Piha T. A descriptive model of the cigarette epidemic in developed countries. *Tob Control* 1994;3:242–247.)

In the United States, cigarettes are by far the predominant form of tobacco consumption, as seen in Figure 2.3.[8] This pattern is seen around the world as the tobacco industry increasingly focuses outside of the more developed economies and into the more developing economies. The leading tobacco leaf importers are the Russian Federation, United States, Germany, Netherlands, Japan, United Kingdom, France, Belgium, Ukraine, and China. However, the top tobacco leaf exporters are very different: Brazil, China, United States, Zimbabwe, Italy, India, Turkey, Malawi, Greece, Argentina.[9] (China, Brazil, India, and the United States produce over two thirds of the 2004 global tobacco crop. India uses a significant proportion of their tobacco for smokeless use.)[9] Thus, the developing countries are more likely to grow and export the tobacco to the richer countries who then manufacture the finished cigarettes. In fact, Altria (the new name for Philip Morris) is the largest transnational tobacco manufacturer, and it is located in the United States. Philip Morris also has the number one global brand of cigarettes: Marlboro, and they sell them in 160 countries of the world.[9] The second largest company is British American Tobacco, located in the United Kingdom, and they have one seventh of the global market. Number three is Japan Tobacco and number four is Imperial Tobacco located in United Kingdom, and these four companies comprise 43% of the market. The largest tobacco manufacturer is the China National Tobacco Corporation, which controls 34% of the market—most of which is still within China. This, of course,

**FIGURE 2.3** Per capita consumption of different forms of tobacco in the United States, 1880 to 1995. (From Burns DM, Lee L, Zhen LA, et al. Cigarette smoking behavior in the United States. In: Burns D, Garfinkel L, Samet J, eds. *Changes in Cigarette-Related Disease Risks and Their Implication for Prevention and Control; Monograph 8.* Bethesda, MD: National Institutes of Health, 1997:13.)
speaks to the size of the Chinese population and the approximately 60% of men who smoke.[9]

Global cigarette consumption has grown dramatically over the past few decades. The global cigarette consumption has gone from 10 billion sticks to 2150 billion sticks in 1960, to 5604 billion sticks in 2002, with an estimated 9 trillion cigarettes in 2025. The top five consumers of cigarettes are China, United States, Russian Federation, Japan and Indonesia.[9]

It is no wonder that the trends for tobacco-related deaths have steadily climbed as cigarette consumption increases. For example, the smoking-related mortality in men in the United Kingdom went from 27% in 1955 to 34% in 1985 and dropped to 27% in 1995, whereas in former socialist countries, the smoking-related mortality in men went from 1.3% in 1955 to 3.7% in 1985 to 5.2% in 1995.[10] This may seem like a low number in former socialist countries; however, in 2001, the smoking prevalence in Belarusian men was 56%, Georgian men 53%, Kazakhstan men 65%, and Russian men 60%.[11] The smoking prevalence rates in women, as of 2001, were relatively low (<10%); however, the tobacco industry is undoubtably targeting this potentially growing market. Evidence has already demonstrated the significant increases in cigarette production in parallel with increased consumption in the countries of the former Soviet Union who have had outside investments from the transnational tobacco industries.[12] There is enough experience to predict the tremendous death toll that these smoking prevalences will have in future years. In China, two thirds of men start smoking before the age of 25, and with projections, 100 million of the current 300 million Chinese men younger than the age of 30 will be killed by tobacco.[10]

Figure 2.4 demonstrates the comparison of cigarette consumption between the United States and Japan from 1990 to the present.[5] With these curves in mind, Figures 2.5 and 2.6[5] demonstrate the trends in lung cancer mortality in six different countries, including the United States and Japan—all are considered industrialized, "western" economies. It is striking to observe the differences between even these "westernized"

economies and between the sexes. It is clear that the United Kingdom, followed by the United States had the earliest and most dramatic decline in male lung cancer death rates, whereas the picture for the women—as predicted by the Lopez curves, lags significantly behind.

It is also very important to consider the state of tobacco control within each country and how this impacts the smoking prevalence rates. Western countries have been at the forefront of tobacco control, with the resultant decrease in the number of people starting smoking, but also importantly, the number of people quitting smoking. Figures 2.7 and 2.8 demonstrate the age-specific prevalence of current and former smokers by birth cohort in U.S. men and Japanese men.[5] It is striking to observe the differences in age of onset of smoking and the numbers of former smokers (those who have quit). These differences explain the differences in the lung cancer mortality age-specific curves in Figure 2.5.

It is already well established that smoking causes lung cancer—at least for the past 50 or more years.[13,14] What is interesting is how the lung cancer epidemic is changing around the world, depending on the changes in the prevalence of cigarette smoking in the specific country. As approximately 10% to 20% of smokers will develop lung cancer—to radically decrease the number of lung cancer deaths, the prevalence of smoking must significantly decrease.

Lung cancers attributable to smoking vary around the world—particularly in women. In more developed countries, smoking causes 90% to 95% of lung cancers in men. For women, the highest rate of smoking-attributable lung cancer occurs in North America (85%), northern Europe (74%), and Australia/New Zealand (72%). In these regions, women have the longest duration of smoking. For other regions, the attributable fraction

is lower and more highly related to exposure to indoor cooking fuels.[6] As the rate of smoking increases in women, the attributable rate necessarily will similarly increase.

The determinants of the risk of smoking to the development of lung cancer depends on the duration of smoking, the number of cigarettes smoked per day, the age of smoking initiation, the type of cigarette smoked, the depth of inhalation, underlying susceptibility, and family history. Additional risks include exposure to environmental factors (especially radon), secondhand smoke, or occupational risks. What has been changing over time is the increasing exposure to both mainstream and secondhand smoke, particularly in developing

**FIGURE 2.9** Annual age-adjusted lung death rates for men and women; and breast cancer deaths in women, 1930 to 2001. Rates are age-adjusted to the 2000 U.S. standard population. (From Jemal A, Murray T, Ward E, et al. Cancer statistics, 2005. *CA Clin J Clin* 2005;55:10–30.)

economies and women, whereas the other causes have remained fairly stable.

In the United States, the relative risk for developing lung cancer has been determined in two large, sequential cohort studies from the American Cancer Society. These relative risks increased between these studies, from 11.9 to 23.2 in men and 2.7 to 12.8 for women, and this reflected the changes in smoking prevalence.[15] A review of the global literature from over 130 studies showed similar relative risks for lung cancer from tobacco ranging from 15 to 30.[16] Figure 2.3 from the U.S. Surgeon General Report, 1997, demonstrates the changes in U.S. tobacco consumption[8] and Figure 2.9[17] shows the changes in male and female lung cancer rates, and for comparison, the breast cancer rates in women over the same time period. From these American data, it was calculated that the cumulative probability of dying from lung cancer is 14.6% for men and 8.3% for women from smoking, versus only 1.1% in men and 0.9% in women lifelong never-smokers.[18]

How can we now relate this information to the rest of the world? We can examine some of the countries around the world to see how the lung cancer mortality rates have changed over time.[19,20] Unfortunately, most countries do not have well-documented smoking histories for the past several decades, but

their historical prevalence can be approximated from the current lung cancer death rates. Figure 2.10 demonstrates the changes over the years in the lung cancer death rates in a few representative countries from Europe. The rates from men can be contrasted with the rates for women. The similarities between how these data relate to the Lopez curves are striking. It simply demonstrates that we can readily predict the death toll from lung cancer if we do not decrease the smoking rates—particularly among women. Figure 2.11 illustrates some of the smoking prevalence rates around the world—where we need to be concerned about the lung cancer epidemic that is occurring in these countries.[21]

## HISTOLOGICAL VARIABILITY

The relative risk of smoking for the development of the different histologies for lung cancer has been confirmed many times.[22–26] Figure 2.12 demonstrates these changes in the United States. However, there is considerable variation between the different histological types of lung cancer over time between genders and between countries. Figure 2.13 illustrate the various proportion of squamous cell versus adenocarcinoma lung cancer in several

**FIGURE 2.10** **A:** Age-standardized death rate (weighted) (ASR-w) for men in Denmark, Germany, Poland, and United Kingdom, 1950 to 2002.[20] **B:** Age-standardized death rate (weighted) (ASR-w) for women in Denmark, Germany, Poland, and United Kingdom, 1950 to 2002. (From Ferlay J, Bray J, Pisani P, et al. *GLOBOCAN 2002: Cancer Incidence, Mortality, and Prevalence Worldwide. IARC CancerBase No. 5, version 2.0.* Lyon, France: IARCPress, 2004.)

**Smoking Prevalence In Adults (%) 2002–2005**

countries in Asia and Europe.[27] This has been attributed to several factors, including genetic susceptibility, but is more likely to be the result of differences in the smoke chemistry of the cigarettes smoked, which has changed substantially over time.[28]

Although smoking patterns vary greatly worldwide, men started smoking before women and smoked the cigarettes of earlier times, whereas women predominantly smoked the cigarettes of several decades later.[29] These latter cigarettes, particularly in many Western countries, are lower in tar, more likely to have ventilated filters, less polycyclic hydrocarbons, and more tobacco-specific nitrosamines.[29–31] It is therefore

not surprising that women are more likely to develop adenocarcinoma than the predominantly squamous carcinoma seen previously in men. The histologic swing to adenocarcinoma seen in men in recent decades is consistent with this concept as they too smoke more of the lower tar and filtered cigarettes. It has also has been demonstrated that nitrosamines vary considerably around the world, even though they may have a common manufacturer.[32]

The occurrence of adenocarcinoma among Asian women, many of whom do not smoke yet have a relatively high rate of lung cancer, requires an alternative explanation.

The literature suggests that the increased risk for lung cancer in Chinese women has been related to indoor air pollution from cooking with oil, especially rapeseed oil,[33,34] biomass fuel, and secondhand smoke.[35,36] Chinese women, and Asian women in general, have low smoking rates; however, in most areas they are increasing. Undoubtedly, these raising rates of cigarette smoking will increase the rates of tobacco-related lung cancers. However, how it will impact the ratios of squamous cell to adenocarcinoma will need to be assessed over time. Presently, there has already been a shift in the rates from predominance of squamous cell to adenocarcinoma in Japan, Israel, and countries in Europe where the prevalence of male smoking is still high.[37–40] As discussed previously, this shift in histologies is probably related to the changing cigarette in the various environments in addition to the increasing prevalence of smoking-related cancer in women. These trends should be followed closely—in addition to following how the cigarette is changing over time in each of these environments. This is a daunting task.

**FIGURE 2.12**  Changes in age-adjusted incidence rates per 100,000 for squamous cell and adenocarcinoma in the United States. (From Charloux A, Quoix E, Wolkove N, et al. The increasing incidence of lung adenocarcinoma: reality or artefact? A review of the epidemiology of lung adenocarcinoma. *Int J Epidemiol* 1997;261:14–23.)
**FIGURE 2.13  A:** Age-standardized death rate (weighted) (ASR-w) for squamous cell and adenocarcinoma from 1993 to 1997 in Asian countries. **B:** Age-standardized death rate (weighted) (ASR-w) for squamous cell and adenocarcinoma from 1993 to 1997 in European countries. (From Parkin DM, Whelan SL, Ferlay J, et al., eds. *Cancer Incidence in Five Continents, Vol. VIII, IARC Scientific Publications No. 15.* Lyon, France: IARC Press, 2002.)

What might be easier would be to decrease the number of people smoking, and therefore, more rapidly decrease the deaths from lung cancer. This decrease can be obtained from tobacco control efforts.[41] Figure 2.14 demonstrates the 6% decrease in lung cancer incidence observed in California caused by the efforts in decreasing initiation and increased cessation through tobacco control efforts since 1988.[42] Peto et al.[43] have concluded that people who stop smoking in middle age can avoid 90% of their tobacco-attributable risk for lung cancer. In the United States, the data suggested that the decline in smoking over the past 50 years, accounted for 40% of the decline in overall male cancer deaths and prevented 146,000 male lung cancer deaths in the time period from 1991 to 2003.[44] Certainly, initiatives of tobacco control, screening, and improved treatment
modalities should be pursued simultaneously. Even with strong tobacco control policies, we will need the research to see how best to identify and treat those that continue to be diagnosed with lung cancer—tobacco related or otherwise.

# Nontobacco-Related Lung Carcinogenesis

Lung cancer is estimated to cause 17,000 to 26,000 deaths among *nonsmokers* annually in the United States.[1] Secondhand smoke exposure explains some deaths among nonsmokers, but many deaths are unrelated to tobacco smoke. Occupational and environmental exposures and genetic characteristics have been identified as risk factors for the development of lung cancer in both smokers and nonsmokers. In this chapter, we review important toxicants, other than tobacco, for which the evidence for pulmonary carcinogenic potential is strong and the population health effects data support a causal relationship between exposure and lung cancer. These toxicants share the common feature of being respirable carcinogens, but otherwise have widely different physicochemical characteristics. The substances include minerals (asbestos and silica), radioactive gas (radon), and products of fossil fuel combustion (diesel-exhaust particles).

Historically, occupational settings have been among the most important sources of exposure to the nontobacco pulmonary carcinogens. Accordingly, many cases of lung cancer attributable to nontobacco carcinogens are work related and, in turn, preventable. Moreover, we review data on some exposures mainly encountered in industrial settings, which are most persuasively linked with lung cancer. It is important to note, however, that since the beginning of the 20th century, an estimated 85,000 chemicals have been introduced into industrial applications, many of which may be encountered in respirable states.[2] Data on the carcinogenic potential of most of these chemicals are limited or nonexistent. Some cases of lung cancer may be attributable to occupational or environmental exposures yet to be recognized as carcinogenic. However, such speculation should not alter the fact that strategies to reduce the total burden of lung cancer worldwide must remain sharply focused on preventing exposure to established pulmonary carcinogens, including tobacco and nontobacco exposures.

## ARSENIC

Arsenic is a naturally occurring element found throughout the earth's crust. Inorganic arsenic complexes are used predominantly to preserve wood, whereas organic arsenic is used in pesticides. In addition, arsenic trioxide (arsenite) is used in the treatment of promyelocytic leukemia.

Concerns over the potential carcinogenicity of arsenic were first raised as early as 1820 when Paris[3] first described its association with skin cancer. In 1930, Saupe[4] described two cases of lung cancer in association with arsenic exposure. Since then, a large amount of data has been published linking arsenic and lung cancer in humans. Blot and Fraumeni Jr[5] uncovered an increased risk of lung cancer–related mortality in smelter workers exposed to arsenic trioxide between 1938 and 1963. Tokudome and Kuratsune[6] found a significantly increased mortality rate from lung cancer in copper smelters employed at a metal refinery in Japan between 1949 and 1971. The average latency period for lung cancer was 37.6 years and was unrelated to the estimated levels of arsenic exposure. Rencher et al.[6a] conducted a retrospective mortality study at a copper smelter in Utah and demonstrated that 7% of all worker deaths were caused by lung cancer compared to 2.7% in the state of Utah and 2.2% at the smelter's associated mine and concentrator. Other investigators have confirmed the association between lung cancer and working directly with copper smelters.[7–11] Other studies have found increased risks of lung cancer in association with exposure to pesticides containing inorganic arsenic[12,13] and even the use of arsenic as a medicinal.[14] Of note, Guo et al.[15] concluded arsenic exposure is most strongly associated with the development of either squamous cell or small cell lung cancer.

Most studies assumed that only inhalational exposures are associated with arsenic-related lung cancer. However, along the southwest and northeast coasts of Taiwan, in the Niigata Prefecture of Japan, in Northern Chile, and in Bangladesh, ground water is heavily contaminated by arsenic, and its ingestion has been associated with increased incidences of lung cancer.[16–20] Chen et al.[21] evaluated the dose–response relationship between ingested arsenic and lung cancer risk as it relates to smoking. They found an increase in the relative risk of lung cancer of 3.29 (95% confidence interval [CI], 1.60, 2.78) among populations exposed to the highest (700 $\mu$g/L) relative to the

lowest (<10 $\mu$g/L) arsenic levels in drinking water. In addition, after the instillation of a tap-water system in southwestern Taiwan, lung cancer mortality declined, further bolstering the likely relationship between ingested arsenic and lung cancer.[22]

The most significant confounding factor in these studies of arsenic and lung cancer is the contribution of smoking. Some more recent studies have tried to adjust for the effect of smoking and have demonstrated a persistent carcinogenic effect of arsenic.[23] In addition, a synergistic interaction between arsenic and smoking likely exists as suggested by Pershagen et al.[24] This study evaluated Swedish copper smelter workers and found that the age-standardized rate ratio for lung cancer death in arsenic-exposed nonsmokers was 3.0. Among those smokers without occupational arsenic exposure, the ratio was 4.9. In arsenic-exposed smokers, the age-standardized rate ratio for lung cancer was 14.6.[24] A metaanalysis by Hertz-Picciotto et al.[25] and the previously described study by Chen et al.[21] also support a synergistic effect.

Nonoccupational exposure to copper smelters (i.e., residential proximity) may also pose a carcinogenic risk. However, most studies failed to establish a statistically significant link within this setting suggesting that arsenic alone may either be a weak carcinogen or may require a cocarcinogen to induce the development of cancer.[26–28]

Reviews of the literature suggest that the average latency for lung cancer diagnosis after exposure to arsenic is about 30 years. In addition, arsenic-related pulmonary malignancies appear to have a predilection for the upper lobes.[29] All histologic cell types are represented in arsenic-related lung cancer and the relative frequencies of each cell type seem to mimic that of the general nonexposed population.[30,31]

Animal data supporting a carcinogenic role for arsenic are limited. Ishinishi et al.[32] found that intratracheal instillation of three forms of arsenic (copper ore, flue dust, and arsenic trioxide) to Wistar-King rats was associated with the formation of lung adenomas and/or adenocarcinomas. In another publication, Ishinishi et al.[33] demonstrated a 10% to 30% lifetime risk of lung adenocarcinoma in Syrian golden hamsters after weekly intratracheal instillation of 3.75 or 5.25 mg of arsenic trioxide. Ivankovic et al.[34] demonstrated the induction of multifocal bronchogenic adenocarcinomas and bronchoalveolar cell carcinomas in 9 of 15 (60%) rats after intratracheal instillation of 0.1 mL of a vineyard pesticide containing calcium arsenate. Soucy et al.[35] found dose-dependent effects of arsenic trioxide on animal models of angiogenesis, as well as melanoma tumor growth and metastasis. Interestingly, the form of arsenic appears to influence the risk of lung cancer in animal studies. Specifically, calcium arsenate appears to have the strongest tumorigenic potential, whereas arsenic trioxide is of questionable carcinogenicity.[36,37]

Arsenic has been shown to induce preneoplastic changes in human fetal lung tissue.[38] The mechanism behind such changes may lie in arsenic-induced overmethylation of DNA. Mass and Wang[39] found that exposure of human lung adenocarcinoma A549 cells to sodium arsenite or sodium arsenate resulted in a significant level of methylation of a fragment of p53, a tumor suppressor gene. This may alter the function of p53 as a checkpoint in the cell cycle permitting eventual transformation into an immortal cell line. Other mouse studies have suggested that arsenic augments the ability of the tobacco-derived carcinogen, benzo(a)pyrene, to increase the number of DNA adducts in both skin and lung, the initiation step in mutagenesis.[40]

In 1980, the International Agency for Research on Cancer (IARC) concluded that the available human data were sufficient to implicate arsenic as a pulmonary carcinogen. In October 2001, the U.S. Environmental Protection Agency (EPA) announced that on January 2006, a permissible exposure limit (PEL) of 10 ppb in drinking water would be enforced.[41]

The National Institute for Occupational Safety and Health (NIOSH) has established a PEL of 2 $\mu$g/m$^3$ during a 15-minute ceiling, whereas the Occupational Safety and Health Administration (OSHA) has established a PEL of 10 $\mu$g/m$^3$ during any 8-hour period for a 40-hour workweek. Potential household exposures to arsenic through ant pesticides containing sodium arsenate and arsenic-treated pressurized wood prompted the EPA to begin phasing out these products in 1989.

## ASBESTOS

Asbestos, derived from a Greek adjective meaning inextinguishable or unquenchable, is a naturally occurring mineral used widely in the 20th century for its insulating and corrosion- and fire-resistant properties. In the late 1800s, the British discovered that asbestos fibers could be woven into textiles permitting its use in everything from brake pads to ship boiler insulators.[42] Asbestos had already been in use for centuries, and its associated adverse health effects had been recognized since at least the time of the Roman Empire when Pliny the Elder, a Roman citizen, noticed that slaves working in asbestos mines succumbed early to lung diseases. It was not until the United Kingdom Annual Report of the Chief Inspector of Factories in 1898 that the potential deleterious effects of asbestos were recognized again.[43]

Doll[44] published the landmark epidemiologic study linking lung cancer and asbestos exposure when he evaluated the autopsy results of 105 employees of an asbestos factory. Selikoff[45] provided further supportive epidemiologic evidence after reviewing the medical records of 1522 members of the asbestos workers unions in New York City and New Jersey. Wagner et al.[46] and Newhouse et al.[47] determined that even casual nonoccupational exposure to asbestos was sufficient to cause lung cancer by recognizing epidemics of mesothelioma among communities surrounding asbestos mines and neighborhoods located near asbestos textile mills.

Recent reports suggest that the mutagenic effect of asbestos involves proto-oncogenes, such as k-ras[48] and c-ras,[49] as well as tumor suppressor genes, such as p53. Nelson et al.[50] found a fivefold increase in the presence of k-ras mutations in patients diagnosed with lung adenocarcinoma who had occupational asbestos-exposure history compared to those patients with lung

cancer without exposure history. Panduri et al.[51] found that p53 induces alveolar epithelial cell apoptosis in cells damaged by asbestos exposure. Supporting the important protective role of p53, Morris et al.[52] demonstrated a fivefold increase in the incidence of asbestos-associated lung cancer in mice after disrupting intrinsic p53 function. Additional findings include alterations in the insulin receptor pathway and associated downregulation of deleted in colorectal cancer (DCC) gene, KU70, and heat shock protein 27.[53] The effects of these gene alterations are the constitutive expression of proteins promoting cell division and the downregulation or removal of proteins involved in checkpoints during the cell cycle.

Possible mechanisms by which asbestos damages DNA appear to involve the production of reactive oxygen species and the activation of mitogen-activated protein kinases. Iwata et al.[54] detected the generation of reactive oxygen species by polymorphonuclear lymphocytes after exposure to anthophyllite asbestos fibers. Schabath et al.[55] demonstrated that homozygotes for the G-myeloperoxidase allele (G/G) exhibited an increased risk of asbestos-related lung cancer (odds ratio [OR] 1.72, 95% CI, 1.09 to 2.66) compared to those subjects with G/A and A/A genotypes. Another possible mechanism proposed by MacCorkle et al.[56] involves the interaction of asbestos fibers with cell's cytoskeletal proteins or proteins involved in cell division resulting in an increase in aneuploid cells.

Another theory regarding the carcinogenicity of asbestos hypothesizes that the asbestos fiber's role is to facilitate the introduction of other carcinogens like those in cigarette smoke to cells. The fibers do so by adhering to surfactant, which then creates a lipid bilayer permitting solubilization of hydrophobic carcinogens such as polycyclic hydrocarbons. This would then permit long-term high concentration exposure of the lung epithelium to carcinogenic substances.[57–59]

The latency period for the development of asbestos-related lung cancer is in excess of 20 years.[60] Asbestos has been linked to all cell types of lung cancer.[61] The risk of lung cancer in persons exposed to asbestos seems to depend on the fiber type (greater with nonchrysotile fibers even though chrysotile exposure is associated with lung cancer),[62] fiber size (greater with longer fibers),[63] exposure environment (greater in textile than in cement industries), and evidence of asbestosis on chest radiograph (greater in patients with opacities).[64–66] The estimated risk of lung cancer in some studies is about fivefold compared to the nonexposed general population. Smoking acts synergistically with asbestos and increases the risk of lung cancer almost 50-fold.[45,67]

The Asbestos Regulations of 1931 were the first attempt to regulate asbestos exposure in the workplace. Unfortunately, the permitted exposure levels were based on a study of workers at a North Carolina asbestos factory, all of whom had been employed for less than 10 years. Another methodologic problem occurred when about 150 workers were fired prior to the initiation of the study because of concerns that they may have had asbestosis. The Asbestos Regulations of 1969 decreased the permitted exposure level 15-fold to 2 fibers/mL of air. However, a company physician untrained in epidemiology based this "safe" level of exposure on an industry-sponsored study. In 1994, the United States lowered the "safe" exposure level to 0.1 fibers/mL of air, whereas Great Britain banned the use of the substance altogether in 1999. In 2001, the World Trade Organization stated that no safe level of asbestos exposure existed.[68] In 1973, the IARC concluded that asbestos was a human lung carcinogen.[69]

As of year 2000, based on data obtained from death certificates in the United Kingdom, deaths from asbestos-related lung cancer and mesothelioma continue to rise. The implication is that those exposed to the substance over the preceding 20 to 40 years will continue to be at risk for developing lung and/or pleural cancers despite cessation of exposure.[42]

Recognition that asbestos is the underlying etiology of a patient's illness should prompt physicians to make the appropriate notifications. In addition, it would be prudent to instruct the patient on the importance of avoiding further exposure to asbestos preferably by changing jobs or using protective respiratory equipment.

**Asbestos-Related Mesothelioma**    Asbestos is the predominant cause of mesothelioma worldwide. In about two thirds of cases, an asbestos-exposure history is present. The risk of mesothelioma varies with the duration and intensity of exposure, as well as the type of asbestos fiber inhaled (highest with amosite and crocidolite). The latency period for mesothelioma is at least 25 to 30 years, and there have been reports of cases occurring more than 40 years after exposure.[70] Diagnosis often requires open-lung biopsy and unfortunately, mesotheliomas are notorious for growing along needle tracts and through surgical incisions. The most important step in evaluating a possible mesothelioma involves distinguishing it from benign mesothelioma, primary bronchogenic adenocarcinomas, and metastatic disease given the potentially different treatment options and outcomes.

# BERYLLIUM

Beryllium is a naturally occurring element found in soil, rocks, coal, and oil. It was first discovered more than 2 centuries ago but was not widely used in industry until the 1940s and 1950s. Beryllium can withstand extreme heat, remain stable over a wide range of temperatures, and act as an excellent thermal conductor. It also enhances other metals when combined with them as alloys. It is essential for numerous items used in our day-to-day activities. Electrical connections in our cell phones, battery contacts, high-definition and cable television, power steering, electronic ignition systems, and air bag sensors are all modern-day systems and/or appliances that rely on beryllium to function. Mancuso et al.[71–76] first reported a potential link between beryllium and human lung cancer followed by other reports. However, other reports found no such relationship.[77–82]

Early animal studies suggested the possible role of beryllium in lung cancer; however, the mechanism is still unknown.[83] Studies have attempted to demonstrate a genotoxic

event but have been mostly unsuccessful.[80–82] One study suggests a potential role for overmethylation of p16, a tumor suppressor gene; however, further work is needed to clarify its possible contribution.[84]

The varying results of beryllium studies have prompted four IARC meetings regarding the element's classification as a pulmonary carcinogen. In 1993, the working group of the IARC concluded that the evidence in human studies is sufficient to implicate beryllium as a carcinogen. The EPA has established that industries may release a total of 0.01 $\mu$g of beryllium per cubic meter averaged over 30 days. The OSHA has set a PEL of 2 $\mu$g of beryllium per cubic meter of air over an 8-hour workday.[85]

## CHLOROMETHYL ETHER AND BIS(CHLOROMETHYL) ETHER

Used predominantly in industries to synthesize plastics, organic chemicals, and exchange resins, chloromethyl methyl ether (CMME) and an associated impurity, bis(chloromethyl) ether (BCME) were initially produced and used in this country soon after the end of World War II. Their potential role as carcinogen was not realized until 1968 when van Duuren[86] demonstrated the development of skin cancers in mice after exposing them to CMME. Leong et al.[87] found that BCME and CMME were pulmonary carcinogens after exposing A/Heston mice to vapors of each chemical 6 hours a day, 5 days a week, for a total of 82 to 130 exposure days. Laskin et al.[88] confirmed this inhalation effect of BCME on rats and hamsters.

The results of these initial animal studies prompted further human investigation. Albert et al.[89] evaluated lung cancer mortality at six of the seven U.S. companies that used CMME at that time. They found a 2.5-fold increase in lung cancer–related mortality among workers exposed to CMME choosing nonexposed employees at those same plants as controls. They also revealed an increase in lung cancer risk with increasing duration and intensity of exposure. DeFonso et al.[90] found that CMME with 0.5% to 4% BCME resulted in a 3.8-fold increase in lung cancer risk at a Philadelphia chemical plant, again using employees without an exposure history from the same plant as controls. Numerous studies have provided additional evidence supporting CMME and BCME's role as pulmonary carcinogens.[91–99]

The literature suggests that the latency period for lung cancer after exposure to BCME and CMME is between 21 to 25 years and is inversely related to exposure intensity and duration. A predominance of small cell carcinomas (80% to 90% of cases) is apparent in most studies.

In the 1970s, restrictions in the use of and safer handling techniques for CMME and BCME were instituted with an apparent decline in the incidence of associated cases of lung cancer.[99] Currently, the use of these substances is highly restricted, thereby minimizing potential exposure. BCME breaks down easily and quickly when exposed to sunlight or water and fortunately, does not build up in the food chain. Consequently, the only likely

sources of exposure today are living near and/or working in industries that still use BCME and CMME.

The IARC officially recognized CMME and BCME as carcinogens in 1987. At this time, the EPA has set a tolerable limit of 0.0000038 parts of BCME per billion parts of water (0.0000038 ppb) in lakes and streams. Any release of more than 10 lb of BCME into the environment must be reported to the EPA. The OSHA has mandated that no more than 1 ppb of BCME be present in the air of a work environment.[100]

## CHROMIUM

Chromium is a naturally occurring mineral found throughout the environment. It is present in multiple forms and is used in wood preserving, dyes, chrome plating, leather tanning, and steel production.

In the United States, recognition of chromium as a potential pulmonary carcinogen began when the chromate industry acknowledged a concern over the incidence of lung cancer among their employees. This prompted Machle and Gregorius[101] to perform a retrospective mortality study encompassing the years 1933 through 1946 of employees at seven different plants located in New Jersey, New York, Maryland, and Ohio. They compared their findings with mortality data for industrial policyholders of the Metropolitan Life Insurance Company for the first 10 months of 1947. They found a 16-fold increase in the risk of lung cancer mortality among employees (range 18 to 50). Several ensuing studies have confirmed the increased risk of lung cancer associated with chromium exposure in occupations ranging from chromate production to the use of chromate-based pigments and/or spray paints.[102–113] Masonry,[114,115] hard-chrome plating,[116–118] and stainless steel production[119] are other occupations associated with chromium exposure and increased risks of lung cancer.

Regarding oral ingestion of chromium, a systematic review of the available data does not support a carcinogenic role for chromium (VI), especially at the current mandated maximal contamination level in drinking water.[120] No data exists supporting any increase in lung cancer among residents in communities surrounding industries, which primarily produce or utilize chromium.[121]

The mean latency period for development of chromium-related lung cancer varies between 13 and 30 years with a duration-of-exposure dependent increase in the risk of cancer. The predominant histologic cell types are small cell and squamous cell carcinoma, but all cell types have been reported in the literature.

Animal studies demonstrated a mild increase in lung cancer risk after exposure to inhaled forms of chromium. Levy et al.[122] found that intrabronchial implantation of two different samples of strontium chromate in rats resulted in a significant number of lung cancers (43 of 99 and 62 of 99), almost all of which were squamous cell carcinomas. Implantation of zinc chromate resulted in a significant increase in lung cancer development as well, but with many fewer malignancies (5 of 100).

The molecular mechanisms underlying the carcinogenicity of chromium carcinogen are still being investigated, but the preponderance of evidence points toward oxidative DNA damage. Cheng et al.[123] found that chromium (VI) in the form of potassium chromate administered to Big Blue transgenic mice by intratracheal instillation resulted in a dose- and glutathione-dependent mutation frequency within 2 weeks of initial exposure. This group suggested that the potential carcinogenic mechanism is mediated through oxidative damage of DNA.

Additional support for an oxidative DNA damage mechanism was provided by Hodges et al.[124] They found that exposing human lung epithelial cells (A549) to sodium dichromate for 1 hour resulted in a significant number of DNA-strand breaks. Immunohistochemistry analysis found that levels of a DNA-repair glycosylase 8-oxodeoxyguanosine (OGG1), were increased in treated cells. In a follow-up study, Hodges et al.[125] found that treating A549 cells with sodium dichromate for 16 hours resulted in a concentration-dependent decrease in levels of OGG1 mRNA expression and OGG1 protein in nuclear extracts. The authors found that these findings demonstrated that sodium dichromate carcinogenesis may be in part mediated by suppression of DNA-repair mechanisms performed by OGG1.

One study offered a potential cocarcinogenic mechanism for chromium exposure and smoking. Feng et al.[126] noted that pre-exposure of normal human lung fibroblasts to chromium (VI) enhances the binding of benzo(a)pyrene diol epoxide to mutational hotspots in the p53 gene, specifically codons 248, 273, and 282.

In the 1950s and 1960s, several steps were taken to decrease worker exposure to chromium—removal of calcium chromate by changing to lime-free processes and better environmental controls. Studies attempting to evaluate these modifications have not found any significant change in lung cancer-associated mortality but were often underpowered.[127]

In 1990, the IARC[128] concluded that chromium was a human pulmonary carcinogen. The OSHA currently mandates a PEL for chromate or chromic acid of 100-$\mu$g $CrO_3$/m³. The NIOSH recommends a 10-hour time-weighted average exposure limit of 1-$\mu$g Cr(VI)/m³. With respect to drinking water, the EPA[129] has established a maximum contamination level of 100 $\mu$g/mL (100 ppb).

## DIESEL EXHAUST

Diesel particulate matter is composed of a core of elemental carbon and adsorbed organic compounds, including polycyclic aromatic hydrocarbons and nitrate, metals, sulfate, and other trace elements. Diesel particulates consist largely of respirable range particulates that have a large surface area where organic substances can adsorb easily. Lung cancer risk has been shown to be elevated among workers in occupations where diesel engines have been used.[130] Concerns over the potential carcinogenicity of diesel exhaust arose as a result of studies demonstrating the development of different carcinomas after exposure to diesel particle extracts[131] and other studies showing mutagenic effects of diesel particulate matter.[132–137]

Garshick et al.[138] performed a case-control study of U.S. railroad workers with at least 10 years of service and born in or after 1900. Using deaths between March 1, 1981 and February 28, 1982 and work history data available from the U.S. Railroad Retirement Board (RRB), they demonstrated an OR for lung cancer of 1.41 (95% CI, 1.06, 1.88) for railroad workers younger than age 65 at death exposed to diesel exhaust for more than 20 years after adjustment for cigarette smoking and asbestos exposure. However, another study published by Garshick[139] in 2004 failed to find an association between the lung cancer mortality and the duration of time that subjects spent as railroad workers. In this study, the increase in lung cancer mortality was restricted to those subjects who worked specifically on locomotives powered by diesel engines.

Swanson et al.[140] demonstrated significantly increased risks of lung cancer after adjustment for age at diagnosis, smoking, and race among truck drivers and railroad workers employed for more than or equal to 20 and 10 years. Their adjusted ORs were 2.5 (95% CI, 1.1, 4.4) and 2.4 (95% CI, 1.1, 5.1), respectively. They also found statistically significant trends for lung cancer in farmers. They are the first investigators to document this group as being at risk. In 2003, Jarvholm et al.[141] confirmed these findings in truck drivers.

Brüske-Hohlfeld et al.[142] described an elevated risk in farmers and found an OR of 6.81 (95% CI, 1.17, 39.51) for exposures of greater than 30 years. The increase in the OR has been attributed to the repeated exposure of farmers to exhaust as they drive tractors back and forth through their fields, thereby possibly increasing the concentration of exhaust and consequently their exposure.

With the amount of evidence linking diesel exhaust to lung cancer, in 2002, the EPA[143] concluded that diesel exhaust is a potential causative agent of lung cancer. By 2007, they required that the sulfur content of diesel fuel be less than 15 ppm.[144]

## MINERAL OIL

Mineral oil has been in use in the textile and metalworking industries since the latter half of the 19th century. Initial concerns over its potential role as a carcinogen were raised after an epidemic of scrotal cancers among mule spinners in the cotton industry.

Jones[144a] was the first to describe abnormalities on chest radiographs of workers exposed to mineral oil aerosols.[145] Several case reports of lung cancer in association with a mineral oil-exposure history appeared between 1940 and 1970 prompting epidemiologic studies to clarify this apparent connection.[146–148]

Other case-control studies in the 1980s found significant associations between lung cancer and mineral oil exposure in workers in the metal industry and in workers using rotary letterpress printing machines.[149] More recently, an association has also been found in aerospace workers.[150] Mineral oil contains varying amounts of polycyclic aromatic hydrocarbons, known carcinogens. These molecules are the presumed carcinogenic component of mineral oil.

In 1984, the IARC[151] concluded that there was sufficient evidence from human studies that mineral oil is a human carcinogen. Currently, OSHA has set a PEL for mineral oil of 5 mg/m$^3$ of air as a time-weighted average concentration over an 8-hour period. The NIOSH has established similar exposure standards.[152]

## NICKEL

Nickel is a naturally occurring element found in the environment in combination with sulfur or arsenic. It is a silvery white metal initially prized for its ability to color glass green. Nickel is hard yet malleable, magnetic, and inert; consequently, it has multiple uses. Presently, most mined nickel is used to produce austenitic stainless steel, whereas the remainder is used for the production of different alloys, rechargeable batteries, catalysts, plating, coins, chemicals, and foundry products.

The carcinogenicity of nickel only became apparent in Europe after case reports of cancer among nickel-refinery workers. Doll[153] provided the first epidemiologic evidence for lung and nose cancer after occupational exposure to nickel; however, his study did not have adequate data on duration of nickel exposure or information on exposure to other potential pulmonary carcinogens such as smoking. Studies of nickel workers continued to demonstrate increased risks for lung cancer, the largest of which was conducted by the International Committee on Nickel Carcinogenesis in Man (ICNCM) in 1990.[154–157] This study evaluated 140,888 nickel workers with a minimum employment period ranging between 6 months and 5 years. The committee concluded that most of the lung cancer risk was associated with exposure to oxidic and sulfidic nickel at high concentration or to a high concentration of the oxidic form alone. Soluble-nickel exposure at low levels was associated with high risks of lung cancer, and metallic nickel had no appreciable associated risk. However, Grimsrud et al.[158] evaluated a group of Norwegian nickel-refinery workers and found that a dose-related effect was evident for lung cancer risk, as well as exposure to water-soluble nickel species but not to sulfidic, oxidic, or metallic forms. In additional studies, Grimsrud et al.[159,160] continued to demonstrate an increase in lung cancer mortality associated with process work at nickel factories. At this time, the controversy over the risks of each specific type of nickel persists.[161,162]

As in all occupational lung cancer studies, smoking has presented a problem in ascertaining the true role of nickel exposure in lung cancer risk. Attempts to tease out the contribution of smoking in lung cancer risk among nickel workers have suggested an additive effect.[163]

The latency period for nickel-related lung cancer is about 15 years. A review of the literature did not reveal any predominance of a particular histologic cell type.

Animal data have not been entirely consistent in supporting the hypothesis that nickel is a pulmonary carcinogen. Ottolenghi et al.[164] were able to induce lung cancers in rats after inhalation of nickel subsulfide. However, Dunnick et al.[165] failed to demonstrate such a response. They also evaluated the inhalational effects of oxidic nickel and again, failed to demonstrate an increase in the development of lung cancer in rats. At higher doses, an increase was found but not statistically significant. Soluble nickel inhalational studies had not been conducted prior to the National Toxicology Program 2-year inhalation study. Again, no significant increase in lung cancer incidence was found after exposure to soluble nickel.[166] Exposing animals to metallic forms of nickel have not demonstrated the development of lung cancer either, except for one study, which did produce lung cancer after intratracheal instillation of elemental nickel in rats.[167] On a molecular level, nickel has been shown to damage and mutate DNA while also preventing DNA repair.[168,169]

In 1990, the IARC concluded that nickel compounds were carcinogenic to humans. The EPA has set a long-term PEL of 0.2 mg of nickel per kilogram of body weight per day in food and drinking water. The OSHA has established an occupational level of exposure to be 1 mg on nickel per cubic meter over an 8-hour workday, 40-hour workweek. The NIOSH has set a recommended exposure level of 0.015 mg/m$^3$.[170]

## RADON

Radon is an odorless, colorless gas, which is derived from the radioactive decay of uranium. Radon itself undergoes radioactive decay with a half-life of about 4 hours and generates two progeny or radon daughters. Radon daughters, with a half-life of about one-half hours, attach easily to dust and other airborne particles, permitting their inhalation and deposition along the respiratory airways. The daughters continue to decay until they become nonradioactive particles. During each decay cycle, release of alpha, beta, and gamma radiation occurs, thereby predisposing nearby living cells to potential DNA damage and/or mutation and subsequent development of malignancy. Numerous studies have demonstrated the mutagenic effects of radiation on cellular DNA[171–173] and the generation of lung cancers in Sprague-Dawley rats[174,175] and A/J mice.[176]

In the 1800s, uranium was used primarily as a dye, and uranium miners in Schneeberg, Germany and Joachimsthal, Czechoslovakia were known to develop lung disease and lung cancer.[177] In fact, the relationship was significant enough that by 1932, both Germany and Czechoslovakia had designated lung cancer in these miners as a compensatable disease.[178]

Studies conducted by the U.S. Public Health Service in the 1950s raised concerns about the possibility of increased risks of lung cancer among uranium miners.[179] By 1964, reports were circulating about the high concentrations of radon in uranium mines,[180] and there were concerns regarding the risk of lung cancer being related to the amount of exposure to radon daughters.[181] However, controversy existed over the influence of smoking on the risk of lung cancer.

Numerous studies among Navajo men were performed to evaluate the effects of uranium/radon on lung cancer. Mining around the Navajo Nation began in 1948, peaked around 1956, and declined to zero by 1967.[182] Several studies demonstrated

an excess in lung cancer–related mortality among Navajo Indians. Archer et al.[183] found 11 lung cancer–related deaths in a follow-up study of 780 predominantly Navajo Native American Indians compared to an expected number of 2.6. Gottlieb et al.[184] documented that between February 1965 and May 1979, 16 of 17 male Navajo patients admitted with lung cancer were uranium miners (94.1%). Samet et al.[185] were able to demonstrate a significantly elevated risk of lung cancer in predominantly nonsmoking Navajo Indians. Of the 32 Navajo men with documented lung cancer between 1969 and 1981, 23 had been uranium miners. Information regarding smoking status was available for 21 of these 23 miners: 8 were nonsmokers; 2 smoked less than one cigarette per day; 6 smoked between one to three cigarettes daily; and 5 smoked between four and eight cigarettes per day. In the same issue of the *New England Journal of Medicine*, Radford et al.[186] also demonstrated an increased incidence of lung cancer in Swedish iron miners who had been exposed to low doses of radon daughters, not affected by smoking status.

In an editorial, Harley[187] discussed the potential implication of environmental exposure to radon. The average environmental radon exposure has been estimated to be about 0.2 working-level months (WLM) per year.[188] A working level is equivalent to 100 pCi/L of air at equilibrium. A WLM is the exposure derived from spending 170 hours (1 month's working hours) exposed to a working level. Based on a risk projection generated by Radford et al.,[186] this level of exposure translates into a lung cancer risk of 15 cases per 1000 persons. Lubin et al.[189] pooled the results from two case-control studies of residential radon exposure in China and found increased ORs for the risk of lung cancer. Specifically, for subjects living in the same home for 30 years or more exposed to 100 Bq/m$^3$ of radon, the OR for lung cancer was 1.32 (95% CI, 1.07, 1.91) where 1 Ci is equivalent to $3.7 \times 10^{10}$ Bq. In 2005, Darby et al.[190] and Krewski et al.[191] also found increases in the risk of lung cancer after pooling 13 European and 7 North American case-control studies, respectively.

The highest recorded environmental radon-related exposure occurred in Pennsylvania at the home of Stanley Watras. His home level of radon was 2700 pCi/L. Geologic surveys of his home revealed that the structure was located on the Reading Prong, a large naturally occurring granite deposit. Other natural soil sources of radon include shale, phosphate, and pitchblende. It has been estimated that 1 in 15 homes have higher than acceptable radon levels as determined by the EPA (4 pCi/L). The average level in the U.S. homes is about 1 pCi/L.

Commercial kits are available to measure radon levels in homes, but consumers should be aware that only certain testing devices are certified as "meeting EPA requirements." Testing should be performed if the home is located over large deposits of granite, shale, phosphate, or pitchblende, as well as if a young patient without a significant smoke-exposure history or significant family history presents with a lung cancer. Removing radon sources from the home requires professional certified contractors. Options include sealing cracks in floors and walls, installing pipes and fans to ventilate the ground below home foundations (subslab depressurization), and/or soil depressurization. One of the most important interventions is smoking cessation, especially inside the dwelling.

## SILICA

Crystalline silica is the cause of silicosis, an inhalational occupational disease. The list of occupations associated with crystalline silica exposure is extensive and includes any occupation that aerosolizes crystal dusts. Mining, sandblasting, ceramic production, and stone working are a few examples.

Hippocrates recognized the development of pulmonary disease in the setting of occupational exposure to crystalline silica dust as early as 400 BC. Silica was not thought of as a carcinogen until the 1980s after several investigators noted the development of lung and pleural cancers in rats after exposure to crystalline silica. Wagner[192–194] demonstrated an increase in the development of lymphosarcomas after intrapleural injection of crystalline silica in Wistar rats, injection of alkaline-washed quartz, cristobalite, and Min-U-Sil in Wistar rats, and injection of six different forms of crystalline silica in three different rat strains. Stenbäck and Rowland[195] demonstrated an increased incidence of respiratory tumors (44%) with intratracheal instillation of silica in combination with benzo(a)pyrene in Syrian golden hamsters compared with benzo(a)pyrene alone (10%). Holland et al.[196] also showed an increased incidence of respiratory tumors (16.7%) in Sprague-Dawley rats after intratracheal administration of silica. His group also showed that Fischer-344 rats, after inhalational exposure to silica, had an increased incidence of respiratory cancers (66.7%) compared to none in the controls.[197]

The potential role of silica in human lung cancer was brought to light with the work of several epidemiologists. In the 1500s, miners from Schneeberg and Joachimsthal had a high mortality rate, and it was recognized only later that the likely cause of this increase was lung cancer.[198] Milham Jr[199] found a threefold increase in the risk of bronchial and lung cancers in metal molders from Washington State based on death certificates between 1950 and 1971. Westerholm[200] examined the Swedish Pneumoconiosis Register and found that those who developed silicosis had a significantly elevated risk of lung cancer–related mortality. The relationship between silicosis and lung cancer has been supported by additional studies.[201–203] Finkelstein et al.[204] also demonstrated a two-fold increase in lung cancer–related deaths in patients receiving workmen's compensation for silicosis between 1940 and 1975 from data obtained from the Ontario Ministry of Labor. Attfield et al.[205] found a dose–response relationship between silica exposure and lung cancer in Vermont granite workers. These case-control studies did not document the prevalence of smoking in the study population, but it was presumed to be significantly higher than that of the control population, which was the general public. In addition, demonstration of pneumoconiosis or silicosis was required in the studies by Westerholm and Finkelstein, respectively, thereby preventing conclusions

regarding the risk of lung cancer in workers exposed to silica without evidence of disease on radiographs.

The controversy over the potential role of silica in lung cancer pathogenesis stems from numerous studies, which failed to find an increase in cancer risk after attempting to account for smoking and exposure to radon daughters, arsenic, and other occupational carcinogens.[206,207] Becker and Chatgidakis[208] did not find a significant difference in the incidence of bronchogenic carcinoma in white male gold miners compared to non-miners. Other studies found that the degree of silicosis did not correlate with the incidence of bronchogenic carcinoma.[209,210] In response to this controversy, Checkoway et al.[211] evaluated the incidence of lung cancer in diatomaceous earth mining and processing facility employees. They found that lung cancer incidence was associated with cumulative crystalline silica exposure and was not dependent on the presence of radiographically evident silicosis. They attempted to further bolster their findings by reviewing the available literature, but found that the design of most studies attempting to better describe the link between silica and lung cancer were potentially confounded by the use of compensation claims to identify patients with silicosis and the lack of adequate quantification of exposure.[212] A recent study concluded that silica exposure in North American industrial sand workers was associated with an increase in lung cancer after controlling for smoking.[213]

Despite these contradictory studies, in 1996, the IARC concluded that the available literature provided sufficient evidence implicating the inhalation of crystalline silica as a carcinogen. The American Thoracic Society (ATS) followed that same year with a statement describing the potential adverse effects of inhaled silica exposure, including lung cancer. However, ATS qualified the statement by questioning the carcinogenicity of silica dust in nonsmokers and in those exposed to silica dust without evidence of silicosis. In 1989, the NIOSH concurred with the findings of the IARC and ATS after conducting their own review of the literature and recommended that crystalline silica be listed as a potential occupational carcinogen.

Occupational exposure controls have been established by government agencies for silica but as part of a group of fibers labeled as synthetic vitreous fibers. The PEL set by OSHA is 5 mg/m$^3$ for the inhalable fraction and 15 mg/m$^3$ for the total dust exposure. The NIOSH has set a recommended exposure limit (REL) of 3 fibers per cubic centimeter for fibrous glass dust over a 10-hour time-weighted average.[214]

## VINYL CHLORIDE

Vinyl chloride (VC) has been used for various applications as early as the 1920s, but techniques to produce a stable form of polyvinyl chloride (PVC) did not arise until the 1930s. The polymerization process required to produce PVC involves the use of a reactor. After completion of the reaction, the tank would need cleaning to remove a layer of PVC that had formed on the walls of the reactor. Currently, high-pressure

jets and solvents are used for this purpose but originally, workers would climb into the reactors with spatulas or hammers and chisels. Consequently, they were exposed to high levels of VC, which was associated with an acute illness manifesting as headaches, dizziness, visual disturbances, anorexia, abdominal pains, and dyspnea.[215]

Initial concerns regarding potential carcinogenicity were raised in animal studies.[216] Soon afterward, Creech et al.[217] published a report on the increased incidence of hepatic angiosarcomas in PVC workers. Based on the results of animal studies and the demonstration of an increase in hepatic angiosarcoma in PVC workers, Tabershaw et al.[218] decided to conduct a historical prospective mortality study of 8384 men who had had at least 1 year of occupational exposure to VC. They found 13 respiratory cancers compared with 10.28 expected suggesting a potential role for VC as a pulmonary carcinogen. The first human study to show a significant increase in lung cancer was conducted by Waxweiler et al.[219] They performed a retrospective cohort study on workers exposed to VC at four plants in the United States and found an excess of respiratory cancers at plant number four (9 compared with 4.6) and 12 cases of respiratory malignancies compared with an expected 7.7 at all plants. Of note, plant 4 contributed more than two thirds of person-years to the study, which was the reasoning provided by the authors for conducting a separate analysis at that particular plant. However, a review of studies of VC and lung cancer has generated conflicting conclusions regarding the potential of VC to act as a pulmonary carcinogen.[220–222] There is little doubt about the role that VC plays in hepatic angiosarcoma, but its contribution to the development of human lung cancer is still under debate today.[222]

Regardless, the IARC concluded that VC is a human pulmonary carcinogen as a result of sufficient evidence on the carcinogenicity in humans. The EPA has mandated that human exposure be no more than 0.002 mg of VC per liter of water. The OSHA has set a PEL of 1 ppm of air during an 8-hour workday during a 40-hour workweek.[223]

## WHERE TO FIND MORE INFORMATION

This chapter provides an overview on the topic of nontobacco-related lung carcinogenesis. More information is available on the Internet. Details about proportionate mortality ratios (PMR) for lung cancer in higher-risk industries may be found through the NIOSH at http://www.cdc.gov/niosh/topics/surveillance/ords/NationalStatistics/Highlights/table13-01(LC01).html. Details about PMR for lung cancer in specific occupations may be found at http://www.cdc.gov/niosh/topics/surveillance/ords/NationalStatistics/Highlights/table13-02(LC01).html. The lists of substances NIOSH has determined are potential occupational carcinogens may be found at http://www.cdc.gov/niosh/npotocca.html. Information about the NIOSH Health Hazard Evaluation program and how to request an evaluation may be found at http://www.cdc.gov/niosh/hhe/.

Other excellent sources of information about pulmonary carcinogens encountered in occupational and environmental settings may be found through Web sites sponsored by the Centers for Disease Control and Prevention (http://www.cdc.gov/), NIOSH (http://www.cdc.gov/niosh/), the U.S. EPA (http://www.epa.gov/), and the IARC (http://www.iarc.fr/).

## CONCLUSION

Lung cancer among nonsmokers is an important cause of morbidity and mortality. Multiple carcinogens have been identified as contributing to the total public health burden of lung cancer. No single carcinogenic exposure accounts for a significant burden of lung cancer among individuals who have not been exposed to tobacco smoke. Although a large body of literature has identified a spectrum of respirable exposures significantly associated with the development of lung cancer in exposed populations, proving a causal link between an exposure and a case of lung cancer in an individual nonsmoker is challenging.

Reducing exposure to carcinogens through engineering controls, production substitution, and personal respiratory protection remains the principal mechanism for reducing occupational lung cancer risk. Environmental controls are relevant in any setting where pulmonary carcinogens may be encountered. If ongoing exposures are of concern, an investigation of the workplace or home environment is critical. If a potential carcinogen is discovered in either setting, trained contractors may be required to assist with clean up. Claims of past or ongoing occupational exposure to pulmonary carcinogens, such as asbestos or uranium, among individuals with lung cancer may be compensable.

# Genetic Susceptibility to Lung Cancer

Lung cancer is the most common cause of cancer death in the United States[1] with 162,000 deaths estimated for 2008 among 215,000 incident cases. Lung cancer became the leading cause of cancer death in men in the early 1950s and in women in 1987. From 1950 to 1988, lung cancer experienced the largest increase in mortality rate of all the cancers,[2] reflecting increases in smoking behavior. Lung cancer prognosis often remains poor because it is usually detected as a stage III or IV malignancy. Identifying genetic factors that influence lung cancer risk could help in identifying subsets of individuals at particularly high risk, in whom early detection strategies could be adopted. In addition, a better understanding of the genetic influences that increase lung cancer risk may lead to the development of novel approaches for chemoprevention and therapy.

Cancer of the lung has frequently been cited as an example of a malignancy that is solely determined by the environment[3] and the risks associated with cigarette smoking[3–6] and certain occupations, such as mining,[7] asbestos exposure, shipbuilding, and petroleum refining,[8–12] are well established. About 85% to 90% of lung cancer risk can be associated with cigarette smoking.[13–15] Environmental tobacco smoke (ETS, passive smoking) has also been shown to be associated with a mild increase in risk for lung cancer in North America and Europe.[6,16–18] A recent prospective European study estimating that between 16% to 24% of lung cancers in nonsmokers and long-term ex-smokers were attributable to ETS.[19] A meta-analysis of 22 studies showed that exposure to workplace ETS increased risk of lung cancer in workers by 24%, and that this risk was highly correlated with duration of exposure.[20]

Dietary studies have found reduction in risk associated with high compared with low consumption of carotene-containing fruits and vegetables.[21–27] Subsequent chemoprevention trials among high-risk subjects with a history of smoking and/or occupation exposure showed a surprising increase in lung cancer risk in these populations associated with beta-carotene supplementation.[28–30] At least one very large metaanalysis[31] found significant protective effects of increased levels of dietary $\beta$-cryptoxanthin, another carotenoid.

There is little doubt that most lung cancer cases are attributable to (i.e., would not occur in the absence of) cigarette smoking and other behavioral and environmental risk factors,[2,6,16,32,33] and most studies indicate that duration of cigarette smoke is a more important risk factor than intensity or number of cigarettes smoked per day.[34–36] However, it was conjectured long ago that individuals differ in their susceptibility to these environmental insults.[37–39] Mutations and loss of heterozygosity at genetic loci such as oncogenes and tumor suppressor genes (TSGs) are involved in lung carcinogenesis,[40–42] but most of these changes are thought to accumulate in individual somatic cells over time, as opposed to the inherited risk to all cells that will result from mutations or risk-increasing polymorphisms occurring in transmission from germ cells. However, numerous studies show that certain allelic variants at some genetic loci affect inherited susceptibility to lung cancer. Furthermore, mounting epidemiologic evidence has suggested that lung cancer shows familial aggregation after adjusting for cigarette smoking and other risk factors, and that differential susceptibility to lung cancer is inherited in some families. This chapter describes inherited major susceptibility loci and findings from well-replicated studies of loci for lung cancer risk that have less pronounced effects. We also relate these risks to the well-known risks as a result of environmental risk factors, particularly personal cigarette smoking.

## INHALATION OF TOBACCO SMOKE

The association between cigarette smoking and lung cancer is strong and well established.[3–5,43–47] The incidence of lung cancer is correlated with the cumulative amount and duration of cigarettes smoked in a dose–response relationship,[6,44,48] and smoking cessation results in a leveling off of risk for lung cancer at the time of smoking cessation.[6,49,50] Lung cancer rates and smoking rates are also highly correlated in different geographic regions.[51] In 1991, Shopland et al.[52] showed that the relative risk (RR) of lung cancer for male smokers versus nonsmokers is

22.36 and that for female smokers versus female nonsmokers is 11.94. They also estimated that 90% of lung cancers in men and 78% in women were directly attributable to tobacco smoking. Kondo et al.[53] showed a significant ($p < 0.001$) dose–response relationship between number of cigarettes smoked and the frequency of p53 mutations in tumors of lung cancer patients, suggesting that somatic p53 mutations may be caused by exposure to a carcinogen/mutagen in tobacco smoke or its metabolites.

## BIOLOGIC RISK FACTORS

In general, all studies suggesting genetic susceptibility have also shown strong risk resulting from cigarette smoking and often have shown an interaction of high-risk genotype and smoking on lung cancer risk. When trying to determine whether a complex disease or trait such as lung cancer has a genetic susceptibility, one asks three major questions:

1. Does the disease (lung cancer) cluster in families? If some risk for lung cancer is inherited, then one would expect to see clustering of that cancer in some families above what would be expected by chance.
2. If the aggregation of lung cancer does occur in some families, can the observation be explained by shared environmental/cultural risk factors? In the study of lung cancer, one needs to assess whether the familial clustering of lung cancer is solely a result of clustering of smoking behaviors or other environmental exposures within families.
3. If the excess clustering in families is not explained by measured environmental risk factors, is the pattern of disease consistent with Mendelian transmission of a major gene (i.e., of transmission through some families of a moderately high penetrance risk allele) and can this gene(s) be localized and identified in the human genome?

In addition, inherited susceptibility factors for lung cancer can also be identified by conducting large-scale case control studies, just as these approaches have been successful for other complex diseases that often result from a complex interplay of genetic and environmental factors.

## EVIDENCE FOR FAMILIAL AGGREGATION OF LUNG CANCER

### Epidemiologic Cohort Studies
Tokuhata and Lilienfeld[54,55] showed familial aggregation of lung cancer over 40 years ago. After accounting for personal smoking, their results suggested the possible interaction of genes, shared environment, and common lifestyle factors in the etiology of lung cancer. In their study of 270 lung cancer patients and 270 age-, sex-, race-, and location-matched controls and their relatives, they found an RR of 2.0 to 2.5 for mortality because of lung cancer in cigarette-smoking relatives of cases compared with smoking relatives of controls. Nonsmoking relatives of lung cancer cases were also at higher risk when compared with nonsmoking relatives of controls. Smoking

was a more important risk factor for men, but family history was the more important risk factor for women. They also noted a synergistic interaction between familial and smoking factors on the risk of lung cancer in relatives, with smoking relatives of lung cancer patients having much higher risk of lung cancer than either nonsmoking relatives of patients or smoking relatives of controls. They observed a substantial increase in mortality resulting from noncancerous respiratory diseases in relatives of patients compared with relatives of controls, suggesting that the case relatives have a common susceptibility to respiratory diseases. However, they found no significant differences between the spouses of the lung cancer cases and controls for lung cancer mortality, mortality from noncancerous respiratory diseases, or smoking habits.

The major weakness of this study was that smoking status alone was used. Therefore, some of the familial aggregation could be a result of familial correlation in smoking levels or age at smoking initiation. However, nonsmoking relatives of cases were at higher risk than nonsmoking relatives of controls.

At present, many other studies have shown evidence of familial aggregation of lung cancer. In 1975, Fraumeni et al.[56] reported an increased risk of lung cancer mortality in siblings of lung cancer probands. In 1982, Goffman et al.[57] reported families with excess lung cancer of diverse histologic types. Lynch et al.[58] reported evidence for increased risk of cancer at all anatomic sites for relatives of lung cancer patients but no significant increased risk for lung cancer alone in these relatives.

In southern Louisiana, case-control studies reported an increased familial risk for lung cancer[59] and smoking-related non–lung cancers[60] among relatives of lung cancer probands (the index case leading the family to be studied) after allowing for the effects of age, sex, occupation, and smoking. In these two studies, familial aggregation analyses were performed on a set of 337 lung cancer probands (cases), their spouse controls, and the parents, siblings, half-siblings, and offspring of both the probands and the controls. The probands were male and female whites who died from lung cancer during the period 1976 to 1979 in a 10-parish (county) area of southern Louisiana, a region noted for its high lung cancer mortality rates. There were about 3.5 male probands to every female lung cancer proband in the data set. A strong excess risk for lung cancer was detected among first-degree relatives of probands compared with relatives of spouse controls, after adjusting for age, sex, smoking status, total duration of smoking, cigarette pack-years, and a cumulative index of occupational/industrial exposures. Parents of probands had a fourfold risk of having developed lung cancer compared with parents of spouses, after adjusting for the effects of age, sex, smoking, and occupational exposures. Women greater than 40 years old who were relatives of probands were at nine times higher risk than similar female relatives of spouses, even among nonsmokers who had not reported excessive exposure to hazardous occupations. Among female heavy smokers who were relatives of probands, the risk was increased from fourfold to sixfold. Overall, male relatives of probands had a greater risk of lung cancer than their female counterparts. After controlling for the confounding effects

of the measured environmental risk factors, relationship to a proband remained a significant determinant of lung cancer, with a 2.4 odds in favor of relatives of probands.

These same families were reanalyzed[60] to determine if non–lung cancers exhibited similar familial aggregation. When analyzing the number of cancers at any site that occurred in a family, proband families were found to be 1.7 times more likely than spouse families to have one family member (other than the proband) with cancer, and 2.2 times more likely to have two family members with cancer. Comparing case relatives and control relatives, families that had three and four or more cancers occurred with RRs of 3.7 and 5.0, respectively. Each risk estimate was significant at the 0.01 level. The most striking differences in cancer prevalence between proband and control families were noted for cancer of the nasal cavity/sinus, mid-ear, and larynx (odds ratio [OR] = 4.6); trachea, bronchus, and lung (OR = 3.0); skin (OR = 2.8); and uterus, placenta, ovary, and other female organs (OR = 2.1). After controlling for age, sex, cigarette smoking, and occupational/industrial exposures, relatives of lung cancer probands maintained an increased risk of non–lung cancer ($p < 0.05$) when compared with relatives of spouse controls.

A family case-control study, drawn from a population-based registry in Saskatchewan, Canada was reported by McDuffie.[61] A total of 359 cases and 234 age- and gender-matched community controls were included in the study. Most families reported at least one member with a history of neoplastic disease exclusive of the proband (62% of patients' families and 57% of control families). However, the families of the lung cancer cases were more likely (30%) to have two or more family members affected with any cancer than the families of the controls. The case families were also significantly more likely to have two or more relatives with lung cancer than were the control families. In addition, a higher percentage of all primary tumors were lung tumors (16.5%) in patients' relatives compared with controls' relatives (10%). The progression of increased risks for observing 1, 2, 3, and 4+ affected relatives in case families versus control families was less than that observed by Sellers et al.'s[60] study but showed the same type of progression.

Family history data from an incident case-control study in Texas were analyzed for evidence of familial aggregation by Shaw et al.[62] A total of 943 histologically confirmed lung cancer cases and 955 age-, gender-, vital status-, and ethnicity-matched controls were interviewed regarding smoking, alcohol use, cancer in first-degree relatives, medical history, and demographic characteristics. After adjusting for personal smoking status, passive smoking exposure (ever/never), and gender, there was a 1.8-fold OR associating lung cancer with having one or more first-degree relatives with lung cancer. Lung cancer risk increased as the number of relatives with cancer increased and was highest when only relatives with lung cancer were considered (ORs of 1.7 and 2.8 for one and two or more relatives with lung cancer, respectively). Lung cancer was diagnosed at a significantly younger age among cases who had first-degree relatives with lung cancer than among those who had no relatives with lung cancer. However, no such age difference was seen

between cases who had first-degree relatives with any cancer versus those who had no relatives with cancer. This study also examined histologic subtypes of lung cancer cases and found that for each histologic type, there were significant risks associated with having any relatives with lung cancer, with ORs of 2.1 for adenocarcinoma, 1.9 for squamous cell carcinoma, and 1.7 for small cell lung cancer. Finally, in this study, only current and former smokers had an increased lung cancer risk associated with lung cancer in relatives.

Cannon-Albright et al.[63] examined the degree of relatedness of all pairs of lung cancer patients in the Utah Population Database (UPD). By comparing this with the degree of relatedness in sets of matched controls, they showed that lung cancer exhibited excess familiality, and three of four histological tumor types still showed excess familiality when considered separately. In the same population, but using different methodology, Goldgar et al.[64] studied lung cancer probands and controls who had died in Utah and their first-degree relatives. They found that 2.55 times more lung cancers occurred in first-degree relatives of lung cancer probands than expected (computing a familial relative risk or FRR) based on rates in control relatives. When they stratified by gender, they observed higher relative risks for female relatives of female probands (FRR = 4.02) versus male relatives of male probands (FRR = 2.5). No adjustment was made in these analyses for personal smoking or other environmental risk factors, so these results may partly reflect the familiality of smoking behaviors. However, the UPD is derived from the Church of Latter-Day Saints records, which is largely a nonsmoking population and Utah has the lowest smoking rates of any state in the United States.

In 2000, Bromen et al.,[65] in a population-based case-control study in Germany, showed that lung cancer in parents or siblings was significantly associated with an increased risk of lung cancer and that this risk was much stronger in younger participants. In 2003, Etzel et al.[66] evaluated whether first-degree relatives of lung cancer cases were at increased risk for lung cancer and for other smoking-related cancers (bladder, head and neck, kidney, and pancreas). They studied 806 hospital-based lung cancer patients and 663 controls matched on age, sex, ethnicity, and smoking history, all from the Houston, Texas area. After adjustment for smoking history of patients and their relatives, there was significant evidence for familial aggregation of lung cancer and of smoking-related cancers. However, they did not find increased aggregation in the families of young onset (less than or equal to age 55) lung cancer cases or in families of never-smokers.

Two studies in China[67,68] both found, after adjusting for age, sex, birth order, residence, family size, chronic obstructive pulmonary disease (COPD), smoking, and cumulative index of smoky coal exposure or occupational/industrial exposure index, that first-degree relatives of lung cancer patients were at significantly increased risk for lung cancer compared with the same relatives of controls. They also observed that families of the lung cancer patients were significantly more likely to have three or more affected relatives than were control families.

A series of studies using the Swedish Family-Cancer Database,[69–72] which totals over 10.2 million individuals,

found that a high proportion of lung cancers diagnosed before the age of 50 appear to be heritable, and that lung cancer patients with a family history of lung cancer were at a significantly increased risk of subsequent primary lung cancers. A recent study[73] utilizing the Icelandic Cancer Registry calculated risk ratios of lung cancer in first-, second-, and third-degree relatives of 2756 lung cancer patients diagnosed between 1955 and 2002. RRs were significantly elevated for all three classes of relatives, and this increased risk was stronger in relatives of early onset lung cancer patients (age at onset less than or equal to 60 years). The effect did not appear to be solely a result of the effects of smoking in all relative types, except for cousins and spouses.

In the United Kingdom, a case-control study of lung cancer prevalence in first-degree relatives of 1482 female lung cancer cases and 1079 female controls,[74] adjusting for age and tobacco exposure (pack-years) in the cases and controls. They found that lung cancer in any first-degree relative was associated with a significant increase in lung cancer risk, and that the increase in risk was stronger in relatives of cases with onset less than 60 years or cases with three or more affected relatives. However, data on personal smoking in relatives were not available.

A study of early onset white and African American lung cancer cases and of 773 frequency-matched controls in Detroit, Michigan,[75] showed that smokers with a family history of early onset lung cancer had a higher risk of lung cancer with increasing age than smokers without a family history, and that relatives of African American cases were at higher risk than relatives of white cases, after adjusting for age, sex, pack-years of cigarette smoking, pneumonia, and COPD.

Studies of familial risk of lung cancer in nonsmokers[65,76–78] have also shown increased risk of lung cancer associated with a family history of lung cancer. Schwartz et al.[76] found increased risk of lung cancer among relatives of younger, nonsmoking lung cancer cases compared with relatives of younger controls after adjusting for smoking, occupational, and medical histories of each family member, suggesting increased susceptibility to lung cancer among relatives of early onset nonsmoking lung cancer patients. Wu et al.[77] found an increased risk of lung cancer in persons with a history of lung or aerodigestive tract cancer in first-degree relatives after adjustment for ETS exposure, which was significant for affected mothers and sisters. Mayne et al.[78] in a population-based study of nonsmokers (45% never-smokers and 55% former smokers who had quit at least 10 years prior to diagnosis or interview; 437 lung cancer cases and 437 matched population controls) in New York State, found that after adjusting for age and smoking status (yes, no) in the relatives, a positive history in first-degree relatives of any cancer including lung cancer, aerodigestive tract cancer, or breast cancer were each associated with significantly increased risk of lung cancer.

**Studies in Twins**    The number of lung cancers observed in some twin studies have been too small to draw conclusions regarding familiality of lung cancer,[79] although possible aggregation of bronchoalveolar carcinoma has been suggested in twins and family studies.[80,81] However, this effect may be a result of aggregation of cigarette smoking because risk of this cancer is linked to tobacco consumption.[82] In 1995, in a study using a large twin registry, the National Academy of Sciences–National Research Council Twin Registry, Braun et al.[83] reported that the observed concordance rates of monozygous (MZ) twins for death from lung cancer compared with that of dizygous (DZ) twins was 1.1 (95% CI, 0.6 to 1.9), although this did not adjust for smoking behaviors in the twins. These results suggest that, as expected, on a population level, smoking behavior is probably a much stronger risk factor than inherited genetic susceptibility. Lichtenstein et al.[84] studied nearly 45,000 twins to identify clustering of excess risk in cotwins of MZ versus DZ twins. Results showed a 7.7-fold increased risk to MZ cotwins and a 6.7-fold increased risk to cotwins of DZ twins. These risks reflect combined effects of environmental and genetic determinants. Further modeling suggested that 26% of excess risk to MZ cotwins was attributed to heritable factors, whereas 12% was attributed to shared environment in the twins, and the remaining 62% was attributed to individual environmental factors. Although a very large sample size of twins was studied, the estimates still had very wide confidence intervals reflecting the study of only 608 index twins who had developed a lung cancer.

A review in 2005 by Matakidou et al.[85] of 28 case-control, 17 cohort, and seven twin studies of the relationship between family history and risk of lung cancer and a metaanalysis of risk estimates, concluded that the case-control and cohort studies consistently show an increased risk of lung cancer given a family history of lung cancer, and that risk appears to be increased given a history of early onset lung cancer or of multiple affected relatives. However, the results of the twin studies and the observed increased risk of disease in spouses highlighted the importance of environmental risk factors, such as smoking, in this disease.

## HIGH-RISK SYNDROMES CONFERRING AN INCREASED RISK FOR LUNG CANCERS

Leonard et al.[86] reported that survivors of familial retinoblastoma may also be at increased risk for small cell lung cancer. The standard mortality ratio for small cell lung cancer is estimated to be 15-fold increased.[87,88] Kleinerman[89] reported that lung cancer developing among those with germline retinoblastoma mutations had the heaviest smoking histories. Retinoblastoma survivors smoke less than the general population, suggesting that targeted counseling to avoid this risky behavior in this high-risk population may be effective.[90] The RB gene is inactivated in 90% of small cell lung cancers, indicating the relevance of this gene to small cell lung cancer etiology.[91]

Mutations in the p53 gene cause Li-Fraumeni syndrome. Individuals with this syndrome are at greatly increased risks for many cancers, including breast and lung cancers, sarcomas, leukemias and lymphomas, and adrenocortical tumors. The standard incidence ratio for lung cancer was estimated to be 38,

using a prospectively followed cohort of carriers of p53 mutations.[92] Cigarette smoking further increased risk threefold.

Mutations in the epidermal growth factor receptor (EGFR) locus are often found in adenocarcinomas of the lung arising in nonsmoking women, particularly among Asian populations[93] (see Chapter 49). One family with multiple adenocarcinomas was found to be segregating a mutation in the EGFR, indicating that rarely inherited mutations of this locus can increase the risk for lung cancer.[94] However, a study[95] of 237 familial lung cancer cases occurring in individuals with three or more relatives affected by lung cancer including 45 bronchoalveolar lung cancers failed to find any mutations of EGFR, suggesting that mutations of this gene are uncommon in the general North American population.

## SEGREGATION ANALYSES OF LUNG AND SMOKING-ASSOCIATED CANCERS

Given the evidence for familial aggregation of lung and other smoking-associated cancers, after accounting for personal tobacco use and occupational/industrial risk factors, segregation analyses have been performed to determine whether patterns of transmission consistent with at least one major, high-penetrance genetic locus may be involved in lung cancer risk.

Sellers et al.[96] performed genetic segregation analyses on the lung cancer proband families of Ooi et al.[59] described previously. The trait was expressed as a dichotomy, affected or unaffected with lung cancer. The analyses used the general transmission probability model,[97] which allows for variable age of onset of the lung cancer.[98–100] The likelihood of the models was calculated using a correction factor appropriate for single ascertainment,[101,102] that is, conditioning the likelihood of each pedigree on the probands being affected by their ages at examination or death.

Age of onset of lung cancer was assumed to follow a logistic distribution that depended on pack-years of cigarette consumption and its square, an age coefficient and a baseline parameter. Results indicated compatibility of the data with Mendelian codominant inheritance of a rare major autosomal gene that produces earlier age of onset of the cancer. Segregation at this putative locus could account for 69% and 47% of the cumulative incidence of lung cancer in individuals up to ages 50 and 60, respectively. The gene was predicted to be involved in only 22% of all lung cancers in persons up to age 70, a reflection of an increasing proportion of noncarriers succumbing to the effects of long-term exposure to tobacco.[97,103]

Gaudermann et al.[104] reanalyzed these same data using a Gibbs sampler method to examine gene by environment interactions and found evidence for a major dominant susceptibility locus that acts in conjunction with cigarette smoking to increase risk; this model was very similar to the previous results, because the codominant Mendelian models predicted very small numbers of homozygous susceptibility allele carriers.

Yang and coworkers[105] performed complex segregation analysis on the families of nonsmoking lung cancer probands in metropolitan Detroit. Evidence was found for Mendelian codominant inheritance with modifying effects of smoking and chronic bronchitis in families of nonsmoking cases diagnosed at ages.[40–59] The estimated risk allele frequency was 0.004. Although homozygous individuals with the risk allele are rare in the study population, penetrance was very high for early onset lung cancer (85% in men and 74% in women by age 60). The probability of developing lung cancer by age 60 in individuals heterozygous for the rare allele was low in the absence of smoking and chronic bronchitis (7% in men and 4% in women), but in the presence of these risk factors it increased to 85% in men and 74% in women, which was the same level predicted for homozygotes. The attributable risk associated with the high-risk allele declines with age, when the role of tobacco smoking and chronic bronchitis become more important.

Wu et al.[106] performed segregation analysis of families of 125 women, nonsmoking lung cancer probands in Taiwan. These lung cancer probands were diagnosed with lung cancer between 1992 and 2002 at two hospitals in Taiwan. Complete data on patients, spouses, and first-degree relatives were collected for 108 families. Data collected on the patients and their relatives included demographic, lifestyle, and medical history variables. Complex segregation analysis using logistic models for age at onset, including pack-years of cigarette smoking in the model was performed on 58 of these families. An ascertainment correction was made using the phenotype of the probands, but this may have been inadequate because the 58 families were a subset of the 108 families where there was at least one additional affected relative in the family. The Mendelian codominant model that included risk caused by personal smoking fit the data best, significantly better than the sporadic or purely environmental models. This model was not rejected against the general model in an early onset (less than 60 years) subset of the families but was rejected in the later-onset families and the total dataset.

Taken together, the Taiwan, Detroit, and Louisiana studies share remarkably similar results and demonstrate statistical evidence for at least one major gene that acts in conjunction with personal smoking and possibly chronic bronchitis to increase risk of lung cancer.

Although most of these studies included measures of personal smoking on the cases (or probands) and controls in the models, some of the aggregation studies did not include measures of amount of cigarette smoking in the relatives, and only one included measures of passive smoking. The segregation analyses did not include passive smoking or occupational risk factors in the models, and only one of these three studies collected data on history of chronic bronchitis. Furthermore, segregation analyses are not sufficient to prove the existence of a major locus because only a subset of all possible models can be tested. However, tracking the inheritance of lung cancer with genetic markers in a family (linkage analysis) can provide definitive evidence for genetic susceptibility to disease. Segregation analyses are useful because they provide a model that can be used for these subsequent analyses, and they provide insights into the best designs for identifying genes that have a high risk for disease.

# ONCOGENES AND TUMOR SUPPRESSOR GENES

In addition to epidemiological evidence, experimental evidence of the role of genes in lung cancer causation has been accumulating. First, it seems probable that genetic changes are responsible for the pathogenesis of most, if not all, human malignancies.[107] In particular, lung carcinogenesis is the result of a series of genetic mutations that accumulate progressively in the bronchial epithelium, first generating histologically identifiable premalignant lesions and finally resulting in an invasive carcinoma (see Chapter 5). The premalignant genetic changes may occur many years before the appearance of invasive carcinoma.

Cytogenetic and molecular studies have shown that mutations in proto-oncogenes and TSGs are critical in the multistep development and progression of lung tumors. Allele loss analyses have implicated the presence of other TSGs involved in lung tumorigenesis. These studies revealed frequent occurrences of chromosomal deletions including regions of 3p, 5q, 8p, 9p, 9q, 11p, 11q, and 17q. These studies are outside the scope of this chapter (see Chapter 6).[108–110] A recent genome-wide analysis found common amplifications of the human telomerase gene on chromosome 5p and in NK2 homeobox 1 (also known as thyroid transcription factor-1 [TITF-1]) on chromosome 14q13.3.[111]

These data have been further explored by genomic profiling of 128 lung cancer cell lines and tumors that revealed frequent focal DNA amplification at cytoband 14q13.3. The smallest region of recurrent amplification spanned TITF-1. When amplified, TITF-1 exhibited increased expression at both the RNA and protein levels. Small interfering RNA (siRNA)-mediated knockdown of TITF-1 in lung cancer cell lines with amplification led to reduced cell proliferation, manifested by both decreased cell cycle progression and increased apoptosis. These findings indicate that TITF-1 amplification and overexpression contribute to lung cancer cell proliferation rates and survival and implicate TITF-1 as a lineage-specific oncogene in lung cancer.[112]

# LINKAGE ANALYSIS OF LUNG CANCER

Linkage analysis is a statistical analysis of pedigree data that looks for evidence of cosegregation through the generations in human pedigrees of alleles at a genetic "susceptibility" locus and some known genetic "marker" locus (usually a DNA polymorphism). Linkage analysis is a very powerful method for detecting genetic loci that are highly penetrant (after adjusting for environmental risk factors). However, power decreases as the susceptibility allele becomes more common and less penetrant. Because cigarette smoking is an extremely strong risk factor for lung cancer,[4] it is appropriate to seek models that incorporate effects from this risk factor.

Bailey-Wilson et al.[113] published the first evidence of linkage of a lung cancer susceptibility locus to a region of chromosome 6q. Data were collected at eight recruitment sites by the Genetic Epidemiology of Lung Cancer Consortium (GELCC): the University of Cincinnati, University of Colorado, Johns Hopkins School of Public Health, Karmanos Cancer Institute, Saccomanno Research Institute, Louisiana State University Health Sciences Center, Mayo Clinic, and Medical College of Ohio. Of the 26,108 lung cancer cases screened at GELCC sites for this study, 13.7% had at least one first-degree relative with lung cancer. Following the initial family history screening process, additional information was collected from the 3541 families with at least one first-degree relative with lung cancer. Probands and/or their family representatives were contacted to collect data regarding additional persons affected with any cancers in the extended family, vital status of affected individuals, availability of archival tissue, and willingness of family members to participate in the study. Further pedigree development and biospecimen collection (blood, buccal cells, or fixed tissue) were performed on 771 families with three or more first-degree relatives affected with lung cancer. Cancers were verified by medical records, pathology reports, cancer registry records, or death certificates for 69% of individuals affected with either lung or throat (LT) cancer, and by reports of multiple family members for the other 31% of family members affected with LT. Of these families, only 52 had enough biospecimens available to make them informative for linkage analyses. DNA isolated from blood was genotyped at the Center for Inherited Disease Research (CIDR, a National Institutes of Health [NIH]-supported core research facility), and DNA from buccal cells and archival tissue and sputum were genotyped at the University of Cincinnati, for a panel of 392 microsatellite (short tandem repeat polymorphism, STRP) marker loci. The data were checked for errors and then analyzed using parametric and nonparametric linkage methods. Marker allele frequencies were calculated separately, and linkage analyses were performed separately for the white American and African American families, with the results combined in overall tests of linkage.

The primary analytical approach assumed a model with 10% penetrance in carriers and 1% penetrance in the noncarriers. This analytical approach weights information only from the affected subjects. This linkage model was used as the primary analytical approach because of uncertainty about the strength of relationship between smoking behavior and lung cancer risk in the high-risk families that were studied, and because the complex "gene+environment" models from the published segregation analyses were not currently available in any multipoint linkage analysis program. In addition, because about 90% of the affected family members smoked, weighting only the affected individuals in the simple dominant, low-penetrance model has the effect of jointly allowing for smoking status, while ignoring information from unaffected subjects. Genetic heterogeneity (different families having different genetic causation) was allowed for during the analysis. Secondary analyses used more complex models that included age and pack-years of cigarette smoking to modify the penetrances. A genetic regressive model obtained from segregation analyses by Sellers et al.[96] was used. Nonparametric analyses were also performed as secondary analyses with variance

**FIGURE 4.1**  Plot of chromosome 6 parametric multipoint HLOD scores (lung cancer affected only analysis) from SIMWALK2 in all 52 families, in the 38 families with four or more affected individuals, and in the 23 multigenerational families with five or more affected individuals. *HLOD*, heterogeneity lod score.

components models using SOLAR (binary trait option) and mixed effects Cox regression models, in which time to onset of disease is modeled as a quantitative trait.

Multipoint parametric linkage under the simple dominant low-penetrance affected-only model (Fig. 4.1) yielded a maximum heterogeneity lod (HLOD) score of 2.79 at 155 cM (marker D6S2436) on chromosome 6q23–25 in the 52 families, with 67% of families estimated to be linked. Multipoint analysis of a subset of 38 families with four affected relatives gave an HLOD of 3.47 at this same location, with 78% of families estimated to be linked, whereas for the 23 highest-risk families (five or more affected in two or more generations), the multipoint HLOD score was 4.26, with 94% of these families estimated to be linked to this region. Nonparametric analyses and the two-point parametric analyses that used the Sellers et al. model[60,96] all provided additional support for linkage to this region.

Additional families have been collected by the GELCC to confirm this linkage result in an independent sample and to narrow the critical region that may contain a susceptibility gene. In addition, several other regions showed suggestive evidence of linkage and these are being pursued.

## ASSOCIATION OF COMMON ALLELES OF SMALL EFFECT (POLYMORPHISMS) WITH LUNG CANCER RISK

Results of hundreds of studies using association analysis to evaluate the effects of various polymorphisms, in metabolic genes, growth factors, growth factor receptors, markers of DNA damage and repair and genomic instability, and in oncogenes and tumor suppressor loci have been published. Many of these studies have yielded inconsistent results. The effects of risk alleles at these loci are expected to be individually small, and they

may interact with smoking and/or other loci to increase lung cancer risk. Two recent reviews[114,115] can help the reader obtain an overview of these studies. On account of the relatively weak effects of these polymorpisms, relatively few consistent replications of effects have been provided, but more recent genome-wide association studies of very large collections of samples have provided some highly significant and reproducible results.

Three manuscripts jointly appeared in *Nature*[116,117] and *Nature Genetics*[118] identifying the same region of chromosome 15q as associating highly significantly with lung cancer risk. The region that was implicated by these studies includes a neuronal nicotinic acetylcholine receptor gene cluster comprising the CHRNA3, CHRNA5, and CHRNB4 subunits. Nicotinic receptors are comprised of pentamers that include alpha and beta units, and are ubiquitously expressed, but have higher levels in the brain. The manuscript of Thorgeirsson initially scanned a population of 14,000 individuals who had provided information about their smoking histories. This study identified the 15q region as associated with smoking quantity and then further explored the regions effects on smoking dependence and lung cancer risk. The other two studies[116,118] started with large collections of lung cancer cases and control samples. Results of all studies reached a surprisingly homogeneous conclusion with increased lung cancer risks of about 1.29 among individuals carrying a heterozygous mutation (44.2% of controls for rs8034191) in the region and about 1.80 among individuals with homozygous variants (10.7% of controls). Because of strong linkage disequilibrium among the markers studied, the specific gene causing increased risks for three studies drew conflicting conclusions about the relevance of this region on smoking behavior and its influence on lung cancer risk. Thorgeirsson[117] claimed that all of the risk for lung cancer in this region appeared likely to be explained by the regions effects on smoking behavior. Amos[118] found an association of this region with both lung cancer risk and smoking behavior

but found stronger effects on lung cancer risk that remained highly significant after adjusting for smoking behavior. Finally, Hung[116] did not find any association of this region on lung cancer risk. None of the studies had enough nonsmoking lung cancer cases to draw strong conclusions, but a subsequent study focusing on nonsmokers[118] fails to find any risk associated with variants in this region and lung cancer risk in this population. Comparing models of the risks of lung cancer among current smokers, Hung[116] found that carriers of the common less susceptible allele had a 14% cumulative risk of lung cancer death compared with a 23% cumulative risk of lung cancer death among those homozygous for the higher-risk variant.

Additional genetic factors are being identified and replicated by using very large collections of lung cancer cases and controls. Polymorphisms in DNA repair genes are repeatedly associated with lung cancer risk, and these are reviewed,[119–121] but many of the individual studies reporting these associations are of moderate size. A rare variant of CHEK2 (I157T) that had previously been associated with increased risk for breast cancer was found in a study of 4015 tobacco-associated cancer cases and 3052 controls to be strongly protective for the development of lung or head and neck cancers (RR = 0.44), but a risk factor for kidney cancer (RR = 1.44). Functional studies of biomarkers of DNA repair and mutagen sensitivity following exposure to clastogens repeatedly show that these are reliable predictors of lung cancer risk,[119] but applying them for patient populations is problematic because of a lack of reference laboratories and the need to study viable cells.

## CONCLUSION

All of these lines of evidence suggest that there may be one or several genes causing inherited increased risk to lung cancer in the general population. Although association studies have given evidence that alleles at various genetic loci may influence lung cancer risk, there has frequently been disagreement between studies. The first linkage study of lung cancer has given significant evidence of linkage to a region on chromosome 6q. If a susceptibility locus is identified in this region, it will be of major public health importance because it will allow identification of individuals at especially high risk who can then be targeted for intensive efforts at environmental risk reduction. In addition, identification of such a gene will lead to better understanding of the mechanism of carcinogenesis in general, perhaps eventually leading to better methods of prevention and treatment. The recent identification of polymorphisms associated with lung cancer risk provides new targets for potential interventions for chemoprevention, but further study is needed to evaluate these new findings and to identify particularly high-risk subjects who might benefit most from such interventions.

Confirmation of a genetic predisposition for lung cancer can be obtained by finding evidence for linkage of the putative susceptibility gene(s) to genetic marker loci in a specific chromosomal region(s). One potential problem in the search for such a linkage is heterogeneity. There are different types of heterogeneity of this disease and of its etiological factors: (a) there is heterogeneity at the level of histological types of lung cancer; (b) there is heterogeneity at the level of exposure to various environmental risk factors; and (c) there could be heterogeneity at the level of inherited susceptibility loci, that is, there could be one locus involved in susceptibility for one family and a different locus involved in susceptibility for another family. All of these types of heterogeneity could possibly confound the identification of a susceptibility locus (or loci) for lung cancer. The suggestive evidence in the published linkage study[113] for susceptibility loci at several other regions of the genome support the possibility of locus heterogeneity in lung cancer.

If, through linkage and positional cloning techniques, a genetic locus or loci that contributes to inheritable risk for lung cancer can be identified, or one of the candidate loci suggested to modify risk by association studies can be confirmed as a susceptibility locus, then the effects of the alleles at this locus and its interaction with cigarette smoking and the other well-known environmental risk factors for lung cancer can be elucidated with much more accuracy than presently possible, and our understanding of lung carcinogenesis in general may be increased.

CHAPTER 5

# An Overview of the Molecular Biology of Lung Cancer

Lung cancer cells have defects in the regulatory circuits that govern normal cell proliferation and homeostasis. Hanahan and Weinberg[1] described the "hallmarks of cancer" as six essential alterations in cell physiology that collectively dictate malignant growth. These acquired capabilities found in lung cancers are self-sufficiency of growth signals, insensitivity to growth-inhibitory (antigrowth) signals, evasion of programmed cell death (apoptosis), limitless replicative potential, sustained angiogenesis, and tissue invasion and metastasis. Transformation from a normal to malignant lung cancer phenotype is thought to arise in a multistep fashion, through a series of genetic and epigenetic alterations, ultimately evolving into invasive cancer by clonal expansion.[2] These progressive pathological changes in the bronchial epithelium—known as preneoplastic or premalignant lesions—occur primarily as one of three distinct morphological forms: squamous dysplasia, atypical adenomatous hyperplasia, and diffuse idiopathic pulmonary neuroendocrine cell hyperplasia.[3] Bronchial squamous dysplasia and carcinoma in situ (CIS) are the recognized preneoplastic lesions for squamous cell carcinoma; atypical adenomatous hyperplasia (AAH), a putative preneoplastic lesion, for a subset of adenocarcinomas; and neuroendocrine cell hyperplasia for neuroendocrine lung carcinomas.[3] These preneoplastic lesions, however, account for the development of only a subset of lung cancers; for example, the precursor lesion for the most common neuroendocrine carcinoma of the lung, small cell lung carcinoma (SCLC), is unknown. Tumors are believed to become increasingly malignant with time, initiating tumorigenesis from possibly only a handful of mutations followed by additional (and different) mutations and epigenetic changes acquired during clonal expansion, where cells possessing in vivo growth advantage become dominant.[2]

The identification and characterization of these molecular changes in lung cancer is of fundamental importance for improving the prevention, early detection, treatment, and palliation of this disease. The overall goal is to translate these findings to the clinic by using molecular alterations as (a) biomarkers for early detection, (b) targets for prevention, (c) tools for new molecular approaches, (d) signatures for personalizing prognosis and therapy selection for each patient, and (e) targets to specifically kill or inhibit the growth of lung cancer in patients.

Lung cancer arises from neoplastic changes to epithelial cells in the lung. However, it is not known whether all lung epithelial cells are susceptible to malignant transformation or only a subset of these cells; specifically, a major question is whether the changes need to take place in lung epithelial cells with stem cell–like properties. Lung cancer is a heterogeneous disease clinically, biologically, histologically, and molecularly. The underlying causes of this heterogeneity are unknown and could reflect changes occurring in cells with various potential for differentiation (e.g., squamous or adenomatous) or represent different molecular changes occurring in the same target lung epithelial cells. This heterogeneity and molecular complexity contributes to the difficulty in unraveling the pathogenesis of lung cancer. Multiple oncogenes, tumor suppressor genes (TSGs), signaling pathway components, and other cellular processes are involved in the molecular pathogenesis of lung cancer. This chapter will review molecular aberrations in lung cancer and the multiple pathways through which it develops.

The two main disease categories of lung cancer, non–small cell lung cancer (NSCLC) (representing 80% to 85% of cases) and SCLC (representing 15% to 20%), are generally classified based on differences in histological, clinical, and neuroendocrine characteristics. NSCLC and SCLC can also differ molecularly with many genetic alterations exhibiting subtype specificity (summarized in Table 5.1). Additionally, molecular studies of NSCLC have also revealed considerable differences between the subtypes of NSCLC, particularly the two most common subtypes: adenocarcinoma and squamous cell carcinoma.

| TABLE 5.1 | Common Genetic Alterations Found in Lung Cancer[a] | | | | |
|---|---|---|---|---|---|

| Gene | SCLC (%) | NSCLC (%) | | | References |
|---|---|---|---|---|---|
| | | **All** | **Adenocarcinoma** | **Squamous Cell** | |
| **Oncogenic Alterations** | | | | | |
| **Mutation** | | | | | |
| BRAF | Rare | 1–3 | 1–5 | 3 | 177,178 |
| EGFR | Rare | ~20 | 10–40 | Rare | 177,179–182 |

# EPIDEMIOLOGY AND SUSCEPTIBILITY IN LUNG CANCER

Eighty-five percent of lung cancers are caused by tobacco smoke, where exposure to carcinogens present in tobacco smoke leads to the acquisition of genetic mutations that may eventually initiate carcinogenesis. However, not all lung cancers arise in smokers, and not all smokers will develop lung cancer. Thus, inherited factors must be involved that may predispose an individual to develop lung cancer—either by increasing susceptibility to the damaging effects of carcinogen exposure or by increasing susceptibility regardless of smoking history. Worldwide, approximately 25% of lung cancer cases are not attributable to smoking.[4] These cases occur more frequently in women, especially in Asian countries, target the distal airways, and are commonly adenocarcinomas. Coupled with molecular data that indicates strikingly different mutation patterns between known lung cancer genes such as *KRAS*, epidermal growth factor receptor *(EGFR),* and *TP53* and clinical data in relation to response to targeted therapies, it has now been suggested that lung cancer in never-smokers be considered a distinct disease from the more common tobacco smoke–related lung cancer.[4]

Many studies have examined the effect of single nucleotide polymorphisms (SNPs) on the risk of developing lung cancer.[5,6] The reported risk effect in these studies is generally modest and often inconsistent, explaining why none are in routine use. However, metaanalyses as well as use of whole-genome SNP microarrays may hold the key to identifying robust and possible synergistic interactions between the modest affect of multiple SNPs. Lung cancer risk was recently associated with genomic variation at 15q24/q25.1 by three separate studies simultaneously that used whole-genome SNP microarrays.[7–9] Although the conclusions of the three studies differed in whether the risk is conferred directly with cancer or through nicotine addiction, the genes within this locus—which include several genes encoding nicotinic acetylcholine receptor subunits—represent important targets for further functional analyses.

# GENOMIC INSTABILITY, TELOMERES, AND DNA DAMAGE IN LUNG CANCER

Malignant transformation is characterized by genetic instability that can exist at the chromosomal level (with loss or gain of genomic material, translocations, and microsatellite instability); at the nucleotide level (with single or several nucleotide base changes); or in the transcriptome (with altered gene expression). Abnormalities are typically targeted to proto-oncogenes, TSGs, DNA repair genes, and other genes that can promote outgrowth of affected cells.[10] The erosion of telomeres at the end of chromosomes is also associated with genomic instability leading to chromosomal abnormalities. Telomere length regulates the replicative capacity of a cell, where progressive telomere shortening occurs with each replication. Once the telomere becomes too short, the cell will undergo cellular senescence or apoptosis. Activation of telomerase, the telomere-lengthening enzyme, in premalignant cells prevents loss of telomere ends beyond critical points and is essential for cell immortality. Although silenced in normal cells, telomerase is activated in >80% of NSCLCs and almost uniformly in SCLCs.[11–13] In normal cells, the presence of DNA damage engenders a DNA repair response, and if this is not successful, the apoptosis program is activated to remove the damaged cell. However, in premalignant and cancer cells the apoptosis program is often itself damaged, thus allowing unrepaired or misrepaired DNA damage to persist in clones of cells.

# ONCOGENES AND GROWTH-STIMULATORY PATHWAYS

Many oncogenes and TSGs have been identified by mapping of copy number changes throughout the cancer genome.[14–23] Earlier genomic analysis technology such as karyotyping and comparative genomic hybridization (CGH) enabled low-resolution characterization of the lung cancer genome identifying whole-arm or large-scale gain or loss on nearly every chromosomal arm, but most commonly 3p, 4q, 9p, and 17p loss and 1q, 3q, 5p, and 17q gain[24,25] (Table 5.1). However, high-resolution microarray analyses can now narrow in on these aberrant regions to detect focal amplifications and deletions often spanning only a handful of genes (Table 5.1).

Oncogenic activation typically occurs by gene amplification, point mutation, rearrangement, or through gene overexpression by other mechanisms including those mediated by microRNAs (miRNAs). These changes can result in persistent upregulation of mitogenic growth signals that induce cell growth. Although promoting the malignant transformation of a cell, persistent upregulation of a particular growth signal or pathway can also result in "oncogenic addiction"—whereby the cell becomes dependent on this aberrant oncogenic signaling for survival.[26] This presents an obvious target for therapeutics; remove or inhibit the oncogenic signal and an addicted tumor cell will die, whereas normal "nonaddicted" cells will be unaffected. Signaling pathways commonly involved in lung cancer are shown in Figure 5.1.

## Epidermal Growth Factor Receptor Signaling The

ErbB family of tyrosine kinase receptors includes four members—EGFR, ErbB-2 (HER-2), ErbB-3, and ErbB-4.[27] Although the intracellular tyrosine kinase domains of the four receptors are highly conserved, the extracellular domain is not so conserved, enabling the receptors to bind different ligands. Following ligand binding, the ErbB receptors form homodimers or heterodimers that results in receptor activation and subsequent activation of various signaling pathways.

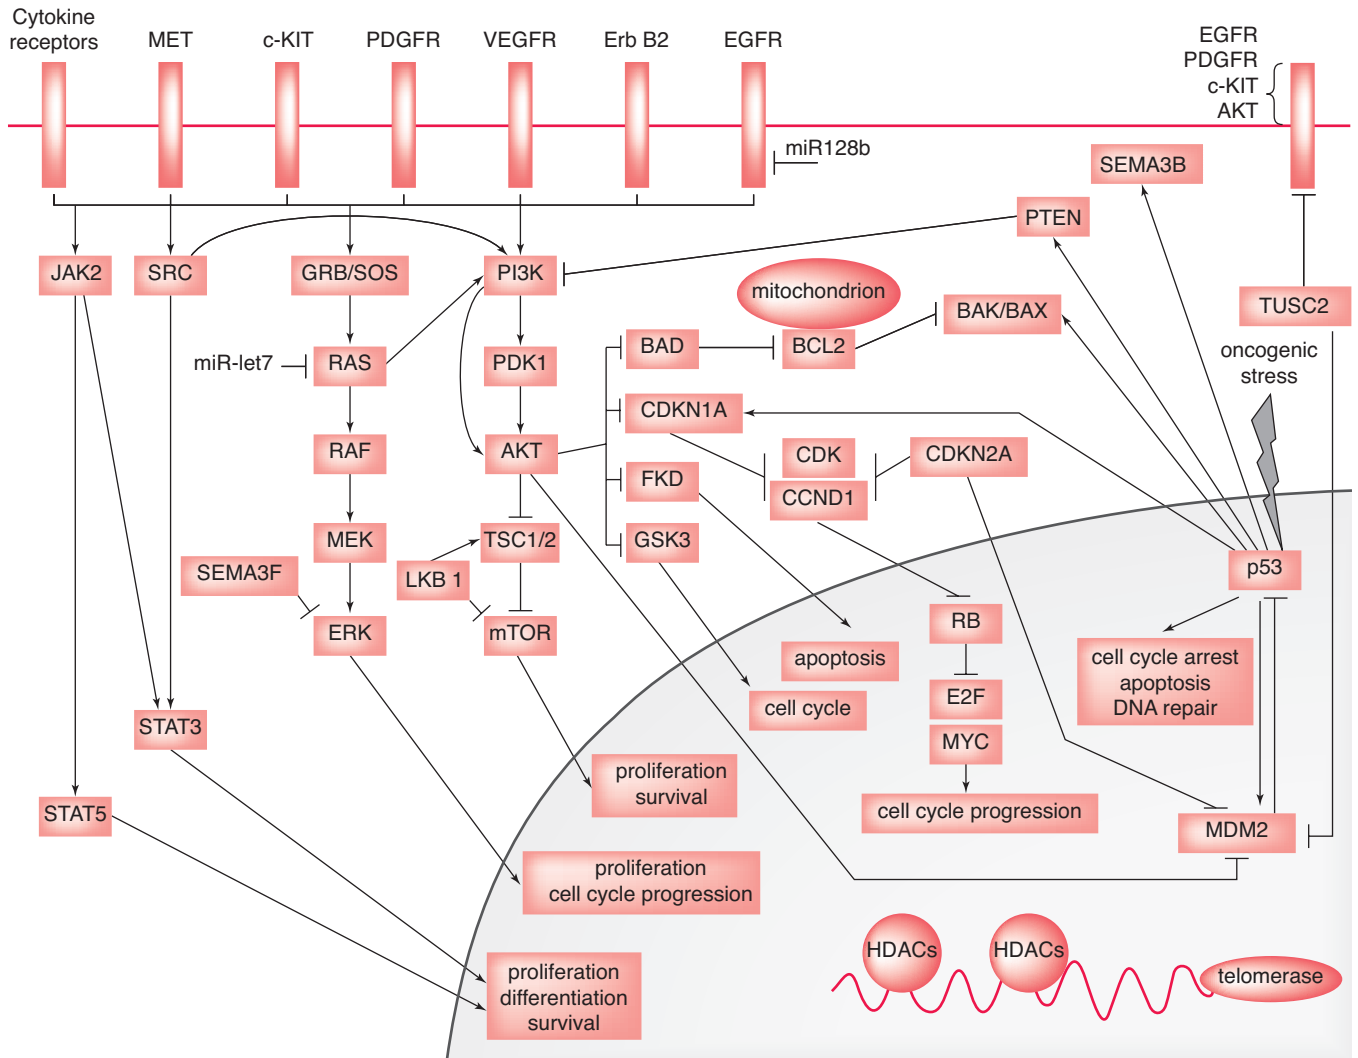
Activation of EGFR through the binding of EGF and EGF-like binding growth factors such as transforming growth factor-$\alpha$ (TGF-$\alpha$) enables the regulation of epithelial cell behavior and the initiation of tumors from epithelial cell origin through multiple signaling pathways. These include the RAS/RAF/MEK/MAPK pathway (cell proliferation), the PI3K/AKT pathway, and signal transduction and activator of transcription (STAT) 3 and STAT5 pathways (cell survival through the evasion of apoptosis)[28] (Fig. 5.1). EGFR exhibits


**FIGURE 5.1    Signaling pathways involved in NSCLC and SCLC.** Aberrant signaling resulting in activation of growth-stimulatory pathways or interference of growth inhibitory pathways has been implicated in lung cancer pathogenesis. Oncogenic activation typically occurs through amplification, mutation, rearrangement, or overexpression. In lung cancer, commonly activated oncogenes include *EGFR*, *ERBB2*, *MYC*, *KRAS*, *MET*, *CCND1*, *CDK4*, and *BCL2*. In contrast to oncogene activation, loss of TSG function is thought to require inactivation of both alleles—generally, LOH of one allele, and point mutation, epigenetic, or transcriptional silencing will inactivate the second allele. In lung cancer, commonly inactivated TSGs include *TP53*, *RB1*, *CDKN2A*, *FHIT*, and *PTEN*. Although EGFR plays a major role in lung cancer pathogenesis, several other receptor tyrosine kinases have been implicated such as members of the platelet-derived growth factor receptor (PDGFR) family c-KIT (expression is common in SCLC but rare in NSCLC[175,176]) and MET (potentially associated with acquired resistance to EGFR TKIs). Table 5.2 lists targeted therapeutic agents that have been developed against many components of these signaling pathways. *AKT*, v-akt murine thymoma viral oncogene homologue; *BAD*, Bcl2-antagonist of cell death; *BAK/BAX*, BCL2-antagonist/killer / BCL2-associated X protein; *BCL2*, B-cell CLL/lymphoma 2; *CCND1*, cyclin D1; *CDK*, cyclin-dependent kinase; *CDKN1A,* cyclin-dependent kinase inhibitor 1A; *CDKN2A*, cyclin-dependent kinase inhibitor 2A; *c-KIT,* v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homologue; *E2F*, E2F transcription factor; *EGFR*, epidermal growth factor receptor; *Erb B2*, v-erb-b2 erythroblastic leukemia viral oncogene homologue 2; *ERK*, extracellular signal regulated kinase; *FKD*, forkhead domain; *GRB/SOS*, growth factor receptor-bound protein/son of sevenless; *GSK3*, glycogen synthase kinase 3; *HDACs*, histone deacetylase; *JAK2*, Janus kinase 2; *LKB 1*, serine/threonine kinase 11; *MDM2*, Mouse Double Minute 2; *MEK*, MAP kinse-ERK kinase; *MET*, mesenchymal–epithelial transition factor; *miR128b*, microRNA 128 b; *mTOR*, mechanistic target of rapamycin; *MYC*, v-myc myelocytomatosis viral oncogene homologue; *p53*, TP53 gene product; *PDGFR*, platelet-derived growth factor receptor; *PDK1*, pyruvate dehydrogenase kinase, isozyme 1; *PI3K*, phosphatidylinositol 3 kinase; *PTEN*, phosphatase and tensin homologue; *RAF*, v-raf-1 murine leukemia viral oncogene homolog 1; *RAS*, rat sarcoma virus oncogene 1; *RB*, retinoblastoma; *SEMA3B*, sema domain, immunoglobulin domain (Ig), short basic domain, secreted, (semaphorin) 3B; *SEMA3F*, sema domain, immunoglobulin domain (Ig), short basic domain, secreted, (semaphorin) 3F; *SRC*, rous sarcoma oncogene cellular; *STAT3*, signal transducer and activator of transcription 3; *STAT5*, signal transducer and activator of transcription 5; *TSC1/2*, Tuberosclerosis 1/2; *TUSC2*, tumor suppressor candidate 2; *VEGFR*, vascular endothelial growth factor receptor.

overexpression or aberrant activation in approximately 50% to 90% of NSCLCs with activating mutations occurring with or without amplification.[29–32] Activating mutations, which are found with increased frequency in certain subsets of lung cancer patients, occur as three different types of somatic mutations—deletions, insertions, and missense point mutations—and are located in exons 19 to 21 that code for the tyrosine kinase domain of EGFR.[17–19] Mutant EGFRs (either by exon 19 deletion or exon 21 L858R mutation) show an increased amount and duration of EGFR activation compared with wild-type receptors,[17] and have preferential activation of the PI3K/AKT and STAT3/STAT5 pathways rather than the RAS/RAF/MEK/MAPK pathway.[33] EGFR mutant tumors (primarily adenocarcinomas) are initially highly sensitive to EGFR tyrosine kinase inhibitors (TKIs).[17–19] This represents an example of oncogene addiction in lung cancer where tumors initiated through EGFR mutation-activation of EGF signaling rely on continued EGF signaling for survival. However, despite an initial response, patients treated with EGFR TKIs eventually develop resistance to TKIs, which is linked (in approximately 50% tumors) to the acquiring of a second mutation at T790M in exon 20.[34–39] The presence of the T790M mutation in a primary lung cancer that had not been treated with EGFR TKIs, however, suggests that this resistance mutation may develop with tumor progression and not necessarily as a response to treatment.[40] Recently, amplification of the mesenchymal–epithelial transition (MET) proto-oncogene has been associated with acquired resistance to EGFR TKIs in 20% of resistant cases[36,41] with MET activating the PI3K pathway through phosphorylation of ERBB3, independent of EGFR and ERBB2.[41] Importantly, inhibition of MET signaling was able to restore sensitivity to TKIs.

### The RAS/RAF/MEK/MAPK/MYC Pathway

The RAS proto-oncogene family (*KRAS, HRAS, NRAS,* and *RRAS*) encode four highly homologous 21kDa membrane-bound proteins involved in signal transduction. Proteins encoded by the RAS genes exist in two states: an active state, in which guanosine triphosphate (GTP) is bound to the molecule and an inactive state, where the GTP has been cleaved to guanosine diphosphate (GDP).[42] Activating point mutations can confer oncogenic potential through a loss of intrinsic GTPase activity resulting in an inability to cleave GTP to GDP. This can initiate unchecked cell proliferation through the RAS/RAF/MEK/MAPK pathway, downstream of the EGFR signaling pathway.[43] Activating *RAS* mutations occur in approximately 15% to 20% of NSCLCs and, in particular, 30% to 50% of adenocarcinomas.[44] In lung cancer, 90% of mutations are located in *KRAS* (80% in codon 12, and the remainder in codons 13 and 61) with *HRAS* and *NRAS* mutations only occasionally documented.[44] *KRAS* mutations are mutually exclusive with *EGFR* and *ERBB2* mutations, and confer resistance to EGFR TKIs and chemotherapy.[45–47] Additionally, whereas *KRAS* mutations are primarily observed in lung adenocarcinomas of smokers, *EGFR* mutations are primarily observed in lung adenocarcinomas of never-smokers.[4] These data demonstrate how

lung adenocarcinoma can develop through different pathways, and it is likely, given the importance of EGFR targeted therapy that determination of *EGFR* and *KRAS* mutations in tumors will soon become part of standard care.

*BRAF* mutations occur in 1% to 5% of lung cancers, and mutant BRAF mouse models can develop lung adenocarcinomas.[48] The MYC proto-oncogene members are targets of RAS signaling and key regulators of numerous downstream pathways such as cell proliferation.[49] Activation of MYC members often occurs through gene amplification. MYC is most frequently activated in NSCLC,[50] with the other two members, MYCN and MYCL along with MYC, usually activated in SCLC.[24,51]

### The PI3K/AKT Pathway

The PI3K/AKT pathway that lies downstream of several receptor tyrosine kinases (RTKs; such as EGFR) is a key regulator of cell proliferation, cell growth, and cell survival and is commonly activated in lung cancer through changes in several of its components, including PI3K, PTEN, AKT, or EGFR or KRAS. In lung tumorigenesis, activation of the PI3K/AKT pathway is thought to occur early[52] and results in cell survival through inhibition of apoptosis. Activation can occur through the binding of the SH2-domains of p85, the regulatory subunit of PI3K, to phosphotyrosine residues of activated RTKs.[53] Alternatively, activation can occur via binding of PI3K to activated RAS. Mutation and more commonly amplification of *PIK3CA*, which encodes the catalytic subunit of phosphatidylinositol 3-kinase (PI3K), occur most commonly in squamous cell carcinomas.[20,54–56] AKT, a serine/threonine kinase that acts downstream from PI3K can also have mutations that lead to pathway activation. One of the primary effectors of AKT is mTOR, a serine/threonine kinase involved in regulating proliferation, cell cycle progression, mRNA translation, cytoskeletal organization, and survival.[57] The tumor suppressor PTEN, which negatively regulates the PI3K/AKT pathway via phosphatase activity on phosphatidylinositol 3,4,5-trisphosphate (PIP3), a product of PI3K,[58] is commonly suppressed in lung cancer by inactivating mutations or loss of expression.[59,60]

### NKX2-1 (TITF1): A Lung Cancer Lineage–Dependent Oncogene

Genome-wide screens for DNA copy number changes in primary NSCLCs found multiple examples of amplification at 14q13.3—and subsequent functional analysis (siRNA knockdowns in NSCLCs) identified *NKX2-1* (also termed *TITF1*) as the most likely target of amplification in lung cancer.[14,15,61] *NKX2-1* encodes a lineage-specific transcription factor essential for branching morphogenesis in lung development and the formation of type II pneumocytes, the cells lining lung alveoli.[62,63] Amplification of tissue-specific transcription factors in cancer has been observed in *AR* in prostate cancer,[64] *MITF* in melanoma,[65] and *ESR1* in breast cancer.[66] These findings have led to the development of a "lineage-dependency" concept in tumors[67] whose survival and progression of a tumor is dependent upon continued signaling through a specific lineage pathways (i.e., abnormal expression of pathways involved in normal cell development) rather than continued signaling

through the pathway of oncogenic transformation as seen with oncogene addiction.[26]

**EML4-ALK Fusion Proteins**   Oncogenic fusion proteins created by recurrent chromosomal translocations are generally not common in solid tumors such as lung cancer; however, recent studies indicate that this infrequency may be attributable to the difficulties in detection. The fusion of PTK echinoderm microtubule-associated protein like-4 (EML4)-anaplastic lymphoma kinase (ALK) was recently associated with lung cancer[68] and occurs in approximately 7% of NSCLCs.[68–70] Fusing with EML4 induces a significant transforming potential in ALK. Whereas wild-type ALK is thought to undergo transient homodimerization in response with specific ligand binding, EML4-ALK is constitutively oligomerized resulting in persistent mitogenic signaling and ultimately malignant transformation.[71] Additionally, EML4-ALK generally appears to be mutually exclusive to that of EGFR or KRAS mutations in NSCLC and is more common in never or former smokers.[72]

# TUMOR SUPPRESSOR GENES AND GROWTH INHIBITORY PATHWAYS

Loss of TSG function is an important step in lung carcinogenesis process and usually both alleles need to be inactivated. Generally, loss of heterozygosity (LOH) inactivates one allele through chromosomal deletion or translocation, and point mutation, epigenetic or transcriptional silencing inactivates the second allele.[73,74] In lung cancer, commonly inactivated TSGs include *TP53*, *RB1*, *CDKN2A*, *FHIT*, *RASSF1A*, and *PTEN*.

**The p53 Pathway**   *TP53* (17p13) encodes a phosphoprotein that prevents accumulation of genetic damage in daughter cells. In response to cellular stress, p53 induces the expression of downstream genes such as cyclin-dependent kinase (CDK) inhibitors that regulate cell cycle checkpoint signals, causing the cell to undergo G1 arrest and allowing DNA repair or apoptosis.[74] p53 inactivating mutations are the most common alterations in cancer, especially lung cancer, where 17p13 frequently demonstrates hemizygous deletion and mutational inactivation in the remaining allele.[75–77] Regulation of p53 can occur through the oncogene MDM2, which reduces p53 levels through degradation, and the p14[ARF] isoform of CDKN2A, which acts as a tumor suppressor by inhibiting MDM2. As such, the genes that encode MDM2 and p14[ARF] are altered in lung cancer with amplification of MDM2 seen in 6% of NSCLCs[78] and loss of p14[ARF] expression in approximately 40% and 65% of NSCLCs and SCLCs, respectively.[79,80] Restoration of p53 expression in vivo has been achieved with p53 gene therapy of lung cancer patients in a subpopulation of tumor cells.[81]

**The CDKN2A/RB Pathway**   The CDKN2A-RB1 pathway controls G1- to S-phase cell cycle progression. Hypophosphorylated retinoblastoma (RB) protein, encoded by RB1, halts the G1/S-phase transition by binding to the transcription factor E2F1. This tumor-suppressing effect can be inhibited by hyperphosphorylation of RB by CDK-CCND1 complexes (complexes between CDK4 or CDK6 and CCND1), and in turn, formation of CDK-CCND1 complexes can be inhibited by CDNK2A.[82] Nearly all constituents of the CDKN2A/RB pathway have been shown to be altered in lung cancer through mutations (CDK4 and CDKN2A), deletions (RB1 and CDKN2A), amplifications (CDK4 and CCDN1), methylation silencing (CDKN2*A* and RB1), and phosphorylation (RB).[83–88]

**Chromosome 3p TSGs**   Loss of one copy of chromosome 3p is one of the most frequent and early events in human cancer, found in 96% of lung tumors and 78% of lung preneoplastic lesions.[89] Mapping of this loss identified several genes with functional tumor-suppressing capacity including FHIT (3p14.2), RASSF1A, TUSC2 (also called FUS1), and semaphorin family members SEMA3B and SEMA3F (all at 3p21.3), and RAR$\beta$ (3p24). In addition to LOH or allele loss, some of these 3p genes (FHIT, RASSF1A, SEMA3B, and RAR$\beta$) often exhibit decreased expression in lung cancer cells by means of epigenetic mechanisms such as promoter hypermethylation.[90–94] Additionally, FHIT, RASSF1A, TUSC2, and SEMA3B will reduce growth when reintroduced into lung cancer cells. FHIT, located in the most common fragile site in the human genome (FRA3B), has been shown to induce apoptosis in lung cancer.[95] RASSF1A can induce apoptosis, as well as stabilize microtubules, and affect cell cycle regulation.[96] The tumor-suppressing effect of *TUSC2* is thought to occur through inhibition of protein tyrosine kinases such as EGFR, PDGFR, *c-Abl*, c-Kit, and AKT[97] as well as inhibition of MDM2-mediated degradation of p53.[98] The candidate TSG SEMA3B encodes a secreted protein that can decrease cell proliferation and induce apoptosis when reexpressed in lung, breast, and ovarian cancer cells[90,91,99,100] in part, by inhibiting the AKT pathway.[101] Another family member, SEMA3F may inhibit vascularization and tumorigenesis by acting on VEGF and ERK1/2 activation,[102,103] and RAR$\beta$ exerts its tumor-suppressing function by binding retinoic acid, thereby limiting cell growth and differentiation.

**LKB1**   The serine/threonine kinase LKB1 (also called STK11) is inactivated in approximately 30% of lung cancers and often correlates with KRAS activation,[104] resulting in the promotion of cell growth. It functions as a TSG by regulating cell polarity, differentiation, and metastasis and can regulate cell metabolism.[105] It has also been reported to inhibit the mTOR pathway.[106]

# EPIGENETIC REGULATION

Genetic abnormalities are associated with changes in DNA sequence; however, epigenetic events may lead to changes in gene expression without any changes in DNA sequence and therefore, the latter are potentially reversible.[107] Aberrant promoter hypermethylation is an epigenetic change that occurs early in lung tumorigenesis and is found both in genes that normally

undergo methylation in response to aging, as well as in genes that normally remain unmethylated regardless of age.[108] Gains of DNA methylation in a normally unmethylated promoter region of a gene results in silencing of gene transcription and is therefore a common method for the inactivation of TSGs. In lung cancer, many genes have been found to be silenced by promoter hypermethylation (summarized in Table 5.1). They include genes involved in tumor suppression, tissue invasion, DNA repair, detoxification of tobacco carcinogens, and differentiation. Recent advances in whole-genome microarray profiling have allowed researchers to globally study DNA methylation patterns in lung cancer, the results of which have led to suggestions that the role of methylation in lung tumorigenesis has been underestimated.[109–112] Restoration of expression of epigenetically silenced genes is a new targeted therapeutic approach. Histone deacetylation is an example of epigenetic change that can inhibit gene expression. Histone deacetylase (HDAC) inhibitors are being studied for the treatment of lung cancer and function by reversing gene silencing through inhibiting histone deacetylation (Fig. 5.1 and Table 5.2).

## MICRORNA-MEDIATED REGULATION OF LUNG CANCER

miRNAs are a recently identified class of non–protein encoding small RNAs present in the genomes of plants and animals. Ranging in size from 20 to 25 nucleotides, miRNAs are small RNA molecules that are capable of regulating gene expression by either direct cleavage of a targeted mRNA or inhibiting translation by interacting with the 3' untranslated region (UTR) of a target mRNA. They are considered to play an important role in the pathogenesis of cancer—as either oncogenes or TSGs—because of abnormal expression found in several types of cancer, including lung cancer.[113–121] Additionally, more than 50% of miRNAs are located in cancer-associated genomic regions or fragile sites.[122,123]

As observed for analyses on mRNA, protein and methylation patterns in lung cancer, miRNA microarrays have enabled the identification of many lung cancer-associated miRNAs.[120,121,124–132] One of the most widely studied miRNAs in lung cancer is the lethal-7 (*let-7*) miRNA family. Functioning as a tumor suppressor, it has been shown to regulate NRAS, KRAS, and HMGA2[133,134] via binding to the *let-7* binding sites in their respective 3' UTRs.[133,135] It is frequently underexpressed in lung tumors, particularly NSCLC, compared with normal lung, and decreased expression has also been associated with poor prognosis.[120,125] Induction of *let-7* miRNA expression has been found to inhibit growth in vitro[120,134,136,137] and reduce tumor development in a murine model of lung cancer.[137,138] In addition to *let-7*, other miRNAs with suggested tumor-suppressing effects in lung cancer include *miR-126, miR-29a/b/c, miR-1*,[125–128] and recently, *miR-128b* was reported to be a direct regulator of EGFR with frequent LOH occurring in NSCLC cell lines.[129] Oncogenic miRNAs found to be overexpressed in lung cancer include the *miR-17-92* cluster of seven

miRNAs (with suggested targets that include PTEN and RB), *miR-205, miR-21*, and *miR-155*.[121,130]

## LUNG CANCER STEM CELLS AND HEDGEHOG, NOTCH, AND WNT SIGNALING

The Hedgehog (HH), Wnt, and Notch signaling pathways are important in normal lung development—specifically, progenitor cell development and pulmonary organogenesis—however, they are now also being studied in regard to their role in tumor development (Fig. 5.2). These signaling pathways are thought to be involved in the regulation on stem/progenitor cell self-renewal and maintenance, and although this process is normally a tightly regulated process, genes that comprise these pathways are often mutated in human cancers,[139–141] leading to abnormal activation of downstream effectors. In relation to cancer treatment, cancer stem cells are of great importance because they are thought to be resistant to cytotoxic therapies. If correct, this presents a need for effective therapies against these self-renewal signaling pathways.

In the HH pathway, increased signaling results in activation of the GLI oncogenes (GLI1, GLI2, and GLI3) that can regulate gene transcription.[142–144] The HH signaling pathway was originally shown to have persistent activation in SCLC with high expression of SHH, PTCH, and GLI1,[145] but an important role in NSCLC was also recently demonstrated.[146] The Notch signaling pathway is important in cell fate determination and can also promote and maintain survival in many human cancers.[147–150] A recent study in mammary stem cells suggests that the cytokine IL-6 may function as a regulator of self-renewal in normal and tumor mammary stem cells through the Notch pathway through upregulation of the Notch-3 receptor,[151] which is expressed in approximately 40% of resected lung cancers.[152] The multifunctional cytokine IL-6 is involved in activation of JAK family of tyrosine kinases,[153] which in turn activate multiple pathways through signaling molecules such as STAT3, MAPK, and PI3K.[154] In lung adenocarcinomas, activated mutant EGFR has also been shown to induce levels of IL-6 leading to activation of STAT3.[155] The Wnt pathway has critical roles in organogenesis, cancer initiation and progression, and maintenance of stem cell pluripotency. In NSCLC, studies have found dysregulation of Wnt pathway members such as Wnt1, Wnt2, and Wnt7a, as well as upregulation of Wnt pathway agonists (Dvl proteins, LEF1, and Ruvb11) and underexpression or silencing of antagonists (WIF-1, sFRP1, CTNNBIP1, and WISP2).[156–162]

## HUMAN PAPILLOMAVIRUS–MEDIATED LUNG CANCER

Human papillomavirus (HPV) has been identified in tumors from many organs, not just gynecological tumors. Nearly 30 years ago, it was suggested to be a risk factor for lung cancer, particularly squamous cell carcinoma,[163] and since then, many studies have investigated the role of HPV in lung cancer

**TABLE 5.2   Targeted Therapies against Oncogenic Pathways in Lung Cancer and Their Development in Clinical Trials**

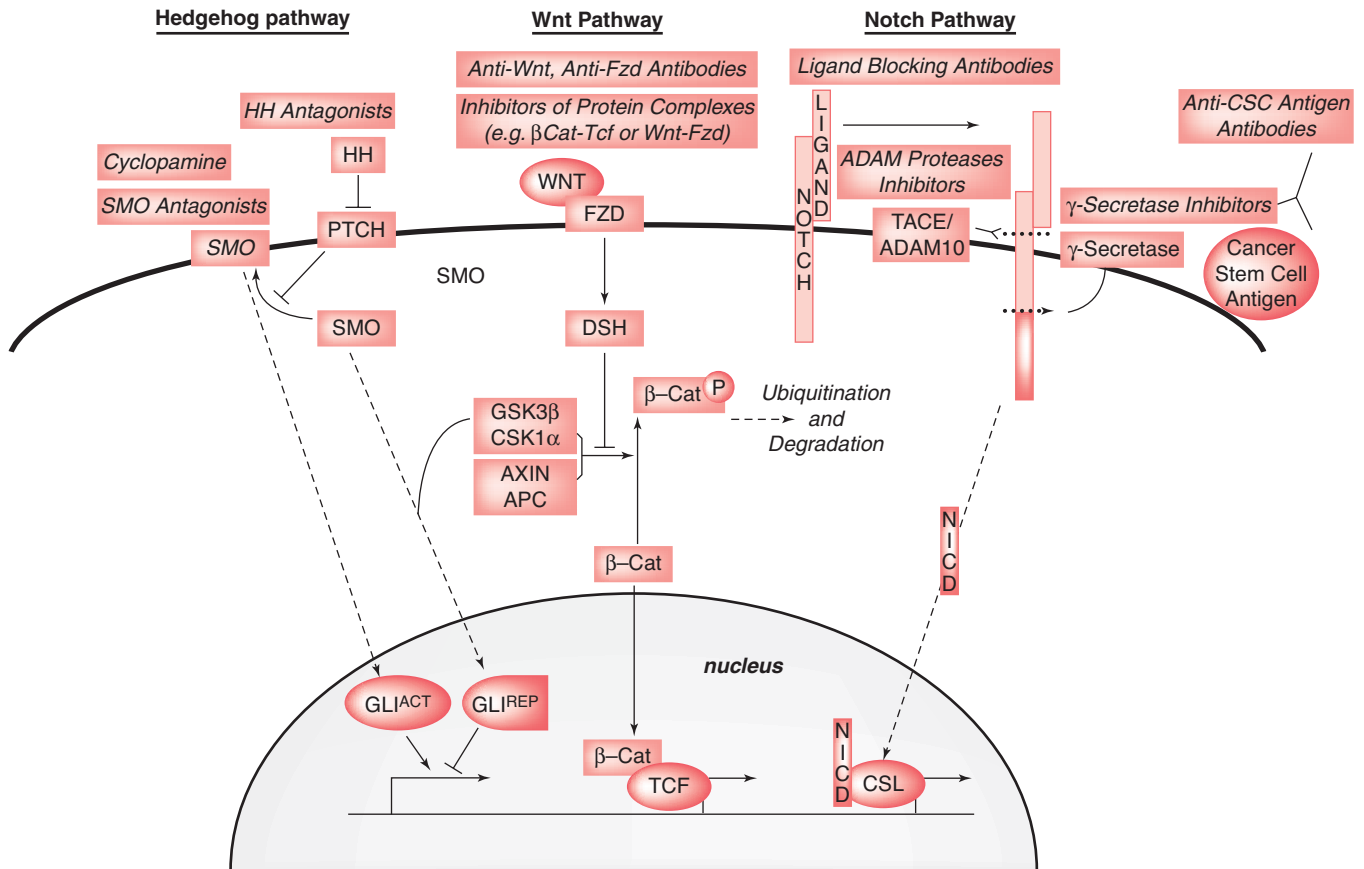
and have reported considerable geographical variation. A recent metaanalysis of 53 publications, comprising 4508 cases, found that the mean incidence of HPV in lung cancer was 25% and was detected in all subtypes of lung cancer, not just squamous cell.[164] Studies from Europe and America had a lower incidence of 15% to 17%, whereas Asian lung cancer cases reported a mean incidence of 38%. This observed high penetrance of HPV in lung cancer suggests more research is required to elucidate its role in lung cancer pathogenesis; however, considering the significant variation observed between studies of cases from the same geographical location, subsequent studies will need to have large sample and a detailed study design.


**FIGURE 5.2** **Stem cell self-renewal pathways and therapeutic strategies to block these pathways in cancer.** Notch, Wnt, and Hedgehog (HH) are stem cell self-renewal pathways that are often deregulated and aberrantly activated in lung cancer, thus representing key therapeutic targets. Modulation of these pathways can be achieved at different levels. In general, it is possible to interfere with ligand–receptor interactions by using ligand antagonists or receptor decoys, by blocking ligand-induced conformational changes, or disrupting protein–protein interaction of complexes involved in the activation of nuclear transcription. More specifically, strategies targeting the HH pathway include the use of antagonists for ligands (HH) or receptors (Smoothened, SMO) as well as cyclopamine, a naturally occurring compound that inhibits SMO. Antibodies against Wnt ligands or the receptor FZD and inhibitors of protein complex formation can be used to inhibit the Wnt pathway. Antiligand antibodies are used as potential agents to block the Notch pathway. Cleavage of Notch receptors by ADAM proteases and $\gamma$-secretase is required to activate this pathway, and inhibitors of these enzymes are being tested for their possible therapeutic implications. At present, two drugs targeting these pathways are in early clinical trials for treatment of some cancer types: phase I trials are studying the effects of an HH antagonist (GDC-0449) on solid tumors and MK-0752, a $\gamma$-secretase inhibitor, is being tested in patients with T-cell acute lymphoblastic leukemia, breast cancer, and central nervous system tumors. Pathways are depicted schematically, and some components were omitted (*dashed lines*) for simplicity. *ADAM*, a disintegrin and metalloprotease domain; *APC*, adenomatous polyposis coli; *AXIN*, axis inhibition protein; *$\beta$-Cat*, $\beta$-catenin; *CSK1-$\alpha$*, cyclin-suppressing kinase 1$\alpha$; *CSL*, C-promoter binding factor 1, suppressor of hairless, and Lag1 protein complex; *DSH*, disheveled; *FZD*, frizzled; *GLI*, glioma-associated oncogene; *GLI*[ACT], active form of GLI; *GLI*[REP], repressor form of GLI; *GSK3-$\beta$*, glycogen synthase kinase 3$\beta$; *HH*, hedgehog; *NICD*, Notch intracellular domain; *P*, phosphorylation; *PTCH*, patched; *SMO*, smoothened; *TACE*, TNF-$\alpha$–converting enzyme; *TCF/HNF4A*, transcription factor; *WNT*, wingless-type MMTV integration site family.

## CONCLUSION

Genetic and epigenetic mechanisms underlying lung cancer development and progression continue to emerge. Over the past decade, research into the biology of many diseases has been spearheaded by the development of whole-genome microarray technology, allowing the simultaneous analysis of expression, copy number, and SNPs across thousands of genes.

In lung cancer, gene expression studies have uncovered novel genes and pathways, as well as identified gene signatures that can better predict patient prognosis, response to treatment, and histology [165–168] reviewed.[169,170] High-resolution mapping of alterations in the lung cancer genome has been able to identify single genes as targets of genomic gain or loss through improved definition of known aberrant regions or by identification of focal alterations undetectable with earlier

technology.[15,171–173] Large-scale sequencing and SNP analyses have also led to the identification of novel somatic mutations or SNPs in the lung cancer genome.[7–9,174] Although such genome-wide screens have the capacity of identifying novel genes or interactions in relation to lung cancer, the functional relevance of these findings still need to be elucidated using in vitro model systems such as tumor cell lines or immortalized human bronchial epithelial cells. These systems allow the characterization of single or sequential genetic alterations in relation to the development, maintenance, and progression of lung cancer and represent a crucial contribution in the understanding of the molecular biology of lung cancer. Functional characterization of genetic alterations and the signaling pathways with which they interact has enabled the development of targeted therapies for the treatment of lung cancer (Table 5.2). Ranging from drugs in clinical use to those in clinical trial, they are directed against all known pathways of lung cancer initiation and progression such as proliferation, inhibition of apoptosis, angiogenesis, and invasion. This chapter has outlined some of the significant molecular alterations known to be involved in the initiation and/or progression of lung cancer. By characterizing these aberrations, researchers endeavor to improve the detection, diagnosis, treatment, and prognosis of lung cancer through the integration of clinical and biological factors—to achieve personalized medicine.

# Genomic Alterations in Lung Cancer

Lung cancer has been the leading cause of cancer-related morbidity and mortality worldwide.[1] These tumors are classified into two major clinicopathological categories, small cell lung carcinoma (SCLC) and non–small cell lung carcinoma (NSCLC). SCLC, accounting for 15% to 20% of lung cancers, displays neuroendocrine features and a propensity for rapid growth and early metastasis. NSCLC, accounting for the balance of approximately 80% of lung tumors, includes adenocarcinoma and squamous cell carcinoma, the two most common histological subtypes. Lung cancers, as other carcinomas, display numerous alterations in gene expression patterns resulting from acquired genetic and epigenetic mechanisms, including DNA methylation or histone modification across large chromosomal regions. Conventional and high-throughput technologies have detected scores of genomic changes occurring in individual specimens. However, few of those are recurrent changes among a large number of tumors, a characteristic that poses a challenge for the precise definition of molecular subtypes.

It is well-known that lung cancers show genetic instability, a persistent state that causes several mutational events leading to gross genetic alterations. This genomic instability is reflected in the heterogeneity of karyotypes and molecular profiles within a given tumor type and among different foci of the same tumor. Genomic changes in cancer may occur at different levels, ranging from the single nucleotide to an entire chromosome. Changes at one or few nucleotides, the mutations, may be completely innocuous or may be responsible for dramatic functional changes depending on the specific mutated site. Changes at the chromosomal level are usually detrimental since most likely affect large number of genes. Characterization of the genomic changes and identification of which molecular events contribute to the mechanisms that are central to tumorigenesis and to the multistep tumor progression are critical needs. Ultimately, the genomic discoveries will be translated into clinical tools that may impact the practice of cancer medicine.

In this chapter, we will review the most important genomic alterations detected in lung cancers. We will also discuss recent findings that have contributed to the better understanding of the molecular features of these tumors and to the development of strategies for earlier diagnosis and more efficient therapies.

## CHROMOSOMAL STRUCTURAL ALTERATIONS AND GENOMIC IMBALANCES: METHODOLOGICAL STRATEGIES FOR DETECTION

Chromosomal alterations in cancer have been detected by classical cytogenetics methods, mainly banding karyotyping (G-, R-, or Q-banding). Solid tumors frequently exhibit numerous changes in chromosome numbers, including gain of whole-genome complement and gains and losses of specific chromosomes. Tumors also have structural intrachromosomal and interchromosomal rearrangements, which change the copy numbers of genes when deletions, duplications, or amplifications occur, and affect the transcription of genes when positioning changes are introduced by insertions, inversions, and translocations. Although conventional cytogenetic methods were fundamental for important discoveries on molecular mechanisms of hematological diseases, they failed to provide similar contribution on solid tumors. Typically, rearrangements in solid tumors are numerous and complex, and the resolution of 5 to 10 megabase (Mb) of the banding karyotype is not satisfactory for identifying the spectrum of genomic changes responsible for most of the specific biological characteristics of the cancer cell.

The development of molecular cytogenetic strategies such as multiplex fluorescence in situ hybridization (M-FISH)[2] and spectral karyotyping (SKY)[3] have facilitated the identification of extranumerary chromosomes and increased the accuracy of identification of chromosomal origins of complexly rearranged chromosomal (Fig. 6.1). M-FISH and SKY, which paint genomic material from each of the 24 human chromosomes in specific fluorescent colors, are technologies especially tailored
**FIGURE 6.1**    SKY of a primary lung adenocarcinoma showing numerous numerical and structural chromosome changes. The classified image with the pseudocolors is shown in **(A)** and the inverted-DAPI image is shown in **(B)**. The specimen was near triploid, with extra copies of chromosomes 1, 10, 12, 19, and 20 and deletions of segments of chromosomes 1, 4, 5, 6, and 11. Translocations were found involving chromosomes 1 and 13, 1 and 17, 3 and 20, 5 and 19, 5 and X, 6 and 22, 7, 15, and X, 18 and 21, 16 and 22, and 18 and 21. Two very small marker chromosomes were found carrying chromosome 2 sequences. (See color plate.)

to uncover interchromosomal rearrangements and have been successful in revealing subtle karyotypic alterations, which would be otherwise overlooked.

For detection of genomic imbalances, the cornerstone technology was the comparative genomic hybridization (CGH), which was introduced in the early 1990s.[4] As proposed initially, CGH involved hybridization of differentially labeled DNA from two genomes, the genome to be tested and a normal genome used as a reference against a normal metaphase template. This approach is called metaphase CGH (mCGH) or chromosomal-based CGH (cCGH). Measuring the fluorescent intensity that dominates each given chromosome region in the template allows the identification of regions in the tested genome carrying normal copy numbers or gains and losses relative to the normal reference. Although mCGH proved to be useful for detection of genomic imbalances in solid tumors, the analysis is performed in metaphases and the high level of chromatin condensation at that cell cycle stage also limit the

resolution of genomic changes to 5 to 10 Mb. Importantly, several studies have shown that the expression of genes located in chromosomal regions of gains or losses varies consistently with the DNA copy number.[5–10] The availability of genomic resources and technological advances has fostered a major improvement in the last decade, represented by the shift from cCGH to microarray-based platforms. In their first generation, called matrix-CGH and array CGH,[11,12] these arrays included only few hundreds of DNA clones. Soon after, two microarray platforms were launched using bacterial artificial chromosome (BAC) clones as DNA probes. These instruments, the tiling BAC array[13] and the 1-Mb resolution whole-genome BAC array[14] were able to mine the entire genome for copy number variants. Despite the fact that the BAC arrays cannot reliably detect aberrations smaller than the BAC insert (100 to 200 kilobase [kb]), these new tools granted a significantly higher detection rate for copy number abnormalities than any of the metaphase-based cytogenetic techniques.

More recently, oligonucleotide-based arrays have emerged as the platform of choice for genome-wide analysis of copy number alterations because of their high-throughput and high-resolution characteristics. Some of the commercially available oligonucleotide arrays have probes specifically developed for detection of copy number variation (NimbleGen Systems and Agilent Technologies), whereas others were developed as genotyping arrays designed to identify single-nucleotide polymorphisms (SNPs) and later modified to uncover copy number variations (Affymetrix and Illumina). The NimbleGen CGH microarrays contain 45- to 85-mer oligonucleotide probes that are directly synthesized on a silica surface using light-directed photochemistry. A whole-genome tiling array is available with 2.1 million probes (HG18 WG Tiling 2.1M CGH v2.0D) and custom tiling arrays are also available. The Agilent Human Genome CGH Microarray (G2519A) contains 60-mer oligonucleotide probes printed onto glass slides through an industrial inkjet printing process. This microarray includes 40,000 probes spanning the human genome with an average spatial resolution of 75 kb, including coding and noncoding sequences, and has an emphasis on the most common cancer-related genes. Agilent arrays may also be customized from more than 8 million predesigned and validated probes. With the NimbleGen Systems and Agilent Technologies platforms, the test and reference genomes are labeled with different fluorophores (usually Cy3 and Cy5), and cohybridized to the same array, similarly to the mCGH technology. The signal intensity ratio of the test sample versus the reference sample is calculated for each probe across the entire genome.

The Affymetrix GeneChip arrays contain 25-mer SNP-based oligonucleotide markers or probes directly synthesized on the array surface. The Genome-Wide Human SNP Array 6.0 features 1.8 million genetic markers designed to uniformly cover the entire genome, including approximately half in SNPs and half in non-SNP probes for the detection of copy number variation. For the evaluation of copy number changes, the test genome is labeled and hybridized to the array and the signal intensity from the probes is computationally compared with a control set (HapMap individuals). The Illumina BeadChip arrays are made from silica beads that are self-assembled on silica slide microwells and each bead is covered with specific 50-mer SNP-based, oligonucleotide probes. The HumanCNV370-quad DNA Analysis Beadchip platform covers approximately 380,000 SNP and non–SNP-based probes. The test specimen is hybridized with the array and the copy number variations are determined by computationally comparing the signal intensity from probes with a control set provided by the platform manufacturer.

These high-resolution platforms have been successfully used to identify copy number changes in lung cancer and other solid tumors. However, two major characteristics of the solid tumors, the largely abnormal number of chromosomes and the intratumor heterogeneity, make copy number analyses difficult in these platforms. Current array CGH platforms were designed under the assumption that the natural ploidy state of the test DNA specimen is diploid, which is rarely the case in solid tumors. Therefore, the detection of a single-copy gain may represent a gain if the specimen is diploid or actually represent a loss if the specimen is tetraploid, a condition that is most common in solid tumors. Additionally, tumors are often mixtures of distinct types of cells, each of them potentially carrying different copy number changes. Because the DNA from the test specimen is extracted from the cell mixture, the results reflect an average change across the different cell types. Changes occurring in cell-specific compartments are likely to be diluted and remain undetected.

For the genome-wide high-resolution arrays, another perceived limitation is the detection of copy number variations that may not be involved in the disease. Recent studies have shown that normal, healthy individuals carry a large number of copy number variations detected by more than one consecutive probe in BAC and oligonucleotide arrays.[15,16] Thus, a more detailed characterization of the variation in the normal genome is necessary before an accurate detection of pathogenic copy number aberrations can be reached in tumors.

Chromosomal abnormalities detected by conventional and molecular technologies and genomic imbalances detected by mCGH or array platforms have been validated by independent laboratory approaches, such as fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR)–based techniques. FISH is a high-resolution technique able to identify specific regions involved in rearrangements and define them accurately (Fig. 6.2). FISH, as opposed to the PCR-based techniques, has among its critical advantages the ability to investigate the target phenomenon in single cells and to preserve the original tissue architecture. However, FISH is not a high-throughput technology and is unable to answer genome-wide questions. Nevertheless, the development of FISH methods has significantly improved the accuracy of solid tumor cytogenetics. Ultimately, it is the combination of multiple technical approaches that provides the most powerful strategy for understanding the molecular pathways underlying the lung tumor development.

## CHROMOSOMAL ABNORMALITIES AND GENOMIC IMBALANCES IN LUNG CANCER: THE PUZZLING PICTURE

Alterations in the DNA content have been well documented in lung carcinomas by flow cytometry and static tissue morphometry. A metaanalysis including data from 4033 NSCLC patients from 35 published studies has shown that the majority of NSCLC were aneuploidy and patients with aneuploid tumors had a significantly shorter survival duration than those with normal DNA content reflecting both diploid and pseudodiploid chromosome NSCLC.[17] However, the aneuploid chromosomal complement in the tumor cells included great variety of structural and numerical changes, many of which could be random events.

The search for recurrent abnormalities in lung cancer, the ones most likely to play specific roles in cancer development,

**FIGURE 6.2**  **A:** SKY of the non–small cell lung cancer cell line Calu 3 showing multiple abnormalities and two copies of abnormal chromosome 17, derivatives from the translocations between chromosomes 17 and 2 and chromosomes 17 and 12. In addition, the chromosome 17 material identified by SKY in the long arm (q-arm) of these derivative chromosomes was larger than expected if that arm was normal. **B:** FISH analyses with a probe set including ERBB2 and CEP 17 sequences demonstrated that there was ERBB2 gene amplification in both derivatives (indicated by the *arrows*). In the FISH assays, ERBB2 probe is highlighted by *red color* and CEP 17 by *green color*. (See color plate.)

has started long ago. The first recurrent changes in lung cancer, the deletions of 3p in SCLC, were identified by classical karyotypic analysis.[18] However, probably because of the complexity of the chromosomal alterations and the limitations of the conventional techniques, few karyotype reports of primary lung tumors or cell lines were published in the 2 decades following that seminal publication.[19–26] Loss of large chromosomal segments in 3p and 8p, gain of whole chromosomal arms, such as 5p, and amplification by homogeneously staining regions (HSR) and double minutes (DM) were reported. However, the conclusions of all those studies were by and large limited, often yielding incomplete karyotypes.

The advent of the CGH technology brought new momentum to the cancer field and has also impacted discoveries. Novel and histological type-specific gains and losses of chromosome segments in lung cancers were revealed in addition to those previously reported by conventional cytogenetic approaches. Chromosomal gains were detected in the long arms of chromosomes 8, 17, and 19 in NSCLC and chromosome arms 3q, 8p, and Xq in SCLC. Chromosome losses were frequent in 1p, 4q, 5q, 6q, 8p, 9p, 13q, and 17p in NSCLC and in 5q, 13q, and 17p in SCLC.[21,22,27–31]

In the end of the 1990s, studies using M-FISH and SKY were performed in lung carcinoma cell lines that had been established previously at the National Cancer Institute laboratories or were newly established by other investigators, and

from resected tumors. Those studies have resulted in the identification of a greater degree of chromosomal rearrangements than it been detected by previous G-banding and mCGH analyses.[32–43] Chromosomal abnormalities were also detected in nonmalignant bronchial epithelium of heavy smokers.[44] M-FISH and SKY technologies enabled the disclosure of cryptic translocations, enhanced the ability to delineate chromosomal breakpoints when integrating information from conventional banding analysis, and clarified the chromosomal composition of unrecognized marker chromosomes. Important similarities were noticed between karyotypic changes in established cell lines and primary tumors. The vast majority of translocations were unbalanced but a significant number of balanced translocations were also detected. These studies have provided a basis for the search of genes mapped at the breakpoints that were potentially deregulated and associated with tumorigenesis.

Despite all these efforts, discovery of recurrent gene fusions generated by structural rearrangements based on cytogenetics approaches has been quite rare. One such example was the identification of a translocation between the chromosomes 15 and 19 [t(15;19)(q11;p13)] in an aggressive lung cancer metastatic to mediastinum and bone arising in a young woman without a history of smoking or a family history of cancer.[45] The breakpoint on chromosome 19 was mapped to the 5' region of the highly overexpressed *NOTCH3* gene, which led to further investigations of the role of this gene in lung cancer.

Notch3 expression was detected in approximately 40% of resected lung tumors and positively correlated with epidermal growth factor receptor (EGFR) expression. Notch inhibition was shown to increase sensitivity to EGFR tyrosine kinase inhibitors (TKIs) and decrease mitogen-activated protein kinase (*MAPK*) phosphorylation, observations that support a role for NOTCH3 signaling in lung cancer through EGFR-related pathways.[46] The translocation breakpoints were later refined to 15q13.2 and 19p13.1 and the cloning of these regions identified a novel fusion transcript in which the 3' end of the *BRD4* gene on chromosome 19p was fused to the 5' end of the *NUT* gene on chromosome 15q. The *BRD4–NUT* fusion was demonstrated to alter the cell cycle kinetics, augmenting the inhibition of the progression G1 to S phase compared with the wild type *BRD4* gene. However, the exact role of the *BRD4–NUT* fusion in the pathogenesis of lung cancers remains unclear and the t(15;19) has not been found in large lung cancer cohorts tested, which suggest that it is not common in lung cancer.[47] Gene fusions detected using other strategies are going to be discussed later. The detection of the intracellular targets of these fusions is expected to bring new insights into molecular pathways that trigger tumor development.

A much more detailed picture of genomic copy number variations has been achieved in the last years with the array analyses. A summary of detected focal gain and losses is presented in Table 6.1 for five studies focusing on SCLC specimens[19,48–51] and in Table 6.2 for 13 studies focusing on NSCLC specimens.[19,51–62] Although data are available for over 70 SCLC and close to 800 NSCLC specimens, including cell lines and primary tumors, it is difficult to compare those results. Different platforms had different probes, and it is not always possible to confirm equivalencies. Despite these limitations, it is evident that there are important recurrent genomic changes in lung cancer. The most frequently occurring high-amplitude focal amplicons in lung cancer determined by at least two studies are listed in Table 6.3. Among those, are members of the MYC family (*MYCL1*, *MYCN*, and *MYC*), participants in the EGFR pathways (*EGFR*, *PIK3CA*, *KRAS*), and other genes, such as *FGFR1*, *TP63*, *TERT*, and the cyclins *CCND1* and *CCNE1*. Some are potentially novel oncogenes in lung (*NKX2-1*, for instance) that cooperate to promote lung cancer cell proliferation.

The consolidation of the available data contributes to a growing body of evidence that multiple cooperating oncogenes participate in these amplification events in an apparently nonrandom frequency. These findings have important implications for the design of functional genomic studies projects aimed at identifying cancer-relevant genes because single-gene assays will not uncover activities that rely on interaction among multiple collaborating genes.

## ABNORMALITIES IN GROWTH-INHIBITORY PATHWAYS: THE TUMOR SUPPRESSOR GENES

The chromosomal, genomic, and epigenomic studies addressed previously have revealed multiple changes involving tumor suppressor genes and oncogenes in clinically evident lung cancers.

The tumor suppressor genes, also known as recessive oncogenes, are inactivated by genetic mechanisms such as point mutations, chromosomal rearrangements, and mitotic recombinations, and by epigenetic events like hypomethylation or hypermethylation of gene promoter regions. It is largely accepted that the inactivation of tumor suppressor genes commonly occurs through a combination of two or more events, the Knudson hypothesis. Still, it is also recognized that the phenomenon in carcinomas is more complex because of mutational instability and chromosomal instability.[63] The major tumor suppressor genes involved in lung cancer are *TP53* (17p13.1), *RB1* (13q14.11), *CDKN2* (*p16^INK4a* or *MST1*, 9p21), and several genes located at the short arm of chromosome 3. The incidence of abnormalities in each of these genes in lung cancer, their main role in the development of the disease, and their contribution as prognostic or predictive markers will be briefly summarized.

The *TP53* gene is well-known for playing a key role on the negative regulation of G1/S-phase transition of the cell cycle[64] and for being the gatekeeper for apoptosis.[65] Mutations and overexpression of *TP53* are present almost universally in SCLC and in approximately 50% of NSCLC.[66–69] Mutations in *TP53* have been associated with smoking[70] and more aggressive tumors[66,71]; nevertheless, some studies have failed to show

a prognostic role for this abnormality.[72] Physical and functional loss of *TP53* and p53 protein overexpression have been identified in dysplastic bronchial epithelium as a highly predictive marker for lung cancer.[65,73–76] *TP53* is regulated upstream by the oncogene *MDM2* (12q13–q14), which is overexpressed in 25% of NSCLCs.[77] The p53 protein also interacts with *BCL2*, which is a negative regulator of cell death prolonging survival of noncycling cells and inhibiting apoptosis.[78] Positive immunostaining for *BCL2* was found in approximately 20% of NSCLC patients and 80% of SCLC.[78–80]

The G1/S transition checkpoint is also deregulated in lung cancer cells by changes in *RB1*, *CDKN2*, *CCND*, and *CDK4*. The retinoblastoma gene (*RB1*) controls the G1/S transition through E2.[81,82] Loss of *RB1* function by deletion and nonsense mutation or splicing abnormalities, together with loss of the wild-type *RB1* allele, are very common phenomena in SCLC while occurs in less than 30% of NSCL.[82–86] In NSCLC, a strong correlation between altered *RB1* protein expression and early stage has been documented.[87] However, correlation between loss of *RB1* and clinical outcome is still controversial, with earlier findings of negative prognostic impact on survival in early stage NSCLC[88] not confirmed in later studies.[89,90]

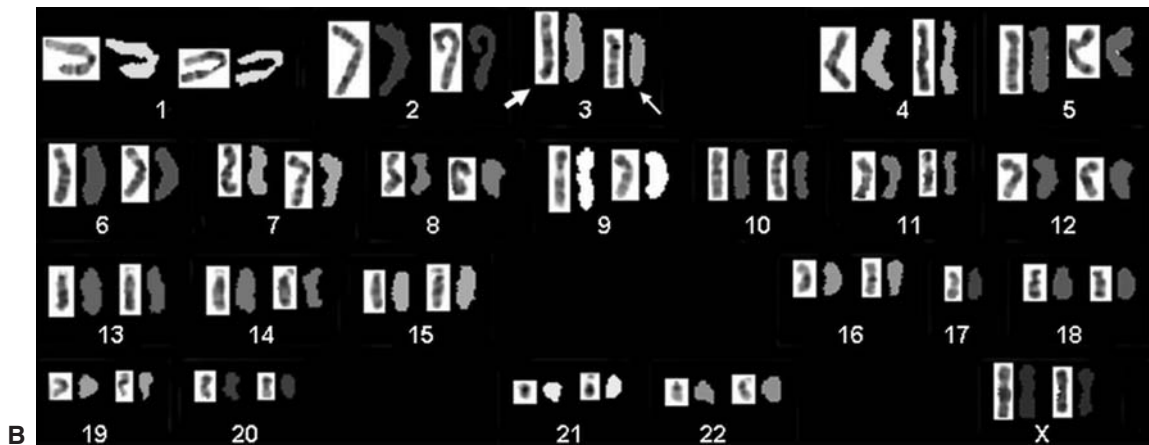
The *CDKN2* gene encodes an inhibitor of the cyclin-dependent kinase 4 and its inactivation occurs through homozygous deletion, or hemizygous deletion coupled with inactivation of the second allele by point mutation or promoter hypermethylation.[91] Loss of 9p has been detected frequently in NSCLC (16% to 100%) (Fig. 6.3A) but not in SCLC.[92–96] Loss of 9p21 is also relatively frequent in very early epithelial lesions such as hyperplasia or dysplasia[70,73,97–99] and hypermethylation at this site was found to increase during disease progression, from 17% in hyperplasia to 50% in CIS.[97] *CDKN2* hypermethylation has been reported to predict poor 5-year survival rate in resectable NSCLC,[100] and early recurrence in resected stage I NSCLC.[101]

In lung cancer, partial deletion of the short arm of chromosome 3 (3p) has been one of the earliest and most common genetic changes (Fig. 6.4). Chromosome 3p deletion occurs in almost 100% of SCLC and 90% of NSCLC.[102,103] Searches for tumor suppressor genes in this large region identified several targets at multiple sites, including *FHIT* (3p14.2), *RASSF1* (3p21.3), *TUSC2* (*FUS1*, 3p21.3), *SEMA3B* (3p21.3), *SEMA3F* (3p21.3), *MLH1* (3p22.3), and *RARB* (3p24). *FHIT* is one of the most extensively investigated suppressor genes in lung cancer[104–106]; allelic imbalance at *FHIT* was observed in 64% of NSCLC patients and loss of protein expression in 50% of lung cancers.[105–107] Allelic imbalance is associated with physical loss of the chromosomal region (Fig. 6.3B). *RASSF1* is inactivated by promoter hypermethylation in the large majority of SCLC and almost half of the NSCLC,[108–111] while not methylated in noncancerous tissues.[112] Expression of TUSC2 protein is absent or reduced in the majority of lung cancers

**FIGURE 6.3**    FISH of sections of non–small cell lung cancer with *CDKN2*-CEP9 **(A)**, *FHIT*-CEP3 **(B)**, *EGFR*-CEP7 **(C)** and *KRAS*-CEP12 **(D)** probe sets. Hybridization spots with the gene probes fluoresce in red color and with the centromere control probes fluoresce in green color. All the CEP probes and the *EGFR* probe are commercially available (Abbott Molecular). Probes for the genes *CDKN2*, *FHIT*, and *KRAS* were developed using BAC clones from the RP11 library. Panels A and B show loss of the gene sequences, respectively, *CDKN2* and *FHIT*, compared with the controls used. Arrows indicate one of the nuclei with loss. Panels C and D show gene amplification, for *EGFR* and *KRAS*, respectively. It is noticeable that the clusters of *EGFR* signals are much more tightly packed than the clusters of *KRAS* signals. Arrows indicate one nucleus displaying gene amplification in each panel. (See color plate.)

and premalignant lung lesions and restoration of its function in 3p21.3-deficient NSCLC cells significantly inhibits tumor cell growth by induction of apoptosis and alteration of cell cycle kinetics.[113] Both *SEMA3F* and *SEMA3B* transcripts are underrepresented in lung cancers, mainly squamous cell carcinomas. A recent review[114] indicated that downregulation of *SEMA3B* and *SEMA3F* is sustained by gene hypermethylation

in lung cancer cell lines.[115,116] Moreover, the loss of function of these genes correlates inversely with grade and stage of lung cancer.[98,117] Additionally, the *SEMA3B* and *SEMA3F* genes were found to be targets of *TP53*,[118,119] which suggests that they could be activated during DNA damage or other stress responses. Deregulation in *MLH1*, a mismatch repair gene, was detected in up to 78% of NSCLC specimens, predominantly

**FIGURE 6.4**  SKY of a bronchial epithelium cell from a heavy-smoking individual showing deletion of the short arm of chromosome 3, with breakpoint at 3p21.1. **A:** Inverted DAPI image. **B:** Karyotype, including both the inverted DAPI and the classified images. (See color plate.)


by promoter hypermethylation[120] and more recently has been associated with poor prognosis in NSCLC.[121] *RARB* mediates growth control responses[122,123] and its expression was found reduced in about 50% of NSCLC and 70% of SCLC.[124] Promoter hypermethylation is the leading cause of silencing of this gene. Conclusions have been controversial regarding the prognostic role of RARB suppression in lung cancer[125,126] as well as regarding the efficacy of retinoids as chemopreventive agents for this disease.[127,128]

## ABNORMALITIES IN GROWTH-STIMULATORY SIGNALLING PATHWAYS: THE PROTO-ONCOGENES

The molecular events that lead to the cancer-initiating cell involve critical mutations in genes regulating normal cell growth and differentiation. There are numerous families of proto-oncogenes that contribute to the tumorigenesis process when constitutively activated. The most relevant molecular pathways to lung cancer pathogenesis include members of the EGFR,[129] MYC,[130] RAS,[131] and STAT[132] families, and other related genes such as *PIK3CA*,[133,134] *CCND1*,[135] and *BCL2*.[136,137] Proto-oncogenes are frequently activated by genetic mutations (*KRAS*,

*EGFR*, and *PIK3CA*) and chromosomal rearrangements, such as translocations and inversions that place these genes under the regulation of constitutively activated genes (*MYC*, *BCL2*) or create chimeric proteins (*EML4-ALK*). Other mechanism of proto-oncogene activation in solid tumors is gene amplification, which recently was shown to occur more commonly in solid tumors than previously acknowledged.[138] Examples of genes found amplified in significant subsets of lung cancers are *MYC*, *EGFR*, *HER2*, *CCND1*, *PIK3CA*, and *NKX2-1* (*TITF-1*), and a summary of their incidence, role in disease initiation and progression, and prognostic and predictive impact in lung cancer will be presented.

Among the most important growth factors for lung tumor growth and proliferation are the tyrosine kinase receptors of the ERBB family, which are coded by *EGFR* (erbB1 at 7p12), *ERBB2* (HER-2/neu, 17q12), *ERBB3* (12q13), and *ERBB4* (2q33.3). The EGFR protein is frequently overexpressed in lung carcinomas (50% to 80%)[139,140] and also in metaplastic lung tissue adjacent to malignant tumors and normal-appearing bronchial epithelium of patients with lung cancer.[141,142] Phosphorylation of EGFR can activate signaling to cell proliferation and survival via RAS/MAPK and PIK3CA/AKT pathways.[143] The *EGFR* gene has been proved a relevant marker in lung cancer. Activating somatic mutations in its tyrosine kinase domain have been identified, and prevail in lung cancer patients of East Asian

ethnicity, of whom 25% to 40% have mutations,[144–148] when compared to American or European patients, of whom only 8% to 15% of patients carry mutations.[146,147,149–152] *EGFR* mutations also occurs more frequently in never-smokers, women, and NSCLC with adenocarcinoma histology.[147] The *EGFR* gene is amplified in approximately 10% to 15% of advanced NSCLC (Fig. 6.3C).[139,152–156] Besides, there is a significant copy number gain for the EGFR gene in lung cancer as consequence of chromosomal aneusomy and nonbalanced translocation or other rearrangements.[157]

Results are still controversial regarding the prognostic characteristic of EGFR protein overexpression and gene amplification. Recent data support no significant impact of these factors despite a trend toward poor prognosis.[139,140,158] The activating mutations have been associated with a better prognosis and indolent disease but, thus far, there is no definitive support for this role.[159–161] Moreover, the status of the EGFR gene has proved a powerful predictive marker for target therapy agents. Not surprisingly, patients with EGFR high copy numbers and activating mutations are more sensitive to EGFR TKIs such as gefitinib and erlotinib.[143,146,149,151,152,155,162–165] NSCLC patients with EGFR gene amplification or high level of genomic gain by chromosomal aneusomy have also shown higher sensitivity to the monoclonal antibody anti-EGFR cetuximab.[154]

Overexpression of ERBB2 in lung cancer is less common than EGFR overexpression, ranging from 10% to 30% in NSCLC.[166] ERBB2 overexpression was detected in early stages of lung cancer[167] and is associated with poor survival.[168–170] FISH analysis documented occurrence of *ERBB2* gene amplification in 6% to 20% of NSCLC patients.[51,171–175] Activating mutations in *ERBB2* are very rare in lung cancer[176–178] and have been associated with resistance to EGFR TKI in cases with all clinical and biological features of sensitivity to such treatment.[178]

*ERBB3* is unique within the EGFR family because of its catalytically deficient kinase domain and its signaling relies on heterodimerization with other EGFR family member, preferentially HER-2.[179] ERBB3 expression was less investigated in lung cancers but between 19% and 58% of tumor specimens revealed an increased level of expression with the highest percentages seen in squamous cell carcinomas[180]; increased expression was also found in association with shorter survival.[181] *ERBB3* gene amplification investigated by FISH was detected in approximately 5% of patients and there was no association with histology subtype.[182] The other member of the family, *ERBB4*, is activated by binding with neuregulins, betacellulin, and heparin-binding epidermal growth factor (EGF)–like growth factor. Its activation leads to cellular proliferation, chemotaxis, or differentiation via activation of specific signal transduction proteins, such as PI3-kinase and Shc.[183] The status of *ERBB4* in lung cancers is still poorly known and this gene seems to infrequently harbor mutations (<3%) in NSCLC.[184]

The genes of the *RAS* family (*HRAS* at 11p15.1, *KRAS* at 12p12.1, and *NRAS* at 1p13.2) encode for highly homologous G-proteins located at the inner surface of the cell membrane that play an essential role in the signal transduction pathways involved in differentiation, proliferation, and survival. The inactive RAS proteins are bound to guanosine diphosphate (GDP) and upon activation release GDP and bind to guanosine triphosphate (GTP). Activated RAS transduces the EGFR activation signal to multiple downstream pathways, including BRAF, MAPK, and PI3K/AKT.[131,185] The intrinsic GTPase activity of RAS terminates signaling by hydrolyzing GTP to GDP, a reaction that is accelerated by the GTPase-activating proteins (GAPs). In lung cancer, *KRAS* is more frequently mutated than *HRAS* and *NRAS*.[186] Point mutations in *KRAS* codon 12, which is prevalent in NSCLC, and in codon 13 result in an increased affinity for GTP, while mutations in codon 61 confer resistance to GAPs. The mutant proteins permanently switch to the active position and constitutively activate the downstream signaling pathways. *KRAS* mutations occur with variable frequency in the major types of lung tumors. They are very scarce in SCLC and prevail in large cell carcinomas and adenocarcinomas, of which 20% to 30% carry a *KRAS* mutation.[187–189] *KRAS* and *EGFR* mutations are almost completely exclusive.[147,176,190,191] *KRAS* mutation has been reported as a negative prognostic factor in terms of survival in NSCLC, especially in adenocarcinoma, in a metaanalysis including 28 studies with NSCLC patients and in more recent studies.[188,192] *KRAS* mutation is also a negative predictor in NSCLC for response to EGFR TKIs.[193–196] The *KRAS* gene was found amplified in lung cancer specimens (Fig. 6.3D), although the frequency in which this phenomenon occurs is unknown at this time. Other downstream effecters of the RAS pathway, such as the *BRAF* gene, which encodes a serine–threonine kinase activated by point mutation, are infrequently (<5%) mutated in lung cancers and likely to have a lesser relevant role in the pathogenesis of those carcinomas.[197,198]

The *MYC* family of genes (*MYC* or c-MYC at 8q24.1, *MYCN* at 2p24, and *MYCL1* at 1p34) encodes basic–helix-loop-helix zipper (bHLHz) transcription factors that, after dimerization with MYC-associated factor X (Max), binds to E-box motifs (CACGTG, CANNTG) and stimulates the transcription of various target genes relevant for cell growth, differentiation, and apoptosis.[130,199] One of these target genes is E2F and, interestingly, it was reported that cMYC activates expression of a cluster of six microRNAs on chromosome 13, two of which (*MIRN17-5p* and *MIRN20A*) negatively regulate *E2F*.[200] These findings reveal a tightly controlled mechanism for activation of transcription and limitation of translation exert by *MYC* on *E2F*. Additionally, there is increasing evidence that the *MYC* genes bind very ubiquitously throughout the genome, apparently to genomic sites of up to 15% of all cellular genes, which hints at a potential nontranscriptional function for them.[201] The alternative model for MYC role in cell growth and tumorigenesis is corroborated by studies showing that MYC promotes DNA replication via nontranscriptional mechanisms and its deregulation causes DNA damage predominantly during the S phase.[202] Amplification and overexpression of the MYC family of oncogenes occurs in 18% to 54% of SCLCs, being more common in chemorefractory disease.[126,203] In advanced NSCLC, from

20% to more than 50% of tumors were found to have *MYC* gene amplification and this phenomenon was associated with tumor progression and worse prognosis.[204,205] A recent investigation using high-resolution array platform showed that *MYC* was the most frequently amplified oncogene in lung cancer cell lines,[138] which 28% of the 53 investigated lung carcinoma cell lines showing amplified levels of its genomic region.

The PI3K–PTEN-AKT signaling pathway overcomes mechanisms that promote apoptosis by transmitting a strong cell survival signal. Interactions between cell surface receptors, such as IGF1R, PDGF, and EGFR, and extracellular ligands, such as EGF and TGF-$\alpha$, result in activation of tyrosine kinases and recruitment of class I PI3Ks, a family of heterodimeric complexes composed of a p110 catalytic and a p85 regulatory subunit.[206] PI3K phosphorylates phosphatidylinositol, which recruits specific intracellular proteins, such as phosphoinositide-dependent kinase-1 (PDK-1) and Akt/PKB, to the cytoplasmic membrane, through mechanisms regulated by the *PTEN* gene.[207] Akt is a serine/threonine kinase that acts downstream of EGFR to regulate numerous other proteins involved in growth, survival, and movement of cells, and angiogenesis. Akt activation results in inactivation of pro-apoptotic proteins, including members of the Bcl2 and caspase families[208,209] and other proteins that indirectly inhibit apoptosis, such as mdm-2 and the forkhead transcription factors.[210] The p110-$\alpha$ catalytic subunit of PI3Ks is coded by the *PI3KCA* gene (3q26) and there is increasing evidence that constitutive activation of the PI3K pathways in lung cancer occur as a consequence of mutation or amplification of the *PIK3CA* gene. *PIK3CA* genomic gain detected by FISH was reported in 43% of lung cancers with prevalence in squamous cell carcinoma.[133,134] High level of phosphorylated Akt expression has been observed in premalignant and malignant human bronchial epithelial cells[134,211,212] and in approximately 50% of advanced NSCLC.[152,213]

High-resolution genomic profiling of lung cancer cell lines and tumors revealed new genes frequently involved in amplifications. One of them is the homeobox transcription factor *NKX2-1* (*TTF-1* or *TITF-1*) mapped at 14q13.3.[60,62] *NKX2-1* plays a master role in induction and maintenance of lung and thyroid morphogenesis and in the differentiation of epithelial cell lineages.[214] *NKX2-1* gene amplification is accompanied by increased expression at both the RNA and protein levels, and knockdown with small interfering RNA (siRNA) in lung cancer cell lines led to reduced cell cycle progression and increased apoptosis. Gain at 14q13.3 was present in 7% to 33% of cell lines and tumors and was significantly more frequent in adenocarcinomas than squamous cell carcinomas.[215] Interestingly, the *NKX2-1* amplification was associated with the presence of *EGFR*-activating mutations but not *KRAS* or *TP53* mutations, and its overexpression was highlighted as a good prognostic factor in a metaanalysis.[216] The oncogenic role of a tissue-specific transcription factor linked to lineage proliferation and survival may look somewhat peculiar but it reflects the principle of the oncology recapitulating ontogeny. This phenomenon has been detected involving other genes and solid tumor combinations, such as breast cancer and *ESR1*, melanoma and *MITF*, prostate

cancer and *AR*, and was also detected previously in lung cancer with the *TP63* gene.[62,217,218] It has been postulated that genetic alterations that directly interfere with transcriptional networks normally regulating lung development may be a more common feature of lung cancer than previously realized.[62]

Genomic changes in proto-oncogenes may occur in association with therapeutic strategies applied to the patients. An interesting example of this phenomenon in lung cancer implicates mesenchymal–epithelial transition (*MET*) (7q31.2), the receptor for the hepatocyte growth factor (*HGF*). *MET* is frequently deregulated in cancers via constitutive kinase activation, paracrine/autocrine activation, mutation, gene amplification, and epigenetic mechanisms.[219] Enhanced *MET* regulation leads to oncogenic changes including cell proliferation, reduced apoptosis, angiogenesis, altered cytoskeletal function, and metastasis. MET overexpression occurs in a varied lung cancer histologies, with stronger expression in NSCLC.[219] Mutations in the tyrosine kinase domain of *MET* were detected in SCLC and NSCLC[220,221] but are uncommon. *MET* gene amplification was relatively frequent (20%) in few NSCLC cell lines tested,[222] but appears to be infrequent (<5%) in unselected clinical NSCLC specimens.[223] Recently, amplification of *MET* was identified in in vitro studies as a major mechanism by which lung tumors overcome therapeutic inhibition of EGFR growth signals.[224] In addition, assessment of tumor tissue from gefitinib or erlotinib resistant NSCLC patients demonstrated *MET* amplification in 21% to 22% of patients,[223,224] a much higher frequency than in the unselected patients. Mechanistically, it was shown that MET protein regulates ERBB3-dependent activation of PI3K at the same time that signals through ERBB3 in amplified cancers, and this redundant activation of ERBB3 supports the downstream signaling even in the presence of EGFR inhibitors.[223,224]

The increased knowledge about the mechanisms leading and maintaining oncogene activation in lung cancer has already provided a striking contribution toward development of new therapeutic approaches. It has also sustained the better understanding of the complex signaling network in normal and cancer cells. Observations that the inactivation of few or even a single oncogene was sufficient to induce a sustained tumor regression have supported the *oncogene addiction* hypothesis by which tumors may become irrevocably addicted to the oncogene that initiated tumorigenesis and a sudden interruption of its activity balances toward proliferative arrest and apoptosis.[225–227] More recently, a compelling alternative has been raised to explain those observations, the "oncogene amnesia" hypothesis. The premise of this hypothesis is that the oncogene activation initiates tumorigenesis by overriding essential mechanisms for cellular mortality, self-renewal, and genomic integrity, thus inducing a state of cellular amnesia.[228] The rationale behind the oncogenic amnesia hypothesis is that the inactivation of a single oncogene in a tumor that has acquired all oncogenic lesions required to overcome the cellular safety mechanisms can restore pathways leading to proliferative arrest, differentiation, cellular senescence, and apoptosis. In this way, the oncogenes initiate cancer inducing a cellular state of enforced amnesia in which, only upon oncogene inactivation, the tumor becomes aware of

its transgression.[228] Oncogene addiction and oncogene amnesia are not necessarily exclusive mechanisms, as the hypotheses are proposed, they may coexist in complex tumors as carcinomas.

## GENE FUSIONS IN LUNG CANCER: RARE OR UNDETECTED?

Gene fusions encoding chimeric oncoproteins usually result from chromosomal structural rearrangements such as translocations, inversions, and insertions. When the coding regions of two genes are juxtaposed, the chimeric transcript produces a novel protein with an altered function. Despite the numerous chromosomal rearrangements detected by karyotyping techniques, only occasional activation of oncogenes has been found as recurrent event in carcinomas through fusions.[229,230] Thyroid carcinomas exhibit the largest number of reported gene fusions, most of them involving the *RET* and *BRAF* genes. Aggressive midline and mucoepidermoid carcinomas have one described gene fusion each (*BRD4-NUT* and *MECT1-MAML2*, respectively), while fusions involving the *TFE3* gene in kidney carcinoma and *ETV6-NTRK3* and *ODZ4-NRG1* in breast carcinoma were reported in very rare patients (<1%). The recent discovery of gene fusions in a large proportion of prostate carcinomas brought new excitement to the field. These fusions are generated by translocations or interstitial deletions, but were identified by advanced technical bioinformatics approaches for analyses of gene expression rather than by cytogenetic approaches.[231] The prostate cancer fusions occur between *TMPRSS2*, a prostate-specific, strongly androgen-regulated gene, and the genes of the ETS transcription factor family (*ERG*, *ETV1*, and *ETV4*)[232,233] or between *ETV1* and other partners.[234] The fusion of the five prime untranslated region (5′ UTR) of *TMPRSS2* to ERG through an intronic deletion is the prevalent event in prostate cancer.[231] Investigation of the prognostic impact of the presence of *TMPRSS2-ERG* fusion in prostate carcinoma has generated conflicting results. A significant association with specific death or development of metastases is supported by some studies,[235,236] whereas longer progression-free survival in patients treated by prostatectomy was reported by other.[237]

More recently, the fusion of the *ALK* (anaplastic lymphoma kinase) and *EML4* (echinoderm microtubule-associated proteinlike 4) genes, separated by 12 Mb in the short arm of chromosome 2 and oriented in opposite 5′ to 3′ directions, has been identified in NSCLC patients of Japanese origin.[238] Soon after that publication, other reports have confirmed the occurrence of the *EML4-ALK* gene fusion, in four distinct variant forms, in Asian and white lung cancer patients.[239–243] All variant forms of the *EML4-ALK* fusion gene possess prominent transforming activity. The fusion creates a chimeric protein with sequences of *EML4* replacing the extracellular and transmembrane domains of *ALK*, which results in constitutive dimerization of the ALK kinase domain and consequent increase in its catalytic activity.[238] The frequency of NSCLC carrying this fusion is reportedly low, ranging from 1.5% to 2.6% in whites[242,244] and from 2.6% to 6.7% in Asians.[238,241–243,245] The frequency of *EML4-ALK* was associated with adenocarcinoma histology and limited smoking history (<10 pack-years).[242] The *EML4-ALK* fusion was found in patients who had exon 19 deletion in the EGFR gene but not in patients with *KRAS* or *BRAF* mutations.[242] The prognostic implication of this fusion in lung cancer is not explored yet, but the overexpression of ALK in the tumors carrying the fusion may qualify them for treatment with inhibitors of ALK kinase, as demonstrated in in vitro models.[242]

The detection of gene fusions with relevant role in cancer causation and progression has been hampered by the challenge of molecularly identifying cytogenetically cryptic rearrangements. The *TMPRSS2* and *ETV* gene fusions in prostate cancer and *EML4-ALK* in lung cancer were identified by cutting-edge investigative tools. The ongoing advances in the development of more sophisticated tools for analyses of the molecular data already available are expected to substantially increase the detection of intracellular targets of fusions in a near future.

## MICRORNAS IN LUNG CANCER

MicroRNAs are a recently identified class of highly conserved, endogenous, short noncoding RNAs of 21 to 25 nucleotides that regulate gene expression in a sequence-specific manner. These molecules work posttranscriptionally by binding to complementary sequences in the three prime untranslated region (3'UTR) of target messenger RNAs (mRNAs), which may lead to repression of protein translation and downregulation of protein expression.[246–248] Expression patterns and function of microRNAs in normal cells are not completely understood. Some microRNAs are located within introns of pre-mRNAs and are likely transcribed together with the cognate protein-coding genes,[246,249,250] whereas others are clustered and transcribed as multicistronic primary transcripts.[251,252] Although the precise functions have not yet been characterized for most of the detected microRNAs, it is known that each individual microRNA can target numerous transcripts,[253,254] whereas each single gene can be targeted by numerous microRNAs.[250,255–258] This new mechanism of gene regulation provides an alternative biologic explanation for the impact of chromosomal loss or gain in one area of the genome on the expression of genes mapped in another part of the genome.

Expression of microRNAs is emerging as an important area in cancer biology because of the evidence that they are essential regulators of various physiologic and developmental processes[249] and are altered in human cancer.[259,260] Most importantly, signatures of microRNA expression can define molecular subsets of tumors[259,261] and predict outcome.[260,262,263]

There are already scores of studies in microRNAs and lung cancer with relevant results. For instance, they have been shown to hold a prognostic effect. Lung adenocarcinoma patients with high expression of either *MIRN155* (21q21.3), *MIRN1*, *MIRN106A*, *MIRN 93*, or *MIRN21* and low expression of either *MIRNLET7A2*, *MIRNLET7A*, or *MIRN145*

were found to have a significantly worse prognosis[262] and shortened postoperative survival in NSCLC.[263] Interestingly, underexpression of two microRNAs mapped at 3p was recently found to be associated with overexpression of RAS and EGFR in lung cancer. Loss of these microRNAs would be equivalent to the loss of a tumor suppressor gene because they downregulate the expression of the target genes. RAS was determined to be downregulated by the *MIRNLET7G* (miRNA let-7g) gene, which resides on chromosome 3p21.2.[264,265] Expression levels of *MIRNLET7G* were on average 30% lower in NSCLC samples than in normal adjacent tissues[264] and reduction of tumor growth was observed in tumor xenographs when overexpression of *MIRNLET7G* was induced from lentiviral vectors.[265] The gene *MIRN128-2* (miRNA 128b) mapped at 3p22 was predicted to target EGFR, which is frequently overexpressed in lung cancer. This finding was hypothesized to provide a functional link between two common molecular phenomena in lung cancer, the loss of 3p, and the deregulation of EGFR.[266] Further exploration of this potential link led to molecular evidence that *MIRN128-2* directly regulates EGFR and, most importantly, studies in clinical specimens showed that loss of this miRNA gene was associated with significantly better disease control and longer survival in NSCLC treated with gefitinib, an EGFR TKI. In short, *MIRN128-1* loss had similar impact in the sensitivity to the EGFR inhibitors as EGFR gene gain.

Under the same premises, overexpressed microRNAs are expected to serve as oncogenes and there are examples of this role in lung cancer, one of which involves the *MIRN17-92* cluster. This gene cluster comprises seven distinct microRNAs residing in intron 3 of the *MIRHG1* gene at 13q31.3 and was shown to be markedly overexpressed and occasionally amplified in lung cancer.[267] The predicted targets for the microRNA cluster comprise a large number of genes, including the tumor suppressors *PTEN* and *RB2*.[255] Therefore, amplification of the *MIRN17-92* cluster offers the molecular conditions for suppression of *PTEN* and *RB2*.

Studies focusing on the functional role of microRNA in cancer, including lung cancer, have been expanded dramatically lately. Ultimately this knowledge is expected to contribute not only to the better understanding of cell growth and differentiation but also to the development of novel therapeutics and translational tools such as biomarkers for assessment of risk for disease, early diagnosis, and selection of patients for treatment with specific agents.

## CONCLUSION

Lung cancer is a challenging disease to patients and their families, to physicians, and researchers. Lung cancers are characterized by an extremely diverse collection of genomic alterations, of which a proportion of unknown dimension is still concealed. However, numerous pathogenetically important changes have already been detected in substantial fraction of patients and translated into a system for detection and determination of the

prognosis of the disease. Specific genomic profiles have supported the development of new treatment strategies and a growing use of customized therapy regimens using molecular targeted or chemotherapeutic agents. These aspects will be discussed in more details in other chapters. Despite the apparent caveat that each of the customized therapies is likely to benefit only a small subset of lung cancer patients, the high incidence of this disease worldwide ultimately guarantees that the benefit will impact a large number of patients. Therefore, it remains critical to improve the characterization of emerging genomic profiles and to discover new subsets of lung cancer patients. The achievement of these goals is dependent on new and important insights into the molecular pathways that underlie lung tumor development.

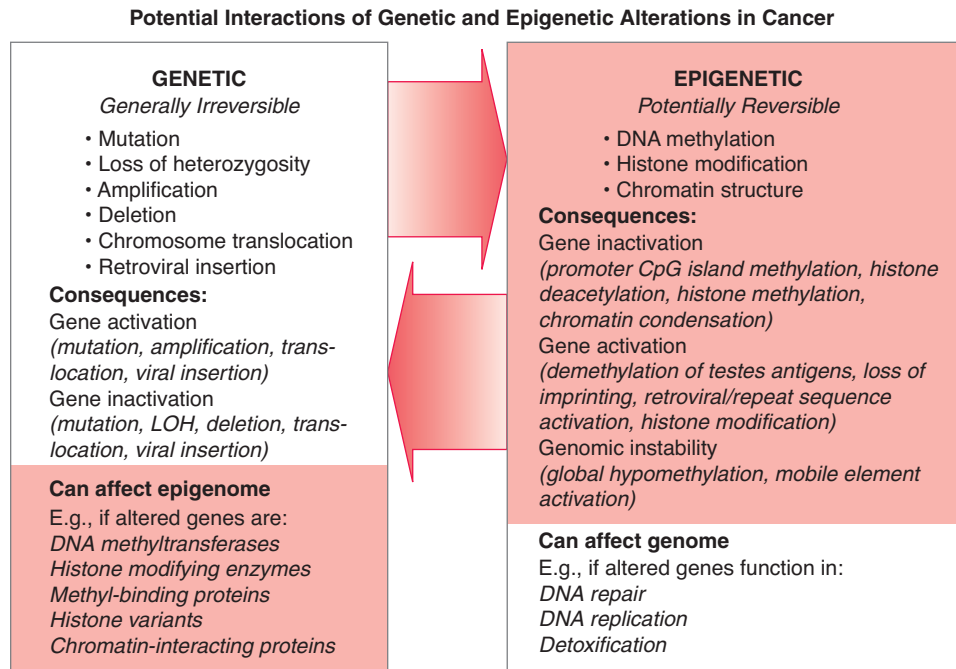
# Epigenetic Changes in Lung Cancer: Pathobiological and Clinical Aspects

Within a decade after the publication of the first human genome sequence,[1] and even before a full understanding of all its implications has been attained, a new frontier has emerged: epigenetics.[2] The study of factors superimposed on the genes, or "epi"genetics, focuses on mitotically heritable modifications of DNA and histones, and the associated chromatin components that affect gene expression without altering gene sequence.[3] Epigenetics is one of the most exciting new frontiers in genome analysis. Two of the most widely studied epigenetic modifications are DNA methylation and histone modification. Many of the interacting proteins that bind directly or indirectly to methylated DNA or modified histones catalyze the formation or removal of other alterations, forming a complex regulatory network that is only beginning to be deciphered.[3–6] It has become clear that epigenetic deregulation contributes very importantly to cancer development and progression.[7–11] Profound epigenetic changes are seen in all cancer types, including lung cancer.[12–16] Epigenetic alterations in lung cancer show potential as molecular markers that could be applied to early detection, tumor classification, risk assessment, prognostication, and monitoring of cancer recurrence.[17–20] In addition, understanding the consequences of epigenetic changes can help dissect the molecular basis of lung cancer, providing new focal points for targeted therapies.

One of the most exciting aspects of epigenetic changes is their inherent reversibility. This has encouraged the development of novel drugs for cancer treatment, such as histone deacetylase inhibitors (HDACI) and DNA methylation inhibitors.[21,22] A number of these drugs are in clinical trials for numerous cancers, including those of the lung. With the advent of ever more powerful tools for genome-wide assessment,[23] our understanding of the lung cancer epigenome and its application to diagnosis and treatment promises to increase dramatically in the years to come.[7] Here, the basic concepts of epigenetics will be reviewed, and our current knowledge concerning epigenetic alterations in lung cancer will be discussed, including the type of changes identified and their pathological and clinical implications. Given the very large number of epigenetic alterations analyzed to date and the dramatic acceleration in acquired data, it is impossible to be comprehensive in one short chapter. Therefore, the important advances made in lung cancer research will be illustrated based on a limited number of key examples, and reviews will be cited throughout as a source of more detailed information.

## GENETIC AND EPIGENETIC INTERACTIONS

Initial research into the molecular basis of lung cancer focused on genetic alterations, such as mutations, loss of heterozygosity, deletions, and gene amplification.[24,25] Examples of genetic alterations in lung cancer include mutations in KRAS and the epidermal growth factor receptor (EGFR), loss of heterozygosity at chromosome 3p, and MYC gene amplification. However, it has become abundantly clear that epigenetic alterations contribute equally importantly to lung cancer development and progression.[12–14] Epigenetic alterations seen in lung cancer consist of DNA methylation changes (both loss and gain of methylation), changes in histone modifications, and alterations in chromatin structure and chromatin-associated proteins. Interactions between genetic and epigenetic hits in cancer cells can result in further alterations,[2,11,26,27] as outlined in Figure 7.1. For example, *genetic* alterations in the genes encoding components of the epigenetic machinery (such as DNA methyltransferases and HDACs) can affect the activity of these enzymes and thereby the transcriptional activity of many additional genes. In numerous cancers, including lung cancer, somatic changes in parts of the epigenetic machinery are seen.[27] This potential for genetic alterations to affect epigenetics is underscored by the reported link between lung cancer risk and genetic polymorphisms in several genes encoding epigenetic enzymes.[27] Conversely, *epigenetic* alterations can lead to further genetic damage. For example, hypermethylation of DNA repair genes or genes encoding detoxification enzymes can affect the cell's susceptibility to mutagenesis and could result in the genetic (in)activation of additional genes.[26] DNA methylation of 6-O-methylguanine DNA methyltransferase (MGMT),


**Potential Interactions of Genetic and Epigenetic Alterations in Cancer**

| GENETIC | EPIGENETIC |
|---|---|
| *Generally Irreversible* | *Potentially Reversible* |
| • Mutation | • DNA methylation |

**FIGURE 7.1**    Interaction between genetic and epigenetic alterations in cancer. **Left panel:** Genetic "hits," which are generally irreversible and can result in activation or inactivation of the altered gene. If such a gene encodes a product involved in epigenetic regulation, like a histone methyltransferase, a DNA methyl-binding protein,[67] a histone isoform, an enzyme that adds or removes histone modifications, or a protein that interacts with such modifications (transcriptional regulators, coactivators, or corepressors), this could result in epigenetic alterations. **Right panel:** Epigenetic hits are potentially reversible, and when they occur in genes that affect the integrity of the genome, such as DNA repair genes or genes encoding proteins involved in DNA replication or detoxification, they can increase the likelihood of acquisition of additional genetic alterations.

an enzyme involved in repair of alkylated guanine, is commonly seen in lung cancer.[15] Inactivation of MGMT has been linked to an increase in RAS gene mutation frequency.[28] In support of their potential to affect cancer development, polymorphisms in MGMT and other DNA repair genes have been linked to lung cancer risk in various populations.[29–31] These examples illustrate that genetic and epigenetic changes should not be seen as independent but as components of a complex interactive network that is responsible for the development and progression of lung cancer (Fig. 7.1). Combined analysis of both types of molecular changes will accelerate the elucidation of the molecular pathways affected in lung cancer, and could be especially helpful in characterizing particular types of lung cancer (e.g., histological subtypes or lung cancer from smokers vs. nonsmokers). This holistic view of (epi)genetic alterations is also highly relevant to the clinic, as the use of certain cytotoxic drugs may potentiate or inhibit the efficacy of epigenetic drugs and vice versa.[21,22]

## DNA METHYLATION

In mammals, DNA methylation occurs at the 5-position of cytosine, in the context of a mini palindrome: a cytosine-phosphate-guanine (CpG) dinucleotide. The palindromic nature of methylation allows the propagation of this modification following DNA replication. In the normal mammalian genome, some areas are heavily methylated, such as sections of the inactive X chromosome in women, pericentromeric regions, and parentally imprinted genes. Indeed, DNA methylation is essential for proper development and viability.[3] Methylation in mammals is carried out by at least three enzymes, the maintenance DNA methyltransferase DNMT1 (which methylates daughter strands following DNA replication) and de novo DNA methyltransferases DNMT3A and 3B.[32] All three genes are essential, as illustrated by mouse knockout experiments.[32] A large number of splice isoforms exists, a number of which appear to target particular genes or areas of the genome and some of which are implicated in cancer.[33,34] In lung cancer, overexpression of the deltaDNMT3B4 variant correlates strongly with RASSF1A methylation, and knockdown of this methyltransferase resulted in a rapid demethylation of the RASSF1A CpG island.[35] This effect was gene-specific, as no changes in methylation of CDKN2A were observed.

CpG dinucleotides exist in two general environments in normal cells: sparsely distributed and clustered. On the one hand, CpGs are sprinkled throughout the genome, and these CpGs

are usually methylated. Spontaneous deamination of methyl-C results in thymine, which is less efficiently repaired than the uracil resulting from deamination of unmethylated cytosine. This has resulted in depletion over time of CpGs in areas that are usually methylated.[36] Thus, the remaining dense clusters of CpGs, called CpG islands,[37] are presumed to be normally unmethylated. It is estimated that 40% of human genes contain such CpG islands in their promoter regions.[1]

In cancer, a profound disruption of DNA methylation is seen (see Fig. 7.2, top).[7–11] Global hypomethylation occurs, which has been proposed to occur very early during cancer development and results in a net loss of methyl-C. This is thought to contribute to carcinogenesis in two possible ways: the transcriptional activation of previously methylated sequences and the loss of chromosome stability. In contrast, the local hypermethylation at promoter CpG islands contributes to carcinogenesis through gene inactivation, silencing a wide variety of growth control and tumor suppressor genes, such as genes involved in growth, adhesion, apoptosis, cell cycle, differentiation, signaling, and transcription.

DNA methylation is by far the best-studied epigenetic change in many cancers, including lung cancer. This is, on the one hand, because promoter CpG island hypermethylation is linked to gene silencing, and such silencing is thought to play a key role in the development and progression of cancer. On the other hand, DNA methylation has been extensively analyzed because it promises to provide powerful molecular markers for lung cancer.[14,15,38] Importantly, straightforward techniques exist to assess this modification.[39] Initially, analysis strategies were based on a target gene approach, utilizing DNA methylation-sensitive restriction enzymes and polymerase chain reaction (PCR)-based methods that rely on bisulfite conversion. Bisulfite conversion, a chemical treatment that converts unmethylated cytosine to uracil while methylated cytosine is protected,[40] allows methylation information to be incorporated into the DNA sequence (otherwise it would be lost during PCR).

**FIGURE 7.2**  Epigenetic abnormalities in cancer. In nontumor cells **(left)**, CpG islands are generally unmethylated (*gray lollipops*), while sporadic CpGs are usually methylated (*black lollipops*). In actively transcribed genes, the structure of chromatin is loose, allowing access of the transcriptional machinery to the promoter region. Acetylation of lysines (*triangles*) in the N-terminal tails of histones 3 and 4 reduces positive charge and relaxes the attraction to negatively charged DNA. Acetylation, monomethylation, dimethylation, and trimethylation (*balls*) and other modifications such as phosphorylation and sumoylation (*stars*) of the histone tails can mediate interactions directly or indirectly with the transcriptional machinery and with enzymes that can add further posttranslational modifications. In cancer cells **(right)**, a genome-wide loss of DNA methylation at sporadic CpGs and previously methylated sequences such as repeats is seen. (In certain cases this can lead to gene activation, *not shown.*) Simultaneously, many promoter CpG islands become hypermethylated. This can result in silencing of tumor suppressor genes. Methyl-binding proteins interacting with methylated cytosines can recruit histone deacetylases, which can in turn lead to reduced chromatin access and transcriptional silencing. This model is a simplification; methylation, histone modification, and transcription are not always concordant—not all methylated genes are silenced, nor are all silent genes methylated.

Bisulfite-converted DNA can be analyzed by many methods, depending on the design and location of the PCR primers. The most common methods are bisulfite genomic sequencing, methylation-specific PCR (MSP), and its real-time version, MethyLight or its variation quantitative MSP (QMSP). Bisulfite genomic sequencing consists of amplification followed by cloning and sequencing and provides information on the methylation status of all the Cs on the same DNA strand in the amplified area.[41] MSP utilizes primers that cover a number of methylation sites,[42] allowing interrogation of one or more CpGs in a small area. MethyLight incorporates the inclusion of a fluorescent probe between the primers, enabling real-time PCR detection, and includes control reactions on fully methylated DNA (treated with *Sss*I enzyme), allowing quantitative measurement of methylation.[43,44] More recently, higher throughput and more genome-wide approaches have been developed, such as restriction landmark genomic scanning[45] and specific amplification/purification of methylated versus unmethylated DNA (using restriction enzymes[46] or binding enrichment)[47,48] followed by probing of microarrays. Expression profiling of cancer cell lines treated with demethylating drugs has also been used to identify DNA methylation-silenced genes (e.g., in non–small cell lung cancer [NSCLC]).[49] In the future, direct sequencing with high-throughput methods[23] using either methylation-enriched or bisulfite-treated DNA will be applied. Although reports based on these latter methods are beginning to be published,[50] these techniques are in their infancy and many technical hurdles remain. In addition, they are extremely costly. At this time, high-throughput bead-based PCR methods combine the best of both worlds in richness of data and affordability, allowing the reproducible and rapid interrogation of thousands of targeted loci (Illumina Inc., GoldenGate platform,).[51] This approach was successfully applied to lung adenocarcinoma (Table 7.1)[51] and has recently been further developed to provide close to genome-wide representation of CpG islands (Illumina Inc., Infinium platform). All of these methods have yielded a great amount of information on DNA methylation changes in many cancers including lung cancer. This knowledge, and further epigenomic profiling, promise to change the way in which lung cancer is detected and treated.

### Effects of Hypomethylation in Lung Cancer

Because an overall hypomethylation is observed in cancer cells, it had originally been assumed that the cancer-causing effect of methylation changes was based on loss of promoter CpG island methylation resulting in proto-oncogene activation.[52] Indeed, loss of methylation can lead to gene activation in lung cancer, although the activated genes are not necessarily considered canonical proto-oncogenes. One category of such genes is the parentally imprinted genes—genes for which either the maternally or paternally inherited allele is normally methylated. Hypomethylation can result in loss of imprinting, thereby contributing to cancer development; biallelic expression of the normally imprinted insulin-like growth factor 2, mesoderm-specific transcript and H19 genes has been seen in lung cancer

and is thought to contribute to the carcinogenic phenotype.[53,54] Another type of gene that can be activated by hypomethylation is the family of testis-specific antigens—these genes are usually methylated and silent in all somatic tissues but the testes.[55] Expression of testis-specific antigens has been noted in many tumor types including lung cancer, and these antigens are seen as potential immunotherapy targets.[55–57] Loss of methylation of transposable elements and repeats is also observed in lung cancer[58] and can lead to mobility of such elements, causing further genetic damage.[11] In addition, read-through from such demethylated elements may result in the aberrant activation of neighboring genes. Hypomethylation might also play a role in the activation of microRNAs (miRNAs), many of which are deregulated in cancer.[59,60] In the lung, the normally methylated let-7a-3 miRNA was found to be hypomethylated in two out of eight lung adenocarcinomas and forced overexpression of this miRNA increased the oncogenic properties of lung cancer cell line A549.[61]

Besides contributing to carcinogenesis through gene activation, a second consequence of hypomethylation is thought to be genomic instability. Mice genetically engineered to underexpress DNA methyltransferases show an increased frequency of loss of heterozygosity and an elevated incidence of hematopoietic malignancies.[62] Inactivation of DNMT1 and DNMT3b in a human colorectal cancer cell line led to aneuploidy.[63] However, there appears to be little evidence that hypomethylation is severely deleterious in this way in lung cancer. A recent analysis of methylation of five human squamous cell lung carcinomas and normal matched tissue showed prominent hypomethylation of repetitive elements but little methylation loss in single-copy sequences.[58] This supports the notion that the effect of hypomethylation in lung cancer might be limited and that clinical benefits might be achieved with methylation-blocking therapies. Importantly, the leukemia-prone DNMT hypomorphic mice mentioned previously show a lower incidence of intestinal cancer, pointing to a protective effect of hypomethylation in certain tumor types.[64] Indeed, treatment of a mouse xenograft model for human lung cancer with DNA methylation and histone deacetylation inhibitors suppressed tumor growth without apparent toxicity.[65] A similar treatment of a murine lung cancer model cut lung tumor development in half, emphasizing the potential of epigenetic drugs for lung cancer treatment.[66]

## HYPERMETHYLATION IN LUNG CANCER: APPLICATION TO MARKER DEVELOPMENT

Although it would appear that the effects of hypomethylation in lung cancer are modest, hypermethylation of promoter CpG islands is widely observed.[12–16,38] Hypermethylation is associated with transcriptional shutdown.[3] This could happen directly through steric interference of methylated cytosines with transcription factor and cofactor binding sites, or indirectly, through the attraction of methyl-binding proteins to the DNA, which in turn recruit HDAC enzymes and other epigenetic

**TABLE 7.1    Epigenetic Profiling of DNA Methylation Loci in Lung Cancer**

| Method | Details[a] | Lung Cancer Type[b] | Promising Markers[c] | Reference |
|---|---|---|---|---|
| MethyLight | Examined 42 candidate loci from 304 prescreened markers. 8 show $p \leq 3 \times 10E\text{-}5$ T (n = 45) vs. AdjNTL (n = 45) | SQ | GDNF, MTHFR, OPCML, PAX8, PITX2, PTPRN2, TNFRSF25, TCF21<br>Top 8 marker panel shows 95.6% sensitivity and specificity on this sample population. | 20 |
| MethyLight | 27 genes on 49 paired T and AdjNTL | NSCLC | BVES, CDKN2A, RARB, RASSF1, $p \leq 0.001$ T vs. AdjNTL | 88 |
| MethyLight | Out of a prescreen of over 100 loci, 28 were chosen for evaluation, 7 show $p < 0.0001$ in 51T vs. 38AdjNTL | AD | CDH13, CDKN2A EX2, CDX2, HOXA1, OPCML, RASSF1, SFPR1, TWIST1<br>Top 4 marker panel CDKN2A EX2, CDX2, HOXA1 and OPCML detects cancer with 94% sensitivity and 90% specificity | 19 |
| Restriction landmark genomic scanning (RLGS) | Analyzed 1184 CpG islands in 16 NSCLC | NSCLC | GNAL and IPF1 methylated in 8/16 NSCLC | 86 |
| MALDI-TOF mass spectrometry analysis of bisulfite-treated, PCRed DNA | 47 gene promoter regions in 96 T with matched AdjNTL | AD, SQ | GAGED2, MGP, RASSF1, SDK2, SERPINB5, TNA, all $p < 10E\text{-}6$ in tumor vs. matched AdjNTL, identify T vs. AdjNTL with 95% sensitivity and specificity | 75 |
| Examined genes differentially expressed in fetal vs. adult lung | Studied a subset of 453 differentially expressed genes in 12 AD+3SQ vs. 5 normal adult lung samples | AD, SQ | MEOX2 is hypermethylated in 14/15 lung cancers | 87 |
| 5-aza-dC/ expression microarray | 132 genes induced by 5-aza-dC, 31 methylated, top 8 analyzed in 20 T vs. 20 AdjNTL lung | NSCLC | Three most promising genes: LOX, BNC1, CTSZ methylated in 19, 18, 10 of 20 tumors vs. 4, 3, 0 of 20 nontumor lung | 49 |
| Microarray-based approach | 245 CpG positions in 59 candidate genes in 26 SQ, 22 AD, 26 AdjNTL | AD, SQ | SQ: ARHI, GP1BB, MGMT, RARB, and TMEFF2<br>AD: TMEFF2, MGMT, and CDKNIC | 89 |
| Methylation-sensitive restriction enzymes/ microarray | Lung cancer cell lines for MSRE/ microarray, chose subset of genes for testing in 22 LuCa T, 1 control lung | LuCa | ASC, PAX3 hypermethylated in 82%, 86% of lung tumors, respectively | 90 |
| Methylation-sensitive restriction enzymes/ microarray | Lung cancer cell lines, validation of two genes in 8AD, 8SQ, 5 SCLC | LuCa | CIDEB methylated in 15/21 lung cancers (71%) | 91 |
| MIRA/microarray | Purification of methylated DNA using methyl-binding domains followed by microarray hybridization | SQ | HOXA3, 5, 7, and 9 are more highly methylated in 4/4 T than AdjNTL | 92 |
| MIRA/microarray of 4 SQ vs. AdjNTL on partial genomic tiling arrays | 4 SQ vs. AdjNTL on partial genomic tiling arrays, detailed analysis of gene subset on 20 SQ T and 20 AdjNTL | SQ | EVX2 (16/20), IRX2 (19/20), MEIS1 (17/20), MSX2 (19/20) NRE2E1 (20/20), OSR1 (20/20), OTX1 (20/20), PAX6 (17/20), ONECUT2 (14/20), TFAP2A (19/20), ZNF577 (18/20) | 58 |
| Illumina GoldenGate | Screened 1536 CpG sites in 371 genes, identified 55-gene panel that is 92% sensitive and 100% specific on 12 AD and 12 matched AdjNTL | AD | Eight markers examined in detail by bisulfite genomic sequencing, all hypermethylated in 4/4 tumors vs. 2 normal lung samples *ASCL2*, *CDH13*, *HOXA11*, *HOXA5*, *NPY*, *RUNX3*, *TERT*, and *TP73* | 51 |

[a]T, tumor; AdjNTL, adjacent nontumor lung.

[b]AD, adenocarcinoma; LuCa, mix of lung cancer types or no type specified; NSCLC, non–small cell lung cancer; SQ, squamous cell lung cancer.

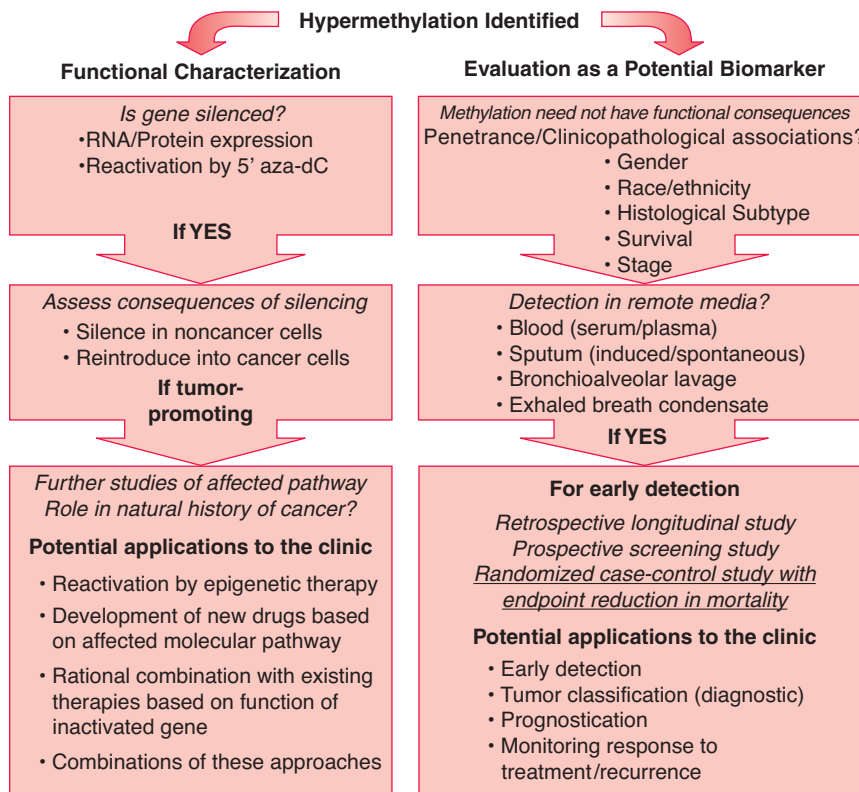
[c]Human Genome Organization name used unless none is available. Sensitivity and specificity numbers based on tumor tissues, not remote media.

modifiers (see Fig. 7.2).[67] In lung cancer, hundreds of studies have been devoted to the characterization of hypermethylation events. One of the driving forces behind this research is the desire to identify DNA methylation markers for early lung cancer detection.[14,15,38] DNA hypermethylation analyses could yield powerful candidate markers for lung cancer because only a small region of each gene needs to be interrogated, and DNA is a PCR-amplifiable substance that can be detected in bodily fluids.[14,15,38] Successful development of markers for cancer is a long process that should culminate in a randomized case-control study that demonstrates a reduction in mortality.[68] The process for the development of DNA methylation loci into markers for early lung cancer detection is diagrammed in the right panel of Figure 7.3.

Most DNA methylation studies in lung cancer have focused on NSCLC, which makes up about 85% of all lung cancers. Small cell lung cancer, a very aggressive cancer with poor survival, is considered by many to be a poor candidate for the development of early detection molecular makers due to the rapid progression of the disease. In contrast, NSCLC patients, which include the major groups adenocarcinoma (~40%), squamous cell carcinoma (~30%), large cell carcinoma (~10%), and miscellaneous other histological subtypes such as carcinoids and neuroendocrine cancers (~5%),[69] could benefit importantly if cancers that would normally lead to death could be detected at an early stage.[70] A comparison of methylation profiles of SCLC and NSCLC cell lines and tumors indicates that hypermethylation profiles are distinct for these two groups.[71–73] Not surprisingly, differences between hypermethylation profiles of NSCLC

histological subtypes have also been observed,[15,20,72,74–77] meshing with other molecular and clinicopathological differences found in these tumor types.[78–81] This suggests that a panel of DNA methylation markers would be optimal, and that this panel should include pan-lung cancer markers as well as ones for distinct histological subtypes. Indeed, a panel of markers would be needed even for a single subtype because penetrance of molecular changes in cancer is usually less than 100%; it would be unexpected to find one marker with very high sensitivity and specificity.[20,74]

The first step in molecular marker development is the identification of promising candidate markers.[68] In the case of DNA methylation markers for lung cancer, it is of high priority to identify frequently methylated genes or loci (we refer to the CpG island section we are probing as a *locus*, because a given gene can be probed in multiple areas within a single or multiple CpG islands). These loci should also show substantially increased methylation levels over those found in healthy tissues. Thus, the initial focus should be on penetrance and DNA methylation levels. Because even noncancerous lung tissue from long-term smokers may have accumulated substantial methylation caused by age and environmental exposure,[77,82–85] many labs, including ours, have chosen to compare cancer tissues to this type of "high-background" control tissue (referred to here as adjacent nontumor lung [AdjNTL]) (Table 7.1). This ensures that identified hypermethylation markers are indeed cancer-specific and not merely indicative of environmental exposure. (Comparison to healthy lung from nonsmokers would be of use for the development of risk markers or identification



**Hypermethylation Identified**

**Functional Characterization**

*Is gene silenced?*
• RNA/Protein expression
• Reactivation by 5' aza-dC

**If YES**

*Assess consequences of silencing*

of candidates for chemoprevention treatments [perhaps even epigenetic ones], once these become available.)

Many of the genes studied early on did not show high methylation frequencies,[15] but more recent efforts by several groups to examine much larger collections of genes have yielded a number of panels that might deliver high sensitivity and specificity, based on the examination of tissues (Table 7.1).[20,49,51,58,74,75,86–92] Some these panels contain genes that were identified early on (such as CDKN2A/p16, MGMT, and RASSF1),[74,75,88] but many new loci have been added to the repertoire, including homeotic genes involved in development, such as members of the HOX and PAX families.[19,20,51,58,90,92] The latter group of methylated loci agrees with the observation that genes occupied in embryonic stem cells by transcriptionally repressive polycomb group complexes appear to be prone to methylation in cancer.[93] The significance of methylation of these genes is unclear, since it is thought that they may already have been silent in noncancerous lung, but their involvement hints at the potential role of stem cells in lung cancer development.[93] Whether the hypermethylation of potential DNA methylation markers is functional or not (i.e., leads to transcriptional silencing) is not relevant, as long as penetrance is high and hypermethylation is associated with the presence of cancer. Many of the marker panels in Table 7.1 must still be validated on independent tumor sets, and their ability to identify lung cancer independently of gender, histological subtype, racial/ethnic group, and/or stages of cancer must be further scrutinized (Fig. 7.3, right panel). Once that is accomplished, they can be taken to the next phase of marker development: clinical assay validation.[68] For these panels to function in early lung cancer detection, they must be detectable in patient remote media: bodily fluids that could carry methylated DNA molecules from the cancer and that could be sampled relatively noninvasively.

## Detection of DNA Methylation Markers in Bodily Fluids

Potential remote media for lung cancer detection are coughed-up sputum (spontaneously collected from smokers or induced in never-smokers or ex-smokers), blood (plasma or serum), bronchoalveolar lavage (BAL, a saline rinse that can be collected during bronchoscopy), bronchial brushings, and exhaled breath condensate (EBC, collected as condensation from breath using a cooling device).[38] DNA methylation markers have been detected in sputum, plasma, serum and BAL, and data from a large number of studies is summarized in Table 7.2 (the table was compiled with special attention to BAL studies, which have provided the most promising results to date; key results are indicated in bold). One problem with many studies is the lack of control subjects, which makes results difficult to interpret. In addition, some studies cite frequencies based on the number of methylation-positive remote samples found in patients in which the tumor is positive. Although this is helpful to determine the experimental sensitivity of the test, it does not provide a good estimate of clinical sensitivity.

There are no published reports of detection of DNA methylation markers in EBC, but microsatellite alterations and p53 mutations have been detected in this material when collected from lung cancer patients.[94,95] While the microsatellite alterations in EBC matched those of the lung tumors, the p53 mutations detected in EBC and the corresponding lung cancer did not match.[95] Thus, the DNA in EBC may not be from the tumor, but might derive from elsewhere in the lung or the throat and mouth.[96] Similar concerns apply to sputum, with the added caveat that sputum is thought to provide samples of DNA and cells from central lung areas, and thus might favor detection of squamous lung cancer over the generally more peripherally located adenocarcinoma. In one sputum study, a high fraction of samples was positive for LAMC2 and SFRP1methylation when using nested MSP (in which a preamplification is incorporated to increase signal).[17] However, a very large fraction of the controls was also positive, perhaps related to the many amplification cycles.

Blood (plasma or serum) would be the easiest bodily fluid to obtain for screening, but analyses to date indicate the medium is not very sensitive (Table 7.2). In addition, DNA methylation signatures observed could arise from anywhere in the body. However, the new high-throughput DNA methylation profiling technologies might make it feasible to identify *lung cancer*–specific DNA methylation signatures. This would require the profiling of DNA methylation in all other common types of cancer, something that is ongoing in different laboratories. Any identified potential lung cancer–specific markers would need to be evaluated in other cancer types using standardized methods. Alternatively, the combination of blood-based methylation signatures with high-resolution imaging (LDSCT) might be sufficient to address the issue of organ of origin. It remains a question what size the tumor must be in order to shed sufficient DNA into the blood for remote detection.

Of the remote media tested, BAL appears the most promising, showing sensitivities for individual loci approaching 50% or higher. Combination of markers into panels will help boost sensitivity, as exemplified by studies of Grote and coworkers.[97,98] The finding that combined methylation analysis of CDKN2A and RARB detects lung cancer cases with a sensitivity of 69% and a specificity of 87% is highly encouraging.[98] Combination of APC, CDKN2A, and RASSF1 also showed promise, detecting 63% of central and 44% of peripheral cancers and exhibiting a very low background of 1/102 cases with benign lung disease.[97] Based on the detection of methylation in BAL from noncancer patients in a number of studies, it would be important to use quantitative measurements and to set a cutoff value for positive methylation.[97–100] The fact that the collection of lavage fluid can be directed to a particular area of the lung makes it especially suited to combine with imaging approaches. This, in addition to the promising results obtained to date, suggest that analysis of DNA methylation in BAL might be the key to early lung cancer detection.

Besides their use for early detection, DNA methylation markers identified in bodily fluids could be utilized for risk assessment and monitoring of recurrence. In the case of quantitative markers, cutoff values could be stratified to distinguish

[a]Human genome organization name used unless none available, the 5′ CpG island of RASSF1 was analyzed, referred to as RASSF1A in the literature.

[b]Blood includes serum and plasma. Bronchial brushing studies, which are very rare and not especially informative, are not listed. There are no reports of DNA methylation detection in EBC. This table lists many studies of blood and sputum but may not be comprehensive; however, due to its highly promising nature, all published BAL studies are included. Separate rows are listed for each locus for studies with and without controls.

[c]Compelling data are highlighted in bold, % methylation is listed only in a few very promising cases.

[d]Order of data matches that in previous column. Compelling data are highlighted in bold, % methylation is listed only in a few very promising cases. n.a. indicates no controls are available.

[e]Order of data matches that of data in previous two columns, *all* indicates that the same procedure was used in all cases. MSP, methylation-specific PCR; QMSP, any form of quantitative MSP; neMSP, nested MSP preceded by a preamplification step; MSSNuPE, methylation-specific single nucleotide primer extension.

[f]In this report, only BAL from tumors positive for methylation was assessed, the total number of tumor cases was 31.

[g]Out of the 19/50 patients with methylation in their tumors.

[h]Out of the 14 of 33 patients with methylation in their tumors.

between methylation detected in normal tissue from non-smokers, histologically normal tissue of cases prior to diagnosis, lung cancer, or recurring lung cancer. Several studies have shown that methylation can be detected long before the cancer becomes clinically apparent.[101–103] However, as noted previously, the sensitivity of the least invasive approaches (sputum, blood) has not been high, and use of BAL would require bronchoscopy, a semi-invasive procedure.

## Functional Implications of DNA Hypermethylation

For the purposes of early detection, the functional consequences of hypermethylation are not important. However, for the purposes of prognostication or providing tailored therapies, whether observed DNA methylation events have functional consequences could be of highly relevant. This idea is supported by the prognostic utility of expression arrays.[104] Figure 7.3 (left panel) outlines the approach to determine whether promoter CpG island hypermethylation of a gene is functionally significant. After lack of expression has been verified by mRNA and/or protein analysis, 5′aza-deoxycytidine treatment of cell lines can be used to determine if the gene can be reactivated by demethylation. A potential caveat of such experiments is that reactivation could be the indirect consequence of demethylation of other genes. Next, reexpression of the gene in cancer cells in which the gene was silenced, and silencing (e.g., through targeted RNAi transfection) of the gene in cells in which the gene is still expressed will help determine the role of the gene in cancer development and progression. In the silencing experiment, the choice of cells is important (primary, immortalized, transformed) and should be influenced by the perceived stage of cancer development at which the gene of interest is thought to play a role. Experiments such as these have implicated a variety of hypermethylated genes in lung cancer.[12,13,15,38,105] It should be noted that methylation of genes that were already silent in lung tissue might not be a functional event per se, but might still be informative, as it could provide hints to the origin of the cancer or the involvement of stem cells.[93]

Genes that appear to be silenced by methylation and that limit any aspect of the transformed phenotype when reactivated can be excellent tools for prognostication or targets for therapy; the testing of associations between clinical data and DNA methylation status in patient populations could provide markers for survival or response to therapy. In addition, the silenced genes could point to the involvement of molecular pathways that might be targeted by new drug therapies. An important caveat of studies of associations between DNA methylation and clinicopathological variables is that a correction should be applied for multiple hypothesis testing when multiple new loci and clinical parameters are examined.[106]

Although many genes/loci silenced in lung cancer by DNA methylation have been studied to date, only a handful have been analyzed in depth. The most intensive focus has been on CDKN2A/p16, a gene encoding an inhibitor of cyclin-dependent kinases 4 and 6, which in turn bind to cyclin D1 and promote the phosphorylation and inactivation of the retinoblastoma gene product, RB. RB is a key cell cycle regulator that is frequently inactivated in SCLC.[25] In contrast in NSCLC, it is CDKN2A that is inactivated in the majority of tumors, and in many cases, this occurs through promoter hypermethylation.[14,15,107,108] Methylation of the CDKN2A promoter CpG island appears to be a very early change in the development of squamous cell lung cancer as well as adenocarinoma.[16,102,109] In a cohort of high-risk long-term smokers from whom sputum was examined for seven DNA methylation markers, hypermethylation of CDKN2A was most strongly associated with lung cancer risk.[17] These observations are consistent with the idea that disruption of cell cycle regulation is an important early event in the transition from normalcy to cancer, an observation that is emphasized by the fact that human bronchial epithelial (HBE) cells can be immortalized through CDK4 activation in combination with overexpression of telomerase.[110] It is intriguing that in NSCLC, the CDKN2A promoter CpG island appears to be the weak link in the regulatory pathway, and it is tempting to speculate that this might be linked to occupancy of this region by polycomb complexes in stem cells.[111] Methylation of the gene appears to become more pronounced during progression[109] and is associated with an unfavorable prognosis in lung adenocarcinoma.[112] These observations fit well with a recent report exploring the potential link between methylation of several genes and risk of progression in stage I NSCLC.[18] In this study, 51 patients with stage I NSCLC who had a recurrence within 40 months after surgery were matched for age, sex, surgery date, and stage with 116 patients who did not have a recurrence. The odds ratio for recurrence was found to be significantly elevated when CDKN2A was methylated in the tumor, regional nodes (N1) or mediastinal (N2) nodes of the patients, or when CDH13 was methylated in the mediastinal nodes. Combination of CDKN2A and CDH13 methylation in the tumor and mediastinal lymph nodes was associated with an odds ratio of recurrent cancer of 15. In a separate validation set of 20 cases, the authors observed an association between methylation of CDKN2A and CDH13 (individually as well as together) in regional nodes, with an odds ratio for recurrence of 8 for methylation of each gene alone, and of 19 when both genes were methylated. These compelling results indicate that methylation profiling may have important applications in prognostication (Fig. 7.4).

One caveat with the design of studies of this kind is potential confounding factors, such as tumor size. If a range is used to categorize tumor size (e.g., ≤3 cm), the distribution of tumor sizes within this range may not be equal for cases (showing recurrence) and controls (no recurrence). Since the actual size of the tumor may be a key factor in progression, it would be important to examine this variable closely in relation to methylation.

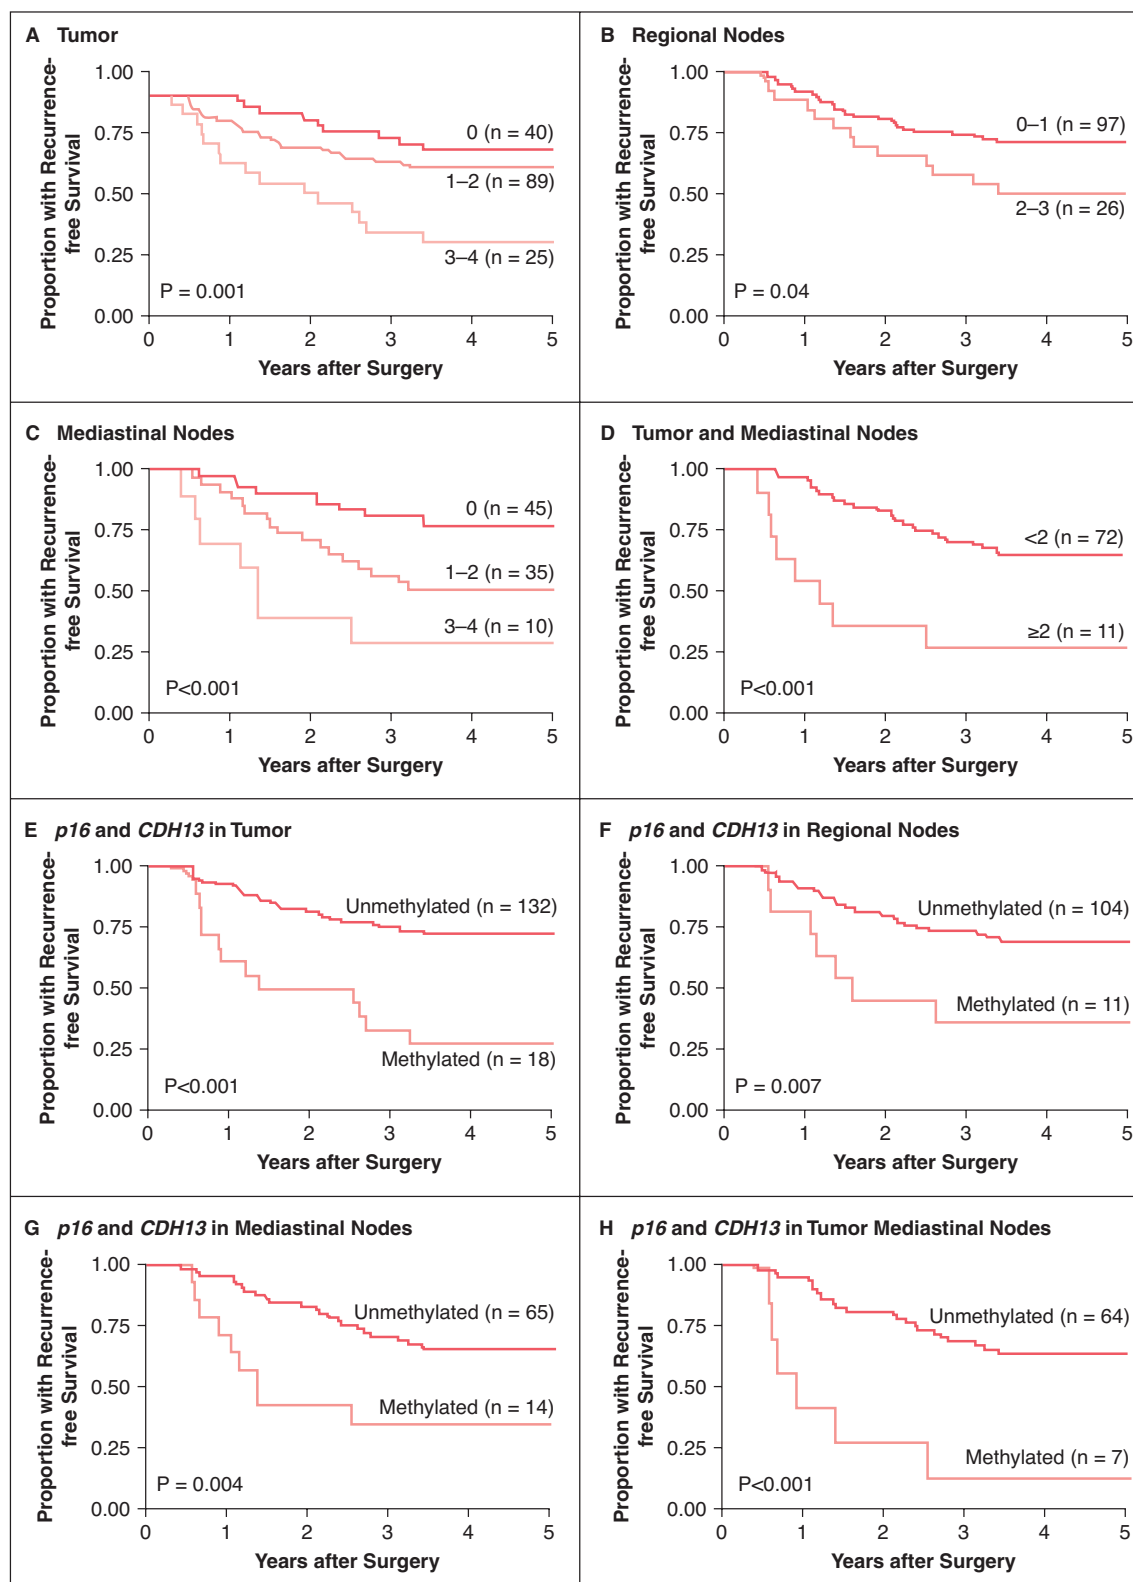
A second gene that has been extensively studied in DNA methylation analysis is MGMT.[14,15] Mentioned previously as a target of epigenetic regulation that could promote further genetic changes, this DNA repair gene appears to be another hot spot for early methylation, showing increasing methylation as cells progress from a field defect to hyperplasia, and


**FIGURE 7.4** Kaplan-Meier estimates of recurrence-free survival among 167 case patients and controls with stage I non–small cell lung cancer from the original cohort, according to the site and number or presence or absence of methylated genes. Data are reported for a four-gene panel consisting of the cyclin-dependent kinase inhibitor 2A gene p16, the H-cadherin gene CDH13, the Ras association domain family 1 gene RASSF1A, and the adenomatous polyposis coli gene APC. In all three types of tissue, the recurrence-free survival rates decrease with an increasing number of methylated genes (**A,B,C**) and when certain genes are methylated (**E,F,G**). This same effect on recurrence-free survival is evident when the tumor and mediastinal lymph nodes are considered together (**D,H**). (From Brock MV, Hooker CM, Ota-Machida E, et al. DNA methylation markers and early recurrence in stage I lung cancer. *N Engl J Med* 2008;358:1118–1128.)

further to adenocarcinoma.[16,109] Interestingly, methylation was also found to be associated with tumor progression and poor survival.[113,114] Conflicting reports about the preferential methylation of MGMT in smokers[115] versus nonsmokers have been made.[113]

Of the genes listed in Table 7.2 as potential DNA methylation markers in lung cancer, RARB is one of the two most promising because it is frequently detected in BAL of cancer cases. This gene encodes the retinoic acid receptor beta. Retinoids, vitamin A, and its analogs, play important roles in development, differentiation, proliferation, and apoptosis.[116] Retinoids have been considered strong candidates for chemoprevention of lung cancer,[116] an idea that makes sense considering the hypermethylation of RARB (Table 7.1). Unfortunately, the outcome of retinoid chemoprevention clinical trials was an increase rather than decrease in the risk of lung cancer.[117] Nevertheless, in vitro experiments suggest that retinoic acid can prevent the oncogenic transformation of immortalized HBE cells.[118] Hypermethylation of RARB was linked with retinoic acid resistance in an HBE cell line and treatment with DNA methylation inhibitor azacitidine restored the cells' ability to respond to retinoic acid.[119] Like methylation of MGMT, RARB hypermethylation appears to be an early event in lung adenocarcinoma development, showing low but detectable levels in adjacent lung and increasing methylation in hyperplasia and adenocarcinoma.[109,120]

Similarly to MGMT and RARB, RASSF1 methylation occurs early, showing a progression in frequency of methylation from the surrounding histologically normal tissue of a tumor, to hyperplasia and to lung adenocarcinoma.[109] RASSF1 methylation is frequently detectable in BAL and appears to be the most specific marker examined in BAL to date (Table 7.2). The gene encodes a putative RAS effector protein.[121] It lies on chromosome 3p21, in an area of common loss of heterozygosity in lung cancer, and is frequently methylated in human malignancies including lung cancer (Table 7.2).[14,15,121] The gene has alternative first exons, alpha and gamma, each with a CpG island. The upstream island (RASSF1A) is hypermethylated in lung cancer, and its methylation is strongly correlated with expression of the delta subfamily of the DNA methyltransferase 3B.[35] This DNMT3B subfamily consists of at least seven splice variants. Knockdown of DNMT3B4 in lung cancer cell lines resulted in reactivation of the RASSF1A but not the CDKN2A promoter, implying that DNMT3B isoforms could be involved in initiating promoter-specific DNA methylation. RASSF1A methylation is suggested to correlate with a poor prognosis, although this observation should be confirmed by an independent study.[122]

Besides CDKN2A, MGMT, RARB, and RASSF1, there are many other genes that could be of interest, functionally or therapeutically. Three genes worth mentioning briefly are CDH13, OPCML, and miRNA-29 (miR-29). As mentioned previously, hypermethylation of CDH13, encoding the cell adhesion molecule heart cadherin, was associated with increased risk of recurrence.[18] OPCML, encoding an opioid-binding cell adhesion molecule-like, had been pegged as a suspected tumor suppressor gene many years ago by Maneckjee and Minna[123] based on the apoptotic response of lung cancer cell lines to opioids, which antagonized the growth stimulatory effect of nicotine. The frequent and high methylation of OPCML in both adenocarcinoma and squamous cell lung cancer suggests that it might function as a pan-lung cancer marker.[19,20] The miR-29 family of three RNAs is an example of miRNAs that are silenced by hypermethylation in lung cancer (in contrast to the activated let-7a-3 mentioned earlier).[124] Expression of these RNAs is inversely correlated with DNMT3a and 3b in lung cancer, which appears to be mediated by targeting of miR-29 to the 3′ untranslated regions of the methyltransferase mRNAs. Reactivation of miR-29 could be one way in which methyltransferase expression and tumorigenic potential of lung cancer cells could be mitigated, as illustrated by the reduced tumor growth in nude mice of A549 lung cancer cells transfected with miR-29.[124]

From the data described previously, it is clear that progress is being made in understanding the functional consequences and clinical implications of DNA hypermethylation. However, much work remains to be done to independently verify observations before they can lead to clinical implementation (such as treatment decisions based on methylation profiles). The general reversal of methylation is already a clinical target though, with numerous drugs that counteract DNA methylation under development and a number of them in clinical trials (see later in this chapter).[21]

## Histone Modifications and Their Role in Lung Cancer

The link between DNA methylation and chromatin structure is formed by proteins that bind directly or indirectly to methylated DNA and modify the flexible histone N-termini (Fig. 7.2). The nucleosomal core around which DNA is coiled is composed of two molecules each of histones 2A, 2B, 3, and 4. The lysine and arginine-rich N-terminal regions extend from the core and can be heavily decorated with monomethylation, dimethylation, and trimethylation, acetylation, ubiquitination, phosphorylation, and other modifications.[5,125] These modifications do not exist in isolation; functional and physical cross talk ensures a complex web of epigenetic signals, in which DNA methyltransferases, methyl-binding proteins, histone variants, histone-modifying enzymes, and other chromatin and transcriptional components play a role (Fig. 7.2).[126] Many of the enzymes that modify histones recognize other modifications on the same or different histone tails, or on DNA. For example, proteins that bind to methylated DNA frequently carry additional domains that interact directly or indirectly with histone-modifying proteins, such as deacetylases.[67] Acetylation of histones on lysine promotes active transcription. On the one hand, this modification reduces positive charge and minimizes the electrostatic attraction of the histone tails for the DNA phosphate backbone, thereby relaxing chromatin structure. In addition, acetylated histone N-terminal tails are landing pads for bromodomain-containing proteins, such as transcriptional coactivator p300/CBP associated factor and TAF1, a component of the transcription initiation complex.[5] Multiple enzymes that add or remove acetyl groups exist in the cell. In contrast to acetylation, methylation does not affect histone tail charge, functioning by altering protein/protein

interactions. One or two methyl groups can be added to arginine and up to three to lysine; the effects depend on the modified position and the number of added methyl groups. For example, histone 3 lysine 9 and lysine 27 trimethylation (H3K9me3, H3K27me3) are repressive marks, while histone 3 lysine 4 trimethylation is found in transcribed regions.

In contrast to the abundance of information about DNA methylation in lung cancer, relatively little is known about how histone modification is affected; molecular changes on the histone N-terminal regions are much more difficult to interrogate in comparison to DNA methylation. The most commonly used technique is formaldehyde cross-linking followed by specific immunoprecipitation of particular histone modifications and PCR-based or global (e.g., microarray, high-throughput sequencing) characterization of the coprecipitated DNA sequences. One recent study classified NSCLC patients into seven distinct groups based on differential histone modifications and observed differences in survival depending on histology and histone 3 modifications.[127] This early study hints at the potential use of this kind of epigenetic characterization to guide treatment.

## EPIGENETIC THERAPY FOR LUNG CANCER

Much more widely studied than the modifications themselves are the enzymes that mediate the decorations of histone tails. The ability to inhibit HDACs, enzymes that are thought to be involved in inappropriate gene repression in cancer, has given rise to a flurry of drug development and preclinical studies using lung cancer cell lines.[21,128] Many studies report inhibition of growth and induction of apoptosis by HDACI, and these drugs are being used in phase I and II in clinical trials.[129,130] Although gene reactivation is observed in many cases, it is not clear whether this is an effect of deacetylase inhibitors on histone tails or on other proteins that are acetylated, such as heat shock protein 90 (HSP90).[129] HDACI LBH589 increased HSP90 acetylation in lung cancer cells, thereby decreasing HSP90 protein chaperone ability, an activity that helps EGFR mutant proteins maintain functionality.[131] The exciting link in lung cancer between EGFR signaling and histone deacetylation has been confirmed by several studies[132–134] and supports the evaluation of combinations of drugs that target deacetylation and tyrosine kinases in clinical trials. Of additional interest is the profiling of lung cancer cells to identify genes that modulate sensitivity to HDACIs[135] and the combination of standard therapies such as radiation treatment with HDACIs—approaches that show promise in preclinical models.[136]

One type of drug that forms a logical combination with HDACIs is DNA methylation inhibitors. A variety of different DNA methyltransferase inhibitors that work through different mechanisms is available.[21] Because some of these DNA methyltransferase inhibitors, such as 5-aza-deoxycytidine work through incorporation into the DNA (where DNA methyltransferases are consequently trapped), their efficacy may be partially related to DNA damage.[21] One study of human lung cancer cells treated with 5-axa-deoxycytidine and HDACI indicated that the synergy with HDACIs was related to DNA damage rather than inhibition of DNA methylation.[137] Despite our incomplete understanding of the mechanism of epigenetic therapy, its clinical promise is high, and phase I and II trials in lung cancer are ongoing (see http://www.clinicaltrials.gov/).[22,129,130]

## CONCLUSION

Powerful tools are being honed for the (epi)genomic analysis of lung cancer, and these will rapidly increase our understanding of its molecular underpinnings, as well as provide molecular markers for detection, diagnosis, prognostication, and monitoring of recurrence. A key area that will require rapid development to make the most of these technologies is bioinformatics, since the staggering amount of data generated must be analyzed and interpreted. The combination of new (epi)genetic insights, novel epigenetic drugs, and an emerging understanding of how these and other drugs function has generated an aura of hope and excitement in the lung cancer field. The possibility to build on existing therapies such as EGFR inhibitors or radiation treatment by combining them with HDACI and DNA methylation inhibitors opens many new therapeutic avenues. With progress looming on the fronts of early detection as well as treatment, it can truly be said that epigenetics has given new breath to the fight against lung cancer.

# Molecular Events Surrounding the Angiogenic Switch of Lung Cancer

Multicellular organisms such as humans require a complex vascular system to supply cells with oxygen and glucose and to dispose of waste products. During embryonic development and at the main phases of organ growth, the vascular system evolves with the growing organism. However, in adulthood, the vascular system is quiescent. A well-controlled angiogenic response (production of blood vessels from existing blood vessels) to specific transient cues may occur. Other than the changes that occur in the female reproductive system or in wound healing, endothelial cells rarely proliferate in adults. This tight control is the result of a continuous balance between angiogenic signaling and inhibition. Several proangiogenic and antiangiogenic molecules have been identified, many of which are potentially active in creating this balance (Table 8.1). The exceptions to this balance include pathologic conditions such as wound healing, inflammation, and cancer, in which the formation of new blood vessels is vital.[1] The abnormal state of cancer, in which proangiogenic signaling does not abate, is reminiscent of what happens in wounds; however, it occurs in a perpetual manner. In this sense, cancer can be regarded as a "wound that never heals."[2]

Blood supply is delivered by a highly organized conduit network that is spread out, designed to reach most cells. The exchange of nutrients and waste molecules between the blood and cells occurs through capillary walls, the thinnest vessels, those that connect the arterial tree to the venous tree. Vascular capillaries are formed from endothelial cells, which create the tubal conduit for blood, surrounded by a basement membrane. Pericytes (mural vascular cells) are embedded in the basement membrane. These cells provide physical support for the blood vessel and provide communication ports with endothelial cells, thus controlling capillary function. Unlike vascular smooth muscle cells, which are found in the media layer of large blood vessels, most pericytes are in direct contact with endothelial cells; cell–cell communications take place between these cell types.[3]

As a malignant growth exceeds the size of a few hundred microns, nutrient diffusion becomes a growth-limiting factor. Hypoxia and various cancer-specific genetic abnormalities drive the secretion of proangiogenic factors and suppression of antiangiogenic factors. In this manner, the tumor microenvironment becomes proangiogenic. New blood vessels are formed, and existing blood vessels are modified to provide a better blood supply to the tumor. The production of blood vessels from existing blood vessels is called *angiogenesis*, whereas production of de novo blood vessels is termed *vasculogenesis*. Both of these processes are controlled by the counteracting effects of proangiogenic and antiangiogenic factors. The tipping of the balance toward a proangiogenic state is called the *angiogenic switch*. This switch seems to be essential to cancer progression. Accordingly, tumoral angiogenesis was suggested as a therapeutic target more than 35 years ago.[4] Only in recent years has this idea entered clinical practice; antiangiogenesis is used to treat colon, kidney, breast, and other cancers. The clinical importance of angiogenesis inhibition in the treatment of non–small cell lung cancer (NSCLC) was demonstrated by an improved outcome after treatment with an antiangiogenic agent and classic chemotherapy.[5,6]

In this chapter, we will discuss the importance of the angiogenic switch in cancer, as demonstrated in studies of whole organs and the major cell types and mechanisms that supply nutrients to cancer. In vitro studies and the major molecular players will be presented. The role of vasculogenesis in tumor perfusion is controversial and sometimes difficult to distinguish from that of angiogenesis. Thus, both are discussed in this chapter. We conclude with the available data on the angiogenic switch and alternative modes of lung cancer vascularization, and a note about the clinical implications of this information.

## ANGIOGENIC SWITCH IN CANCER: WHOLE-ORGAN STUDIES

A milestone of molecular biology and cancer research is the development of specific gene silencing and upregulation techniques in in vivo mouse models. Several mouse models of the angiogenic switch are described in the succeeding discussion.

**TABLE 8.1** **Proangiogenic and Antiangiogenic Factors**

| Factor Type | Proangiogenic | Antiangiogenic |
| --- | --- | --- |
| Physical and biochemical factors | Hypoxia, hypoglycemia (VHL→HIF, VEGF) | Normoxia, normoglycemia |
| Transcription factors | HIF-1α[133] | p53[136] |
| Coagulation system components | Plasmin[133] | Angiostatin[100] |
| MMP-mediated ECM degradation | MMP9→VEGF release[51] | MMP→endostatin, arrestin, canstatin, tumstatin |
| Immune system effects | TAMs,[216] mast cells[163] | Macrophage-derived methalloelastase (produces angiostatin from plasminogen),[132] NK cells[118] |
| Stromal fibroblast derived | SDF-1,[70] VEGF,[161] HGF[229] | |
| Basement membrane–derived molecules | MMP9, VEGF, fragments of collagen IV | Endostatin, arrestin, canstatin, tumstatin |
| Chemokines | IL-8/CXCL8[253] | PF-4/CXCL4, variant PF-4/CXCL4[254] |
| Cell–cell adhesion molecules | ICAM-2[103] | Membranous E-cadherin |
| Context dependent | Ang-2 (if high VEGF), pericytes (stabilizing blood vessels, allowing better functionality) | Ang-2 (if low VEGF), pericytes (stabilizing blood vessels and preventing their evolvement) |

ECM, extra-cellular matrix; HGF, hepatocyte growth factor; HIF, hypoxia inducible factor; ICAM, inter-cellular adhesion factor; IL-8, interleukin-8; MMP, matrix metalloprotease; PF, platelet factor; SDF, stromal cell derived factor; TAM, tumor-associated macrophages; VEGF, vascular endothelial growth factor; VHL, Von Hippel-Lindau.

**Mouse Models** The RIP-Tag mouse model was created by genetically manipulating mouse pancreatic β-cells to express the SV40 large T antigen; a hyperproliferative stage arises in about half the pancreatic islets, and in a minority of those, pancreatic islet cell carcinoma develops. The induction of angiogenic activity demarcates an angiogenic stage, which is found in islets that have progressed past the proliferative stage and apparently precedes carcinoma.[7] The isolation and examination of these islets revealed that an angiogenic phenotype is not a direct outcome of oncogene expression, nor is it the inevitable effect of a proliferative mass that requires an increased blood supply. The RIP-Tag model demonstrated discrete stages of tumor progression in which additional genetic manipulation can be used to determine the roles of various molecules in each phase. Thus, this model was used to evaluate the roles of vascular endothelial growth factor (VEGF) in the angiogenic switch,[8] matrix metalloproteases (MMP9) in the release of VEGF from the extracellular matrix (ECM),[9] and VEGF receptor 2 (VEGFR-2) expression on vascular endothelial cells[10] (see succeeding discussion).

Tumor fragments transplanted onto the irises of rabbits were used in a classic model that demonstrated the importance of the angiogenic switch.[11] In some cases, the tumor fragments induced angiogenesis and progressed; in others, they remained clinically dormant. Active proliferation and apoptosis were found at the cellular level in clinically dormant tumors. Similar apparent dormancy has also been described in other conditions in which angiogenesis was inhibited.[12]

The angiogenic switch is required not only for the progression of primary tumors but also for the growth of metastatic deposits. In a mouse model of metastatic disease, removal of the primary tumor induced rapid growth in previously dormant metastatic deposits. An angiogenesis inhibitor produced by the primary tumor

was later identified. The rapid growth of the micrometastasis was accompanied by angiogenesis induction and a concomitant apoptosis reduction, with no change in the proliferative rate.[12] Both activators and inhibitors of angiogenesis are produced in intact organisms, and the balance between them determines the vascularity of the tumor and its metastasis and progression.

**Angiogenesis Evaluation in Human Cancer** In clinical studies, the most useful method for evaluating tumor vascularity is counting microvessel density (MVD) in tumor sections by immunohistochemically staining for one of several molecular markers of endothelial cells, namely factor VIII, von Willebrand factor, CD31, or CD34. Under low magnification, areas of high MVD can be observed, usually at the tumor periphery. The actual MVD is determined in those areas by counting the number of capillaries per high-power field. Various protocols for counting or subjective visual evaluation exist.[13] MVD has been correlated with imaging-determined tumor perfusion[14] and clinical outcome in many tumor types. However, many vessels visualized by immunohistochemical staining may not be functional. CD105 staining was recently suggested to be specific for active blood vessels as opposed to general endothelial markers that stain also nonfunctional vessels.[15] Proliferating endothelial cells can also be assessed by immunohistochemical analysis, because they are a more reliable marker of ongoing angiogenesis than MVD. Double-staining for endothelial-specific proteins and Ki-67 is used to estimate the proportion of proliferating cells; this method was better correlated with stage than counting MVD in colorectal cancer.[16] An important caveat of these methods is the high variability within tumors[17]; thus, sampling errors may be significant. Although highly useful and clinically prognostic in many studies (see later), these methods

provide no information about tumor perfusion, which is the biologically relevant end point of the angiogenic switch. For this, other approaches must be used.

An indirect method of evaluating tumor angiogenesis is the assessment of tumor hypoxia. Carbonic anhydrase IX, a transcriptional target of hypoxia-inducible factor 1 (HIF-1), may be a surrogate marker of tumor hypoxia. High levels are found in hypoxic areas in several cancer types, including NSCLC, and its expression is associated with a poor prognosis.[18] Pimonidazole is an exogenous marker of hypoxia[19] that can be used in immunohistochemical analyses of biopsy samples[20]; however, this method is not commonly used, because it requires pimonidazole to be intravenously infused to patients prior to biopsy. Interestingly, tumor cell necrosis, a plausible indicator of tumor hypoxia, has not been reported to be a prognostic factor in lung cancer. Nuclear medicine allows molecular imaging, including the ability to detect hypoxia. The positron emission tomography tracer 18F-misonidazole[21] and other tracers are being assessed as prognostic or predictive markers in several cancer types. However, such tools require further validation and are not yet available in most cancer centers.

Major inducers and inhibitors of angiogenesis can be used as surrogate markers for angiogenesis in cancer. The levels of VEGF, its receptors, and various endogenous facilitators and inhibitors of angiogenesis can be evaluated in patients' tumor tissues or serum. Importantly, such studies can be performed in large-scale setups and may be useful clinically. Alternatively, immunohistochemical analyses of protein expression in tumors can be performed, but these have the same potential sampling bias of MVD studies.

Additional parameters of angiogenic activity that can be assessed from a blood sample include circulating endothelial cells (CECs) and circulating endothelial progenitor cells (circulating EPC; CEPs). CECs were first reported more than 30 years ago by Hladovec and Rossmann.[22,23] Mature CECs probably originate from cells shed from vessel walls. Some of such cells possess progenitor characteristics and are referred to as CEPs; they are thought to originate from the bone marrow. Both CECs and CEPs may be useful surrogate markers for angiogenic activity and for tumors' response to antiangiogenic treatment.[24] However, the assessment of CECs or CEPs in patients' blood is technically challenging, and no consensus exists about assessment methods or even CEPs' significance (see discussion later).

Tumor perfusion can be assessed in vivo using various imaging studies. Most of these methods are investigational, although promising. Microscopic bubbles can be used as contrast material in sonography studies to demonstrate blood flow in vivo. Computed tomography and magnetic resonance imaging using intravenous contrast material can also be used to measure blood flow and volume. Positron emission tomography nuclear imaging using [11]C- or ^{15}O-marked carbon monoxide can be used for the same purpose. Molecular imaging, in which the contrast material is conjugated to a molecule that binds to a cancer endothelial-specific epitope, is currently being evaluated.[25]

## Angiogenic Switch in Human Cancer

Stepwise progression is evident in several cancer types, and discrete stages can be differentiated in pathologic specimens. For example, breast cancer is preceded by carcinoma in situ, in which vessel density is correlated with several poor prognostic factors.[26] Additional indicators of angiogenic activity, such as messenger RNA (mRNA) expression levels of VEGF and its receptors, were upregulated in breast in situ carcinoma, similar to what was found in invasive breast cancer.[27] Cervical squamous cell intraepithelial neoplasia is the precursor of cervical carcinoma and is graded according to the proportion of dysplasia. Vessel density in the stroma below the basement membrane of the dysplastic epithelium was correlated with the grade of epithelial dysplasia.[28] Evaluation of dysplastic bronchial epithelium, lung premalignant lesions, revealed increased MVD and increased levels of VEGF levels compared with normal controls. A characteristic pattern of VEGFR and VEGF isoform expression comparable to invasive lung cancer was found. Apparently normal lungs of heavy smokers harbored enhanced VEGF mRNA levels.[29] Abnormal microvasculature structure was described to appear near dysplastic squamous bronchial epithelium.[30] The results of these studies suggest that, similar to what was demonstrated in mouse models, human cancer must acquire a vascular supply in order to progress. At least in some types of cancer, including lung cancer, the angiogenic switch occurs prior to the invasive phase of cancer progression.

## Angiogenic Signaling in Response to Hypoperfusion

Oncogene activation and tumor suppressor gene inactivation can activate the angiogenesis switch (see later). However, hypoperfusion is an alternative, and conceptually antagonizing, source of proangiogenic signals. Tumors that outgrow their blood supply experience reduced oxygen and glucose levels. Hypoxic regions are commonly found in several cancer types. These regions may indicate highly dysregulated cell growth; they are associated with a poor prognosis.[31,32] Hypoxia may select for more aggressive tumor cells[33] or activate signaling pathways that lead to increased invasion and metastasis. For example, in NSCLC cells, hypoxia induced in a HIF-1$\alpha$-dependent manner CXCR4 expression.[34] CXCR4 is a cytokine receptor involved in invasion and metastasis.[35] A direct consequence of hypoxia and hypoglycemia is HIF-dependent induction of VEGF expression in malignant cells.[36] VEGF activates an angiogenic response, which results in new blood vessels, improved tumor vascularization, and potentially relief of hypoxia and hypoglycemia. VEGF induction by hypoxia or hypoglycemia involves an apparently normal feedback mechanism, in which reduced perfusion activates a corrective mechanism. Normally, once perfusion has improved, VEGF secretion is reduced.[36] Hypoperfusion-induced signaling is not perpetual, unlike the angiogenic switch. However, newly formed blood vessels of tumors are not as functional as mature vessels of normal tissues: They are only partially covered by pericytes and are highly permeable, torturous, and chaotic.[25] The inefficiency of the newly formed tumor blood supply causes the hypoxia-induced signaling to prevail and paradoxically contributes to cancerous growth.

## CELLULAR PLAYERS AND MECHANISMS IN TUMOR VASCULARIZATION

### Endothelial Sprouting and Pericyte Coverage

Tumor blood vessels form and develop with tumors by several mechanisms, the most studied of which is endothelial sprouting, whereby new capillaries bud from nearby existing ones. Sprouting can proceed through a phase of a vascular network that is superfluous and undergoes pruning, or it can be guided to hypoperfused regions as it is created, mostly by VEGF gradients.[37] The phases of endothelial sprouting have been carefully described.[38] The basement membrane of postcapillary venules is degraded at the location of the future endothelial sprout. Through the resultant opening in the basement membrane, endothelial cells migrate and form a cord of cells; this is followed by the appearance of a lumen. According to another report, the sprouting vessel sustains a lumen and continuous intracellular junctions as it is produced, rather than going through a stage of dedifferentiated cord of cells as commonly thought.[39]

Endothelial cell migration is a major process in angiogenesis. It is regulated by chemotaxis toward VEGF, basic fibroblast growth factor (bFGF), and other angiogenic factors. It is also controlled by haptotaxis, the migration toward a gradient of immobilized ligands, which is dependent on integrin-ECM interactions. Mechanotaxis is the sensing of sheer stress of blood flow by cytoskeletal elements and migration in its direction and is another mechanism that controls endothelial migration.[40,41]

The last phase of the angiogenesis process is the recruitment of pericytes and deposition of new basement membrane.[42] Pericytes of the parent blood vessel proliferate and migrate to envelop the new vessel.[39] The platelet-derived growth factor (PDGF) pathway is the major regulator of pericyte recruitment and maintenance. PDGF-B is secreted mostly by endothelial cells. Acting on PDGF receptor-$\beta$ (PDGFR-$\beta$) on pericytes, it facilitates their recruitment to new blood vessels. Pericytes, in turn, contribute to the stability and functionality of blood vessels, partly through the secretion of VEGF.[43] Importantly, tumor blood vessels that lack pericyte coverage are the first to regress after VEGF pathway inhibition.[44] Tumor blood vessels contain more than one subtype of pericytes, which vary in their molecular marker expression and dependence on PDGF signaling for tight adhesion to endothelial cells.[45]

The origin of tumor vascular pericytes is thought to be mesenchymal progenitor cells,[43] which are characterized by Tie2 expression,[46] or bone marrow–derived hematopoietic stem cells.[47] Some models indicate that endothelial cells and pericytes share a common angioblast progenitor cell.[48] The differences between vascular smooth muscle cells and pericytes are not clear, suggesting that they are similar cell types in different phases of phenotypic change.[3] Regardless of the origin of these cells, the clinical activity of PDGFR inhibition in the treatment of cancer indicates that pericytes are important in the maturation and modulation of tumor angiogenesis[43] (see Fig. 8.1 for a schematic representation of the major cell types and niches that modulate tumor angiogenesis).

### Vasculogenesis: Cells from the Bone Marrow

Vasculogenesis is the de novo formation of blood vessels from vascular progenitor cells. Circulating bone marrow–originating cells travel to specific foci and undergo in situ differentiation

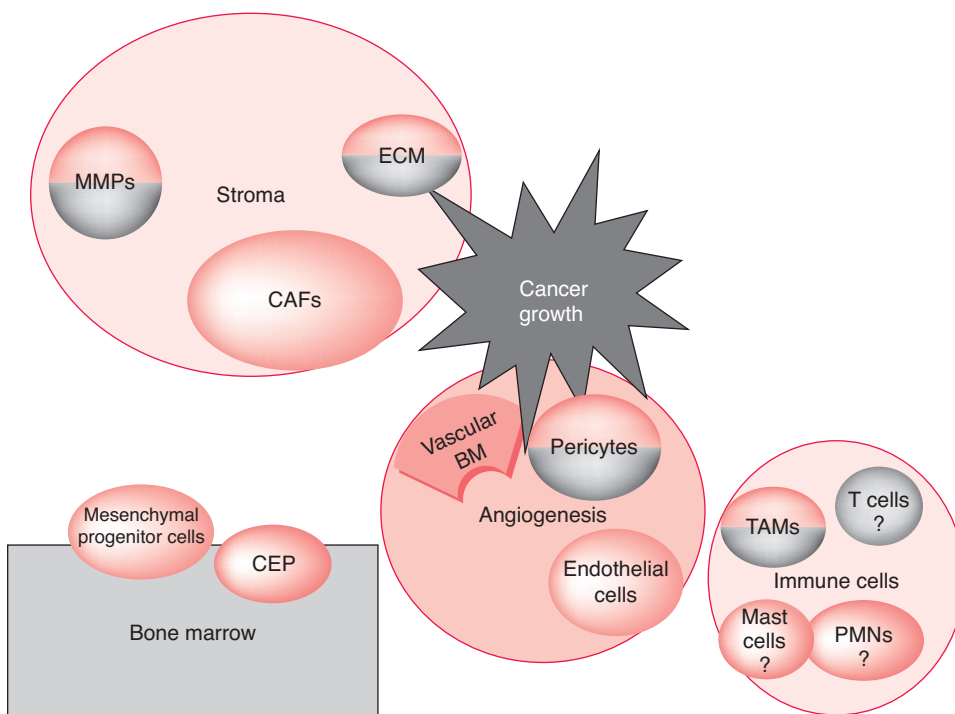

**FIGURE 8.1** The major cell types and niches that play a role in angiogenesis. Red marks factors that positively regulate cancer angiogenesis, blue marks antiangiogenic factors. Half-red and half-black indicates different effects in different circumstances. ? indicates equivocal evidence. *BM*, basement membrane; *CAFs*, Cancer-associated fibroblasts; *CEP*, circulating endothelial progenitor cells; *ECM*, extracellular matrix; *MMPs*, matrix metalloproteases; *PMNs*, polymorphonuclear neutrophils; *TAMs*, tumor-associated macrophages

to form mature components of blood vessels. Vasculogenesis was initially thought to occur only in embryonic tissues, but it has been found to occur in adults as well. Bone marrow–derived endothelial progenitor cells (EPC) were found to be mobilized (thus becoming CEPs) by GM-CSFs or ischemia in experimental animals and travel to areas of ischemia.[49] Studies in which mice underwent bone marrow transplantation from mice that expressed a unique marker demonstrated that bone marrow–derived cells contribute directly to blood vessel formation.[49,50] VEGFR-2 is critical for vasculogenesis in embryos[51] and adult tissues.[52] In addition, increased expression of stromal cell–derived factor-1 (SDF-1, also called CXCL12)-in peripheral blood and ischemic tissues, in parallel to reduced SDF-1/CXCL12 expression in bone marrow, may enhance the recruitment of CEPs to ischemic tissues. SDF-1/CXCL12 enhanced the number of EPC in ischemic vessels by promoting their adhesion through $\alpha 2$, $\alpha 4$, and $\alpha 5$ integrins to fibronectin and collagen I.[53] CEPs have also been found in patients, in numbers that were correlated with plasma levels of VEGF 165.[54]

CEPs were also shown to contribute to the formation of blood vessels in cancer. Id knockout mice display defective angiogenesis, not allowing them to support the growth of implanted tumors.[55] This phenotype was saved by transplantation with wild-type bone marrow. Donor-derived, VEGFR-2-positive CEPs formed most of the tumor blood vessels in this model. Donor-derived, VEGFR-1-positive myeloid precursors were also recruited to the tumors, where they were thought to have secreted angiogenic cytokines.[52] The role of inflammatory cells in angiogenesis will be discussed later. The expression of the transcription factor Id1 in CEPs was essential for their contribution to lung metastasis in another mouse model.[56] Systemic 17-$\beta$ estradiol administration contributed to the recruitment of CEPs to tumors in a mouse model of breast cancer.[57] Blood counts of CEPs may be a promising surrogate marker for angiogenesis or vasculogenesis, possibly useful in the real-time assessment of the efficiency of treatment targeting tumor blood vessels.[24] For example, vascular-disrupting agents induced a surge in the CEP blood concentration in a mouse cancer model. Treatment with anti-VEGFR-2 antibody disrupted this surge and augmented the efficacy of cancer eradication. Blocking the CEP surge prevented the regrowth of tumor from the rim of viable cells that typically remain when most of the tumor necrotizes.[58] Cancer-associated fibroblasts (CAFs), a prominent component of the stromal reaction to cancer, contributed to the recruitment of CEPs.[59] SDF-1/CXCL12 release by CAFs is critical to this recruitment.[59] CEPs were found in the blood of cancer patients and were demonstrated to respond to effective systemic therapy.[60] Therefore, bone marrow–derived EPCs may be one of the important manners by which tumors develop their vascular supply.

The importance of EPCs is controversial, spurring disputes in the scientific literature.[61,62] Estimations of their contributions to tumor endothelium vary from significant (10% to 50%) to negligible.[24,63] Studies finding no evidence of EPC contribution to tumor endothelium were also reported.[61] A plausible

explanation for this variability was suggested when time-dependent changes in EPC contribution were evaluated. Using high-resolution microscopy, aided by flow cytometry, bone marrow–originating cells can be located in inoculated tumors in mice that have undergone bone marrow transplantations of GFP-positive cells. In this model, the proportion of EPCs among endothelial cells was about 30% in the first 4 to 6 days of tumor growth but dropped to less than 1% after 4 weeks. This study also demonstrated bone marrow–derived cells close to endothelial cells, suggesting that they are a source of EPC overestimation in tumor vessels.[64] A study of cancers that developed in bone marrow transplant recipients that are gender mismatched with their donor revealed that about 5% of their tumor endothelial cells are donor-originated.[63] Importantly, almost all of the CEC that had a significant proliferative capacity, were donor-originated.[65] This study suggests that even very low numbers of EPC might contribute significantly to tumor vasculature.

The evaluation of CEPs in blood samples of cancer patients is hampered by the low numbers of these cells in circulation and the technical difficulties of their positive identification. Identification methods include enrichment by cell sorting and immunomagnetic beads. However, these methods depend on specific surface markers, which are lacking. For example, CD146 may be a specific marker of CEPs or CECs and may be measurable in the serum of cancer patients. CD146 mRNA levels in serum were correlated with CECs in breast cancer patients.[66] However, a fluorescence-activated cell sorting analysis of blood mononuclear cells demonstrated that CD146 was expressed mainly on a subpopulation of T cells.[67] Recently, tumor endothelial marker 1/endosialin/CD248 was reported to be highly expressed in CEPs, suggesting a new method of measuring or potentially eradicating blood CEPs.[68] An important property of CEPs that may be useful in their identification is their ability to proliferate, but this would not differentiate CEPs from hematopoietic progenitor cells. The technical difficulties of detecting a minute subpopulation of cells in the blood have not been satisfactorily solved.[24] The results of studies of CEPs and CECs in the blood of cancer patients must be interpreted cautiously.

## Alternative Mechanisms of Enhanced Vascularization

In vessel co-option, tumors or metastatic foci develop along existing blood vessels. In this way, tumors become vascularized with no need for blood vessel formation.[69] Vessel co-option occurs in the initial growth phase of tumors. As cancer cells proliferate, the tumor outgrows its blood supply. The co-opted host blood vessels then undergo regression, possibly as a host defense mechanism. The endothelial cells of these vessels are detached from their supporting cells, at which point they undergo apoptosis. Angiopoietin 2 (Ang-2) expression is induced in the co-opted vessels prior to their regression. Ang-2 is involved in physiologic vessel remodeling in a VEGF-dependent manner (see succeeding discussion). Co-option of existing vessels may be an important method for obtaining a vascular supply in early tumors. Its extent is controlled by the local production of VEGF, Ang-1, and Ang-2.

Intussusceptive microvascular growth, the longitudinal separation of existing vessels into daughter vessels, is another mechanism of enhancing blood supply to tumors. In this way, the network's complexity and efficiency improves, with no need for endothelial cell proliferation.

Vasculogenic mimicry, which has been observed mostly in melanomas, is the ability of cancer cells to transform into endothelial-like cells in specific sites, thus forming blood vessels made of cancer cells.[38] The importance of these alternative mechanisms of vascular supply in cancer growth is not known.

## Role of Immune System Cells in Angiogenesis

The stroma of cancer is infiltrated by immune system cells in varying proportions. The role of the immune system in the progression of cancer is not obvious but seems to be context dependent. The immune system has a cancer-inhibitory effect, as evidenced by the high risk of cancer in immunocompromised patients. In addition, a correlation was found between increased effector memory T-cell infiltration of the tumor and a good prognosis in colon cancer patients.[70] However, in many other settings, the immune system apparently contributes to cancer progression. The adaptive immune system can mount an antitumor response in some conditions. In contrast, innate immune system cells may be more commonly recruited by cancer cells and function in a pro-cancer manner.[71] Neutrophilic infiltration of tumors is common, but its clinical significance is not clear. In bronchoalveolar carcinoma, it has been associated with a poor prognosis,[72] but data on its importance in other cancers are limited. Lung cancer–infiltrating lymphocytes exert an anticancerous effect, as in colon cancer. High densities of CD4$^+$ and CD8$^+$ lymphocytes in the stroma of NSCLC tumors have been found to be associated with a good prognosis.[73,74]

Monocytes circulate in the blood; once recruited to sites of tissue inflammation, they differentiate into macrophages. Various chemoattractants play a role in the chemotaxis of monocytes into tumors, possibly mostly to hypoxic areas of tumors.[75] Macrophages constitute a major subset of the immune system cells that populate the tumor stroma: tumor-associated macrophages (TAMs). TAMs seem to promote the progression of cancer.[76] Unlike classically activated macrophages (M1 macrophages), TAMs have a poor antigen-presenting ability and produce factors that suppress T-cell proliferation and activity. The chemokines and chemokine receptors profile they express is adapted for scavenging for debris, promoting cell migration and angiogenesis, and repairing and remodeling wounded or damaged tissues. Cancer microenvironment exposure to interleukin (IL)-4 and IL-10 can induce monocytes to develop into TAMs (otherwise known as polarized type II [alternatively activated] or M2 macrophages).[77] Proangiogenic monocytes that localize in tumors are also characterized as Tie-2 expressors.[46] Macrophage infiltration was found to be associated with vessel density in several types of cancer. In a mouse model of breast cancer, depletion of macrophages inhibited the angiogenic switch and cancer progression. Increased macrophage infiltration was correlated with earlier tumor progression.[78]

IL-1$\beta$ is a proangiogenic cytokine that depends on macrophage recruitment to tumor sites for its angiogenic effect.[79] MMP9 release by macrophages, leading to mobilization of VEGF,[80] is a mechanism in which the infiltration of macrophages or other myelomonocytes[81] induces angiogenesis. In addition, IL-8/CXCL8, another proangiogenic factor, was upregulated in both cancer cells and macrophages when these two cell types were cultured together, and IL-8/CXCL8 mRNA levels in lung cancer specimens were correlated with MVD and poor patient prognosis.[82] Relating an angiogenic response to inflammation, which is common in cancer, IL-1$\alpha$ was shown to recruit VEGF-expressing inflammatory cells. VEGFR-2 blockage prevented this angiogenic response.[83] Regardless of the available data on the contribution of macrophages to angiogenesis, tumor islet infiltration by macrophages was a good prognostic factor in a study of 175 NSCLC patients. On the other hand, stromal macrophage infiltration was associated with a poor prognosis.[84] These results were reproduced in a study of 199 NSCLC patients.[85] Importantly, the studies that showed a positive prognostic effect of macrophages in lung tumors differed from earlier studies by differentiating between stromal and tumoral macrophages.

Natural killer (NK) cells are another part of the innate immune system that have important interactions with cancer and cancer-induced angiogenesis. NK cells recognize and lyse cancer cells and are thought to have important roles in immune surveillance against cancer. IL-12 is an antiangiogenic agent that depends on NK cell recruitment to affect cancer angiogenesis.[86] NK cells secrete interferon-$\gamma$, causing inhibition of endothelial cell proliferation; this is probably the major mechanism of NK cells' antiangiogenic effects.[87]

Mast cells were found to be essential for tumor progression in a mouse model of squamous cell carcinoma and were required for neoangiogenesis.[88] Mast cell infiltration was correlated with MVD in a study of NSCLC specimens.[89] However, mast cell tumor infiltration was associated with a good prognosis in NSCLC specimens.[84] More detailed studies of the role of mast cells in lung cancer are required. In light of the inhibitory effect of most anticancer treatments on the immune system, further insight is required into the effect of immune system cells on angiogenesis and cancer progression.

**Tumor Stroma–Dependent Effects** The stroma of tumors is more than a mechanical scaffold; stromal cells seem to be reprogrammed by cancer cells to participate in cancer progression. A mouse model demonstrated activation of the VEGF gene promoter in tumor stroma fibroblasts.[90] CAFs also contribute to cancer progression,[91] apparently by activating angiogenesis. Activation of hepatocyte growth factor (HGF)–c-Met signaling is another role of the stroma in tumor angiogenesis (see succeeding discussion).[92]

MMPs are a family of Zn2++ proteases that are produced mostly by stromal fibroblasts and by cancer and endothelial cells. These proteases have important roles in angiogenesis. MMP2 and MMP9, for example, mediate the breakdown of collagen type IV, a major component of the vascular basement membrane. The mobilization of growth factors, including

VEGF[80] and additional angiogenic molecules from the ECM, is another angiogenic activity of MMP. This mobilization may be essential in the initial stages of cancer, becoming less important as the tumor progresses and alternative sources of VEGF become available. MMP9 was also shown to be required for the recruitment of bone marrow–derived cells into the tumor microenvironment, for the maturation of tumor vasculature, and for pericyte coverage.[93] In contrast, at later stages of tumor growth and MMP activity, the dominant end products of MMP protein cleavage are antiangiogenic factors.[94] Although MMPs are correlated with angiogenic activity in lung cancer, general MMPs inhibition did not improve the clinical outcome of NSCLC patients.[95] Modification of specific MMP(s) might be required for impacting clinical end points.

### Vascular Basement Membrane

The ECM that envelops endothelial cells, and within which pericytes are embedded, is called the *vascular basement membrane*. The major collagen that constitutes the basement membrane is collagen IV, which has the unique ability to self-assemble into sheets. Additional components are laminins, which bind cell membrane anchors such as integrins on one side and ECM collagen on the other side. The mature basement membrane signals differentiation and reduced proliferation to adjacent endothelial cells. The same protein constituents, while being deposited as a new basement membrane, present different molecular moieties to the cells around them. Through integrins, they provide proliferation and migration signals. The ECM structural components also include molecular messengers, such as endostatin, that can be proteolytically released from collagen XVIII and functions as an antiangiogenic effector. Arrestin, canstatin, and tumstatin are also collagen-derived antiangiogenic molecules. On the other hand, triple-helix fragments of collagen IV activate endothelial cell migration. Therefore, specific molecules in the ECM/basement membrane can convey different messages at different phases of tumor growth. Deposited by the resident cells, the ECM/basement membrane is an important manner of cell–cell indirect communication. This adds another level of complexity to the cellular events occurring in the process of new blood vessel formation.

## IN VITRO ASSAYS OF ANGIOGENIC AND ANTIANGIOGENIC FACTORS

The search for proangiogenic and antiangiogenic molecules has been made possible by methods that enable the measurement of angiogenesis activity. Unlike cell proliferation or death, which can be easily evaluated in convenient in vitro assays, angiogenesis involves complex interactions between endothelial cells and their surroundings. Because of this, angiogenesis measurements are subject to substantial assay-dependent biases. Several angiogenesis bioassays that represent various in vivo phases of angiogenesis have been developed. The assays used most often are those of endothelial cell proliferation and migration, two biologic events that are critical to the formation of new blood vessels. Proliferation is evaluated by measuring cell number changes, cell cycle alterations, or DNA incorporation, whereas migration assays usually involve scoring cells that migrate across a porous membrane toward a putative chemoattractant (Boyden chamber assay).

Additional assays include the tube formation assay, aortic ring assay, and chick-embryo chorioallantoic-membrane bioassay. The tube formation assay involves visualizing tubelike structures that form when endothelial cells are cultured on an artificial ECM, and the aortic ring assay evaluates similar structures that grow from a slice of rat aorta in culture. The chick-embryo chorioallantoic-membrane bioassay uses the vascular structures in a fertilized chick egg, either in uvo or in vitro.[96] The rabbit cornea implant assay involves placing a pellet of sustained-release polymers in a normally avascular cornea and examining the evolving blood vessels.[97] The matrigel-plug assay is a simpler version of the cornea implant assay. It involves the subcutaneous injection of a matrigel plug into a mouse and evaluation of its vascularization. None of these assays is flawless; thus, caution must be exercised when interpreting results from a single type of angiogenesis assay.

## MAJOR MOLECULAR PLAYERS

### VEGF Signal Transduction Pathway

**VEGF Family Members** VEGF, also called VEGF-A, increases endothelial permeability[98]; therefore, it was initially named vascular permeability factor. This protein was found to function as a mitogenic and survival factor, specific to endothelial cells.[99] VEGF is a heparin-binding glycoprotein with at least five family members, VEGF-A to -D and placental growth factor (PlGF). VEGF binds mostly Flt-1(fms-like tyrosine kinase-1)/VEGFR-1 and Flk-1(fetal liver kinase-1)/VEGFR-2/KDR (kinase domain region), parts of a family of tyrosine kinase receptors. VEGFR-1 and -2 are mainly expressed by vascular endothelial cells[100] but are also expressed by monocytes,[101] hematopoietic stem cells,[102] and some cancer cells.[103] VEGFR-2 is a major positive regulator of the vascular system. Its ligands are VEGF, VEGF-D, and VEGF-C. It activates the proliferation and migration of endothelial cells and acts as a survival factor for these cells. The role of VEGFR-1 in angiogenesis is less clear, demonstrating a higher binding affinity of VEGF than for VEGFR-2 but lower kinase activity and no mitogenic response. Mice manipulated not to express VEGFR-1 have an abnormal vascular system because of an increased number of hemangioblasts.[104] Interestingly, mice expressing a VEGFR-1 that lacks the kinase domain developed normally, suggesting that this protein functions as a negative regulator of the VEGF pathway by trapping ligand molecules.[105] The ligands of VEGFR-1 include VEGF, VEGF-B, and PlGF. The differences between VEGFR-1 and VEGFR-2 lie mostly in the intra-cellular C-terminal domain of these receptors.[106] VEGF-C and VEGF-D mainly regulate lymph vessel formation through activation of VEGFR-3,[107] although VEGFR-3

activity seems to be required also for blood vessel angiogenesis.[108] Interestingly, LKB-1, a serine/threonine kinase that is mutated in almost a third of lung cancers, was found to repress VEGF-C, among other targets[109] (see Fig. 8.2 for a scheme of the VEGF pathway).

The induction of VEGF production can result from various signals. Physiologically, it is controlled by the HIF-1 pathway in response to hypoxia. Mitogenic signals, including phosphatidylinositol 3-kinase (PI3K) and Ras, also increase VEGF mRNA levels.[110,111] Various isoforms of protein kinase C (PKC) have also been shown to induce VEGF.[112] EGFR inhibition reduced VEGF levels in a HIF-1–dependent and in a HIF-1–independent manner.[113] In addition, activated oncogenes and deregulated tumor suppressor genes contribute to VEGF's activation in tumors. Src kinase was found to be induced by hypoxia and to activate the VEGF promoter.[114,115] Wild-type p53 suppressed VEGF promoter activity, whereas mutant p53 had no effect or activated it.[115,116] HIF-1$\alpha$ degradation induced by p53 was also demonstrated, secondary to p53-dependent activation of Mdm2.[117]

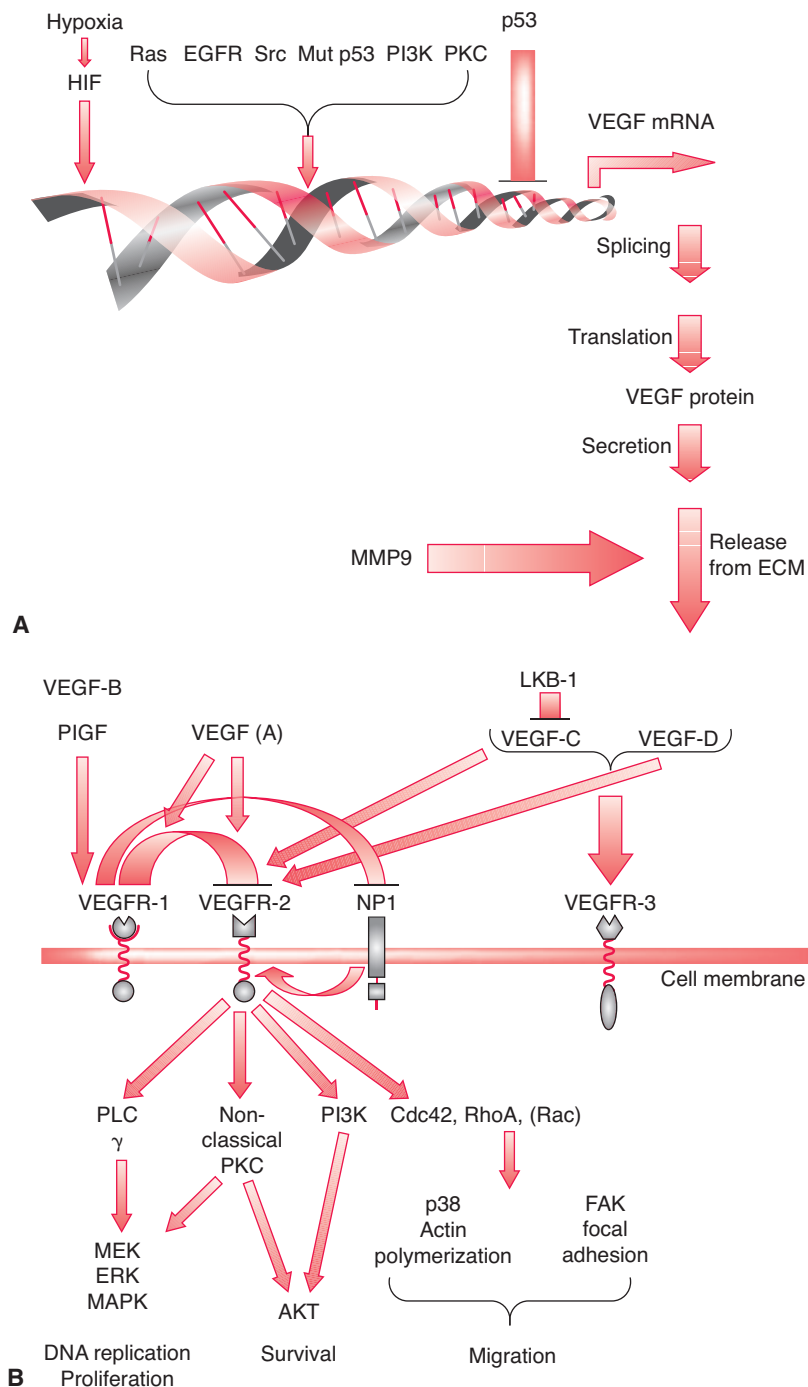

**FIGURE 8.2** **A:** Control of VEGF transcription and posttranscriptional control. **B:** Major signaling activated by the VEGF pathway. For simplicity, only the major interactions and pathways are delineated. *AKT*, AKT8 virus oncogene homologue; *Cdc*, cell division control protein; *ECM*, extracellular matrix; *EGFR*, epidermal growth factor receptor; *ERK*, extracellular signal regulated kinase; *FAK*, focal adhesion kinase; *HIF*, hypoxia-inducible factor; *MAPK*, mitogen acturated protein kinase; *MEK*, MAPK/Erk kinase; *MMP9*, matrix metallopeptidase 9; *mRN*A, microRNA; *Mut*, methylmalonyl Coenzyme A mutase; *NP1*, Neuropilin1; *PI3K*, phosphatidylinositol 3 kinase; *PIGF*, placental growth factor; *PKC*, protein kinase C; *PLC*, phospholipase C; *RhoA*, ras homolog gene family, member A; *Src*, rous sarcoma oncogene cellular; *VEGF*, vascular endothelial growth factor.

VEGF receptors are activated by receptor dimerization induced by binding of the ligand dimer. This dimerization allows cross-phosphorylation of specific tyrosine residues of the receptors, creating docking sites for adapter molecules. The phosphorylation map and site-specific adapter proteins of VEGFR-2 have been delineated.[118] Various signaling pathways are activated downstream of VEGF receptors. VEGFR-2 is a survival factor for endothelial cells through PI3K and AKT.[119] VEGFR-2 also activates phospholyphase Cγ (PLCγ), which is not activated by VEGFR-1, EGF, or FGF. Signaling through VEGFR-2 independently activated phospholyphase Cγ, PKCε, and PI3K.[120] VEGFR-2 activates mitogen-activated protein kinase (MAPK) through mitogen-activated protein kinase kinase (MEK) and phospholyphase Cγ. Blockage of PKC reduced DNA replication induced by VEGF but had no effect on DNA replication induced by FGF or EGF.[120] Therefore, the signaling pathways used by VEGFR-2 are different from those used by other mitogens, although the end points of these cascades overlap. The MEK-ERK, PKC, and PI3K control DNA replication, cell proliferation, and survival signals in response to VEGF.

Some modulation of the VEGF pathway occurs through regulation of the receptor. For example, vascular endothelial (VE)-cadherin, a cell–cell adhesion molecule that is specifically expressed by endothelial cells, modulates signaling relayed by VEGFR-2. By blocking the internalization of this receptor, VE-cadherin inhibits its downstream signaling in confluent endothelial cells.[121] Downregulation of VEGFR-2 may occur in a PKC-regulated manner.[122] Another important modulator of VEGF receptor activity is neuropilin-1, a coreceptor of VEGF, originally recognized as a semophorin coreceptor that participates in neuronal guidance. Neuropilin-1 enhances the activation of VEGFR-2 by VEGF and the mitogenic and chemotactic response it evokes. It functions in an isoform-specific manner, binding VEGF165 but not VEGF121 (see below).[123] VEGFR-1 can also bind neuropilin-1, possibly as a negative regulator of its activity.[124] Neuropilin-1 is expressed by endothelial cells and cancer cells and contributes to their migration and in vivo progression. Neuropilin-1 mRNA levels were measured in the tumors of 60 NSCLC patients and were found to be an independent negative prognostic factor.[125]

New blood vessel formation requires endothelial cell migration, a biologic phenomena that involves complex modifications of cell–cell and cell–matrix adhesions. VEGF activates actin cytoskeleton remodeling and motility. These phenomena are mediated through VEGFR-2 and various adapter proteins, including src family kinase proteins such as Fyn and the small GTPases Cdc42, RhoA, and Rac-1. SAPK2/p38 activation modulates actin fiber polymerization, and focal adhesion kinase controls the formation of focal adhesion.[126,127] These molecular events are critical for the motility and migration of endothelial cells in response to VEGF signaling.

VEGF signaling apparently affects not only the cells that surround the tumor but also distant tissues. Activation of VEGFR-1 in the lungs of mice, in a premetastatic phase, was required for the induction of MMP9. This induction was evident only in the lungs of tumor-bearing mice; thus, it was the result of a tumor-originated influence. Lung endothelial cells and lung macrophages had elevated MMP9 levels in tumor-bearing mice, and this increase was essential for the formation of lung metastasis.[128] VEGFR-1 bearing hematopoietic progenitor cells localized to a premetastatic niche and were followed by metastasis formation in another mouse model.[129]

Five isoforms of VEGF are expressed by human cells, all of which are produced from the same VEGF gene through alternative splicing. These isoforms are named VEGF121, VEGF145, VEGF165, VEGF189, and VEGF206, according to the number of amino acids of the produced protein.[130] VEGF121 is the only isoform that does not bind heparin and is thus freely diffusible. The other four isoforms bind heparin; the two shortest, VEGF145 and VEGF165, are also secreted. VEGF145 binds ECM in a heparin-independent manner.[131] VEGF189 and VEGF206 are basic large proteins that are associated with the cell surface through their high affinity to proteoglycans or bound to the ECM, where they can activate VEGF signaling and be released to a soluble form.[132] Interestingly, VEGF189 was found to be prognostically important in NSCLC,[133] whereas VEGF165 had prognostic implications in osteosarcoma patients.[134] Thus, the various isoforms of VEGF exert different biologic activities in different tissues.

The RIP-Tag mice model offers insight into the activation of the VEGF pathway during the angiogenic switch. Targeted knockout of VEGF or inhibition of VEGFR-2 by small molecule inhibitors in the RIP-Tag mice, reduced tumor initiation and progression, demonstrating the critical role of this molecule.[8] Progression of carcinomas in this model was accompanied by an increased release of VEGF from the tumor mass and increased binding of the ligand to VEGFR-2. Interestingly, no increase in the expression of this protein or its receptors was found. MMP9 expression was found to be increased in stromal cells in progressing tumors. It was shown to increase the release of ECM-bound VEGF and thus its ability to activate the receptor.[9] Therefore, nontumorigenic cells in the tumor stroma can control the angiogenic switch by producing MMP and modulating the release of VEGF from the ECM.

**Angiopoietins and Tie Receptors** Angiopoietins are a family of angiogenesis modulators composed of four ligands that bind the Tie-2 tyrosine kinase receptor. Ang-1 and Ang-4 function mostly as positive regulators, whereas Ang-2 and Ang-3 are mostly antiangiogenic. However, these roles are context dependent. Knockout Ang-1 mice do not form a normal vascular network in utero, at least partly because of reduced pericyte coverage. Ang-2 overexpression has a similar phenotype to that of Ang-1 knockout, indicating that Ang-2 has an antagonistic role in Tie-2 activity. Ang-2 antagonizes the Ang-1-dependent recruitment of pericytes to new blood vessels, thus preventing their stabilization. However, Ang-2 knockout mice have defects in adult vascular sprouting. This

finding suggests that destabilization of the vessel structure is needed for angiogenesis to progress. Ang-2 seems to have a proangiogenic role when VEGF is abundant but an antiangiogenic role when VEGF levels are low.[135] The Tie-2 receptor is expressed by endothelial cells and by pericytes and smooth muscle cells. Its expression by blood monocytes might be important for their recruitment to tumor tissues.[136] Importantly, Ang-2 expression has negative prognostic implications in lung cancer patients, especially when VEGF expression is high[137] (see succeeding discussion). Ang-2 and Tie-2 apparently regulate the survival of vessels co-opted by cancer[138] (see previous discussion). Interestingly, Ang-1 has a negative role in tumor angiogenesis, probably secondary to enhanced pericyte vessel coverage and reduced vessel permeability.[139] The resultant vessels do not allow extravasation of plasma proteins and a less proangiogenic environment is formed.

### Unexpected Outcomes of VEGF Inhibition

In studies in which the VEGF pathway was effectively attenuated, rebound angiogenesis was observed despite persistent inhibition of the VEGF pathway. Alternative angiogenic mechanisms were upregulated when the VEGF pathway was suppressed, including induction of FGF family members, angiopoietins, and vessel co-option.[10] The activation of additional proangiogenic pathways may be triggered by hypoxia in tumors subjected to VEGF inhibition. However, increased levels of some of these factors persist when no hypoxia is apparent. Therefore, pathologic angiogenesis is controlled by various signaling pathways that may be important therapeutic targets.[97]

The other important finding in models of VEGF-dependent tumor growth treated with VEGF inhibitors is increased invasiveness of tumors that thrive in these conditions.[9,10] This phenomenon could be secondary to hypoxia-induced activation of the HGF-Met pathway,[140] urokinase-type plasminogen activator,[141] or other survival pathways. Hypoxia may select for tumor cells with increased aggressiveness, such as through loss of p53[142,143] or other genetic events.[144] As VEGF pathway inhibition is assayed as a cancer therapeutic strategy, further understanding about cancer escape mechanisms is needed.

### HIF

HIF-1 is the major transcription factor that regulates the response of tissues to oxygen deprivation.[145] It is expressed ubiquitously in humans, where it upregulates erythropoiesis and blood vessel formation and controls metabolic pathways. HIF-1$\alpha$ subunits are tightly regulated by hypoxia through control of their degradation, in addition to hypoxia-independent regulation by growth factor signaling.[146] Under normoxia, they are marked for degradation via the 26S proteosome by its E3-ubiquitin ligase von Hippel-Lindau (VHL), a tumor suppressor gene.[147] Oxygen levels are sensed by prolyl hydroxylase, an enzyme that hydroxylates specific prolyl residues of HIF-1$\alpha$ when oxygen is available. This modified domain of HIF-1$\alpha$ is the binding site of VHL, which activates its rapid degradation. Lack of oxygen thus prevents VHL-dependent degradation of HIF-1$\alpha$, causing an accumulation of this protein.[148,149]

HIF-1$\beta$ is expressed constitutively, forming a heterodimer with a HIF $\alpha$ subunit, thus activating more than 70 genes whose products carry out the complex regulation mastered by HIF-1. HIF-1$\alpha$ and HIF-2$\alpha$ are the products of two different genes, regulated similarly by hypoxia, both of which can heterodimerize with HIF-1$\beta$ and activate each a distinct set of genes.[150] Both $\alpha$ subunits are produced by various cell types, including endothelial cells.[151,152] The relative contributions of HIF-1 or -2$\alpha$ differ under different conditions.[153] HIF-1$\alpha$ expression by tumor cells was found to contribute to tumor progression.[154] HIF-2$\alpha$ is highly expressed in tumor-infiltrating macrophages, and this expression was correlated with tumor angiogenesis in a series of breast carcinomas.[155] Thus, HIF-2$\alpha$ may participate in the contribution of the tumor microenvironment to tumor vascularity.[152] In addition, the role of HIF-3$\alpha$ has yet to be defined. A splice variant of HIF-3$\alpha$ was found to antagonize the transactivation of hypoxia-inducible genes by HIF.[156]

### Endogenous Antiangiogenic Factors

Some antiangiogenic factors are produced by cleavage of larger proteins. For example, angiostatin, a potent angiogenesis inhibitor, is the cleavage product of plasminogen, a component of the coagulation control mechanism.[157] Macrophage-derived methalloelastase is thought to be responsible for the in vivo conversion of plasminogen to angiostatin.[158] Thus, tumor-infiltrating macrophages may determine the production of antiangiogenic factors. In addition, cancer cells may secrete enzymes that can produce angiostatin.[159] The conversion of plasminogen to the proangiogenic plasmin is essential for the production of angiostatin.[159] Angiostatin's mechanism of action might be through inhibition of plasmin production.[160] This cross-talk between an angiogenic molecule and an antiangiogenic factor is consistent with the continuous balancing mechanisms between these effects.

Endostatin is an antiangiogenic factor that was shown to be generated by tumor cell lines. A biochemical analysis indicated that it is a fragment of collagen XVIII.[161] Recently, $\alpha$(II) collagen prolyl-4-hydroxylase [$\alpha$(II)PH] was found to catalyze a rate-limiting step in collagen synthesis that is apparently required in endostatin production. Importantly, $\alpha$(II)PH was found to be a direct transcriptional target of p53, a well-recognized tumor suppressor gene, in tumor cells. p53 expression was found to increase the expression of $\alpha$(II)PH, leading to enhanced endostatin production. By an apparently similar mechanism, p53 led to the production of tumstatin from collagen IV.[143] Thrombospondin-1 is another antiangiogenic molecule induced by p53, through transcriptional activation.[33] Thrombospondin-1 secretion decreases with malignant progression,[162] possibly a reflection of the common loss of p53 transcriptional activity in tumor cells. Endostatin and tumstatin function through binding of integrins and modulating various signaling pathways,[163,164] whereas the mechanism of action of thrombosponsdin-1 involves inhibition of MMP9 activation[165] and activating endothelial cell apoptosis through CD36.[166]

Additional potent antiangiogenic factors are produced by the cleavage of common proteins,[167] suggesting a paradigm. C-terminal fragments of various collagens are cryptic antiangiogenic agents, becoming active once released from the parent collagen.[168] The control of angiogenesis seems to require reserves of antiangiogenic factors available for rapid mobilization.

**PDGF**  Platelet-derived growth factor beta polypeptide (PDGF-BB) and PDGF-$\beta$ receptor are the major molecules involved in regulating the pericytes perivascular envelope.[169,170] PDGF-B is secreted by tumor endothelial cells, and tumor cells in some cases, and forms the active dimer of PDGF-BB. PDGF-$\beta$ receptor is expressed mainly by pericytes, although it has also been found on tumor endothelial cells. The activation of the PDGF-$\beta$ receptor results in the recruitment of pericytes to the developing tumor vessel, as in physiologic angiogenesis.[171] Pericytes have a supportive and modulating role in the evolving vessel. Abnormal pericyte coverage in PDGF-B null mice resulted in vessel dilatation, leakage, aneurism formation, and hemorrhage in late gestation.[172] Interestingly, the retention of PDGF-B on the surface of the secreting cell is important for correct pericyte deposition, at least during embryonic development. Local retention of growth factors is a mechanism whereby extracellular matrix and proteases affect biologic phenomena. The retention of PDGF-B is mediated by its C-terminal motif of positively charged amino acids, which bind negatively charged heparan sulphate proteoglycans.[173] Blood vessels of tumors inoculated into mice that expressed an ECM retention-defective mutant PDGF-B had defects in pericyte coverage. PDGF-B expression by tumor cells only partially compensated for this defect, suggesting that PDGF-B must be expressed by endothelial cells[174] to facilitate the correct homing of pericytes to blood vessels.

**bFGF**  bFGF is a potent angiogenic factor that stimulates the proliferation and migration of endothelial cells as well as the production of MMPs. However, unlike VEGF, bFGF affects various cell types, including endothelial cells, smooth muscle cells, fibroblasts, and epithelial cells.[175,176] bFGF can be found in high levels in some low-proliferation tissues, indicating tight control of its activity after its production. bFGF is at least partly regulated by its extracellular export.[177,178] In addition, binding of the FGF receptor by bFGF requires the presence of an ECM/basement membrane proteoglycan such as perlecan.[179] Capillary endothelial cells express and secrete bFGF and thus induce their own proliferation and migration.[180] bFGF signaling cross-talks with additional angiogenic pathways. Hypoxic induction of HIF-1$\alpha$ in endothelial cells is bFGF dependent.[181] bFGF signaling has been shown to activate transcription of the PDGF receptor, whereas PDGF-BB amplified bFGF receptor expression.[182] bFGF has a major role in angiogenesis, but its involvement in many other pathologic and normal processes makes it a problematic therapeutic target.

The overexpression of FGF-10 in respiratory epithelial lung cells in mice induced multifocal pulmonary adenomas within 1 to 4 weeks. Interestingly, all these tumors regressed shortly after withdrawal of the transgene-activating agent, indicating that no irreversible carcinogenic change occurred and that the tumors were dependent on FGF-10 expression. Angiogenesis measures were not reported for this model, but given the importance of the FGF pathway in tumor angiogenesis, an angiogenic switch was plausibly involved.[183]

**Chemokines**  Chemokines are small (8–10 kDa) proteins that regulate mainly leukocyte trafficking. Various chemokines also influence angiogenesis, both negatively and positively. The C-X-C chemokine family can be divided to two subfamilies. Those that contain a Glu-Leu-Arg motif at the NH3-terminus (ELR+), activate the CXCR2 receptor, and are mostly angiogenic. CXC chemokines that lack this motif (ELR−), act through CXCR3 and are angiostatic. Platelet factor-4 (PF-4, also called CXCL4) is an example of an ELR− chemokine, which is a strong inhibitor of angiogenesis. A variant of PF-4/CXCL4 exists, which is a stronger inhibitor of angiogenesis than PF-4/CXCL4.[184] IL-8/CXCL8 is an ELR+ chemokine and is indeed a potent angiogenic factor.[82] SDF-1/CXCL12 is an exception to the aforementioned rule, being an ELR− chemokine, but activating the CXCR4 receptor, and thought to have an angiogenic effect.[185] In a mouse model of lung cancer, inhibition of SDF1/CXCL12 abrogated metastasis formation but did not affect angiogenesis,[35] suggesting it might not have a major angiogenic role in lung cancer. The C-X-C chemokines act through the activation of G-protein–coupled serpentine (seven-transmembrane spanning) receptors.

**Cell–Cell Adhesion Molecules**  The various cellular events that occur during the formation of new blood vessels involve interactions among endothelial cells, pericytes, smooth muscle cells, inflammatory cells, and epithelial cells that are governed mainly by cell–cell adhesion molecules. Several of these molecules have a role in modulating angiogenesis.

Platelet endothelial cell–cell adhesion molecule-1 (PECAM-1 or CD31) is commonly used as a marker of endothelial cells in immunohistochemical studies.[186] Binding of this molecule by an inhibitory antibody suppresses angiogenic activity.[187] PECAM-1 is expressed also by platelets and inflammatory cells. It plays a role in leukocyte migration, and is involved in several signaling pathways.[186] PECAM-1 might contribute to endothelial cells function. It can also be speculated that the contribution of this molecule to angiogenesis might be through recruitment of inflammatory cells, or through the anchoring of platelets in angiogenic sites. Platelets seem to have an important role in storing and delivering angiogenic and antiangiogenic factors.[97,188]

Intercellular adhesion molecule 2 (ICAM-2), a member of the immunoglobulin superfamily, is a transmembrane protein that is involved in binding various integrins and other molecules. In addition, through homophilic interactions (binding the same protein expressed on another cell), ICAM-2 is involved in endothelial cell survival and migration. It is commonly expressed in endothelial cell–cell junctions[189] and was found in a mouse model to be involved in angiogenesis. Mice that did not express this protein were defective in angiogenesis

in in vivo assays, and endothelial cells from these mice demonstrated defective migration and increased apoptosis.[190] Importantly, plasma ICAM levels were found to be prognostic in a clinical study of lung cancer patients treated with an anti-VEGF antibody (see later).[191]

Cadherins are transmembrane proteins that populate adherence junctions. The extracellular domains of cadherins form calcium-dependent, homophilic transdimers when they bind similar proteins on neighboring cells, mediating cell–cell adhesions. The cytoplasmic tails of cadherins bind to several potential signaling proteins, most notably $\beta$-catenin, a transcriptional cofactor in Wnt signaling. $\beta$-catenin bound to a cadherin intracellular domain participates in cell–cell interactions and does not function as a transcription factor. When cadherin membranous localization is disrupted, $\beta$-catenin is released from the cytoskeleton and can enter the nucleus, where it functions as a transcription factor with oncogenic features. Membranous E-cadherin expression in NSCLC tumor specimens was found to be prognostic.[192–194] Tumors that expressed low levels of membranous E-cadherin were more likely to metastasize to regional lymph nodes, accompanied by reduced survival. It can be speculated that low membranous localization of E-cadherin allows enhanced oncogenic transcriptional activity of $\beta$-catenin, and an angiogenic switch (see succeeding discussion).

**TGF-$\beta$ and EGFR Pathway**  Transforming growth factor (TGF)-$\beta$ is a pleiotropic factor that can have different effects on different cells. It is required for endothelial differentiation[195] and induces angiogenesis in vivo[196]; however, in a different experimental setup, disruption of TGF-$\beta$ signaling induced angiogenesis and tumor formation.[197] TGF-$\beta$ was shown to cause endothelial cell apoptosis, which appears to be essential for angiogenesis.[198]

This apparent correlation between endothelial cell apoptosis and enhanced angiogenesis underscores the complexity of angiogenesis and the potential biases of studies that use endothelial cell proliferation or survival as a surrogate for the in vivo end point. Importantly, TGF-$\beta$ levels in adenocarcinoma NSCLC tumor samples were correlated positively with MVD and negatively with prognosis.[199] Tumor endothelial cell survival involves also the EGFR pathway, demonstrated to depend on EGF secretion by tumor cells.[200] ERK activation downstream of EGFR was found to activate a crosstalk between cancer cells and endothelial cells that promotes angiogenesis.[201] Some prostaglandins (a large group of signal mediators) also induce angiogenesis; the most notable of these is prostaglandin E2. The angiogenic effect of prostaglandin E2 is dependent on TGF-$\beta$ and MMPs.[202]

**Nitric Oxide**  Nitric oxide is a small signaling molecule that is involved in many biologic phenomena. It affects angiogenesis both negatively and positively, depending on its concentration.[203] For example, nitric oxide regulates thrombospondin 1 levels in a triphasic manner.[204] It participates in the biologic response to both angiogenic and antiangiogenic factors, possibly through their effects on nitric oxide synthase.

The nitric oxide synthase 2 isoform was found to be correlated with VEGF levels and MVD in 106 NSCLC tissue specimens.[205] Treatment with nitric oxide donors combined with chemotherapy given to NSCLC patients, improved their outcome in a large randomized phase II trial.[206] The complex and dosage-dependent effects of nitric oxide on various aspects of cancer biology makes it difficult to predict the possible effect it might have had on angiogenesis in those lung cancers.

## ROLE OF ANGIOGENIC SIGNALS IN LUNG CANCER

**Prognostic Markers of Angiogenesis**  MVD is commonly used as an immunohistochemically derived indication of angiogenesis in tumors. MVD was found to be correlated with prognosis in NSCLC in several studies.[207–215] However, MVD has not been found to be correlated with prognosis in other studies.[205,216,217] In one of the larger studies that reported no correlation of MVD with prognosis,[216] MVD was assessed in tissue microarrays, which are comprised of small cores taken from each tumor. The manner in which tumor areas were chosen for the tissue microarray probably differed from those normally chosen for MVD scoring (see previous discussion). This difference might explain the discordant results regarding the prognostic value of MVD. In another study of 106 NSCLC patients,[205] MVD was correlated with clinical disease stage, but not with survival.

MVD, as assessed immunohistochemically with CD105, is suggested to mark only active blood vessels. MVD assessed by CD105 was more strongly correlated with VEGF tumor levels than was MVD assessed by CD34 (panendothelial marker). MVD by CD105 was also more strongly correlated with clinical outcome in a study of 236 NSCLC patients.[15] CD34 apparently marks all blood vessels, including vessels that are not functional. Overall, the evidence suggests that angiogenic activity as assessed by tumor MVD is prognostically important in lung cancer. Fine tuning and standardization of the MVD measurement methods is needed.

Tumor expression of VEGF, as evaluated by immunohistochemical analysis, was found to have a negative prognostic value in NSCLC patients,[216,218–221] although a lack of correlation has also been reported[103] (see Table 8.2 for a summary of the prognostic angiogenic factors in lung cancer). Regarding a different type of lung cancer, small cell lung cancer (SCLC), tumor VEGF expression was also found here to be a poor prognostic factor in a study of 75 surgically resected patients.[222] In another study of SCLC, serum levels of VEGF of 69 patients were found to be associated with poor outcome and poor survival,[223] attesting to the importance of angiogenesis also for this type of lung cancer.

Levels of VEGF (and bFGF) in NSCLC tissue extracts, including both tumor and stromal components, have prognostic implications.[224] Interestingly, VEGF-C expression in stromal cells of NSCLC was found to have a positive prognostic value.[216] Given the important role of the stroma in tumor progression and regression, this finding entails further investigation.

| TABLE 8.2 | Angiogenic Factors and Importance in NSCLC | | | | | |
|---|---|---|---|---|---|---|
| **Angiogenic Factor** | **Poor Prognostic Factor by Immunohistochemical Analysis** (N of Patients in the Study Cited) | **Poor Prognostic Factor by Levels in Tumor Extract** (N of Patients in the Study Cited) | **Poor Prognostic Factor by Blood Levels** (N of Patients in the Study Cited) | **Predictive Value** | **Targeted Therapy** | **Clinically Effective** (N of Patients in the Study Cited) |
| VEGF | Y (105),[209] (109 SCCa),[219] (85, Stg I),[220] (120, Stg I and II)[221]; N (69, Stg I and II)[103] | Y (71)[224] (57, only VEGF189 mRNA isoform)[133] | Equivocal | Y: Plasma levels Predictive of response to bevacizumab[191] | Bevacizumab | Y (878)[5] |
| bFGF | Y[229] | Y (71)[224] | Equivocal[229] | | | |
| PDGF | | | | | Multikinase inhibitors | Phase III trials |
| IL-8/CXCL8 | | Y: mRNA levels[82] | | | | |
| HGF | | Y (53)[244] | | | | |
| VEGFR | Y: VEGFR3 (335)[216] | | Y: mRNA levels of VEGFR2 higher in nonresponders (53)[226] | | Multikinase inhibitors | Phase III trials |
| Ang-2 | Y: only with high VEGF (236)[137] | | | | | |
| PlGF | Y (91)[233] | Y (91)[233] | | | | |
| BNIP | Y (105)[237] | | | | | |
| HIF-1$\alpha$ | Y (172)[238] | N: (54, Stg IIb–III)[239] | | | | |
| Trx-1 | Y (102)[243] | | | | | |
| CEP | | | Y: (CD34$^+$VEGFR2$^+$, FACS)[226] | | | |

FACS, fluorescence-activated cell sorting; N, no; SCCa, squamous cell carcinoma; Stg, stage; Y, yes.

VEGF mRNA levels were investigated in NSCLC tissue specimens and were found to be associated with a grim prognosis.[225] An in-depth study of VEGF splice variants in tumor tissues revealed that the 189 isoform was associated with a poor prognosis in resected NSCLC patients.[133] Other VEGF splice variants were not associated with prognosis in that cohort of patients, suggesting that VEGF levels in tissues studies should differentiate between the various VEGF splice variants.

Serum VEGF levels have been found to be prognostic in some studies[227,228] but not others.[229,230] E4599, a study of 878 NSCLC patients with advanced disease, was retrospectively analyzed to determine the prognostic and predictive significance of VEGF plasma levels. All patients had received carboplatin and paclitaxel, and some were randomly assigned to bevacizumab. VEGF plasma levels were predictive of response to bevacizumab but were not prognostic of survival.[191] Another study evaluated 462 early stage lung cancer patients for polymorphisms in the VEGF gene, and reported them to be prognostically important. The examined polymorphisms are expected to correlate with reduced VEGF serum levels,[231]

but actual serum level evaluations were not available. It can be speculated that VEGF levels within a cancer are important whereas serum levels are modulated by additional mechanisms, irrelevant for tumor biology.

VEGF receptor levels have also been evaluated. One large study evaluated VEGF and VEGFR isoform levels by immunohistochemical analysis in 335 NSCLC patients (stages I to IIIa).[216] These levels were evaluated separately in tumor and adjacent stroma tissue. Although several factors were found to be associated with poor prognosis in univariate analysis, this association was found only for VEGFR-3 tumor expression in multivariate analysis.[216] In another study of NSCLC patients, real-time RT-PCR analysis revealed that VEGFR-2 mRNA blood levels were correlated with response to treatments and with clinical outcome.[226]

Tumor expression of Ang-2, a context-dependent modulator of angiogenesis, was found to have a negative effect on survival in a study of 236 resectable NSCLC patients. This effect was evident only among tumors that expressed high levels of VEGF and was not significant in those with low VEGF

levels.[137] This result is consistent with the known molecular mechanisms involved; Ang-2 positively controls angiogenesis only when VEGF is abundant (see previous discussion).

bFGF is considered an important angiogenesis inducer and prognostic factor in tumors: Its expression in NSCLC tissue is associated with a poor prognosis. However, data on the prognostic value of bFGF blood levels vary.[229]

Interleukin-8 (IL-8, also called CXCL8) was shown to be highly expressed in bronchiogenic lung carcinomas. Its expression in lung cancer cells was significantly induced by coculturing with macrophages. Tumor-infiltrating macrophages and IL-8/CXCL8 mRNA levels in NSCLC tumors were found to be correlated with microvascular density and patient survival.[82] A study of specific neutralizing antibodies demonstrated that IL-8/CXCL8 was responsible for endothelial cell migration and for the angiogenic response elicited by NSCLC tumor extracts in a corneal neovascularization assay.[232]

PlGF, a VEGFR-1 ligand was also found to be correlated with stage in NSCLC. PlGF protein levels (as measured by immunostaining) and gene transcript levels (as measured by RT-PCR) were correlated with poor prognosis.[233] Because VEGFR-1 is a negative regulator of the VEGF pathway, PlGF's correlation with poor prognosis might be through a different pathway. Possibly related is an in vitro study of NSCLC cell lines, where PlGF was found to influence cell motility, through ROCK1, a major regulator of the cytoskeleton.[234]

Aberrant expression of p53, commonly used as an indicator of mutant p53, was correlated with increased mRNA levels of VEGF, IL-8/CXCL8, and MVD and poor prognosis in 65 NSCLC patients.[235] A larger study reported poor prognosis for patients with an aberrant p53 expression, after tumor resection with no further treatment. However, such patients gained significant benefit when given adjuvant chemotherapy.[236] It can be speculated that tumors with an aberrant p53 have higher levels of angiogenic factors in their microenvironment; chemotherapy agents might thus be better delivered to micrometastasis disease.

A transcriptional target of HIF-1, BNIP3, was evaluated in 105 NSCLC patients. BNIP3 is a pro-apoptotic mitochondrial protein that can activate necrosis-like cell death and may be important in the necrotic response to hypoxia in tumors. BNIP3 levels were found to be highly correlated with poor prognosis in patients with resectable disease.[237] HIF-1$\alpha$ protein levels, as assessed by immunohistochemical analysis, were correlated with poor prognosis in 172 NSCLC tumors (stages I to IIIa).[238] On the other hand, HIF-1$\alpha$ mRNA levels, as measured by RT-PCR, were not correlated with clinical outcome in a study of 54 NSCLC patients.[239] Therefore, HIF-1$\alpha$ regulation at a posttranslational level, by VHL-mediated degradation, might be its dominant regulatory mechanism in NSCLC. Regarding another surrogate marker of hypoxia, carbonic anhydrase IX was also found to be associated with poor prognosis in early NSCLC.[18]

A more direct method of quantifying hypoxia in NSCLC is with the use of nuclear medicine tracers. An 18F-misonidazole evaluation of 14 NSCLC patients predicted recurrence after curative radiotherapy in those patients that had evidence of significant tumor hypoxia.[240] Additional hypoxia tracers exist, such as copper-60 derivate ([60]Cu-ATSM), which also has prognostic value in NSCLC.[241]

Trx-1 is a small redox protein that modulates the activity of various enzymes, including DNA binding and transactivation by transcription factors. Trx-1 was shown to increase the protein level and activity of HIF-1$\alpha$ in cancer cells.[242] Interestingly, Trx-1 levels were found to be correlated with lymph node invasion and a poor prognosis in a study of 102 early stage NSCLC patients.[243] Although possibly related to several other pathways, Trx increased levels could have activated the HIF pathway and thus disease progression.

HGF-Met signaling is also implicated in the progression of lung cancer. HGF levels, as quantified in lung tumor tissue, were associated with a poor prognosis.[244] Recently, somatic mutations were discovered in the c-Met receptor of NSCLC specimens. The mutations were concentrated in a region close to a splice junction and led to an alternatively spliced protein. This protein was defective in Cbl-mediated degradation, demonstrating prolonged ligand-induced activation.[245] The HGF-Met pathway affects multiple cellular pathways, including tumor angiogenesis.[92] In many cases, HGF production is enhanced in tumor-associated fibroblasts, demonstrating another tumor-stroma interaction that promotes cancer progression.

Blood levels of CEPs were investigated in 53 patients with various stages and histologic subtypes of NSCLC. CEPs were detected in this study by a flow cytometric CD34$^+$VEGFR2$^+$ analysis. In the multivariate analysis, the CEP count was a statistically significant prognostic marker, whereas surprisingly, disease stage had no prognostic value.[226] The blood mRNA transcript levels of several possible CEPs' molecular markers (CD34, CD-133, and VE-cadherin) were not correlated with prognosis or with the CEP count, whereas high mRNA levels of VEGFR2 were correlated with a lack of response to therapy.[226] Another small study reported the feasibility of magnetic bead separation for CEP identification in lung cancer.[246] The lack of consensus in the field about the importance of CEP and the lack of reliable methods for CEP detection hinder our understanding of their role in lung cancer.

Immune system cell infiltration affects angiogenesis and prognosis in NSCLC. In bronchoalveolar carcinoma pathologic specimens, neutrophil accumulation in the alveolar lumen was associated with a poor prognosis. Neutrophil count was correlated with IL-8/CXCL8 levels in the BAL fluid of these patients. The origin of the secreted IL-8/CXCL8 seemed to be the cancer cells.[72] Thus, IL-8/CXCL8 can function as an angiogenic factor either by directly activating endothelial cells[247] or indirectly by recruiting immune system cells to tumor sites. IL-8/CXCL8 also has a direct mitogenic effect on lung cancer cells.[248]

**Nonangiogenesis Variant of NSCLC**   In contrast to the data implicating vascular angiogenesis as a critical requirement to tumor growth, notable exceptions have been observed.

In NSCLC, a nonangiogenic histologic pattern with a higher incidence of lymph node metastasis and a poorer prognosis was described.[249,250] Histologically, it had a nondestructive, alveolar pattern of malignant cell spread. A detailed analysis of the tumor vessels suggested that the tumor had co-opted existing blood vessels and possibly even lymphatic vessels.[251] Although suggestive to be a subtype of bronchoalveolar carcinoma, analysis of squamous cell lung cancers revealed also a subgroup of low-vascularity squamous cell tumors.[252] These squamous cell carcinomas were characterized by a high proliferation rate, low apoptotic activity, high VEGF expression, and low bFGF expression, and were associated with a poor prognosis. In another study, c-ErbB2 overexpression was correlated with a poor prognosis in a low-angiogenesis subgroup of NSCLC tumors.[253] These findings indicate that lung cancer can grow without neoangiogenesis. A lack of new vessel formation does not necessarily hinder tumor progression, although it dictates a specific growth pattern. More data is required about the molecular mechanisms involved in the progression of low-angiogenic tumors and about potential therapeutic targets in this subgroup.

### Lymphangiogenic Switch in Lung Cancer

Most research on cancerous vascularization has focused on angiogenesis and blood vessels' connections to the tumor. The tumor's vascular supply is essential to its growth; thus, angiogenesis induction is a critical turning point. However, the lymphatic network is also being recognized as important in later stages of lung cancer progression. Lymphangiogenesis is correlated with lymph node metastasis and prognosis.[251] VEGF-C controls lymphangiogenesis and lymph node metastasis in mouse models of lung cancer.[254] Accordingly, VEGF-C protein levels in the serum of 116 NSCLC patients were correlated with the risk of lymph node metastasis.[255] Targeting in parallel VEGF-A and VEGF-C might be pharmacologically applicable and could be therapeutically advantageous.

### Mouse Models of Lung Cancer Angiogenic Switch

K-Ras is activated by a somatic mutation in 20% to 30% of NSCLCs.[256] A correlation was found between K-Ras mutation and high VEGF expression in a group of 181 NSCLC tumors.[257] Another report did not find a correlation between K-Ras mutations and vascularity or VEGF levels.[258] Mice manipulated to express active K-Ras in lung epithelium (KRas[LA1] mice) developed atypical adenomatous hyperplasia and adenomas, which progressed to adenocarcinoma.[259,260] The oncogenic effect of K-Ras in this model was shown to be Rac1 dependent.[261] PI3K activation and increased phophatidyleinositole[3–5] triphosphate levels probably also mediated the oncogenic effect of K-Ras, as PTEN deletion accelerated K-Ras–induced lung cancer formation.[262] c-Met-HGF signaling contributes to tumor progression in this model, at least partly through enhanced angiogenesis.[263] Accordingly, an inhibitor of c-Met led to reduced VEGF production and enhanced thrombospondin-1 expression in lung cancer cells.[264] In addition, Ras signaling activated expression of CXCR2 ligands, causing accumulation of inflammatory cells

and vascular endothelial cells in the premalignant lesions of the KRas[LA1] mice. Blockage of CXCR2 signaling prevented the progression of these lung lesions and caused apoptosis of vascular endothelial cells within them.[265] CXCR2 inhibition had a tumor-inhibitory effect in a microenvironment-dependent manner. This suggests that KRas activation in lung cancer is proangiogenic and tumorigenic through recruitment of inflammatory cells and vascular endothelial cells.

A mouse model of lung cancer involving the targeting of either a wild-type c-Raf kinase or a constitutively active c-Raf kinase to lung epithelial cells was reported.[266] After a relative long latency period, isolated foci of lung adenomas developed, with no evidence of invasion or metastasis.[266] Additional genetic events are assumed to take place in some of the primed cells to explain these observations, making this model suitable for studies of lung cancer progression. In a study using the c-Raf mouse lung cancer model, disruption of intercellular adhesions through the downregulation of E-cadherin promoted an angiogenic switch.[267] E-cadherin disruption led to nuclear localization of $\beta$-catenin and secondary upregulation of VEGF-A, VEGF-C, and VEGFR-3. Phenotypically, this resulted in a marked increase in MVD, and evidence of increased permeability, typically seen when the VEGF pathway is activated. Lymphatic vessel density was also increased, accompanied by micrometastasis in draining lymph nodes.[267] Loss of E-cadherin–mediated cell–cell contacts might be a major regulator of the angiogenic switch in lung cancer.

## CLINICAL IMPLICATIONS OF ANGIOGENESIS INHIBITION IN LUNG CANCER

Although beyond the scope of this chapter, we will mention briefly a few of the major angiogenesis inhibitors that are in clinical use or are being studied in lung cancer patients. This issue is discussed comprehensively later in this manuscript by Christian Manegold and Alan Sandler.

Bevacizumab (Avastin, Roche) is a monoclonal antibody that is directed against the VEGF ligand. It was the first anti-angiogenic treatment to be approved for cancer. Bevacizumab was evaluated in a phase III study of 878 patients with advanced disease who received paclitaxel and carboplatin and was found to result in an increased survival duration, from 10.3 to 12.3 months.[5] Bevacizumab treatment was also evaluated in combination with cisplatinum and gemcitabine and was shown to increase progression-free survival (http://meeting.ascopubs.org/cgi/content/abstract/25/18_suppl/LBA7514, 2007).

Recombinant endostatin was evaluated as a treatment for 42 neuroendocrine cancer patients, with no documented responses.[268] Endostar, (YH-16, Medgenn Co.) is a recombinant human endostatin modified by the addition of nine amino acids. In a study of 493 advanced NSCLC patients, addition of endostatin to chemotherapy led to increased time to progression, from 3.6 to 6.3 months (http://meeting.ascopubs.org/cgi/content/abstract/23/16_suppl/7138, 2005). These findings suggest that endostatin has an important role in lung

cancer treatment. Endostar was recently approved for the treatment of NSCLC patients in China. It remains to be seen if this drug will be reevaluated in other countries.

Vandetanib (ZD6474) is a multikinase inhibitor that targets VEGFR, EGFR, and Ret. It is being studied in several phase II trials as a treatment for NSCLC.

Many other phase I and II studies of multikinase inhibitors are ongoing, many of them targeting VEGFR and PDGFR. This active clinical research is a result of the studies cited previously that demonstrated VEGF as a major regulator of angiogenesis. PDGFR is being evaluated as a clinical target, reflecting the understanding that pericyte coverage is an essential part of vascular small vessels. Many other targeted therapies are being studied as potential antiangiogenic or vascularization-disrupting agents. The bench-to-bedside transition of angiogenesis and vasculogenesis inhibition is among the shortest in cancer research. Hopefully, the combination of preclinical research and antiangiogenic treatment development will evolve to result in effective treatments for lung cancer patients.

# CHAPTER 9

# Applications of Proteomics to the Management of Lung Cancer

Lung cancer is the third most common cancer in the United States, yet it causes more deaths than breast, colon, pancreas, and prostate cancer combined.[1] Attempts to alter these statistics have been challenging in all respects. From risk assessment to diagnosis, staging, assessment of response to therapy, and prognostication, there is much room for improvement in this disease (Fig. 9.1). Rapid developments in technology have allowed the direct analysis of patterns of protein expression in tumors and blood samples, and these proteomic analyses promise to assist in making progress in each of these areas.

Proteins are ultimately responsible for the function of the vast majority of biological systems, and it is clear that many of the crucial proteins in a cell are primarily regulated by post-translational modifications such as proteolytic processing, phosphorylation, or acetylation. Thus, a full knowledge of the derangement in the expression, modification, and function of proteins in cancer cells is likely to be more informative than study of DNA or RNA alone. The aim of proteomics is therefore the characterization of proteins to obtain a more integrated view of the biology. In order to further understand the molecular biology of lung cancer, we need to probe these tissues and related biological materials with tools that address the molecular complexity of the proteome in lung cancer. New technologies are being rapidly developed to allow the increasingly thorough, systematic, and simultaneous analyses of thousands of proteins in cancer cells. In particular, these studies give us a unique insight into the biology of cancer, can yield important new therapeutic targets, and may enable the identification of novel biomarkers to differentiate tumor from normal cells and predict individuals likely to develop lung cancer.

In this chapter, we will review the progress made in clinical proteomics as it applies to the management of lung cancer. We will focus our discussion on how this approach may advance the areas of early detection, response to therapy, and prognostic evaluation.

## PROTEOMICS TECHNOLOGIES

**Sample Preparation**   With proteomics strategies, one strives to identify novel proteins and understand their structure, function, interaction with proteins and other molecules, and to bring this knowledge to the clinic by means of new diagnostic and predictive biomarkers and well as identification of therapeutic targets. The rapid advance of mass spectrometry (MS) and related technologies offers powerful new tools to analyze the proteome. In contrast to standard protein biochemistry, proteomics is defined as the study of the proteome, the complete set of proteins produced by a species, using the technologies of large-scale protein separation and identification (Table 9.1).[2]

Protein biochemistry has long been exploited to understand how biological systems function and lead to a cancer phenotype. Early efforts were geared to study primarily one protein at a time with biochemical methods of increasing power and sensitivity. The world of immunoassays brought and continues to bring major contributions to the field alone or in combination with MS.

In proteomic analysis, the isolation and preparation of samples for analysis is of critical importance, and the precise technique chosen depends on the scientific question being addressed, whether it may be a comprehensive expression analysis, evaluation of secreted proteins, nuclear proteins, proteins with a particular modification (e.g., phosphorylation), or those that bind to other proteins. Many approaches are available: some gel-based, some based on separation by reverse phase chromatography, affinity, size exclusion, ion exchange, and isoelectric focusing. The separation/purification strategies all have the advantage of separating the targets of interest from very abundant proteins in the milieu. The trade-off is between the addition of complexity and variability to the analysis and increased sensitivity. For example, proteomics of blood samples is complicated by the fact that the vast majority of the proteins in blood are made up of albumin and immunoglobulin, but the proteins of interest may be 7 to 10 orders of magnitude less abundant, and much more readily found if the abundant proteins are removed. An example of successful

separation strategy is immunoaffinity phosphoproteomics, which combines immunoaffinity purification with tandem MS. Using this approach, Rikova et al.[3] discovered oncogenic kinases such as platelet-derived growth factor receptor (PDGFR)-alpha and discoidin domain receptor family, member 1 (DDR1) that had not been implicated in the pathogenesis of lung cancer.

**The Mass Spectrometer** A mass spectrometer analyzes proteins after their conversion to gaseous ions, based on their mass to charge ratio. It is essentially made of three basic elements: an ion source for converting them to gaseous ions, a mass analyzer for separating the ions by mass, and a detector for detecting the ionized proteins (Fig. 9.2).

Tandem mass spectrometry (MS/MS) is a major analytic tool used for evaluating proteins and protein complexes. With this approach, protein samples are first digested with proteases into a mixture of peptides and analyzed. Peptide ions are separated in the first stage, then each peptide is fragmented in the collision cell, and the fragments are then separated again to identify them. The precise measurement of the mass of these fragments allows the reconstruction of the identity and composition of the original peptide (Fig. 9.3). There are many modes of MS/MS. Different mass analyzers currently used for MS/MS analysis are quadrupole ion trap (QIT), triple quadrupole (TQ), quadrupole time of flight (QTOF), or Fourier transform ion-cyclotron resonance (FTICR).

Specific mass spectrometers have specific applications. For example, electron transfer dissociation (ETD) MS allows detailed analysis of phosphorylated peptides that is of optimal

Samples ▷ Ion sources ▷ Mass analyzers ▷ Detectors ▷ Data analysis

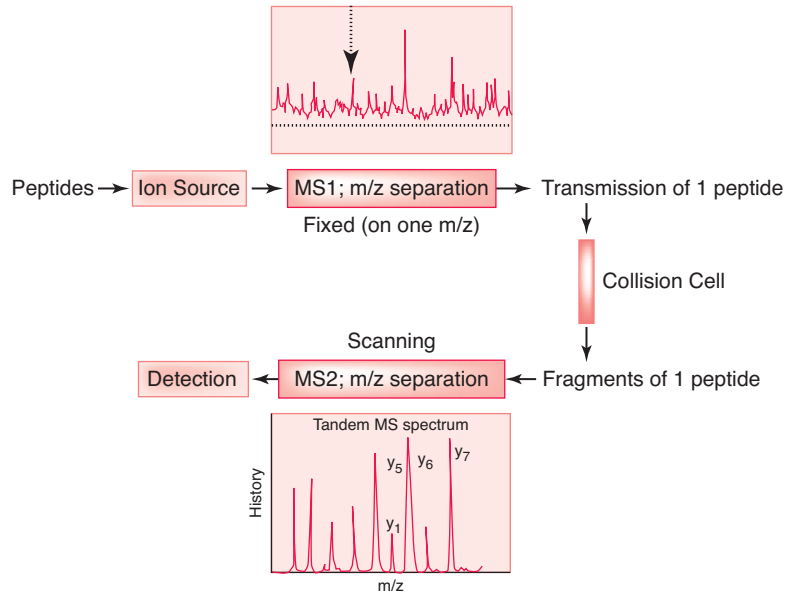
**FIGURE 9.2** Principles of mass spectrometry analysis. The time-of-flight (TOF) analyzer uses an electric field to accelerate the ions, and then measures the time they take to reach the detector. A quadrupole mass analyzer acts as a mass-selective filter. The quadrupole ion trap works on the same physical principles as the quadrupole mass analyzer, but the ions are trapped and sequentially ejected. *BAL*, bronchoalveolar lavage; *FTICR*, Fourier transform ion-cyclotron resonance; *LTQ*, linear quadrupole ion trap; *MALDI*, matrix-assisted laser desorption ionization; *MS*, spectometry. The Orbitrap is a novel form of MS instrumentation with 60 to 100 k resolution and <2 ppm mass accuracy.

**FIGURE 9.3**   Principle of tandem mass spectrometry. A peptide mixture is injected into the MS. Unlike the single-stage mass spectrometer that scans the entire range of masses, the first analyzer is set up to transmit only one peptide—therefore, one mass over charge (m/z). This peptide is then broken apart in a collision cell to generate peptide fragments. The m/z of these peptides is then determined by another mass analyzer. The amino acid sequence of the peptide is determined by subtracting fragment ion masses from each other, yielding the residue mass of a particular amino acid. The process is repeated until the sequence has been resolved.



quality.[4] The LTQ integrates the steps of mass analyzer, collision cell, and then another mass analyzer actually does it tandem in time, meaning that three steps occur in the same location—in an ion trap. An LTQ tandem MS is particularly well equipped for excellent throughput, good sensitivity, MSn capabilities, and a robust instrument. Each clinical question needs to be addressed separately and proteomics may provide tools to address them. The suite of technologies available to researchers is ever increasing and their selection very much depends on the goals and the type of samples to analyze.

**Analysis of Complex Protein Mixtures**   The proteome has multiple layers of complexity. The composition of the proteome is not static like DNA. The structure is at least an order of magnitude more complex than the genome, the dynamic range in protein concentrations in given biological specimens is huge ($10^{12}$), we have no target amplification method such as PCR for genomic analysis, and the methods used still have limitations in sensitivity primarily because of our ability to separate protein complexes in subgroups pure enough for analysis. Quantitative analysis is also challenging, but new methodologies are being developed to address this challenge. High-throughput analysis of the proteome without compromising reproducibility is difficult as well.

The analysis of the complex mixture can be conceptualized in two major ways, the *top-down* and the *bottom-up* approaches. In the top-down approach, one starts with a specific protein candidate; it is then separated, purified, and its structure is identified. Recent technologies, such as FITRC MS, increase the resolution and allow the analysis of larger peptide fragments. However, the bottom-up approach takes the challenge of embracing complexity from the start and directly analyzes complex mixtures with a large number of proteins, and uses computational peptidomics to reconstruct the identities of the proteins in the mixture. This later approach is less intuitive and may benefit from higher throughput.

It is recently being facilitated by modern bioinformatics tools, enabling the analysis of proteomic digestion with different enzymes than trypsin and therefore increasing the likelihood of detecting increasing number of peptides mapping to the same protein therefore improving the confidence of identification.

**Biomarkers**   The assumption underlying the concept of proteomic biomarkers is that certain characteristics of proteomes are highly correlated with specific clinically relevant biological states. These characteristics include changes in expression levels of proteins and the presence of specific modified protein forms (Table 9.2). Specific effort has been exerted in cancer proteomics to develop biomarkers for the early detection of disease by analysis of plasma or serum proteins. Detection of cancers at early stages maximizes survival, and identification of blood-borne markers would lead to minimally invasive tests.

The best biomarkers are those that are reproducibly measured, related to the disease process, and trigger a clinical decision

| TABLE 9.2 | Characteristics of a Biomarker and the Process Selection of Candidates |
|---|---|

**Characteristics of a Biomarker**

1. Should be an indicator or surrogate marker of clinical end point
2. Should be measurable, quantifiable, reproducible
3. Should evaluate a biological process and predict the outcome

**Process of Selection of Candidates**

1. Demonstrate that marker appears in accessible material
2. Establish quantitative criteria for the presence of the marker
3. Validate marker against accepted end points
4. Confirm its predictive value in prospective study

resulting in improved clinical outcomes. Despite an intense search for such biomarkers in the last 20 years, there are none currently available for early diagnosis of lung cancer.[5] One reason for such a lack of success thus far is the enormous challenge offered by lung cancer development. The onset of the disease process is extremely slow (months to years) and we have no means of evaluating the rate of progression. Therefore, there is a critical need for new biomarkers that are related to the disease process and that can be measured early, easily, and repeatedly to assess progression of the process.

## Approaches to Biomarker Discovery Using Proteomics
Biomarker identification has been addressed by multiple proteomic technologies (Fig. 9.4). MALDI profiling is rapid, high throughput, but detects only the most abundant proteins of relatively low molecular weight, and does not enable direct identification when applied to complex proteomes. Two-dimensional (2D) gel-based analysis suffers problems of interlaboratory reproducibility and throughput. More recent in-depth proteomic analyses are trying to overcome these limitations and are summarized here.

### High-Throughput Profiling Techniques
The rapid proteomic profiling of blood, tissue, or urine with minimal sample preparation, using the peak pattern as a diagnostic tool, has generated great enthusiasm and yet has been minimally successful at providing robust signatures to translate to the clinic. In this approach, the focus is on the use of MS peak patterns of abundant proteins or peptide fragments that correlate with an early disease stage but are usually not part of the disease mechanism. MALDI TOF MS is capable for very high throughput where a sample can be analyzed in seconds and has higher tolerance for salts, buffers, and other biological contaminants. Because of these qualities, MALDI MS has been utilized to study proteins/peptides in serum,[6–10] urine,[11] tissue extracts,[12,13] whole cells,[14] and laser-captured microdissected cells.[15]

**FIGURE 9.4** Proteome and analytical coverage of its complexity by current technologies according to protein concentration (depth) and molecular weight (breath). *MALDI MS,* matrix-assisted laser desorption ionization mass spectrometry.

Profiling using this technology in biological fluids or tissue samples is not without challenges. The enormous complexity of the sample composition, the large dominance of few proteins in the sample, and their ability to mask lower abundance limits the informativity of this approach. Truly tumor-derived markers are likely to be present at low levels in blood, similar to levels of the thousands of other proteins in blood that derive from normal tissue leakage. Thus, the dynamic range of protein concentrations adds a new dimension of technical considerations to successful analysis of the serum/plasma proteome.[16] These profiling experiments have been applied to a series of biological specimens. Yet, reproducibility between platforms and institutions remains a problem such that none of the profiling experiments have yet made an impact in clinical medicine. This is in contrast with greater early steps in the translation of genomic signatures to the clinic.[17,18]

Finally, protein arrays have recently been developed and offer a series of targets printed onto different surfaces. Proteins,[19] peptides, antibodies,[20,21] or lysates[22] will then be detected by antibodies, serum, or multicolor detection systems. The Swedish Human Protein Atlas (HPA) program proposes a systematic analysis of the human proteome using antibody-based proteomics combining affinity-purified antibodies with protein profiling assembled in tissue microarrays.[23]

### In-Depth Proteomics Analysis
The analysis of the plasma proteome has made great progress in the last few years. http://www.hupo.org/research/hppp/. This is largely a consequence of novel methods of serum fractionation and MS-based protein identification techniques; the number of plasma proteins now includes major categories of proteins in the human proteome.[24] The list confirms the presence of a number of interesting candidate marker proteins in plasma and serum.[25] The detection of low-abundance proteins in the plasma requires combinations of powerful technologies. The identification of proteins whose expression levels are altered with the disease state progression (2DE, MS, shotgun proteomics) requires methodological improvements over the profiling experiments. Methods related to separation of ions and ionization have moved the field forward.

Two technology platforms have been developed to enable unbiased discovery of candidate markers from tissues and biofluids and verification of candidate markers by targeted analysis. Unbiased discovery employs a shotgun proteomics platform based on isoelectric focusing of peptides from tissue protein digests, followed by reverse phase LC-MS-MS on Thermo LTQ or LTQ-Orbitrap instruments. Verification is done by targeted quantitation of peptides derived from biomarker candidate proteins using liquid chromatography–multiple-reaction monitoring MS (LC-MRM-MS).[26–28]

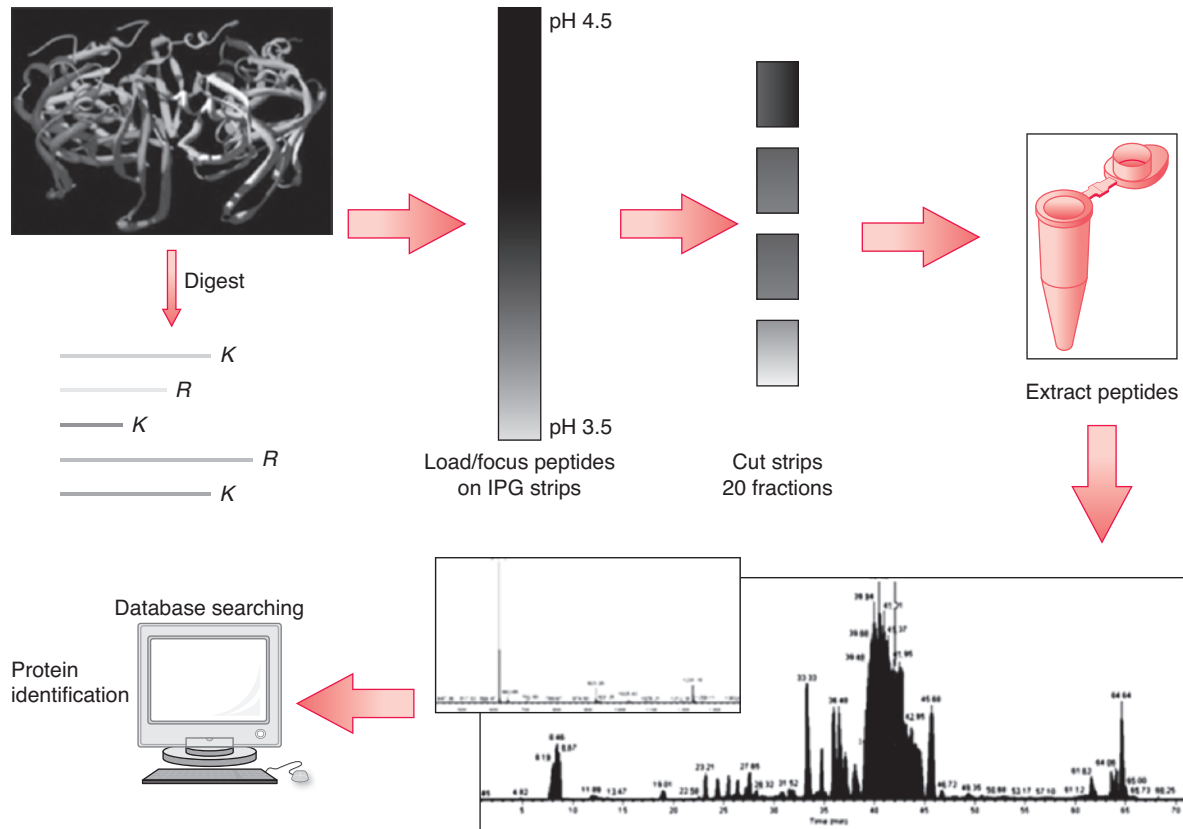
In shotgun analyses, protein mixtures are digested to peptides, which then are analyzed, most commonly by multidimensional LC-MS-MS. MS-MS spectra encode the sequences of peptides, as well as the masses and sequence positions of any modifications (Fig. 9.5). Matching of MS-MS spectra to database sequences enables identification of the peptides and the


**FIGURE 9.5**   Overview of tissue shotgun proteomics.

proteins from which they were derived. Shotgun analyses by LC-MS-MS also result in direct identification of the peptides detected and provide for quantitative analysis of protein components. Shotgun proteomics has proven the most versatile and effective method for dissecting multiprotein complexes, signaling networks, and complex subcellular proteomes.[29] Shotgun analyses can confidently identify 3000 to 5000 proteins from a 200-$\mu$g protein sample. Shotgun analyses have generated the most complete proteomic inventories to date of major eukaryotic subcellular organelles, whole cell and tissue proteomes, and proteomes of human biofluids, including plasma and serum.[28,30–33]

Targeted quantitative analysis of top candidates can be done by LC-MRM-MS analysis, as a first level of verification of the shotgun results. Briefly, tissue lysates are run on a NuPAGE gel and peptides are extracted, then injected in a TSQ Quantum Ultra mass spectrometer. Peptides are loaded and desalted and resolved in reverse phase chromatography, eluted with a linear gradient. For MRM, four transitions are recorded, and chromatographic peak areas for the transitions are summed and compared to summed peak areas for beta actin. Differences between peaks are evaluated for statistical significance. Targeted LC-MRM-MS analyses can analyze up to 100 candidates per run in individual tissue or plasma specimens. Moreover, the application of both stable isotope tagging and label-free quantitation has enabled the application of

shotgun proteomics to quantitative comparisons of complex proteome samples.[34–39]

**Proteomic Data Analysis**   Analysis and interpretation of the data derived from MS-based proteomic technologies represents unique challenges as well. From MALDI MS experiments, Spectra are generated in the mass-to-charge (m/z) 3000 to 50,000. Internal calibration is performed using internal or external calibrants. The data processing consists of internal calibration, smoothing, baseline correction, normalization to the total ion current, feature selection with a signal-to-noise ratio, and binning of features. This processing results in 100 to 300 m/z peaks per spectrum on average, using conservative parameters. Statistical analyses of these data for biomarkers focus on the selection of MS features and differential expression levels between the study groups and on building class prediction models based on the selected features.[40–44] The misclassification rate is typically estimated using the leave one out cross-validation.

From tandem MS analysis, raw data is extracted for individual spectra with filters applied to remove obvious background ions and low-quality spectra. These spectra yield a list of peptide sequences and the frequency that each peptide is detected. These sequences are searched against the NCBI protein database to generate candidate proteins from which they may have come. This list is filtered in various ways to reduce

the likelihood of false matches, and the protein and hit count lists from different study groups are compared to generated candidate biomarkers.

In summary, while genes carry the genetic information, proteins are principal actors of vital regulatory processes. Proteomics has many theoretical advantages over the more established genomic and transcriptomic approaches to these questions, but has been hampered by a number of technical problems (Table 9.3). Another major challenge is the need for extensive validation in using these novel global proteomics research platforms prior to routine clinical applications. Once interested in applying any new technology, one should remember to carefully frame a biological question, understand the literature, consider the limitations of each approach, and use the most appropriate technology to answer the question.

## EARLY DETECTION

Biomarker discovery for early detection of disease is made challenging by the fact that patients are often identified late in the course of disease, while it is abundantly clear that those treated during early disease stages have a much better prognosis. Access to samples before diagnosis is very difficult. Another major challenge is the target sample to be analyzed. Complex samples such as serum or urine although readily accessible add to the complexity of the task. Tumor biomarkers for lung cancer can be categorically classified into serum biomarkers, tissue biomarkers, and sputum. Exhaled breath condensate is an interesting source of material, but has not proven feasible yet. Serum biomarkers stand out as being the most attractive at this time because of their easy and routine accessibility. See also Chapter 22.

Biomarkers of early detection of lung cancer are still at an early stage of development.[45] The Early Detection Research Network (National Cancer Institute, division of cancer prevention) has proposed a stepwise method for evaluating biomarkers, and to identify people at risk (http://www.cancer.gov/edrn).[46] None of current biomarkers for the early detection of lung cancer have passed the early validation (phase II). While genetics

has provided considerable insights into the molecular biology of lung cancer,[47] the overall correlation between level of expression of the messenger RNA molecules and protein expression is relatively poor.[48] It is possible that proteomic technologies offer a new avenue for biomarker discovery.

Proteomics-based early detection strategies for cancer diagnosis include the analysis of complex mixtures such as tissue samples, serum, plasma, sputum, and exhaled breath condensate. The inherent analytical advantages of MS, including sensitivity and speed, promise to make MS a mainstay of biomarker discovery. The optimal use of these technologies depends on the desired goal, such as protein identification, identification of posttranslation modification, or determination of protein–protein interactions.

The direct analysis of serum proteomes to detect disease markers has attracted widespread interest and intense scrutiny. Early work using either MALDI or a proprietary MALDI variant termed surface-enhanced laser desorption ionization (SELDI) demonstrated that spectra of crude serum protein mixtures or subfractions displayed differences in spectral features that appeared to correlate with disease status.[49–51] The application of multivariate analytical methods generated models that correlated spectral features with disease status.

To determine the diagnostic accuracy of MALDI mass spectrometric analysis of serum in lung cancer, we used MALDI-MS to analyze undepleted and unfractionated serum from a total of 288 NSCLC patients and matched controls divided into training (92 cases and 92 controls) and test (50 cases and 56 controls) sets.[10] In the training set, they defined a seven-signal proteomic signature distinguishing lung cancer serum from matched controls with an overall accuracy of 78%, a sensitivity of 67.4%, and a specificity of 88.9%. In the test set, the signature reached an overall accuracy of 72.6%, a sensitivity of 58%, and a specificity of 85.7%. As diagnosis of early stage lung cancer is important, authors searched for a protein signature discriminating stage I lung cancers from controls and found a six-signal signature reaching 70.8% sensitivity and 84.4% specificity in the training set, and 57.1% sensitivity and 71.4% specificity in the test set (Fig. 9.6).

With a multivariate logistic regression model applied on a total of 223 cases and controls, they showed that the serum signature was associated with lung cancer diagnosis independently of gender, smoking status, smoking pack-years, and C-reactive protein levels, and had the strongest association with lung cancer diagnosis among all the covariates in the model. Using SELDI-TOF-MS on serum samples from 158 lung cancer patients and 50 controls, Yang et al.[52] reported a five-signal protein signature distinguishing lung cancer cases from controls with 86.9% sensitivity and 80.0% specificity in the validation set.

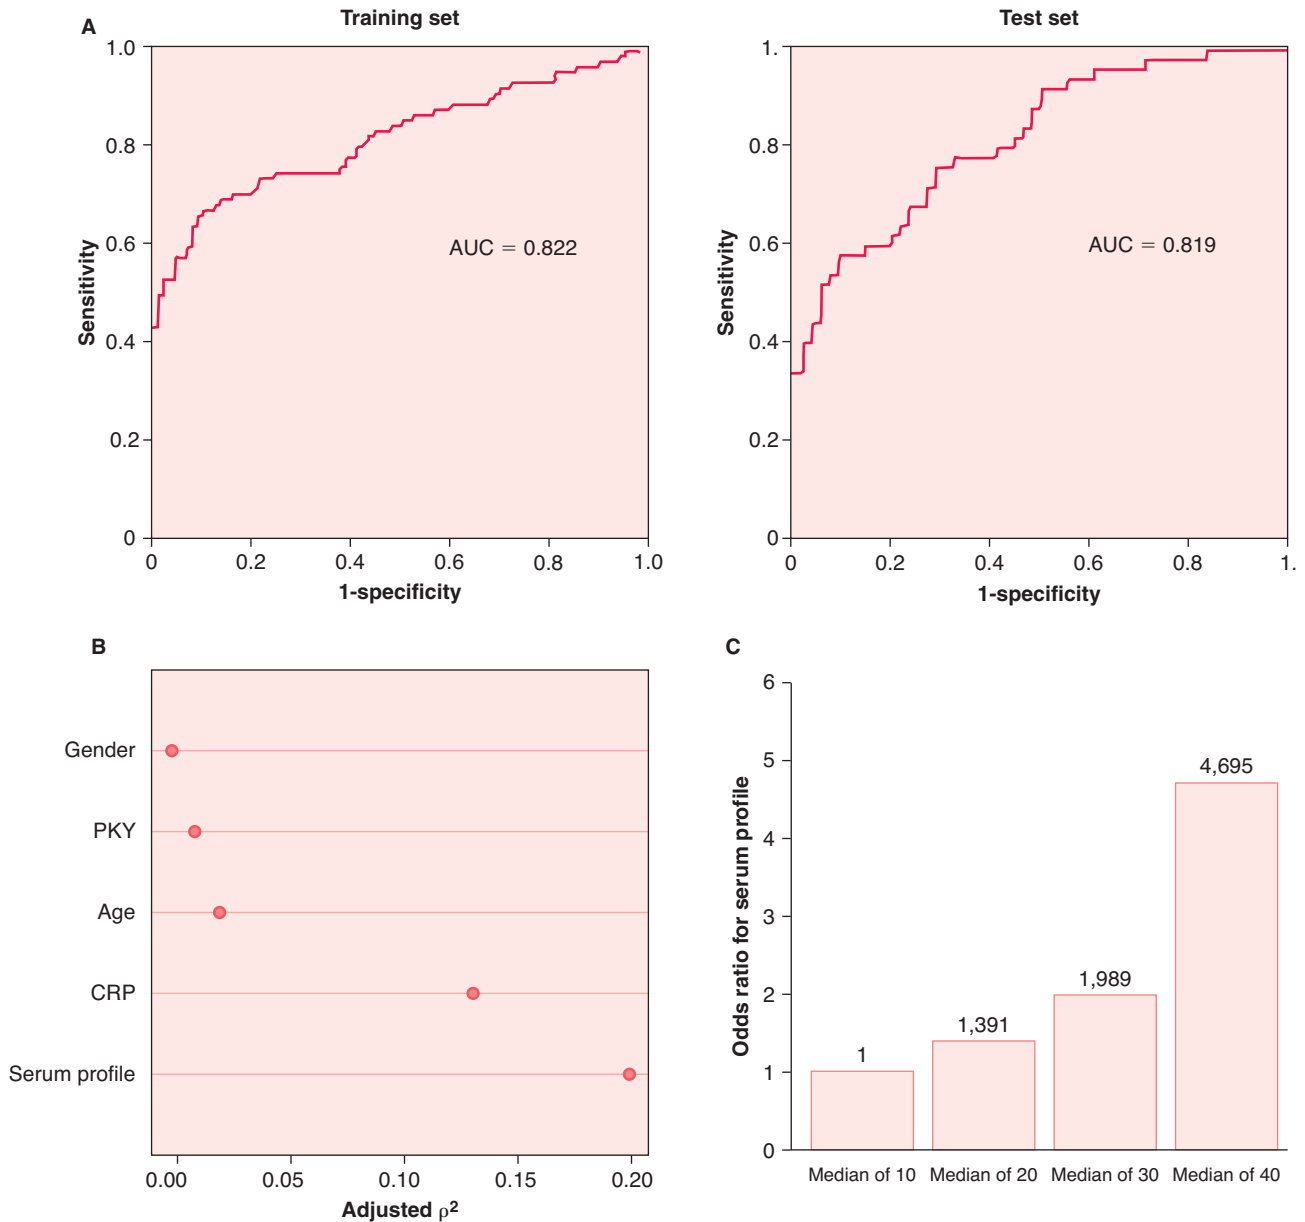
Initial reports suggesting that these features comprise new families of biomarkers were followed by considerable critical analysis, which pointed out several problems.[53–55] First, MALDI and SELDI analyses were subject to systematic bias due to inconsistent sample collection, processing, and poor instrument calibration. Second, the analyses of small numbers of samples displaying large numbers of spectral features led to


**FIGURE 9.6** **A:** Receiver operating characteristic curves addressing diagnostic efficacy of cases and controls in the two datasets (182 training sample set, 106 matched test set). **B:** Nonmonotonic (quadratic in ranks) generalization of the Spearman rank–correlation coefficient, for each of these five predictors. The generalized Spearman coefficient helps to describe the strength of marginal relationships between each of these predictor variables and the response (being with lung cancer or not). This plot shows that the serum profile has the strongest correlation with the response among these five predictors. **C:** Odds ratio of being diagnosed with lung cancer according to serum profile quantile distribution. *AUC*, area under the curve; *CRP*, C-reactive protein; *PKY*, Smoking Pack Years. (From Yildiz PB, Shyr Y, Rahman JS, et al. Diagnostic accuracy of MALDI mass spectrometric analysis of unfractionated serum in lung cancer. *J Thorac Oncol* 2007;2:893–901.)

models that "overfit" the data and did not scale effectively to larger sample numbers. Third, spectral features that correlated to disease state were found to be poorly reproducible between different laboratories. Finally, MALDI- and SELDI-based methods did not enable direct identification of the protein and peptide species that constituted putative markers. Eventual identification of some of the species associated with spectral signals revealed that they were all abundant blood proteins or their proteolysis products, many of which were produced ex vivo during sample handling or serum preparation.[56,57]

Moreover, some of the most characteristic markers (e.g., serum amyloid A) were associated with multiple cancers.[10,58] Recent work by Villanueva et al.[59] demonstrated that blood from patients with different cancer types yielded characteristic

Early Diagnosis
of Lung Cancer

**FIGURE 9.7**   MS approaches and integration in a multivariable model for the early diagnosis of lung cancer. *ESI MS*, electrospray ionization mass spectrometry; *FT*, Flow Through; *LC*, liquid chromatography; *MALDI MS*, matrix-assisted laser desorption ionization mass spectrometry; *Prot ID*, Protein Identification; *RP*, Reverse Phase; *SCX*, Strong Cation Exchange.

sets of proteolysis products of abundant blood proteins during serum preparation.

The proteomic characteristics observed in MALDI and SELDI analyses are interesting but may ultimately be of questionable value in the detection and diagnosis of cancer in human populations. Clearly, the majority of identified species do not arise from cancers themselves, but rather from systemic responses to disease. The distribution of protein proteolysis products is exquisitely sensitive to sampling methods and processing, and the different proteolysis products can only be distinguished by MS instruments. Most importantly, the relationship of these putative markers to cancer is unclear, as is their ability to distinguish different cancers.

Ultimately, the early diagnosis of lung cancer will be addressed in an integrated way after gathering information from clinical, biological, imaging, and molecular data (Fig. 9.7).

## PROTEOMICS FOR CLASSIFICATION OF PROGNOSIS

The clinical behavior of individual patients with lung cancer is extremely diverse. Some tumors progress rapidly with widespread metastases, and some grow only very slowly over the course of years and never result in clinical symptoms. Knowledge of this propensity when selecting initial therapy would be extremely useful in determining whether treatment is needed at all and how aggressive an approach is indicated. Deciding on the need for adjuvant chemotherapy is an example. Presumably, this diversity results from variability in the precise molecular makeup of individual tumors, and a pattern of molecular features associated with clinical course, independent of therapy, is referred to as a prognostic signature. Features associated with the benefit or lack of benefit from a specific intervention are considered to make up a predictive signature, and will be addressed in the next section.

As discussed previously, many of the functionally important molecules in the development of cancer are regulated by posttranslational modifications, implying that direct assessment of the proteins themselves might be more informative than RNA or DNA. Attempts have been made to apply proteomic technologies to uncovering an accurate prognostic signature for lung cancer. Gharib et al.[60] used 2D gels to study the differences in protein expression patterns for 93 resected lung adenocarcinomas and 10 normal lung samples, and assessed their association with survival. In this study, they found that two of the five cytokeratin 7 isoforms, one of eight CK8 isoforms, and one of three CK19 isoforms were associated with survival. One of these, CK19, had independently been found to be a useful tumor marker for lung cancer. Also uncovered in this dataset was the significant downregulation of selenium-binding protein 1, also strongly associated with survival.[61] Another study used 2D gels to study 20 squamous cell lung cancers with matched normal tissues[62] and identified tumor/normal differential expression of mdm2, c-jun, and EGFR, and found 26 proteins reactive to patient autoantibodies, but no survival analysis was done. The finding that not all of the CK19 isoforms conveyed prognostic significance underscores the power of proteomic technologies to uncover these associations. Unfortunately, because specific antibodies for individual isoforms are rarely available, it also underscores a problem with this approach in the practical clinical measurement of these features.

MALDI-TOF has also been applied to this problem, and in a study of 79 tumors and 14 normal lung tissues, classifiers were defined that were able to discriminate tumor from normal, and lung cancer from metastatic disease.[40] A 15-protein classifier was constructed that was able to predict survival after resection (Fig. 9.8).

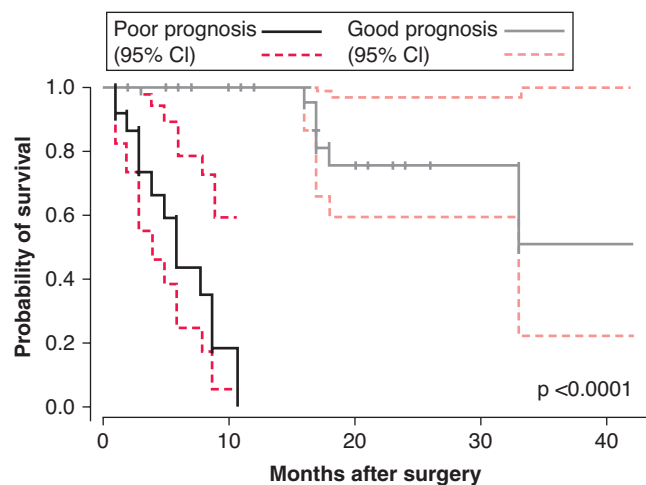

**FIGURE 9.8**   Kaplan-Meier survival curves for groups with poor and good prognosis according to proteomic pattern compromised of 15 distinct MS peaks. *p* <0.0001 according to log-rank test. *CI*, confidence interval. (From Yanagisawa K, Shyr Y, Xu BJ, et al. Proteomic patterns of tumour subsets in non-small-cell lung cancer. *Lancet* 2003;362:433–439.)

These proteins included thymosin beta4 and SUMO-2, both with interesting biological implications. Thymosin beta4 has been associated with inhibition of caspase-3 in taxol-induced tumor cell death,[63] as well as stabilization of HIF-1 alpha,[64] and its expression is regulated by hMLH1.[65] SUMO-2 is also associated with multiple important cancer pathways.[66–70] A subsequent study of a larger cohort of 174 NSCLC tumors with a longer follow-up derived a 25 signal classifier overlapping with the previous classifier, and also able to divide patients into high- and low-risk groups.[71] However, MALDI-TOF is limited by nonstandardized or transportable analytic platforms and its low sensitivity and selectivity for low–molecular-weight proteins. It is also difficult to identify the precise protein detected, making translation to clinical practice difficult.

Analysis of serum by SELDI-TOF has also uncovered an unidentified 4628 Da protein associated with survival in 87 advanced stage NSCLC patients.[72] However, this was evaluated only in a cross-validation approach and not an independent test set, and needs additional validation.

LC-MS/MS analysis of lung cancer tumors has great promise for the discovery of tumor signatures, as it is capable of detecting many more proteins than MALDI-TOF and gives the identity of the observed protein features. In one very preliminary study,[73] 24 surgically resected adenocarcinomas were analyzed by SDS-page gel followed by in-gel digestion and C-18 LC separation and MS/MS analysis. They identified 51 candidate signals and selected two of the corresponding proteins, myosin IIA and vimentin, as biomarkers. When evaluated by immunohistochemistry, they were able to use these two markers to classify good and poor prognosis groups (Fig. 9.9).

None of these markers have reached routine clinical practice to date, at least partly due to the difficult steps of taking a research lab–based assay for large numbers of candidate markers and translating that into a reproducible and accurate high-throughput commercial product capable of validating them in a prospective fashion in large enough cohorts of patients. Work continues in this direction, however.

## RESPONSE TO THERAPY

More important than simple prognostic classification is predicting response to therapy. Identification of patients destined to do poorly regardless of therapy is much less interesting than identification of specific therapies capable of assisting in the selection of the optimal intervention able to alter a patient's outcome.

Several proteomic studies have attempted to define protein signatures capable of predicting benefit from specific interventions. In its simplest form, single immunohistochemical marker studies are being tested for their utility in defining patients who will benefit from specific therapies. For example, immunohistochemical expression of excision repair cross-complementing rodent repair deficiency, complementation group 1 (ERCC1) is associated with lack of benefit from platinum-based therapy,[74] and high thymidylate synthase expression in squamous cell lung

**FIGURE 9.9**    Kaplan-Meier curves for disease-free survival after complete resection in patients with stage I lung adenocarcinoma. **A:** Cases lacking both myosin IIA and vimentin expression (nonrelapse survival rate at 5 years: 100%). **B:** Cases negative for myosin IIA and positive for vimentin, or positive for myosin IIA and negative for vimentin (nonprelapse survival rate at 5 years: 58.0%). **C:** Cases positive for both myosin IIA and vimentin (nonrelapse survival rate at 5 years: 42.0%). Group a showed significantly higher survival than group b, and significantly higher survival than group c (a, b: $p = 0.029$; a–c: $p = 0.006$). (From Maeda J, Hirano T, Ogiwara A, et al. Proteomic analysis of stage I primary lung adenocarcinoma aimed at individualisation of postoperative therapy. *Br J Cancer* 2008;98:596–603.)

cancer predicts lack of benefit from pemetrexed.[75] Some studies are attempting to use proteomic technologies to measure the levels of several candidate markers and cytokines in the blood and correlate these with response. One such study[76] looked at biomarkers associated with benefit from bevacizumab, and antibody against VEGF, and found that baseline intercellular adhesion molecule (ICAM) levels were prognostic for survival and predictive of response to chemotherapy with or without bevacizumab, and that VEGF levels were predictive of response to bevacizumab but not survival. Other studies have attempted to find blood-based biomarkers of response to VEGFR tyrosine kinase inhibitors.[77] Using high-throughput platforms, several groups are now studying the utility of measuring 100 or more such markers simultaneously.[78,79]

2D gel analysis of squamous cell lung cancer has identified candidate proteins associated with resistance to mitoxantrone,[80] and taxanes,[81] but no clinical candidate markers have been identified in these datasets. A study of H322 and H1299 lung cancer cells using 2D gels identified thioredoxin reductase to be associated with resistance to the histone deacetylase inhibitor depsipeptide.[82] 2D differential in-gel electrophoresis (DIGE) technology also identified nine proteins associated with response to the EGFR tyrosine kinase inhibitor gefitinib.[83] These proteins included fatty acid binding protein and glutathione-S-transferase P, and application of this signature to an external sample set confirmed the predictive ability, but only involved 14 patients.

To date, MS/MS proteomic analysis of lung cancer tumors has also failed to find markers predictive of response to

uracil-tegafur,[73] but other studies looking at other chemotherapies are in progress. The potential power of tandem MS not only for identification of markers predictive of benefit from therapy, but also new targets for therapy in specific tumors is demonstrated in a recent study of the phosphoproteome of lung cancer cells.[3] This study evaluated tyrosine phosphorylated peptides in 41 NSCLC cell lines and over 150 tumors and found known therapeutic target phosphorylation as well as activation of potential but not previously identified kinases such as DDR1. In spite of this progress, to date, none of the markers from 2D gels or mass spectrometric analysis of lung tumors has advanced to careful clinical testing.

Probably most surprising is the report that a serum protein signature has been reported that could accurately define patients with good or poor survival after treatment with gefitinib or erlotinib.[84] It is more intuitive that an accurate predictive signature is more likely to be defined from tumor protein expression patterns than from patterns in the blood, but this group defined a signature of eight proteins that was capable of classifying good and poor outcomes in a training cohort of 139 second-plus line patients treated with gefitinib and applied this classifier in a blinded way to two independent test cohorts, one second-plus line treated with gefitinib, and one a cooperative group trial of erlotinib in first-line therapy (E3503) (Fig. 9.10).

Remarkably, highly statistically significant classification was achieved for both progression-free survival and overall survival

Number of Patients at Risk:

| Time [Days] | 0 | 50 | 100 | 150 | 200 | 250 | 300 | 350 | 400 |
|---|---|---|---|---|---|---|---|---|---|
| Good | 69 | 64 | 56 | 51 | 43 | 37 | 26 | 18 | 6 |
| Poor | 27 | 22 | 16 | 12 | 8 | 7 | 3 | 3 | 2 |

**FIGURE 9.10** Kaplan-Meier analysis of overall survival in the Eastern Cooperative Oncology Group validation cohort (n = 96). These patients had advanced non–small-cell lung cancer and had been treated first line with erlotinib alone. *Solid lines*, event-free fraction; *dashed lines*, 95% confidence intervals; *tick marks*, censored patients. (From Taguchi F, Solomon B, Gregorc V, et al. Mass spectrometry to classify non-small-cell lung cancer patients for clinical outcome after treatment with epidermal growth factor receptor tyrosine kinase inhibitors: a multicohort cross-institutional study. *J Natl Cancer Inst* 2007;99:838–846.)

in these cohorts, and not in three control cohorts treated with chemotherapy or surgery alone. None of these patient cohorts was from a randomized trial, however, so it is impossible to determine if this classifier is truly specifically predictive of benefit from erlotinib. This test has been commercialized and prospective testing is in progress.

## CONCLUSION

The rapid development of proteomic technologies has provided a large amount of novel information leading to the assembly of large protein inventories and a better understanding of how they interact, the role of specific posttranslational modifications, and advances in biology. Proteomic analysis has the potential to profile differences between lung tumor and no tumor, between different stages and histology of cancer, and between different cancer samples at the same stage of progression. The ability to identify important proteins involved in the transformation process may lead to early markers for detection of specific types of cancers and treatments based on the molecular profile of lung cancer. Molecular profiling may assist in identifying high-risk populations and offers a unique opportunity to study early carcinogenesis and potentially to reduce cancer mortality through its integration with genomics. The importance of clinical proteomics comes from the fact that it will have a fundamental impact on our understanding into complex disease processes, such as lung cancer, and will offer new opportunities in the diagnosis, prognosis, and therapy of disease. The development of specific and sensitive diagnostic biomarkers using biological fluids, such as sputum and serum, should improve screening, early detection, monitoring of disease progression, treatment response, and surveillance for recurrence. Proteomic biomarker discovery analysis is still early in this process and will benefit from these technologies to detect, identify, and specifically quantify protein markers. The biological amplification of protein signals through the immune system may also claim autoantibodies as potential biomarkers. The development of immunoaffinity assays to validate candidate biomarkers is required. Finally, a major challenge is the need for extensive validation in using these novel global proteomics research platforms prior to routine clinical applications.

# Molecular Prognostication of Lung Cancer

At present, the best prognostic indicator of long-term survival for patients with lung cancer is tumor stage. The recent proposed revisions to the *TNM Classification of Malignant Tumours* by the International Association for the Study of Lung Cancer (IASLC) are an analysis of 67,725 cases of non–small cell lung cancer (NSCLC) to further refine the prognostic accuracy of tumor staging (see Chapter 30).[1] Regrettably, however, up to 30% of patients who undergo curative resection for stage I lung cancer will have recurrence of their disease. Present conventional wisdom is that the long-term survival in many cancers may be increased if clinicians had the means to identify and treat patients who would benefit from adjuvant therapy that might not otherwise be indicated based on their initial tumor stage. To this end, many investigators have examined molecular and genetic factors that may influence tumor behavior and therefore long-term prognosis.

A number of genetic alterations and abnormal expression of several regulatory genes have been detected and described for lung cancer. These alterations are caused by gene mutation, chromosomal modification, epigenetic silencing, and deregulated messenger RNA (mRNA). In addition, several studies have correlated specific molecular genetic changes with clinical prognosis and survival for patients with lung cancer. Currently, several clinical trials are underway to further define patients' molecular "signatures" in an effort to predict both overall prognosis as well as response to therapy for lung cancer (http://www.clinicaltrials.gov).

Early studies attemping to comment on prognostic variables in lung cancer are summarized in a comprehensive and systematic review of 887 studies, which identified 169 host- and tumor-related molecular factors associated with prognosis in lung cancer.[2] Several factors were significantly associated with survival, independent of stage and reported in more than three studies: p53, p21, Ki-67, and p185 gene status; serum cytokeratin 19 fragments; agryophilic nucleolar organizer region; and markers of angiogenesis such as vascular endothelial growth factor (VEGF) expression and vessel invasion. Other studies have used molecular, immunohistochemical, and clinical–pathologic markers to predict patient prognosis and outcomes.[3–5]

The subsequent development of oligonucleotide and complementary DNA (cDNA) arrays to analyze gene expression on a larger scale has contributed significantly to the understanding of molecular and genetic alterations in lung cancer. These tools allow for the simultaneous analysis of literally thousands of genes such that a genetic profile or signature can be constructed for a particular patient or tumor. In addition to genetic profiling, investigators have identified several proteomic (see Chapter 9) and microRNA (miRNA) profiles for lung tumors. These profiles are correlated to clinical behavior, thereby providing prognostic information for patients with lung cancer.

## INDIVIDUAL GENE ALTERATIONS AND PATIENT SURVIVAL

**K-ras**  Members of the *ras* gene family encode cell membrane-associated G-proteins, which serve as mediators of signal transduction for cellular proliferation (also reviewed in Chapter 5). Up to 30% of NSCLCs are characterized by mutations in the *k-ras* gene[6,7]; most of these mutations are found in adenocarcinomas and are associated with a history of tobacco use.[8] The most common mutation of *k-ras* is a G→T transversion in codon 12 that results in constitutive activation and continuous transmission of growth signals to the nucleus. Alterations in *k-ras* appear to be early events in lung carcinogenesis, having been observed in atypical alveolar hyperplasia lesions that are thought by many to be precursors of lung adenocarcinomas.[9] The prognostic significance of *k-ras* mutations in lung cancer remains controversial. Although many studies report an association between decreased survival and worse prognosis in patients whose tumors exhibit *k-ras* mutations, others, including a metaanalysis of 881 cases, report no significant link between ras mutation status and prognosis.[10–13]

**p53**  The p53 tumor suppressor gene is mutated in more than half of all human malignancies, and alterations in the p53 gene are the most frequently found in human cancer (also

reviewed in Chapter 5). Approximately 50% of NSCLCs and over 90% of small cell lung cancers (SCLC) harbor mutations or deletions of the p53 gene.[10,14] Inactivation of p53 results in diminished efficiency of DNA repair, derangements of cell cycle regulation, and overall increased genomic instability.[15] In the normal state, the p53 network is quiet and senescent. In times of cellular injury or stress, however, the p53 network is activated and its downstream effects include cell cycle regulation, induction of apoptosis and DNA repair mechanisms.

A prospective study by Ahrendt et al.[16] demonstrated that p53 gene mutations were independently predictive of decreased survival in stage I tumors but not in stage II or III tumors. Missense mutations were not significant for patient outcome. However, p53 mutations that were truncating, structural, or those abolishing DNA contact were associated with a poorer overall patient outcome among all samples. The relationship between p53 mutational status and adverse survival outcomes has been corroborated by several other studies incorporating NSCLC samples from all tumor stages.[17–25]

Immunohistochemical studies of p53 have been less consistent. In the largest studies examining p53 expression levels, some authors have reported a correlation between abnormal p53 expression and poor prognosis; however, others report no statistically significant relationship.[3,26–33] Carbognani et al.[34] examined the role of p53 status in long-term survival following resection of NSCLC. Using immunohistochemical analysis of several prognostic markers, p53 status was the only independent predictor of 10-year survival following resection of adenocarcinoma. In another study, Tsao et al.[13] observed that p53 protein overexpression was a marker of poor prognosis and shorter overall survival. In addition, patients with tumors containing wild-type p53 had a survival benefit from adjuvant chemotherapy as compared to those with functionally aberrant p53 status. Despite the mixed evidence from immunohistochemical studies, however, a metaanalysis of 56 studies was conducted to further investigate the role of p53 alterations and lung cancer.[35] Abnormal p53 status was associated with decreased overall survival in patients with NSCLC across all stages and in both squamous cell and adenocarcinoma histologies.

## Cell Cycle Regulation

**Rb and p16**    The retinoblastoma (*Rb*) susceptibility gene is a tumor suppressor gene with a key role in human carcinogenesis (also reviewed in Chapter 5). The *Rb* gene is inactivated in 20% to 30% of NSCLCs and up to 90% of SCLC.[10] Despite this, the effect of *Rb* mutation or abnormal expression on patient prognosis is controversial, with most studies demonstrating no significant relationship between *Rb* abnormalities and survival.[27,36–38]

However, Burke et al.[39] recently demonstrated that the additive effect of concurrent abnormalities in either or both of the *Rb* and p53 pathways was predictive of patient prognosis in NSCLC. In this study, there was no association between patient survival and isolated abnormalities of the Rb pathway proteins pRb, cyclin D1, and p16[INK4A] and p53 pathway proteins p53

and p21[Waf1]. However, certain combinations of abnormalities were predictive of poor prognosis. These included concurrent pRb negative status and cyclin D1 overexpression; concurrent pRb negative, cyclin D1 overexpression, and p53 mutation; concurrent cyclin D1 overexpression and p53 mutation.

The p16[INK4A] gene, located on chromosome 9p21, is a tumor suppressor gene that encodes a cyclin-dependent kinase (CDK) inhibitor (see also Chapter 14). Normally, p16 binds to the cyclin D/CDK4/6 complexes to inhibit phosphorylation of the Rb protein, thereby inhibiting G1→S progression. In a recent analysis of tumors from patients with histologically proven N2 NSCLCs, the immunohistologic presence of both p16 and p21 protein correlated with improved long-term survival.[40]

Similarly, dysfunctional or absent p16 expression can result in unchecked progression through the cell cycle. p16 plays a prominent role in NSCLC; inactivation is present in 40% to 70% of NSCLCs. Mechanisms of p16 inactivation include point mutations or deletions in coding regions, as well as epigenetic silencing by hypermethylation of the gene promoter cytosine-guanine-phosphate (CpG) island. Alteration and inactivation of p16 are associated with a number of clinical correlates in NSCLC, including metastases, poor prognosis and overall decreased survival.[41–44]

**The cyclins, p21[WAF1/CIP1], and p27**    Other cell cycle regulatory genes of interest include cyclin D1, cyclin E, cyclin B1, p21[WAF1/CIP1], and p27. Cyclin D1 plays a role in cell cycle regulation by allowing transition from G1 to S phase. Although overexpression of cyclin D1 occurs in 25% to 47% of NSCLC, its prognostic effects are somewhat controversial. In some studies, overexpression has been correlated with the presence of lymph node metastasis, advanced pathologic stage, and shorter overall survival.[38,45] However, other investigators have reported favorable outcomes associated overexpression of cyclin D1.[5,46]

Cyclin E helps to regulate entry into the S phase of the cell cycle by formation of a complex with CDK2 and subsequent phosphorylation of pRb. High levels of cyclin E expression in NSCLC are found in up to 53% of NSCLCs, and have been correlated with tumor invasion, unfavorable prognosis, and decreased patient survival.[47,48] The cyclin B1/CDC2 complex regulates the G2-M phase checkpoint of the cell cycle. In early stage NSCLCs, overexpression of cyclin B1 occurs more commonly in tumors of squamous histology, and high levels of expression have been linked to shorter survival.[49]

p21 and p27 belong to the Cip/Kip family of CDK inhibitors, which bind to and inactivate CDKs in times of cellular stress, hypoxia, DNA damage, and in response to growth inhibitory signals (also reviewed in Chapters 5 and 14). p21[WAF1/CIP1] can inhibit cell cycle progression at multiple sites. Early in G1, p21[WAF1/CIP1] binds to the cyclin D/CDK4 and cyclin E/CDK2 complexes. Prior to transition from S phase to G2, p21[WAF1/CIP1] can inhibit the cyclin A/CDK2 complex. Although some authors determined that p21 expression was associated with improved survival, others found no relationship.[50–52] p27[Kip1] interacts with both cyclin D1 and cyclin E to regulate the cell cycle. Several studies have

employed immunohistochemical techniques to determine p27 expression; decreased levels of p27 expression have been uniformly correlated with poor prognosis in NSCLC.[53–55]

## Protein Kinases

**EGFR** The epidermal growth factor receptor (EGFR) family (also reviewed in Chapters 5 and 49) includes a group of tyrosine kinases whose activation results in a cascade of downstream signals that ultimately enhance cellular proliferation, tumor cell motility and angiogenesis, and decrease apoptosis.[56] Although EGFR is overexpressed in many epithelial cancers, including 40% to 80% of all NSCLCs, these aberrations are rare in SCLC.[57] Downstream targets of EGFR activation include the *ras* and *raf* pathways that directly regulate gene transcription and cellular proliferation. Another gene targeted by EGFR activation is the serine threonine kinase *Akt*, which acts as a key regulator of cellular survival through suppression of apoptosis.[58]

EGFR mutations in lung cancer are associated with nonsmokers, women, patients from East Asian countries, adenocarcinoma histology, and, specifically, bronchoalveolar subtype.[59–63] In addition, tumors with *k-ras* mutations (associated with tobacco exposure) and those with EGFR mutations appear to be mutually exclusive.[60,63] It was initially thought that EGFR tyrosine kinase inhibitors such as erlotinib and gefitinib might revolutionize the treatment of patients with overexpression of EGFR in NSCLC. However, clinical studies have demonstrated significant responses in only specific subsets of patients, limiting gefitinib to use as a second- or third-line agent and erlotinib as a first-line agent specifically for elderly patients and those with EGFR mutations.[64,65]

The impact of EGFR mutation and overexpression on lymph node metastasis, patient prognosis, and overall survival is controversial. Gene amplification often occurs with EGFR overexpression (as opposed to transcriptional or translational modification), and this has been associated with lymph node metastasis and advanced pathologic stage.[66] Although many have found that EGFR mutation and overexpression correlates with worse survival in NSCLC, other studies report no significant association between the two.[59,63] A recent metaanalysis of 16 studies found that immunohistologic expression of EGFR does not correlate with overall prognosis in patients with NSCLC.[67]

**ErbB2/HER-2/neu** Another member of the protein kinase gene family is *ErbB2/Her2/neu*. Screening studies for mutations in the kinase domain of *ErbB2/Her2/neu* in NSCLCs have revealed that mutations in squamous cell carcinomas are rare, but found in approximately 10% to 30% of adenocarcinomas.[68–70] As with mutations of EGFR, mutations of *ErbB2/Her2/neu* are more common in nonsmokers than in smokers.[63] *ErbB2/Her2/neu* overexpression has been associated with early tumor recurrence, chemotherapeutic drug resistance, poorer prognosis, and overall shorter survival time.[71–74]

## Angiogenesis and Growth Factors

(see also Chapters 8 and 48) For tumors to grow, they must obtain oxygen and nutrients. Tumors greater than ~1 mm in size cannot depend on simple diffusion and therefore must create a vascular supply to meet these metabolic demands. VEGF is a potent growth factor for endothelial cells, promoting angiogenesis by increasing vascular permeability and stimulating endothelial cell proliferation. The VEGF receptors, VEGFR-1, -2, and -3, are tyrosine kinases. VEGF expression has been demonstrated in NSCLCs and is stimulated by tissue hypoxia, other growth factors, and cytokines.[75,76]

The presence of VEGF in NSCLC tumors of all stages has been uniformly correlated with poorer prognosis and impaired survival.[77] Bevacizumab (Avastin) is a humanized monoclonal antibody that binds to circulating VEGF and inhibits its interaction with the VEGF receptors. The Eastern Cooperative Oncology Group (ECOG) phase III trial E4599 demonstrated an overall survival benefit for patients with advanced stage adenocarcinoma who received bevacizumab in addition to paclitaxel and carboplatin.[78] Another phase III trial, the European AVAstin in Lung cancer (AVAiL) trial, demonstrated a favorable progression-free survival for patients with nonsquamous NSCLC receiving bevacizumab in addition to cisplantin and gemcitabine.[79] In addition to other studies of bevacizumab in NSCLC, several multitargeted tyrosine kinase inhibitors are under clinical investigation. Targets of interest include several VEGF receptors, EGFR, platelet-derived growth factor (PDGF), raf, and kit.

Interleukin-8 (IL-8) also has angiogenic properties in NSCLC.[80] IL-8 expression in tumors has been correlated not only with angiogenesis and microvessel density, but also with advanced stage, lymph node metastasis and overall patient prognosis.[81] Other growth factors of interest include PDGF and basic fibroblast growth factor (bFGF). PDGF increases DNA synthesis, tumor growth, and endothelial cell migration; it has been correlated with decreased 5-year survival for patients with resected primary lung adenocarcinomas.[77,82] FGF2 stimulates tumor growth and angiogenesis, and in vitro studies have established a synergistic effect of FGF2 and PDGF.[83]

## The Matrix Metalloproteinase Family

The matrix metalloproteinase (MMP) family is a group of proteolytic enzymes associated with degradation of extracellular matrix and penetration of basement membranes, two key elements in the metastasis of tumors. MMP-2 (also known as gelatinase A) has been associated with lymphatic and vascular invasion of NSCLC.[84] Overexpression of MMP-2, as measured by immunohistochemical analysis, has been identified as a negative prognostic factor in lung cancer survival.[85] Similarly, differential levels of MMP-7 expression were found between resected squamous cell carcinomas and adenocarcinomas, with higher levels in the squamous cell carcinomas.[86] MMP-7-positive status was significantly associated with poor prognosis and shorter overall survival. In contrast, the data regarding MMP-9 are controversial. Although some studies suggest a negative prognostic influence of MMP-9, others have found no significant relationship between the two.[87–89]

Recently, Sienel et al.[90] described a role for the extracellular matrix metalloproteinase inducer (EMMPRIN) in determining prognosis for lung adenocarcinoma. EMMPRIN is a transmembrane glycoprotein that has been shown to stimulate synthesis of several MMPs, including MMP-1, -2, -3, and -9. EMMPRIN expression was determined in a cohort of NSCLCs using immunohistochemical staining, and a score was assigned to each specimen. Furthermore, investigators recorded either a membranous or cytoplasmic pattern of staining. For patients with adenocarcinoma, a membranous staining pattern was independently associated with poor prognosis, defined as either local recurrence or distant metastasis. These relationships were not significant for other histologic subtypes.

Maspin is a member of the serpin (serine protease inhibitor) family and has been shown to be a suppressor of tumor growth and metastasis in several types of tumors. Maspin can inhibit invasion and metastasis of malignancies, although direct evidence of the clinicopathologic significance of cytoplasmic relative to nuclear expression is limited. Cytoplasmic and nuclear expression patterns of maspin are involved in the cellular differentiation of normal lung tissue and the histogenesis of different lung carcinomas. The cytoplasmic maspin may play an important role in lung carcinomas by regulating apoptosis and thus is a favorable prognostic marker for AD patients, whereas the nuclear location may be linked to promotion of angiogenesis. Immunohistochemistry reveals that maspin expression is virtually universal in NSCLC, but squamous cell carcinoma show almost exclusively a combined nuclear-cytosolic stain. In contrast, nuclear maspin, but not combined nuclear-cytoplasmic maspin, significantly correlates with low histological grade, lower proliferative rate, absence of invasion, and negative p53 stain in ACa. Nuclear localization of maspin may thus stratify subtypes of NSCLC with favorable clinical–pathological features.[91–95]

## GENE EXPRESSION ARRAYS

The development of gene expression microarrays has enabled investigators to move beyond analysis of single genes and not only explore patterns or profiles of gene expression in tissues but also compare these patterns between tissue types. These gene expression profiles have been shown to be consistent between institutions, with good comparability of sample characteristics.[96,97] Examining the expression profiles of tumors allows for novel identification of genes previously not associated with malignancy. In addition, comparing expression profiles between groups of patients has enabled investigators to perform molecular phenotyping and classification of tumors. Unique and characteristic profiles have been identified not only for the histologic types of NSCLC, but also for subgroups within these histologic classes.[98–101]

There are other potential uses for data acquired from microarray-derived gene expression profiles. Correlating these profiles with defined tumor behavior may help to elucidate specific processes or pathways involved in carcinogenesis. For example, profiling invasive and metastatic tumors may reveal novel genes or pathways of interest that could subsequently be targeted for anticancer therapeutics. Also, these methods may be used to investigate a tumor's response (or nonresponse) to therapy, elucidating possible mechanisms of drug resistance and providing a basis for predicting future clinical behavior (see Chapter 47).

Gene expression profiles have also been used to refine and predict prognosis and survival among patients with identical TNM staging but differing clinical outcome,[102,103] and is the focus of this chapter. Other uses include identification of novel biomarkers associated with and specific to lung tissue and/or NSCLC.[104] In the current era of molecular therapeutics, there is potential to use these gene expression profiles and biomarkers not only to classify tumors with molecular staging techniques, but also to identify targets for therapy and treatment. As these techniques continue to develop, it is possible that lung cancer staging, and therefore treatment, will depend not only on TNM status but also on the genetic profiles generated by these methods.

**Lung Cancer Heterogeneity**   Clinically, lung cancer is classified as small cell (SCLC) and non–small cell (NSCLC), with NSCLC accounting for approximately 80% of all lung cancers. Within each histologic subtype, there is significant heterogeneity such that NSCLCs are further classified as adenocarcinoma, squamous cell carcinoma, large cell carcinoma, and neuroendocrine carcinoma as well as tumors with mixed histology such as adenosquamous tumors.[105] Among adenocarcinomas, further variation is present in acinar, papillary, bronchoalveolar carcinoma (BAC), and mucinous carcinoma subtypes. For example, BAC appears to arise from type II pneumocytes and is generally associated with better prognosis compared with invasive adenocarcinomas.[106]

The heterogeneity among primary lung tumor subtypes likely reflects the potential cell derivation, and these differences may be further increased by the diverse genetic alterations observed in lung cancers.[107–110] Additional tumor heterogeneity may be a result of alterations in gene expression that affect diverse processes such as proliferation, apoptosis, and cellular differentiation, among others.[111,112] To this end, gene expression profiling methods have been employed to better understand this heterogeneity and to identify specific pathways or genes that might distinguish tumors of different cellular origin or clinical behavior.

One of the first studies of gene profiling for lung cancer was performed by Petersen et al.[113] Comparing a metastatic lung adenocarcinoma with human small airway epithelial cells, cDNA libraries of upregulated and downregulated genes were constructed. DNA sequencing of over 500 clones revealed 315 unknown and 205 known cDNA fragments. Gene expression analysis of 167 of these clones was performed using northern blot techniques, confirming differential expression in 58% of the clones. In addition, an expression pattern similar to that of the metastatic adenocarcinoma was observed in lung cancer cell lines. No primary lung tumors were examined in this study.

Garber et al.[114] performed a more global analysis of gene expression using 23,100 element cDNA arrays and 12,600 transcript containing oligonucleotide arrays. Samples in this study

included 41 adenocarcinomas, 16 squamous cell carcinomas, 5 large cell carcinomas, and 5 small cell lung tumors. In addition, there were 11 tumors with corresponding lymph node or intrapulmonary metastasis as well as 5 normal lung samples. Hierarchical clustering was performed on a subset of genes representing only 918 of the 23,100 transcripts. These methods distinguished relatively distinct groups of squamous cell, small cell, and large cell carcinomas; in addition, three groups of adenocarcinomas were recognized. These results suggested that the histologic origin of these tumors was reflected in the expression patterns determined by these 918 genes. Furthermore, the authors suggested that the division of adenocarcinomas into three groups reflects tumor heterogeneity within this subgroup of NSCLC and that cumulative patient survival differed between these clusters. It should be noted, however, that clinical factors such as differentiation, grade, or tumor stage were not used in determining the three groups. In addition, most of the paired samples of primary and metastatic tumors demonstrated relatively similar gene expression patterns. Specific genes differentially expressed in the three adenocarcinoma clusters included VEGFc (highly expressed in the poor outcome group) and thyroid transcription factor (highly expressed in the good outcome group). These results are consistent with known information regarding VEGF expression, differentiation status, and prognosis for patients with lung adenocarcinoma.[2,76,99]

Bhattacharjee et al.[99] also utilized gene expression profiling to classify lung tumors into histologic subtypes. Using oligonucleotide arrays, they examined 125 adenocarcinomas, 21 SCCs, 20 carcinoid tumors, 6 SCLC tumors, and 17 normal lung samples. Hierarchical and probabilistic clustering of the 3312 most variably expressed transcripts separated the tumors into distinct clusters, which reflected their histologic subtype. In addition, primary lung tumors were distinguished from adenocarcinomas of colonic origin metastatic to the lung based on their expression profiles.

Specific genes with high expression levels in each histologic group were identified. Marker genes such as TGF-$\beta$ receptor type II, tetranectin, and ficolin 3 characterized normal lung samples. Both carcinoid tumors and small cell tumors expressed high levels of neuroendocrine genes such as insulinoma-associated gene 1, gastrin-releasing peptide, and chromogranin A. However, few other markers were common between SCLC and carcinoid tumors. For SCLC, high expression of cell proliferation-associated genes such as PCNA, thymidylate synthase, MCM2, and MCM6 was demonstrated. Similarly, carcinoid tumors were defined by a distinct expression profile. A separate clustering of the adenocarcinoma expression profiles defined four subclasses, C1 to C4. Consistent with the Garber et al.[114] study, many of the genes associated with each of the four clusters appeared to reflect tumor differentiation status or stage-related differences. In addition, Kaplan-Meier analysis revealed a significantly worse median overall survival for patients in the C2 subgroup, comprised of tumors with high expression levels of neuroendocrine genes.

Nacht et al.[114a] investigated patterns of gene expression in NSCLC using serial analysis of gene expression (SAGE).

Libraries were established from normal human bronchiole epithelial cells, small airway epithelial cells, two squamous cell carcinomas, two adenocarcinomas, and the A549 lung adenocarcinoma cell line. From these samples, 18,300 independent clones were sequenced and 574,634 tags were generated, representing 66,502 distinct transcripts. Adenocarcinomas demonstrated high levels of the CD74 antigen, major histocompatibility complex (MHC) class II, and immunoglobulin (Ig) heavy constant $\gamma$3, whereas genes highly expressed in squamous cell tumors included glutathione peroxidase 2 (GPX2) and tumor necrosis factor receptor subfamily member 18. Consistent with other studies, high levels of surfactants A and B were observed in adenocarcinoma; however, this likely reflects the differences in the cell type derivation of these tumors.[99,114] Additional investigation was performed on 10 NSCLCs, 4 normal controls and a larger panel of 32 normal lung and lung tumors using both real-time reverse transcription polymerase chain reaction (RT-PCR), and 12,600-element containing (U95) oligonucleotide arrays. Although only a small number of genes were compared by both approaches, 21 of 23 exhibited similar expression patterns as determined by both SAGE and the oligonucleotide-based techniques. Although the basic molecular features of adenocarcinoma and squamous cell carcinoma can be distinguished by gene expression profiling, the authors suggested that the histological and clinical behavior of the tumors may depend on more subtle changes in expression levels for a variety of genes and pathways.

Several studies have used gene expression arrays to determine differences between matched tumor and normal samples. Using differential cDNA library screening, McDoniels-Silvers et al.[115] examined differentially expressed genes between primary lung adenocarcinoma, SCC, and corresponding normal lung tissues. Dot-blot hybridization techniques confirmed that 1163 clones were differentially expressed between the normal and tumor tissues. Using RT-PCR methods, the authors confirmed that 113 genes were differentially expressed between normal and tumor tissues, some of them underexpressed or overexpressed in tumors relative to normal lung, or selectively expressed in adenocarcinoma versus squamous cell carcinoma. With this approach, genes that were highly overexpressed were selected with the greatest frequency. In addition to some genes with unknown functions, the gene identified as highly overexpressed included genes involved in glycolysis, cell respiratory complex, inflammation, and cell adhesion.

Nakamura et al.[116] used 425 element cDNA arrays to examine stage I tumors, including both adenocarcinoma and squamous cell carcinoma, for genes that are differentially expressed between tumors and corresponding noncancerous lung tissue. In the tumor samples, 74 genes were underexpressed and 40 genes were overexpressed when compared to normal controls. Elevated expression of plasminogen activator, MMPs 1, 3, 7, and 10 and keratins 4, 6B, 8, 13, 14, 19, and 20 were observed in the carcinoma group. Conversely, several cell adhesion–related genes including cadherin 5, cadherin 6, protocadherin 2, catenin beta 1, integrin beta 1, and CD31 had decreased expression in the tumor group.

Wikman et al.[117] described the use of arrays containing 1176 genes to compare fourteen lung adenocarcinomas with normal lung tissue as well as lung tissue from four normal references. Two statistical methods, principal component analysis and permutation tests, were used to identify the most differentially expressed genes between the tumors and normal tissues. Three main groups of genes were identified to be dysregulated most frequently: those involved in cell motility and structure, matrix maintenance and degradation, and cell cycle regulation. Genes upregulated in tumors relative to normal samples included known tumor markers such as *topoisomerase 2A (TOP2A), KRT19, KRT8, tenascin, polo-like kinase (PLK) 1,* and *cyclin B1 (CCNB1).* In addition, *MMP11, MMP12,* and tissue inhibitor of metalloproteinase 1 *(TIMP1)* were upregulated in the tumors, whereas *TIMP3* was downregulated. For lung cancer, previous reports have demonstrated high levels of expression of MMP genes, whereas TIMP3 is subject to epigenetic silencing by methylation.[118–120] In addition, the elevated mRNA expression of cytokeratins *(KRT8, 18,* and *19)* was consistent with the gene profiling studies of others.[102,121] Other genes elevated in the adenocarcinoma group included *CCNB1,* macrophage migration inhibitory factor *(MIF),* high-mobility–group protein Y (HMGI) and hepatocyte-derived growth factor *(HDGF).* Genes that were downregulated in the tumors included *SOCS2* and *SOCS3,* caveolins 1 and 2, gravin, and the mitogen-responsive phosphoprotein *DOC2/DAB2.*

## Gene Expression Arrays and Prognostication

Several studies have correlated results from gene expression arrays with patient prognosis. In a study of 19 stage I and II adenocarcinomas, Miura et al.[122] used cDNA microarrays to examine tumors from 14 smokers versus 5 nonsmokers; among these patients, 6 were 5-year survivors and 12 died of lung cancer recurrence. Gene expression patterns differed between the smokers and nonsmokers. Several genes exhibiting lower levels of expression in smokers were those located in known regions of genomic imbalance for NSCLC such as chromosome 3p21.3.[123] Other genes with lower expression among smokers were located in chromosomal regions 4q, 11q23–24, 19p, and19q. The authors suggested that inactivation of these genes was related to tobacco carcinogenesis. In addition, tobacco-related carcinoma was associated with high expression levels of RAB4, DJ1, MCT, and ribosomal protein L22. Of the genes examined, 27 genes were differentially expressed between nonsurvivors and survivors. Fourteen genes had high expression levels in nonsurvivors, including anaphase-promoting complex 2 (APC2). In contrast, expression levels of the mitotic spindle checkpoint regulatory genes hBUB3 and hZW10 were lower in tumors from nonsurvivors, highlighting the importance of cell cycle regulation in human carcinogenesis.

Wigle et al.[124] utilized 19,200 element-containing cDNA arrays and examined 39 NSCLCs that showed either cancer recurrence or no recurrence. The cohort included adenocarcinoma and squamous cell carcinoma as well as other histologic subtypes; stage I, II, and III lung cancers were included. Based on unsupervised hierarchical clustering of a subset of 2899 genes, two groups differed significantly in disease-free survival. Genes associated with a more aggressive NSCLC behavior included ataxia telengiectasia mutated (ATM), upregulation of the flt1 VEGF receptor, and phosphoinositide-3-kinase regulatory subunit (PIK3R2). Using Cox proportional hazards model testing, investigators determined 22 genes that were significant for disease-free survival.

Beer et al.[102] examined 86 lung adenocarcinomas using oligonucleotide arrays (HuGeneFL) containing 6800 transcripts. Sixty-seven of the samples were stage I tumors, whereas 19 were stage III; 10 samples of normal lung tissue were also examined. Three clusters of tumors were identified using hierarchical clustering and other supervised analytical approaches. Significant relationships were observed between cluster and tumor differentiation as well as cluster and tumor stage. Suggesting that the gene expression profile of some early stage tumors is similar to that of more clinically aggressive tumors, the authors noted that some of the stage I adenocarcinomas clustered with higher stage tumors. To help determine which genes were best related to patient prognosis, a 50-gene "risk index" based on the top 50 survival-related genes was devised. Using this approach, low- and high-risk stage I adenocarcinomas that differed significantly with regard to survival were correctly identified.

The survival-related genes identified in this study were broadly grouped into the following categories: cell cycle and cell signaling related; apoptosis related; transcription and translation; cell adhesion and structure; genes encoding chaperones, receptors, enzymes, and transcription factors; and those with unknown function. Genes of particular interest included VEGF, keratin 7, cathepsin L, and the CRK oncogene. Other lung cancer profiling studies had reported elevated expression of cathepsin L and keratin 7 genes in aggressive tumors.[99,114] In addition, VEGF has been previously identified as being associated with poor prognosis lung cancer.[2,76]

Kikuchi et al.[125] and Inamura et al.[126] identified genes associated with lymph node metastasis among primary lung ADs, and Hoang et al.[127] identified genes associated with nonmetastatic tumors, those with micrometastases, and those with overt metastasis. Xi et al.[128] used the Bhattacharjee et al.[99] (see previous discussion) and the Beer et al.[102] (see discussion on prognosis later) datasets to examine whether gene expression in primary AD tumors was indicative of lymph node metastases. A 318-gene signature was able to accurately classify node positive patients in the training[102] and test[99] sets, but frequently misclassified node negative patients. The classification as node negative or positive in the node-negative patients was associated with survival. These studies suggest that the survival differences observed among stage I ADs in the Garber et al.[114] and Bhattacharjee et al.[99] datasets might be related to the presence of micrometastases or metastatic potential. The use of gene expression for "molecular staging" may enhance the sensitivity of clinical and pathologic methods for staging tumors, improving treatment decisions and ultimately outcomes for lung cancer patients.

Several studies using the primary lung tumor to predict lymph node metastases Kikuchi et al.[125] examined 37 NSCLCs using cDNA microarrays containing 23,040 genes. The initial

data set was trimmed to 899 genes and investigators used hierarchical clustering methods to separate the tumors into groups based on their histologic subtypes. Next, the investigators established a predictive scoring system based on the expression profiles of selected genes. When used to calculate the predictive score, 40 genes provided the best separation of node-positive and negative adenocarcinomas. Previous studies have reported an association between tumor metastasis and several of the genes used to calculate the predictive score: ARHA, DB1, NESH, and TACSTD1.[129–132] Finally, the authors studied the expression of the metastasis-related genes after treatment with six different chemotherapeutic agents: cisplatin, docetaxel, gemcitabine, irinotecan, paclitaxel, and vinorelbine. Analysis revealed a number of genes correlating the sensitivity of the adenocarcinomas or SCC to the six drugs. In particular, YWHAQ gene expression levels correlated with the sensitivity of lung adenocarcinomas to cisplatin, docetaxel, gemcitabine, and paclitaxel. Xi et al.[133] used the Bhattacharjee et al.[99] (see previous discussion) and the Beer et al.[102] datasets to examine whether gene expression in primary adenocarcinoma tumors was indicative of lymph node metastases. A 318-gene signature was able to accurately classify node-positive patients in the training and test[99] sets, but frequently misclassified node negative patients. The classification as node negative or positive in the node-negative patients was associated with survival. These studies suggest that the survival differences observed among stage I adenocarcinomas might be related to the presence of micrometastases or metastatic potential.

In 2006, Potti et al.[134] reported the use of gene expression arrays to develop a risk model of recurrence for early stage lung cancers. Using an initial set of 89 NSCLCs, which included both squamous cell carcinoma and adenocarcinoma, investigators first established a collection of gene expression profiles, which they termed *metagenes*. Prognostic models were built from the metagenes using classification- and regression-tree analysis. In the initial training cohort, the metagene model predicted disease recurrence with an accuracy of 93%, compared with 64% as predicted by the prognostic model built with clinical data alone. These data were supported in Kaplan-Meier survival analyses. Validation of the metagene model was performed on two independent cohorts from multicenter cooperative group trials, the American College of Surgeons Oncology Groups (ACOSOG) Z0030 study and the Cancer and Leukemia Group B (CALGB) 9761 trial. With these results, investigators described a possible role for predicting disease recurrence for patients with early stage lung cancers, thereby identifying patients for whom adjuvant chemotherapy might otherwise not be indicated.

More recently, Chen et al.[135] reported the use of gene expression arrays to develop a five-gene model for prediction of relapse-free and overall survival in lung cancer. Expression arrays were used on 125 tumors. Through Cox regression analysis and calculation of hazard ratios (HR), 16 genes were correlated with death from any cause. Risk scores were calculated for these 16 genes and patients were classified as having a high- or low-risk gene signature. Expression levels of the 16 genes were confirmed by RT-PCR and further statistical analysis

identified 5 genes that were significantly associated with patient survival: monocyte-to-macrophage differentiation-associated protein (MMD), dual-specificity phosphatase 6 (DUSP6), v-erb-b2 avain erythroblastic leukemia viral oncogene homologue 3 (ERBB3), signal transducer and activator of transcription 1 (STAT1), and lymphocyte-specific protein tyrosine kinase (LCK). Some of these have previously been described as playing a role in carcinogenesis: DUSP6 has been implicated in tumor suppression and apoptosis; ERBB3 is a tyrosine kinase and member of the EGFR family; STAT1 has been implicated in cell growth and apoptosis through induction of p21[Waf1] and caspase; and LCK is a member of the Src family of tyrosine kinases and has been shown to regulate mobility of cancer cells.[136–142] The predictive value of the five-gene signature was subsequently validated on an independent cohort of 60 additional patients. Compared to those with a low-risk gene signature, patients with a high-risk gene signature had a significantly shorter median survival. Results were similar when patients with stage I disease were examined separately; however, there was no correlation between gene signature and overall survival for patients with stage II disease. An insightful editorial regarding this work was published by Herbst and Lippman[143] who pointed out that since the specimens were not microdissected, the analysis could be misleading with regard to the importance of invasion-related genes, which can vary in expression throughout a tumor. Moreover future studies must analyze molecular epidemiologic, stromal, and vascular factors that are critical to the metastatic process. Finally, the choice of the cutoff of expression levels and filtering of the data could influence how the genes were selected. Nevertheless, further validation studies on a set of 86 tumors previously analyzed by another group[102] also demonstrated a significant risk for death from any cause with the high-risk gene signature as well as a trend toward significance when analyzed for survival.

**Reproducibility of Data**   One challenge in the use of gene expression arrays for prognostication in lung cancer is the reliability of platforms across institutions and reproducibility of data or identification of candidate genes involved in prognosis across institutions. Some investigators have addressed this by validating their predictive models with cohorts from outside studies and institutions.[135,144] In an effort to investigate the variability between laboratories and across institutions, Dobbin et al.[97] reported both "within-laboratory" and between-laboratory reproducibility of microarray data across four institutions for a set of primary tumors, lung cancer cell lines and purified RNA samples. Although the between-laboratory variation was highest, the investigators concluded that the reproducibility, and therefore, the comparability of the data were adequate for the samples studied.

Hayes et al.[100] evaluated three cohorts of adenocarcinomas, each from a different institution and with its own gene array platform. Statistical analysis identified 2553 genes that were present and reliable across the three platforms. Adenocarcinoma tumor subtypes, named bronchioid, squamoid, and magnoid

by the authors, were each distinguished by several hundred genes. Lists of genes characteristic of tumor subtype in one cohort were predictive of tumor subtypes in the other two cohorts. While investigators were able to analyze survival data for only one cohort of patients, patients with stage I and II tumors had significantly shorter survival times when their tumors were classified as squamoid and magnoid. In contrast, for patients with stage III and IV tumors, there was a trend toward increased survival for patients with squamoid subtype.

Sun et al.[145] used two lung cancer oligonucleotide microarray data sets of adenocarcinoma and squamous cell carcinoma as training sets to select prognostic genes independent of conventional predictors. The top 50 genes from each set were used to predict the outcomes of two independent validation data sets of 84 and 91 NSCLC cases. Adenocarcinomas with the 50-gene signature from *adenocarcinoma* in both validation data sets had a 2.4-fold (95% confidence interval [CI], 1.3 to 4.4 and 1.0 to 5.8) increased mortality after adjustment for conventional predictors. Squamous cell carcinoma with the same high-risk signature had an adjusted risk of 1.1 (95% CI, 0.4 to 3.2) in one data set and 2.5 (95% CI, 1.1 to 5.8) in another. Adenocarcinoma with the 50-gene signature from *squamous cell carcinoma* had an elevated risk of 3.5 (95% CI, 1.4 to 9.0) after adjustment for conventional predictors. Squamous cell carcinoma with this high-risk signature had an adjusted risk of 1.8 (95% CI, 0.7 to 4.6). The authors thus illustrated that two nonoverlapping but functionally related gene expression signatures provided consistently improved survival prediction for NSCLC regardless of the histologic cell type.

Skrzypski et al.[146] studied the expression of 29 progression and metastasis genes derived from previous lung cancer microarray data. Their expression was assessed by reverse transcriptase quantitative PCR in frozen primary tumor specimens obtained from 66 SCC patients who had undergone surgical resection.

In a multivariate Cox model, the genes CSF1 (HR, 3.5; $p = 0.005$), EGFR (HR, 2.7; $p = 0.02$), CA IX (HR, 0.2; $p < 0.0001$), and tumor size $>4$ cm (HR, 2.7; $p = 0.02$) emerged as significant markers for survival and the expression of the three genes (CSF1, EGFR, and CA IX) as risk factors was positively validated in a separate cohort of 26 patients in an independent laboratory ($p = 0.05$)

Raz et al.[147] generated a four-gene model based on expression of WNT3a, ERBB3, LCK, and RND3 that was used to generate a risk score. The Gene Risk score predicted mortality better than clinical stage or tumor size (adjusted HR, 6.7; 95% CI, 1.6 to 28.9; $p = 0.001$). Among 70 patients with stage I disease, 5-year overall survival was 87% among patients with low-risk scores, and 38% among patients with high-risk scores ($p = 0.0002$). Among all patients, 5-year overall survival was 62% and 41%, respectively ($p = 0.0054$). Disease-free survival was also significantly different among low- and high-risk score patients.

Most recently, Shedden et al.[148] reported results from a large retrospective multisite, blinded study of 442 lung adenocarcinomas designed to test the prognostic performance of gene microarray data alone versus performance with the inclusion of clinical covariates. Data were generated using a common platform, and training set data were generated at two of the participating sites. The results were validated using independent data generated from two additional sites after a blinded protocol. Eight different methods, including gene clustering, univariate testing, and mechanistic groupings, were used to provide prognostic data. Many genes were identified as important for prognosis in more than one statistical method, including those involved in cell proliferation such as cyclins, checkpoint genes, topoisomerases, and chromosomal and spindle protein genes. The most successful classifier methods incorporated both gene expression and clinical data, and the investigators stressed the importance of coordinating the collection of both clinical and pathologic data across multiple institutions for future prospective studies.

## EPIGENETIC SILENCING AND GENE METHYLATION

In addition to the role of genetic alterations in the pathogenesis of lung cancer, epigenetic modification, or DNA methylation, also plays a key role in human carcinogenesis (see also Chapter 7). Gene promoter regions have CpG islands that are subject to aberrant hypermethylation by cytosine-DNA methyltransferases. When this occurs, the composition of chromatin around the island is modified, and access to the promoter region by key regulatory proteins involved in transcription is denied. Through the amplification of methylated alleles in the promoter region of specific genes, the methylation-specific PCR (MSP) assay allows for rapid detection of methylation in genes of interest. As a result, several key genes have been identified, which are altered by DNA methylation in the development of lung cancer.

Genes involved in all aspects of cellular function—regulation of cell cycle, DNA repair, *RAS* signaling and invasion, apoptosis—are affected by epigenetic silencing in the development of NSCLC. Methylation of the death-associated protein kinase (DAPK) is found in up to 48% of adenocarcinomas and approximately 25% to 33% of squamous cell carcinomas.[149] *DAPK* is a serine/threonine kinase involved in apoptosis resulting from DNA damage, through TNF-α, FAS-, or γ-interferon–associated pathways, or by downstream activation of p53. An association has been made between methylation of DAPK and increasing pathologic stage in NSCLC[150]; for those patients with resected stage I tumors, methylated DAPK has been associated with poorer disease-specific and overall survival.[151]

The family of cadherins includes cell-surface glycoproteins, which are responsible for adhesion and cell recognition. Two of these, *E-cadherin* and *H-cadherin*, are methylated in NSCLC. Methylation of *E-cadherin* ranges from 16% to 45%, whereas that of *H-cadherin* was found in approximately 43% of NSCLCs.[152,153] Impaired or absent expression of E-cadherin has been linked to poor differentiation, lymph node metastasis and poorer prognosis and survival in patients with NSCLC.[154] Metastatic potential is also regulated by the tissue inhibitor

of metalloproteinases (TIMPs), which inhibit the proteolytic activity of MMPs. Methylation of TIMPs has been observed in 19% to 26% of NSCLCs.[153]

One of the best studied genes in DNA methylation and NSCLC is p16[CDKN2A]. It is affected in up to 67% of adenocarcinomas and 70% of squamous cell carcinomas.[155] In experimental models of cancer development and progression, methylation of p16[CDKN2A] is an early event in lung carcinogenesis, and its prevalence increases with disease progression.[156] In addition, methylation of p16[CDKN2A] is associated with increased tobacco exposure.[157] In a large study of NSCLCs in which methylation status of five genes was examined, Toyooka et al.[158] determined that only methylation of p16[CDKN2A] was associated with poor survival.

The *RASSF1* gene is a member of a family of genes that encode for *ras*-binding proteins; several different transcripts are produced by alternative promoter selection and splicing. mRNA expression of *RASSF1A* is often lost in NSCLCs; this led to the observation that *RASSF1* is methylated in 30% to 40% of primary NSCLCs.[159,160] However, the association between methylation of *RASSF1A* and patient survival is controversial. While Burbee et al.[159] determined that methylation of *RASSF1A* in lung cancer was associated with shorter overall survival, Toyooka et al.[158] were unable to confirm these findings in a larger study.

In 2003, Harden et al.[161] examined promoter methylation in 90 primary stage I lung cancers and their associated lymph nodes. Methylation at p16 was demonstrated in 15/90 tumors (17%); 14/90 (16%) at O[6]-methylguanine-DNA-methyltransferase (MGMT); 7/90 (8%) at glutathione S-transferase P1 (GSTP1), 15/90 (17%) at the DAPK1 gene, and 65/90 (72%) at the adenomatous polyposis coli (APC) gene. Methylation of both APC and GSTP1 were more often associated with squamous morphology and a worse clinical outcome. Interestingly, data from gene expression profiles have demonstrated significantly diminished levels for *APC* in adenocarcinomas, and that tumors with lower levels of expression showed a trend toward worse outcome.[102]

Gu et al.[162] examined the methylation status in a cohort of 155 patients with stages I to III NSCLC. Nine genes were studied: p16, CDH1, TIMP3, RASSF1A, HFIT, APC, DAPK, MGMT, and GSTP1. The investigators calculated a methylation index (MI), defined as the ratio of the number of methylated genes to the number studied, nine in this case. They determined that the MI was significantly higher in adenocarcinomas relative to SCCs and in patients with >50 pack-year smoking history relative to <50 pack-years. In addition, the MI was higher in older patients (>66 years) relative to the MI of patients younger than 66 years of age. However, there was no difference between early stage tumors and late-stage tumors. Survival analysis revealed that patients with methylation of *CDH1* had a significantly longer survival than those without. In contrast, patients with p16 methylation had worse survival than those without p16 methylation. As the number of unfavorable methylation events increased, the median survival time was significantly diminished.

Recently, Brock et al.[163] demonstrated a relationship between gene methylation, specific combinations of gene methylation and tumor recurrence for patients with resected stage I NSCLC. From a cohort of 71 patients, seven genes were studied from tumor and associated mediastinal lymph nodes sampled at the time of surgery. The four genes with the largest differences in the frequency of methylation between tumors and controls were p16, the H-cadherin gene 13 (*CDH13*), *RASSF1A*, and *APC*. A higher number of methylated genes in each sample was associated with poorer survival. Specifically, patients with two or more methylated genes of interest in either the primary tumor or mediastinal lymph nodes had a 5-year recurrence-free survival rate of 27.3%, compared to 65.3% for patients with fewer than two methylated genes of interest. There was an additive effect to patients whose samples demonstrated methylation of both p16 and *CDH13*. Methylation of both genes in either the primary tumor, regional or mediastinal lymph nodes, was associated with significantly shorter recurrence-free survival. Although these results suggest a possible role for using methylation status as a means of detecting occult micrometastasis, large-scale, prospective, multi-institution studies have yet to be conducted.

## PROTEOMIC ANALYSIS AND PROGNOSTICATION

Proteomic approaches involve the comprehensive investigation of proteins using high-throughput technologies such as two-dimensional (2D) polyacrylamide gel electrophoresis or mass spectrometry (see also Chapter 9). One disadvantage of genomic approaches is the ability to study posttranslational modification of proteins such as phosphorylation, glycosylation, or proteolytic processing. These processes are important not only for determining protein function, but are also dysregulated in malignancy.[164,165] Proteomic approaches may be used to profile tumors through examination of proteome expression; other possible study mechanisms include protein–protein interactions or even specific proteins and their posttranslational modification.

As with genomic strategies, investigators have demonstrated that patterns of protein expression correlate with specific histopathologic features of the primary tumors. In one study using 2D electrophoresis, a group of 52 protein spots differed in intensity between small cell carcinoma, squamous cell carcinoma and adeoncarcinoma tumor specimens.[166] Another study comparing of proteomic patterns between squamous cell carcinoma and corresponding normal tissues identified 76 proteins that were differentially expressed between tumor and normal tissues. The identified proteins were subsequently identified and classified as oncoproteins, signaling molecules, and cell cycle regulators.[167]

Other proteomic analysis of a group of NSCLC tumors with known survival and outcome data revealed a characteristic pattern comprised of 15 mass spectrometry peaks. Using this, investigators were able to distinguish between patients with favorable versus adverse outcomes.[168] In the same study, class-prediction models were able to distinguish primary lung

tumors from lesions metastatic to the lungs (of other organ primary); these methods were also used to identify the presence of tumor metastatic to lymph nodes with 85% accuracy.

Differential expression of specific protein isoforms have been correlated with patient survival in NSCLC. Gharib et al.[169] determined that four cytokeratin types, CK7, CK8, CK18, and CK19, had at least one isoform that was significantly increased in lung adenocarcinoma compared to normal lung tissue. Of these, all five CK7 isoforms, one CK8 isoform and one CK19 isoform were associated with unfavorable prognosis. There was little correlation between these isoforms and other clinicopathologic characteristics. Highlighting the advantages of proteomic analysis, several isoforms were detected for each of the cytokeratin types, suggesting the presence of several levels of regulation and posttranslational modification.

Chen et al.[170] examined 682 protein spots from a cohort of adenocarcinomas. They identified 46 proteins that were significantly associated with patient survival and 33 of these were subsequently identified by mass spectrometry. Of these, increased expression was demonstrated in four proteins and seven mRNAs encoding enzymes in the glycolysis pathway. These were all associated with poor survival, potentially reflecting increased metabolic activity in these tumors. Furthermore, the authors devised a risk index based on the 20 proteins (of the original set of 46) most associated with survival. Using this index, they were able to identify a subset of patients with stage I adenocarcinoma that had significantly worse outcomes.

More recently, Yanagisawa et al.[171] described a proteomic signature of 25 mass spectrometry signals to predict prognosis for NSCLC. First comparing NSCLC tissue and normal lung tissue, they found 694 proteomic signals that were differentially expressed. Based on these 694 signals, groups with high and low risk of recurrence based on clinical data were compared. From this, a weighted voting prognosis signature using 25 proteomic signals was devised to predict patient outcomes. Validation studies demonstrated that for patients with stage I NSCLC, relapse-free and overall survival were significantly different between the high- and low-risk groups as determined by the risk score. This was also true for patients grouped together with stage II or stage III disease, thereby predicting clinical prognosis with relative accuracy.

## MICRORNAS AND PROGNOSTICATION

miRNAs are regulatory RNAs found in humans, plants, and animals where they play a role in regulating important cellular processes such as cell development, proliferation, and even cell death. They are noncoding fragments of RNA that hybridize to complementary gene sequences in the 3′ untranslated region (3′ UTR) of target mRNA. Initially discovered in *Caenorhabditis elegans* miRNAs and their associated proteins are abundantly present in cells.[172] Their role in human carcinogenesis has yet to be clearly defined. However, the gene loci for many miRNAs correspond to fragile chromosomal sites

and abnormal expression of miRNAs have been demonstrated in a number of human cancers including leukemias, lymphomas, colorectal cancer, and lung cancer.[173]

miRNAs are initially transcribed into long precursor RNAs called pri-miRNAs and processed by Drosha, a cellular nuclease, into pre-miRNAs.[174,175] Following transport to the cytoplasm by Exportin-5, the DICER enzyme cleaves the pre-miRNAs, resulting in a mature intermediate measuring 17 to 24 nucleotides long.[176–178] miRNAs can regulate mRNA translation or increase the stability of mRNA, thereby altering the amount of final product.[179] Through posttranscriptional regulation and subsequent alteration of gene expression, miRNAs can affect a number of cellular functions such as cellular differentiation, proliferation, or even apoptosis.[180]

Unique miRNA expression profiles have been described for NSCLC and these have been correlated with patient survival. Comparing lung tumors to noncancerous lung tissue, Yanaihara et al.[181] identified a panel of 43 miRNAs differentially expressed in the lung tumors. Six of these miRNAs were expressed differently between tumors of squamous cell carcinoma and adenocarcinoma histology. Analysis of clinical data demonstrated that high expression of *hsa-mir-155*, *hsa-mir-17-3p*, *hsa-mir-106a*, *hsa-mir-93*, and *hsa-mir-21*, along with low expression of *hsa -let-7-a-2*, *hsa -let-7b*, or *hsa-mir-145* was associated with a significantly worse prognosis for patients with adenocarcinoma. In addition, Kaplan-Meier survival analysis demonstrated that high expression of *hsa-mir-155* was an unfavorable prognostic factor for adenocarcinoma, independent of other clinicopathologic variables. Markou et al.[182] evaluated the prognostic value of mature miRNA-21 (miR-21) and mature miRNA-205 (miR-205) overexpression in NSCLC. We detected overexpression of mature miR-21 in 52% NSCLC specimens and overexpression of miR-205 in 65%. miR-21 overexpression correlated with overall survival of the patients ($p = 0.027$), whereas overexpression of mature miR-205 did not.

In another study, Yu et al.[183] identified a five-miRNA signature from a cohort of 56 NSCLC tumors, which included both squamous cell carcinoma and adenocarcinoma. Two of the miRNAs, *hsa-mir-221*, and *hsa-let-7a*, were protective, whereas *hsa-mir-137*, *hsa-mir-372*, and *hsa-mir-182* were "risky." A risk-score formula was devised based on the expression levels of these five miRNAs. Compared to those with low-risk miRNA signatures, patients whose tumors had high-risk miRNA signatures had significantly shorter median relapse-free survival times and shorter median overall survival times. These findings were validated in the same study using an independent set of samples. In addition, multivariate regression analysis demonstrated that the risk conferred by the miRNA signature was independent of tumor histology. However, when patients were classified by stage, the miRNA signature was predictive only of relapse-free survival in stage I patients. For stage II patients, no statistically significant associations were made, possibly due to small sample size. For stage III patients, the miRNA signature was predictive of both relapse-free survival and overall survival.

A specific subset of miRNA of interest in lung cancer is the *lethal-7* (*let-7*) miRNA family, which is abundantly expressed in normal human lung tissue. In a study of 143 lung cancer cases for which follow-up and survival data were available, Takamizawa et al.[184] demonstrated that reduced *let-7* miRNAs expression was associated with significantly shorter long-term survival, and that this was independent of disease stage. In addition, at least one member of the *let-7* family has been shown to negatively regulate *ras* expression in human cells.[173] These findings suggest a possible mechanism for *let-7* in the pathogenesis of lung cancer, and additional study will further elucidate the role of this and other miRNAs in the development and pathogenesis of lung cancer.

Identifying miRNAs regulators in lung cancer could also improve patient selection for targeted agents in addition to their prognostic potential. Since allelic loss in chromosome 3p is frequent and early in lung carcinogenesis, Weiss et al.[185] investigated if the loss of miRNA-128b, a miRNA located on chromosome 3p and a putative regulator of EGFR, correlated with response to targeted EGFR inhibition. Weiss et al.[185] found that miRNA-128b directly regulated EGFR and that miRNA-128b loss of heterozygosity (LOH) was frequent in tumor samples. Moreover, miRNA-128b LOH correlated significantly with clinical response and survival following gefitinib, while EGFR expression and mutation status did not correlate with survival outcome.

## CLINICAL POTENTIAL AND FUTURE DIRECTIONS

Lung cancer is a complex disease that involves a number of molecular and cellular processes, several of which may be altered in the process of tumor development. In this chapter, we have reviewed a small yet pertinent number of studies demonstrating the potential of molecular biologic techniques to predict prognosis for patients with NSCLC. Currently, the most reliable prognostic method remains clinical staging. As molecular techniques continue to undergo refinement both in predictive capability and reproducibility, it is conceivable that future staging systems will incorporate genetic, proteomic, or miRNA signatures.

However, several challenges need to be addressed prior to everyday use of these molecular techniques. First, continued progress must be made toward reproducibility of testing and profiling of tumors across institutions. Recent contributions from Shedden et al.[148] have demonstrated that interlaboratory and intralaboratory variation can be minimized to provide relatively consistent gene expression profiling data for a set of tumors. To date, similar studies have not been conducted across institutions to validate methylation or proteomic profiles for primary lung tumors and associated lymph nodes.

Another challenge in bringing molecular techniques into everyday clinical use is expanding the application of these techniques beyond the laboratory of the academic medical center to the bedside and practitioner in the community hospital.

Furthermore, most patients with lung cancer are diagnosed at an advanced stage and not considered to be candidates for surgery. In contrast, the vast majority of studies defining molecular profiles for lung cancer have involved patients with early stage tumors who have undergone surgical resection. While profiling techniques are being developed to predict those with resected early stage disease that may benefit from therapy not otherwise indicated, further work is underway to characterize more advanced tumors based on their gene expression profiles and response to chemotherapeutic agents. Molecular techniques may soon be used to select chemotherapeutic agents for patients based on their tumors' molecular chemoresistance profiles.[186] In that case, the challenge will be to generate an accurate molecular profile with minimally invasive sampling techniques or serum-based assays that avoid subjecting the patient to major surgery.

Finally, the heterogeneity of NSCLC tumors creates a significant challenge for the identification and development of effective treatments. Gene expression profiling and other molecular techniques have added much to our understanding of the biology of NSCLC. Targeted therapies such as bevacizumab and erlotinib have demonstrated effectiveness for many of patients with lung cancer. Similarly, an ideal application for gene expression profiling of NSCLC would be to use the expression data to better understand tumor heterogeneity and discover what may be unique properties for specific subsets of these tumors. Future studies have the potential to further enhance our understanding of NSCLC and identify novel pathways and mechanisms in the pathogenesis of this disease. Undoubtedly, this will result in the identification of additional prognostic markers as well as unique targets for development of future therapies, with their clinical application ultimately being used to benefit patients.

# Examining the Cancer Stem Cell Hypothesis in Human Lung Cancers

The cancer stem cell (CSC) hypothesis, which suggests that tumors are maintained by a population of cells possessing stem cell characteristics, has emerged as an attractive explanation for tumor growth, recurrence, and metastasis. CSCs in human leukemia, breast, brain, colon, and pancreatic cancers have been identified in transplantation assays.[1–6] Whereas the incidence of oncogenic mutations, such as those in K-ras or the epidermal growth factor receptor (EGFR), in human lung cancers has been well described, the role of CSCs in lung tumors remains poorly defined. An important goal for lung cancer research is now to determine the role of CSCs in lung tumorigenesis. An improved understanding of the cellular mechanisms of lung CSC renewal should elucidate new therapeutic approaches for lung cancer.

## THE CANCER STEM CELL HYPOTHESIS

Although many current cancer therapies are based on their ability to kill most cells within a tumor, it has been recognized for more than 30 years that not all cells within a tumor are alike. Studies have shown that only a fraction of cells within a tumor can be propagated in patients, mouse transplants, or cell cultures.[7–10] These rare *clonogenic* cancer cells were hypothesized to arise in a stochastic fashion: although the overall occurrence is rare, any cell within the tumor is equally likely to exhibit clonogenic activity. An alternative hypothesis to explain these findings is that a rare subpopulation exists within tumors, and that these rare tumor cells have unique biological characteristics that provide clonogenic activity. In support of the latter hypothesis, it has been recently demonstrated that several types of hematopoietic and solid tumors harbor a distinct subpopulation of cells called CSCs that can propagate the tumor phenotype in vivo.[1–6,11] These cells are called CSCs because the same molecular markers used to isolate the normal tissue stem cells could be used to isolate clonogenic tumor cells in some tissues, the cells could be passaged serially through mice (demonstrating their ability to self-renew, a hallmark property of

stem cells), and the isolated tumor cell population gave rise to a heterogeneous tumor (suggesting an ability to differentiate, a second hallmark property of stem cells).[12]

The CSC hypothesis has also emerged as an attractive explanation for tumor resistance to chemotherapy, recurrence, and metastasis. It has been hypothesized that CSCs have distinct biological mechanisms that render them more resistant to chemotherapy than other cancer cells, explaining the refractory nature of many tumors to treatment.[12–14] Specifically, CSCs are hypothesized to be resistant to chemotherapy because they may be quiescent and may efficiently export drugs, like stem cells in normal tissues.[15] CSCs may also be the cells that are required to generate metastases. For example, the pathways responsible for the dissemination and homing of normal stem cells during development may be aberrantly upregulated in CSCs. Therapeutic strategies that specifically eliminate the CSC population may therefore be more effective than standard means of therapy.[16–19]

## STRATEGIES FOR IDENTIFICATION OF CANCER STEM CELLS

Methods used in identification and characterization of stem cell populations from normal adult tissues have proven to be useful in uncovering CSC populations. The most widely used technique for isolating stem cells has been fluorescent-activated cell sorting (FACS) using a combination of cell-surface markers that select cells with markers of more primitive cells and exclude cells of differentiated cell lineages, followed by transplantation of sorted cancer cells into immunodeficient mice (Table 11.1). For example, CSCs were first identified in human acute myeloid leukemias as the cancer cells that had the same surface marker status as human hematopoietic stem cells (CD34+ CD38−).[1] CD133, a positive marker of hematopoietic stem cells and neural stem cells, has been used as a marker of CSCs from brain and colon cancer.[3–5] CSCs have also been shown to exhibit similarities to normal stem cells

| **TABLE 11.1** | **Summary of Cell-Surface Markers Used to Prospectively Isolate Putative Cancer Stem Cells from Multiple Tissues*** | |
|---|---|---|
| **Type of Cancer** | **CSC Expression Pattern** | **Reference(s)** |
| Leukemia | CD34+ CD38− | 1,89–91 |
| Breast | CD44+ CD24−/low | 2 |
| Brain | CD133+ | 92 |
| Pancreatic | CD44+ CD24+ ESA+ | 44 |
| Colon | CD133+ | 4,6 |
| Head and neck | CD44+ | 93 |
| Lung | CD133+ | 94 |

*The marker-expression patterns used to enrich for cells with tumor-propagating potential from multiple types of cancer are shown.

+, cells expressing this marker; −, cells not expressing this marker; CSC, cancer stem cell; ESA, epithelial-specific antigen.

with regard to their ability to self-renew in serial-plating experiments in culture[5,20–24] as well as their demonstrated activation of developmental pathways known to function in normal stem cells. For example, chronic myelogenous leukemia CSCs exhibit Wnt pathway activation as determined by elevated levels of nuclear $\beta$-catenin,[25] and mixed-lineage leukemia CSCs are granulocyte-macrophage progenitors that share a gene-expression program with hematopoietic stem cells.[24] Several pathways known to be crucial for development, such as the Wnt, Hedgehog, Notch, and Polycomb-group protein pathways, have been implicated in adult stem cell self-renewal, and dysregulation of these pathways contributes to many types of cancer.[26,27]

## NON–SMALL CELL LUNG CANCER

Lung cancer remains the major cause of death from cancer worldwide,[28] and relatively little is known about the molecular heterogeneity of the cells within lung cancers. Lung cancer can be divided into two histopathological groups: 80% are non–small cell lung cancers (NSCLCs), and 20% exhibit neuroendocrine features. NSCLCs can be further subdivided into adenocarcinomas (50% to 60%), squamous cell carcinomas (20% to 25%), and large cell carcinomas. The average 5-year survival rate for NSCLC is only 16% because most lung cancers are refractory to chemotherapeutics or quickly become resistant to therapeutic response.[29] Also contributing to lung cancer morbidity, most NSCLC patients already have advanced diseases at the time of diagnosis; 21% of diagnosed cases have distant metastases in the brain, bone, liver, or adrenal glands.[29–31] Surgery or therapies that treat primary lung tumors rarely prevent metastases. For example, 72% of patients who had NSCLC tumors surgically removed eventually develop distant metastases, most commonly in the bone or brain.[32] Lung CSCs may be responsible for these observations, and an improved understanding of the cellular mechanisms operating in lung cancers should elucidate new therapeutic approaches.

## Therapeutic Resistance of Lung Adenocarcinomas Harboring Epidermal Growth Factor Receptor Mutations

The recent treatment success of gefitinib (Iressa) and erlotinib (Tarceva), two small molecule inhibitors of EGFR, in a fraction of patients with NSCLC has solidified the premise that EGFR is an important molecule in the pathogenesis of lung cancer (see Chapter 49). Several groups have independently identified frequent somatic mutations in the kinase domain of the EGFR gene in lung adenocarcinoma. These occurred in up to 10% of lung adenocarcinoma specimens sequenced in the United States and up to 30% of those sequenced in Asia. The mutations are associated with sensitivity to both gefitinib and erlotinib, explaining in part the rare and dramatic clinical responses to treatment with these agents.[33–35] Subsequent studies by multiple groups have now identified EGFR kinase domain mutations from more than 600 lung cancer patients. These mutations cluster in four groups or regions: exon 19 deletions, exon 20 insertions, and point mutations at G719S and L858R. Exon 19 deletions and exon 21 L858R point mutations account for more than 85% of all EGFR kinase domain gefitinib- and erlotinib-sensitizing mutations.

In the clinical setting, although these EGFR-mutant NSCLCs initially respond rapidly and dramatically to gefitinib and erlotinib, tumors eventually become refractory to treatment, and nearly all patients who initially respond to these drugs subsequently relapse.[36–38] Three studies identified EGFR T790M mutations in approximately 50% of the tumors from patients who relapsed.[39–41] These mutants, when combined with sensitizing EGFR kinase domain mutation, permit the continued growth of tumor cells in the presence of erlotinib and gefitinib. Structural studies suggest that the T790M mutation introduces a bulky methionine residue in the EGFR kinase domain, which sterically hinders tyrosine kinase inhibitor (TKI) binding.[36–38] Whereas gefitinib and erlotinib are reversible inhibitors that mimic adenosine triphosphate (ATP), irreversible inhibitors such as HKI-272 or BIBW2992 mimic ATP and covalently bind to EGFR, enabling them to inhibit EGFR

kinase activity even in the presence of T790M.[42–44] Although irreversible inhibitors are currently being tested in clinical trials, animal models suggest that tumors will eventually become refractory to these treatments as well.[44] Thus, it is crucial to determine the cellular basis of lung adenocarcinoma resistance to treatment and develop new therapeutic strategies that will not be susceptible to resistance mechanisms.

### Evidence for Non–Small Cell Lung Cancer Stem Cells

Several pieces of evidence suggest that NSCLC tumors, including adenocarcinomas, contain a rare population of cells with stem cell characteristics. The initial sensitivity of human adenocarcinomas with activating EGFR mutations to EGFR TKIs and the acquired resistance to these treatments suggest that drug-resistant CSCs may be present in these tumors.[36–38] *Side population cells*, isolated by their ability to efflux Hoechst dye, were identified in six human NSCLC cell lines. These cells exhibit several stem cell characteristics, including increased drug-exporting transporter expression, enriched tumor-initiating capacity, and resistance to multiple chemotherapies.[45] Additionally, CD133+ cells from human lung tumors were recently shown to form self-renewing spheres in culture that could propagate tumors when transplanted subcutaneously into immunodeficient mice.[46] Importantly, although these studies support the likelihood of CSCs in lung cancers, the isolation and characterization of a population of human lung cancer cells that can serially passage the lung tumor phenotype in the lung microenvironment has not been reported, and the operation of pathways that regulate stem cells in advanced lung tumors has not been understood.

### Identification of Normal Lung Stem Cells

Recent identification of putative endogenous and extrinsic lung stem cell populations has added to the diversity of the respiratory system.[47–52] The pulmonary system contains various epithelial cell populations. Each population resides in a distinct anatomical location, or niche.[53] Basal cells, secretory Goblet cells, submucosal glands, and ciliated cells line the trachea and upper airways. The nonciliated columnar Clara cells that line the bronchioles and terminal bronchioles secrete surfactants to aide in oxygen exchange and provide a protective epithelial barrier in the airways. The alveolar epithelium is composed of alveolar type II (AT2) cells, the cuboidal epithelial cells that produce surfactants and the resulting surface tension required for gas exchange, as well as alveolar type I (AT1) cells, the flat epithelial cells that deliver oxygen to the blood. Human and murine lung adenocarcinomas most frequently arise in the distal lung where AT2 and Clara cells reside, and these tumors are frequently positive for molecular markers of either AT2 cells or Clara cells.

Our laboratory determined that cells expressing both the AT2 cell marker, prosurfactant protein-C (SP-C), and the Clara cell marker (CCSP [also known as CCA], CC10, utergloblin, Scgb1a1) are present in normal murine lung, and that they constitute a stem cell population in the distal lung epithelium. These cells, named bronchioalveolar stem cells (BASCs), reside in the bronchioalveolar duct junction (BADJ) in terminal bronchioles, which is the last portion of the airway before the alveolar space. BASCs can be isolated from mouse lung using a FACS methodology based on the presence of the surface markers (stem cell antigen-1 [Sca-1] and CD34) and the absence of the hematopoietic and endothelial cell markers (CD45 and CD31), respectively. BASCs self-renew over multiple passages and give rise to bronchiolar and alveolar cells in culture, providing evidence that they are a stem cell population. Further supporting the hypothesis that BASCs are stem cells, they are quiescent in normal lung and proliferate in response to lung injury.[47] Notably, Sca-1 cannot be used to isolate human cell populations; separate studies are underway in our laboratory to identify additional markers of murine BASCs that may help in identification of human BASCs and human lung CSCs.

### Role of Bronchioalveolar Stem Cells in Murine Lung Tumorigenesis

To examine lung stem cells and their role in cancer, we have used a mouse model that accurately recapitulates human lung adenocarcinoma. K-ras, a component of the Ras signal transduction pathway, functions in multiple aspects of growth control and is mutated to an oncogenic form in 15% to 50% of human lung adenocarcinomas.[54–56] In "Lox-Stop-Lox" *K-ras (LSL-K-ras)* mice, expression of oncogenic *K-ras* is spatially and temporally controlled by a removable transcriptional termination (stop) element. Intranasal infection with a recombinant adenovirus-carrying Cre recombinase (AdenoCre) results in deletion of the stop element, producing the *Lox-K-ras* allele that expresses oncogenic *K-ras G12D* from the endogenous *K-ras* promoter. These mice develop epithelial hyperplasia that appear to progress to adenomas and overt adenocarcinomas.[57] The tumors recapitulate the histopathological and molecular signature of human lung adenocarcinomas.[57,58] Interestingly, BASCs were also detected in these lung adenocarcinomas, indicating that they may contribute to tumor growth and progression.[57] This raises the possibility that BASCs in these murine lung cancers are the CSC population.

## MOVING FORWARD IN LUNG CANCER STEM CELL BIOLOGY

### Designing Experiments to Test the Cancer Stem Cell Hypothesis: Transplantation and Culture

An important aim of basic lung cancer research is to determine if human lung adenocarcinomas contain a CSC population. Following the methodology that has been successful in other malignancies, one method to test this possibility would be to examine dissociated cells from human lung adenocarcinomas, sort cells by FACS, and test the ability of tumor cell subpopulations to propagate tumors with orthotopic transplantation assays.

CSCs in human leukemia, melanoma, breast, brain, colon, and pancreatic malignancies have been shown to be required for serial rounds of tumor propagation in transplantation assays that

often utilize orthotopic strategies.[1–6,11] For example, the function of breast CSCs was elucidated by injecting cancer cells into the mammary gland, thereby mimicking the normal environment of the tumor cells.

A current literature search indicates that the CSC hypothesis remains largely untested for lung cancer. Experiments with human lung cancer cell lines and sphere-forming lung cancer cells have suggested that cancer cells that exhibit some properties of stem cells are present within lung cancers. These studies relied on the use of the Hoechst dye exclusion method to isolate the side population and the presence of the CD133 cell-surface marker, respectively. Importantly, fresh lung tumors were shown to contain a CD133+ cell fraction that could propagate lung tumors when injected subcutaneously in immunodeficient mice.[46]

Although the studies described previously constitute an important beginning in addressing the CSC hypothesis in lung cancer, several key experiments have not yet been reported. First, serial transplantation of lung CSCs has not been demonstrated. Because multiple rounds of propagation of tumors are typically used to show the self-renewal capacity of putative CSCs, this key property of stem cells has not been shown for human lung cancer. Second, the use of subcutaneous injection to test lung CSC activity does not reflect the normal cellular milieu in which lung cancers arise, grow, and progress. Particularly important for future work to develop therapeutic intervention of CSCs, previous studies have shown that lung tumor cells growing in subcutaneous regions do not exhibit the same physiological response to chemotherapy as do tumors growing in the lung.[59,60] Therefore, experiments to test for lung CSC activity have not yet been done in the most relevant tissue setting.

Future experiments should build upon the valuable studies described previously with human lung cancer cell lines and work in primary murine lung adenocarcinomas to determine if human lung adenocarcinomas contain a CSC population. Importantly, serial transplantations of uncultured primary tumor cells from human lung and characterization of the resulting tumors are required. Furthermore, testing the ability of cells sorted by both the putative lung CSC marker CD133 and novel cell-surface markers in serial transplantation assays will likely be helpful in learning how to prospectively identify CSCs. If CSC surface markers from other tissues are not useful for the lung, a side population of human lung adenocarcinoma cells might be isolated by their ability to efflux Hoechst dye; this technique has already been verified to work well in human lung cancer cell lines.[45] Adenocarcinoma side population cells with CSC activity could be isolated by FACS and characterized by microarray analysis to elucidate new lung CSC surface markers. Transplantation of tumor cells into the lung, where the normal microenvironment may have important roles on cancer progression, niche effects on CSCs, and cancer cell response to therapeutics,[61,62] should be done to more clearly define the role of CSCs in human lung adenocarcinomas or other types of lung cancer.

In parallel to testing for CSCs using murine transplantation assays, a culture-based method to determine if a subset of lung cancer cells exhibits the stem cell properties of self-renewal and differentiation will be valuable. Self-renewing sphere colonies were originally observed when primary tumor cells from human brain were cultured on nonadherent plates in serum-free media supplemented with EGF and basic fibroblast growth factor (bFGF),[20] and have been subsequently established from primary tumor cells of colon, breast, and melanoma in human.[5,21–23] Tumor sphere culture conditions could be used to identify human lung cancer cells that can be propagated over multiple passages, providing a surrogate assay to complement in vivo cell transplantation studies. The development of this in vitro cell culture system would likely assist in the isolation and characterization of human lung adenocarcinoma CSCs. The establishment of cultures of lung adenocarcinoma CSCs would also enhance future studies of the pathways that regulate self-renewal and differentiation of these cells, as well as for identification of small molecules that inhibit CSC activity. Importantly, culture assays should only be used if the culture conditions retain cells that exhibit the ability to propagate tumors in the lung that are indistinguishable from those arising from primary cell injections. The combination of in vivo and in vitro assays for CSCs would provide the repertoire of tools needed for functional analysis of lung CSCs.

### Connecting Cancer Stem Cells and Chemotherapeutic Resistance

Distinct aspects of CSC biology, such as more active DNA-damage response, may render CSCs more resistant to therapeutics than other cancer cells.[12–14] In addition, the quiescent nature of CSCs or their proposed ability to efficiently export drugs, characteristics that have both been shown in some stem cells in normal tissues,[63] may impact the response to therapy. Elucidation of a lung CSC population and therapeutic strategies that specifically eliminate lung CSCs may offer more effective means of therapy that can be combined with current clinical approaches.[12,14,64]

Resistance to chemotherapy is a major cause of the high mortality rate associated with advanced lung cancer. Chemotherapy is associated with only a 20% to 40% chance of tumor regression in advanced NSCLC, and thus, for most patients, chemotherapy is ineffective.[65] Adenocarcinomas bearing mutations in oncogenic K-ras are among the most chemorefractory lung tumors, suggesting that mutant K-ras CSCs in these tumors may be more inherently drug resistant than other lung cancer CSCs.[66,67] The initial sensitivity of human adenocarcinomas with activating EGFR mutations to EGFR TKIs and the acquired resistance to these treatments suggest that drug-resistant CSCs may be present in these tumors.[36–38] The molecular mechanisms of EGFR-inhibitor resistance have been well characterized in comparison with other forms of chemotherapy for lung cancer, yet the cellular nature of these mechanisms is poorly understood. For example, it is not yet clear whether EGFR-inhibitor resistance arises from de novo EGFR mutations after treatment or if rare preexisting chemoresistant subclones expand after initial treatment response.

CSCs may play an important role in the resistance of lung adenocarcinomas. More specifically, it is possible that CSCs

are either more numerous or more chemorefractory in K-ras mutant lung adenocarcinomas than in other forms of adenocarcinoma. Second, EGFR-mutant NSCLC tumors may recur during TKI treatments because of the presence of a resistant CSC population. Evidence supports these ideas in other solid malignancies. For example, it was recently shown that the percentage of breast CSCs is significantly increased in the tumors of patients treated with chemotherapy.[22]

Future studies to connect CSCs to therapy response in lung cancer may be best done by analysis of murine lung cancers, because they currently offer several advantages over patient samples for understanding the role of CSCs in adenocarcinoma. First, the identity of human lung CSCs has not yet been established, whereas a stem cell population that appears to be important in tumorigenesis in a mouse model of adenocarcinoma has been identified (above). Second, there is typically no clinical basis for biopsy or surgical removal of recurring or chemoresistant lung adenocarcinomas from patients. In addition, with the exception of EGFR-mutant tumors, the timing of acquired chemoresistance is not known in patients. These facts make it challenging to acquire large numbers of fresh chemoresistant human lung cancer samples in which to examine CSCs, and even more difficult to have matched chemonaive and chemoresistant cancer cells from the same patient. Many mouse models of lung cancer are now available that accurately recapitulate the mutational status and chemoresistance of human lung adenocarcinomas, and one can easily obtain genetically matched tumors that arise in the absence of chemotherapy and at specific time points during or after the development of chemoresistant tumors, providing materials that are simply not available from patients in the same numbers. When possible, primary human samples should be used to validate findings in mice that establish the relationship between lung CSCs and chemotherapeutic response.

## Metastasis and Cancer Stem Cells: Another Missing Link

The CSC hypothesis predicts that stem cell characteristics, which allow CSCs to disseminate and colonize to new tissues, are responsible for metastatic disease. Importantly, even for known CSCs, their role in metastasis is largely unexplored, and it is possible that cells with stem cell properties cause metastases. Just as described for matched chemonaive and chemoresistant human lung cancer samples, it is challenging to obtain large numbers of matched primary and metastatic lung cancer samples from patients. In addition, although lung cancer metastases to the brain are surgically removed, most advanced stage primary and metastatic lung cancers in these patients are not surgically removed. There is no documented improvement of patient survival for operation of these advanced stage lesions. Therefore, the question of metastasis and stem cells is another setting ideal for the use of mouse models to obtain genetically matched primary and metastatic lung adenocarcinoma cells. In particular, *LSL-K-ras p53-lox/lox* mutant murine lung tumors are an ideal model to use for the study of metastatic disease because of the observed incidence of metastasis in these mice.

Archived human samples could also be examined to determine if pathways identified in mouse studies are useful prognostic markers of metastatic disease in patients.

## Searching for Molecular Targets in Cancer Stem Cells

The CSC hypothesis predicts that the same pathways, which are essential for promoting self-renewal of normal stem cells, are also important for propagating the growth of cancer cells. In fact, many cancer mutations cause upregulation of pathways that promote self-renewal.[26] In addition, it has been shown that CSCs, which are identified by markers distinct from markers of normal tissue stem cells, can exhibit shared gene-expression signatures with stem cells.[24] Thus, stem cell pathways may be upregulated in chemoresistant lung adenocarcinomas compared to chemonaive tumors.

A logical place to start examining the importance of stem cell regulatory molecules in lung cancer are the Wnt, Hedgehog (Hh), and Bmi-1 pathways, because they have been implicated in stem cell self-renewal and lung biology. In addition, evidence suggests that dysregulation of these pathways contributes to NSCLC. Wnt pathways play a crucial role in lung embryonic development, and more specifically, in cell fate decisions and differentiation.[68–70] $\beta$-catenin levels are elevated in some NSCLCs; however, unlike many other cancers, APC and $\beta$-catenin mutations are rare in NSCLC.[70–74] The mechanisms leading to elevated $\beta$-catenin levels in primary NSCLCs, therefore, most likely occur upstream of $\beta$-catenin, for example, via overexpression of Wnt effectors or repression of Wnt antagonists.[70–75] The Hh pathways play a crucial role in lung embryonic development.[76] Most NSCLC tumors exhibit increased expression of Hh-signaling proteins compared to normal lung tissues, and 87% of lung adenocarcinomas have increased levels of GLI1.[77] Moderate-to-high levels of Bmi-1 are expressed in most NSCLC tumors, and Bmi-1 status is a useful prognosis factor of lung adenocarcinoma tumor metastasis and patient survival.[78,79] We have also recently found that Bmi-1 is required for lung tumorigenesis in the K-ras mouse model of lung cancer and is also required for BASC self-renewal, suggesting that the Bmi-1 pathway is one molecular link between stem cell function and tumorigenesis in the lung.[80] Future studies will likely elucidate the connections between these important pathways and others to test for activation in lung cancer.

In addition to the pathways discussed previously, the CSC hypothesis also predicts that the pathways responsible for the dissemination and homing of normal stem cells during development and wound healing are upregulated in metastatic tumor cells. In support of this idea, adhesion, chemokine, and cytokine receptors have been implicated in metastasis.[81] The SDF-1/chemokine (C-X-C motif) receptor 4 (CXCR4) axis plays a crucial role in hematopoietic stem cell (HSC) trafficking and has been hypothesized to be harnessed by CSCs during metastasis.[82] During embryogenesis, a chemokine SDF-1 gradient secreted by the bone marrow attracts HSCs expressing CXCR4 from the fetal liver, and in adults, the gradient is also crucial for retention of the HSCs in the adult bone marrow.[82]

The SDF-1/CXCR4 axis is crucial in CSC-driven pancreatic metastasis, whereas in CD133+ pancreatic CSCs propagated primary tumors, only CD133+ cells that were CXCR4+ were capable of producing metastases.[83] Although the role of CXCR4 in tumor metastasis is the most well defined, other chemokine receptors are also involved in invasion and migration: CCR7 is involved in the dissemination of many types of tumor cells to the lymph nodes; CCR10 is involved in homing of melanoma cells to the skin[84,85]; and chemokines such as CCL2, CCL5, and CXCL8, can stimulate the migration of some types of tumor cell lines.[84]

Lung CSCs with chemokine receptors may initiate lung cancer invasion and migration. Many types of human tumors that exhibit high CXCR4 expression levels, including NSCLCs, are prone to metastasis.[84,86] In NSCLC, recent studies have shown that high primary tumor CCR7 and CXCL8 mRNA levels are correlated with the presence of lymph node metastases.[87,88] Thus, it is likely that other chemokine receptors play a role in lung cancer metastasis and that a more global survey of chemokine receptors in adenocarcinoma could provide additional molecules to examine in lung CSC studies.

## POTENTIAL CAVEATS IN THE STUDY OF LUNG CANCER STEM CELLS

Several aspects of CSC biology may limit the ability to propagate human lung cancer cells in mice or in culture, and thus make it difficult to test the CSC hypothesis in lung cancer. First, human lung CSCs may require human stromal cells or other factors from the human lung microenvironment for growth and tumor propagation. Instead of sorted cells, it is possible to implant intact pieces of tumor subcutaneously for a first round of tumor growth in mice. This technique has been performed in prior studies used to identify breast CSCs.[2] In addition, lung tumor samples that can be obtained from patients will be early stage tumors, as these are typically the only stage of lung cancer that is treatable with surgery. It is possible that these early stage tumors will not have an adequate number of CSCs for propagation. It may be necessary to use more advanced cancer samples to identify lung CSCs.

It remains possible that no unique population of cells has the ability to preferentially propagate human lung adenocarcinoma tumors, which would argue more in favor of the stochastic theory of tumor cell clonogenicity (above) in lung cancer rather than the CSC hypothesis. For example, different subsets of cancer cells may acquire CSC activity through mutation during tumor growth, and there may not be cell-intrinsic properties that separate cancer-propagating and nonpropagating populations within lung tumors beyond their genetic component. CSCs from brain tumors do not have a significantly different pattern of genetic alterations compared with the non-CSC from the same tumors,[3] indicating that genomic changes alone do not account for all observed CSC activity; yet, it will be important to compare the genomic status of cancer cell subpopulations. Second, the inherent difficulty with the CSC hypothesis is that negative results may not completely rule out the hypothesis. It may not be possible to formally exclude that the correct marker or strategy was not applied to identify the elusive lung CSC. Given the potential promise for future cancer therapy that has been associated with the CSC concept, it is imperative to perform studies such as those discussed here to begin determining if the CSC hypothesis is a valid model for understanding lung cancer biology despite these challenges.

## CONCLUSION

At least three distinct, yet complementary, aspects of the CSC hypothesis remain to be addressed for human lung adenocarcinomas and all forms of lung cancer: to determine if a CSC population exists in human lung cancers, to determine how tumor-propagating frequency and activation of stem cell pathways are changed in chemoresistant lung cancer cells, and to identify molecular markers that may connect lung CSCs and metastatic cells. If CSCs are identified in human lung cancers, many important future directions will be possible. Gene-expression profiling of human lung CSCs may lead to the identification of new lung CSC markers or pathways that regulate CSCs. Furthermore, molecules identified as differentially expressed in lung CSCs, chemoresistant cancer cells, or adenocarcinoma metastases could be investigated for their causal role in these aspects of tumorigenesis and their usefulness as biomarkers for screening patients for lung cancer. Strategies such as those described here will make important inroads to future studies to use the biology of stem cells to improve the outcome of lung cancer patients.

# Lung Cancer and Its Microenvironment

The association between inflammation and cancer was identified in the 19th century. Initially, it was believed that leukocyte infiltrates in tumors represented an attempt by the host to eradicate malignant cells. It was later demonstrated that several chronic inflammatory conditions, such as inflammatory bowel disease, *Helicobacter pylori* infection, hepatitis B or C infection, and prostatitis, predisposed people to cancer of the colon, stomach, liver, and prostate, respectively. In addition, malignant tissues that contain inflammatory cells such as macrophages in breast cancer or neutrophils and mast cells in lung cancer are associated with an unfavorable outcome.

Lung cancer risk is clearly enhanced by cigarette smoking, and chronic inflammation associated with chronic obstructive pulmonary disease probably enhances this risk, although an increase is difficult to demonstrate. Some lung cancers that occur in association with scars could have no relationship with smoking habits. In patients with idiopathic fibrosis, lung cancer incidence is much higher than in the general population.[1] Oncogene activation is often associated with inflammatory response. For example, scar-associated cancers seem to more often have *KRAS* (codon 12) mutations. Further, a transgenic mouse model of lung cancer generated by *KRAS* activation showed a robust inflammatory response compared to the wild-type mice.[2,3] Lastly, in several mouse models, this inflammatory response has been demonstrated to be not only associated with but also required for tumor initiation or growth.[4,5]

The tumor microenvironment is composed of structural (extracellular matrix [ECM]), soluble (growth factors, chemokines, cytokines, proteases, and hormones, among others), and cellular components (tumor cells, fibroblasts, inflammatory cells, vascular and lymphatic endothelial cells, and vascular smooth muscle cells and pericytic cells, among others). Characterization of the inflammatory cells within tumors has revealed both the adaptive and innate arms of the immune response. For example, dendritic cells (DCs) present tumor antigens to T lymphocytes (CD4+, CD8+, and natural killer [NK]), promoting an antitumor cytotoxic T-cell response. This response is negated by a population of immature myeloid cells called myeloid-derived suppressor cells that promotes the development of FOXP3+ CD4+ T cells or Tregs, which suppress the antitumor cytotoxic T-cell response and induce polarized differentiation of monocytes into tumor-associated macrophages (TAMs or M2 macrophages). TAMs, vascular endothelial cells, and fibroblasts within the tumor stroma secrete a number of growth factors and chemokines that promote tumorigenesis. Thus, conflicting immunologic forces fight for supremacy in the tumor microenvironment. This chapter will deal with recent research on the tumorigenic and antitumorigenic effects of the immune system on the lung. The latter was discussed fully in a recent review.[6]

## ANGIOGENESIS

Angiogenesis is the growth of the new blood vessels, necessary for cancerous tumors to keep growing and spreading (see Chapter 8). Many proteins and other smaller molecules have been identified as *angiogenic*, particularly vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and CXC chemokines, among others. The binding of these molecules to their appropriate receptor activates a series of relay proteins that transmits a signal into the nucleus of the endothelial cells. The nuclear signal ultimately prompts a group of genes to make products needed for new endothelial cell growth. First, the activated endothelial cells produce matrix metalloproteinases (MMPs), a class of degradative enzymes that break down the extracellular matrix, thus permitting the migration of endothelial cells that had been tethered to the matrix. As they migrate into the surrounding tissues, activated endothelial cells begin to divide. Soon they organize into hollow tubes that evolve gradually into a mature network of blood vessels. Cancer cells originating in a primary tumor can spread to another organ and form metastases that can remain dormant for years. The induction of this vasculature in primary tumor or in metastases, termed *angiogenic switch*, can occur at various stages of tumor progression, depending on the tumor

type and the environment (see Chapter 8).[7] In many studies, angiogenic switch has been reported to be closely associated with malignant transition. Cancer cells themselves could release molecules to activate this process, as could cells from the tumor microenvironment. This review will describe effects of the cells from the tumor microenvironment on angiogenesis.

## FIBROBLASTS

Normal stroma contains fibroblasts in association with physiological extracellular matrix. Reactive stroma is associated with an increased number of fibroblasts, enhanced capillary density, and type I collagen and fibrin deposition. In chickens that are cancer-prone because they have been infected with Rous sarcoma virus, wounding leads to invasive carcinoma, demonstrating that reactive stroma provides oncogenic signals that facilitate tumorigenesis.[8] Fibroblasts are associated with cancer cells (tumor-associated fibroblasts [TAFs], carcinoma-associated fibroblasts [CAFs]) at all stages of cancer progression. The growth factors, chemokines, and extracellular matrix—these fibroblasts produce facilitate angiogenic recruitment of endothelial cells and pericytes. They are phenotypically and functionally distinct from fibroblasts that are not in the tumor microenvironment. The modified phenotype they acquire is similar to that of fibroblasts associated with wound healing. Smooth muscle differentiation (myofibroblasts) is prominent in stromal cells of malignant breast tissue but rarely seen in normal breast tissue.[9] The signals that mediate the transition of normal fibroblasts into TAF or CAF are not fully understood, but transforming growth factor-$\beta$ (TGF-$\beta$), platelet-derived growth factor (PDGF), and fibroblast growth factor 2 (FGF2) are the main mediators to induce fibroblast activation. TGF-$\beta$ induces the acquisition of activated phenotype of fibroblasts in culture[10] and has been shown to be correlated with desmoplastic reaction and poor prognosis in breast cancer.[11] PDGF induces the proliferation of fibroblasts and has been shown to be associated with cancer progression in breast cancer.[12] FGF2 also stimulates proliferation of fibroblasts and is also recognized for its potential to induce angiogenesis.[13]

The fact that fibroblasts contribute to tumor initiation, growth, and metastasis have been demonstrated by both in vivo and in vitro study.[14] Whereas normal fibroblasts are required to maintain epithelial homeostasis, CAFs probably initiate and promote tumorigenic alterations in epithelial cells. Fibroblasts cultured from malignant tumors have stimulatory effects on breast tumor cell lines, whereas fibroblasts cultured from normal tissue are inhibitory.[15] If CAFs are coinoculated with prostate, breast, or bladder tumor cell lines into nude mice, tumor latency is shortened and tumor growth increased,[16] whereas normal fibroblasts do not have this effect. Increased cell proliferation and angiogenesis also result. Lastly, fibroblasts could promote metastasis by secreting growth factors that create a niche that promotes the growth of cancer cells at distant sites.[17]

CAFs could also modulate the immune response. CAFs isolated from primary non–small cell lung cancers (NSCLCs) were able to enhance or suppress tumor-associated T-cell function.[18]

The epithelial-to-mesenchymal transition (EMT) might be an additional source of fibroblast-like cells (with an altered genome). In EMT, epithelial cells lose cell–cell contacts and acquire mesenchymal properties. Cancer cells undergoing EMT develop invasive and migratory abilities and express EMT markers (E-Cadherin, Vimentin) that have been shown to be markers of tumor progression.[19–21] This phenotype has also been shown to be associated with resistance to certain therapies such as epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor (TKI) in NSCLC.[21,22]

## MACROPHAGES

Most solid tumors are abundantly populated with TAMs. These cells can compromise clinical outcome. Clinical studies have shown a correlation between TAM density and poor prognosis for several types of cancer, an association that is particularly strong for breast, prostate, ovarian, and cervical cancers.[23] For NSCLC, TAM density correlated significantly and negatively with overall survival or relapse-free survival in two of three published studies.[24–26]

Macrophages are recruited to tumors by a wide variety of growth factors—granulocyte colony-stimulating factor (G-CSF), granulocyte-monocyte colony-stimulating factor (GM-CSF), macrophage-stimulating protein (MSP), VEGF, TGF-$\beta$—and chemokines, which include CC chemokines, monocyte chemoattractant protein family, macrophage inflammatory protein-1 (MIP-1), and macrophage migration inhibitory factor (MIF).[27]

Tumor-derived molecules probably influence TAM phenotype. Exposure to IL-4 and IL-10 in tumors may induce TAMs to develop into M2 macrophages, which are characterized by poor antigen-presenting capacity and production of factors that suppress T-cell proliferation and activity and induce angiogenesis, whereas M1 macrophages are efficient immune cells.[28]

Macrophages induce angiogenesis. Correlations between number of macrophages and microvessel count have been observed for many tumor types including lung cancer.[24,25,29] Macrophage infiltration into tumor is not homogeneous: studies using hypoxic markers have shown that TAMs accumulate in hypoxic and necrotic areas. Hypoxia induces synthesis of macrophage chemoattractants such as VEGF by upregulating hypoxia-inducible factor (HIF), which recruits and immobilizes macrophages in such areas.[30] Here, these cells synthesize angiogenic regulators, which results in formation of new blood vessels. These regulators are angiogenic factors (VEGF, PDGF, IL-8) and angiogenesis-modulating enzymes (MMPs and cyclooxygenase-2 [COX-2]). In vitro studies, based on coculture experiences, showed that exposure of macrophage to tumor cells increases synthesis of angiogenic factors.[25,31,32] In transgenic

mice susceptible to mammary cancer (PyMT mice), malignant transition was demonstrated to be regulated by infiltrated macrophages in primary mammary tumors. Inhibition of macrophage recruitment into the tumors delayed the angiogenic switch and malignant progression, while genetic restoration of the macrophage population rescued angiogenesis.[33]

Macrophages have been shown to stimulate proliferation of tumor cells. In K-ras[LA1] mice, which develop lung adenocarcinoma through somatic activation of a K-ras allele, intraepithelial and airspace macrophage infiltration is observed beginning at the earliest stage of neoplasia and increasing with malignant progression.[3] In this model, inhibition of malignant progression by a targeted treatment directed against the mTOR pathway was accompanied by macrophage loss. Conditioned media from primary cultures of macrophages stimulated the proliferation of lung tumor cells, which was consistent with previous reports demonstrating a stimulatory effect of alveolar macrophages on the proliferation of normal and distal airway epithelial cells in other animal models.[34–36] In a transgenic mouse model of preneoplastic progression in the mammary gland, conditional depletion of macrophages inhibited epithelial cell proliferation and lateral budding.[37]

Macrophages are involved in invasion and metastasis. In the PyMT mouse model of breast cancer progression, leukocytic infiltrates were present in areas of basement membrane breakdown[38] suggesting their involvement in tumor invasion; macrophage depletion resulted in reduced formation of lung metastases.[4] In coculture experiments, interaction between macrophages and tumor cells facilitated invasion of tumor cells into a collagen matrix.[39] In a chemotaxis-based in vivo invasion assay, a paracrine loop involving macrophages and tumor cells was essential for motility and invasion of tumor cells in mammary tumor.[40] Colony-stimulating factor-1 (CSF-1) secreted by carcinoma cells leads to the activation of macrophages to secrete EGFR ligands, leading to stimulation of carcinoma cell movement.[40]

## NEUTROPHILS

Neutrophil infiltration has been described in NSCLC, and particularly in the bronchioloalveolar subtype.[41,42] Recent studies support the fact that this could be induced by Ras activation, one of the most common oncogenic events in pulmonary adenocarcinoma.[5] Neutrophils could be recruited to tumors by CXC chemokines with an N-terminal Glu-Leu-Arg (ELR) motif. These chemokines are also autocrine growth factors for certain types of cancer cells.[43–45] Mutations in the proto-oncogene *KRAS* occur in 10% to 30% of lung adenocarcinomas,[46] and expression of mutant *KRAS* in the alveolar epithelium leads to the development of lung adenocarcinoma in mice.[45–50] In addition to its role in the transformation of alveolar epithelial cells, the presence of *KRAS* mutations is a predictor of shorter survival in NSCLC patients[51] and of resistance to therapy.[52] Sparmann et al.[5] demonstrated that the CXC chemokine CXCL8 (interleukin-8) is a transcriptional

target of Ras signaling and is required for the initiation of tumor-associated inflammation and neovascularization in xenograft models. In this model, neutralization of CXCL8 in RasV12-expressing subcutaneous tumors attenuates neoplastic growth; CXCL8 inhibition does not affect tumor cell proliferation but leads to an increase in tumor cell death and an impairment of tumor vascularization coincident with an impairment of stromal infiltration of neutrophils. In the heterotopic and orthotopic Lewis lung cancer models, tumor growth is associated with enhanced neovascularization, neutrophil inflammation, and expression of CXC chemokines. Neutralization of CXC chemokine receptor decreases tumor size and increases tumor necrosis.[53]

In Kras[LA1] mice, a mouse model in which lung adenocarcinoma develops through somatic activation of a *KRAS* allele carrying an activating mutation in codon 12 (G12D),[50] neutrophils, and vascular endothelial cells infiltration increased during malignant progression, and the murine functional homologues of human CXCR2 chemokines (KC, MIP-2) and their receptor CXCR2 are highly expressed.[54] CXCR2 inhibition blocks the expansion of early alveolar neoplastic lesions, but this antitumor effect does not occur outside the presence of the tumor microenvironment.

In humans, adenocarcinomas with bronchoalveolar features are also characterized by an intense inflammatory reaction, predominantly consisting of alveolar neutrophils and macrophages. Increased numbers of tumor-infiltrating neutrophils are linked to poorer outcome in these patients.[41] The tumor environment drives local neutrophil recruitment and activation via CXC chemokine release, but it also prolongs alveolar neutrophil survival through the production of soluble antiapoptotic factors GM-CSF and G-CSF.[55] The mechanisms by which neutrophils influence the prognosis of adenocarcinomas with bronchoalveolar features could be multiple. It has been postulated that the persistence of neutrophil alveolitis would result in persistent release of proinflammatory mediators such as cytokines, proteases, and reactive oxygen and nitrogen species that can damage DNA and activate oncogenes.[56,57] Among these factors released by neutrophils, hepatocyte growth factor (HGF) seems to be particularly involved in the progression of these types of tumors, especially through its mitogenic and scattering properties, favoring c-Met–expressing tumor cell migration along the alveolar basal membrane.[58] Lastly, neutrophils might be involved in luminal tumor spread by promoting tumor cell shedding,[59] which is described pathologically as the presence of micropapillary clusters that are also involved in the mechanism of aerogenous progression.[60]

## MAST CELLS

Several different studies showed a significant association between mast cell density, angiogenesis, and poor prognosis in NSCLC.[61–64] Using monoclonal antibodies for tryptase—a specific marker for mast cells—and for endothelial cell surface

molecules, several studies quantified mast cell and microvessel density in lung cancer tissue. Takanami et al.[61] showed a correlation between mast cell density and microvessel count in a study of 180 patients with resected pulmonary adenocarcinoma. Mast cell density was also associated with N classification and was an independent factor for survival duration. Production of angiogenic factors such as VEGF or other proinflammatory cytokines by mast cells is probably involved in this phenomenon.[64]

## DENDRITIC CELLS

Effective antitumor responses require antigen-presenting cells (APCs), lymphocytes, and NK effectors. DCs are bone marrow–derived leukocytes characterized by a high level of expression of major histocompatibility complex (MHC) and costimulatory molecules. They are the most effective APCs. To initiate and maintain an effective antitumor response after antigen uptake, DC should migrate to draining lymph nodes and to prime T cells. This priming reaction is triggered by an activation-driven maturation process of DC characterized by upregulation of costimulatory molecules (CD40, CD80, and CD86), a switch in the chemokine receptor repertoire, and production of immunomodulatory cytokines (IL-12 and IFN-a) necessary for the generation of cytotoxic T lymphocytes.[65] However, immunosuppressive cytokines such as IL-10, TGF-b, prostaglandin E2 (PGE2), and VEGF interfere with DC maturation and migration, altering tumor response. To improve antitumor immunity, tumor cells have been transduced with genes encoding molecules able to attract and to activate DC but with limited efficacy in curing established tumors. To overcome tumor microenvironment-associated suppressive effect on the DC, a recent work used a strategy that incorporates ex vivo–activated DC as the delivery for chemokine expression. The authors transduced the gene of the secondary lymphoid chemokine (CCL21, CCR7 receptor ligand) into DC ex vivo and delivered the gene-modified DC (DC-AdCCL21) in a mouse model of spontaneous bronchoalveolar carcinoma.[66] A single intratracheal administration led to a marked reduction in tumor burden with extensive mononuclear cell infiltration of the tumors. The reduction of tumor burden was accompanied by the enhanced elaboration of type I cytokines (IL-12 and IFN-g and GM-CSF) and antiangiogenic cytokines and a decrease in immunosuppressive cytokines (IL-10, TGF-b, PGE2) in the tumor microenvironment.[66] Continuous administration of DC-AdCCL21 significantly prolonged survival of mice.[66] In another study, repeated treatments with a combination of a microbial stimulus (a Toll-like receptor 9 ligand, CpG oligonucleotide) and an antibody blocking the IL-10 receptor reversed the functional paralysis of DC and reestablished IL-12 production.[67] Lastly, a combination of local treatment of CCL16 and cpG together with systemic administration of antibody blocking the IL-10 receptor cured syngeneic tumors in mice.[68]

## ADAPTATIVE IMMUNITY

Lung cancer cells themselves find a way to avoid activating the adaptive immune system. Although they express tumor antigens, the limited expression of MHC antigens, defective antigen processing, and lack of costimulatory molecules make them ineffective APC.[69] For example, the absence of expression of costimulatory B7 molecules renders tumors invisible to the immune system, whereas enhanced expression of inhibitory B7 molecules protects them from effective T-cell destruction.[70]

Tumor-reactive T cells accumulate in the lung tumor microenvironment but fail to respond because of suppressive tumor cell–derived factors. These factors can reduce T-cell survival. Lymphocytes exposed to lung tumor supernatant undergo enhanced apoptosis with an impairment of nuclear factor κB activation due to reduced IκB kinase (IKK) activity.[71]

A high proportion of tumor-infiltrating lymphocytes in the tumor microenvironment are regulatory T cells. The CD4+ CD25+ T regulatory cells found in lung tumors have been shown to selectively inhibit the host immune response and contribute to the progression of lung cancer. They mediate potent inhibition of autologous T-cell proliferation while they fail to inhibit the proliferation of allogeneic T cells.[72]

B cells also play a crucial role in the onset of chronic inflammation associated with epithelial cancer development.[73] In a recent study using a transgenic mouse model of skin carcinogenesis where the gene of human papillomavirus 16 (HPV-16) is expressed under control of the human keratin 14 promotor, B cells were shown to be activated peripherally—with no need to be recruited in neoplastic tissue. They were also shown to initiate immunoglobulin deposition into neoplastic tissue, paralleling the recruitment of inflammatory cells (mast cells and granulocytes) and malignant progression.[73] Antibodies mediate recruitment of innate immune cells via engagement of FcR expressed on immune cells. Other studies have reported that humoral immune responses potentiate in vivo growth and invasion of injected murine and human tumor cell lines via recruitment and activation of granulocytes and macrophages.[31] The authors suggested that pharmacological intervention attenuating B cell activation or blocking B cell–mediated recruitment of innate immune cells may be effective in preventing premalignant epithelial progression.

## CLINICAL IMPLICATIONS

Ongoing biochemical processes in the tumor microenvironment create new targets for cancer therapy. One advantage of therapies targeting the microenvironment is that these nontumor cells are presumably genetically stable, whereas tumor cells are genetically unstable and thus can accumulate adaptive mutations and rapidly acquire drug resistance. Several drugs directed against nontumor cells or their soluble mediators have been developed and are now being evaluated in clinical trials.

MMPs that break down the ECM are necessary for angiogenesis and invasion of tumor cells, into both the surrounding normal tissue and the blood and lymphatic systems. ECM is also a rich source of sequestered heparin, binding progrowth and proangiogenic factors, which are made available following increased production of matrix-degrading enzymes. Clinical trials were undertaken to determine if inhibitors of MMPs (MMPI) improved overall survival in NSCLC or SCLC. Marimastat, a nonselective MMPI, has also been tested in a number of malignancies, including small cell lung cancer and breast, gastric, and pancreatic cancers; the results were negative.[74–77] Musculoskeletal toxicity was a significant problem in all studies. The failure of the broad-spectrum MMP inhibitors (MMP-I) in the clinic has been explained by the fact that some MMPs can also release antiangiogenic proteins. Prinomastat, a more targeted MMPI with activity mainly against MMP2 and MMP9, was given versus placebo in patients with advanced NSCLC in combination with gemcitabine–cisplatin chemotherapy. This study was closed after an interim analysis showed a lack of efficacy.[78] A parallel study of similar design found no benefit when prinomastat was administered in addition to paclitaxel and carboplatin in patients with advanced NSCLC.[79] Another selective MMPI, BAY 12-9566, has been evaluated in several disease settings, but after disappointing results in studies of SCLC and pancreatic cancer, its development has been suspended.

Fibroblasts might be a novel therapeutic target in cancer. The cell-surface serine protease known as fibroblast activation protein (FAP) is mostly expressed in wound healing and in tumor stroma. A phase I dose escalation study with an antibody directed to human FAP (sibrotuzumab) in patients with colorectal cancer or NSCLC has shown that the antibody bound specifically to the tumor sites.[80] Targeting CAFs as a therapeutic strategy against cancer needs further study.

A plethora of antiangiogenic agents inhibiting either angiogenic growth factors or their receptors have been developed and tested in preclinical experiments. More recent data from the clinical trials of the VEGF-specific antibody, bevacizumab (Avastin), showed that in patients with metastatic colorectal cancer, breast cancer, and NSCLC, there was a significant survival benefit when combined with chemotherapy,[81,82] leading to the Food and Drug Administration (FDA) approval of bevacizumab. Treatment with thalidomide, another antiangiogenic agent, was not associated with a significant improvement in survival of SCLC patients. However, there was pronounced heterogeneity in survival outcomes between groups of patients.[83] Some benefit was observed among patients with a performance status (PS) of 1 or 2, showing that angiogenesis deserves further study as a therapeutic target in this disease.

Epidemiological studies have demonstrated that people taking nonsteroidal anti-inflammatory drugs (NSAIDs) have a clear reduction in their risk of developing colorectal cancer,[84] and possibly other tumors. As a result, there were high expectations for the next-generation NSAIDs, the selective COX-2 inhibitors, in the prevention and treatment of cancers associated with chronic inflammation. Celecoxib had demonstrated ability to reduce the incidence of colorectal cancer.[85] The addition of rofecoxib did not improve overall survival compared with first-line treatment with cisplatin plus gemcitabine in patients with advanced NSCLC in a prospective, open-label, randomized phase III trial.[86] Most of the clinical trials have closed early because long-term high-dose COX-2 inhibitor elevates the risk of cardiovascular events[87]; alternative drugs will need to be identified.

## CONCLUSION

A growing body of evidence demonstrates that cancer cells have accomplices. Quite early in tumor development, cancer cells co-opt blood vessels and recruit leukocytes and fibroblasts, reprogramming them to provide nourishment in the form of peptides that support cell proliferation and metastasis. Although their ability to dupe the host into becoming an ally provides cancer cells with a selective advantage, it may also be their Achilles heel. Initial efforts to elucidate the mechanisms by which cancer cells interact with surrounding cells within the tumor has revealed several potential therapeutic opportunities. Future research will better define these bidirectional interactions between tumor and host, and future clinical trials should be designed to capitalize on this understanding.

# Mouse Models of Lung Cancer

Lung cancer has increased in incidence throughout the 20th century and is now the most common cancer in the Western World. Compared to other cancers, the pathogenesis of lung cancer remains highly elusive because of its aggressive biologic nature and considerable heterogeneity. Most patients die of progressive metastatic diseases despite aggressive local and systemic therapies. To better understand the different steps in lung cancer progression and, most importantly, to devise more effective lung cancer therapies, there is considerable need for improved experimental models of lung cancer.

Currently, several animal species are widely used for experimental lung cancer research, including dogs, primates, hamsters, and mice.[1–3] Among the different animal species, mice have become the preferred model to study lung cancer development and progression because of their relative cost-effectiveness, the ease of genetic manipulation, and the large number of genetically altered mice available for experimentation. Primary lung tumors in mice have morphologic, histogenic, and molecular features similar to human lung adenocarcinoma, particularly the bronchioloalveolar carcinoma subtype. Because of this, and because of the genetic homology between man and mouse, this model system is receiving intense research attention.

Three major different models are commonly used to induce lung cancer in mice, namely chemically and/or carcinogen-induced lung cancer, orthotopic models of lung cancer, and genetic models of lung cancer. In addition, spontaneous lung cancer develops in approximately 3% of mice and has a strain-dependent incidence in inbred mice (Fig. 13.1).[4] Mice that develop spontaneous lung tumors also respond to chemicals and carcinogens, thus making them an ideal system to study chemically and/or carcinogen-induced lung cancer. Each of the mouse models available allows the analysis of different aspects of the disease, such as carcinogenesis, initiation, promotion, metastasis, as well as host–tumor interaction and angiogenesis. For example, the chemically induced lung cancer models allow the study of tumor initiation and promotion; the orthotopic model allows the analysis of primary as well as metastatic lung cancers, whereas the genetic model allows the identification of genes involved in lung cancer development and progression.

Despite the fact that these models reflect the histopathology and the steps involved in lung cancer progression, each of them has limitations. These include lack of metastasis (genetic- and chemically induced lung cancer), the development of tumors only late in their course of development (chemically induced lung cancer), and the development of only one subset of lung cancer, namely adenoma and/or adenocarcinoma. For these reasons, more than one model is used when studying the etiology, pathogenesis, and progression of lung cancer.

In this chapter, we will describe the main features of the available mouse models of lung cancer, and how these models can be used for translational research. We will mainly point out practical benefits, such as their application for identifying therapeutic strategies for the treatment and prevention of lung cancer.

## CHEMICALLY INDUCED LUNG CANCER

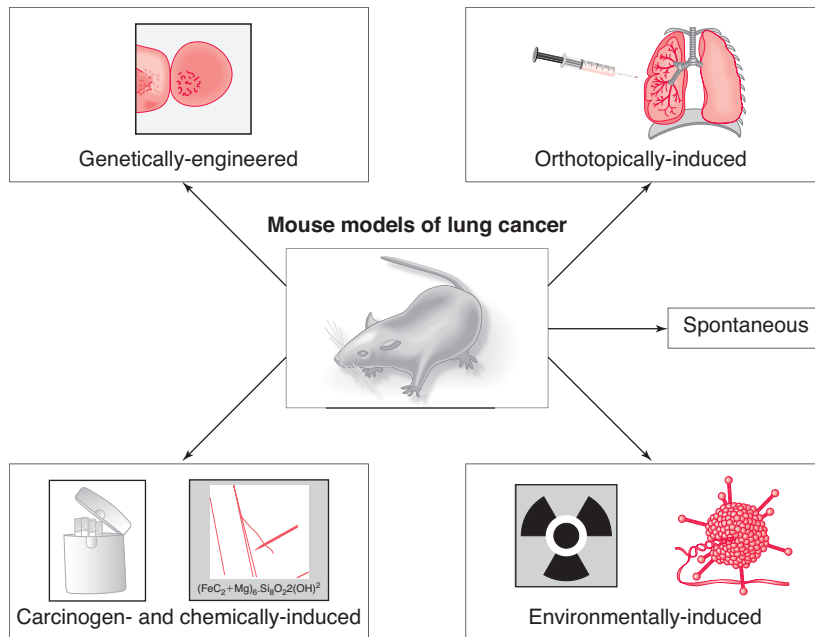
Cigarette smoking represents the prominent cause of lung cancer. More than 20 lung carcinogens have been identified in cigarette smoke, and they can act as initiators and/or promoters of lung cancer by accelerating tumor onset and increasing tumor multiplicity.[5] Although 85% of lung cancers are thought to be as a result of cigarette smoking, individuals exposed to asbestos, arsenic, nickel, radiation, and those with pulmonary fibrosis are also at increased risk.[6] For this reason, chemically and carcinogen-induced animal models of lung cancer have been developed. They are used not only to identify possible molecules and/or environmental factors able to induce lung cancer but also to study the early stage of carcinogenesis and cancer progression. Chemically and/or carcinogen-induced lung tumors have been described in various species, including dogs, cats, ferrets, and mice.[6] The susceptibility of mice to develop chemically and/or carcinogen-induced lung cancer is strain dependent. Mouse strains have been categorized into sensitive, intermediate, and resistant,[7] based on the time of occurrence of lung tumors after


**FIGURE 13.1** Examples of murine models of lung cancer. Mouse models of lung cancer include spontaneous lung tumors; carcinogen- and/or chemically induced tumors (i.e., tobacco, asbestos); environmentally induced tumors (i.e., radiation, viruses), genetically induced tumors (i.e., transgenic expression or germline disruptions of genes), and orthotopically induced tumors (i.e., injection of human tumor cells directly in the lung).

chemical exposure, and on the number of tumors. The A/J mouse strain belongs to the sensitive group with at least 20 times higher susceptibility than resistant strains like C57BL/6J and C3H/HeJ or intermediate strains like BALB/c. The propensity of these sensitive strains to develop lung tumors strongly correlates with a polymorphism in the second intron of the K-ras gene.[8] The polymorphism is a 37-nucleotide–intronic sequence that is tandemly duplicated in resistant strains and is present as a single copy in sensitive strains. This polymorphism seems to confer different nuclear protein-binding abilities that may influence gene expression.[9] In addition to the K-ras gene, the pulmonary adenoma susceptibility 1 (Pas1) locus on chromosome 6 has been implicated in the development of lung cancer in the A/J strain.[10] Based on the fact that both the Pas1 and K-ras genes map on chromosome 6,[11] it has been proposed that the Pas1 gene could be identical to the K-ras oncogene, and natural and/or chemically induced point mutation in Pas1 gene could lead to lung tumors similarly to what observed with the K-ras gene.[8] When A/J mice are exposed to urethane, mutations in either one of these polymorphic loci occur, resulting in the development of benign lung adenoma within few months from the exposure.[12] Some of these tumors can progress to adenocarcinomas with histopathology similar to that seen in humans.[13]

More recently, Stathopoulos and colleagues[14] have elegantly shown that epithelial nuclear factor (NF)-$\kappa$B activation facilitates urethane-induced lung carcinogenesis. In this context, mouse strains susceptible to lung tumor formation (i.e., FVB, BALB/c) exhibited early NF-$\kappa$B activation and inflammation in the lungs after urethane treatment. In contrast, the resistant strain C57B6 failed to activate NF-$\kappa$B or induce lung inflammation. Interestingly, selective NF-$\kappa$B inhibition resulted in increased apoptosis of airway epithelial cells after urethane exposure, highly suggesting that NF-$\kappa$B signaling in airway epithelium is integral to chemically induced tumorigenesis.[14]

Another common example of carcinogen-induced lung neoplasia is the classical two-step initiation/promotion model. Injection of the initiator 3-methylcholanthrene, followed by various exposures to the promoter butylated hydroxytoluene, has been shown to induce adenocarcinoma in BALB/c mice within 16 weeks from the exposure to the initiator. The first stage in this two-stage carcinogenesis procedure (initiation) induces an irreversible lesion in the DNA of a single cell, while the second stage (promotion) initiates cell clonally expands.

Mice are also used to assess carcinogenic activity of various chemicals, including benzopyrenes, metals, nitrosamines, and polyaromatic hydrocarbons.[12] Biochemical effects of lung chemicals can be detected within hours or days of their administration. In strains susceptible to lung tumorigenesis, exposure to chemicals leads to rapid formation of hyperplastic foci in the bronchioles and alveoli. All or some of these foci then evolve into microscopic adenomas, and few months later, some of these adenomas display the nuclear atypia and invasiveness of adenocarcinomas in situ.[15] In contrast, exposure of chemicals in resistant strains only leads to the development of few adenomas and/or papillary tumors within several months from the original exposure.

Given the high incidence of cigarette-induced lung cancer, many animal models have been used to determine the effect of cigarette smoke on lung cancer incidence, formation, and progression.[3] Despite the vast research conducted, it is debatable whether the measured response to cigarette smoke in animal species for assessing carcinogenic potential in humans reflects the strong epidemiological evidence in human smokers. In a recent review article, Coggins[3] points out some of the pitfalls related to exposure of animal models to cigarette smoke. In this context, the cigarettes used in many studies were unfiltered and had very high yields; thus being very different from the cigarettes commonly smoked today. In addition, whereas some

studies used nose-only smoking machines, others used whole-body exposures. Moreover, whereas certain animal models were exposed to single cigarettes, others were exposed to rotating carousels. Finally, when dogs were used for studies, invasive tracheotomy technique was used to facilitate smoke breathing. As results, often lung necrosis and/or inflammation with no apparent neoplasm were evident. Thus, these studies not only do not entirely mimic the exposure of smoke as observed in humans, but also do not recapitulate the events of lung cancer initiation/formation. Lastly, studies performed in rats and mice exposure for lifetime to cigarette smoke suggested that, although both species developed alveolar epithelial hyperplasia, alveolar adenomas, and alveolar carcinomas, the incidence of all three were more evident in the rats. Thus, mice might not represent the most suitable model for smoke-mediated lung cancer.[16]

Mice, however, have been successfully used to study susceptibility to lung cancer following exposure to environmental agents such as radiation and viruses.[17,18] Although these two nonchemical models have the advantage that they are not strain dependent, they present the major disadvantage that tumors develop in various organs, beside the lungs, making the analysis of primary versus potential metastatic lung cancer more difficult to evaluate.

The observation that sensitive mice are more susceptible to chemically induced lung cancer became the basis for quantitative carcinogenicity bioassay[12] and screening systems for chemopreventive agents.[19] Cancer chemoprevention can be defined as the use of agents able to prevent, inhibit, or reverse the process of carcinogenesis.[20] Various anti-inflammatory drugs such as indomethacin or aspirin have been used to lower chemically induced lung tumor development and multiplicity,[21] and specific cyclooxygenase-2 inhibitors have been used to reduce the growth of adenocarcinoma after treatment with carcinogens.[15] In addition, pretreatment of mice with drugs able to inhibit DNA methylation showed chemopreventive efficacy in primary mouse lung tumors induced by nitrosamines (see Chapter 7).[22] Finally, the effect of natural products can be tested for their preventive effect on carcinogen-induced lung cancer. Kohno and colleagues[23] identified chemopreventive factors (i.e., beta-cryptoxanthin and hesperidin) in commercial mandarin juice, able to suppress lung cancer initiated with nitrosamines in A/J mice. In addition, pretreatment with perillyl alcohol, a naturally occurring monoterpene found in lavender, cherries, and mint, 1 week before lung tumor initiation with nitrosamines, significantly reduced tumor incidence and tumor multiplicity, strongly suggesting that this monoterpene is an effective chemopreventive compound in mouse lung tumor bioassay.[24]

In summary, chemically and/or carcinogen-induced lung cancer models offer the major advantage that the induction of lung tumors is highly reproducible, and they can also be used to screen potential carcinogens as well as to identify chemopreventive agents. There, however, disadvantages of these models. In particular, they are time consuming, strain dependent, lead primarily to the development of non–small cell lung carcinoma (NSCLC), allow the detection of lung tumors at late stage of progression, and lead to the development of tumors with low metastatic potential. Moreover, for study related to cigarette-smoke–induced lung cancer, mice might not represent the best animal models available. Finally, administration of chemicals or carcinogens can yield to various different tumor cell types, many of which might not be directly relevant to human lung cancer.

## ORTHOTOPIC MODEL OF LUNG CANCER

Orthotopic models of cancers consist in the injection of tumor cell suspension as well as in the implantation of fresh tumor tissues directly into the appropriate organ of origin. Human tumors and/or human cancer cells can be orthotopically implanted in various organs, including stomach, colon, pancreas, prostate, mammary gland, bladder, and lung.[25] The availability of immunodeficient mouse strains such as the nude mice, the Rag2$^{-/-}$ mice, and the severe combined immunodeficient (SCID) mice facilitated the establishment of human orthotopic models of cancer because of the inefficiency of these mice to reject human cells. The injection of tumor cells in the organ of origin clearly allows a better understanding of the role of the microenvironment in the development of primary tumors. In addition, a major advantage of this model is that it allows studying and recapitulating of the entire process of tumor progression consisting of local tumor growth, vascular and lymphatic invasion at the local site, flow in the vessels and lymphatic, extravasation at the metastatic organs, and seeding and growth at relevant metastatic sites. The availability of both human NSCLC and small cell lung carcinoma (SCLC) cells make the orthotopic model an attractive assay to study lung cancer growth and development as, at present, there is only one genetic mouse model of primary SCLC available (see discussion later). In addition, based on the observation that the microenvironment profoundly affects the phenotype and progression of many tumor types,[26] the injection of lung cancer cells directly into the organ of origin may recapitulate the events of lung cancer growth and progression similar to those observed in humans. Several orthotopic injection routes have been developed for lung cancer, including intrabronchial,[27–29] intrathoracic,[30] intrapleural or intravenous,[31] and direct injection of tumor cells[32,33] as well as implantation of fragments of subcutaneously growing tumor tissues[34] into the lung parenchyma of recipient mice. Of these models, the direct injection of tumor cells into the lung parenchyma represents an exceptionally rapid procedure with limited trauma to the mice and reduced intrapleural leakage of tumor cells. In addition, this method had been successfully used to produce a solitary tumor nodule in the lung followed by metastasis to the mediastinal lymph nodes. It is well recognized that the orthotopically growing tumors will grow and metastasize to organs similarly to the human situation. Thus, the presence of tumors in the contralateral noninjected lung, as well as presence of metastases in lymph nodes, liver, brain, and bones can be used to evaluate the metastatic efficiency of different lung cancer cell lines.[33]

One of the major issues related to cancer is the detection of micrometastases (single cell or clusters of fewer than 10 cells). To improve the visualization of tumors in different organs, tumor cells can be stably labeled with different fluorescent or bioluminescent markers such as green fluorescent protein (GFP)[35] and luciferase.[36] Single GFP-labeled tumor cells can be detected in freshly isolated organs with a fluorescence microscope,[37] and the number of tumors growing on the surface and/or within the organs can be evaluated, and quantitative measurements can be obtained using computer software imaging programs.[33] Retroviral delivery of GFP has been successfully used not only to label primary human tumors, but also to analyze regional and distant metastases.[38] A significant advantage of using GFP- or luciferase-expressing cells is that tumors can be visualized and measured externally in live mice. Hoffman[37] implanted highly metastatic human cell line expressing GFP into the left lungs of nude mice and then followed primary and metastatic growth in real time by analyzing the mice under fluorescence light. Similarly, Rosol and colleagues[39] injected into the left ventricle luciferase-labeled metastatic cells and followed in real time their localization in the lungs by using in vivo bioluminescent imaging. More recently, Acuff and colleagues[29] have used luciferase-labeled human NSCLC cells to determine in real time the contribution of host-derived matrix metalloproteinases to the survival and the early establishment of tumors in the lung. Finally, noninvasive in real-time imaging has been recently employed to determine the effect of systemic delivery of capsid-modified adenoviruses in an orthotopic model of advanced lung cancer.[40] Thus, the use of labeled cells clearly facilitates in vivo imaging as well as longitudinal studies as the same mouse can be monitored over time (Fig. 13.2).

The different orthotopic models of lung cancers, in combination with the intravital imaging of GFP-expressing cells, clearly allow one to follow in real time the effects of chemopreventive and/or antimetastatic drugs. In addition, they allow to asses some critical parameters related to the use of these drugs for cancer treatment and/or prevention, such as (a) the selection of the tumor models that better resemble the phases of tumor progression in humans, (b) the route of administration of the drug, (c) the maximal dose tolerated, (d) the relationship between the desired therapeutic benefits and the length of the treatment, and (e) how long the beneficial effects of the drug last upon withdrawal. It has been observed that orthotopically transplanted human SCLC display a different chemosensitivity pattern compared with the subcutaneously transplanted model,[41] clearly suggesting a different pharmacodynamics between the orthotopic lung and the ectopic subcutaneous sites. Using an orthotopic human lung cancer model, Liu and colleagues[42] showed that KP-392, a potent selective inhibitor of integrin-linked kinase, can be used in combination with cisplatin to enhance tumor necrosis and decrease lung cancer progression. In addition, in vivo inhibition of both vascular endothelial growth factor receptor 2 (VEGFR2) and epidermal growth factor receptor (EGFR) signaling pathways by ZD6474 resulted in profound reduced angiogenesis as well as growth of human lung adenocarcinoma cells orthotopically injected in mice,[43] suggesting that blocking both EGFR and VEGFR signaling might be viewed as a valid tool for the management of locally advanced lung cancer. Finally, aerosol nonviral gene delivery system has been recently used to successfully deliver p53 gene to mice intratracheally inoculated with H358 human NSCLC cell line,[44] strongly indicating this therapeutic strategy might be viewed as an option for patients with early lung cancer.

**FIGURE 13.2** Noninvasive imaging reveals individual variation in mice treated with conditionally replicating oncolytic adenoviruses (CRAds). Examples of treatment results in mice treated with Ad5-Δ24RGD. The labels at left indicate the day of imaging, and each mouse is identified with a number. Mice *1*, *7*, and *12* had progressive disease; mice *5*, *9*, and *11* had stable disease; and mice *6*, *8*, and *10* achieved tumor response. (From Sarkioja M, Kanerva A, Salo J, et al. Noninvasive imaging for evaluation of the systemic delivery of capsid-modified adenoviruses in an orthotopic model of advanced lung cancer. *Cancer* 2006;107:1578–1588.) (See color plate.)

Thus, the orthotopic models of human cancer offer a tool for the discovery of new chemopreventive and antimetastatic agents, for the design of drug treatment regimes, and for investigating their mechanism of actions in a model that better resembles the phases of tumor progression observed in humans.

## GENETIC MODELS OF LUNG CANCER

The generation of transgenic mouse strains able to develop lung cancer similar to the human situation enabled the identification of the genes that drive lung cancer development and progression. Multiple genetic changes are involved in the development and progression of lung cancer.[45] These genetic changes were found to inactivate tumor suppressor genes, activate oncogenes, cause loss of heterozygosity (i.e., deletion of one of two copies of allelic DNA sequences in particular chromosomal regions), or amplify specific chromosomal regions. Three major tumor suppressor genes have been identified as being inactivated in lung cancer. The p53 and retinoblastoma (Rb) genes are frequently inactivated by genetic alterations such as chromosomal deletions and loss-of-function mutations, whereas the p16 gene is inactivated by genetic alterations as well as by transcriptional silencing because of hypermethylation.[45] Among the oncogenes, K-ras represents the main member of this family involved in the development of lung cancer and up to 30% of adenocarcinomas contains activated K-ras.[46]

To recapitulate the events of lung tumor development and progression, mice harboring genetic mutations similar to that observed in human lung cancer have been generated. Most of these genetically manipulated mice are suitable for the study of genetic alteration in NSCLC as they primarily develop pulmonary adenomas and adenocarcinomas. Transgenic mice that express SV40 large T antigen, under the control of promoters specific to pulmonary epithelium, develop multiple lung tumors that cause early death.[47] Moreover, transgenic mice expressing the proto-oncogenic H-ras under control of its own promoter have a high incidence of lung tumors,[48] and transgenic mice carrying a dominant negative mutation in the p53 gene placed under the control of its own endogenous promoter[49] or under a Clara cell secretory protein promoter to target p53 expression specifically in the lung[50] are more susceptible to several potential lung carcinogens, including nitrosamines and benzo(a)pyrene. The lung adenomas generated in the dominant negative p53 transgenic mice exposed to carcinogens possess activating mutations in the K-ras proto-oncogene.[51] Thus, the dominant negative p53 transgenic mice not only offer a suitable model to study the additive effects of genetic alteration and environmental factors in the development of lung cancer, but also clearly demonstrate that the progression of lung cancer is a multiple-hit genetic event.

Besides mutations in key genes such as oncogenes or tumor suppressor genes, altered expression of various growth factors can be used as prognostic marker for lung cancer. Increased plasma levels of insulin-like growth factor-II (IGF-II), for example, are associated with a poor prognosis in human pulmonary adenocarcinoma[52] and specific transgenic overexpression of IGF-II in lung epithelium induces spontaneous lung tumors in 69% of mice older than 18 months of age.[53] These tumors display morphological characteristics of human pulmonary adenocarcinoma (i.e., epithelial origin, tubuloacinar architecture), strongly suggesting a critical role for IGF-II in NSCLC development.

In addition to transgenic mice, mice that have germline disruptions of genes involved in lung cancer have been generated. Mice heterozygous and homozygous deficient for the tumor suppressor genes p53[54] and p16INK4a[55] are viable but have shortened life span because of the predominant occurrence of lymphomas and various sarcomas. Although the incidence of lung cancer is not increased in the p53- and p16INK4a-null mice, most likely because of their short life span, bronchiolar neuroendocrine cell hyperplasia has been described in p53-null mice.[56] Interestingly, similar histological findings have been noted in some patients with benign obstructive respiratory disorders or with carcinoid tumors of the lung, an uncommon human pulmonary epithelial malignancy that rarely metastasizes.[57]

Thirty percent of human tumors carry Ras gene mutations. Of the three genes in this family, composed of K-ras, N-ras, and H-ras, K-ras is the most frequently mutated member in human tumors, including adenocarcinomas of the pancreas (~70% to 90% incidence), colon (~50%), and lung (~25% to 50%). Mice harboring the latent oncogenic mutation G12D in the endogenous K-ras gene (K-rasLA) have been generated.[58] Because early expression of oncogenic K-ras causes mice to die very early during development, the K-rasLA mice have been generated using the "hit-and-run" gene-targeting procedure that involves two distinct steps of homologous recombination. The first recombination event (insertion event) is created in embryonic stem cells ("hit" step), whereas the second recombination event (excision event) occur in vivo only upon a somatic recombination event ("run" step). All mice, carrying this latent allele of K-ras, develop multiple lung tumors, evident as early as 1 week after birth, with histological features of human NSCLC. These tumors, unlike the human situation, do not or rarely metastasize, most likely because of a significant reduced life span of the mice.[58]

The K-rasLA mice have been either crossed with various transgenic mice, or treated with selective drugs to determine the contribution of specific gene products in K-ras–mediated lung tumorigenesis (Table 13.1). In this context, treatment of K-rasLA1 mice with anti-CXCR2 neutralizing antibodies[59] or the EGFR inhibitor gefitinib[60] has resulted in inhibition of lung cancer progression and reduced number/expansion of alveolar neoplasia, respectively. Similarly, the cross of K-rasLA2 mice with mice lacking the collagen receptor integrin-$\alpha 1\beta 1$ resulted in prolonged survival as well as reduced number and size of NSCLC, suggesting that collagen receptors and K-ras might cooperate in lung cancer progression (Macias-Perez, Pozzi, unpublished; Table 13.1 and Fig. 13.3). In contrast, the cross of K-ras-LA with TGF-$\beta$ heterozygote[61] or p53-null mice[58] led to decreased survival rate with accelerated onset and

**TABLE 13.1**   **Examples of How Mice Expressing Oncogenic K-Ras Have Been Used for Analysis of NSCLC Progression and/or Treatment**

| Mouse Lung Cancer Model | Animal Model of Interest | Treatment | Results | References |
|---|---|---|---|---|
| KrasLA1 | | Anti-CXCR2 neutralizing antibodies | Inhibition of malignant lung cancer progression | 59 |
| KrasLA1 | | Gefitinib | Reduced number and expansion of alveolar neoplasia | 60 |
| KrasLA2 | Integrin-$\alpha$1 null | | Prolonged survival with reduced number, size, and incidence of NSCLC | Figure 13.3 |
| KrasLA | TGF-$\beta$ heterozygotes | | Decreased survival with accelerated progression of adenocarcinomas | 61 |
| *KrasLA1* | p53 null | | Accelerated onset of cancer, resulting in significant decreased survival | 58 |
| Conditionally activatable oncogenic *K-ras* | Rac1$^{fl/fl}$ | AdenoCre intranasal infection | Prolonged survival with reduced number, size, and incidence of NSCLC | 64 |
| Conditionally activatable oncogenic *K-ras* | p53$^{fl/fl}$ | AdenoCre intranasal infection | Increased tumor multiplicity and decreased median survival | 65 |
| Conditionally activatable oncogenic *K-ras* | p6$^{Ink4a}$ null | AdenoCre intranasal infection | Mild increased tumor multiplicity with no changes in median survival | 65 |
| Conditionally activatable oncogenic *K-ras* | Ink4a/Arf null | AdenoCre intranasal infection | Increased tumor multiplicity with no changes in median survival | 65 |
| Conditionally activatable oncogenic *K-ras* | Lkb1$^{fl/fl/}$ | AdenoCre intranasal infection | Increased tumor multiplicity and decreased median survival | 65 |
| Conditionally activatable oncogenic *K-ras* | LucRep mouse | AdenoCre intranasal infection | In vivo detection of single lesion measuring 1–2 mm in diameter | 66 |

progression of lung cancer, suggesting that TGF-$\beta$ and p53 inhibit K-ras–mediated lung cancer initiation/progression.

Clearly, the generation of transgenic mice carrying the same mutated genes observed in human lung cancer has enabled scientists to better characterize the mechanisms by which these genes drive lung cancer development. However, these genetic models of lung cancer present the major disadvantages that (a) mice develop primarily a subset of lung cancer; (b) tumors usually do not metastasize, unlike in the human situation; and (c) because of the short life span of tumor-bearing mice, it is impossible to study the progression of lung cancer. To improve mouse models of lung cancer initiation and progression, Jackson and colleagues[62] generated a Lox-Stop-Lox K-ras conditional mouse strain in which expression of oncogenic K-ras is controlled by a removable transcriptional termination *stop* element. Upon removal of the stop element, achieved by intranasal administration of AdenoCre virus, the mice develop lung cancer. Usually, tumors are visible within 2 weeks postinfection, and they evolve from adenomatous hyperplasia to adenocarcinoma within 16 weeks postinfection. Similarly, Meuwissen and colleagues[63] generated transgenic animals in which the chicken $\beta$-actin promoter drives the expression of GFP and oncogenic K-ras$^{V12}$ gene. As a polyadenylation signal behind the GFP cassette prevents read-through into the K-ras$^{V12}$ gene, expression of K-ras$^{V12}$ is dependent on Cre-lox–mediated deletion of the GFP fragment. Within up to 56 weeks postinfection, all mice developed multiple lesions that subsequently developed into larger, papillary-like tumors within 8 weeks postinfection.[63]

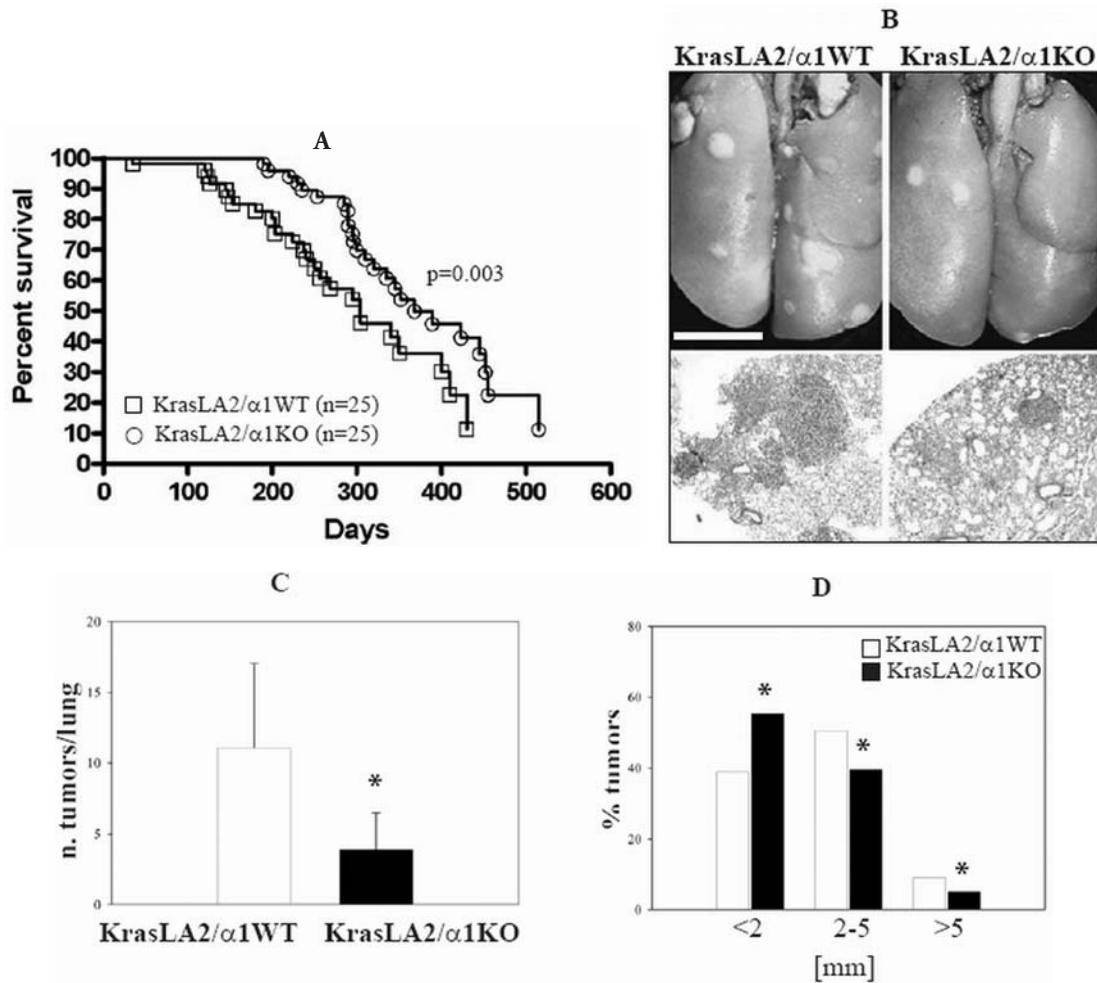
Without any doubt, the advances of these inducible methods over existing models are that timing of tumor initiation and location can be controlled and tumor multiplicity can be adjusted by varying the administration of AdenoCre. Recently, the K-ras–floxed mice described previously have been crossed with either the Rac1$^{fl/fl}$ mice[64] or the Lkb1$^{fl/fl}$ mice[65] and the incidence of lung cancer was followed upon AdenoCre intranasal infection. Whereas expression of oncogenic K-ras in the absence of small GTPase Rac1 led to prolonged survival with reduced number, size, and incidence of NSCLC[64] (Table 13.1), expression of oncogenic K-ras in the absence of the serine/threonine kinase 11 Lkb1 increased tumor multiplicity and metastasis, but decreased median survival[65] (Table 13.1). Thus, these studies establish Rac1 as a critical key player in lung cancer progression, whereas LKB1 can be viewed as antipulmonary tumorigenic kinase, controlling initiation, differentiation, and metastasis. Finally, Lyons and colleagues[66] have crossed the K-ras–floxed mice with the LucRep transgenic mouse that enables bioluminescence imaging only upon AdenoCre treatment. Direct imaging of the lungs from K-ras–floxed/LucRep mice treated with AdenoCre revealed the in vivo detection of single lesion measuring between 1 and 2 mm in diameter.[66] Thus, the LucRep mice can be successfully used not only for noninvasive bioluminescence


**FIGURE 13.3** Increased survival and reduced tumor development in KrasLA2 mice crossed with integrin $\alpha$1-null mice. **A:** KrasLA2 mice crossed with the integrin $\alpha$1-null mice (KrasLA2/$\alpha$1KO) showed significantly increased survival compared to KrasLA2 mice crossed with integrin $\alpha$1 wild-type mice (KrasLA2/$\alpha$1WT). **B:** Top: Photograph of the lungs of KrasLA2/$\alpha$1WT and KrasLA2/$\alpha$1KO male mice sacrificed 120 days after birth. *Scale bar*, 5 mm. Bottom: Hematoxylin and eosin staining of lungs of KrasLA2/$\alpha$1WT and KrasLA2/$\alpha$1KO mice. Magnification, $\times$200. (See color plate.) **C**,**D:** KrasLA2/$\alpha$1WT and KrasLA2/$\alpha$1KO mice were sacrificed 120 days after birth and tumor number (**C**) and size (**D**) were evaluated. The number of tumors visible on the lung surface was evaluated and expressed as average number of tumors per lung (**C**). Tumor diameter was measured with a caliper in 170 tumors from KrasLA2/$\alpha$1WT and 102 tumors from K-rasLA2/$\alpha$1KO mice, and tumors were divided into three groups as indicated (**D**). (Data from Macias-Perez I, Borza C, Chen X, et al. Loss of integrin alpha1beta1 ameliorates Kras-induced lung cancer. *Cancer Res* 2008;68(15):6127–6135.)

imaging, but also for the analysis of tumors that cannot be easily identified by traditional histology.

Administration of AdenoCre has also been used for the establishment of the first mouse genetic model of SCLC 9.[67,68] Meuwissen et al.[67] have produced an animal model of SCLC that closely resembles the human disease. Conditional mice carrying combined floxed Rb and p53 genes were treated with AdenoCre via intratracheal injection to delete these two tumor suppressor genes specifically in the lung. Cre-mediated deletion of all four conditional alleles resulted in the development of lung tumors with the histological and immunohistochemical characteristics of human SCLC. The originality of this model is that

lung tumors not only present the typical neuroendocrine features as seen in human SCLC, but they also metastasize to sites that mimic the human disease, including adrenal gland, ovaries, and liver. Interestingly, in certain double floxed Rb and p53 mice treatment with AdenoCre led to conditional inactivation of the p53 gene only, but not Rb gene, giving rise to NSCLC-like adenocarcinomas.[67] Thus, this model suggests that whereas inactivation of a single tumor suppressor gene is sufficient for the development of NSCLC, simultaneous inactivation of at least two different tumor suppressor genes is necessary for the establishment of SCLC. In addition, this model emphasizes the importance of Rb during the development of SCLC.

The genetic models of lung cancers, similarly to the chemical and orthotopic models, appear to be particularly applicable not only for basic mechanistic studies, but also for analyzing the efficacy of chemopreventive and/or chemotherapeutic agents. This kind of study, however, is limited to primary lung cancer, as in these genetic models of lung cancer, primary tumors do not or rarely metastasize, making the comparison with human tumors, and the evaluation of potential antimetastatic drugs difficult to evaluate. Interestingly, it has been proposed that the effect of genetic mutations on the development of metastatic tumors can be influenced by the genetic background of the mouse. Using a transgene-induced mouse tumor model that exhibits a high incidence of pulmonary metastases and a breeding strategy to vary genetic background, Lifsted and colleagues[69] found significant differences in metastatic efficiency between the original strains and first-generation hybrids, without altering tumor initiation or growth kinetics. As all tumors are initiated by the same oncogenic event, differences in the metastasis are most likely because of genetic background effects, rather than different combinations of oncogenic mutations. Quantitative genetic mapping in the different backcrossing has allowed the identification of at least three loci that are associated with altered metastatic potential, strongly reinforcing the notion that tumorigenesis and metastasis are complex phenotypes involving not only cellular responses to extrinsic stimuli, but also inherent genetic components.[70] Thus, finding the ideal genetic background for the development of primary as well as metastatic lung cancers might enable researchers to study the different steps involved in lung cancer progression, to screen potential antimetastatic molecules, and to understand their mechanism of action.

## CONCLUSION

Cancer susceptibility is a complex interaction of an individual's genetic composition and environmental exposures. Tremendous work has been done to understand cancer over the past 100 years, from recognition of cancer as a genetic disease to identification of specific carcinogens, isolation of oncogenes, and recognition of tumor suppressors. Lung cancer is most likely the result of an intricate interaction of polymorphic susceptibility genes with many environmental factors. Although genetic mutations in mice and humans do not always lead to the same tumor spectrum, the underlying molecular mechanisms are frequently relevant to both species. The different mouse models of lung cancers described in this chapter, mainly if used in combination with one another, will facilitate the identification of genes that modulate an individual's susceptibility to cancer after a certain environmental exposure, and will clearly allow researchers to gain important insights into lung cancer development, treatment, and, most importantly, prevention.

CHAPTER 14

# Cell Cycle and Vascular Targets for Radiotherapy

## CELL CYCLE TARGETS FOR RADIOTHERAPY

The cell cycle checkpoints ensure that cells replicate their genomes with high fidelity. In response to DNA-damaging agents such as ionizing radiation or cytotoxic chemotherapy, cell cycle checkpoints delay progression through cell cycle to allow repair before completion of mitosis. Critical parts of the cell cycle machinery are the evolutionarily conserved cyclin-dependent kinases (Cdks), which regulate the transition from one phase of the cell cycle to the next. The Cdks are activated by cyclins and inhibited by naturally occurring Cdk inhibitors (CKI). Cell cycle arrest after DNA damage is critical for maintenance of genomic integrity, and loss of normal cell cycle checkpoint signaling is common in cancers and is considered a pathologic hallmark of neoplastic transformation.[1]

The ability to manipulate cell cycle signaling has important clinical implications in lung cancer. For example, modulation of the checkpoints before the completion of DNA repair could enhance cellular sensitivity to DNA damage agents such as radiotherapy, leading to cell death.

This chapter focuses on the cell cycle dysregulation present in lung cancer, the cell cycle effects of radiotherapy, and on the role a cell cycle modulator may play in combination therapy. The knowledge of these concepts might lead to more efficient use of current anticancer therapies and to the development of novel agents.

### Cell Cycle Signaling Response to Ionizing Radiation

Cell proliferation results of the repeated progression through a cycle made of four phases and regulated by a defined set of protein complexes.[2,3] Molecular mediators of the cell cycle include cyclins that promote cell cycle transition; Cdks that regulate the cell cycle by forming complexes with their cyclin catalytic partners; and endogenous CKIs that inhibit cyclin–Cdk complexes (Fig. 14.1). The cellular response to DNA damage is the activation of cell cycle checkpoints that serve as natural surveillance mechanism for DNA integrity (Fig. 14.2). Irradiation induces both single- and double-stranded DNA breaks (DNA DSBs), the latter being generally considered the lethal event.[4–7] Two major systems contribute to the repair of DNA DSBs induced by radiation. Homologous recombination, during the late S and G2 stages of the cell cycle, is critical in cell signaling and is regulated by the cell cycle, whereas nonhomologous end-joining is more important during G1 and early S phases and is the predominant mechanism of DNA DSBs repair.

Central to the signal transduction pathways are two phosphatidylinositol 3-kinase–like kinases (PIKKs), ataxia telangiectasia mutated (ATM), and ATM and Rad3-related (ATR), which transmit the damage response signal through phosphorylation.[8] Radiation-induced DNA damage activates ATM, serving as proximal damage sensor, by autophosphorylation at $Ser^{1981}$ resulting in ATM dimmer dissociation.[9–12] Evidence suggests an activating role for the Mre11-Rad50-NBS1 (MRN) complex that binds independently to DNA DSBs and facilitate the signaling of ATM.[13,14] Cells with defective or lacking ATM or mutated ATM gene are extremely sensitive to irradiation, suggesting that ATM is a cornerstone in the DNA damage response.[15–17] ATM and ATR respond to single-stranded regions of DNA by replicative stress.[18] Once activated, ATM can potentially activate signaling receptors and stimulate cell cycle checkpoints, p53 activity, and DNA repair complex function.[19–21]

Cell cycle checkpoints monitor the structural integrity of chromosomes before progression through crucial cell cycle stages.[22] Checkpoints occur at entry into S phase (the G1/S checkpoint), entry into mitosis (the G2/M checkpoint), as well as during replication (intra-S checkpoints).[23,24] After irradiation, the damage response signaling pathways facilitate communication between damage recognition proteins and the checkpoint machinery to effect arrest of cell cycle progression (G1 or G2 arrest) and increase the opportunity for repair before undertaking important events such as replication or mitosis.[25]

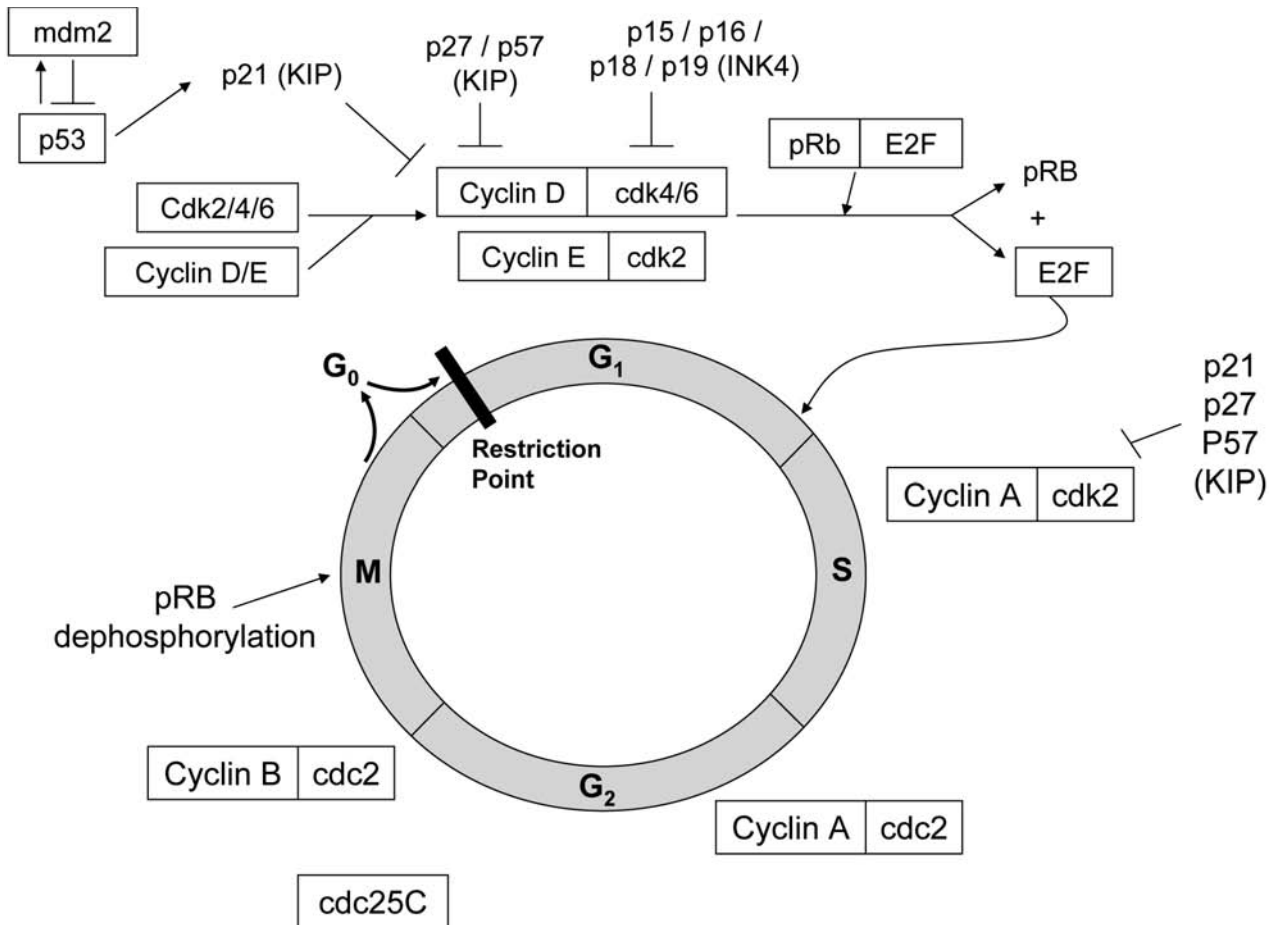
In most solid tumor cells, G1 arrest is dependent on the activation of the tumor suppressor gene p53 and the downstream CKI p21, which also plays a role in cellular senescence, apoptosis, and DNA repair.[26,27] It is not clear whether p53


**FIGURE 14.1** Schematic overview of cell cycle regulation. The cell cycle has four phases: M, G1, S, and G2, defined by the status of the genetic material. DNA replication occurs in S phase, and chromosome segregation occurs in M phase or mitosis. Two gap phases serve as checkpoints for entry into S and M (G1 and G2, respectively). These gap phases are characterized by DNA content, 2N in G1 and 4N in G2. Resting or quiescent cells are in a phase called G0. Entry into each phase of the cell cycle is strictly ordered and regulated. Passing of the cell through the restriction point is a key step in cell cycle progression. G1/S transition is promoted by the E2F transcription factor, whereas the G2/M transition can be induced by Cyclin B. Furthermore, cell cycle regulation occurs via a complex of cyclin proteins and catalytic kinases known as cyclin-dependent kinases (Cdk), which are held in an inactive state by physical interactions with endogenous Cdk-inhibitors (CKI) such as p16, p21, and p27. *cdc25C*, cell division cycle 25 homologue C; *Cdk2/4/6*, cyclin-dependent kinase 2/4/6; *E2F*, E2F transcription factor 2; *KIP*, kinase-interacting protein; *mdm2*, Mdm2 p53 binding protein homologue; *pRB*, phosphorylated-Retinoblastoma.

gene and G1 arrest have an influencing role in radioresistance in solid tumor cells.[28] In contrast, G2 arrest, which can be influenced by p53, may have a radioprotective function by providing cells time to repair DNA damage, and is controlled by the nuclear activities of the cyclin B1-CDC2 complex.[29,30] Two ATM-dependent G1/S checkpoints can be individualized. First, ATM activation in G1 leads to CHK2 phosphorylation and in turn, to phosphorylation of the phosphatase CDC25A. This increases the proteolytic degradation of CDC25A and prevents activating dephosphorylation of CDK2 and initiation of the G1/S checkpoint.[31,32] Second, ATM phosphorylates the tumor suppressor p53, either directly or indirectly through CHK2, stabilizing the protein and prolonging its half-life, which function as a transcription factor for the CKI p21. p53

serine 15/20 phosphorylation disrupts the normal binding of the oncoprotein MDM2 to p53, thereby inhibiting its degradation process and prolonging its half-life. This pathway has a role in the maintenance of the G1/S checkpoint.[33]

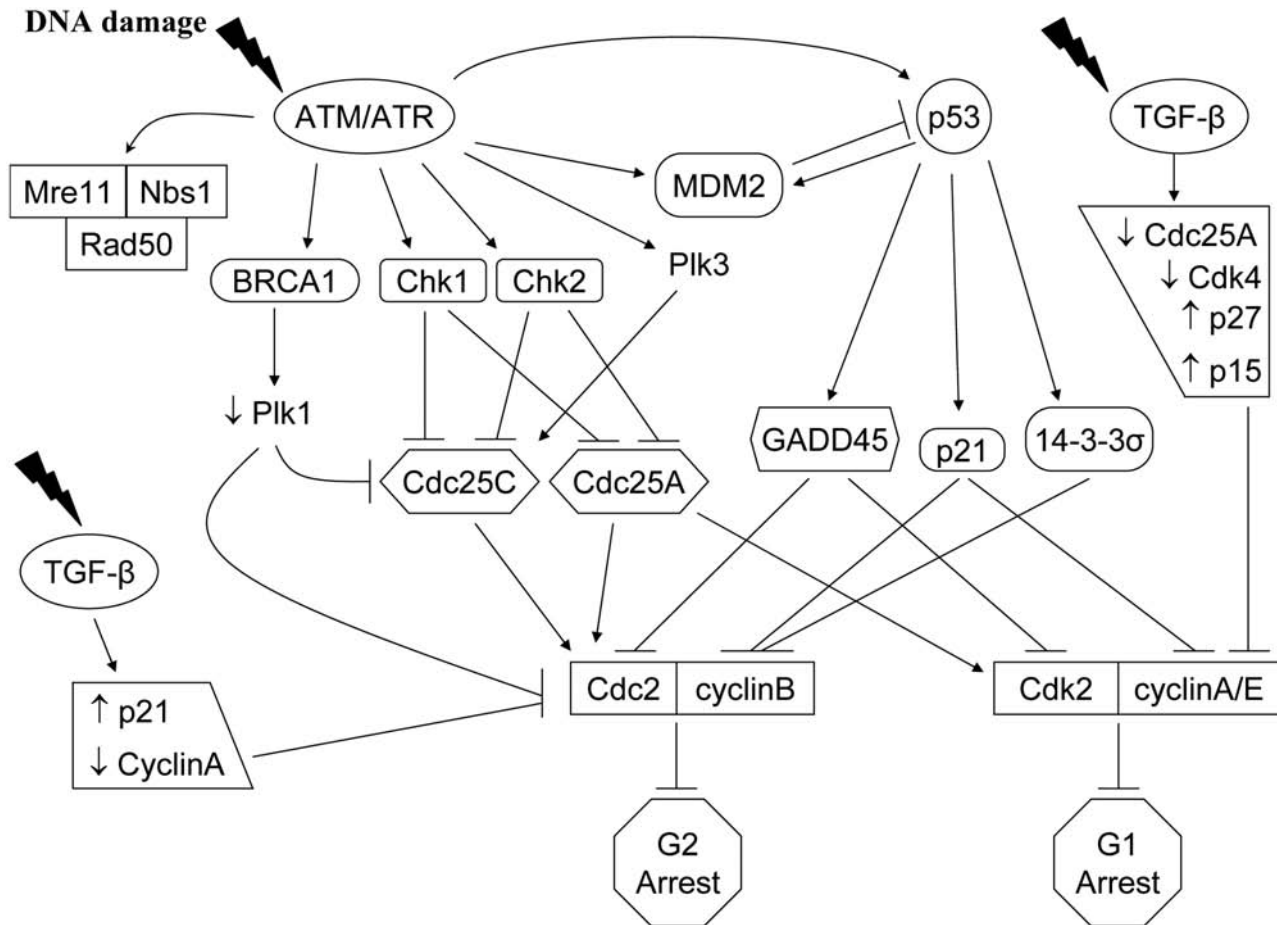
Two distinct G2/M checkpoints can also be identified, determined by the kind of DNA damage and by the time sequence.[34] The first checkpoint, ATM dependent, occurs rapidly after radiation-induced damage and is controlled by CHK1-mediated signaling that leads to inhibition of cyclin B1/CDC2 activity. It represents the failure of cells that had been in G2 at the time of irradiation to progress into mitosis. This G2/M checkpoint, which is dose independent, may be the transducer element linking low-dose hyperradiosensitivity to the subsequent process of resistance.[35] In contrast, the dose-dependent G2/M


**FIGURE 14.2** Schematic overview of cell cycle checkpoints after irradiation. In mammalian cells, radiation-induced DNA damage is first detected by sensor DNA-bound protein complexes. ATM and ATR are primary signal transducers that are activated by DNA damage at all points in the cell cycle. p53 is a key effector of the G1 and G2 checkpoint responses. Expression of p53 can arrest cells in the G1 phase in response to DNA damage, thereby arresting DNA replication for repair. Many cells also exhibit a G2 arrest following exposure to ionizing radiation, allowing repair before progressing through the cell cycle. However, a major mechanism underlying the G2 DNA damage checkpoint is p53 independent. It involves chk1 and chk2, which inhibit CDC25C to carry out the activating dephosphorylation of cdc2. Therefore, G2 cells accumulate inhibited cyclin B/cdc2 complexes and are incapable of entering into mitosis. CDC25A, responsible for activating dephosphorylation of cdk2, is a key target. In response to DNA damage, phosphorylation of CDC25A by chk1 or chk2 leads to its destabilization and the accumulation of inactive cdk2 phosphorylated complexes. Because ongoing DNA replication requires the activity of cdk2, DNA synthesis ceases until damage is repaired. *ATM/ATR*, ataxia telangiectasia mutated/ataxia telangiectasia and Rad3 related; *BRCA1*, breast cancer 1; *Cdc2*, cell division cycle 2; *Cdc25A*, cell division cycle 25 homologue A; *Cdc25C*, cell division cycle 25 homologue C; *Cdk2*, cyclin-dependent kinase 2; *Cdk4*, cyclin-dependent kinase 4; *Chk1*, checkpoint kinase 1; *Chk2*, cell cycle checkpoint kinase 2; *GADD45*, growth arrest and DNA damage-inducible protein 45; *MDM2*, Mdm2 p53 binding protein homologue; *Mre11*, meiotic recombination 11; *Nbs1*, Nijmegen breakage syndrome 1; *Plk1*, polo-like kinase 1; *Plk3*, polo-like kinase 3; *Rad50*, RAD50 homologue; *TGF-β*, transforming growth factor, beta.

accumulation begins to be measurable several hours after irradiation. This mechanism is ATM independent, and represents the accumulation of cells that were in earlier phases of the cell cycle at the time of exposure.[34] G2/M accumulation after exposure to radiation is not affected by the early G2/M checkpoint and is enhanced in cells lacking the radiation-induced S-phase checkpoint, such as those lacking NBS1 or BRCA1 function.[34] It is initiated by the phosphorylation of checkpoint kinases, CHK1 and CHK2, and CDC25A/C, which inactivate the enzymes,

blocking activation of CDK1, and causing a G2 arrest. p53 was shown to suppress promoters of cdc2 and cyclin B, which leads to G2/M arrest, and to have a regulation role in the sustain of the G2/M arrest.[36] DNA damage by radiation blocks pRb phosphorylation through p21 to maintain the pRb-regulated cell cycle arrest to complete DNA damage repair. The further identification of cell cycle signaling elements in response to ionizing radiation will have important implication for the development of anticancer targeted strategies.

**TABLE 14.1** **Most Frequent Cell Cycle Genes/Proteins Presenting Mutations or Altered Expression in Lung Cancer**

| Gene | Protein | Function | Cycle Phase | Alteration in Lung Cancer |
|---|---|---|---|---|
| ATM | ATM | Checkpoints, repair | S | Mutated, deleted |
| AURKA | Aurora A | Mitotic kinase | M | Overexpressed |
| CCND1,2,3 | Cyclins D | Positive regulator of cdk4/6 | G1/S | Overexpressed |
| CCNE1 | Cyclin E1 | Positive regulator of cdk2 | G1/S | Overexpressed, deregulated |
| CDK4 | Cdk4 | Inactivates pRb | G1/S | p16-resistant mutations |
| CDKN2A | p16INK4a | cdk4/6 inhibitor | G1/S | Mutated, deleted, methylated |
| CDKN1B | p27Kip1 | cdk2 inhibitor | G1/S | Underexpressed |
| CDKN1C | p57Kip2 | cdk2 inhibitor | G1/S | Underexpressed, methylated |
| CDKN2A | p14Arf | Activator of p53 | G1/S | Mutated, deleted |
| CHK2 | chk2 | Checkpoints | S | Mutated |
| CKS1,2 | cks1, cks2 | cdk-binding proteins | G1/S | Overexpressed |
| hCDC4 | hCdc4 | Turnover of cyclin E | G1/S | Mutated, deleted |
| MTBP | MDM-2 | Inhibitor of p53 | G1/S | Overexpressed |
| NBS1 | Nbs1 | Checkpoints, repair | S, G2 | Mutated |
| PLK | Plk1 | Mitotic kinase | M | Overexpressed |
| PTTG1 | Securin | Anaphase inhibitor | G1/S | Overexpressed |
| RB1 | pRb | Represses E2F transcription | G1/S | Mutated, deleted |
| RB2 | p130 | Inhibits cdks, represses E2F | G1/S | Mutated, deleted |
| SKP2 | Skp2 | Turnover of p27 | G1/S | Overexpressed |
| TP53 | p53 | Checkpoints, apoptosis | G1, G2/M | Mutated, deleted |

**Cell Cycle Alterations in Lung Cancer** Molecular analysis demonstrates that alterations in components of the cell cycle machinery and checkpoint signaling pathways occur in most lung tumors (Table 14.1). Alterations in the cell cycle machinery that occur most frequently include overexpression of cyclins, cdks, and Cdc25 phosphatases, loss or mutation of the RB tumor suppressor, and loss of cdk expression. The most frequently altered cell cycle checkpoint signaling molecule is the p53 tumor suppressor.

**Cyclins D1** Following a mitogenic signal during the G1 phase, cyclin D1 assembles with cdk4 and a CDK-interacting protein (CIP) (p21)/kinase-interacting protein (KIP) (p27) protein. This complex enters the nucleus and phosphorylates the retinoblastoma tumor suppressor protein Rb1,[37] promoting the release of E2F transcription factor from the Rb1/E2F complex[38] and thus the progression from G1 to S phase. During G1/S transition, glycogen synthase kinase (GSK)-3$\beta$ enters the nucleus and phosphorylates cyclin D1, allowing its nuclear export by Crm1[39,40] and degradation by the 26S-proteasome.[40,41] Under certain conditions, the cyclin D1/cdk4 complex can also act as a mediator of programmed cell death.[42,43] Cyclin D1 can also directly interact with several nuclear receptors and transcription factors,[44–48] by repressing or inducing them. This transcriptional function links cyclin D1 not only to cell cycle and apoptosis but also to migration, invasion, differentiation, inflammation, and angiogenesis. Cyclin D1 has been identified as a proto-oncogene, PRAD1, and

was found to be overexpressed relative to normal tissue in many human cancers.[3,49,50] Overexpression of cyclin D1 is associated with dysregulation of cell cycle and is reported in 25% to 60% of non–small cell lung cancer (NSCLC),[51,52] varying from 30% to 35% in squamous cell carcinoma (SCC) and 36% to 56% in adenocarcinoma (ADC) in the largest series.[53–55] Cyclin D1 overexpression is less common in neuroendocrine tumors (NE) and, among these, more frequent in atypical carcinoids (20%) and large cell neuroendocrine cancers (LCNE) (9.5%). Cyclin D1 dysregulation is frequently an early event in tumorigenesis, elevated levels being already found in bronchial[56,57] and alveolar hyperplasia.[58,59] Cyclin D1 level has also been linked to heavy smoking and said to constitute a marker of tobacco exposure.[52,60,61]

### Cdk Inhibitors

**p21.** p21 was the first CKI to be discovered. It is a member of the KIP family of proteins that nonspecifically inhibit cyclin–cdk complexes in the nucleus.[62] It can inhibit the cyclin D/cdk4 and cyclin E/cdk2 complexes early in G1, and it can also inhibit the cyclin A/cdk2 complex later, prior to the S-phase/G2-phase transition.[63] p21 transcript is directly activated by p53 and seems to be a fundamental partner for p53. It contributes to p53-induced apoptosis[64] and blocks the G2/M transition through cdc2 inhibition, mediating the pro-apoptotic and cell cycle–arresting effects induced by p53 in response to genotoxic stimuli.[65] Recent studies have

shown potential new roles for p21 and p27, as inhibitors of apoptosis and so, as potential oncogenes. These roles have been related to their relocalization to the cytoplasm,[66–70] whereas the cell cycle inhibitory activity is dependent on the nuclear localization. Although p21 is infrequently expressed in normal lung,[71] it is overexpressed in 35% to 51% of NSCLC cases, without significant differences between ADC and SCC.[71–75] p21 expression has been correlated with better differentiation in NSCLC.[71,73,74] In two studies adequately controlled for disease stage, p21 expression was associated with improved survival,[72,75] whereas another study reached slightly different conclusions.[76] In an analysis combining p21 and TGF-$\beta$, an improved survival was observed in early stage NSCLC when p21 and TGF-$\beta$ were in concordance, presenting both high or both low expression.[76] Absence of p21 expression has been correlated to a worse prognosis when associated with p53 positivity[75] and absence of p16 expression.[77]

**p27.**    p27, another member of the KIP family, blocks the activity of cyclin D1-CDK4/6 and cyclin E-CDK2 and is an important negative regulator of the G1 to S transition.[66,78] In the normal resting cell, concentration of p27 is high and declines in response to proliferative stimuli. p27 overexpression leads to cell cycle arrest, whereas its loss of expression may result in tumor development and/or progression. As described for p21, some studies have suggested p27 to be an oncogene by inhibiting apoptosis, and that this role is related to its cytoplasmic relocalization.[66,79] In vivo studies have shown that p27 expression decreases progressively during lung carcinogenesis.[80] Increased p27 proteolytic activity has been associated to low levels of p27.[77,81] Low p27 expression has been associated with higher stages of lung cancer,[82] as well as poor survival in NSCLC, either by itself[77,81–83] and/or when associated to other abnormalities like p53 mutations and/or Rb loss,[84] Ras mutations,[85] high cyclin E levels,[79] high proliferative rates[84,85] and aneuploidy.[84] A favorable response to chemotherapeutic agents, including drugs targeting EGFR and HER-2, has been correlated to increased p27 expression.[86,87]

**p16.**    p16 is a member of the INK4 family of proteins that inhibits cdk4 and cdk6 activation through a competitive mechanism for cyclin D binding site and specifically during the G1 phase.[88] Loss of p16 has similar effects on G1 progression than overexpression of cyclin D and loss of Rb. The discovery of p16 overexpression in Rb −/− cells, which alters the relationships between cyclin D, cdk4, and cdk6, suggests the existence of a feedback mechanism between p16 and Rb.[89] Decreased p16 is one of the most frequent alterations in lung cancer. Interestingly, loss of p16 is usually found in NSCLC, whereas loss of Rb is found in SCLC. These changes in p16 and Rb seem to be mutually exclusive.[90–93] The strong inverse correlation is more evident in SCC and SCLC than in ADC.[94,95]

**p14.**    p14 is an alternate transcription product from the INK4/ARF locus shared with p16.[96–98] By its ability to antagonize the MDM2-mediated ubiquitination and degradation of p53,[99–102] it induces apoptosis[103,104] and growth inhibition.[99] p14 is decreased in 50% of NSCLC,[97,101] where it has

an inverse relationship with MDM-2 expression.[101] p14 can be lost secondary to losses at the p16 locus, and also because of the gene promoter methylation.[103,105]

**p53 TUMOR SUPPRESSOR.**    p53, mapped on chromosomic region 17p13, is a tumor suppressor gene that, after sublethal DNA damage, mediates cell cycle arrest in the G1 phase.[106,107] In this pathway, p53 interacts with several genes. The first one is mdm2: Levels of p53 are kept low by its association with the mdm2 oncogene product, which binds p53 and shuttles it out of the nucleus for proteolytic degradation, establishing an autoregulated feedback circuit. The second gene target is gadd45, that belongs to a gene family implicated in cellular growth arrest.[108,109] The third target is the gene coding for p21, which develops inhibitory action on multiple cyclin–cdk complexes and also complexes with PCNA, a protein playing a key role in DNA reparation processes.[110] The fourth target is the gene coding for Bax, which promotes apoptotic mechanisms and forms a heterodimer with Bcl-2 gene.[111] As a key regulator of cell growth and cell death, p53 is activated by several kinases that regulate the DNA damage checkpoint following many environmental stimuli, including DNA-damaging agents such as ionizing radiation, and is crucial in preventing the propagation of mutations in normal cells.[67] Activated p53 induces cell cycle arrest (p21$^{\text{Cip1/Waf1}}$) to allow cells to repair the damage or apoptosis if the damage is too severe and/or irreparable.[112] During carcinogenesis, p53 is frequently inactivated by multiple mechanisms. The most common mechanism is mutation at the p53 gene, which occurs in more than 50% of all human cancers. In response to DNA damage, some p53 mutants show less capacity to bind and initiate transcription from their target genes, such as p21, Mdm2, Bax, and cyclin G, and so, some of the p53-mediated effects are blunted,[113] resulting in insensitivity to growth-inhibitory signals as well as evasion of apoptosis. Mouse models have confirmed cooperation between mutated p53 and mutative active K-ras in NSCLC development[114] and between p53 and Rb in SCLC development.[115]

p53 mutation is one of the most common genetic alterations in lung cancer, with about 70% of SCLC and 50% of NSCLC presenting mutations in one allele of p53, often accompanied with loss of the wild-type allele.[116] In NSCLC, p53 mutations are more frequently found in SCC than ADC.[117] The p53 mutational spectra of lung cancer are different from those of other cancers with an excess of G:C to T:A observed,[118] these ones especially linked to exposure to tobacco carcinogens such as benzopyrene.[119] Several studies investigated the association of p53 abnormalities with prognosis in lung cancer, with discordant results. Some of them showed an association of p53 overexpression (mutants form have a longer half-life and lead to the detection of high levels of protein by IHC) with shorter survival,[120–122] others failed to find such an association.[123,124] Concurrent p53 and p16 abnormalities have been associated to a worse prognosis.[125,126] Many reports have linked the presence of p53 mutations to resistance to DNA-damaging chemotherapeutics agents,[127] and this is not surprising as we know that most chemotherapeutics agents act by stimulating apoptosis.

## Cell Cycle as Target for Combined Treatment with Radiotherapy

Cellular radiosensitivity varies along the different phases of cell cycle. The majority of cells surviving after a first dose of radiation were most likely in a less sensitive (G1 phase) or in a resistant phase of the cell cycle (late S phase). Those cells will then progress into a more sensitive cell cycle phase, that is at or close to mitosis, which represents a more ideal time for delivering radiation therapy. Several cell cycle regulatory proteins are potential molecular targets for cancer therapy, and agents can be combined to radiation to enhance its effects on lung cancer. Efforts have been made to sensitize cancer cells to the cytotoxicity of DNA damage by anticancer agents as early as four decades ago with compounds such as caffeine, which resulted in abrogation of the G2 cell cycle checkpoint. Many malignant cells, including lung cancer, have defective G1 checkpoint mechanisms and depend far more on G2 checkpoint than normal cells. More recently, several potent agents have been studied in preclinical and clinical trials. Among them is flavopiridol, the first CKI to enter clinical trials as a potential anticancer agent that exerts both cytostatic and cytotoxic actions on cancer cells. Another well-known drug is UCN-01, a potent prototypical chk1 inhibitor, which function as a CKI at high concentrations. Such compounds seek to force cells to enter mitosis without allowing adequate time for DNA repair, increasing the likelihood that cell death will occur by accumulation of DNA lesions. Treatment strategies consisting in abrogation of G2 checkpoints can also be achieved with the use of microtubule-targeting compounds, such as taxanes and epothilones to stall cells in G2/M (by preventing mitosis, thereby trapping cells in the phase of the cell cycle where ionizing radiation have the greatest effects). Microtubule-stabilizing agents will be discussed as mitotic targets in combination with ionizing radiation. Finally, Aurora kinases, part of the spindle checkpoint, are recent agents that can also be used in combined anticancer therapy (Table 14.2).

## Cyclin-Dependent Kinases (CDK) Modulators

Cell cycle regulatory proteins such as CDKs are potential molecular targets for radiation therapy.[128–130] The rationale for targeting the cell cycle and the CDKs in lung cancer therapy has been based on the frequency of their perturbations in lung tumors (overexpression of cyclins, and/or absent or diminished levels of CKI).[54,55,131,132] For example, overexpression of cyclin D1 and loss of p16 gene expression has been associated with the development of lung cancer (see previous discussion). These defects in tumor cells lead to uncontrolled proliferation as a result of the loss of checkpoint integrity. In addition, cell cycle arrest by CKI has been shown to induce apoptosis.[1,133–135]

**FLAVOPIRIDOL.** Flavopiridol is a semisynthetic flavone that directly competes with the ATP substrate and reversibly inhibits kinase activity of multiple classes of CDKs, including cdk1, cdk2, cdk4, cdk6, cdk7, and cdk9 at submicromolar concentrations (IC50 values of 100 to 400).[136] This pancyclin inhibitor causes arrest at both G1 and G2/M phases of the cell cycle by several mechanisms: direct inhibition of cdks 1, 2, and 4, and indirect inhibition by downregulating cyclin H-cdk7,[137–140] as well as tumor growth arrest in most solid tumors and xenografts.[140–144] Flavopiridol also promotes a decrease in the level of cyclin D1,[135] which is commonly overexpressed in many cancers including lung cancer where it has been described as a poor prognosis marker.[51–55,131,145–149] However, at considerably higher concentrations than necessary to inhibit CDKs, flavopiridol inhibits the activity of several other protein kinases[150,151] including signal transducing kinases protein kinase A (PKA), PKC, and Erk-1, the receptor tyrosine kinase EGFR, and receptor-associated protein kinases such as c-Src.[152] In addition, although described as cytostatic, flavopiridol has been shown to be also cytotoxic to many lung cancer cell lines[143,144,153,154] by induction of apoptosis except in the A549 lung carcinoma cell line.[154] Normally, DNA-damaging agents induce p53, which in turn transcriptionally induces p21 and Mdm-2, the later binds p53 and targets it for degradation.[155] Although upregulating p53, flavopiridol was shown to inhibit transcription of p21 and Mdm-2 and to inhibit cell proliferation in A549 lung cancer cells.[153]

**TABLE 14.2** **Potential Cell Cycle Targets for Combination Therapy with Ionizing Radiation**

| Pathway Target | Role | Agents | Treatment Category | References |
|---|---|---|---|---|
| Cdks | Mitotic entrance, chromosome condensation, bipolar spindle assembly, APC/C regulation, nuclear envelope breakdown | Flavopiridol, UCN-01 | CDK inhibitor | 130,156 |
| Chk1/Chk2 | DNA damage checkpoint, mitotic entrance | UCN-01 | Chk inhibitor | 29,338,339 |
| Tubulin | Mitotic spindle structure | Taxanes, epothilones | Microtubule-stabilizing agent | 52,60–63 |

Despite promising preclinical data, flavopiridol has not demonstrated in trial significant clinical activity as a single agent in patients with metastatic lung cancer.[129] The unexpected and significant toxicity of this agent given as single cancer therapy in all these clinical trials have so far discouraged its use in monotherapy.

Another approach for the use of flavopiridol in anticancer therapy is to take advantage of its potential to augment cytotoxic actions of chemotherapeutic agents and radiation. This strategy of combining flavopiridol with chemotherapy has been investigated in several studies showing promising results. Flavopiridol enhanced the cytotoxic effects of many chemotherapeutic agents in vitro (12, 13, 14, 15, 16, and 17) as well as in vivo (8, 13, and 15), in a sequence-dependent manner. Similar results were observed in the combined approach with ionizing radiation both in vitro,[156,157] and in vivo[130] in various human cancer types.[156,158–160] Flavopiridol sensitized human cancers to radiation in a dose-dependent manner, by cell cycle redistribution, by inhibiting cellular repair from radiation damage, and possibly by effects on angiogenic factors. In addition, studies also demonstrated the effects of flavopiridol in enhancing apoptosis and tumor regression.[160–163] The therapeutic ratio of radiotherapy in the in vivo tumor models was increased by flavopiridol.[130,156] More specifically, the radiosensitizing action of flavopiridol was recently determined in zebrafish embryos using cyclin D1 (CCND1) downregulation by antisense hydroxylprolyl-phosphono peptide nucleic acid oligomers compared to control.[164] This study demonstrated that the specific sensitizing effects of flavopiridol in response to radiation were in part caused by the inhibition of cyclin D1, one of its primary pharmacologic targets.[158] Another study analysed the sequence-dependent effects of flavopiridol when combined to radiation and showed that the maximum radiopotentiation and apoptosis were observed when the lung cancer cells were treated with the sequence of docetaxel, then radiation, and finally flavopiridol both in vitro and in vivo. Therefore, the combined, sequence-dependent strategy radiation/flavopiridol has the potential to enhance outcome in many types of cancer and needs to be further investigated in a well-designed clinical trial.

### Chk1 Inhibitors

**UCN-01.** Staurosporine is a potent nonspecific protein and tyrosine kinase inhibitor (TKI). UCN-01 or 7-hydroxystaurosporine, an analogue of staurosporine, was found to be a nonspecific inhibitor of CDKs, protein kinase C (PKC) isoenzymes, and causes cell arrest in G1 and G2 phases in different cell types.[165] UCN-01 is a checkpoint protein kinase inhibitor that promotes cellular G1 arrest by inhibiting the activity of CDK-1 and CDK-2, thereby downregulating cyclins and increasing the expression of CKI, p21. Interestingly, UCN-01 abrogates the G2 checkpoint induced by radiation, leading irradiated cells into early mitosis and the onset of apoptotic death.[29,166] The mechanisms by which the cells enter mitosis include activation of cdc2 kinase, and a direct inhibiting effect on the G2-associated checkpoint protein kinase 1 (Chk1).[167,168] UCN-01 inhibits the cdc25C regulatory pathway and interferes with DNA damage-mediated inhibition of cdc2-cyclin B1-kinase. It targets more strongly Chk1 than Chk2 (IC50 −20 nM vs. −1 pM).[29,168,169] It has been shown that Chk1 is required for the radiation-induced G2 checkpoint.[170,171] Chk1 may control the $G_2$ checkpoint via phosphorylation-mediated negative regulation of Cdc25A, Cdc25C, and Cdc25B.[170,172,173] Thus, the potential of Chk1 inhibitors would most likely be as sensitizer to other anticancer treatments such as radiotherapy because inhibiting Chk kinases forces the cell to enter mitosis with DNA damage accumulation. Cancer cells could likely be particularly sensitive to such treatment, since they commonly lack normal G1 checkpoint control and may rely more on the S and G2 checkpoints compared to normal cells.[174] In vitro, UCN-01 exhibits a potent radiosensitivity effect in mutated p53 carrying NSCLC cell models.[175,176] Despite encouraging preclinical results, combination studies of UCN-01 with radiotherapy have not yet been opened, whereas UCN-01 alone has undergone phase I and II clinical trials in several cancer types.[177–179]

### Microtubule-Stabilizing Agents

In all eukaryotic cells, microtubules are essential components of the cytoskeleton, and crucial in the successful process of mitosis and cell division, via uniquely rapid dynamics in the mitotic spindle.[180] Microtubule-stabilizing agents, which interfere with microtubule dynamics, have been particularly effective as anticancer therapy and are a well-known strategy to induce G2/M arrest.[181] These agents suppress cancer cell growth by promoting accelerated assembly of excessively stable microtubules, resulting in G2/M cell cycle arrest and cell death. The abrogation of the G2 cell cycle checkpoint will lead to the forced accumulation of tumor cells in the radiosensitive G2/M phase of the cell cycle, where irradiation could achieve a higher rate of unrepaired chromosomal aberrations during mitosis. Additionally, antimicrotubule agents have the capacity to induce apoptosis, mediated through inactivation of bcl-2 protooncogene, even in p53-mutated and radioresistant cells.[182–184] It has been increasingly recognized that the combined use of microtubule-stabilizing agents such as taxanes in combination with radiotherapy is a clinically interesting strategy to improve anticancer treatment.[185]

**TAXANES.** Taxanes, such as paclitaxel and docetaxel, have already been proved to have a potent anticancer activity against many cancer types.[186] In addition, they are able to block cells at the radiosensitive G2/M phase of the cell cycle, suggesting the rationale for the use of taxanes to enhance radiotherapy.[185] Several studies showed the effectiveness of taxanes in enhancing tumor radiosensitivity in vitro and increasing significantly tumor growth delay in vivo.[187,188] Paclitaxel mechanism of action, however, is not limited to G2/M accumulation and results from direct cytotoxic effect in addition to the cell cycle effects as well. Furthermore, taxanes showed significant clinical efficacy for several tumor types, including non–small cell

lung, breast, and ovarian cancers. The specific molecular mechanisms of taxanes antitumor activity in lung cancer have been extensively reviewed.[189] The use of taxanes in cancer treatment, however, is often limited by resulting toxicities, such as neutropenia (which can be very severe), and peripheral neuropathy,[190,191] and by multidrug resistance (MDR).[192] This has lead to the development of novel microtubule-stabilizing agents, such as epothilones, with improved overall safety and broader antitumor activity, particularly in MDR.[193,194]

**EPOTHILONES.** Epothilones are natural products fungicidal macrolides, originally isolated from the myxobacterium *Sorangium cellulosum*. They were found to exert strong microtubule-stabilizing effects similar to that of paclitaxel, even though structurally unrelated to taxanes.[193,194] Epothilone B (Patupilone, EP0906) and epothilone A (demethylated epothilone B) are both natural products, whereas semisynthetic epothilones were developed including ixabepilone (BMS-247550, the lactam analog of epothilone B) and epothilone D (KOS-862). Epothilone and its analogs can sensitize both paclitaxel-sensitive as well as paclitaxel-resistant cells to ionizing radiation at low concentration both in vitro and in vivo.[52,60–63] BMS-247550 has been characterized for its radiosensitizing potential against human paclitaxel-sensitive lung carcinoma cells showing additive apoptosis and enhanced tumor growth delay when used in combination with ionizing radiation.[79] Similarly, epothilone B sensitized P-glycoprotein–overexpressing p53-mutated colon ADC to radiation in vitro and in vivo.[80] Kim et al.[195] reported the radiosensitizing effects of BMS-247550 in human lung carcinoma model. The study also demonstrated that the enhancement was correlated with the percentage of G2/M arrest induced by epothilone and with the induction of apoptosis. These preclinical results support the concept of combining epothilones with radiation to enhance lung cancer response to therapy. To date, only a phase I study of epothilone B administered concurrently with radiotherapy is ongoing for cancer patients presenting advanced solid tumors or recurrent disease for which there is no standard therapy or tumors have failed standard therapy. Objectives of the trial are to evaluate the safety and toxicity profile of epothilone B, and tumor response, when combined to radiation therapy.

**Aurora Kinase Inhibitors** Aurora kinases represent a novel family of serine/threonine kinases crucial for cell cycle control. In mammals, there are three types of Aurora kinases: Aurora A, B, and C.[196] Thus far, very limited data are reported on Aurora C, which expression is limited to the testes.[197] Despite the fact that they share >70% homology in their catalytic domain, Aurora A and Aurora B have different subcellular localization and functions during mitosis.[198] Aurora A is localized at the centrosome during duplication and to the spindle poles in mitosis. Aurora A kinase activity is regulated by TPX2, a protein required for spindle assembly. Silencing of Aurora A leads to abnormal spindle morphology in human cells.[199] Aurora A reaches the maximum activity at the G2-M transition.[200] At the G2-M transition, centrosome separation requires functional Aurora A.[199] Aurora A

contributes also to transition from G2 to M phase. Suppression of Aurora A by RNA interference results in G2-M arrest of HeLa cells and promotes apoptosis.[201] It was shown that ectopic expression of Aurora A results in a bypass of the G2-M checkpoint induced by DNA damage.[202] Inhibitors of Aurora kinases were developed to take advantage of these targets to modulate the abnormal cell cycle regulation for cancer therapy and tested in cultured cells and xenograft models.[203,204]

We and others reported on the effects of combining Aurora kinase inhibition with ionizing radiation.[205–207] ZM447439 is one of such Aurora A and B inhibitors,[208] but is known to produce cellular phenotypes consistent with inhibition of Aurora B rather than A, including the Aurora B–specific inhibition of histone H3 phosphorylation on serine 10.[208,209] ZM447439 caused p53-dependent multinucleation, growth inhibition in a colony-forming assay with a marked toxicity toward proliferating cells, and increased the amount of apoptotic cells. Interestingly, expression of Aurora B and survivin, two of the proteins that constitute the chromosomal passenger complex, was increased after irradiation of mesothelioma cells, consistent with their known activity and levels peaking in G2/M that correspond to the radiation-induced cell cycle arrest.[197] We found that ZM447439 sensitized mesothelioma cells to irradiation, and that the combination of both Aurora B and survivin inhibition resulted in a deeper radiosensitization.[207] This effect can be explained by the small molecule, ATP-binding nature of ZM447439, which can disrupt cell division but not the binding to survivin and thus the localization to centromere. Tao et al.[205] demonstrated that inhibition of Aurora A either by PHA680632 or by small interfering RNA (siRNA) against Aurora A enhanced cell killing after exposure to radiation in vitro. Moreover, they also showed that PHA680632 alone were able to induce a marked tumor growth inhibition in vivo and that irradiation treatment combined with PHA680632 led to an additive tumor growth inhibition compared with each agent alone, especially in p53-deficient cells. Although it did not act as radiosensitizer, this study showed the potential of PHA680632 when used in combined-modality strategy and can serve as proof of concept for Aurora A targeting with ionizing radiation. More encouraging results were very recently reported using VX-680 with radiation.[206] VX-680, also known as MK-0457, targets the ATP-binding site of Aurora kinases for reversible inhibition, and was proven to greatly inhibit tumor growth in three xenograft models in vivo, including leukemia, colon, and pancreatic tumors.[210] In a laryngeal SCC in vitro model, VX-680 upregulated p53 and effectively sensitized tumor cells to radiotherapy, whereas overexpression of Aurora A generated radioresistance.[206] Taken together, these promising preliminary results suggest the possibility to use Aurora kinases as a target for radiation therapy.

**mTOR Inhibitors** The mammalian target of rapamycin (mTOR), a serine/threonine kinase, is a downstream mediator in the phosphatidylinositol 3-kinase/Akt signaling pathway, which plays a critical role in regulating basic cellular functions including

cellular growth and proliferation.[211] The PI3K/Akt/mTOR signaling pathway is altered in many cancer types, including lung.[212] Rapamycin (sirolimus), and its improved analogs (rapalogs: CCI-779 - temsirolimus, RAD001 - everolimus, and AP23573 - deforolimus), the main mTOR inhibitors used in studies have shown G1-phase arrest[213] and significant antitumor activity in various radiation models. mTOR inhibition combined with radiation showed decreased tumor vascular density in murine models and sensitized vascular endothelium.[214] Moreover, RAD001 has been shown to increase the radiosensitivity of breast[215] and prostate[216] cancer cells, mainly via induction of autophagy cell death. Phosphatase and tensin homolog (PTEN)-deficient prostate cancer cells were even more sensitive to ionizing radiation as compared to PTEN-efficient cancer cells,[216] suggesting important clinical implications given the frequent presence of PTEN deletions in many types of cancer.[217–219] Interestingly, mTOR inhibitors seems to be more effective in tumor cells than in normal cells, possibly because transformed cells have increased activation of the Akt/mTOR pathway.[220] RAD001 has also been shown to further enhance the radiosensitization obtained by inhibition of apoptosis in either lung or breast cancer cells, again by increased autophagy.[221,222] These findings suggest potential autophagy targets to enhance efficacy of therapeutic strategies using mTOR inhibitors.[223] Currently, mTOR inhibitors are being evaluated in multiple clinical trials. In phase I and II trials, mTOR inhibitors appear to be well tolerated, with most common and transient adverse events being skin reactions, stomatitis, myelosuppression, and metabolic abnormalities.[224–230]

Interestingly, recent data suggest a certain antitumor activity, such as tumor regressions and prolonged stable disease, which has been reported among patients with various malignancies, including NSCLC. Based on these encouraging data, a phase I/II study of RAD001 and radiation therapy in patients with brain metastasis from NSCLC is currently ongoing at Vanderbilt University.

## VASCULAR TARGETS FOR RADIOTHERAPY

One of the most important promoters of angiogenesis is the vascular endothelial growth factor (VEGF), which binds to specific receptors including VEGF-receptor 2 to stimulate blood vessel formation, growth, and permeability. Clinical correlative studies have established that tissue VEGF expression is correlated with a poorer prognosis in NSCLC.[231–235] VEGF, fibroblast growth factor (FGF), and platelet-derived growth factor (PDGF) receptors are tyrosine kinase receptors that are expressed on the surface of endothelial, stromal, and tumor cells, and play important roles during tumor angiogenesis. Studies of these factors and their receptors have led to the development of antiangiogenic agents that target the function of VEGF, FGF, and PDGF.

Radiotherapy promotes expression of angiogenic activators, VEGF, FGF, and PDGF.[236–238] Radiation-induced VEGF activation subsequently attenuates vasculature damage and lead to a reduced tumor cytotoxicity.[239] Serving as a paracrine proliferative stimulus, VEGF also instigates the growth of previously dormant microtumors located out-of-field with respect to the radiation treatment field.[240] In addition, radiation triggers phenotypic changes favorable for tumor angiogenesis.[241] Recently, the combination of radiotherapy with antiangiogenic agents has been found to ameliorate the problem of vascular radioresistance. Antiangiogenic agents act on the endothelial cells by suppressing the radiation-induced release of proangiogenic factors. Just as with radiation alone, antiangiogenic agents used as a monotherapy results in objective response rates of 10% or less[242] with a gradual loss of activity and efficacy.[243–245] This is a result of the protean nature of tumor cells in being able to activate secondary angiogenic pathways when the primary angiogenic pathway is inhibited.[246] When antiangiogenic agents and radiation are combined, however, their antitumor effects become additive or synergistic under the principles of nonoverlapping toxicities and spatial cooperation.[247] This phenomenon has been shown in most preclinical studies, suggesting that the combination of antiangiogenic agents with radiation treatment has the potential to enhance tumor cytotoxicity and prevent the development of distant metastases.

Radiotherapy also activates initiator of prosurvival signaling pathways, such as phospholipases, lipid kinases, and phosphatases, thereby increasing viability of vascular endothelial cells. Therefore, this section will focus on potential targets for radiation therapy, including VEGF inhibitors, as well as the eicosanoid, sphingolipid, and ceramide pathways. Only representative antiangiogenic agents are discussed (Table 14.3 provide a more comprehensive list).

**VEGF Inhibitors**    VEGF is a ligand with a central role in controlling tumor blood vessel development and survival.[248–250] Numerous evidence indicate that targeting VEGF and its signaling pathway, when combined with radiation, could significantly enhance tumor toxicity in preclinical models.[238,251–255] Interestingly, VEGF inhibition does not increase the hypoxic cell fraction in tumors.[251,252] These results are encouraging because hypoxia is associated with enhanced radioresistance and malignant progression in tumors of the uterine cervix, head and neck, and sarcomas.[256] Furthermore, emerging concepts, such as the tumor vascular normalization, suggest that the combination of antiangiogenic agents and radiotherapy could engender a transient normalization of the abnormal tumor vasculature and a time period of increased oxygenation.[257] Anti-VEGFR-2 antibody can create such a time dependent enhancement of radiation-induced tumor regression.[258] Alternatively, Lee et al.[251] attributed this transient oxygenation to the capacity of radiation therapy to ablate mainly immature tumor vessels and oxygen-consuming cells. Nevertheless, the two therapeutic modalities combined are superior than either alone.

VEGF inhibitors include VEGF receptor TKI VEGF trep and anti-VEGF antibody. When combined with radiation, these inhibitors have produced promising antitumor efficacy in preclinical studies. Three of these agents, bevacizumab,

**TABLE 14.3** **Potential Vascular Target for Combined Treatment with Radiation Therapy**

| Agent | Target / Action | Growth Delay | Clinical Trial (Combined with Radiotherapy) | References |
|---|---|---|---|---|
| AZD2171 | VEGFR TKI inhibition of PDGF and c-Kit | + | − | 258–260 |

| IC486068 | PI3K inhibitor | + | − | 363 |

sorafenib, sunitinib, are currently in clinical trials. Many inhibitors of VEGFR TKI have proved to be potent radiosensitizers in mouse models of lung cancer. One such example is AZD2171, an orally available pan-VEGFR TKI with activity against PDGF receptor and c-Kit.[259] AZD2171 has been shown to induce a synergistic tumor growth delay when given on days 4 to 6 prior to fractionated RT.[258,260] Alternatively, the administration of ZD6474 (Zactima), an EGFR and VEGFR TKI, on xenograft models of lung cancer showed greater antitumor effects when given 30 minutes after radiotherapy (36 $\pm$ 1 days, $p <$ 0.001 vs. radiation alone or the concurrent schedule).[261] The results regarding sequence optimization vary across studies, and might be dependent on many factors including the drug's intrinsic properties, total radiation dose, dose per fraction, and overall treatment time. Conversely, a recent report showed that the sequencing of ZD6474/radiotherapy had little impact on treatment outcomes in a human colorectal carcinoma model,

although this combined strategy had a clear therapeutic advantage.[262] Further studies examining the sequencing of therapies are needed to ascertain the most favorable schedule of VEGF antagonist with radiation therapy.

Other VEGFR TKIs investigated to date with radiation in preclinical models include SU6668 and SU11248. With SU6668, a synergistic tumor growth delay was observed with concurrent radiation therapy, and it was found to inhibit Akt phosphorylation and activation in mouse models with Lewis lung carcinoma or glioblastoma multiforme (GL261).[263] SU11248 (sunitinib) is a low nM-selective inhibitor of multiple angiogenic RTKs including VEGFR1, VEGFR2, VEGFR3, c-KIT, PDGFR-$\alpha$, and PDGFR-$\beta$.[264] When given as a maintenance dose after concurrent radiation therapy, sunitinib effectively prevented tumor regrowth and significantly prolonged local tumor control.[265]

PTK787/ZK222584 (valatinib) is a small molecule-VEGFR TKI shown to enhance tumor hypoxia in a range that is

associated with enhanced radioresistance when given in mono-therapy but was reverted by concurrent ionizing radiation in vivo.[266] The bimodality treatment resulted in a supra-additive growth delay of tumor allografts and was associated with the highest apoptotic rate and the lowest tumor cell proliferation index. This study suggests that the risk of treatment-induced hypoxia by antiangiogenic agents exists but is minimized by concurrent radiotherapy, thus providing a mechanistic basis for the combination of antiangiogenic agents with radiation for cancer therapy. A study by Zips et al.[267] used different combination schedules of a PTK787/ZK222584 with irradia-tion of human SCCs in nude mice. Short-term neoadjuvant and simultaneous administration showed no effect on tumor growth delay, whereas long-term inhibition of angiogenesis after radiotherapy significantly reduced the growth rate of local recurrences but did not improve local tumor control. These results suggest that recurrences after irradiation depend on VEGF-driven angiogenesis, whereas surviving tumor cells re-tain their clonogenic potential during adjuvant treatment with PTK787/ZK222584. In addition, irradiated vessels appear to be more sensitive to VEGF inhibition, which is supported by the observation that in vitro–irradiated endothelial cells show an increased VEGFR2 expression.[268] In this setting, however, the radioprotective function of VEGF will not be counteracted during radiation therapy.

The study performed by Kozin et al.[252] on human xeno-graft tumors treated with the anti-VEGFR-2 antibody DC101 and irradiation showed promising results. In the 54A and U87 tumor models, the combined treatment resulted in a statisti-cally significant decrease of the dose necessary for local tumor control. Specifically, $TCD_{50}$ (radiation dose yielding 50% tumor cure) values were decreased by 41% in 54A carcinoma and by 24% in U87 tumors. Finally, AEE788, a dual TKI of both epidermal growth factor receptor (EGFR) and VEGFR, was shown to improve tumor control when combined with radiation in prostate cancer cells, especially highly EGFR-expressing tumors.[269] These studies indicate the potential of anti-VEGF strategies to improve the outcome of curative radiotherapy.

### Eicosanoid and Lysophospholipid Signaling Pathways

The phospholipase A2 ($PLA_2$) superfamily produces arachidonic acid, precursor of the eicosanoid metabolites and lysophosphocholine (LPC). $PLA_2$ is activated in irradiated en-dothelial cells.[270]

### Eicosanoid Pathways

$PLA_2$ catalyzes the hydrolysis of the sn-2 position of glycerophospholipids-releasing arachi-donic acid, which in turn is metabolized to prostaglandins by the cyclooxygenase (COX) pathway. COX is the rate-limit-ing enzyme in the conversion of arachidonic acid to prosta-glandins. Two isoforms of COX were described, COX-1 and COX-2. Whereas COX-1 is constitutively expressed in most tis-sues, COX-2 is induced in pathological states such as inflam-matory processes and cancer.[271] Overexpression of COX-2 is

frequently present in lung cancer and may play a significant role in carcinogenesis.[272,273] Upregulation of COX-2 and its major metabolite, prostaglandin E2 (PGE2), has been im-plicated in angiogenesis, tumor growth, invasion, metastasis, apoptosis resistance, and suppression of antitumor immu-nity.[272–275] It has also been associated with aggressive biologi-cal tumor behaviour, resistance to standard cancer treatment, and adverse patient outcome in patients with resected early stage ADC of the lung.[274,275] More precisely, COX-2 par-takes in tumor angiogenesis via various mechanisms includ-ing the increased expression of VEGF, generation of prosta-glandins known to stimulate endothelial cell migration, and inhibition of endothelial cell apoptosis.[276–278] Nonselective COX inhibitors, such as indomethacin, have been shown to enhance tumor radiation response in vitro,[279,280] and preclinical studies provide evidence that administration of COX-2 inhibitors with radiation increases local tumor con-trol.[281,282] Antitumor effects may be related to the enhance-ment of irradiation-induced apoptosis,[283,284] although this hypothesis remains controversial.[281,285] Other mechanisms include the modulation of tumor intrinsic radiosensitiv-ity[285] and tumor angiogenesis.[281,284] It has been suggested that COX-2 inhibition confers radiosensitivity through the suppression of prostaglandin production. Prostaglandins can play a cytoprotective role against irradiation,[286,287] and the removal of COX-2 derived $PGE_2$ has been demon-strated to enhance the efficacy of radiotherapy.[276] However, a recent study by Shin et al.[288] suggests that radiocytoxic-ity enhancement by COX-2 inhibitors is attributed to their alterations of cell cycle and is unrelated to $PGE_2$. In this study, the addition of $PGE_2$ after the administration of cele-coxib, a COX-2 inhibitor, produced no significant radiation-enhancing effects in A549 and COX-2 transfected HCT-116 cells. They hypothesized that COX-2 inhibition might alter the G2-M checkpoint after noting a correlation between COX-2 overexpression and prolonged radiation-induced G2-M arrest. Most experimental data, however, do not support this hypothesis, and additional studies are needed to delineate the specific mechanism of radiation therapy en-hancement by COX-2 inhibitors.

Two COX-2 inhibitors, celecoxib and SC-236, were tested in preclinical studies and showed interesting results. Celecoxib in monotherapy strongly inhibited neovasculariza-tion and reduced tumor growth and metastasis.[277,289] A pos-sible correlation between basal COX-2 expression level and celecoxib-induced radiation sensitivity has been suggested.[283] Interestingly, celecoxib exerted an inhibitory effect on the EGFR-mediated mechanisms of radioresistance, specifically by preventing both basal and radiation-stimulated nuclear transport of EGFR.[290] SC-236 also induced significant growth delay effects when administered orally in irradiated sarcoma FSA rodent model.[281] The enhanced radiation re-sponse was associated with decreased $PGE_2$ levels and mark-edly reduced neoangiogenesis. A greater than additive pro-longation of tumor growth was achieved by a combination of

radiation and SC-236 in human glioma U251.[285] Based on these observations several ongoing clinical trials are currently evaluating COX-2 inhibitors as adjuvants with radiation therapy in patients with advanced NSCLC, and preliminary results are encouraging. Further understanding of the mechanisms of COX-2 in interaction with radiation may facilitate future development of targeted strategies for lung cancer treatment.

### Lysophospholipid Pathways

Schematicaly, the PLA$_2$ superfamily can be divided into four main types: the cytosolic (cPLA$_2$), the secretory (sPLA$_2$), platelet-activating factor acetyl-hydrolases (PAF-AHs), and the calcium-independent cytosolic PLA2 enzymes (iPLA$_2$).[291] Activation of cPLA$_2$ leads to the increased production of lysophospholipids, such as LPC.[292,293] LPC functions as a second messenger in the signal transduction pathways that regulate vascular proliferation,[294–296] migration, expression of adhesion molecules,[297–299] and inflammation.[292,293] LPC stimulates proliferation in endothelial cells by transactivating VEGFR-2 and activating Akt and ERK1/2.[295] Ionizing radiation activates prosurvival pathways in the vascular endothelium, including PI3K/Akt (PI3K/Akt)[300–302] and MAPK pathways,[301,303] thereby regulating the cellular response and sensitivity to radiation. Recently, Yazlovitskaya et al.[270] identified a molecular sequence involving activation of cPLA$_2$ followed by the increased production of LPC, transactivation of Flk-1, and phosphorylation of Akt and ERK1/2 in irradiated vascular endothelial cells, constituting an immediate radiation-triggered prosurvival signaling pathway. These data suggest that cPLA$_2$ signaling mediates radiation-dependent prosurvival response in vascular endothelial cells and participates in endothelial radioresistance.

Recent studies have established that autotaxin (ATX), also known as phosphodiesterase-I$\alpha$ or nucleotide pyrophosphatase/phosphodiesterase 2, mediates the conversion of lysophosphatidylcholine to lysophosphatidic acid (LPA) and stimulates tumor cell motility.[304] LPA acts on specific G-protein–coupled receptors to stimulate the proliferation, migration, and survival of malignant cells.[305] ATX is also strongly implicated in tumor aggressiveness, metastasis, and angiogenesis in preclinical models,[306,307] and is overexpressed in various cancers including lung.[308,309] Therefore, the ATX-LPA pathway is an attractive target for anticancer and antiangiogenesis therapy.

### Ceramide Signaling Pathway

During recent years, evidence has been provided that sphingolipids including ceramide, sphingosine, and sphingosine 1-phosphate (S1P) are more than just structural components. Sphingolipids play important roles in cell growth as well as cell survival and death signaling,[310–312] and ceramide has been shown to function as a lipid second messenger.[313] The best characterized membrane signaling pathway is initiated by radiation-induced activation of enzymatic hydrolysis of the membrane sphingomyelin by sphingomyelinases (SMase), into the formation of ceramide.[312,314–317] In vitro and in vivo studies showed the crucial roles of acid sphingomyelinase enzyme activation and a rapid ceramide generation in radiation-induced endothelial cell death.[314] Ionizing radiation acts directly on bovine aortic endothelial cell membrane preparations devoid of nuclei, proving that ceramide generation after irradiation is independent of DNA damage and cell cycle regulation induced by DNA DSBs.[318] Importantly, only high radiation dose (at least 15 Gy) was shown to induce ceramide production, as opposed to low-dose irradiation that did not result in ceramide generation.[239] It has also been shown that cells deficient in sphingomyelinases are more resistant to radiation-induced apoptosis.[319,320] There are several isoforms of SMase based on required pH for their optimal activity: acid (ASMase), neutral (NSMase), or alkaline (Smase). Ceramide generation via activation of SMase precedes apoptosis in response to many different stimuli in addition to radiation, including TNF-$\alpha$ (tumor necrosis factor $\alpha$), Fas ligand, and exposure to glucocorticoid.[321] Ceramide-mediated response to radiation has been shown to activate various protein kinase cascades, including the classical mitogen-activated protein kinase (MAPK/ERK) cascade,[322,323] and the stress-activated protein kinase/c-Jun N-terminal kinase (SAPK/JNK) signaling pathway, leading to p53-independent apoptosis.[324] This molecular cascade triggered by ceramide is mediated by MEKK1 and involves sequential phosphorylation and activation of SEK1/MKK4 and SAPK/JNK that lead to the phosphorylation of c-Jun, a transcription factor in the nuclei.[324–326] Once generated, ceramide may accumulate or be converted into ceramide 1-phosphate by ceramide kinase phosphorylation,[312] sphingosine by ceramidases deacylation, and subsequent sphingosine-1-phosphate (S1P) by further phosphorylation by sphingosine kinase.[327] Interesingly, ceramide and S1P exert opposing functions in the regulation of cell death and survival, hence the relative balance between ceramide/S1P determines the fate of cells in response to specific stimuli.[328] Modulation of sphingolipid-induced apoptosis has been proposed as a way to increase the sensitivity of tumors to various therapeutic agents.[328,329] Sphingosine kinase, ceramidase, and glycosylceramide synthase, among other enzymes important to sphingolipid metabolism, are being studied as potential new drug targets. S1P promotes cell growth and survival, angiogenesis, vascular maturation, and mediates cell migration. Using a monoclonal antibody with high affinity for S1P, Visentin et al.[330] have shown that selective absorption of S1P is sufficient to block angiogenesis and endothelial cell migration in response to VEGF and basic FGF and could thus represent a promising approach to cancer therapy. Multiple investigators have demonstrated the dependence of radiation-induced apoptosis on ceramide,[320,331–334] and that radiation sensitivity may be augmented by addition of exogenous sphingoid bases or modulators of endogenous ceramide production.[335–337] Preclinical studies of existing drugs, and the development of new drugs for novel targets in the various sphingolipid pathways, are warranted to enhance radiation therapy for lung cancer.

CHAPTER **15**

# Population-Based Lung Cancer Prevention: An Overview

Lung cancer remains the leading cause of cancer-related mortality in the United States, with 160,390 deaths projected for 2007.[1] Lung cancer accounts for the largest number of cancer deaths worldwide as well, with an estimated 1.3 million deaths in 2005.[2] These dismal numbers reflect persistent national and global challenges to lung cancer control.

Cancer control in general relies upon prevention, early detection, and treatment. Advances in the treatment of lung cancer, including minimally invasive surgery and targeted molecular therapies, have a limited impact on the burden of lung cancer because of the fact that most cancers continue to be diagnosed at an advanced stage. The presence of symptoms at the time of diagnosis is associated with a high probability of advanced disease. The failure of screening with chest radiography and sputum cytopathology to impact lung cancer mortality suggests that detection of asymptomatic disease is necessary but not sufficient to achieve this goal. A resurgence of interest in early detection has followed the widespread availability of chest computed tomography (CT). Although this technology has proven superior to chest radiography in detecting early stage lung cancers, a beneficial effect on lung cancer mortality remains to be proven.[3] Smoking control programs continue to represent the most logical approach to curtailing lung cancer incidence, but economic and political forces oppose such efforts.[1] Reducing smoking prevalence decreases an individual smoker's risk of lung cancer as well as that of others through a reduction in secondhand smoke exposure. Unfortunately, an elevated risk of lung cancer persists for many years after smoking cessation.[4,5] This risk is highest among individuals who have undergone a curative resection for lung cancer, who have a 1% to 5% annual risk of developing a second primary lung cancer.[6] Chemoprevention has been studied as a mechanism to decrease lung cancer risk in these high-risk groups as well as in the general population.

A population-based approach to lung cancer prevention will be required to achieve the greatest reduction in lung cancer mortality, as many individuals lack access to the healthcare system and may not otherwise be aware of their lung cancer risk. High-risk individuals must therefore be actively selected from the general population to ensure that the majority has the opportunity to receive appropriate preventive measures. Investigators have used such an approach to identify and recruit subjects into an ongoing chest CT screening trial,[7] and we have previously reviewed the criteria for a population-based approach to early lung cancer detection.[8] In contrast to breast or colon cancer, where the major defining risk factor is age, the profound risk associated with tobacco use allows for a powerful and economical additional selection factor to enrich for lung cancer risk. Other risk factors of lung cancer exist, however, and these collectively account for about 10% of lung cancer diagnoses. Which preventive measures should be applied to which specific subgroups of the population are questions that ongoing studies will help to address, but the answers will likely be dynamic as novel approaches are developed. This chapter will review contemporary lung cancer prevention strategies with a focus on their potential for implementation at a population level.

## PREVENTION OF PRIMARY DISEASE

**Smoking Cessation**    Lung cancer initially had a humble beginning, with early case reports remarking on the rarity of the disease. Only after the tremendous increase in smoking worldwide following World War I did lung cancer begin to achieve its current level of notoriety.[9] Since the initial linkage between tobacco smoke and lung cancer in 1950,[10,11] this risk factor has been extensively investigated. Smoking currently accounts for 87% of lung cancer deaths,[12] and thus smoking cessation represents the most broadly applicable approach to primary prevention. Initiatives in the United States have only recently begun to result in a reduction in lung cancer mortality.[3] One reason for this sluggish response is that a former smoker's risk of lung cancer never returns to that of a nonsmoker.[4,5] In fact, at present, about 50% of cancer diagnoses are made among former smokers.[5,9] New medications may improve the success of individual smoking cessation attempts, but this rate remains below 10% over the long term with heavy smokers. Despite

these limitations, tobacco control and smoking cessation re- main key components of the primary prevention of lung can- cer, with the long-term potential to banish this lethal disease back into obscurity. Lung cancer risk increases with duration of smoking. However, the increasing risk of lung cancer stops rising with smoking cessation.

**Obstacles to Population-Level Smoking Cessation Initiatives**   Several obstacles stand in the way of smok- ing cessation initiatives. Smoking prevalence remains high. Worldwide smoking prevalence is 47% among men and 12% among women.[9] An estimated 45 million Americans are current smokers, with a like number of former smokers.[13] Adolescent smoking is also a persistent and serious problem. Tobacco ad- diction is not typically considered a pediatric disease, but data suggest that most adult smokers become addicted between age 13 and 17.[9] With this background, the fact that about 30% of high school students report the use of some form of tobacco product within the previous month[14] takes on greater signifi- cance. Secondhand smoke expands the reach of lung cancer to nonsmokers. About 126 million nonsmoking Americans are exposed to secondhand smoke in the workplace, home, vehicles, or public places,[15] and about 3000 nonsmokers die of lung cancer as a result each year.[16] Despite legally imposed limitations, the tobacco industry continues to advance its inter- ests, with promotional expenditures exceeding tobacco control spending by a ratio of 23 to 1 in 2003. Declines in smoking cessation rates among adults and high school students appear to have stalled,[17] likely as a consequence of increased industry marketing expenditures, decreased funding for comprehensive

tobacco control programs, and lack of a significant increase in tobacco prices.[18] While rates of smoking prevalence in other developed countries have largely mirrored the decline observed in the United States, increased marketing in the face of limited financial resources has resulted in increased tobacco consump- tion in developing countries.[19]

**Recommendations for Smoking Cessation Initiatives**
The U.S. Surgeon General's report specified the goals of pre- venting tobacco use initiation among the young, promoting quitting, and eliminating nonsmokers' exposure to secondhand smoke.[1] A subcommittee of the U.S. Interagency Committee on Smoking and Health (ICSH), with public input, developed a national action plan consisting of ten recommendations for smoking cessation.[20] The Centers for Disease Control and Prevention provided recommendations for the essential com- ponents of comprehensive tobacco control programs.[21] The World Health Organization recently published its recommen- dations to curb the global smoking epidemic.[19] These recom- mendations are summarized in Table 15.1, most of which will be discussed in more detail.

**Youth Access Laws**   Laws aimed at restricting children and adolescents from purchasing tobacco products have not been very successful. Some studies suggest that such laws have no impact on adolescent smoking,[22,23] whereas others demon- strate a decrease in the number of adolescents who experiment with smoking.[24] Regardless, most smokers become addicted before they can purchase cigarettes legally.[25] Lack of enforce- ment may largely explain the lack of efficacy of this approach.

| **TABLE 15.1**   Recommendations for Tobacco Control Initiatives[1,19–21] | |
| --- | --- |
| **Intervention** | **Effect(s)** |
| Monitor tobacco use and prevention policies | Assesses control program and industry compliance |
| Protect people from tobacco smoke<br>-Comprehensive smoke-free laws | Decreases tobacco consumption and smoking prevalence |
| Offer help to quit tobacco use<br>-National tobacco quit line<br>-Comprehensive coverage of counseling and pharmacotherapy | Increases long-term smoking cessation rate<br>Expands access by underserved individuals |
| Warn about the dangers of tobacco smoke<br>-Antismoking media campaign | Decreases tobacco consumption and smoking prevalence |
| Enforce bans on advertising, promotion, and sponsorship | Decreases tobacco consumption |
| Raise taxes on tobacco | Decreases tobacco consumption<br>Provides funding for control program |
| Smoking cessation research | Discovers better interventions |
| System-based improvements<br>-Training of clinicians<br>-Systematic implementation by health systems<br>-Add smoking cessation as health systems quality indicator | |

**Smoke-Free Laws**   As of January 2008, 26 states, encompassing 53% of Americans, had enacted or implemented legislation that prohibits smoking in the workplace, restaurants, or bars.[26] However, only 5% of the global population is protected by smoke-free laws.[19] Comprehensive public smoking bans are the most effective, with exposure to secondhand smoke being reduced from 46% in countries without regulations to 12% in those with extensive restrictions, but only to 35% in countries with limited restrictions.[27] Additional benefits of such programs are a reduction in smoking prevalence and tobacco consumption by smokers, as well as lower rates of youth smoking specifically.[15] A metaanalysis reported a 3.8% reduction in smoking prevalence and decrease by 3.1 cigarettes per day per continuing smoker. These results equate to a 29% reduction in cigarette consumption per employee. Public smoking bans decrease youth smoking prevalence, and school bans decrease daily consumption.[22]

Greece has the highest proportion (45%) of adult smokers in Europe. Many European countries have now adopted public smoking bans. Ireland was the first European country to implement a comprehensive ban on smoking in public places in March 2004. Norway followed soon after, but allowed a smokers' corner in workplaces. Italy banned workplace smoking in January 2005 and Naples and Verona have made smoking illegal in public parks. Belgium allows smoking in cafes and bars if they have ventilation installed and are at least 50 sq m (538 sq ft) in area. In France, a law forbidding smoking in public places was extended to bars, cafes, and hotels in January 2008, with fines up to 450 euros (£332; $662). Eight German states, including Berlin, have also ushered banned smoking in 2008 declaring their pubs and restaurants smoke free. Almost a third of Germans smoke and the authorities in Berlin decided not to enforce the restrictions actively for the first 6 months.

In summary, highly restrictive smoke free laws have a tremendous potential to reduce smoking prevalence and tobacco consumption at the population level, but are underutilized even in developed countries.

**Methods to Improve Individual Smoking Cessation Rates**   The rate of smoking cessation without any intervention is about 1% per year. This value varies by population, however, with this low rate being typical of smokers seen in a general medicine clinic. Higher baseline rates can be expected of individuals presenting to a smoking cessation clinic or following hospitalization for a smoking-related illness, such as myocardial infarction. Despite this discouraging figure, many smokers are motivated to make cessation attempts, with about 42% reporting at least one attempt in the prior 1 year.[14,28] A significant opportunity exists for healthcare providers to intervene, as 70% of smokers visit their physicians annually. Physician counseling for only 2 to 3 minutes increases the rate of smoking cessation to 3%, making this intervention more cost-effective than treatment of dyslipidemia or mild-to-moderate hypertension. Tobacco quit lines are another means of providing counseling. Smokers are four times more likely to utilize a quit line than to seek help in person, and success rates of up to 20% can be achieved.[20] Quit lines are toll free and thus expand the access of underserved populations to smoking cessation resources. Telephone counseling in more effective than mailed self-help materials,[29] and personalized correspondence is superior to standardized letters.[22] Pharmacologic therapy, in the form of nicotine replacement, bupropion, or varenicline, also improves long-term smoking cessation rates.[30] Although counseling and pharmacotherapy are cost-effective when compared to other covered services,[20] insurance coverage of smoking cessation treatments varies. Only 20% of employer-sponsored plans provide at least some coverage,[31–34] Medicaid provides no coverage in 14 states,[31] and Medicare only covers treatment of individuals with smoking-related diseases.[35] Clearly, support for at least some of these interventions is a realistic goal for any country in the world.

**Antismoking Media Campaigns**   Many smokers are not aware of the negative health consequences of smoking. Media campaigns offer a mechanism of providing education and countering specific misconceptions about smoking. Most recently, these campaigns have successfully targeted child and adolescent smoking. A media campaign coupled with a school-based program resulted in a decrease in reported smoking and weekly smoking in children in grades 4 through 6. Twelve- to thirteen-year-old individuals who reported seeing antismoking advertisements (ads) had half the chance of becoming established smokers as those who did not see the ads.[24] A nationwide antismoking media campaign was credited with 22% of the decline in youth smoking between 1990 and 2002.[36] Additional factors in this decline were restrictions on public smoking and an increase in the price of cigarettes.[37–39] Securing the financial resources necessary to conduct large-scale antismoking media campaigns is a challenge, made more serious by expanded tobacco industry marketing in developing countries, but it can be offset or overcome in the following way.

**Excise Taxes**   Imposing a tax on tobacco products has the potential to accomplish several goals. Currently, taxes are levied by state and local governments in the United States, resulting in striking disparities in the price of tobacco products across the country. Not surprisingly, most smokers obtain cigarettes in geographic locations with the lowest cost or employ other high-price avoidance strategies.[40] This practice is associated with a lower probability of making a cessation attempt and possibly a lower quit rate.[41] A federal tax on tobacco products would have the effect of equalizing their price, thereby preventing this evasion tactic. Imposing such a tax would have at least two other potential benefits. A 10% increase in cigarette price reduces consumption by 3% to 5%.[42] This effect is more pronounced among economically disadvantaged individuals, including children and adolescents.[20] Although smoking cessation is the preferred outcome, a reduction in consumption may decrease the risk of lung cancer. A 50% reduction in consumption among those smoking 15 or more cigarettes per day is associated with a 27% reduction in lung cancer risk.[43] The second direct benefit is the revenue that these taxes generate, which is generally sufficient to fund other components of a comprehensive tobacco control program. Tobacco companies spend about $11 billion per year to offset these taxes.[44]

**Outcomes of Comprehensive Tobacco Control Programs** The fundamental measures employed by comprehensive tobacco control programs are excise taxes, antismoking media campaigns, and smoke-free laws. Results from two programs, in Massachusetts and New York, have been published. The Massachusetts Tobacco Control Program (MTCP) reduced consumption from 547 million packs to 280 million from 1992 to 2004, a decline of 4% per year. Even after adjustment for unequal increases in excise taxes, this decrease exceeded that of states that did not have control programs in place over the study period. Smoking prevalence decreased from 23.5% to 19.4% over 1990 to 1999. High school smoking prevalence decreased from 30.2% to 20.9% from 1993 to 2003. Smoking bans decreased exposure to smoking in the workplace from 44% to 15% from 1993 to 2001, in the home from 28% to 16%, and in restaurants from 64% to 37% from 1993 to 2002.[24] New York City's program incorporated a tax increase, workplace smoking ban, and free nicotine patch program. These efforts resulted in an 11% reduction, from 21.6% to 19.2%, in smoking prevalence over 1 year, equating to 140,000 individuals who quit smoking. Forty-five percent of smokers reported cutting down, thinking about quitting, trying to quit, or quitting as a result of these initiatives. Forty-six percent of individuals reported less exposure to secondhand smoke following introduction of the program. The proportion of nonsmokers reporting secondhand smoke exposure at home decreased 29%, from 8.5% to 6%, equating to 105,000 fewer nonsmokers exposed. The proportion reporting workplace exposure decreased 18%, from 8.9% to 7.3%, a reduction of 67,000 nonsmokers exposed. Not surprisingly in a program implemented within a relatively narrow geographic region, purchases through alternative channels increased 89%, but nevertheless yielded a net reduction in consumption of 15%.[45] A statewide ban on public smoking decreased exposure to secondhand smoke from 19.8% to 3.1% in restaurants and from 52.4% to 13.4% in bars in New York. Salivary cotinine levels, a marker of smoke exposure, decreased from 0.078 ng/mL to 0.041 ng/mL among nonsmokers.[46] Overall findings from comprehensive tobacco control programs suggest that warning labels and advertising restrictions are less effective than increased taxes, smoking bans, and counteradvertising.[22] Concordant with the results observed in Massachusetts, per capita cigarette purchases declined 16% to 20% in states implementing tax-supported antismoking programs.[22]

**Impact on Lung Cancer Mortality** Smoking prevalence fell from 42.3% to 23.2% in the United States between 1965 and 1997, but lung cancer incidence increased 230% between 1965 and 1999.[9] This highlights the fact that lung cancer risk reduction is both delayed and incomplete following smoking cessation. The cumulative incidence of lung cancer through age 75 is about 16% for lifelong smokers, compared to less than 1% for lifelong nonsmokers. Smoking cessation at age 30, 40, or 50 years results in cumulative incidence rates of about 2%, 3%, and 6%, respectively.[47] These data indicate that a significant burden of lung cancer risk, and thus lung cancer mortality,

can be eliminated by early smoking cessation, but that the risk never decreases to the level of a lifelong nonsmoker. This reality suggests that smoking cessation remains a critical prevention strategy; however, in an evolving situation where the number of former smokers whose significant lung cancer risk never normalizes, additional public health measures are required.[48]

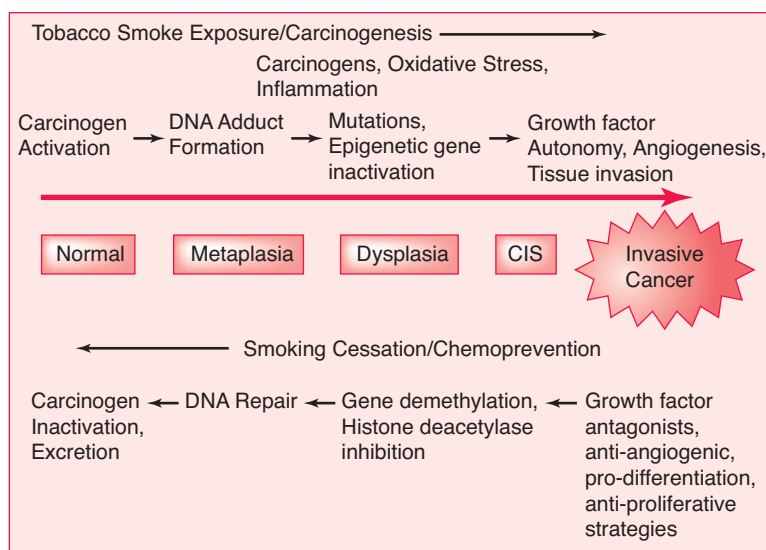
**Population-Based Screening** Published lung cancer screening trials have generally involved current and former smokers. Family history may be an additional factor to consider when selecting the population to screen. A family history of lung cancer is an independent risk factor for lung cancer. The diagnosis of squamous cell carcinoma in a first-degree relative appears to confer the greatest risk.[49] The risk of lung cancer in secondhand smoke–exposed individuals is measurable but significantly lower than in smokers. This means the potential cost benefit ratio will not be as favorable as for the smoking cohort and no prospective information addresses this circumstance as yet. Two large ongoing trials are accruing to address this issue (Flight Attendants Medical Research Institute, [FAMRI] and the International Early Lung Cancer Action Project [I-ELCAP]). Other risk factors for lung cancer include radon, asbestosis, certain metals (chromium, cadmium, arsenic), some organic chemicals, radiation, air pollution, tuberculosis, and genetic factors.[1] Other approaches to early lung cancer detection have been reported such as with techniques to evaluate tobacco-exposed bronchial epithelial cells recovered in the sputum of smokers. An antibody against heterogeneous nuclear ribonucleoprotein A2/B1 has demonstrated high sensitivity and specificity for the detection of lung cancer in high-risk individuals.[50–52] However, scaling such a test to achieve the requisite accuracy at affordable cost is a profound challenge given the comparable cost and availability of spiral CT screening.[53]

## CHEMOPREVENTION

Lung cancer, like many other cancers, appears to be the final consequence of dysregulation involving varied pathways. However, this results in a common "phenotypic" outcome. Population-based lung cancer screening has yet to evolve into an established format. Looking forward, population-based screening could evolve as a multifaceted public health strategy, including successful youth-directed tobacco control, more effective smoking cessation for existing smokers, and integrated early detection, management, and chemoprevention for current and former smoker.

The conceptual basis for chemoprevention arises from the consideration of the long evolution of an epithelial cancer. This opportunity is best demonstrated by considering the colon cancer model. Multiple steps cumulatively define a continuum at the cellular level. These steps then served as watershed points at which more aggressive histopathologic progression could be identified and thereby mark the point at which cancer had evolved. In general, it is believed that lung cancer evolves by two potential pathways. The first involves the proliferation

**FIGURE 15.1**    Schematic representation of the evolution of normal bronchial epithelium to invasive lung cancer. (Reprinted with permission from Keith RL, Miller YE. Lung cancer: genetics of risk and advances in chemoprevention. *Curr Opin Pulm Med* 2005;11:265–271.)



of aberrant cells that continue to devolve into carcinoma by sequential progression from hyperplasia through metaplasia and dysplasia. The second pathway involves "redifferentiation" or the dedifferentiation of bronchial epithelial cells that eventually redifferentiate into carcinoma.[54] It is conceivable that combinations of both pathways at various points ultimately results in the phenotypic presentation of lung cancer.

The term *chemoprevention* was introduced by Sporn et al.[55] in 1976 and was used to describe interventions used to slow or reverse progression of premalignant lesions to frank cancer. Targeting the "at-risk" population is crucial to the success of population-based chemoprevention. In lung cancer, chemoprevention strategies are targeted at the following three main groups:

1. Primary—chemoprevention among individuals at high risk who are otherwise healthy
2. Secondary—chemoprevention among individuals at high risk with premalignant conditions
3. Tertiary—chemoprevention among individuals with a known history of malignancy aimed at preventing second malignancies[56]

Chemoprevention agents encompass a tremendous number of potential natural and synthetic agents. These can be broadly subdivided into pharmaceutical, nutritional, and molecular targets. Each one of these broad categories can be further subdivided.

**Chemoprevention Strategies**    Experimental work in rodents suggests that specific drugs can mitigate the progressive development of lung neoplasias after the exposure to specific tobacco-carcinogen exposures.[57,58] Additional impetus arises from the clinical experience with antiestrogens in the chemoprevention of breast cancer.[59,60] However, the clinical development of these drugs is fraught with a number of challenges, including the protracted time and profound monetary resources required for such commercial development efforts.

Defining objective surrogates of long-term outcomes has also been an unresolved challenge.[61] As previously mentioned, it is largely held that a multistep carcinogenesis pathway exists from the normal bronchial epithelium to the frankly malignant tissue (Fig. 15.1). Along this pathway, changes from hyperplasia, atypia, metaplasia, and dysplasia are believed to occur and these changes are being utilized as surrogate end point biomarkers rather than frank carcinoma.[62–64]

**Diet and Nutrition**    The literature is replete with articles that espouse or refute the benefits of a specific type of diet on the risk associated with lung cancer. There are no randomized controlled trials evaluating the advantages or disadvantages of the consumption of any particular food group and its putative cause of lung carcinogenesis. The conclusion that the consumption of meat and fish plays a role in the development of lung cancer is controversial at best. Some studies have demonstrated that consumption of meat defined as pork, chicken, or red meat is associated with a protective effect[65,66] whereas others have demonstrated the opposite effect.[67]

Case-control studies have shown an inverse relationship between the amount of fruits and vegetables consumed and the risk of lung cancer among both smokers and nonsmokers.[68,69] Similar results have been observed in other studies, however, with less profound findings.[70]

Vitamin supplementation, on the other hand, has yet to be associated with any significant chemopreventative impact. Its use has not been shown to positively influence lung cancer mortality.[71,72]

**Pharmaceutical Interventions**

**CYCLOOXYGENASE INHIBITORS.**    The inflammatory pathway in which arachidonic acid is metabolized to prostaglandins, prostacyclins, and leukotrienes by the cyclooxygenase (COX) enzyme is one of the mechanisms by which lung cancer is thought to develop. There are two isoforms of this COX

enzyme, COX-1 and COX-2, of which COX-2 is thought to involved in carcinogenesis, primarily through a variety of downstream effects.[91] Naturally, inhibition of either one or both COX enzymes is perceived as a theoretical means by which lung cancer may be prevented.

Although some case-control studies have suggested that aspirin (ASA) use is associated with a decreased risk of lung cancer,[73–76] others have either failed to demonstrate a protective effect, demonstrated only a statistically marginal benefit, or have revealed only a nonstatistically significant beneficial trend of ASA use with lung cancer.[77–82] When examining the population with a positive tobacco history, several investigators have been able to show a decreased risk of lung cancer.[74,75,83] Harris et al.[74] demonstrated a risk reduction among heavy smokers. While Moysich et al.[75] did not identify a dose-dependent relationship with ASA in smokers, they found a risk reduction with greater frequency of use.

Population-based cohort studies have demonstrated that nonsteroidal anti-inflammatory drugs (NSAIDs) for greater than 1 year in duration can be associated with a decreased relative risk in the development of lung cancer.[84] Among ever-smokers, a protective effect of NSAID use has been demonstrated.[83] Among high-risk heavy smokers, case-control studies have shown a decreased risk of lung cancer also.[74] Other studies have demonstrated that there is no protective benefit to NSAID use in the development of lung cancer, but these epidemiologic studies have been limited by the fact that confounding information is present precluding a definitive conclusion.[85,86]

The potential role of inhibiting the COX-2 pathway has been supported by successful results in the animal models that blocked this enzyme specifically.[87,88] Manipulation of the prostaglandins distal to the COX-2 pathway in other animal models further demonstrated the antineoplastic potential of manipulating this pathway.[89] Several investigators have extensively reported on the use of specific cycloxygenase-2 inhibition with celecoxib to modulate several surrogate end point biomarkers in human bronchial epithelium.[90–92] Presently, clinical trials studying the role COX-2 inhibition in lung cancer chemoprevention are ongoing.[72]

**STATINS.**   Recent evidence has suggested that 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, otherwise known as *statins*, may be protective against the development of lung cancer.[93] In their retrospective case-control study, Khurana et al.[93] reported that statin use of greater than 6 months was associated with a significant reduction in lung cancer by 55%. This decrease was noted to increase to 77% among those using statins for greater than 4 years. Unfortunately, the retrospective nature of this study did not allow for the detection of any meaningful interaction between statin use and other significant factors associated with lung cancer, including smoking history.

**CAROTENOIDS.**   However, particularly recently, a large body of evidence based on randomized controlled trials has established β-carotene at best as having a conflicting role in the prevention of lung cancer. In two large randomized control trials, the α-tocopherol β-carotene (ATBC) and the β-carotene and α-tocopherol (CARET) studies, there was no protective benefit noted among the overall population in the development of lung cancer. In fact, in both studies, β-carotene intake was found to be associated with a significantly increased lung cancer incidence and mortality.[94,95] In the ATBC trial, the participants were all male current smokers,[95] whereas the participants in the CARET trial were male and female current and former smokers.[94] In the Physician's Health Study, randomization of the participants into the β-carotene versus placebo groups was performed in an attempt to evaluate a positive effect in reducing the incidence of malignancies or cardiovascular outcomes. Of the participants, 50% were either current or former smokers. Ultimately, there was no difference in the incidence of lung cancer between the two groups.[96] Similar findings were observed in the Women's Health Study. In that study, no differences in lung cancer rates were observed among current, former, and never-smokers who took β-carotene compared to those receiving placebo, and thus no beneficial effect of β-carotene could be demonstrated.[97] This confusing situation highlights the challenge in trying to find effective chemoprevention agents.

**RETINOIDS/VITAMIN A.**   There is a profound wealth of data supporting the role of vitamin A in the prevention, attenuation, or regression of carcinogenesis.[98–100] Since the aforementioned CARET study intimately tied together the use of β-carotene and vitamin A, the conclusion that β-carotene did not have any chemopreventative role was only half of the story. The other half reads similarly, in that the administration of vitamin A also had no beneficial effect and, in fact, was associated with a significantly increased relative risk of lung cancer.[94]

Tertiary chemoprevention trials also have not demonstrated any benefit of retinoids in the prevention of second primary lung cancers. Individuals who have been successfully treated for stage I NSCLC by operative resection, has not been shown to realize benefits in terms of recurrence, second primary tumors, or mortality rates when given oral vitamin A. In fact, secondary analysis demonstrated an earlier time to recurrence and mortality among current smokers.[101] In Europe, the European Study on Chemoprevention with Vitamin A and N-Acetylcysteine (EUROSCAN) showed similar results with retinyl palmitate having no effect on the rate of survival or second primary tumor among patients who had been treated with curative intent prior to this chemoprevention trial.[102] It was surmised that the reason for this result was that retinyl palmitate was not efficiently converted into *all*-trans retinoic acid (the active form of the drug).

The negative results of the aforementioned trials may have been due to the establishment of inadequate vitamin A levels within the lung tissue itself. In the trial by Lippman et al.,[101] only a homeopathic dose of retinyl palmitate was employed and this may have resulted in lower lung tissue concentrations. In the original work by Hong et al.[103] demonstrating a beneficial effect of vitamin A in carcinogenesis, there was also an associated

increase in significant side effects associated with the administration of high doses of vitamin A. Not surprisingly, while other trials since theirs have demonstrated less toxic side effects, there has also been an absence of beneficial effects observed with lower doses of vitamin A. The benefits of increased local concentrations of vitamin A in lung tissue is further supported by experimental work with animal models and vitamin A deficiency demonstrating that only aerosolized vitamin A in animals shows a consistent beneficial effect.[58] Clinical trials in humans have yet to establish this effect with consistency, although an aerosolized trial from Germany was able to show regression of bronchial dysplasia.[104] It is believed that the aerosol form of vitamin A is successful because it functions directly at the bronchial epithelium where vitamin A exists and is depleted.

**TOCOPHEROLS/VITAMIN E.**   In the double-blind, randomized, placebo-controlled ATBC trial mentioned earlier, there was a 2% reduction in lung cancer among the participants that were given vitamin E. This reduction however, was not significant during the 5- to 8-year follow-up period. Interestingly, during this same follow-up period the overall mortality rate among recipients receiving $\alpha$-tocopherol was slightly higher than among those not receiving $\alpha$-tocopherol. In the randomized, placebo-controlled Women's Health Study, women receiving vitamin E did not have a statistically significant difference in lung cancer rates than those receiving placebo.[105] In Heart Outcomes Prevention Evaluation (HOPE) trial and its continuation study, the HOPE-The Ongoing Outcomes (HOPE-TOO) trial the incidence of lung cancer was no different between the participants given vitamin E versus the placebo as identified. The median follow-up for the 7030 participants that went on to the HOPE-TOO continuation was 7 years.[106]

**BUDESONIDE/FLUTICASONE.**   Lam et al.[107] conducted a phase II study to determine whether inhaled budesonide had a beneficial effect in smokers with known bronchial dysplasia. Ultimately, the authors showed that inhaled budesonide had no effect in causing regression of the previously identified dysplasia nor in the prevention of new lesions. In another trial, patients at risk of developing lung cancer had a decrease in the number of indeterminate pulmonary nodules on CT scan when given fluticasone.[108] Although encouraging, this was a secondary analysis of patients given fluticasone as part of a chemoprevention trial that ultimately demonstrated its administration was not associated with an alteration of the natural course of premalignant lesions. This study was not designed to look at cancer end points and as such did not look at the actual cancer rates.[109] More recent studies have demonstrated a dose-dependent decreased risk of lung cancer associated with inhaled corticosteroids in patients with COPD after adjusting for various confounding factors.[110]

**SELENIUM.**   In 1996, the results of the Nutritional Prevention of Cancer (NPC) trial were published. The initial objective of this study was to evaluate the role of selenium in decreasing the rate of skin malignancies in 1312 high-risk participants. Although this study demonstrated that there was no decrease in skin malignancies, a secondary end point identified was a substantial, but not a significant, 26% decrease in the incidence of lung cancer.[111] Presently, there are ongoing clinical trials evaluating selenium in both secondary and tertiary chemoprevention protocols.

**OTHER AGENTS.**   Currently, there are several other investigational agents being evaluated in their role in chemoprevention such as the organosulfurs Oltipraz and Anethole Dithiolethione (ADT).[65] Other agents may be evaluated in their role as chemopreventative agents as more information is learned from their role as biomarkers in early detection (see succeeding discussion).[56,65,112–115]

# SECONDARY PREVENTION OF LUNG CANCER

Over 210,000 new cases of lung cancer will be diagnosed in 2008. Of these, only 20% are surgically resectable.[1] Of this subset, only 15% are stage I lesions, that is, lesions that have not progressed to involve the lymph nodes. While detecting early stage NSCLC is considered secondary lung cancer prevention (or prevention of metastatic cancer), it is important because the patient still has the possibility of being cured, typically with a surgical approach. In addition to being associated with an improved survival, this is crucial to the prevention of the presentation of the typical patient with lung cancer with advanced or metastatic lung cancer. Currently, the most promising approach to early lung cancer detection is with an imaging study, namely, a chest CT scan.

## Radiology Screening

**CT Screening**   Screening with chest CT has the potential to detect small lesions at an earlier stage than would occur with a conventional approach. Seventy-five percent of cancers diagnosed following the onset of symptoms are stage III or IV. In one recent study, 85% of lung cancers diagnosed in the context of screening current or former smokers were stage I, and only 5 of the 484 lung cancer diagnoses were made following the development and evaluation of symptoms. Five-year survival was estimated at 84%,[116] compared to 14% for lung cancer diagnosed conventionally.[117] Further details on the CT screening of lung cancer are seen in Chapter 16.

In 2003 based on early CT trial reports, the U.S. Preventive Services Task Force did not find the evidence strong enough to support a benefit with CT-based screening but neither did they find evidence of harm. This inconclusive recommendation is the same as their current recommendation for prostate cancer screening and surprisingly prostate cancer screening has been federally reimbursed for many years.[118]

**Clinical Management for Screened Lesions**   One of the most challenging areas of lung cancer screening is the rapidly evolving ability of higher-resolution CT scanners to find a large number of lung nodules in the lungs of smokers. CT screening identifies nodules that have baseline features suggestive of lung cancer such a size, shape, or pattern of calcification. Newer approaches to CT-based lung cancer detection involve evaluation

of features such as nodule growth.[97] In the most recent series, about 13% of individuals undergoing an initial CT screening will have findings that require further action. Of those with negative or "non-actionable" initial scans, only about 5% will have findings requiring further intervention on their annual follow-up screening CT. In both cases, this intervention is most often a repeat CT scan, with only approximately 2% to 4% of individuals being screened requiring an invasive test to achieve a definitive diagnosis.[119,120] This may involve various approaches. In the screening setting, it is critical to optimize the efficiency of this process especially through the parsimonious use of invasive procedures. At highly qualified institutions, the diagnostic workup typically involves using an aspiration needle biopsy to confirm that a growing nodule is cancer. When a biopsy is performed in the context of the specific protocol, it yields a diagnosis of cancer at least 90% of the time.[119] The frequency of complications such as pneumothorax requiring tube thoracostomy are low enough (5%) to justify its use.[121] This approach is associated with an extremely low frequency of futile thoracotomy (thoracic resection for a nonmalignant diagnosis). Other institutions include positron emission tomography (PET) scan to evaluate questionable nodules. The investigators in their screening trial reported an efficient process with an accuracy rate of CT/PET being 91%, but they did report a futile thoracotomy rate of approximately 5% (8/157).[122]

## Surgical Management Issues

In the large prospective experience of the I-ELCAP, postoperative mortality for earlier stage lung cancers removed by anatomic resection has been 0.5% (2/411). This mortality rate within the context of a lung cancer screening trial is similar to the mortality rate of 0.6% reported by Pastorino et al.[99] associated with lobectomy for stage IA NSCLCs identified by current conventional methods. Interestingly, these same investigators also participated in another lung cancer screening trial in the same city and reported a surgical mortality rate of 0% for early stage lung cancers.

Through the efforts of population-based screening protocols, the detection of smaller nodules and ultimately earlier stage lung cancers is occurring.[123,124] Commensurate with the lesser size of early stage lung cancers has been the advent and popularization of less invasive procedures. This has ultimately translated into a lower mortality and morbidity rates for the thoracic surgeon. In the largest video-assisted thoracoscopic surgery (VATS) lobectomy series reported from the United States, McKenna et al.[125] reported a morbidity rate of approximately 15% and a mortality rate of less than 1%. Most of the complications were non–life threatening. In the recently published ACOSOG Z0030 trial that prospectively collected data to compare outcomes of patients undergoing mediastinal lymph node dissection versus lymph node sampling, the morbidity rate after lobectomy was 37% and 1%, respectively. The majority of these tumors were early stage lesions.[126]

In addition to minimally invasive approaches to the very early stage I lung cancer, lung cancer screening with modern day CT scanners has resurrected interest in parenchymal sparing operations for small and peripheral NSCLCs. In 1995, the results of the only randomized, controlled trial comparing limited resections, including wedge resection and anatomic segmentectomy, to the formal anatomic lobectomy were reported. This study found that, while not statistically significant, there was an increased rate of recurrence and mortality in the limited resection population. Based on these findings, the investigators advised against lesser resections for known stage I NSCLCs[127]. The applicability of this study to current practice may be limited by a number of differences. The tumors included in the aforementioned study were those that were up to 3 cm in size. Asamura et al.[128] argued that the current staging system that defines $T_1$ tumors as less than 3 cm may be too heterogeneous. Their review of the 1994 Japanese lung cancer registry found that patient with lesions less than 2 cm actually fared better than those between 2.1 and 3.0 cm, which would still be classified as a $T_1$ lesion in the current staging system. Their findings suggested, and they argue, that subclassification of $T_1$ lesions into those that are ≤2.0 cm would be of benefit for prognostic purposes. In addition to this potential difference in tumor biology, current CT scanner technology is more advanced than when the limited resection study was performed. Furthermore, since lung cancer screening at this time was not in practice, none of the enrolled patients were those identified by lung cancer screening protocols.

A metaanalysis evaluating limited resection versus lobectomy for small (≤3 cm) peripheral NSCLCs found that survival was not significantly different. Interestingly, this finding occurred despite the fact that the most common reason for a limited resection was poor cardiopulmonary function, a condition that would suggest a more fragile patient.[129] In the context of lung cancer screening, the role of a limited resection has resurfaced as a question. Asamura et al.[123] reviewed their experience with subcentimeter lung cancers, some of which were identified by lung cancer screening protocols. The subcentimeter nodules identified were categorized into three groups based on their appearance, nonsolid ground-glass opacity (GGO), part-solid GGO, and solid-type tumor. Of the 28 GGO lesions, 15 underwent a limited resection, versus only 4 of the 20 solid-type lesions. No difference in 5-year survival differences were observed between the GGO, part-solid GGO, and solid-type tumors. Similar outstanding survival rates have been observed in studies evaluating sublobar resections for slightly larger GGOs (≤2 cm) identified by high-resolution CT scanners.[130] The findings of these studies might suggest that small nodules identified by screening CT scans, particularly GGOs, may not require an anatomic lobectomy and may be equally served with a limited resection. The question of whether a limited resection suffices for stage IA tumors, of which many will be identified by screening protocols, may not be answerable until the mature data from randomized comparisons of standard compared to more limited surgical approaches, such as with Cancer and Leukemia Group B (CALGB) Study 140503, are reported.[131]

Pennathur et al.[132] and Dupuy et al.[133] have furthered the role of minimally invasive surgery to include percutaneous ablative techniques without the use of the conventional thoracotomy or newer thoracoscopy.[134] Currently, this modality of therapy has not replaced the established role of surgery in the medically

fit patient. However, it is a reasonable alternative in the medically inoperable patient that is found to have stage I disease.[132,133] With increased experience in this subset of patients, the indications for percutaneous ablation may expand to include those with subcentimeter stage I lung cancers that are identified by screening protocols. This, in fact, may be occurring as some pulmonary radiofrequency ablation studies have incorporated medically fit patients who have simply refused surgery.[134]

From a survival standpoint, it has been suggested that by virtue of detecting earlier stage lesions, 5-year survival may be improved over conventionally cited survival.[119] Some investigator argue that an increased survival following surgery for any screened lung cancer may reflect lead-time bias. Henschke et al.[135] have suggested that a lung cancer mortality reduction benefit will not ultimately be found unless there is an improved lead time. Furthermore, true lead-time bias is thought to occur when relatively short-term survivals (such as 5-year interval) are compared between groups. This may not be the case with current screening regimens that have improved long-term (10 year) survival.[136]

Other investigators have suggested that the apparent benefit of lung cancer screening relates to finding more indolent lung cancers. This is referred to as overdiagnosis bias and has been suggested as a reason why prior efforts at lung cancer screening with chest radiographs and sputum cytopathology did not result in significantly improved lung cancer–related mortality.[137,138] This has been questioned recently by Raz et al.[136] who reviewed the long-term survival of patients with completely untreated stage I NSCLC. They discovered that the median survival among patients not treated by any modality including surgery, chemotherapy, or radiation was 9 months overall and 13 months in the subset with $T_1$ disease. This led the authors to conclude that treatment of identified stage I NSCLC is imperative.

The medically stable patient with a lung cancer detected by screening techniques deserves an opportunity for intervention. Despite the criticisms leveled against screening for lung cancer, recent mathematical modeling has suggested benefit in the form of mortality reduction associated with screening.[139,140] Furthermore, the decreased morbidity and mortality associated with minimally invasive techniques in the proper hands makes surgical resection of the suspicious lesions that are identified by screening an attractive and effective treatment option.

While the goal of surgical resection or ablation includes the eradication of ever smaller early stage NSCLC, invariably there will be lung nodules that are removed, which will ultimately prove to be benign. The decreased mortality and morbidity associated with newer surgical approaches and other experimental intervention techniques may improve the therapeutic index with surgical intervention in screening settings.

## Special Considerations

### Gene Therapy in the Prevention of Primary Lung Cancer
As mentioned earlier, the development of lung cancer is thought to follow a stepwise progression. The underlying mechanism of this progression is thought to be dependent on genetic alterations that occur at key points. Naturally, the earlier genetic changes that manifest as the early or precancerous changes could possibly be targets of therapy. Despite this knowledge, genetic therapy for lung cancer is well short of this desired goal. Most genetic therapy centers on the role of the tumor suppressor gene p53.[62,141] Despite its purported role in the progression of disease from either bronchial atypia or squamous metaplasia to low-grade dysplasia, much of the work on the p53 tumor suppressor gene appears to center on promoting its activity in patients with advanced malignancy.[62,141] At present, including the work regarding the p53 tumor suppressor gene, no genetic therapy is available that definitively halts the progression of normal bronchial epithelial cells down the sequence of hyperplasia to dysplasia and ultimately to carcinoma. This remains a conceptually exciting area for ongoing research.

### Biomarkers in the Early Detection and Prevention of Primary Lung Cancer
In terms of early detection, serum and plasma analysis of circulating DNA has been thought to be a novel biomarker. In particular, identifying free DNA that has undergone changes such as methylation, (Refer to Laird Offinga Chapter) loss of heterozygosity, allele shifts, microsatellite instability, or other mutations may allow for identification of early lung cancers.[142] These genetic changes may add to the variety of proteomic biomarkers that are forthcoming.

From a population-based lung cancer screening perspective, there are currently no established biomarkers routinely targeted in the prevention of lung cancer or used in the early detection of lung cancer. However, much work is being pursued in the field of proteomics to arrive at a point where proteins expressed in the sputum or serum of patients may be able to complement or direct image-guided screening protocols. Presently, the American Association of Cancer Research has established a task force to evaluate the possibility of identifying biomarkers of precancerous lesion along the multistep carcinogenesis pathway. Identifying and intervening at these surrogate end point biomarker milestones may potentially ultimately reduce the rates of lung cancer.[143] A detailed description of all the researched biomarkers is beyond the scope of this chapter, but presently a concerted effort in proteomic analysis is being undertaken to identify targets for lung cancer detection and/or prevention.

Within the context of chemoprevention, two pathways that have received a substantial amount of attention for their potential role in biomarker protein detection and cancer prevention include the COX pathway and epidermal growth factor receptor (EGFR) pathway. The EGFR pathway involves a tyrosine kinase receptor that results in autophosphorylation and activation of downstream pathways. One of the significant downstream pathways involves the COX-2 pathway. The products of both pathways may work to potentiate the effectiveness of the other.[144,145] Simultaneous inhibition of the COX-2 and EGFR pathways has demonstrated an augmented antiproliferative and pro-apoptotic effect in cancer cell lines in vitro. This presumed potentiation of the EGFR pathway inhibition by COX-2 is thought to be representative of a more complete blockade of both pathways.[144] Chemoprevention efforts aimed toward inhibiting the pathway or products of

COX-2 and identifying and blocking the EGFR pathway are attractive targets for chemoprevention, but in both instances approaches to manage side effects of this therapy may be needed prior to large-scale application, if sufficient efficacy data emerges.

Identification of circulating DNA released from tumor cells, genetic alterations such as microsatellite instability in addition to actual mutations, epigenetic changes such as tumor suppressor gene promoter methylation, as well as an entire host of other expressed proteins represent potential biomarkers that may be available in the future.[146] Unfortunately, these and other serum, plasma, sputum, and tissue assays are only in their investigational stages and have yet to definitively be associated with lung cancer and much less play a role in chemoprevention.

# Screening for Lung Cancer

## WHY CONSIDER SCREENING

Lung cancer makes, at present, for quite a sad chapter in pulmonary medicine. In the United States, some 170,000 cases are diagnosed annually[1]; the average cost of care per patient is about $50,000[2–4]; and yet, the annual number of deaths from this disease is almost as high as the number of cases diagnosed, some 160,000.[1] This is to say that, despite the very costly care, the *case–fatality rate*—the proportion of cases that are fatal—is near 95%.

While the overall case–fatality rate remains dismal, cases diagnosed in stage I—before clinically manifest metastases—are quite commonly curable and, thus, nonfatal. Depending on the size of the tumor at diagnosis, the curability rate ranges from some 50% to more than 90%[5–8] (see Chapters 30 and 32). Thus, the problem with lung cancer now is that those stage I diagnoses remain quite uncommon, representing only some 15% of all diagnoses of lung cancer.[9]

The solution to this problem potentially is the pursuit of early, latent-state diagnosis in persons at relatively high risk for lung cancer; that is, *screening* high-risk people for lung cancer, before any overt, clinical manifestations of the disease.

That *some* increase in stage I diagnoses can be achieved by means of a suitable regimen of screening is obvious; but the question is whether the attainable increase is substantial enough to justify the screening, especially for people with only moderately elevated risk for lung cancer. It is thus important to know the *magnitude* of the stage shift, notably the increase in the proportion of stage I diagnoses, and this in reference to a well-thought-out, realistic regimen of the screening. For, the attainable rate of curability is, to a close approximation, the proportion of stage I diagnoses multiplied by the curability rate of stage I cases, specifically such stage I cases that are diagnosed in the context of the screening—asymptomatic and with the tumor typically smaller than in stage I diagnoses in the absence of screening.

Screening for lung cancer has been of interest not only because of the generally dismal prognosis in the absence of screening but also for two other reasons: highly discriminating risk assessment is possible to identify those at high risk, and the small, latent-state lung cancers tend to be relatively well identifiable against the backdrop of the airy parenchyma of the lungs in radiographic imaging, particularly in computed tomography (CT) imaging.

Interest particularly heightened when several studies demonstrated the considerable superiority of CT over traditional radiography (chest x-ray [CXR]) in the identification of small pulmonary nodules.[10–13] What is more, research on CT screening for lung cancer has already led to quite a well-established regimen for it,[14,15] and the research also has produced evidence indicating the attainability of quite a high rate of curability of this, thus far, near-uniformly fatal disease.[16–18] Thus, the time has come for physicians to consider CT screening for lung cancer of persons at high risk for the disease or for persons who are asking their doctors about it. These decisions should be made on a case by case with the individual at issue suitably informed by his or her doctor.

**Research on Screening for Lung Cancer** In the early 1970s, the National Cancer Institute (NCI) funded a screening trial for lung cancer.[19] In this trial, sputum cytology was the screening test and half of the 30,000 high-risk participants were to be randomly assigned to the "intervention" (sputum cytology every 4 months for 6 years) and half to the "control" (no screening). All participants were to have annual CXR. This study evolved into three separate ones, each having about 10,000 participants: the Memorial Sloan-Kettering Lung Project (MSKLP),[20,21] the Johns Hopkins Lung Project (JHLP),[22,23] and the Mayo Lung Project (MLP).[24,25] The MSKLP and JHLP performed the study as planned for 6 years. The MLP investigators, however, wanted to test both sputum cytology and the CXR and thus developed a different protocol. They first screened all of the 10,933 participants using both sputum cytology and CXR, and then assigned 9211 people with no evidence of cancer on the baseline round to either receive sputum cytology and CXR every 4 months for 6 years

or to no screening; all received the usual Mayo Clinic advice of having annual screening.

At the completion of these studies in the late 1970s, none showed a reduction in lung cancer mortality because of screening using sputum cytology. Beyond this, because of the results of the MLP, CXR was also deemed not to be useful, even though the investigators themselves[26–28] as well as independent experts[29–31] judged the MLP to be inconclusive and seriously flawed. Further, the International Union Against Cancer (UICC) workshop on screening for cancer[32] in 1984 concluded that "the effectiveness of annual CXR in reducing lung cancer mortality was not evaluable in these trials. A case-control study was proposed to attempt a relatively quick evaluation, to be followed by a randomized trial if indicated. A search for new screening procedures is warranted."

Subsequently, in Japan where screening with CXR continued as a matter of national policy, five case-control studies were performed.[33–37] These five studies considered the timing of diagnosis with respect to the screening test, accumulated many more lung cancers than have been found in the randomized trials, and provided convincing evidence that deaths from lung cancer were less common if the diagnosis was achieved within 12 months of having CXR, but not when the delay was longer.

Ultimately in the United States, the NCI funded another screening trial to assess the benefit screening for prostate, lung, colorectal, and ovarian cancer, known as the PLCO trial.[38] For lung cancer, participants were randomly assigned to receive the "intervention" (baseline and two annual CXRs) or no screening. It was started in 1993, but the conclusions of this trial have not yet been reported.

Interestingly, at the same time as the lung cancer trial was being planned in the early 1970s, the NCI also funded a trial to assess the benefit of screening for colorectal cancer.[39] This trial enrolled 45,000 participants, 15,000 received annual screening, 15,000 biannual screening, and 15,000 no screening, but even with the greater number of participants, it did not show a mortality reduction after 5 years of screening and further follow-up. But for this trial, different from the lung cancer trials, the decision was made to provide another 5 years of screening and ultimately some 20 years after the trial started, it demonstrated a significant mortality reduction, improved survival rate, and a decrease in the incidence of late-stage cancers due to screening.[39,40] Since then, many advances in screening for colon cancer have been introduced, and they are accepted and reimbursed without any further evidence from randomized trials.

### Research in the CT Era

In 1993, we initiated the Early Lung Cancer Action Project (ELCAP) for research on CT screening for lung cancer.[10,11,41] To us, different from the prior randomized trials, screening is not a single test nor an intervention, rather it is a sequential process of pursuing early, latent-stage *diagnosis* of the cancer in order to provide for early treatment of it.[42] From this vantage, we saw it necessary to first endeavor to develop a justifiable regimen for the diagnostic process; that is, a suitable definition of the initial test, of its positive result, and of the workup that is to follow that positive result, possibly leading to diagnosis of the cancer.[42] Thereupon, the principal concern was the *diagnostic* performance properties of the regimen, and updating of this regimen based on emerging evidence and new technologies. Secondarily, there was going to be need for *prognostic* research, focusing on the curability of screen-diagnosed cases of lung cancer, stage I cases in particular.

Initially, the first version of the CT screening regimen was compared with its CXR counterpart, applying both to all participants in the study.[11] Each regimen's diagnostic performance was addressed in terms of the proportion of stage I diagnoses among all diagnoses and the proportion of screen-diagnoses among all diagnoses. In the baseline round, 29 cases of lung cancer were diagnosed, 27 of them screen-diagnosed, two interim-diagnosed. Of the 29, 25 were in clinical stage I, all of them screen diagnosed.[11] CXR screening identified only seven of the 27 cases of screen diagnosed by the CT regimen, and only 4 of the 23 stage I cases. Consequently, only CT was used in the 1184 repeat screenings.[41] In these repeat screenings, seven cases of lung cancer were diagnosed, and there were no interim diagnoses. Of the seven, six were in clinical stage I.

Subsequent studies of the expanded ELCAP in New York State[43] and then throughout the world[44] showed that the proportion of diagnoses in clinical stage I has remained high, around 85%, for both baseline and annual repeat rounds of screening, with rare interim diagnoses, confirming the initial ELCAP results.

Prognostic research as to the curability of screen-diagnosed cases of lung cancer was provided after long term follow-up of the diagnosed cases of lung cancer. This research demonstrated an estimated curability rate of 80% for all those diagnosed with lung cancer, regardless of stage and treatment. If diagnosed in clinical stage I and promptly resected, the estimated rate was 92%.[44] The high curability rates are not surprising as others previously had shown that when lung cancer is diagnosed when it is still small and in stage I, it is highly curable.[5–8]

The high proportion of stage I diagnoses and the high estimated curability rate have raised the concern by some that these may be due to "overdiagnosed" lung cancers,[45] meaning that CT screening identifies slow-growing cancers which, if not resected, would not lead to death. The I-ELCAP protocol aims to minimize "overdiagnosis"[15] by requiring documentation of growth of small nodules prior to biopsy, biopsy diagnosis prior to resection, review of the resected specimens by a panel of expert pulmonary pathologists, and by addressing the outcomes of patients diagnosed in stage I but not treated. The review by pathologists who are experts in pulmonary pathology has confirmed that all diagnosed with lung cancer had genuine lung cancers whose pathologic criteria met the World Health Organization (WHO) criteria of malignancy,[46] and patients diagnosed with stage I lung cancer who had no treatment, all died of it.[44]

Other studies had also shown that if left untreated, stage I lung cancers identified in the absence of screening, are usually fatal[47,48] and so are stage I cases diagnosed by CXR screening.[49–51] If, nevertheless, substantial concern about overdiagnosis still exists, then a randomized trial could ethically be performed by randomly assigning patients diagnosed with potential overdiagnosed lung cancers to either immediate treatment or delayed treatment. For early prostate cancer, such a trial was performed and it demonstrated that even for a cancer with a much lower fatality rate, surgical resection was significantly better.[52]

Slower-growing cancers are proportionately more common among cases diagnosed in the baseline round of screening, a phenomenon that has been termed *length bias*.[45] This bias is reflected by the pathologic subtypes of cancers diagnosed in the baseline round in which a higher proportion of adenocarcinomas and lower proportion of squamous and small cell carcinomas were identified as compared with the repeat rounds.[46] Further insight as to which cancers might be slower growing was provided by the initial 1000 ELCAP participants as we had identified a higher proportion of cancers manifesting as subsolid (nonsolid and part-solid) nodules in the baseline rounds than in the repeat rounds.[53,54] The significance of finding subsolid nodules, previously termed *ground-glass opacities*, relative to lung cancer had not been fully appreciated (see Chapter 33). Remarkably, the rate of malignancy was significantly higher for part-solid nodules than for either solid or nonsolid ones.[53] We also found that the distribution by type of malignancy was very different, with the malignancies manifesting as subsolid nodules either being adenocarcinomas with bronchioloalveolar features or adenocarcinomas-mixed subtype, whereas malignancies manifesting as solid nodules included the entire spectrum of the cell types of lung cancer with the exception of adenocarcinoma with bronchioloalveolar features.[46] Analyses of the growth rates of adenocarcinomas has allowed us to identify those manifesting as nonsolid nodules as being slower growing lung cancers.[54]

The clinical concern about slowly growing malignancies is to understand their course in the absence of treatment and then to treat them appropriately. In the lung, typical carcinoid tumors are a good example. Although considered to be benign in the 1970s, this cell type was reclassified as a malignancy in the 1980s when it was recognized that this was a neuroendocrine tumor, albeit a slowly growing one. Faster-growing neuroendocrine tumors are atypical carcinoids, and small cell carcinomas. Clinical management has taken these differences into account so that different treatment options are provided for these different subtypes. Similarly, clinical management and treatment might well be different for certain subtypes of adenocarcinoma, particularly those manifesting as nonsolid nodules.

It now is quite commonplace to think about overdiagnosis as encompassing identification not only of slowly growing cancers but also of genuinely life-threatening cancers in persons who die of some other cause. In the former case, the person is thus subjected to overtreatment, that is, treatment of a screen-detected cancer when not at risk of dying of the cancer, the cancer being effectively benign. Diagnosis of the latter type occurs when screening is performed on wrong indications (as for life expectancy) as the person has a genuine life-threatening cancer but dies of another cause. We do not view this latter type as an overdiagnosed cancer and have addressed competing causes of death in the context of CT screening separately.[55]

Important updates on the regimen of screening were based on information obtained from the initial ELCAP and its successors. With the technologic advances in CT scanners markedly reducing the image thickness, the definition of a positive result of the initial test at baseline needed to be updated to avoid unnecessary diagnostic workup. From the accumulated information on the very small noncalcified nodules less than 5.0 mm in diameter, ever more frequently detected at baseline, we found that such nodules only required a follow-up CT scan 1 year later, at the time of the first annual repeat screening.[56] We also found that short-term follow-up CT obviated the need for further evaluation of up to 75% of the newly identified nodules on repeat screenings, as they had either resolved or regressed.[57] The usefulness of growth as an indication for biopsy of small nodules was tested[58–62] and was found to minimize unnecessary biopsies, so that for recommended biopsies the malignancy rate was above 90%,[43,44] while when not recommended but performed, the malignancy rate was essentially zero. The workup following other findings on the CT scans, such as mediastinal masses,[63] cardiac calcifications,[64] and emphysema[65] were formulated leading the way to combined screening of the major tobacco-related diseases in the chest, that is, lung cancer, emphysema, and coronary artery disease.

## Curability Gain and Mortality Reduction

As should be evident from the foregoing, screening for lung cancer is a complex topic of *diagnostic* pursuit in *clinical* medicine, not one of population-level intervention in community medicine. The proximal aim of the screening is the attainment of early diagnosis; the purpose of pursuing early diagnosis is to provide for early treatment; and the purpose of seeking to provide for early treatment is the ultimate one: to thereby enhance the probability that treatment results in *cure* of the cancer in the cared-for person. Were the screening to be provided in the framework of community medicine—as "mass" screening in the meaning of more or less indiscriminate application of a single, simple test to members of the cared-for population—"its ultimate purpose would be seen to be reduction in the rate of lung cancer mortality in the cared-for population, consequent the test-positives" referrals to clinical care—for further diagnostic workup, ultimately leading to early diagnoses of the cancer and their associated enhanced curability in individual cases.

The consequence of screening on the rate of a cancer's curability can be studied through rates of surviving the cancer, although only with attention to an important subtlety in this. A misleading way, it is generally understood, is to

compare, say, 5-year survival rates between those whose cancer is diagnosed in the framework of screening (screen- and interim-diagnosed cases combined) and those in whom the cancer is diagnosed in the absence of screening. Most of the cases diagnosed under screening are diagnosed with a "lead time," earlier than they would be diagnosed in the absence of screening—pursuit of this lead time being the very essence of screening. Consequent to this, assessment of the curability gain from screening in terms of comparison of survival rates can be marred by "lead time bias": the, say, 5-year survival rate following diagnosis among the screened is prone to be higher than among the unscreened already on the basis of the lead time peculiar to the screened, even if early treatment is no more commonly curative than is treatment in the absence of screening.

Study of a cancer's curability requires a "survival analysis" in which survival over a particular, rather short span of time subsequent to diagnosis—5 years, say—is replaced by long-term survival, in a particular meaning of this. The survival rate naturally is a decreasing function of time since diagnosis; but in the absence of deaths from other, "competing" causes, this time function levels off and reaches its asymptote. This "cause-specific" asymptotic survival rate represents the rate with which the cancer has been cured. By the same token, this survival rate is the cancer's *curability rate* provided that the most effective treatment has been applied in all of the cases, without any undue delays after their diagnoses. Competing causes of death cannot be eliminated, of course; but elimination of their role can be achieved statistically, so as to address the cause-specific survival rate that refers to the cancer in the absence of other causes of death.

In the I-ELCAP, we addressed the curability of lung cancer, given its diagnosis in the framework of such screening as had been applied in that program.[44] Of all the diagnoses, 85% had been achieved in clinical stage I; and for those in whom stage I diagnosis had been followed by timely resection, the 10-year cause-specific survival rate—apparently representing the survival function's asymptote—was 92%. These results suggested the overall curability rate of 0.85 (0.92) = 78%. This may, however, be an overestimate, on the basis not only of involvement of some overdiagnosed cases but also of application of the Kaplan-Meier estimation of the survival rate to follow up well past the time of the last death from lung cancer, with very few subjects contributing to the follow-up beyond that time.

Insofar as overdiagnosis is perceived to be a possibility in ELCAP-type screening for lung cancer, the need in practice may be to refrain from routine early treatment of the types of stage I cases that are most likely to be very slowly progressing, to treat them only once follow-up shows definite further growth at a substantial rate. The frequency with which this provides for avoidance of overtreatment—of overdiagnosed cases—has not yet been assessed in the I-ELCAP, nor elsewhere. But the assessment is feasible, and it will be done, possibly leading to downward adjustment of the curability-rate

estimate. Accrual of further experience with long-term survival may have the same effect.

The curability gain can, in principle, be quantitatively assessed through *mortality* reduction also. If the screening of a cohort is continued long enough, there comes a period of follow-up time in which the proportional gain in curability is manifest in the same proportional reduction in the cause-specific mortality rate. This, however, is not a practical way of assessing the curability gain from CT screening for lung cancer.

Now, there are those who take interest in quantification of the mortality reduction associated with screening of for an arbitrary, short duration, and without concern to focus on the period of follow-up time in which the curability gain takes its maximal manifestation in proportional reduction in the cause-specific mortality—addressing, instead, the reduction in the cumulative mortality from the cancer over the entire, arbitrarily long duration of follow-up. This was the case in the Mayo Lung Project originally,[24] and also upon a subsequent major extension of its duration of follow-up.[66] There is concern that the duration of screening and follow-up for the ongoing National Lung Screening Trial (NLST)[67] could be impacted by its study design and could prematurely create the impression that not much is gained from the screening—or, even, that nothing is gained.[68]

### Guidelines for Screening for Lung Cancer and Needed Revisions

Prior to the late 1970s, CXR had been recommended by the American Cancer Society (ACS) for people at high risk of lung cancer, that is, heavy smokers and workers in asbestos industry.[69] Subsequently, the ACS adopted new guidelines for making the recommendations that called for good evidence of "test efficacy" in that the medical benefits were to outweigh the risks, the cost of the testing was to be in reasonable proportion to the expected benefits, and the test was to be practical and feasible. Largely as a result of the randomized trials described previously, the ACS changed its recommendation to be against screening for lung cancer in 1980.[69] Later in 2000, a nine-point protocol was introduced which placed primary importance on the results of randomized trials, less on nonrandomized studies and even less on expert opinion.[70] In 2001, the ACS clarified its recommendation against screening for lung cancer, stating that "The ACS does not recommend lung cancer screening for asymptomatic individuals at risk for lung cancer," but pointed out that the ACS distinguishes between recommendations concerning mass screening from those pertaining to clinical decisions on or by individuals. Thus the recommendation against screening expressly was not intended to discourage early-detection tests on individuals, as it was stated that "individual physicians and patients may decide that the evidence is sufficient to warrant the use of these screening tests on an individual basis."[71]

The U.S. Public Health Service convened the U.S. Preventive Services Task Force (USPSTF) in 1984 to provide

guidelines for screening. Later in 1998, this task force was placed under the Agency for Healthcare Research and Quality (AHRQ). The mission of the USPSTF was to evaluate the benefit of preventive services with specificity to age, gender, and risk factors for disease; to make recommendations about which preventive services should be incorporated into primary-care routines, for which populations, and to develop a research agenda for clinical preventive care.[72,73] It has subsumed screening under preventive (rather than diagnostic) services. The recommendations are graded according to the strength of the evidence and the magnitude of the net benefit (benefits minus harms) on a scale from a strong recommendation for to recommending against, or to neither recommending for or against. The quality of the evidence is graded as being good, fair, or poor and randomized trials are considered to be superior to "cohort and case-control" studies. In 1998, the USPSTF recommended against screening for lung cancer, against use of either CXR or sputum cytology as a screening test.[73] In 2004, the USPSTF changed its recommendation to the judgement that there is insufficient evidence to recommend for or against the screening with either CT, CXR, or sputum cytology.[74] This change in recommendation by the USPSTF was stated to be primarily based on five case-control studies performed in Japan as previously reported, which demonstrated a benefit of annual CXR screening.[33–37]

The practically exclusive reliance of both the ACS and the USPSTF on randomized trials in evaluating screening for lung cancer has persisted, despite two extensive reviews having demonstrated that well-designed "cohort" and "case-control" studies on screening show little evidence of overestimation of the benefit.[75,76] And it has persisted even when both agencies have recommended screening for breast and colorectal cancers, before there was any evidence from randomized trials, and despite controversial results from these.

Both the ACS and USPSTF guidelines state that a person interested in being screened for lung cancer discuss it with his/her physician. Needed for such a discussion naturally is information on the benefit from the screening specific to the individual's risk characteristics.

The benefit from screening needs to be addressed in terms of individual's probabilities of: (a) the screening if now applied, resulting in the diagnosis of lung cancer; (b) surviving all other potential causes of death over particular periods of prospective time; and (c) cure resulting from presymptomatic treatment of lung cancer.[77] We addressed the survival benefit specific to the baseline round of screening for smokers 60 to 84 years of age. The estimated probability of survival gain was 0.4% for a 60-year-old individual with 10 pack-years of smoking who quit 20 years ago, 3.1% for a 70-year-old current smoker with 100 pack-years, and 2.0% for an 85-year-old current smoker with 150 pack-years. Clearly, the benefit increases with increasing age up to 70 years and ultimately decreases. We provided this information both for current and former smokers. Thus, when seeking counsel about initiation of screening for lung cancer,

an estimate of the probability of survival gain from the first round of CT screening, specific to the person's age and history of smoking can be provided. Based on this information, we believe there is sufficient evidence for it to be reasonable for a person at high risk for lung cancer with a sufficient life expectancy to pursue screening.

## CONCLUSION

There is a growing body of evidence collected over the past 12 years that CT screening for lung cancer leads to a dramatic increase in the proportion of early stage genuine (fatal in the absence of early treatment) lung cancer relative to symptom-prompted diagnosis and a marked improvement in long-term survival (Table 16.1). As lung cancer is the most common cause of cancer death in both men and women in the industrialized world, it is a major public health problem. We think that the guidelines should be revised to recognize the following points as has already been published by the Society of Thoracic Radiology in the minority report[82]:

1. It is well-accepted that the curability of Stage I lung cancers is very high relative to the curability of late-stage cancers; and within Stage I, cancers less than 3 cm in diameter (Stage IA) are more curable than those that are larger (Stage IB);
2. Studies on annual CT screening have established that the lung cancers are much more commonly diagnosed at Stage I and at smaller sizes than by chest radiography.
3. Based on the points above, it is knowable that annual CT screening for lung cancer provides for prevention of death from lung cancer by early intervention. Quantitative assessment of the actual magnitude of this benefit is being pursued by studies in the U.S. and elsewhere.
4. A person at high-risk for lung cancer yet free of suspicion-raising symptoms of it, who is interested in potentially being screened, should be fully apprized of the implications of screening and of the treatment that may result. In light of this, it is reasonable for the individual to choose to be screened by a suitably defined CT regimen.

Point 3 follows from points 1 and 2. Point 4 draws from point 3 together with the principle of Patients' Autonomy, recently enunciated by a prestigious European–U.S. Joint Commission.[83]

*Editors note: The screening of lung cancer is a highly controversial topic and the results of the NLST will not be known when this edition of Lung Cancer is published. Unfortunately, there are few other organized programs in the United States or abroad besides the I-ELCAP which continue to offer "fee for service" lung cancer screening with a methodology that insures that the client as well as the referring physician is appraised of the status of the studies. The I-ELCAP group has made a strong argument for the use of lung cancer screening in high risk individuals, yet validation of benefit remains a topic for future discussion.*

[a]Included six limited small cell in stage I for consistency with other studies.

[b]One typical carcinoid included.

[c]Six had been identified at baseline low-dose CT, either <5 or >5 mm and considered benign and were identified as cancers on first annual.

[d]Clinical staging prior to surgery.

NR, no record.

**Summary**

1. Lung cancer prevalence rate depends on risk characteristics. It ranged from 0.1% to 0.8% per 1000 screened depending on age and smoking history.

   *Stage I diagnoses include non–small and small cell cancers without lymph node metastases and multiple adenocarcinoma without lymph node metastases (based on pathology if resected).

2. Seven studies showed consistency in finding a high proportion of stage I diagnoses ranging from 71% to 100% and the frequency depends on the regimen of screening and adherence to it.

3. Two studies reported overall long-term survival rates 71% or higher. Survival was 92% or better if in stage I and resected. Survival rate reflects proportion in stage I.

4. Few interim diagnoses of lung cancer (symptom-prompted between screenings) and few detected only by sputum cytology.

5. For comparison, a consistent definition of baseline, repeat cancers, and interim cancers is needed: (a) baseline cancer: nodule is identified on initial CT at baseline, (b) annual cancer: nodule is first identified on initial CT at annual repeat, and (c) interim cancer: symptom-prompted diagnoses between screenings.

# Low-Dose Computed Tomography Screening: Experiences from the Randomized Population-Based Nelson Screening Trial

## NELSON TRIAL DESIGN

The Dutch–Belgian lung cancer screening trial (NELSON) investigates whether 16-detector, low-dose, multislice computed tomography (MSCT) screening in year 1, 2, and 4 will decrease lung cancer mortality compared to a control group without screening. Secondary end points of the study are to estimate the cost-effectiveness of this screening program and to assess the impact on quality of life. The design of the NELSON trial is shown in Figure 17.1. NELSON is the only large-scale, randomized, controlled, population-based lung cancer CT-screening trial in Europe, with 15,523 participants. Recruitment started in the second half of 2003, and the first CT screenings were made in April 2004. As of October 2007, the baseline-screening round has been completed, the second round is near its completion, and the third round has recently been started. The screening part of the trial will be finished by the end of 2009, but the follow-up period will continue until the end of 2015. During the first round, lung function tests have been performed, and biosamples (blood, plasma, serum, and sputum cytology) have been taken. The blood sampling and lung function test are repeated during the last screening round.

**Recruitment**   During the first recruitment phase (second half of 2003), addresses of all men born between January 1, 1928 and January 1, 1953 were obtained from the population registries in seven districts in the Netherlands (Groningen, Drenthe, Utrecht, Eemland, Midden-Nederland, Kennemerland, and Amstelland-de Meerlanden) (Fig. 17.1). In addition, addresses of all men and women of the same age were obtained from the population registries of 14 municipalities around Leuven in Belgium. They received a first questionnaire about general health, alcohol consumption, physical exercise, cancer history, family history of lung cancer, body weight and length, education, and their opinion on screening programs in general. The questionnaire contained 11 questions on smoking from the Minimum Common Dataset (May 2002) of the EU–U.S.

Collaborative Spiral CT-working group, adapted from the National Cancer Institutes Cancer Data Standards Registry, the recommended smoking measures of the Behavior Change Consortium of the U.S. National Institutes of Health, and from Pistelli et al.[1–3] The most important questions were: "When you last smoked every day, on average, how many cigarettes (shag) do/did you smoke a day?" (<5, 5 to 10, 11 to 15, 16 to 20, 21 to 25, 26 to 30, 31 to 40, 41 to 50, 51 to 60, >60); "What is the total number of years you have smoked/smoke cigarettes or shag every day? Do not include any time you stayed off cigarettes or shag for 6 months or longer." (0 to 5, 6 to 10, 11 to 15, 16 to 20, 21 to 25, 26 to 30, 31 to 35, 36 to 40, 41 to 45, 46 to 50, >50 years) and; "If you have quit smoking, how long has it been since you quit?" (<1 month, 1 to 6 months, 7 months to 1 year, 1 to 3 years, 3 to 5 years, 6 to 10 years, 11 to 15 years, 16 to 20 years, >20 years, not applicable). The questionnaire was accompanied by brief information about the trial.

During this first recruitment phase, 106,931 of the 335,441 subjects (32%) who received the first NELSON questionnaire responded. Mean age of the respondents was 61 (standard deviation: 6.8 years). Response rates were lower in Belgium where we approached more women than in the Netherlands, but were overall equally distributed over the age categories (Table 17.1). Table 17.2 shows the number of respondents for each level of smoking duration, the number of cigarettes smoked per day, and the duration of smoking cessation. Nearly one third of the 106,931 respondents (33,909 [32%]) never smoked, 26,733 (25%) has been smoking for less than 20 years, and 24,783 (23%) quit smoking for more than 20 years.

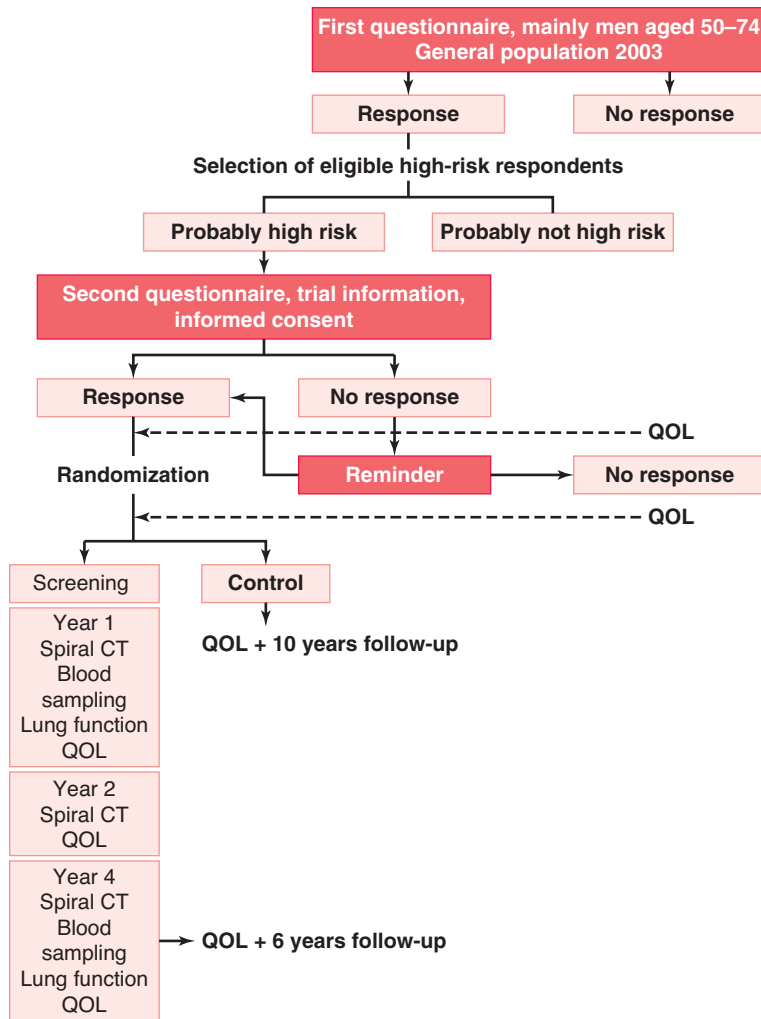
**Selection of Potential Participants**   In the Netherlands, at present, 23% of women smoke compared to 32% of men.[4] In the past, this difference was greater when even fewer women and more men smoked. Therefore, fewer women in the Dutch population have accrued a long-term exposure to cigarettes compared to men. Because of the lower fraction of high-risk subjects among women, we anticipated before start of the trial that recruiting an equal number of


**FIGURE 17.1** The different steps in the recruitment process of the Dutch–Belgian helical CT lung cancer screening trial (NELSON) and the different time point at which quality of life will be assessed. *CT,* computed tomography; *QOL,* quality of life.

high-risk women and men would require an enormous effort. Therefore, the Dutch Health Council and the Ministry of Health agreed to invite first men and only in the second phase also women. In that way, we would still be able to demonstrate possible differences in lung cancer detection between men and women, and at the same time limit our recruitment efforts.

Because the smoking exposure history of all respondents on the first NELSON questionnaire was available, a careful decision could be made on whom to invite for the trial. First, the estimated lung cancer mortality risk of the respondents was determined. Next, the required sample size to show a mortality benefit of screening of 20%, 25%, and 30%, and the corresponding number of eligible subjects was determined for various selection scenarios, and finally, the *required participation rate* was determined, defined as the required response of eligible subjects to reach the required sample size. In the optimal selection scenario, the required participation rate was as low as possible, and the required sample size was within the ranges of our capacity in the Netherlands and Belgium (±16,000 participants).

Our estimates of lung cancer mortality were based on the U.S. Cancer Prevention Study II (CPS II), a cohort study that started in 1982 and followed 508,579 men and 676,527 women, aged 30 years or older for 6 years.[5] The CPS II reports lung cancer mortality rates per 100,000 person-years (PY) for groups of men with attained ages 50 to 79 (50 to 59, 60 to 69, and 70 to 79 years), smoking duration of 20 years or more (20 to 29, 30 to 39, 40 to 49, and ≥50 years), and one or more cigarettes smoked per day (1 to 19, 20, 21 to 39, 40, and ≥41 cigarettes per day). Because the CPS II monograph included only data on current smokers, the U.S. Cancer Prevention Study I (CPS I) was used to estimate the effect of smoking cessation. This prospective cohort study started following up 456,491 men and 594,551 women older than 30 years on July 1, 1960. Follow-up was a maximum of 12 years.[6] By varying the thresholds for duration of smoking, the duration of smoking cessation, and the number of cigarettes smoked per day, the mean-estimated expected lung cancer mortality rate (per 1000 PY) for various selection scenarios was determined. Based on the most optimal selection scenario, current and former smokers with 10 years or less

*Only in Belgium women were approached in the first recruitment round.

†The population registries of some communities in Belgium did not supply us with data on gender and/or birth date, and gender was not asked in our first questionnaire.

‡Age at mean date of response, which was October 1, 2003.

§Total also includes 69 subjects who responded, but returned a blank questionnaire.

From van Iersel CA, de Koning HJ, Draisma G, et al. Risk-based selection from the general population in a screening trial: selection criteria, recruitment, and power for the Dutch–Belgian randomised lung cancer multi-slice CT screening trial (NELSON). *Int J Cancer* 2007;120:868–874.

of cessation, who smoked more than 15 cigarettes a day for more than 25 years or 10 cigarettes a day for more than 30 years, were selected.[7] Persons with a moderate or bad self-reported health who were unable to climb two flights of stairs and persons with a body weight greater than or equal to 140 kg were excluded from participation. Lung cancer patients diagnosed less than 5 years ago, subjects symptomatic for lung cancer, and persons who had a chest-CT examination less than 1 year before they filled in the first NELSON questionnaire were excluded as well.

### Power and Required Sample Size

The required sample sizes to demonstrate a lung cancer mortality reduction of 20%, 25%, or 30% were calculated for the various selection scenarios. A 1:1 randomization, a power of 80%, a one-sided $\alpha$-significance level of 0.05, 95% compliance in the screen group, 5% contamination rate in the control group, and 10 years of follow-up after randomization were assumed.[8] With a power of 80%, enrolment of 17,300 subjects in NELSON is required to demonstrate a lung cancer mortality reduction of 25% or more and 27,900 subjects to demonstrate a lung cancer mortality reduction of 20% or more 10 years of follow-up. In Denmark,

4100 men and women, current and former smokers (quit <10 years), aged 50 to 70, with at least 20 pack-years of smoking have been recruited through the public media. It is planned to pool mortality data with the Danish trial, so that the total number of participants in the NELSON trial will be more than 20,000. NELSON will then be the only trial without screening in controls that is expected to have an 80% power to show a lung cancer mortality reduction of at least 25% 10 years after randomization. When pooling with the Danish trial data, the fraction of women, which comprises 45% of all Danish trial participants, will also increase.

Our population-based recruitment gave insight in the risk profiles of the general population and we estimated that about 15% to 25% of the general (Dutch) population, age 50 to 75 would be the target for routine screening if our eligibility criteria would be applied. We, therefore, believe that our results are generalizable to a sufficiently large part of our population. Another advantage of a population-based recruitment approach is that it is less likely that potential participants exaggerated their smoking history to increase their chance to be invited for the trial, because they were unaware of the selection criteria.

**TABLE 17.2** **Number of Current smokers and Former Smokers (n = 73,022) of Total Respondents (106,931) on the First NELSON Questionnaire, Grouped by Smoking History (Ages 50–75)***

## NELSON MANAGEMENT SYSTEM

To conduct this logistically complex multicenter study, the NELSON Management System (NMS) has been developed. It is a Web-based, interactive database application used for data collection and management of all study-related processes with a completely trackable data collection, study monitoring, reporting of scan results, and scheduling of appointments for follow-up scans. Because the system works with action dates, it provides us with a complete overview and control of the planned actions, such as the planning of follow-up scans, sending of invitations to participants, test results and workup, and evaluation of suspicious nodules.

**Screens** The participants randomized to the screen arm were invited by an invitation letter to one of the four screening sites (University Hospital Groningen, University Hospital Utrecht and Kennemer Gasthuis Haarlem in the Netherlands, and University Hospital Gasthuisberg Leuven in Belgium). The CT scans used were all 16-detector MSCT scanners (M×8000 IDT or Brilliance 16P, Philips Medical Systems, Cleveland, OH, U.S.A., or Sensation-16, Siemens Medical Solutions, Forchheim, Germany). All scans were realized in about 12 seconds in spiral mode with 16 × 0.75-mm collimation and 15-mm table feed per rotation (pitch = 1.5), in a cranial–caudal scan direction, without contrast in low-dose setting. Depending on the body weight (<50 kg, 50 to 80 kg, and >80 kg), the kilovolt (peak) (kV[p]) settings were 80 to 90, 120, and 140 kV(p), respectively; and to achieve a volume computed tomography dose index (CTDIvol) of 0.8, 1.6, and 3.2 milligrays (mGy), respectively, the milliampere second (mAs) setting were adjusted accordingly depending on the machine used. To minimize breathing artefacts, scans were performed in inspiration after appropriate instruction of the participants.

**Image Reading** Images have been read on Siemens workstations using the syngo LungCARE software package (version Somaris/5 VB 10A-W) for multidimensional image processing and computer viewing. Lung windows were assessed at a width of 1500 and a level of −650 Hounsfield units. After a first reading by qualified and dedicated radiologists with on average 7 years of reading experience, the data were stored locally on the PACS system, and sent overnight via a protected internet connection to Groningen for second reading and central storage. The consensus double readings were also performed by two qualified radiologists, full time engaged with 1 and 4 years of experience after board certification, respectively. Both the first and second readers evaluated the CT scans independently and uploaded their results into the central database. The nodule management system automatically

matched all nodules detected by the first and second reader based on location and size. Subsequently, the second reader checked this automatching for each individual nodule and made manual adjustments in case the matching was incorrect. During this procedure of consensus double reading, the second reader was not blinded for the results of the first reader. This procedure provided three groups of nodules: nodules detected by both readers, nodules detected only by the first reader, and nodules detected only by the second reader. The second reader also checked the consistency of the follow-up recommendations of both readers. If there was a discrepancy, the second reader informed the first reader and both readers reevaluated the CT scan to reach consensus. If no consensus was reached, an expert reader (radiologist with more than 20 years of experience) made the final decision.

During CT evaluation, for each evaluable nodule, the surface characteristics, distance to the pleura, and the aspect of the nodule (i.e., solid, partial solid, or nonsolid) were entered by the radiologist in an electronic data collection form customized for the LungCARE Siemens workstation. Nodules were classified as peripheral if the distance to the thoracic wall was less than one third of the total distance to the lung hilum. Together with the calculated sizes and volumes generated by the Siemens software, these data were automatically uploaded in NMS immediately after completion of the reading for an unlimited number of evaluated nodules per scan. In case of consecutive CT scans, nodules were matched with the same nodules documented on previous scans to determine changes in volume and to estimate the volume doubling time (VDT). After the second reading of the CT scan and after reaching consensus about the screen result and the planned actions to be taken, the NMS generated the appropriate standard letter to inform both the participant and the general practitioner within 3 weeks after the CT scan. Throughout the study, the definition of growth was kept constant and was defined as a percent volume change (PVC) of 25% or more after at least a 3-month interval according to the following formula:

$$(1) \qquad PVC\ (\%) = 100\ (V_2 - V_1)/V_2$$

### TABLE 17.3 NELSON Classification of the Different Noncalcified Nodules According to Size at Baseline Screening

| NODCAT Baseline | Definition |
|---|---|
| 1 | Benign nodule (fat or benign calcifications) or other benign characteristics |
| 2 | Any nodule, smaller than NODCAT 3, and no characteristics of NODCAT 1 |
| 3 | Solid: 50–500 mm$^3$ <br> Solid, pleural based: 5–10 mm $d_{min}$ <br> Partial solid, nonsolid component: ≥8 mm $d_{mean}$ <br> Partial solid, solid component: 50–500 mm$^3$ <br> Nonsolid: ≥8 mm $d_{mean}$ |
| 4 | Solid: >500 mm$^3$ <br> Solid, pleural based: >10 mm $d_{min}$ <br> Partial solid, solid component: >500 mm$^3$ |

From Xu DM, Gietema H, de Koning H, et al. Nodule management protocol of the NELSON randomised lung cancer screening trial. *Lung Cancer* 2006;54:177–184.

**Baseline Screen Protocol** Noncalcified nodules (NCN) were classified in four nodules categories (NODCAT) based on size, either 3D (solid and partial solid lesions) or 2D (solid pleural lesions and nonsolid lesions), or based on growth (GROWCAT) according to formula (Table 17.3).[1] NODCAT 1 was defined as benign, NODCAT 2 as nonsignificantly small, NODCAT 3 as indeterminate, and NODCAT 4 as potentially malignant. Based on the highest nodule category found, participants with NODCAT 1 and 2 received a negative test result and were invited for an annual repeat scan (first incidence screen) 1 year later because the likelihood of malignancy in a NODCAT 2 nodule at baseline is less than 1% (Table 17.4).[9,10] NODCAT 3

### TABLE 17.4 NELSON Management Protocol for Noncalcified Nodules at Baseline Screening

| Nodule Type | NODCAT 1 | NODCAT 2 | NODCAT 3 | NODCAT 4 | GROWCAT C |
|---|---|---|---|---|---|
| Solid | Negative test <br> Annual CT | Negative test <br> Annual CT | Indeterminate test <br> 3-month follow-up CT | Positive test <br> Refer to pulmonologist for workup and diagnosis | Positive test <br> Histological diagnosis required |
| Partial solid | Negative test <br> Annual CT | Negative test <br> Annual CT | Indeterminate test <br> 3-month follow-up CT | Positive test <br> Refer to pulmonologist for workup and diagnosis | Positive test <br> Histological diagnosis required |
| Solid/pleural based | Negative test <br> Annual CT | Negative test <br> Annual CT | Indeterminate test <br> 3-month follow-up CT | Positive test <br> Refer to pulmonologist for workup and diagnosis | Positive test <br> Histological diagnosis required |
| Nonsolid | Negative test <br> Annual CT | Negative test <br> Annual CT | Indeterminate test <br> 3-month follow-up CT | Nonexisting category | Positive test <br> Histological diagnosis required |

From Xu DM, Gietema H, de Koning H, et al. Nodule management protocol of the NELSON randomised lung cancer screening trial. *Lung Cancer* 2006;54:177–184.

was defined as an indeterminate test result that required a re-
peat scan 3 to 4 months later to assess growth. If there was no
significant growth on the repeat scan, the test result was called
negative, and participants were scheduled for an annual repeat
CT scan 8 to 9 months later. If there was significant growth, the
test result was positive (GROWCAT C), which means that a his-
tological diagnosis had to be obtained (Table 17.4). NODCAT 4
was also a positive test result, which required referral to a pulmo-
nologist for workup and diagnosis. In case of NODCAT 4 and
GROWCAT C, the general practitioner was first informed by
the radiologist of the screening site by phone about the test re-
sults and its consequences, followed by a letter to the participant
and the general practitioner.

## INCIDENCE SCREEN PROTOCOL

At annual repeat screening, there are two possibilities: either an
NCN already exists, and comparison with baseline screening
is possible, or the NCN is new. For the new nodules, the same
classification according to size was made as for the baseline
screening round. Follow-up was different, however, because at
incidence screen, new nodules are supposed to have a relatively
higher growth rate (Table 17.5).[9]

For all existing nodules, except for NODCAT 1, always
a comparison with the baseline screening round was made. If
in solid nodules or solid components of partial solid nodules
the PVC was 25% or more (Table 17.5), the VDT based on

changes in calculated volumes over time ($VDT_v$) was deter-
mined according to formula (2):[11]

(2)     $VDT_v \text{ (days)} = [\ln 2 \times \Delta t]/[\ln(V_2/V_1)]$

In situations in which a reliable volume estimate could not
be made because of software limitations and/or manual mea-
surement was preferred in either one of the two evaluations,
changes in volumes based on changes in estimated diameter
over time ($VDT_d$) was determined according to formula (3):

(3)     $VDT_d \text{ (days)} = [\ln 2 \times \Delta t]/[3\ln (MaxDiamXY2/$
$MaxDiamXY1]$

where MaxDiamXY is equal to maximum diameter in X/Y-axis.

However, if *both* scans had to be evaluated by manual mea-
surements, such as for pleural-based solid nodules or nonsolid
nodules, the following formula for growth determination was
applicable:

(4)     $VDT_d = [\ln2 \times \Delta t]/[\ln((MaxDiamXY2 \times$
$PerpDiamXY2 \times MaxDiamZ2)/$
$(MaxDiamXY1 \times PerpDiamXY1 \times$
$MaxDiamZ1)]$

where MaxDiamXY is equal to maximum diameter in X/Y-axis,
PerpdiamXY is equal to maximum diameter perpendicular to
MaxDiamXY, and MaxDiamZ is equal to maximum diameter
in Z-axis. If MaxDiamZ was missing, then MaxDiamZ equalled
$0.7 \times$ |Caudal slice number − Cranial slice number|.

**TABLE 17.5  Follow-up Protocol for Noncalcified Nodules at Annual Repeat Screening**

|  | Year 1 | Year 2 | Year 3 | Year 4 |
|---|---|---|---|---|
| Volume | $V_1$ | $V_2$ | $V_3$ | $V_4$ |
| Percentage volume change : PVC (%) (solid nodules only) |  | $100 (V_2 − V_1)/V_2$ | $100 (V_3 − V_1)/V_1$ | $100 (V_4 − V_1)/V_1$ |
| Growth (%) |  | PVC <25%: no  PVC ≥25%: yes | PVC <25%: no  PVC ≥25%: yes | PVC <25%: no  PVC ≥25%: yes |

According to the VDT, growing NCNs were classified in three growth categories: GROWCAT A with a VDT more than 600 days, GROWCAT B with a VDT between 400 to 600 days, and GROWCAT C with a VDT less than 400 days. Nonsolid nodules in which a new solid component appeared were also classified GROWCAT C (Table 17.6).[9]

During incidence screening, the test result (negative, indeterminate, positive) was based on the highest GROWCAT or the highest NODCAT in case of a new nodule. Subjects with no growth or GROWCAT A received a negative test result, and they were rescheduled for a CT scan in year 4. For subjects with GROWCAT B or a new NODCAT 2, the test result was indeterminate, and a repeat scan was made 1 year later (year 3) (Table 17.4). A new NODCAT 3 was also an indeterminate test result, which however, required a repeat scan 6 to 8 weeks later. Participants with GROWCAT C or a new NODCAT 4 had a positive test result and were referred to a chest physician for workup and diagnostic evaluation.[9]

## Management of NODCAT 4 and GROWCAT C Nodules

**Baseline NODCAT 4** If the highest category was a NODCAT 4, the participant was referred to the chest physician of choice via the general practitioner, usually the chest physician associated with the screening center. Primary objective was to confirm the presence of malignancy by performing routine physical examinations, routine laboratory tests, and a bronchoscopy (bronchial washing for cytology and culture and transbronchial biopsy or brushing on indication). A percutaneous CT-guided fine-needle aspiration (FNA) to obtain histology or cytology of the lesion is not a routine procedure in the Netherlands and Belgium, and if the FNA technique was used, it was only for large peripheral nodules with good access. The FNA result can be malignant, specific benign, or nonspecific benign. Specific benign diagnoses include tuberculosis, mycoses, nocardia, hamartoma, or a benign

lymph node. If a malignancy was proven, the patient was further staged and followed by surgical resection. A definitively specified benign diagnosis required treatment or just observation, but if no diagnosis or a nonspecific benign diagnosis was obtained, the follow-up strategy was based on the assessment of nodule growth similar as to NODCAT 3 (i.e., a repeat scan after 3 to 4 months). If at that time there was no growth, the test result was negative, and participants were scheduled for an annual repeat CT scan 8 to 9 months later. If there was growth, the test result was positive (GROWCAT C), which meant that a definitive histological diagnosis had to be obtained. Actually, this workup was according to our national CBO guidelines for the diagnosis and treatment of non–small cell lung cancer,[12] with the exception that a ^{18}F-fluorodeoxyglucose (FDG)-positron emission tomography (PET) scan was not routinely included in the workup of a NODCAT 4, primarily because our NELSON trial is a CT-screening trial, in which the presence or absence of growth of the nodule is leading, and not the outcome of the PET scan. Furthermore, the pretest probability of malignancy in this population of current and former smokers is very high, and a substantial proportion of the PET scan is false negative because of bronchioloalveolar cell carcinomas (BAC) or adenocarcinomas with BAC features, limiting the diagnostic value of the PET in the context of this CT-screening trial.[13–15]

**Baseline or Incidence: GROWCAT C** The workup for participants with growing lesions (GROWCAT C) was essentially the same as for NODCAT 4, except that for these nodules a final histological diagnosis had to be obtained either by FNA, video-assisted thoracoscopic surgery (VATS), or wedge resection and examination on frozen section, and that further observation by follow-up CT scans was no longer allowed. If malignant, the nodule had to be surgically removed after appropriate staging. If the outcome of the investigation was that the lesion was benign, the participant was rescheduled for the next regular annual CT scan.

# Fine-Needle Aspiration Cytology of Benign and Malignant Tumors of the Lung

The cytologic diagnosis of lung cancer can be made by the evaluation of exfoliated cells in sputum and/or cells obtained by transbronchoscopic techniques including bronchial washing, bronchial brushing, bronchoalveolar lavage, and by fine-needle aspiration biopsy (FNAB), most commonly, transthoracic FNAB under computed tomography (CT) guidance. The sensitivity of a single sputum specimen for the detection of lung cancer is approximately 50% and increases with the number of specimens examined.[1] The highest sensitivity is obtained for centrally localized squamous cell carcinoma and the lowest for small cell carcinoma. For endobronchial lesions that can be directly visualized with a bronchoscope, the sensitivity of a single bronchial washing or brushing for detecting lung cancer is about 65%, similar to endobronchial or transbronchial biopsy.[2] Combining sputum cytology with bronchial brush cytology increases the sensitivity than with either method alone.[3] Bronchoalveolar lavage utilizing narrow-diameter bronchoscopes has the higher yield for the detection of lung cancer in peripheral lesions with a reported sensitivity of 35% to 65%.[4] By far, the most reliable cytologic method for diagnosing a localized peripheral lung lesion is transthoracic CT-guided FNAB, which has a sensitivity that exceeds 85% for the detection of lung cancer. Metaanalyses of transthoracic needle aspiration biopsy reports show a high sensitivity (0.88 to 0.99) and specificity (0.99 to 1.00) for the diagnosis of lung cancer.[5] Most of the work on cytology screening for lung cancer has been on sputum specimens for the diagnosis of squamous cell carcinoma and its precursors. Lung cancer is thought to arise from a series of sequential preneoplastic changes that have been well defined for centrally arising squamous cell carcinoma but not other lung cancer subtypes. There are different patterns of molecular alterations in small cell carcinoma, squamous cell carcinoma, and adenocarcinoma. For example, Wistuba and colleagues[6] found a higher incidence of deletions at 17p13 (TP53), 13q14 (RB), 9q21 (p16 INKa), 8p21–23, and several 3p regions in squamous cell carcinoma than in adenocarcinoma. On the other hand, K-RAS mutations have been detected in bronchoalveolar lavage fluids from patients with adenocarcinoma but not in patients with other lung cancer subtypes.

It has been hypothesized that molecular analysis of sputum for biomarkers of lung cancer may provide an effective means of screening smokers to enable early lung cancer detection. However, the use of biomarkers for lung cancer screening is complicated by the fact that they can be detected in chronic smokers long before any clinical evidence of neoplasia. For example, p16 promotor hypermethylation and TP53 have been detected in sputum in chronic smokers without lung cancer and K-RAS mutations have been detected in atypical adenomatous hyperplasia (AAH).[7] At our institution, the focus has shifted from the use of cytology for screening for early lung cancer to the diagnosis of CT screen–detected lung cancer by transthoracic FNAB. It is minimally invasive, does not require hospitalization, and serious risks are uncommon and limited to pneumothorax and minimal hemorrhage. The FNAB is performed using a 22-gauge Westcott needle with immediate on-site assessment of air-dried smears utilizing the Diff-Quik staining method (Dade AG, Dudingen, Switzerland). Smears are also submerged in alcohol for Papanicolaou staining and blood clots are submitted directly in formalin for a cell block preparation.

## SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (Figs. 18.1 and 18.2) is strongly associated with cigarette smoking. It is a malignant epithelial tumor that was the most common histological subtype, but its incidence has now been surpassed by adenocarcinoma reflecting trends in reduced tobacco exposure with introduction of filters and low tar contents.[8] Squamous cell carcinoma arises from dysplastic squamous epithelium and can present centrally or peripherally. In addition to the classic squamous cell carcinoma, the World Health Organization recognizes several additional histological patterns including papillary, clear cell, small cell, and basaloid variants.

Typically, squamous cell carcinomas are classified into well, moderately, and poorly differentiated categories, and the cytological appearance is dependent on the extent of differentiation.
**FIGURE 18.1** Squamous cell carcinoma. **A:** A syncytial cluster and rare single cells with high nuclear:cytoplasmic ratios and irregular nuclear borders (Diff-Quik, 40×). **B:** Orangeophilic cells present as clusters and singly with hyperchromatic nuclei and relatively low nuclear:cytoplasmic ratios; anucleate squames are also present (Papanicolaou stain, 20×). **C:** Cell block with intercellular bridges and keratinizing cells (cell block, hematoxylin and eosin [H&E], 40×). **D:** Polygonal-, spindle-, and bizarre-shaped squamous cells (Papanicolaou stain, 40×). (See color plate.)

In general, squamous cell carcinomas can be associated with tumor diathesis, acute inflammation, or foreign body–type giant cell reaction.[9] In cytological preparations, squamous cell carcinoma occurs as single cells or loose clusters; tissue fragments are more common in aspirates.[10] Nuclear:cytoplasmic ratios may range from low to high, with lower ratios being more frequent in the well-differentiated carcinomas.[11] The cells have sharp distinct cell borders,[11] and the nuclei are often hyperchromatic to pyknotic *India ink* with coarse chromatin.

On histological sections, squamous cell carcinoma is defined by keratinization and/or intercellular bridges. In smears and liquid-based preparations of well-differentiated squamous cell carcinoma, intact intercellular bridges and keratin pearls are uncommon,[10] but they may be readily seen in cell

**FIGURE 18.2** Squamous cell carcinoma. **A:** Atypical tadpole-shaped cell with hyperchromatic nucleus (Papanicolaou stain, ThinPrep, 40×) **B:** Marked acute inflammation and necrotic debris associated with squamous cells. *Inset:* malignant cells are also present (Papanicolaou stain, ThinPrep, 40× [*inset:* 60×]). (See color plate.)

blocks sections. Rather, squamous cells are characterized by dense dark blue cytoplasm or orangephilia on Diff-Quik and Papanicolaou-stained specimens, respectively. Polygonal cells, bizarre cells with tadpole/caudate and spindle cell configurations,[10] and Herxheimer spirals in cytoplasmic tails are also associated with squamous differentiation. As squamous cell carcinoma becomes less differentiated, the aforementioned features become less prominent. Poorly differentiated carcinomas form syncytial groups especially in aspirates, and the cells have cyanophilic cytoplasm, higher nuclear:cytoplasmic ratios, and prominent nucleoli.[9]

The remaining relatively uncommon variants of squamous cell carcinoma have predominantly been described in surgical pathology literature but awareness of these variants is important to preclude misdiagnosis. Histologically, basaloid squamous cell carcinoma shows cells with peripheral palisading, scant cytoplasm, and hyperchromatic nuclei admixed with areas of typical squamous differentiation.[12] The small cell variant has focal squamous differentiation and small cells with morphologic traits of non–small cell carcinoma including coarse or vesicular chromatin, prominent nucleoli, and distinct cell borders.[12,13]

Carcinomas are often classified as non–small cell or small cell carcinoma for appropriate therapeutic management. An attempt to distinguish between squamous cell carcinoma and adenocarcinoma, rather than cataloging the two as poorly differentiated non–small cell carcinoma, is also becoming important as new agents for treatment are emerging. Bevacizumab, an antivascular endothelial growth factor monoclonal antibody, is being implemented for non–small cell lung cancer treatment, but it is contraindicated in patients with squamous cell carcinoma because of reports of pulmonary hemorrhage.[14] Tyrosine kinase inhibitors of epidermal growth receptors are also being used to treat adenocarcinoma with bronchioloalveolar features likely being more sensitive than other non–small cell carcinomas.[15] Given the differences in treatment options, subclassification of histological subtype can avert side effects as well as tailor appropriate therapy.

**Immunohistochemistry**    Most squamous cell carcinomas express high–molecular weight cytokeratin, cytokeratins 5/6 and p63. Thyroid transcription factor-1 (TTF-1)[16] and cytokeratin 7 (CK7)[17] staining is present in a subset of cases.

**Differential Diagnosis**    Cytology specimens with predominantly well-differentiated squamous cells have to be diagnosed cautiously. Such cells may represent mature keratinized superficial cells of a carcinoma without adequate sampling of smaller malignant cells, especially on exfoliative respiratory specimens,[11] or they may reflect reactive, metaplastic, or degenerative changes, even in the presence of nuclear hyperchromasia and cellular irregularities.[11] Reparative processes have atypia, but two-dimensional polarized "school of fish" sheets with enlarged nuclei, vesicular chromatin, and prominent nucleoli distinguish them from carcinoma.[9] Atypical squamous cells can accompany marked acute inflammation and necrosis, suggestive of an abscess.[11] An infectious process (e.g., aspergillosis)

has to be considered, but intense orangephilia and increased number of single cells should raise the possibility of squamous cell carcinoma.[18] A histiocytic reaction to keratin can erroneously be interpreted as *granulomatous inflammation*.[11]

Basaloid and small cell variants of squamous cell carcinoma have similarities to (combined) small cell carcinoma.[13] Cytological features, including dense cytoplasm, lack of nuclear molding, coarse chromatin, and nucleoli favor squamous cell carcinoma. Immunostains can aid in the diagnosis.

Finally, primary pulmonary squamous cell carcinoma is morphologically similar to its head and neck counterparts, and clinical history is necessary in determining the origin.

## ADENOCARCINOMA

There has been a shift in the predominant histological subtype of non–small cell carcinoma. Adenocarcinoma (Figs. 18.3 and 18.4) has surpassed the incidence of squamous cell carcinoma, once the foremost culprit of lung carcinomas.[8] Like squamous cell carcinoma, adenocarcinoma is linked to smoking, but it is also prevalent among nonsmokers and women.[19,20] Adenocarcinoma, defined by glandular differentiation or mucin synthesis, tends to present peripherally. The World Health Organization classifies adenocarcinoma into acinar, papillary, bronchioloalveolar, solid with mucin production, and mixed patterns; less common variants such as fetal, mucinous cystadenocarcinoma, mucinous *colloid*, signet ring, and clear cell adenocarcinomas also comprise this category.[12] Most adenocarcinomas demonstrate pattern heterogeneity and therefore are mixed subtype,[21] whereas pure subtypes are comparatively infrequent.

The histological features of adenocarcinoma, including well, moderate, and poor differentiation, are often mirrored in cytology specimens. In general, adenocarcinoma has a clean or necrotic background,[9] and has cyanophilic yet more translucent cytoplasm than squamous cell carcinoma.[12] The cytoplasm may be foamy, granular, lacy, or vacuolated. Based on the underlying architecture and differentiation, the neoplastic cells are arranged as single cells, two-dimensional sheets, three-dimensional clusters, syncytial groups, acini, or papillae. Similarly, the cellular (cytoplasmic vacuolization) and nuclear features (intranuclear inclusions, intranuclear grooves, chromasia, chromatin pattern, and nucleoli) reflect the differentiation of the tumor.

**Bronchioloalveolar Carcinoma**    Bronchioloalveolar carcinoma (BAC) is the in situ component of adenocarcinoma, which may be mucinous or nonmucinous. Histologically, BAC is defined as adenocarcinoma with predominantly lepidic growth along alveolar walls without stromal (desmoplastic reaction), vascular, or pleural invasion.[12,22] Pure BAC is rather uncommon,[23] but intermingling with other patterns, as in mixed subtype, is quite frequent. Among adenocarcinomas, BAC has a greater predilection among women[24] and is more prevalent in nonsmokers. Because most BACs present peripherally, they are less likely to occur in

**FIGURE 18.3** Adenocarcinoma. **A:** Monolayer sheets of relatively monotonous epithelial cells with pale chromatin and no significant nuclear overlap suggestive of BAC features (Papanicolaou stain, 20×). **B:** Two-dimensional sheet with bland nuclei containing pinpoint nucleoli and nuclear grooves often associated with BAC differentiation (Papanicolaou stain, 60×). **C:** Acinar formation (Diff-Quik, 20×). **D:** Fibrovascular cores surrounded by epithelial cells suggestive of papillary features (Diff-Quik, 10×). **E:** Epithelial cells enveloping delicate core in carcinoma with papillary architecture (Diff-Quik, 60×). **F:** Columnar cells line a fibrovascular core consistent with papillary features (cell block H&E section, 20×). (See color plate.)

**FIGURE 18.4** Adenocarcinoma. **A:** Three-dimensional cluster with nuclear pleomorphism, conspicuous nucleoli, and vacuolated cytoplasm (Papanicolaou stain, ThinPrep 60×). **B:** Cluster of epithelial cells with fine chromatin, inconspicuous nucleoli, intranuclear grooves, and inclusion (Papanicolaou stain, 60×). **C:** Adenocarcinoma with mucin: abundant mucin with scattered clusters of epithelial cells (Diff-Quik, 4×). **D:** Adenocarcinoma with mucin: malignant epithelial cells with conspicuous nucleoli and relatively abundant cytoplasm associated with mucin. *Inset:* Cells have vacuolated cytoplasm and nuclear membrane irregularities (Diff-Quik, 40×; inset Papanicolaou stain 60×). (See color plate.)

sputum, lavages, and washes and are more amenable to aspiration biopsies. Relatively benign biological behavior and propensity for multifocality[24] make identification of BAC significant rather than mere academic interest.

Several studies have demonstrated BAC cytological and histological correlation.[23,25–27] BACs tend to have a clean background, monolayered sheets[23] in orderly arrangement without nuclear overlap,[26] single relatively uniform cells containing moderate to abundant cytoplasm, pale fine chromatin, and inconspicuous nuclei; intranuclear inclusions and invaginations may also be present.[25] Most BACs are deceptively bland, but low-grade cytology should exclude neither a reactive process (over BAC) nor a well-differentiated invasive adenocarcinoma.[27] Conversely, mild cellular pleomorphism is evident in BACs[23] and does not imply invasive adenocarcinoma. Significant features distinguishing mucinous BAC from adenocarcinoma include abundant nuclear grooves, extracellular mucin,[23] and greater propensity toward three-dimensional groups than sheets.[28]

Pure BAC or predominant BAC pattern in mixed adenocarcinoma is associated with better prognosis,[26,29] so rendering a diagnosis of adenocarcinoma with BAC prominence on aspiration biopsy may guide therapeutic options. Lesions with a predominantly BAC may be amenable to relatively conservative surgical excision[30] and preoperative testing for sensitivity to specific drugs.[31,32] Detecting BAC on cytology also preoperatively alerts to the tendency of aerogenous spread and multifocal disease.[26,33]

Diagnostic accuracy of BAC is achieved by correlation with radiologic presentation (i.e., ground-glass opacity and solid component), operator expertise and adequate sampling. BAC features by cytology may yield predominantly non-BAC adenocarcinoma upon resection (or vice versa) as consequence of inadequately or peripherally sampled tumor.[27] Although cytological examination can indicate BAC features, histological examination to unequivocally exclude invasion is necessary for definitive diagnosis.[27]

## Adenocarcinoma

In contrast to BAC, other subtypes of adenocarcinoma tend to have greater architectural complexity with three-dimensional clusters, cell balls, and syncytia. Presence of papillary fronds (often containing intranuclear inclusions, ± psammoma bodies[34,26]) and luminal/glandular formations echo histological papillary and acinar architectures, respectively. Micropapillary morphology, associated with aggressive behavior in breast, has also been described in the cytology literature.[35] Cells of non-BAC tend to have conspicuous nucleoli,[27] chromatin ranging from finely granular to coarse and hyperchromatic and minimal to marked pleomorphism in well to poorly differentiated adenocarcinomas, respectively. In poorly differentiated carcinomas, a non–small cell carcinoma rather than either squamous cell carcinoma or adenocarcinoma[27] diagnosis is sometimes rendered. If available, material for immunostains to distinguish the two is beneficial as the tumors have different levels of sensitivity and adverse effects to therapeutic agents.

## Immunohistochemistry

Lung adenocarcinomas are frequently cytokeratin 7 (CK7)-positive and cytokeratin 20 (CK20)-negative. TTF-1,[36] although specific for pulmonary (and thyroid) origin, is not 100% sensitive; incorporating thyroglobulin stain into the immunohistochemical panel, especially in presence of papillary architecture, is beneficial for excluding thyroid metastasis. Surfactant apoprotein, associated with lung origin, is also expressed in a fraction of nonpulmonary adenocarcinomas.[37] Mucinous adenocarcinomas are often immunoreactive with CK7 and CK20, but not TTF-1.[36]

A CK7+, CK20−, TTF-1− immunoprofile in a lung mass is not uncommon. Because breast and upper gastrointestinal tract adenocarcinomas also exhibit this staining pattern, excluding metastatic disease is crucial. Inclusion of estrogen and progesterone receptors,[38] gross cystic disease fluid protein, mammaglobin, and caudal-type homeobox transcription factor-2 (CDX-2) in the battery of stains is prudent in such cases. Estrogen/progesterone[38] and CDX-2[39] expression have been also described in a subset of pulmonary adenocarcinomas.

Adenocarcinoma, BAC, and reactive atypia are morphological diagnosis. Although limited, evidence supporting application of p53 in discriminating BAC from non-BAC adenocarcinoma may have a role in cytology.[28]

## Differential Diagnosis

The main differential diagnosis problem is the distinction between peripheral adenocarcinoma of the lung and malignant pleural mesothelioma of epithelioid type. Malignant epithelioid mesothelioma has tubular and papillary architecture and CK7+/CK20−/TTF-1− profile like adenocarcinoma. Immunostains CD15, CEA, BerEP4 (for adenocarcinoma) and calretinin, CK 5/6, WT-1 (for mesothelial origin) can resolve the diagnosis of an epithelioid pleural-based lesion.

Several entities mimic adenocarcinoma including nonneoplastic lesions, metastases, mesothelial cells, and benign pulmonary neoplasms. Benign processes such as chemotherapy/radiation, pneumonia, and infarcts can mimic adenocarcinoma (see section on pitfalls). Reactive atypical pneumocytes can be challenging to differentiate from BAC on aspirates. Hyperplastic reactive cells display cilia and terminal bars. Also cellular enlargement, pleomorphism, binucleation, and nucleoli tend to be more prominent in reactive cells than BAC.[27]

Metastatic adenocarcinoma can appear histologically identical to pulmonary adenocarcinoma, and cytological features, although not unequivocally diagnostic, may steer in the distinction. Metastatic colon cancer is characterized by dirty necrosis and elongated nuclei. Primary lung adenocarcinoma often has mixed subtype with bronchioloalveolar features, whereas metastasis tends to illustrate morphological homogeneity.[12] Although these morphological features are helpful, confirmatory immunostains are necessary.

Sheets of mesothelial cells may result in misdiagnosis of BAC[25]; presence of intercellular bridges in mesothelial cells is helpful in separating the two entities.

Histologically, BAC is separated from its precursor AAH, with the latter measuring <5 mm and absence of interstitial

inflammation and fibrosis.[12] In cytology, lesions that are suspicious but not diagnostic of adenocarcinoma, defined as scant clusters of bland, yet atypical bronchioloalveolar cells with uniform round nuclei, pinpoint nucleoli in a histiocytic background, are designated *atypical bronchioloalveolar cell proliferation* (ABP) and demonstrate BAC or invasive adenocarcinoma on resections,[27] the discrepancy possibly a consequence of inadequate sampling.

Sclerosing hemangioma and hamartoma are benign/low-grade pulmonary neoplastic mimickers of adenocarcinoma, and their differentiation from adenocarcinoma can alter surgical management. Sclerosing hemangioma is defined histologically by its constellation of architectural patterns including solid, papillary, hemorrhagic, and sclerotic and relatively bland stromal and surface cells.[12] The architectural patterns of sclerosing hemangioma resemble those of adenocarcinoma, and the cells with bland cytology, inconspicuous nucleoli, intranuclear inclusions, and sparse/absent mitotic activity recapitulate features of BAC.[40] Presence of hyalinized stromal tissue, foamy and/or hemosiderin-laden macrophages, two cell populations, and absence of marked pleomorphism are consistent with sclerosing hemangioma.[40]

Pulmonary hamartoma is a benign neoplasm composed of mesenchymal tissue (connective tissue, muscle, adipose tissue, and cartilage) with entrapped respiratory epithelium.[12] The undifferentiated fibromyxoid component and bronchiolar cell proliferation with intranuclear inclusions and mild atypia resemble mucin and atypical cellular proliferation, respectively, suggestive of mucinous adenocarcinoma.[41] Smears of the fibromyxoid stroma display fibrillar edges and entrapped spindle-shaped cells, whereas mucin is devoid of these characteristics; mildly atypical epithelial hyperplasia is described in hamartomas.[41] Cartilaginous fragments and "popcorn calcification" on imaging are diagnostic of hamartoma.

# NEUROENDOCRINE NEOPLASMS

Pulmonary neuroendocrine tumors comprise approximately 20% of lung malignancies.[42] According to the most recent World Health Organization classification, they are histologically divided into a three-tier, four-category system including low-grade (typical carcinoid), intermediate-grade (atypical carcinoid), and high-grade (small cell carcinoma and large cell neuroendocrine carcinoma) tumors.[22] Overall, all tumors have characteristic neuroendocrine architecture including organoid, nesting, trabecular, insular, palisading, ribbon, papillary, cord, or rosettelike patterns. The distinction among the spectrum of neuroendocrine tumors is largely based on the number of mitoses and presence/absence of necrosis. Typical carcinoids have less than two mitoses per 2 $mm^2$ and no necrosis; atypical carcinoids have between 2 and 10 mitoses per 2 $mm^2$ and/or necrosis; large cell neuroendocrine carcinomas and small cell carcinomas have greater than 10 mitoses per 2 $mm^2$ and necrosis. Although the diagnostic criteria are primarily based on histological features, the architectural patterns and nuclear features are often reflected in cytological specimens. However, application of these criteria to neuroendocrine tumors in small biopsy specimens[42] and cytological specimens can be challenging.

## Typical and Atypical Carcinoids

**Typical Carcinoid**   Typical carcinoid (Fig. 18.5) comprises approximately 1% to 2% of pulmonary neoplasms,[42] and it is not associated with smoking. Typical carcinoid occurs at any age, with the mean age being 50 years.[42] Carcinoid aspirates are usually hypercellular and demonstrate loose cell clusters and single cells.[43] The cell groups often form syncytia, rosettes,[43] and trabeculae. Clusters may also be associated with a prominent streaming, arborizing capillary network in a hemorrhagic background,[44] a feature characteristic of typical and atypical carcinoids but not high-grade neuroendocrine carcinomas.[45–47] Papillary architecture is also seen in some carcinoids.[48,44] Single cells are also frequently seen in aspirates of carcinoids. Overall, the cells can have eccentrically placed nuclei with faint eosinophilic granular cytoplasm imparting a plasmacytoid appearance, or they may be stripped of their fragile cytoplasm and show bare nuclei.[44] Nuclei are relatively uniform/monomorphic and round with smooth contours. Spindle-shaped cells are also present in spindle cell carcinoids. Slightly larger and pleomorphic cells can also be observed in carcinoids.[47] The nuclei have fine granular chromatin and inconspicuous nucleoli. Rare intranuclear inclusions have also been described.[44] No obvious nuclear molding, necrosis, or mitoses are observed. In addition to the aforementioned characteristics, carcinoids may also have oncocytic, acinic cell, signet ring cell, and melanocytic features, but these traits have no impact on prognosis.[42]

**Atypical Carcinoids**   Atypical carcinoid (Fig. 18.6) patients have a mean age of 54 years[42] and tend to be nonsmokers. Most of the cytology literature describing atypical carcinoid predates the current World Health Organization's classification of neuroendocrine tumors. Despite the modification, the overall cytological features of atypical carcinoid are similar to typical carcinoids with few minor exceptions. The neoplastic cells may be slightly more pleomorphic and larger. In addition, atypical carcinoids are associated with mitoses and/or necrosis, similar to their histological counterparts.

**Immunohistochemistry**   Typical carcinoid stains with cytokeratin but a minority may be negative. Staining with neuroendocrine markers (chromogranin, synaptophysin, and CD56) is often strong. TTF-1 staining is variable with some series reporting no staining,[49] and others demonstrating expression in approximately one third of typical carcinoids.[50] Atypical carcinoid, like typical carcinoid, stains with cytokeratin. Expression of neuroendocrine markers is relatively less intense,[42] but TTF-1 staining is more common in atypical carcinoids.[50]

**FIGURE 18.5** Typical carcinoid. **A:** Arborizing capillary network associated with monomorphic, loosely cohesive epithelial cells (touch prep, Diff-Quik, 20×). **B:** Loosely cohesive monotonous cells with eccentric nuclei and *plasmacytoid* features (touch prep, Diff-Quik, 40×). **C:** Bland cells with speckled chromatin (touch prep, H&E, 60×). **D:** Carcinoid with hyalinized stroma (cell block, H&E, 40×). **E, F:** Spindle cell carcinoid (Diff-Quik and Papanicolaou stains, 100×). (See color plate.)

**Differential Diagnosis** Carcinoid and atypical carcinoid can be challenging to distinguish from each other as well as other neuroendocrine neoplasms. Typical and atypical carcinoids can be difficult to differentiate from each other in a limited aspirate sample where mitoses and necrosis cannot be thoroughly assessed. A typical carcinoid may be misclassified as an atypical carcinoid following necrosis that may occur during a prior fine-needle aspiration.[42] Furthermore, presence of some large and pleomorphic cells may suggest a high-grade neuroendocrine tumor; however, a diagnosis of small cell and large cell neuroendocrine carcinoma should be avoided in the absence of necrosis and brisk mitotic activity.[47] Ki67 and Pax-5 immunostains may also be helpful; often >50% staining favors a high-grade neuroendocrine neoplasm.[51,52]

The monomorphism of carcinoid and prominent papillary pattern may be confused with sclerosing hemagioma.[48,44]

**FIGURE 18.6** Atypical carcinoid. **A:** Epithelial cells with mild pleomorphism (Diff-Quik, 60×). **B:** Loose cell clusters with speckled chromatin and rare mitotic figure (touch prep, H&E, 60×). (See color plate.)
Sclerosing hemangiomas tend to have hyalinized stromal tissue, foamy and/or hemosiderin-laden macrophages, two cell populations, and stippled chromatin[40]; also, neuroendocrine markers are negative. Carcinoids can also mimic metastatic breast carcinoma,[12] especially those with neuroendocrine features.[53] Comparison with the primary breast carcinoma histology and immunostains (TTF-1, estrogen receptor and progesterone receptor, BRST-2) can be helpful in determining the primary.

**Small Cell Carcinoma**  Small cell carcinoma (Fig. 18.7) comprises approximately 20% to 25% of lung carcinomas.[42] Small cell carcinoma, unlike carcinoid, is related to tobacco use and occurs in slightly older patients with a median age of 62 years. The significance of separating small cell carcinoma from non–small cell carcinoma is well established. Similarly, the distinction between small cell carcinoma and other pulmonary neuroendocrine tumors is also critical; this can be challenging because the diagnosis is often made on small biopsies and cytological specimens.

Aspirates of small cell carcinoma show clusters or linearly arranged cells with prominent nuclear molding and single cells with high nuclear:cytoplasmic ratios, round, ovoid, and spindle-shaped cells with scant basophilic cytoplasm. In the surgical pathology literature, the cells are typically less than the diameter of three small resting lymphocytes.[54] The nuclei have fine "salt and pepper" stippled chromatin with absent/inconspicuous nucleoli. The background demonstrates nuclear smearing/crush artifact, necrosis, and apoptosis. Paranuclear blue inclusions, which are spherical light to dark blue structures that indent the nucleus,[55] are often associated with small cell carcinomas and seen primarily on air-dried smears.[56]

**Immunohistochemistry**  Neuroendocrine markers including chromogranin, synaptophysin, and NCAM (CD56) can also be helpful, but they stain approximately up to two third of cases.[54] TTF-1 expression has been described in up to approximately 95%[42] of small cell carcinomas of the lung; however, it also stains small cell carcinomas of extrapulmonary origin and non–small cell carcinomas.

**FIGURE 18.7**   Small cell carcinoma. **A:** Clusters and single cells with scant cytoplasm and focal nuclear molding (Diff-Quik, 40×). **B:** Small cell carcinoma with rosettes, nuclear molding, and crush/smearing artifact (Diff-Quik, 40×). **C:** Small cell carcinoma with a dirty background and scattered apoptotic cells (Diff-Quik, 60×). **D:** Cells with high nuclear:cytoplasmic ratios, fine chromatin, and inconspicuous nucleoli (Papanicolaou stain, 60×) **E:** Eosinophilic necrotic areas and malignant small cells (cell block, H&E, 40×) **F:** Rare cell clusters and scattered single cells in small cell carcinoma mimicking lymphoma (ThinPrep, Papanicolaou stain, 60×). (See color plate.)

**Differential Diagnosis** In surgical specimens, cellular dyscohesion is also noted in rare cases of small cell carcinoma.[54] An aspirate from such areas as well as the small size[57] of low-grade lymphomas may lead to an erroneous diagnosis of lymphoma. Unlike carcinomas, lymphomas are associated with lymphoglandular bodies in the background. Confirmation of epithelial origin with a cytokeratin stain is valuable too. Paranuclear blue inclusions, often associated with small cell carcinoma, have also been described in minority of rhabdomyosarcomas,[56] non–small cell carcinomas,[55] and lymphomas.[55]

## Large Cell Neuroendocrine Carcinoma

Large cell neuroendocrine carcinomas predominate in smokers and men, and the median age of presentation is approximately 63 years.[58] Histologically, large cell neuroendocrine carcinomas have the typical neuroendocrine architecture. They also have tumor necrosis and high mitotic rate like small cell carcinomas. Unlike the latter, however, large cell neuroendocrine carcinomas on histological sections have large tumor cells with low nuclear: cytoplasmic ratio, eosinophilic cytoplasm, coarse chromatin, and frequent nucleoli.[59] These features are recapitulated in cytological specimens.[60–62] The aspirates show neoplastic cells in flattened three-dimensional sheets with peripheral palisading and single cells comprised of pleomorphic large cells with moderate to scant cytoplasm, large nuclei with thick membranes and coarse or finely granular chromatin, prominent nucleoli, focal nuclear molding, and crush artifact.[60]

**Immunohistochemistry** By definition, large cell neuroendocrine carcinomas should express at least one of the neuroendocrine markers (chromogranin, synaptophysin, CD56). Approximately 50% of large cell neuroendocrine tumors express TTF-1.[49] These tumors typically do not express high–molecular weight cytokeratin.[49,63]

**Differential Diagnosis** Given the brisk mitotic activity and necrosis, large cell neuroendocrine carcinoma could be mistaken for small cell carcinoma. The cell size (3 to 5 times the size of a red blood cell in large cell neuroendocrine carcinoma and 1 to 2.5 times the size of a red blood cell in small cell carcinoma) and distinct nucleoli (in large cell neuroendocrine carcinoma) can be used to distinguish the two entities.[61] A few prominent nucleoli can be seen in small cell carcinoma, and the diagnosis should be based on the cytological features of the predominant cell type.

## Combined Small Cell Carcinoma

Combined small cell carcinoma has small cell carcinoma and non–small cell carcinoma, which may constitute large cell carcinoma, adenocarcinoma, squamous cell, spindle, or giant cell carcinoma.[54]

**Prognosis and Treatment** The subclassification of neuroendocrine tumors is important because it impacts prognosis and treatment. Statistically significant differences in survival have been reported between typical/atypical carcinoids and large cell neuroendocrine carcinomas[22]; however, a significant difference in survival has not been identified between large cell neuroendocrine carcinoma and small cell carcinoma.[64]

## Large Cell Carcinoma

Large cell carcinoma is a diagnosis of exclusion of poorly differentiated carcinoma without evidence supporting squamous, glandular, or neuroendocrine components. The cells have large cells with vesicular nuclei and prominent nucleoli.[12] Ultrastructurally, there is evidence of minimal differentiation toward squamous cell carcinoma or adenocarcinoma.[12]

# PRIMARY SALIVARY GLAND-TYPE NEOPLASMS

Salivary gland-type neoplasms are rare and histologically indistinguishable from their head/neck counterparts. The World Health Organization classifies adenoid cystic and mucoepidermoid carcinoma as salivary gland tumors and pleomorphic adenoma as adenoma of salivary gland type. These tumors usually present centrally and the former arise in large airways (i.e., trachea, carina, or main stem bronchus) from submucosal tracheobronchial glands.[65] Uncommon presentation, rather than salivary gland-type morphology, makes the diagnosis of this neoplastic subtype in the lung challenging. Because these tumors have equivalents in the head/neck and other organs, particularly adenoid cystic carcinoma, determining primary versus metastatic disease can be problematic. Prior clinical history, location, and multifocal pulmonary disease may favor metastasis over primary.

## Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is rare lung tumor with predisposition for local recurrences and late distant metastasis[12] typically presenting as a central submucosal mass, therefore, usually not present on exfoliative cytology examination. As a result of its uncommonness and location, adenoid cystic descriptions are relatively more prevalent in the histological than cytological literature. The cribriform (most common), tubular, and solid architecture described in surgical pathology are recapitulated in cytological specimens. The cellular adequacy is dependent on sampling. The neoplastic cells are arranged as two-dimensional sheets, cohesive three-dimensional clusters, and singly.[66] The cells are basaloid appearing, bland, small, round to oval, and hyperchromatic with scant cytoplasm. The nuclei have finely distributed hyperchromatic chromatin and inconspicuous nucleoli.[67] Metachromatic (Diff-Quik) or light blue (Papanicolaou stain) characteristic hyaline basement membranelike globules or cylinders are intimately associated with the cells, yet sharply demarcated from them.[68] The globules also appear independent of the cellular component[66] and are scant or absent in the solid variant. Intracytoplasmic and nuclear inclusions, nuclear molding, and dual cell population of round and spindle cells may occur.[66]

**Immunohistochemistry** The epithelial and myoepithelial cell phenotype is reflected in the dual immunophenotype. The

tumors express cytokeratin (an epithelial marker) and vimentin, smooth muscle actin, S-100, and p63, markers associated with myoepithelial origin.

**Differential Diagnosis** Reserve cell hyperplasia also has small cells, but the cells are even smaller than those of adenoid cystic carcinoma and cuboidal to columnar surfaced by cilia or terminal bars. The small cells of adenoid cystic carcinoma solicit a diagnosis of neuroendocrine tumors like carcinoid and small cell carcinoma. Slightly greater degree of pleomorphism, hyperchromasia, and coarse chromatin are present in carcinoid. Small cell carcinoma demonstrates necrosis, brisk mitotic activity, stippled chromatin, and nuclear molding, although the latter is described focally in adenoid cystic carcinoma.[66] Ancillary immunohistochemical studies can be highly useful for differentiating neuroendocrine tumors from adenoid cystic carcinoma. Extracellular substances such as amyloid[66] and corpora amylacia are alternative potentials for the cylindrical globules; however, lymphoplasmacytic cells as opposed to epithelial cells surround amyloid.[66]

**Mucoepidermoid Carcinoma** Mucoepidermoid carcinoma is a malignant tumor spanning a broad age range but with a predilection for younger (<30 years) patients.[12] The tumor is classified as either low-grade or high-grade and has low metastatic rate or locally aggressive/metastatic potential, respectively.[69] Histologically, glandular, tubular, and cystic structures with mucin and bland nuclei predominate in low-grade subtype, whereas intermediate and squamous areas with pleomorphism and mitoses largely comprise high-grade tumors.[12]

Cytologically, mucoepidermoid carcinoma has three cell types—mucinous, squamous, and intermediate—occurring singly or as clusters, with or without associated extracellular mucin, and necrotic debris.[67] The glandular cells tend to have eccentrically placed nuclei, sometimes secondary to indentation by cytoplasmic vacuoles, indistinct cell borders, and delicate cytoplasm, in contrast to the intermediate/squamous cells that have denser cytoplasm, centrally located nuclei and sharp borders.[67] The nuclear:cytoplasmic ratio among the cell types is variable.[67]

**Immunohistochemistry** Immunohistochemical stains may be helpful for separating mucoepidermoid carcinoma from adenocarcinoma. Both are CK7+ and CK20−; TTF-1 is expressed by adenocarcinoma and CK 5/6 by mucoepidermoid carcinoma.[70]

**Differential Diagnosis** Failure to recognize the combination of cell types, may lead to an erroneous diagnosis of either adenocarcinoma or squamous cell carcinoma. Conversely, appreciation of the different cells can suggest adenosquamous carcinoma. The distinction, if it exists,[71] may only be evident histologically, with identification of an in situ component, exophytic endobronchial growth,[12] absence of single cell keratination,[21] squamous pearls,[12] transition from low- to high-grade areas,[69] and central location in mucoepidermoid carcinoma.[17]

**Pleomorphic Adenoma** Pleomorphic adenomas of the lung are biphasic tumors with epithelial and myoepithelial components not sufficiently described in cytology, but likely to have similar traits as in the head and neck tumors. Unlike in the salivary gland, pulmonary pleomorphic adenomas lack significant glandular[69] and chondroid areas[12] but have branching ductules lined by epithelial and myoepithelial cells and periodic acid-Schiff material on histology.[72] Pleomorphic adenomas also have fibrillar metachromatic stroma.

**Immunohistochemistry** All cells stain with pancytokeratin; however, vimentin, smooth muscle actin, and glial fibrillary acidic protein is specific for the myoepithelial cells.[12]

**Differential Diagnosis** Like adenoid cystic carcinoma, pleomorphic adenoma has hyaline material, but it is more fibrillar, and its transition with the cells is more gradual than in adenoid cystic caricinoma.[66,68]

## PITFALLS IN PULMONARY CYTOLOGY

Pulmonary cytology has sensitivity and specificity ranging from 60% to 90%.[73] Even among the experienced cytopathologists, there are equivocal cases that are diagnostic dilemmas.[74] Majority of the medicolegal pathology cases involve surgical pathology, but approximately one third comprise cytology specimens, with false-positive diagnoses on sputum cytology/bronchial washing and lung aspirates being the third leading source of errors.[75] False-positive diagnoses tend to be more common than false-negative diagnoses.[74,76,77] Although difficult to entirely avoid in an active, high-volume pulmonary cytology practice, knowledge of complete clinical history (e.g., presence of localized mass lesion versus rapid clinical course/acute pulmonary damage), radiological findings, and common origins of cytological misinterpretations can minimize errors.

**False-Negative Diagnosis** Sputum, bronchoalveolar lavage, and transthoracic fine-needle aspiration cytology specimens are often used to diagnose pulmonary lesions. Sputum and bronchovoleolar lavage specimens may not be accessible to small peripheral lesions, so CT-guided transthoracic fine-needle aspirations are employed to target the specific pathological process. Despite image-guidance, false-negative diagnoses in pulmonary fine-needle aspirations occur and are frequently a consequence of inadequate sampling,[76,77] for which repeat aspiration is recommended.[77] The negative predictive values of fine-needle aspirations range from 53.3%[77] to 77%.[76]

In some instances, false-negative diagnoses result from interpretive errors, especially in squamous cell carcinomas associated with marked active inflammation. A *carcinomatous abscess* with few dysplastic, foreign body reaction to keratin[9] and malignant cells in a predominantly inflammatory could be dismissed as reactive epithelial changes.[78] Malignant characteristics include keratinous fragments and/or ghost cells, irregular cells, and pyknotic nuclei.[9] Metastatic breast carcinoma can appear bland and be misclassified as a benign process.[74]

**FIGURE 18.8   A:** Granuloma: enlarged spindle-shaped and epithelioid histiocytes (Diff-Quik, 40×). **B,C:** Granuloma with atypia. **B:** Atypical spindle-shaped and epithelioid histiocytes in clusters. *Inset:* areas with streaming pattern associated with reactive changes (Papanicolaou stain, bronchial brush, 40×; *inset* 40×). **C:** Histological section from same case demonstrating histiocytes and giant cells without evidence of malignancy (H&E, 40×). **D–F:** Aspergillus with atypical squamous cells. **D:** Sheet of atypical squamous cells in an inflammatory/dirty background. *Inset:* high magnification of rare single cells with dense cytoplasm and high nuclear:cytoplasmic ratio (Diff-Quik, 10×; *inset* 40×). **E:** Atypical cells with dense cytoplasm and high nuclear: cytoplasmic ratios associated with rare fungal form and neutrophils. *Inset:* silver stain demonstrating fungal organisms. (ThinPrep, Papanicolaou stain, 60×; inset: Gomori methanamine stain, 40×) **F:** Histological section demonstrating atypical squamous cells and intraluminal necrotic debris (H&E, 40×) (See color plate.)

## False-Positive Diagnosis

Since the implementation of lung screening and CT scans, greater numbers of pulmonary lesions are detected. In some instances, sophisticated imaging modalities such as positron emission tomography (PET) are used. PET positivity results indicate malignant/"active" lesions, but sometimes, inflammatory processes also yield false-positive results (Figs. 18.8 and 18.9).

Similarly, in cytology, several benign processes can mimic carcinoma. Devoid of architectural clues evident in histological sections, the distinction between reactive change/atypia and malignant processes in cytology can be difficult. Some lesions have been reported more often in exfoliative specimens and others in fine-needle aspirations. Also, the various entities usually emulate squamous cell carcinoma and/or adenocarcinoma.

There are several sources of pulmonary cytological pitfalls including infectious/granulomatous disease (fungal infections, dirofilariasis, tuberculosis, *Pneumocystis carinii*, cytomegalovirus), acute lung injury (diffuse alveolar damage [DAD], thromboemboli, infarction), iatrogenic effect (chemotherapy, radiotherapy), meosthelial cell proliferation, benign neoplasms (e.g., hamartoma), prior procedure-related changes, and vegetable contaminants.[79]

## Infections

**Fungal**   Granulomas in the lung are associated with various etiologies, including infectious processes. Fungal infections (e.g., *Aspergillus*) are a source of reactive squamous atypia that mimics keratinizing squamous cell carcinoma.[18,80,81] The cytological specimens from the infections show squamous cells arranged singly and in clusters[18] with eosinophilic to orangeophilic cytoplasm, hyperchromatic nuclei, high nuclear: cytoplasmic ratio, and smudgy chromatin. In contrast, squamous cell carcinomas have more orangeophilic cytoplasm and greater numbers of single atypical cells.[18] Necrosis may be associated with both lesions[18] and cannot, therefore, be useful in discriminating between the two.

**Mycobacterial**   Similarly, mycobacterial infections (i.e., tuberculosis) produce granulomatous inflammation, which can simulate carcinoma.[78] However, coexistence of tuberculosis and lung carcinoma including squamous cell carcinoma

**FIGURE 18.9** Therapy-related changes. **A:** Markedly atypical cells (postchemotherapy and stem cell transplant) (Diff-Quik- 20×). **B:** Cytomegaly with prominent nucleoli and relatively preserved nuclear:cytoplasmic ratios in an inflammatory background (postchemotherapy and stem cell transplant) (Diff-Quik, 60×). **C:** Atypical cells in cohesive cluster with vague *streaming pattern* without significant population of single atypical cells (postchemotherapy and stem cell transplant) (Papanicolaou stain, 60×). **D:** Multinucleated cell with prominent nucleoli and cytoplasmic vacuolization (postchemotherapy and stem cell transplant) (Papanicolaou stain, 60×). (See color plate.)

(the predominant subtype[82]), adenocarcinoma, large cell carcinoma, and small cell carcinoma has also been described.[83]

**Parasitic (Dirofilariasis)**   *Dirofilaria immitis* is a canine heart roundworm that can infect humans. Pulmonary disease may be incidental or symptomatic, present as solitary or multiple nodule(s),[84] and suggest malignancy radiographically and clinically.[85] The infection can cause infarction secondary to pulmonary artery embolization of the parasite from the right ventricle and granulomatous reaction surrounding a thrombosed artery.[84] Some cytological cases are associated with reactive squamous metaplasia of surrounding airways, which may be erroneously diagnosed as squamous cell carcinoma,[84] whereas others demonstrate papillary clusters with cells containing high nuclear:cytoplasmic ratio, nuclear irregularity, mild hyperchromasia, and prominent nucleoli in the perilesional bronchiolar epithelium suggestive of adenocarcinoma. Scarcity of atypical cells and lack of significant hyperchromasia should favor a reparative/reactive process in pulmonary dirofilariasis.[86,87] This distinction is important because dirofilarial infection is benign and requires no surgical intervention.[85]

**Pneumocystis Pneumoniae and Cytomegalovirus**
False-positive diagnoses have been linked with cytomegalovirus[88] and *P. pneumoniae*[89] as well.

**Wegener Granulomatosis**   Wegener granulomatosis, although not of infectious etiology, is a systemic vasculitis characterized by a triad of upper respiratory, lower respiratory, and renal involvement. Pulmonary Wegener granulomatosis has

different histological appearances with the characteristic pattern demonstrating geographic necrosis, multinucleated giant cells, and mixed inflammatory infiltrate. Similar to the infectious and granulomatous entities, cytological atypia of Wegener granulomatosis may be a potential source of false-positive diagnosis.[90] Hyperchromatic atypical squamous cells in a background of necrosis, acute inflammation, and hemorrhage may be misdiagnosed as squamous cell carcinoma[90,91] and atypical bronchial cells as BAC.[92]

**Acute Lung Injury**   Reactive type II pneumocytes, progenitors of type I pneumocytes in response to injury, are present in specimens when they are hyperplastic, thereby posing a potential diagnostic pitfall.[74,93,94] In bronchoalveolar lavage specimens, reactive type II pneumocytes have been associated with acute lung injury,[95] organizing pneumonia,[78] alveolar hemorrhage,[89] ventilator-associated pneumonia,[89] hypersensitivity pneumonitis,[89] eosinophilic pneumonia,[89] medication-induced injury,[89] DAD, and embolism/infarction. The cells tend to be large with high nuclear:cytoplasmic ratios and vacuolated cytoplasm[89] suggestive of adenocarcinoma.

**Diffuse Alveolar Damage**   DAD has acute and organizing stages during which alveolar hyperplasia develops. Bronchoalveolar lavage specimens obtained from patients with DAD demonstrate cellular specimens with single cells, two-dimensional sheets, and three-dimensional cell clusters[96] that can occasionally form glandlike structures with scalloped edges suggestive of adenocarcinoma.[93] The cells have nuclear atypia, cytoplasmic hobnails characteristic of hyperplastic cells, ≥1 prominent nucleolus,[96] hyperchromasia, slight

nuclear irregularities, high nuclear:cytoplasmic ratio,[93] and infrequently, dense cytoplasm suggestive of squamous differentiation.[96] Many of these features overlap with malignancy, but lack of uniformity among cell clusters, lack of markedly increased nuclear:cytoplasmic ratio, scalloping of cell groups with hobnails, and intercellular clearing "windows" support type II pneumocyte hyperplasia over carcinoma.[93]

### Pulmonary Embolism/Infarction

Pulmonary embolism with or without infarction can cause cytological atypia suggestive of adenocarcinoma.[97–100] Atypical cytological features include three-dimensional cell clusters with cytoplasmic vacuolization, enlarged nuclei with regular borders, and prominent nucleoli. Unlike malignant neoplasms, the atypia is focal and fleeting, often apparent 2 to 3 weeks postthromboembolism.[99] Single atypical cells often seen in conjunction with malignant neoplasms are lacking.[98,99,101]

### Type II Pneumocytes versus Malignancy

There is definite overlap between reactive type II pneumocyte hyperplasia and carcinoma, particularly BAC. Several criteria have been outlined in the literature to distinguish the lesions. First and foremost, a search for cilia and/or terminal bars is an important and simple clue to make a diagnosis oriented to a benign process. Reactive/reparative processes tend to have two-dimensional sheets, maintain uniformity and polarity,[79] and demonstrate cellular streaming.[102] Two cell populations[102] (i.e., relatively uniform and loosely cohesive benign cells and dyscohesive malignant cells with large nuclei), tissue fragments consisting of ≥2 cells with common inner or outer *community* borders and single cells, elongated or *tenacious* cytoplasmic borders, intranuclear intracytoplasmic inclusions, paucity of multinucleated giant cells, and increased nuclear area are more frequent in adenocarcinoma.[103] Other characteristics such as hyperchromasia, prominent nucleoli, nuclear membrane irregularities, elevated nucleus:cytoplasmic ratio,[103] and mitotic activity,[79] although often associated with malignancy, are also evident in reactive processes.[103]

### Asthma

Bronchial asthma results in excessive columnar epithelial cell shedding, sometimes as papillary formations suggestive of adenocarcinoma.[104] The cells tend to be of uniform shape and size with peripheral palisading.[104] Presence of eosinophils and Charcot-Leyden crystals is also helpful, but lacking in the acute phase.[104]

### Lipoid Pneumonia

Cytoplasmic vacuolization in lipid pneumonia may also resemble vacuoles of mucinous adenocarcinoma.[79] Lack of a mucinous background and histochemical/immunostains (mucicarmine, cytokeratin, CD68) can be helpful in making the distinction.

### Chemotherapy and Radiotherapy

Many anticancer drugs can cause atypical changes in the respiratory tract that resemble adenocarcinoma and squamous cell carcinoma.[102]

Cellular changes associated with chemotherapy and/or radiation include cytomegaly with preserved nuclear:cytoplasmic ratio, multinucleation, macronucleoli, and nuclear pleomorphism.[105] The chromatin is uniform or smudgy, but a coarse chromatin pattern can be present.[102] Abnormal-appearing cells are often part of a tightly cohesive cluster or sheet without prominent single atypical cells (Fig. 18.9).

### Mesothelial Cell Proliferations

In transthoracic aspirates, particularly of pleural-based lesions, mesothelium is sometimes inadvertently sampled. Sheets of mesothelial cells can be misdiagnosed as squamous cell carcinoma,[80] or the honeycomb arrangement of relatively bland cells may suggest a diagnosis of BAC. Recognition of intercellular windows in mesothelial cells and, if necessary, immunohistochemical stains for mesothelial cells (calretinin, cytokeratin 5/6, WT-1) and epithelial cells (B72.3, BerEP4, CEA) are also helpful.

### Pulmonary Hamartomas

Pulmonary hamartomas may also be mistaken for adenocarcinoma.[74,41] The myxoid background may be interpreted as mucin, whereas bronchiolar hyperplasia, intranuclear inclusions, intranuclear invaginations, and multinucleation can suggest adenoarcinoma.[41,106,74]

Unlike mucin, fibromyxoid stroma has fibrillar edges and spindle-shaped nuclei. A cell block can also be made at time of on-site evaluation for further characterization. The mucicarmine stain would be negative, and S-100 immunostain would highlight the spindle stromal cells. In addition, when present, the chondroid/cartilaginous component may be better preserved in cell block sections but not easily visualized in smears.

### Suture Granuloma and Posttracheostomy Atypia

Fine-needle aspirate of a PET-active lesion in a patient with a history of multiple primary carcinomas was interpreted as non–small cell carcinoma based on presence of dysplastic cells. Surgical excision showed an inflammatory nodule at the prior suture site.[107] Posttracheostomy atypia following laryngectomy and/or tracheostomy can show cells with irregular nuclear contours and fine or coarse chromatin suggestive of squamous cell carcinoma.[108] Absence of a mass clinically should dictate caution.

### Vegetable Contaminant

Patients with aspiration pneumonia may have vegetable cells contaminants suggestive of pulmonary epithelial cell atypia.[109] Features suggestive of malignancy include linear arrangement of asparagus cells suggestive of metastatic lobular breast carcinoma,[109] vacuolated and swollen cytoplasm indicative of mucin,[109] and dark cytoplasm reminiscent of atypical enlarged nuclei.[109] Regular quadrangular shape, extremely large size and refractory walls favor vegetable cell contamination.[109]

### Megakaryocytes

Megakaryocytes are seen incidentally in histological specimens as large, hyperchromatic, irregular cells bulging from capillaries in patients with smoking history, sepsis,

cardiovascular disease, and metastatic malignancy.[110] Although rare in cytology, their atypical appearance can mislead to a diagnosis of malignancy.[11] Lobulated nuclei (single or multiple), ruffled border, and variation in cytoplasm (dense centrally and pale peripherally) are clues to megakaryocytic origin.[11]

## CONCLUSION

A cytological diagnosis is a synthesis of clinical, radiological, and morphological features with appropriate sampling and specimen preservation. False-positive diagnoses, particularly in sputa, are of 10 related to insufficient clinical history.[73] Adjunct studies such as immunohistochemical stains and fluorescence in situ hybridization (FISH) analysis[74] may be helpful in some cases. Despite these measures, cytology has limitations, and a definitive diagnosis cannot always be ascertained. If uncertainty remains, it is prudent to suggest additional sampling or a frozen section prior to definitive surgery.

# Early Detection of Lung Cancer Using Bronchoscopy

Although the overall lung cancer survival is poor with only 15% of patients surviving 5 years after diagnosis,[1] patients with tumors <2 cm have a 5-year survival of 77%.[1] The survival of those with preinvasive or microinvasive bronchial cancers is even better at >90%.[2] Over the last 2 decades, the largest gain in life expectancy in lung cancer patients is among those with localized disease versus those with regional or distant metastasis.[3] Clearly, strategies to improve outcome by detecting and treating the disease in the preinvasive or localized stages is needed.

There are unique challenges to localize preneoplastic lesions or early cancers in the lung. In contrast to other epithelial organs such as the oral cavity, cervix, or colon, the lung consists of a complex branching system of conducting airways leading to alveoli with a surface area the size of a tennis court. In addition, instead of a single cell type, lung cancer consists of several cell types and they are preferentially located in different parts of the tracheobronchial tree. Squamous cell carcinoma and small cell carcinoma, accounting for approximately 45% to 50% of the lung cancers are preferentially located in the central airways (trachea, main, lobar, and segmental bronchi). Adenocarcinoma, accounting for approximately 40% to 50% of all lung cancers, is preferentially located in the peripheral airways inaccessible to standard fiberoptic/video bronchoscopes because of the size of these instruments with an outer diameter of ≥4.9 mm. Ultrathin bronchoscopes with an outer diameter of 2.9 mm are available, but they cannot reach peripheral airways ≤2 mm in diameter. Thus, there is no single method that can scan the entire bronchial epithelium and allow tissue sampling for pathological diagnosis and molecular profiling.

## DETECTION OF EARLY CANCER IN CENTRAL AIRWAYS

Rapid evaluation of the central airways became possible with the development of flexible fiberoptic white-light bronchoscopy by Dr. Shigeto Ikeda in the late 1960s. There has been continuing technological advancement over the last 40 years. The development of videobronchoscopy, with better image resolution and quality, is now replacing the former fiberoptic systems. However, early central lung cancers remain difficult to detect with white-light bronchoscopy even with the improved image capability of videobronchoscopy.[4] Recent incorporation of optical zoom or magnifying lenses may enhance the examination of the bronchial mucosa and improve the detection of early vascular changes that can be associated with early malignant change.[5] Other developments that can be used in adjunct with white-light imaging for localization of preneoplastic lesions and early lung cancer include autofluorescence bronchoscopy (AFB), narrow-band imaging (NBI), and optical coherence tomography (OCT). The recent development of endobronchial ultrasound is an additional tool for the bronchoscopic assessment of central early lung cancers.

## Autofluorescence Reflectance Bronchoscopy

Autofluorescence reflectance bronchoscopy has been shown in multiple studies to significantly increase the detection of preneoplastic lesions and carcinoma in situ when used as an adjunct to white-light bronchoscopy[6–26] (Table 19.1). In addition, it is important in the staging of early central lung cancers prior to curative endobronchial therapy.[27,28] It enables the bronchoscopist to obtain a more accurate visualization of the margins and assessment of lesion size.[27,28]

This technique utilizes the spectral differences in fluorescence and absorption properties of normal and dysplastic bronchial epithelium and has served as the basis for the design of several autofluorescence imaging devices for localization of early lung cancer.[6,12,13] More recent versions of these devices use a combination of reflectance and fluorescence for imaging.[14,22,23,25,29,30]

AFB was first developed in the early 1990s at the British Columbia Cancer Research Centre in Vancouver, British Columbia, and became commercially available in 1998.[10] The LIFE-Lung system (Xillix Technologies, Vancouver, BC) used a helium–cadmium laser for illumination (442 nm) and detected

the emitted red and green autofluorescent light with two image-intensified charge-coupled device (CCD) cameras. Normal areas appear green, and abnormal areas appear reddish brown because of reduced green autofluorescence in preneoplastic and neoplastic lesions.

Subsequent improvements in technology made it possible to use nonimage intensified CCDs for detection. Two second-generation devices approved by Food and Drug Administration (FDA) made use of a combination of fluorescence and reflectance to enhance contrast between normal and abnormal tissues (Table 19.2). The Onco-LIFE system (Novadq Technologies, Richmond, Canada) utilizes a combination of reflectance and fluorescence imaging. Blue light (395 to 445 nm) and small amount of red light (675 to 720 nm) from a filtered mercury arc lamp is used for illumination (Fig. 19.1). A red reflectance image is captured in combination with the green autofluorescence image to enhance the contrast between premalignant, malignant, and normal tissues as well as to correct for differences in light intensities from changes in angle and distance of the bronchoscope from the bronchial surface.[14] Using reflected near infrared red light as a reference has the theoretical advantage over reflected blue light in that it is less absorbed by

hemoglobin and hence less influenced by changes in vascularity associated with inflammation. The D-Light system (Karl Storz Endoscopy of America, Culver City, California) consists of a red/green/blue (RGB) CCD camera and a filtered Xe lamp (380 to 460 nm). It combines an autofluorescence image from wavelengths >480 nm with a blue reflectance image.[25] Frame averaging is used to amplify the weak autofluorescence signal.

These earlier autofluorescence systems were developed to be used with fiberoptic bronchoscopes. With the advanced CCD sensor technology and more widespread use of video-bronchoscopy, autofluorescence systems that can be used with videobronchoscopes have been developed (Table 19.2). The Pentax SAFE-3000 system (Pentax Corporation, Tokyo, Japan) uses a semiconductor laser diode that emits 408 nm wavelength light for illumination and detects autofluorescence using a single high-sensitivity color CCD sensor in the fluorescence spectrum 430 to 700 nm (Fig. 19.2). Reflected blue light is used to generate a fluorescence-reflectance image. The white-light and fluorescence images can also be made displayed simultaneously.[29] The Olympus autofluorescence imaging bronchovideoscope system (Olympus Corporation, Tokyo, Japan) uses blue light (395 to 445 nm) for illumination. An

autofluorescence image (490 to 700 nm) as well as two reflectance images, one green (550 nm) and one red (610 nm) are captured sequentially and integrated by a videoprocessor to produce a composite image.[30]

A reduction in specificity has been associated with the increased sensitivity for detection of early lesions. However, there is some data that shows that areas with abnormal autofluorescence contain increased chromosomal aberrations despite a benign histopathology, and that the presence of multiple areas of abnormal autofluorescence is an indicator of overall increased lung cancer risk.[31,32] Recently, the use of a quantitative score during autofluorescence examination has been shown to improve specificity.[33]

**Optical Coherence Tomography** Currently, there are two imaging modalities with sufficient spatial resolution and tissue depth penetration to address the relatively high false-positive AFB results and to determine whether the tumor has already invaded through the basement membrane (Fig. 19.3). Confocal microendoscopy offers spatial resolution down to the submicron range, but epithelial cells do not autofluorescence strong enough to allow detection without application of a contrast agent.[34,35] In addition, because contact with the bronchial surface is required, fragile epithelium can be scraped off during imaging. Motion artifacts caused by cardiac pulsation and respiratory movements can also lead to suboptimal confocal imaging of cellular details. OCT is a promising micron-scale–resolution method that may be more suitable for rapid endoscopic imaging. OCT is a noncontact method that delivers near infrared light to the tissue and allows imaging of

cellular and extracellular structures from analysis of the backscattered light with a spatial resolution of 3 to 15 $\mu$m and a depth penetration of approximately 2 mm to provide near-histological images in the bronchial wall.[36–39] Preliminary studies showed that invasive cancer can be distinguished from carcinoma in situ (CIS), and that dysplasia can be distinguished from metaplasia, hyperplasia, or normal.[39–41] A progressive increase in the epithelial thickness was found to parallel the severity of the histopathology grade. The nuclei of the cells also became darker and less light scattering in lesions that were moderately dysplastic or worse. The basement membrane became disrupted or disappeared with invasive carcinoma.[41] However, CIS could not be distinguished from high-grade dysplasia. Therefore, systems with higher resolution and Doppler capability and polarization sensitivity that can measure tissue microstructures in greater detail and quantify microvascular blood flow are needed.[42] Doppler OCT (DOCT) systems already exist that can detect extremely slow blood flow (<20 $\mu$m/sec in blood vessels as small as ~15 $\mu$m diameter).[43,44] DOCT's unprecedented micron-scale spatial resolution and

ability to monitor functional blood flow parameters at the microvascular level should prove valuable for (a) structural and functional lesion assessment,[45] (b) differential diagnosis/staging (invasion through the basement membrane and hence may no longer be curable by endoscopic therapy such as electrocautery treatment),[39,41] and (c) therapeutic feedback monitoring during endobronchial therapy such as photodynamic therapy.[44,46]

### High-Magnification Videobronchoscopy

Increased vessel density in the bronchial submucosa is often present in squamous dysplasia and may play an early role in cancer pathogenesis.[47] Angiogenic squamous dysplasia is a specific lesion characterized by a collection of blood vessels juxtaposed to and projecting into an area of epithelial dysplasia.[47] High-magnification bronchoscopy (Olympus Optical Corporation, Tokyo, Japan) combines both fibreoptic and videobronchoscope technologies to produce 100 to 110× magnification of the bronchial wall compared with standard videobronchoscopes.[5,48] This enables the visualization of microvascular networks in the bronchial mucosa. An increase in microvessels can be seen by high-magnification imaging in most areas of abnormal autofluorescence and dysplasia, and discrimination from bronchial inflammation is possible.[5]

### Narrow-Band Imaging

NBI (Olympus Optical Corporation, Tokyo, Japan) is a novel system that also utilizes the changes seen in the microvascular network of bronchial dysplasia. This technique uses a narrow-band filter rather than the conventional broad RGB filter used in standard videobronchoscopes. The conventional RGB filter uses 400 to 500 nm (blue), 500 to 600 nm (green), and 600 to 700 nm (red). NBI uses three narrow bands 400 to 430 nm (blue covers hemoglobin absorption at 410 nm), 420 to 470 nm (blue), and 560 to 590 nm (green) to create the images. Blue light has a short wavelength, reaches into the bronchial submucosa, and is absorbed by hemoglobin. On evaluation of airway lesions that were abnormal under autofluorescence imaging, this technique provides more accurate images of microvessels compared with high-magnification videobronchoscopy using broadband RGB technology.[48] Further evaluation of NBI in a small series has been performed in comparison with standard white-light videobronchoscopy. It was found to improve the detection of dysplasia/malignancy when used as an adjunct to white light compared with white-light imaging alone. The relative sensitivity was 1.63.[49] A direct comparison between NBI and AFB to determine their relative merits have not been conducted.

### Endobronchial Ultrasound for Central Lesions

Endobronchial ultrasound is a new technology that is likely to have a significant contribution to the correct staging of early central lung cancer. The layers of the bronchial wall can be visualized, and detection of unsuspected invasion is improved.[50–52] The use of endobronchial ultrasound may also be used as an

**FIGURE 19.4** Endoscopic ultrasound of a central lesion referred for curative endobronchial therapy. Destruction of the bronchial wall structures can be seen on the left (*arrow*).

adjunct to AFB, where it may be used to further assess lesions with significantly abnormal autofluorescence and improve prediction of malignancy.[53]

Evaluation of the curability of early central lung cancers with endobronchial therapies such as photodynamic therapy, electrocautery, and cryotherapy has previously relied on endobronchial characteristics. These include size, visual margins, and nodularity particularly under autofluorescence imaging. These have been correlated with risk of bronchial wall invasion and lymph node metastasis.[54–56] However, it is important to evaluate the depth of invasion and involvement of the cartilaginous layer to make the most appropriate choice of curative therapy. Thoracic computed tomography (CT) scan is not useful for small central lung cancers either for detection of the lesion or the assessment of intrabronchial wall invasion.[27,51,57] Endobronchial ultrasound using a radial probe inserted through the working channel of a flexible bronchoscope can be used to assess depth of invasion of a central cancer into or through the bronchial wall with a sensitivity of 86% and specificity of 67% (Fig. 19.4).[51,53] This will assist the physician in choosing either endobronchial therapy or immediate referral for surgery if unsuspected invasion is detected.[58]

## DETECTION OF EARLY CANCER IN PERIPHERAL LUNG

The advent of multidetector row CT scanners has resulted in the detection of multiple small nodules in many patients both in a research setting, where CT scan is being investigated as a lung cancer screening tool, and in the clinical setting.[57,59,60] Although most small nodules have low risk of malignancy, persistent serial

growth on CT follow-up or change in appearance of nonsolid lesions is worrisome for malignancy and requires investigation.[57,59,61] The diagnosis of these small peripheral lung lesions presents particular challenges because of invisibility on fluoroscopy and the inability of standard bronchoscopic access. Overall, the sensitivity of bronchoscopy for peripheral lesions is 78% but falls to <35% with lesions <20 mm in diameter.[62] Approach with transthoracic fine-needle aspiration is also difficult even under CT guidance because of the small size of these lesions, and it carries a significant risk of pneumothorax.

A promising approach is to use image guidance to assist the bronchoscopist in locating the lesions. Techniques that have been developed include endobronchial ultrasound or electromagnetic navigation (see Chapter 28).

## Endobronchial Ultrasound for Peripheral Lesions

The use of miniaturized radial high-frequency (20 MHz) ultrasound probes through a flexible bronchoscope enables the localisation and characterisation of peripheral lung lesions. Detailed 360-degree images of lesions with spatial resolution <1 mm can be seen.[63] Different patterns of ultrasound echoes may indicate the presence of malignant or benign disease.[63–65] In general, a heterogenous internal echogenicity, absence of linear-discrete air bronchogram, and/or a continuous hyperechoic margin appears more suspicious of malignancy.[63–65] The presence of two or more of these ultrasound features increases the likelihood of malignancy to 89%, and absence of any of these features is highly likely to exclude malignancy (negative predictive value 85%).[65]

Early use of the radial probe for localization of peripheral lesions was followed by removal of the probe and insertion of sampling tools into the chosen airway. The use of a guide sheath as an extended working channel was then incorporated into the procedure. Thus, once the lesion had been localized, the probe was removed leaving the guide sheath in place, then forceps and/or a bronchial brush could be advanced through the sheath to obtain specimens. Diagnostic yields vary between 63% and 77%[66–74] (Table 19.3). Results are influenced by size of the target lesion and position of the probe within the lesion.[68,69,73,74] The diagnostic yield for lesions ≤15 mm diameter is 40% compared with 76% for lesions >15 mm diameter.[74] If the probe is able to be positioned within the lesion, the yield is higher at 83% compared with 61% if adjacent to the lesion or 4% when outside the lesion.[74] In addition, the diagnostic yield is increased with up to five cumulative sequential transbronchial biopsies.[74]

Therefore, this is an effective technique that can achieve good diagnostic yield for peripheral lung lesions without the associated radiation exposure of fluoroscopy or CT. However, small lesions <10 to 15 mm remain a challenge.

**Electromagnetic Navigation**   A promising approach to examine small peripheral lung lesions is to use an electromagnetic navigation guidance system to guide a small sensor-tipped catheter to the peripheral lung, using virtual CT as a road map.[75–81] Registration points are first marked in the virtual CT constructed from a spiral CT scan. During the procedure, the patient lies on top of a board that generates a weak electromagnetic field. The physician uses the sensor-tipped catheter to touch the same registration points corresponding to that marked on the virtual CT (e.g., main carina, upper-lobe entrance, middle- and lower-lobe entrance). After that, a sheathed catheter that bends in eight directions is maneuvered using virtual CT as a road map similar to a global positioning system (GPS) device. Once the target is reached, the sensor catheter is removed. Forceps

are introduced through the sheath, and transbronchial biopsies are performed. Most of these reports used the device in combination with fluoroscopy, which is not used for bronchoscopy in all clinical centres.[75–79] Two centers achieved similar results without fluoroscopy[80,81] (Table 19.4). The diagnostic yield appears to be independent of size, but few lesions ≤10 mm have been included in these studies. Early experience showed improved diagnostic accuracy from <30% to ≥50% for tumors ≤2 cm in diameter. Accuracy is better when the geographic miss is minimized, specifically when the deviation from the target lesion is ≤4 mm.[80]

**Multimodality Bronchoscopic Diagnosis**   Diagnostic accuracy may be improved further by the combination of endoscopic ultrasound with electromagnetic navigation. In one series without the use of fluoroscopy, an endobronchial ultrasound probe was used to verify catheter placement within the target before biopsies were performed. This technique was able to achieve a diagnostic accuracy of 88% compared with ultrasound alone (69%) or electromagnetic navigation alone (59%).[82]

Coupling electromagnetic navigation with endosocopic ultrasound or optical imaging such as OCT may allow better localization and characterization of small lung lesions, increase biopsy yield, and separate preneoplastic or early cancer lesions from benign lesions. It may also enable delivery and placement of fiducial markers to facilitate radiofrequency ablation, radiosurgery or photodynamic therapy (PDT) of peripheral lesions, and potentially allow treatment-induced changes to be monitored in real time.[44,45]

## CONCLUSION

Advances in optical imaging such as AFB, NBI, OCT, and endobronchial ultrasound as well as an image-guided navigation system provide unprecedented opportunity to localize preinvasive lung cancer and preneoplastic lesions in the lung, allow biopsy to

characterize these lesions better, and to study their natural history. Localization of these early central lesions enables minimally invasive endobronchial treatment without removing adjacent normal lung tissue and, in the future, may also assist with minimally invasive techniques for treatment of peripheral lesions.

# Evolving Early Detection Modalities in Lung Cancer Screening

It would seem intuitively obvious that early detection efforts of a lethal disorder such as lung cancer would increase the chances for cure of that disease for individuals, and therefore, the population from which they derive, and thereby lead to a reduced death rate (reduced mortality) from that disease. This has proven to be the case for cervical and breast cancer screening.[1,2] However, to date, no molecular nor imaging modality of the lung, although suggestive, has yet been sufficiently evaluated to incontrovertibly confirm that it reduces mortality for early lung cancer detection.[3] Several studies of various lung imaging and other modalities are currently under way, are promising, and are described elsewhere in this textbook (see Chapters 15 to 17).

The lung is a visceral organ; therefore, access is necessarily limited. It is virtually impossible to directly examine all ramifications of the complex branching structures of the bronchial tree by external imaging, endobronchial fiberoptics, or other modalities. Therefore, certain aspects of a transforming epithelium must go unexamined, even by the most sophisticated sampling techniques. This inherent problem is reflected in imperfect sensitivity for all molecular lung cancer–screening modalities tested to date. Clearly, lung epithelial sampling approaches are evolving.

Also underappreciated is that any given screening modality will necessarily be imperfectly specific, in isolation, but two or more complementary stages in screening may, when coupled, offer vast improvements in predictive value of a positive test. That is, serial molecular monitoring for risk stratification could complement or even leverage imaging approaches to disease detection, by allowing enrichment of the disease prevalence ("risk") of the population destined for disease detection by more specific imaging approaches. Thus, in a typical population of otherwise unselected middle-aged smokers and ex-smokers, where lung cancer prevalence is about 2%, the positive predictive value (PPV) of a noncalcified nodule detected on spiral computed tomography (CT)—where typically specificities are ~90%—proves to be lung cancer in only about 18%.[4] However, if one uses a biomarker of risk to

identify a higher-risk portion of the population, where prevalence for lung cancer is 20%, the PPV (probability that same CT-detected nodule represents lung cancer in this context), is much greater at ~70%.

Therefore, a staged approach to screening, first using a risk assessment tool, followed by a disease detection tool, implies that two different tiers or levels of performance can, when coupled, have synergistic effects on early detection efficacy. Here, the first tier of screening would identify less deterministic "risk factors," perhaps both demographic and molecular. Such nondeterministic but informative risk-assessment tools abound in the literature but are often underappreciated as such. Then, the second tier testing would entail much more stringent, and specific, conventional performance criteria for actual lung cancer detection markers or imaging features.[4]

Candidate noninvasive risk assessment tools for lung cancer screening might simply collect readily available clinical information in sophisticated risk prediction models.[5,6] Alternatively, as will be demonstrated, one can biologically sample the entire, or portions of, lung epithelium and include, for example, germline genetic polymorphisms in carcinogen metabolism or DNA repair genes (blood- or buccal cell–based); blood-based proteomic signatures; transcriptional signatures in a related airway specimen (e.g., brush-exfoliated buccal cells), sputum oncogene mutation, or tumor suppressor gene silencing (spontaneously exfoliating lung epithelial and inflammatory cells); or exhaled breath tests of volatile (alkanes or aldehydes) or nonvolatile compounds (DNA), derived from as yet undetermined airway origin (e.g., bronchial or alveolar lining fluids).

Conventional clinical disease detection tools might include anatomic-based CT scans, functional imaging such as positron emission tomography (PET) scans (see Chapter 27), various conventional and enhanced optical bronchoscopic techniques (see Chapters 19 and 28), or other localizing modalities, all discussed elsewhere in this text, followed by definitive tissue sampling where indicated, with attendant conventional or newer molecular assays applied. In this chapter, we will largely emphasize less invasive, molecular-oriented approaches to both

risk assessment and disease detection that are inherently more easily applied to an asymptomatic population determined by clinical history to have some propensity to lung cancer.

## AIRWAY IMAGING APPROACHES

**Bronchoscopic Optical Techniques** Although invasive, fiberoptic bronchoscopy has been considered in certain high-risk lung cancer screening contexts. Autofluorescence bronchoscopy (AFB), based on altered refractile properties of multilayered hyperplastic or dysplastic epithelium, has proven superior to conventional white-light bronchoscopy (WLB) in detecting moderate-to-severe dysplasia, and carcinoma in situ with 56% to 82% sensitivity (AFB), versus 9% to 58% sensitivity (WLB).[7,8] AFB is not universally available. Because there are several localized responses to detection of premalignancy and overt but confined bronchial malignancies (Nd:YAG laser therapy, photodynamic therapy [PDT], electrocautery, cryotherapy, and brachytherapy), some have advocated routine bronchoscopic screening of individuals determined as high risk by other means (e.g., high-grade sputum atypia, chronic obstructive pulmonary disease [COPD], asbestos exposure).[9,10] Specificity of AFB has been a question. Advancement of WLB techniques, including light-scattering technologies and videobronchoscopy, is imminent.[4,11–14] High-density radiographic CT image reconstruction has allowed for the development of *virtual bronchoscopy*, a technique that is completely noninvasive, although radiation dose is not trivial, and radiologist/computer evaluation strategies still evolving[15] (see Chapters 19 and 28).

## LUNG TISSUE–BASED MOLECULAR ASSAYS

Of course, the gold standard for lung cancer detection is examination of lung tissue itself, either by conventional means (microscopy, immunohistochemistry, and the like), or by newer molecular means. Among the newer means, fluorescence in situ hybridization (FISH) for larger-region genomic deletions or duplications (see Chapter 49), microsatellite examinations (see Chapter 7), DNA methylation patterns (see Chapter 7), microarray messenger RNA (mRNA) expression signatures, candidate mRNA expression signatures, microRNA microarrays, candidate microRNA expression signatures, proteomic and antibody arrays, and metabolomic approaches are all in use in experimental and/or beta-testing for early clinical application. The National Cancer Institute (NCI) empowered, in the last decade, the Early Detection Research Network (EDRN) to create a consortium of tissue repositories and technology platforms for this purpose, and the technologies presented at the most recent 2008 meeting are truly astonishing. As this chapter emphasizes evolving early detection modalities, largely by molecular assays on noninvasively obtained tissues from individuals without symptoms, those molecular techniques requiring robust, large surgical level tissue specimens are covered elsewhere in this volume.

For noninvasively obtained tissues used in early detection studies on asymptomatic populations, such as exfoliated cells in sputum, or the circulating macromolecules of blood, polymerase chain reaction (PCR)-based assays of DNA and RNA are most often employed in the translational research setting. Their sensitivity is extraordinary, allowing analysis of these lung-surrogate tissues with greater ease. It must be acknowledged that although conferring great sensitivity, these nucleic acid end points may, even for cancer syndromes, often be considered more biologically proximate, or twice-removed end points, as opposed to direct measurement of the full-dimensional cancer biological phenotype (uncontrolled growth, invasion, metastasis), which is generally not feasible. Even other proximate markers (metabolites or proteins/enzymes generating those metabolites) that are the direct underpinnings of these cancer phenotypes are often beyond the level of sensitivity of current assays, although proteomic, and antibody microarray technologies are advancing rapidly as are informatic approaches to these multidimensional data sets.

*DNA-based genome-wide search for aberrant copy number in tumors* have revealed copy number aberrations using single nucleotide polymorphism (SNP) arrays or array comparative genomic hybridization (CGH) and reveal that many of the copy number alterations found to cluster in lung cancer involve unknown genes.[16]

*DNA-based methylation markers in lung tissue, by example*: cytosine-phosphodiester-guanine (CpG) methylation of gene promoter DNA is a major correlate of biologic pathway regulation and deregulation.[17–19] In many ways, progressive DNA methylation of tumor suppressor genes has been revealed over the last 10 to 15 years to be a strong correlate of lung carcinogenesis.

As a recent example of a comprehensive methylation biomarker search, a concerted genome-wide effort to assay in vitro genes likely to be methylated, and responsive to a methylation inhibitor, was checked for consistency with expression and methylation profiles in human lung. Those genes whose expression was most discriminatory for lung tumor from adjacent nontumor tissue (for lung, specifically) by methylation-specific PCR (MSP) sampling of one or a few (CpG) methylation sites in each gene locus, included *BNC1*, *MSX1*, *CCNA1*, *RASSF1A*, *p16*, *ALDH1A13*, *LOX*, and *CTSZ*. This is one of the first such comprehensive genome-wide searches for methylation-silenced genes in lung cancer[20] and has been followed up by others.[21]

In another study, a panel of candidate gene DNA methylation markers, using methylation-specific PCR sampling was constructed, and using the top four markers (*CDKN2A EX2*, *CDX2*, *HOXA1*, *OPCML*) could distinguish lung tumors from normal tissue with 94% sensitivity and 90% specificity.[22]

A workshop was convened in 2005 on the use of methylated DNA sequences as cancer biomarkers, in risk assessment and disease detection, enjoining the NCI's EDRN and the National Institute of Standards and Technology. The summary[23] has emphasized the importance of specimen choice and handling, bisulfite modification strategy, choice of assay based on scale, sensitivity and cost, tissue specificity, and other factors. These issues remain at play for current lung cancer screening biomarkers (see Chapter 7).

## BLOOD-BASED MARKERS

Blood is an attractive surrogate specimen source because of its availability and the presumed pooling of metabolic processes in the circulation, as reflected, it is postulated, in that compartment.

### DNA-Based Markers in Blood

The quantity of DNA leaching into the blood itself has been proposed as a marker,[24] albeit controversially.[25,26] Attempts to detect DNA-based somatic markers in the blood have been myriad,[27] including oncogene mutations, somatic mutations, and other modifications, with mixed results. For the most proximate steps in tobacco carcinogenesis, the measurement of DNA adducts of known tobacco carcinogens in blood cells, several large European studies using ^{32}P postlabeling of adducts did not show consistent relation to smoking, nor risk.[28,29] A more recent large, pooled data analysis also suggests a weak association of bulky DNA adducts and lung cancer, perhaps apparent in current and recent smokers only.[30]

Aberrant DNA methylation in blood has been detected for the last decade, albeit its origin remains *unclear*, but these have been as disappointing as diagnostic tools.[31–33]

For risk assessment, blood-based genome-wide association and family linkage studies for germline variants associated with lung cancer have emerged, although in somewhat sparse number. A susceptibility locus on chromosome 6q23–25 was reported from a multi-institutional consortium examining high-risk family pedigrees, led by National Institute of Health (NIH) investigators[34] (see Chapter 4). The individual candidate genes in the region have not yet been confirmed with regard to association of their variants with lung cancer risk.

Individual variants in component enzymes in specific pathways have been explored in some detail in cross-sectional, case-control population-based studies, with particular attention paid to carcinogen metabolism,[35] DNA repair,[36–38] and inflammation.[39] In general, these data for individual variants have been inconsistent across populations but may have some incremental information when integrated into comprehensive risk assessment models that include demographic data. These are reviewed in greater detail in the cited references.

### RNA-Based Markers in Blood

There have been a small number of well-executed and suggestive studies of RNA expression in recovered circulating tumor cells[40–42] and/or peripheral blood lymphocytes.[43] Free circulating RNA studies are inherently challenging for quality template recovery, RNA-specific amplification, and detection of signal above background.

### Proteomic-Based Markers in Blood

A variety of proteomic-based approaches to obtaining patterns that distinguish cancer from noncancer tissue, premalignancy from normal tissue, and the corresponding signals reflected in the blood, have been approached[44] in a validation population, for example, a signature yielded a sensitivity of 58% and a specificity of 85.7%.[45] A more recent study combining proteomic-detected protein markers and proteins involved in known lung cancer pathways has suggested that a four-protein panel

in blood may have significant diagnostic value.[46] None of the protein studies to date entail a temporal component.

### Candidate Proteins in Blood

Several academic and commercial ventures have proceded from proteomics studies generating candidates to protein identification and construction of panels that distinguish lung cancer cases from appropriate controls with independent validation in separate populations.[45] Candidate proteins such as circulating serum carcinoembryonic antigen (CEA) and cytokeratin 19-fragment (CYFRA 21-1) values and lymphocyte antigen 6 complex locus K (LY6K) have demonstrated some signal in distinguishing lung cancer cases from controls, particularly in combination, although classification is not adequate for disease diagnosis, even in combination (sensitivity 65% to 70%).[47]

*Autoantibodies* with lung tumor–specific epitopes have been reported as showing some signal in lung cancer.[48] A recent report suggested that a panel of p53, c-myc, HER-2, NY-ESO-1, CAGE, MUC-1, and GBU4-5 autoantibodies detected by enzyme-linked immunosorbent assay (ELISA) in blood conferred a sensitivity of 76%, specificity of 92%.[49] On-chip synthesis of protein libraries that are used for detecting antitumor antibodies appear promising.

### Metabolomics in Blood

To our knowledge, the promise of metabolomics, using high-throughput generation of spectroscopic signatures representative of the metabolic states of a cell,[50–52] have not been applied to early detection of lung cancer. For candidate metabolites in blood, levels of S-adenosylmethionine have been reported as higher in lung cancer cases than in smoking controls.[53] Overall, there is a general paucity of investigations of lung cancer–related metabolites in blood.

### Molecular Phenotypes in Blood

Mutagen sensitivity and DNA repair capacity have been evaluated extensively in blood, particularly by several groups working at the MD Anderson Cancer Center in Houston, Texas. The identification of the phenotypes, measuring cytogenetic or more precisely ascertained DNA damage, presumably integrate a large number of genes and pathways into a cancer-relevant trait with impressive capacity to distinguish lung cancer cases versus controls in cross-sectional studies.[54,55,37] Performance in prospective studies in "integrative epidemiologic" investigations are pending.

## AIRWAY-BASED MARKERS

### Bronchoscopically Procured Airway Specimens for DNA and RNA and Protein Analyses

It is clear that if directly procured, histologically dysmorphic airway specimens yield important clinical information, as discussed elsewhere in this volume. Newer molecular modalities have been applied to bronchial biopsy specimens and bronchoalveolar lavage (BAL). For example, computer-assisted fluorescence immunophenotyping and interphase cytogenetics as a tool for the investigation of neoplasms has been applied to BAL in the region of a nodule with provocative results.[56,57]

However, it also appears that field carcinogenesis patterns of transcriptome-wide gene expression can be obtained in the major airways, which reflect the likelihood that a radiographically detected peripheral lesion, far remote from the bronchoscope, is a malignancy.[58,59] Given that cigarette smoke creates a field of injury throughout the airway, Spira et al.[58,59] sought to determine if gene expression in histologically normal large-airway epithelial cells obtained at bronchoscopy from smokers with suspicion of lung cancer could be used as a lung cancer biomarker. Using gene-expression profiles from Affymetrix HG-U133A microarrays, an 80-gene biomarker that distinguished smokers with and without lung cancer was identified. When the biomarker was tested on an independent test set, an accuracy of 83% (80% sensitive, 84% specific) was obtained. The biomarker profile had 90% sensitivity for stage I cancer among all subjects. When cytopathology of lower airway cells obtained at bronchoscopy was combined with the biomarker,

a 95% sensitivity and a 95% negative predictive value (NPV) were obtained. These findings indicate that gene expression in cytologically normal large-airway epithelial cells can serve as a lung cancer biomarker, potentially owing to a cancer-specific airway-wide response to cigarette smoke. This novel version of the field cancerization concept is now being tested in less invasively obtained airway specimens, such as exfoliated buccal and nasal epithelium. Justification for such an investigation comes from data that bronchial and nasal epithelium from nonsmokers were most similar in gene expression when compared with other epithelial and nonepithelial tissues and with several antioxidant, detoxification, and structural genes being highly expressed in both the bronchus and nose. Smoking had a similar effect on gene expression in nasal epithelium as in the bronchus.[60] The expression of several detoxification genes was commonly altered by smoking in all three respiratory epithelial tissues, suggesting a common airway-wide response to tobacco exposure (Fig. 20.1).

**FIGURE 20.1** Hierarchical clustering of genes commonly perturbed by smoking across intrathoracic and extrathoracic airway epithelium. **A:** Supervised hierarchical clustering of the expression of 45 genes induced by smoking in the bronchial airway that are present in both the nasal and buccal "leading edge subsets" in samples from smokers and nonsmokers. These represent genes upregulated by smoking in bronchial, nasal, and buccal epithelium. **B:** Supervised hierarchical clustering of the expression of 50 genes repressed by smoking in the bronchial airway that are present in the nasal leading edge subset in samples from smokers and nonsmokers. High expression (*red*), average expression (*white*), low expression (*blue*). (See color plate.) (From Sridhar S, Schembri F, Zeskind J, et al. Smoking-induced gene expression changes in the bronchial airway are reflected in nasal and buccal epithelium. *BMC Genomics* 2008;9:259.)

**Sputum-Based Cytology**  Although significant skepticism remains regarding the utility of standard sputum cytology as a lung cancer detection tool, and after the Mayo lung project and other NCI-sponsored studies yielded no overall mortality benefit, it has been long known that proximal and perhaps slower-growing lesions, such as that of squamous cell histopathology, could be detected in expectorated sputum with significant sensitivity (e.g., 30% to 50%). Additionally, automated, computerized image analysis can augment yield.[61]

**Sputum for DNA-Based Markers**  Sputum-based detection has been studied extensively for somatic genetic and epigenetic alterations.

For *somatic genetic mutations*, credible studies have suggested a plethora of *k-ras* and *p53* mutations found in sputum that correlate, albeit imperfectly, with lung cancer prevalence, in the case-control context.[62,63] Of the more recent studies, one group has reported a correlation of FISH-detected HYAL2 and FHIT deletions in both tumor tissue and sputum in those with a smoking history in both lung cancer cases and smoking controls.[64] Another group examined three loci for loss of heterozygosity (LOH) and microsatellite instability (MSI) within the FHIT locus in sputum, with sensitivity of 55% and specificity of 82%.[65]

**DNA Methylation by MSP in Sputa**  DNA methylation has been extensively studied in sputum for several presumed tumor suppressor gene promoters.[66] Among recent studies, Belinsky et al.[67] describe a case-control study nested within a high-risk cohort consisting of smokers with >30 pack-year smoking histories and spirometric airflow obstruction consistent with COPD. Results suggested qualitative sputum methylation increased with temporal proximity to the diagnosis, and with the number of genes methylated progressively conferring increased risk. Sensitivity and specificity of the 14-gene panel were both 64%. Methylation of three or more genes in sputum was associated with a 6.5-fold increased risk for lung cancer within 18 months. In stage III lung cancer, a methylation panel in sputum has been reported to reflect in the tumor itself, with 44% to 72% PPV and >70% NPV.[32] In most instances, sputum performed better than serum for the same gene panel (see Chapter 7).

A comprehensive study of quantitative MSP, using methylation-sensitive probes and primers, was carried out by Shivapurkar et al.[33] Eleven genes suggested to be silenced by methylation were examined in lung tumors, adjacent nonmalignant lung tissues, and sputum. Of all genes, *3-OST-2, DCR-1,* and *RASSF1A* showed the highest levels in tumors and the lowest in adjacent nonmalignant tissues. Peripheral blood mononuclear cells (PBMCs) were uniformly nonmethylated at the probe sites. For sputum, when *3-OST-2, RASSF1A, mp16,* and *APC* were combined, significant discriminatory power in distinguishing cases from controls was apparent (ROC [receiver operating characteristic] − AUC [area under curve] = 0.8).

**Sputum for RNA-Based Markers**  There are a few reports of RNA-based sputum studies in lung cancer detection that credibly identify the amplicon as RNA. Lacroix et al.[68] and Jheon et al.[69] reported an ability to amplify several transcripts (including preproGRP) from sputum, although in neither study there were no real-time controls employed to confirm the avoidance of contaminating DNA pseudogene amplification.

**Sputum for Protein-Based Markers**  Claims of protein expression in sputum are more easily affirmed as credible than that for RNA, yet there have been relatively few to date. By example, the ribonucleoprotein has been suggested as a sputum-based biomarker by immunocytochemistry,[70] although there has been little follow-up data. A recent study correlating tumor and sputum telomerase activity found 68% sensitivity and 90% specificity, for concurrent lung cancer by sputum analyses, in a case-control context.[71]

**Exhaled Breath for Volatile Small Compounds**
There is a considerable recent literature on the use of the gas phase of exhaled breath to identify individual volatile components or complex volatile mixtures that correlate with the presence of lung cancer. Study design has typically been case-control, such that predictive capacity for incident disease is largely unknown.

In a very carefully executed study, Wehinger et al.[72] collected tidal volume breathing mixed expiratory gas samples into 3-L pounds per cubic foot (pcf) bags, prior to any subject diagnostic or therapeutic interventions. They used a proton transfer reaction mass spectrometry (PTR-MS) approach to exhaled gas analysis, which avoids preconcentration steps otherwise required for gas chromatography-based techniques, but cannot distinguish compounds of the same mass. Among 17 predominantly early-stage lung cancer cases and 170 controls, mass-to-charge (m/z) = 31 or volatile organic compound (VOC)-31 (tentatively protonated formaldehyde) and VOC-43 (tentatively a protonated fragment of isopropanol) were the most discriminatory; impressive twofold to threefold differences of cases versus smoker controls, with some overlap, were found. Overall test performance, in simulations, showed sensitivity for detecting lung cancer was 54%, accuracy was 96%, specificity was 99%, PPV (given 5% prevalence) was 90%, and NPV was 96%. ROC curves showed AUCs for those aged >50 years old of 0.82 and 0.95, respectively.

In some of the initial studies on volatile compounds in the gas phase that correlate to lung cancer, in a case-control context, Phillips et al.[73,74] reported significant correlations of gas chromatography–coupled mass spectrometry (GC-MS) patterns and the likelihood of having lung cancer. In one study, the approach yielded a training set sensitivity of 90% and specificity of 85% for lung cancer. In the test set, 83% sensitivity and 80% specificity was obtained.[74] Distinction from the exhaled volatile patterns of active or former cigarette smokers without apparent lung cancer was made.[74] Most recently, Phillips et al.[75] measured VOCs in 1-L alveolar breath from 193 subjects with primary lung cancer and 211 controls with a negative chest CT. Subjects were randomly assigned to a training set or to a prediction set in a 2:1 split. A fuzzy logic model of

breath biomarkers of lung cancer was constructed in the training set and then tested in subjects in the prediction set by generating their typicality scores for lung cancer. Mean typicality scores employing a 16 VOC models were significantly higher in lung cancer patients than in the control group ($p < 0.0001$ in all TNM stages). The model predicted primary lung cancer with 84.6% sensitivity, 80.0% specificity, and 0.88 AUC of the ROC curve. Predictive accuracy was similar in TNM stages I through IV, and was not affected by current or former tobacco smoking. The predictive model achieved near-maximal performance with six breath VOCs and was progressively degraded by random classifiers (Fig. 20.2). Predictions with fuzzy logic were consistently superior to multilinear analysis. If applied to a population with 2% prevalence of lung cancer, a screening breath test would have a NPV of 0.985 and a PPV of 0.163 (true-positive rate = 0.277, false-positive rate = 0.029).

Another group reported 71% sensitivity and 92% specificity for lung cancer detection in a case-control setting, using a commercialized sensor array "electronic nose."[76] In the sensor array method, the actual volatile components of the unique signal are not directly evaluated, although additional workup has revealed them to be predominantly volatile hydrocarbons. Corroborative later reports simplifying the sensor array have been reported,[77] although these patterns do not directly identify the responsible biomarker compounds. A recent uncorroborated study on training dogs, the ultimate biosensors, in study-blinded fashion, reports an extraordinary performance in distinguishing exhaled breath from those with lung cancer versus healthy controls (sensitivity and specificity both 99%).[78] A recent report that lung cancer cells in vitro evolve unique volatile metabolites in the gas phase above the culture dish lends some credence to the cancer specificity of the evolved exhaled gas detection approach.[79]

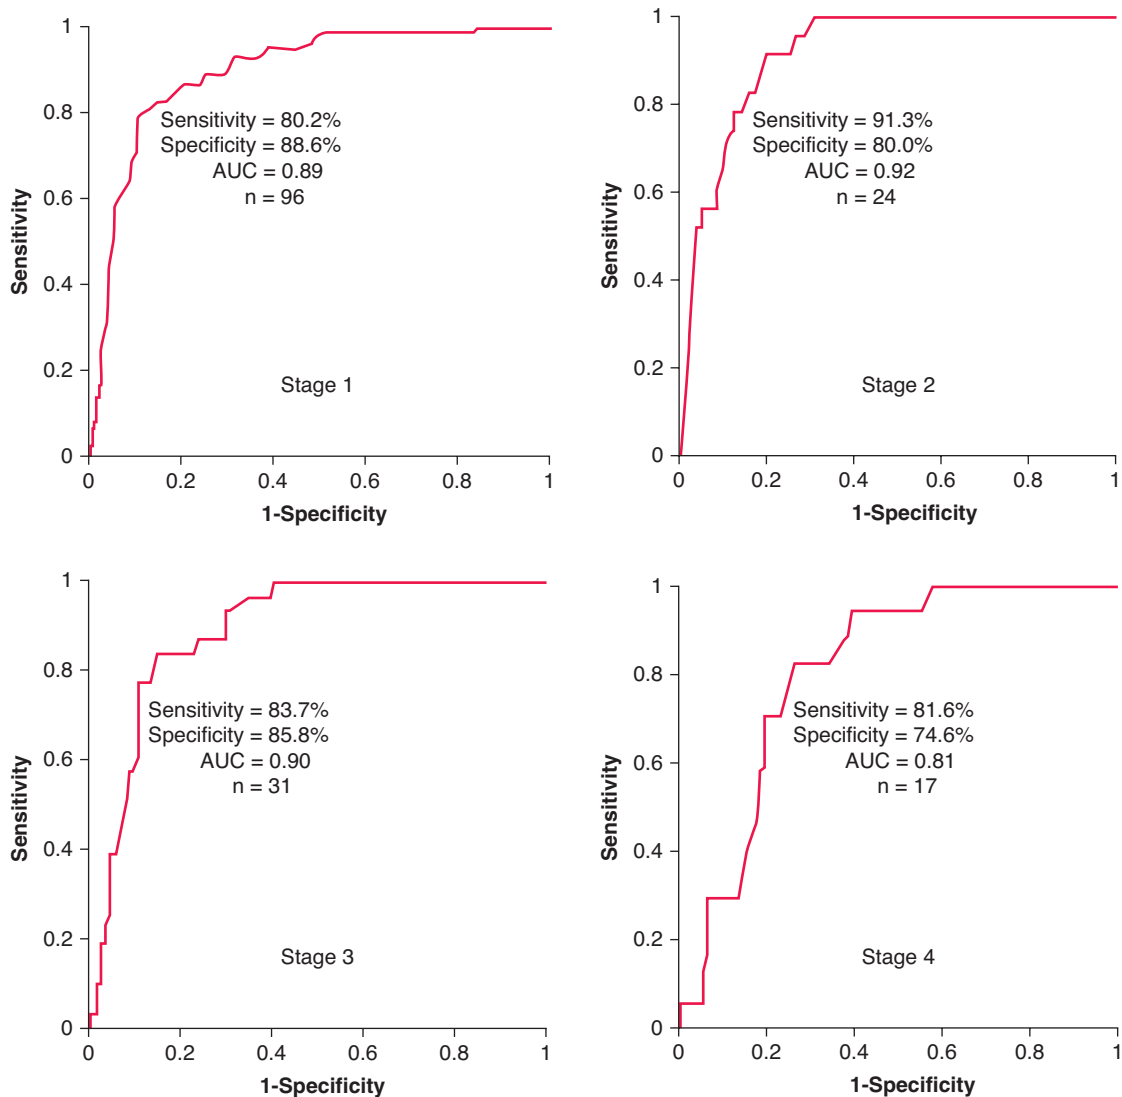

**FIGURE 20.2**  Measurement of VOCs from patients with various stages of lung cancer revealed accuracies of prediction that were similar across all stages. (From Phillips M, Altorki N, Austin JH, et al. Prediction of lung cancer using volatile biomarkers in breath. *Cancer Biomark* 2007;3:95–109.)

For molecules in the condensate (aqueous fraction) of exhaled breath, small molecules such as IL-2, tumor necrosis factor $\alpha$ (TNF-$\alpha$), and leptin have been correlated to the presence of clinically apparent lung cancer cases versus controls.[80] Notable is that macromolecules directly reflective of carcinogenesis have also been detected in exhaled breath condensate. It is not intuitively obvious how large macromolecule markers of lung carcinogenesis, such as DNA and proteins, can be suspended in the breath, but there are multiple reports of this phenomenon from several laboratories, including our own. It is possible that a fraction of the components of bronchial lining fluid are suspended merely by entrainment by adjacent high-velocity airflow, or alternatively, alveolar lining fluid components are suspended by the agitation inherent in tidal volume inflation and deflation and/or the occasional opening snap of underinflated or atelectatic airspaces. Whatever the mechanism, several groups have reported the presence of DNA in exhaled breath, allowing DNA-based markers such as specific *p53* gene mutations,[81] microsatellite markers,[82,83] or DNA sequence annotated at high resolution for methylation.[84,85] In each case, a provocatively higher rate of carcinogenesis-related DNA aberrancy was detected in the lung cancer cases versus controls; the sensitivities and specificities are in the 80% range. Whether these case-control correlations will translate to meaningful predictive power for risk for lung cancer, in prospective studies, remains unevaluated.

## SURROGATE AIRWAY EPITHELIA

### Exfoliated Upper Airway Cells
Brush-exfoliated buccal cells are transcriptionally active and potentially provide an easily procured window on gene–tobacco interaction that might be relevant to risk for tobacco-related malignancy. In one case-control study, expression of a candidate gene set of carcinogen metabolism pathway transcript in buccal epithelium was highly correlated with those in lung.[86] Genome-wide studies from other laboratories are underway for both buccal and nasal epithelia. Additionally, there have been intermittent reports of nasal epithelial access, in transcriptional and other studies, for gaining easier access to respiratory epithelium.

## CONCLUSION

There is an impressive array of innovative approaches being developed for the early detection of lung cancer. Both optical and molecular-based methods are under study, in case-control discovery phase endeavors. Validation for a few of the most promising markers, be they somatic DNA mutation, DNA methylation, transcript assemblies, proteomic, or other markers, are underway, although prospective validation is clearly lacking. Rather than expect a single marker that is definitive and sensitive for both screening and diagnosis, it might be more practical to evolve a multistage approach employing population-wide risk assessment, followed by early disease detection approaches. The precise formulation of risk assessment

approaches, and even disease detection tools, is in rapid flux. It is the high potential for public health impact of improvements in lung cancer diagnosis that has attracted a very considerable pool of innovations, strategies, and talent to focus on early detection approaches to this lethal disease.

# Molecular Carcinogenesis and Chemoprevention of Lung Cancer

Lung cancer is by far the leading cause of cancer-related death, worldwide and in the United States.[1] Despite substantial progress in the treatment of lung cancer, which correlates with improvements in surgery, radiation oncology, and chemotherapy, 5-year survival has improved from 7% to only 16% over the last 2 decades. Although median survival in all stages of disease has improved somewhat, the low likelihood of obtaining a cure even with optimal modern therapy is largely because of the clinical presentation of this disease in its advanced stages The late diagnosis is almost certainly related to a covert carcinogenesis phase that often evolves over 10 to 20 years and requires multiple molecular genetic changes to facilitate the development of invasive lung cancer.[2,3] Thus, there exists a strong rationale for intervening in those stages of lung carcinogenesis that could result in arrest or delay of disease progression to the stage of frank cancer. Therefore, the strategies that are likely to be successful will likely optimally target both better biological understanding of lung cancer–mediated field carcinogenesis, and the development of reliable biomarkers that can accurately assess the likelihood of efficacy and toxicity across target populations. Ultimately, strategies involving screening and early detection, biomarker-based chemoprevention, smoking cessation, and better biological understanding of the phenomenon of lung carcinogenesis are all likely to be coupled with individualized risk stratification in the development of modern approaches to prevent this dreaded disease and reduce the societal burden of lung cancer.

## LUNG CANCER EPIDEMIOLOGY

In most cases, lung cancer is strongly associated with direct consumption of tobacco products.[4] In fact, 87% of all lung cancers are detected in individuals who are active or former smokers, with an additional 6% to 7% composed of partners of smokers or their offspring (see Chapter 2). The second most common known cause of lung cancer is radon, which is associated with a significant increase in lung cancer risk, and with

other risk factors including asbestos exposure. Nonetheless, despite the high degree of certainty that currently exists over the link between tobacco smoke and lung cancer, the understanding of these facts took several decades to clarify.

## LUNG FIELD CARCINOGENESIS

The original description of *field carcinogenesis*, or *field cancerization* as it was originally called, dates back to Slaughter and coworkers,[5] who showed that multiple foci of epithelial hyperplasia, hyperkeratinization, atypia, dysplasia, and carcinoma in situ occurred in otherwise normal-appearing epithelium adjacent to cancers of the oral pharynx. This empiric evidence strongly suggested that carcinogen exposure has widespread effects throughout the entire carcinogen-damaged epithelial field. These diffuse histological changes suggested that the development of malignancy in the proximal upper aerodigestive tract is a result of the dose of carcinogen impacting exposed cell populations spread throughout this area. Auerbach and colleagues[6] observed and demonstrated the same pattern of heterogeneous, multifocal histological changes in the bronchial epithelium of smokers, many of whom have lung cancer. Thus, the concept of field cancerization or carcinogenesis was coined to describe the diffuse damage done by chronic exposure to carcinogens. Field carcinogenesis also forms the basis for the observation that individuals who survive a first cancer are often likely to develop a second malignancy in the region of the condemned epithelium.[7–9]

As these findings have been validated over the last several decades, increasing evidence has come to bear explaining the molecular genetic abnormalities that lead ultimately to the stepwise development of clonal invasion-competent cancer of the airway. Among the earliest findings in the aerodigestive tract of chronic smokers are loss of heterozygosity in chromosomes 3p, 9p, and 17p[2,10–14] (see Chapter 6). Clonal genetic abnormalities seen in normal histologic regions of the airway and not necessarily in areas that had detectable changes were

further evidence that damage was scattered throughout the entire field (see Chapter 19). It also brought to bear the limitations of modern histologic techniques in detecting the extent of the damage induced by tobacco smoke in the airway. The importance of these losses of hererozygosity are crystallized in the fact that, for example, the short arm of chromosome 3, which is often the earliest loss and is demonstrated on occasion even in early hyperplasia,[10] results in the loss of a region rich in tumor suppressor genes. There is also evidence for losses of the short arms of chromosomes 9 and 17, resulting in loss of tumor suppressor genes in p16 and p53, both of which are important to the cell's ability to repair DNA damage done by the tobacco carcinogen. p53 in particular, acts as a transcription factor in the control of G1 arrest and apoptosis, or programmed cell death, thereby allowing the cell to repair existing DNA damage or make the determinant decision to push a cell into the apoptotic process once it is too far damaged for repair. p16, found on chromosome 9p, negatively controls cyclin-dependent kinases (CDK)–cyclin activity by overexpression of cyclin-D1. By inhibiting cyclin-D1/CDK, the damaged cell is also prevented from entering into mitosis and proliferating with damaged DNA (see also Chapter 14).

Increasing evidence shows that the loss of these and other tumor suppressor genes in lung cancer is augmented by the activation of several critical proto-oncogenes. For example, RAS, c-MYC, and the epidermal growth factor receptors (EGFRs), are all tumor-promoting genes that are activated progressively during lung carcinogenesis. K-ras mutations are particularly common in adenocarcinomas of the lung, with some studies showing 30% of lung adenocarcinomas in smokers containing K-ras mutations.[15] The EGFR is frequently amplified in non–small cell lung cancers (NSCLCs) and in fact in lung carcinogenesis[16] (see Chapter 49). Mutations have been detected in the EGFR tyrosine kinase binding domain conferring sensitivity to small molecule EGFR-tyrosine kinase inhibitors (EGFR-TKIs).[17,18] Interestingly, both K-ras mutations and EGFR mutations have been found in the airways of smokers and nonsmokers in regions distant from the primary tumor, suggesting that both play important roles in field carcinogenesis. Thus, modern molecular tools can help us better understand the process of field carcinogenesis and, as we will discuss, implement the development of targeted agents that can arrest or inhibit this otherwise inexorable progression.

## Epigenetic Abnormalities in the Airway

Loss of function of tumor suppressor genes and greater function of oncogenes through mutations or gene activations are not the only mechanisms by which carcinogenesis is augmented in lung cancer patients. A growing body of evidence suggests that gene silencing through epigenetic means can be crucial in lung carcinogenesis (see Chapter 7). For example, in NSCLC, some tumor suppressor genes such as RASSF1A, also located in the tumor suppressor gene–rich chromosome 3p, encodes a protein that heterodimerizes with Nore-1, an important RAS effector with pro-apoptotic effect.[19] Evidence from several groups suggests that in NSCLC, RASSF1A can be frequently inactivated by hypermethylation.[20,21] Another important gene that can be inactivated by epigenetic means is the retinoic acid receptor-$\beta$ (RAR-$\beta$), which also maps to chromosome 3p. RAR-$\beta$ is a nuclear retinoid receptor with vitamin A–dependent transcriptional activity.[22] RAR-$\beta$ is a gene that is shown to be gradually lost in lung carcinogenesis,[23] and this can be regulated either by loss or by hypermethylation.[24,25] Interestingly, the maintenance of RAR-$\beta$ in mature tumors is a factor for poor prognosis[26] and it is differentially regulated in current versus former smokers. For example, a recent retrospective study on methylation status and occurrence of second primary tumors (SPTs) in completely resected NSCLC patients revealed a strong association between RAR-$\beta$2 hypermethylation in the development of SPTs only in former smokers.[27] In current smokers, hypermethylation was associated with a protective effect, pointing to the critical value of context with regard to smoking status in understanding the biological effects of retinoid receptors in lung cancer.[27,28]

## Lung Cancer Susceptibility and Risk Stratification

Although there is little doubt that exposure to tobacco smoke is the major risk factor for the development of lung cancer, there is also progressive evidence that the risk of developing lung cancer, even among the heaviest smokers, varies widely according to genetic and perhaps even dietary factors. This is reinforced by the fact that 85% of heavy smokers will not develop lung cancer, implicating important differences in lung cancer susceptibility across the population in the likelihood of developing overt disease. However, there are significant competing risks for death of heavy smokers, including cardiovascular disease, chronic obstructive pulmonary disease, and other malignancies including those of the upper airway, bladder, cervix, kidney, and pancreas. Evidence exists, however, to show that every other smoker dies of a smoking-related cause.[29] Despite this, accumulating evidence suggests that genetic and epigenetic factors are critical in modulating individual susceptibility to lung cancer or other consequences of tobacco exposure.[30] The various carcinogens from cigarette smoke, benzpyrine and 4-(methylnitrosoamino)-1-(3-pyridil)-1 butanone (NNK) require metabolic activation before they can exert their full carcinogenic effects. Various activation pathways compete with detoxification pathways and the balance between the two is critical in modulating cancer risk. Cytochrome P450s serve as carcinogen-metabolizing enzymes, whereas glutathione transferases serve as detoxification enzymes. Both sets of these important genes are known to have significant polymorphisms correlating with variations in lung cancer risk (see Chapter 4).

Other important modulators of risk in lung cancer include diet and gender. Dietary factors play an important role as epigenetic modulators of lung cancer susceptibility. In several case-controlled studies, defective detoxification and defective repair of genetic damage have been shown to be associated with increased individual susceptibility to lung cancer.[31–34] However, certain food constituents appear to afford a significant degree of protection to individuals with limitations to their detoxification capacity.[35] This relationship between diet and lung cancer has been extensively explored and used as the basis

| TABLE 21.1 | Levels of Prevention in Lung and Aerodigestive Cancer | |
|---|---|---|
| **Level** | **Definition** | **Example** |
| Primary | Diminish risk for normal healthy individuals | Smoking cessation or prevention; chemoprevention in asymptomatic smokers |
| Secondary | Decrease progression of preneoplasia | Reversal of preneoplasia or biomarkers of preneoplasia with chemoprevention |
| Tertiary | Decrease morbidity for patients treated or cured of an initial cancer | Chemoprevention of second primary tumor |

for the development of novel approaches to the prevention of lung cancer. For example, large studies suggest that diets that have a high intake of fruits and vegetables are associated with a reduced risk of lung cancer.[36] Further evidence suggests that a Mediterranean diet is associated with a substantial reduction in several cancers, including lung cancer.[37]

## Basis of Clinical Strategies in Lung Cancer Prevention

As several dietary adjustments and micronutrients have been associated with lower risks of lung cancer, including vitamin E, selenium, isothiocyanates, and BMT-polyphenols, several large randomized trials have sought to delineate which compounds in complex human diets are most responsible for the protective effects seen.[36,38] Initially, the greatest degree of evidence existed around the potency of carotenoids and retinoids and the broad epidemiologic indications implicating them in reduction of cancer risk in general, and lung cancer risk in particular.[39,40] In fact, the original definition of chemoprevention coined by Michael Sporn as "attempts to reverse, suppress, and prevent carcinogenic progression to overt cancer"[41] is based on his and other's experimental work showing that vitamin A analogues are capable of reversing or preventing epithelial carcinogenesis in mouse models of cancer.

Consequently, the identification of populations at risk for development of this disease followed suit. For example, target populations in many of the early prevention studies included broad populations of individuals at risk because of their exposure to tobacco and/or asbestos. Others sought to develop strategies for uranium miners, also a population believed to be at enhanced risk for developing lung cancer. Thus, with several decades of broad epidemiologic and dietary investigation, augmented by important experimental systems showing several classes of compounds, especially the retinoids and carotenoids, were capable of reversing cell damage, a strong drive to develop this approach in human populations was born. The trials focused on broad patient populations, including those of individuals at even higher risk, in other words, individuals with known premalignancy of the airway, or those patients who had already developed a primary tobacco-related cancer, and thus were at the greatest risk for developing a second primary tumor.

## Clinical Chemoprevention Trials

Laudable as smoking cessation efforts have been, it is clear that lung cancers are developing in former smokers.[42,43] Thus, the design of lung cancer trials has taken the approach to develop strategies based on the different populations considered for each intervention. Risk categories were different across these populations, and thus the categories of chemoprevention were defined as primary, secondary, and tertiary prevention (Table 21.1). Primary prevention involved intervening in patient populations at increased risk but with no histological or clinical evidence of cancer. The end point here was reduction in incidence of lung cancer, and reduction in death from lung cancer. Secondary prevention involved attempts in individuals with evidence of lung premalignancy to prevent progression of that premalignancy or, ideally, to reverse it to an earlier stage of carcinogenesis. Finally, studies in the highest risk population were undertaken in those individuals who had already developed tobacco-related malignancy. Here, the goal was to prevent the development of SPTs. As expected, many of the early trials focused on using retinoids and carotenoids as the chemoprevention agents of choice, given that the weight of epidemiological and experimental evidence for these compounds was significantly greater than that for other classes of compounds.

## Primary Chemoprevention Studies

Several large randomized studies were undertaken in populations deemed to be at increased risk of lung cancer caused by exposure to tobacco, asbestos, or their occupation as uranium miners. Three major studies, the $\alpha$-tocopherol/$\beta$-carotene (ATBC), $\beta$-carotene and retinol efficacy trial (CARET), and the U.S. Physician Study, were carried out using increasingly high doses of the carotenoid, $\beta$-carotene (Table 21.2). None of the three studies showed any reduction of lung cancer risk utilizing these compounds, and two of these studies, the ATBC and CARET studies, had surprising findings, both showing significant increases in lung cancer risk associated with supplementation with $\beta$-carotene. Both of these studies, which were 2 plus 2 factorial studies, also involved a second agent as an intervention. In these cases neither the second agent nor vitamin A itself was found to be associated with an increased risk of lung cancer, but neither were they protective against lung cancer incidence. Interestingly, both of these studies showed that the risk was increased only in populations

| **TABLE 21.2** | **Primary Randomized Chemoprevention Trials in Lung** | | | |
| --- | --- | --- | --- | --- |
| | **Intervention** | **End point** | **No. of Patients** | **Outcome** |
| ATBC[39] | $\beta$-Carotene/ $\alpha$-tocopherol | Lung cancer | 29,133 | Negative/harmful |
| CARET[46] | $\beta$-Carotene/ retinol | Lung cancer | 18,314 | Negative/harmful |
| Physician's Health Study[47] | $\beta$-Carotene | Lung cancer | 22,071 | Negative |

that were heavy smokers, and particularly so in those individuals who had evidence of pulmonary asbestosis, as measured by manifestation of pleural plaques on chest radiograph.

The ATBC cancer prevention study was a randomized 2 by 2 factorial, double-blind, placebo-controlled, primary prevention study in which 29,133 Finnish male smokers received either $\alpha$-tocopherol (50 mg/day alone), $\beta$-carotene (20 mg/day), both $\alpha$-tocopherol and $\beta$-carotene, or a placebo. The participants, between 50 and 69 years of age, all of whom smoked at least five cigarettes per day, were enrolled on the study and received follow-up observation for 5 to 8 years. Although lung cancer incidence, the primary end point, was not modified by the addition of $\alpha$-tocopherol alone, both groups who received $\beta$-carotene supplementation either alone or with $\alpha$-tocopherol had an 18% increase in the incidence of lung cancer and a significant increase in lung cancer mortality. This study showed a stronger adverse effect from $\beta$-carotene in men who smoked more than 20 cigarettes per day, and was the first to raise the concern that pharmacologic doses of $\beta$-carotene could be harmful in active smokers. A recent update suggested that the excess risk for $\beta$-carotene recipients was no longer evident 4 to 6 years after any intervention and at that point, morbidity was largely caused by cardiovascular diseases.[39,44]

The CARET confirmed the results of the ATBC trial. This was also a randomized, double-blind, placebo-controlled trial testing the combination of 30 mg/day of $\beta$-carotene and 25,000 IU of retinyl palmitate in 18,314 men and women ages 50 to 69 years old who were considered at increased risk for lung cancer. The majority of participants had a smoking history of at least 20 pack-years, and were either current smokers or recent former smokers. Significant and even extensive occupational exposure to asbestos was noted in 4060 men on this trial.[45] The trial was stopped early by the Data Safety Monitoring Committee because of evidence of possible harm, consistent with the ATBC study. In fact, lung cancer incidence, the primary end point, increased 28% in the active intervention group, with an increase in overall mortality of 17% in this group.[46]

By contrast, the Physicians Health Study a randomized, double-blind, placebo-controlled trial studied 22,071 healthy male physicians, half of whom received 50 mg/day of $\beta$-carotene on alternate days and the other half received placebo. The use of supplemental $\beta$-carotene in this study comprising a majority of nonsmokers showed virtually no adverse or beneficial effects on cancer incidence or overall mortality rate during a 12-year follow-up.[47]

Subsequent subgroup analyses of the ATBC and the CARET studies have indicated that $\beta$-carotene had a harmful effect only in the high-risk heavy smokers, or those with previous exposure to asbestos.[48]

### Reversal of Premalignancy or Secondary Prevention

Although there has been much dispute over which are the optimal premalignant markers of lung cancer to follow, the success in developing chemoprevention agents in this arena has been extremely limited. To date, eight randomized trials have used various end points, including reversal of sputum atypia, reduction in DNA micronuclei, and reversal of dysplasia or hyperplasia (Table 21.3). Some of these trials have used retinoids, and have shown that in the absence of smoking cessation, retinoids are incapable of reversing premalignant lesions. Although some biomarker-driven studies utilizing novel pan-retinoids, such as 9-*cis*-retinoic acid, or atypical retinoids such as fenretinoid, have shown that these agents can modulate biomarkers such as RAR-$\beta$ or human telomerase reverse transcriptase (hTERT) expression, respectively, there is little evidence to suggest that any of the compounds listed in Table 21.3 are capable of consistently reversing premalignant lesions. To date, one of the most positive studies has been one that utilized folate and vitamin $B_{12}$, which showed some improvement in bronchial epithelial metaplasia in smokers. Given the difficulty with validation of the end points, even these positive results must be viewed with caution. Larger trials using biologic end points are needed to confirm efficacy.[49]

Although several trials examining reversal of premalignancy in upper aerodigestive tumors with high doses of retinoids had shown significant initial efficacy, results have yet to be duplicated using retinoids in reversal of lung preneoplasia. Most importantly, findings from a trial by Lee et al.[50] indicated that retinoids could be effective in the presence of smoking cessation, but were highly ineffectual in active smokers. Recent studies employing novel retinoids have indicated that they may have significant promise. One such trial by Kurie et al.[51] reported the results of a randomized controlled trial in former smokers who received either 9-*cis*-retinoic acid or 13-*cis*-retinoic acid with $\alpha$-tocopherol. The end point of this

| TABLE 21.3 | Secondary Randomized Chemoprevention Trials in Lung Cancer | | | |
|---|---|---|---|---|
| | **Intervention** | **End point** | **No. of Patients** | **Outcome** |
| Lee et al.[50] | Isotretinoin | Metaplasia | 86 | Negative |
| Kurie et al.[88] | Fenretinide | Metaplasia | 82 | Negative |
| Arnold et al.[89] | Etretinate | Metaplasia | 150 | Negative |
| McLarty et al.[90] | $\beta$-Carotene/retinol | Sputum atypia | 755 | Negative |
| Heimburger et al.[91] | Vitamin B12/folic acid | Sputum atypia | 73 | Positive |
| Kurie et al.[51] | 9-*cis*-retinoic acid | RAR-beta expression | 226 | Positive |
| Mao et al.[80] | Celecoxib | COX-2 expression and Ki-67 | 20 | Positive |
| Kim et al.[81] | Celecoxib | COX-2 expression and Ki-67 | 204 | Positive |

trial was upregulation of RAR-$\beta$, the loss of which is gradually seen in pulmonary carcinogenesis. Of 177 evaluable patients, those treated with 9-*cis*-retinoic acid were found to have restoration of RAR-$\beta$ expression ($p$ <0.03) and reduction of metaplasia ($p$ <0.01). There was no significant effect in the 13-*cis*-retinoic acid with $\alpha$-tocopherol arm, encouraging this group of investigators to move forward with 9-*cis*-retinoic acid, a pan-retinoid agonist, targeting former smokers. Similar results were seen with fenretinide, an atypical retinoid that does not bind to any of the cognate X retinoid receptors, which was shown to downregulate hTERT, a critical component in human telomerase.[52] These promising data, albeit preliminary, suggest that continued investigation with novel retinoids may have substantial merit.

**Second Primary Tumor Prevention**    Patients with tobacco-related cancers who have undergone successful treatment remain at a substantially elevated risk for developing subsequent tumors in the tobacco-damaged epithelium.[7,8,53–57] Although the treatment for the initial cancer can often be successful, these patients are at dramatically increased risk for developing and dying from a second primary tumor[58] (Table 21.4). The concept of SPTs initially described by Warren and Gates[59] explains the high likelihood of multiple oral and pharyngeal premalignancies, both synchronous and metachronous, disseminated

throughout the condemned epithelium. Although modern molecular work by Sidransky et al.[60] has shown that the clonal origin of some of these SPTs can be indeterminate, some are a result of clonal evolution and the malignant clone can be found throughout the epithelium.[61,62] Clinical data continue to suggest that this remains a devastating long-term problem for patients definitively treated for primary tumor. The Warren and Gates criteria defined SPT as one that (a) is a new cancer of a different histological type, or (b) is a cancer, regardless of site, that occurs after more than 3 years, and (c) if it is also located in the head and neck region, the lesion is separated from the initial primary tumor by at least 2 cm of clinically normal epithelium, and (d) if found in the lung, and of squamous histologic subtype and developing within 3 years, it presents as a solitary mass with no evidence in the patient of local or regional disease, with changes consistent with dysplasia or carcinoma in situ within the surrounding bronchial epithelium. Using these criteria, the risk of local recurrence was shown by Vikram[58] to decline over time, whereas the risk of SPTs is constant for approximately the first decade following the initial head and neck cancer. Therefore, the lifetime risk of developing a SPT in the head and neck region is approximately 20%, with a similar incidence in the lung. Although estimates have varied between 3% to 7% per year, evidence remains incontrovertible that SPTs are the major cause of death after curative surgery in head and

| TABLE 21.4 | Lung and Aerodigestive Second Primary Tumor Prevention Studies | | | |
|---|---|---|---|---|
| | **Intervention** | **End point** | **No. of Patients** | **Outcome** |
| Pastorino et al.[69] | Retinyl palmitate | SPT | 307 | Positive |
| EUROSCAN[71] | Retinyl palmitate /N-acetylcysteine | SPT | 2592 | Negative |
| Lippman et al.[72] | 13-*cis*-retinoic acid | SPT | 1166 | Negative |
| Khuri et al.[68] | 13-*cis*-retinoic acid | SPT | 1190 | Negative |

| Hong et al.[66] | Isotretinoin | SPT | 103 | Positive |

neck cancer, and can be a major cause of death in early stage disease.[56–58,63–65]

Because of the high likelihood of both recurrence and SPTs in patients with advanced oral, oropharyngeal, or laryngeal squamous cell cancers, Hong et al.[66] launched a randomized, placebo-controlled study of 103 patients with stage I to IV head and neck squamous cell cancer, definitively treated with either previous surgery and/or radiation therapy. The patients were randomized to receive either high dose 13-*cis*-retinoic acid (100 mg/m²/day) or placebo for 1 year after definitive local therapy. The dosage of 13-cRA was reduced to 50 mg/m²/day after 13 of the first 44 patients experienced intolerable side effects. The primary end points were primary tumor recurrence and SPT development. In the two treatment arms, there was no difference in local recurrence or distant metastases. However, the patients treated with 13-cRA had a dramatically lower incidence of SPTs. Of the 103 patients followed for a median of 42 months, SPTs developed in 6% (3 of 49) of those in the 13-cRA arm, whereas 28% (14 of 51) of the patients on the placebo arm developed SPTs. Consistent with the findings of field carcinogenesis, the vast majority of the SPTs developed in the upper aerodigestive tract, esophagus, and lung, and 14 of 17 were found to be histologically of squamous cell type. Despite only 47% of the 13-cRA–treated patients completing the therapy as prescribed, the reduction in SPT development was still significant. Long-term follow-up has also revealed that the effects of 13-cRA decreased over time.[67]

A large scale follow-up to this trial using a much lower dose of 13-cRA was completed and presented a few years ago. In this trial, a randomized, double-blind, placebo-controlled study, launched in 1991, more than 1382 patients were registered and 1192 were randomized to either low dose 13-cRA at 30 mg/day versus placebo. These patients were definitively treated for stage I or II head and neck squamous cell cancer. With a median follow-up of 7 years, no effect was seen of the low dose retinoid on reducing the incidence of SPT in the lung or aerodigestive tract.[68]

Several other phase III trials have been launched in lung cancer in an attempt to prevent SPTs. The first of these was a trial by Pastorino et al.[69] that randomized over 300 patients with early stage lung cancer to retinyl palmitate or placebo. This study showed a significant reduction in the development of second primary lung cancers on the retinyl palmitate arm. A subsequent study by Bolla et al.[70] using a different synthetic retinoid, etretinate, failed to show a significant reduction in SPTs.

Two large phase III trials reported in the last decade include the EUROSCAN and the U.S. Intergroup NCI trial. EUROSCAN, a randomized adjuvant chemoprevention study of the European Organization for Research and Treatment of Cancer (EORTC), head and neck and lung groups studied the effects of vitamin A (retinyl palmitate) and N-acetylcysteine (NAC) in patients with early stage head and neck and lung cancer.[71] In this trial 2592 patients with cancers of the larynx, TIS-T3 and 0-N1, oral cavity, TIS-T2 and 0-N1, and NSCLC, T1-T2 and 0-N1, received retinyl palmitate, 300,000 IU per day in year 1, 150,000 IU/day in year 2, NAC 600 mg/day for

2 years, both drugs, or placebo. No significant differences were seen between the three active treatment arms and the placebo group in terms of recurrence rates, SPT development, or survival. More than 90% of the patient population was regular smokers, with 43 median pack-years of tobacco exposure.

The U.S. Intergroup NCI 91-0001 trial was a randomized, double-blind, placebo-controlled study utilizing the same low dose of 30 mg 13-cRA after complete resection of stage I NSCLC.[72] This trial completed accrual in 1997, having accrued 1486 participants. The study objectives were to evaluate the efficacy of low-dose daily 13-cRA for 3 years at 30 mg/day versus placebo in the prevention of SPTs. Patients were required to have complete resection of primary, stage I NSCLC (postoperative T1 or T2 and 0) and registered between 6 weeks to 3 years after completion of therapy. After a median follow-up of 3.5 years, no statistically significant differences were seen between the placebo and 13-cRA arms with respect to time to SPT development, recurrence rate, or mortality. Multivariate analyses showed that the rate of SPTs was not affected by any stratification factor, with recurrence rate affected only by treatment stage, and evidence for a treatment-by-smoking interaction (hazard ratio [HR] for treatment-by-current versus never-smoking status = 3.11, 95% confidence interval [CI], 1.00 to 9.71). Therefore, 13-cRA was not shown to affect overall survival rates or SPTs, recurrences, or mortality in stage I NSCLC. Subsequent subset analyses have indicated that 13-cRA was potentially harmful in current smokers and beneficial in never-smokers.

Finally, researchers at Yale University conducted a randomized, double-blind, placebo-controlled trial studying the effects of $\beta$-carotene at 50 mg/day in reducing local recurrence and SPTs in head and neck cancer.[73] Two hundred sixty-four patients with curatively treated early stage squamous cell carcinoma of the oral cavity, pharynx, or larynx were randomized to either 50 mg/day of $\beta$-carotene or placebo and were followed for 90 months for the development of SPTs and local recurrences. After a median follow-up of 51 months, no difference was seen between the two groups in time to failure, local recurrences or SPTs. Supplemental $\beta$-carotene had no effect on overall mortality, SPT rates, or rates of local recurrences.

## FUTURE STRATEGIES IN LUNG CANCER PREVENTION

After more than 2 decades of unsuccessful interventions in NSCLC, evidence has now accumulated to suggest that approaches relying exclusively on the development of epidemiologic guidance for selection of compounds are unlikely to lead to effective interventions across broad and disparate populations. Although clues continue to emerge from the epidemiologic literature, including a study by Schabath et al.[74] showing that dietary phytoestrogens appear to significantly reduce lung cancer risk, few have suggested moving aggressive prevention approaches forward without further, well-designed, biomarker-driven trials.

Current targeted approaches focus on several pathways. To date, significant evidence exists to show that overexpression of the EGFR occurs throughout lung carcinogenesis,[16,75,76] and that mutations of the EGFR tyrosine kinase (EGFR-TK) binding domain can be seen diffusely across the normal-appearing airway in patients with resected adenocarcinomas who are nonsmokers and harbor an EGFR-TK binding domain mutation in their primary tumor. This discovery by Tang et al.[77] of a novel field effect in which EGFR-TK mutations are seen in apparently normal-appearing, nontobacco damaged airways suggests that despite the absence of an identifiable carcinogen leading to EGFR mutations, this represents a new and as yet etiologically unclear type of field effect. Several investigators have proposed novel chemoprevention approaches using the EGFR-TK inhibitors, erlotinib, and gefitinib, in high-risk patient populations. Given the fact that the incidence of EGFR-TK mutation-bearing adenocarcinoma of the lung is most frequently seen in Asian, female nonsmokers with lung cancer,[78,79] the identification of those individuals at greatest risk would likely lead to recognition of a target population, thereby enhancing the likelihood of a successful intervention with an EGFR-TKI.

Important data also implicate the progressive upregulation of cyclooxygenase-2 (COX-2) in lung carcinogenesis, and exciting preliminary trials targeting both suppression of COX-2 with selective COX-2 inhibitors by Mao et al.[80] and Kim et al.[81] have shown provocative results to date. Another approach taken by the University of Colorado group has sought to upregulate prostacycline, thereby downregulating prostaglandin E2 (PGE-2), potentially the critical downstream effector pathway for COX-2.[82] Another promising targeted approach is based on epidemiologic data. Govindarajan et al.[83] showed that thiazolidinediones (TZD), peroxisome proliferator-activated receptor (PPAR) stimulators, are able to induce cell cycle arrest. These investigators examined a large cohort study in 87,678 male veterans older than 40 years, and showed a 33% reduction of lung cancer risk among the 11,289 TZD users. Although the study failed to account for variations by smoking status, this represents a potentially exciting and useful chemopreventive approach. As reviewed by Nemenoff,[84,85] activation of PPARγ inhibits lung tumorigenesis as demonstrated by animal studies in which increased PPARγ may be chemopreventive against developing lung tumors. In established lung cancer, PPAR-γ activation inhibits proliferation, induces apoptosis, and promotes a less invasive phenotype by promoting epithelial differentiation, and perhaps blocking epithelial mesenchymal transition. PPAR-γ inhibition of chemokine production may also negatively impact tumor progression and metastasis. Although activation of PPAR-γ can occur by direct binding of pharmacological ligands to the molecule, emerging data indicate that PPAR-γ activation can occur through engagement of other signal transduction pathways, including Wnt signaling and prostaglandin production. Defining the molecular targets of TZDs mediating a specific response will be critical in the further development of second-generation PPAR-γ drugs. Cardiac events have been recorded with the use of TZDs, and the development of more selective PPAR-γ activators could potentially be therapeutically effective, without leading to adverse cardiac events.

Other methods have involved utilizing corticosteroids, both inhaled and oral, or inhaled retinoids, all of which have shown promise. Unfortunately, two randomized phase II studies in high-risk patients have failed to show a trend in favor of inhalational corticosteroids.[86,87]

While these and other data continue to be attractive, a surprising trial that sought to prevent SPT skin cancer in a selenium-poor population in Arizona resulted in the fortuitous finding of a dramatic reduction in lung cancer incidence (34% reduction).[38] The phase III Eastern Cooperative Oncology Group (ECOG) selenium trial, E5597, has accrued approximately 1300 of 1900 planned patients. This trial randomizes patients in a 2:1 ratio to receive selenium methionine at 200 $\mu$g/day versus placebo. Patients must have the identical criteria to the prior intergroup study, that is, a history of stage I to II NSCLC fully resected, patients being registered between 6 weeks and up to 3 years after surgery. Whether the selenium trial ultimately yields definitive answers, the recommendation must be to continue to build biomarker-driven, targeted, phase II approaches that appropriately pursue modulation of a critical biomarker, and confirm it prior to proceeding with aggressive, broad, studies in large patient populations. Once the appropriate biomarkers have been shown to be consistently modulated in selected populations, only then can we proceed with confidence to develop targeted agents that can meaningfully reduce the incidence of lung cancer in at-risk populations.

# Molecular and Cellular Pathology of Lung Cancer

Despite advances in imaging techniques and the molecular characterization of lung tumors described elsewhere in this volume, the histopathology of lung cancer remains the basis for diagnosis and treatment of the disease and is essential for the interpretation of imaging studies and molecular analyses. Histopathology has recently taken on added importance as it has been recognized that targeted agents affect specific lung tumor subtypes differently and that successful treatment may depend on histological distinctions that have been previously unrecognized or ignored. Historically, the classification of lung cancer rested on the expertise of individual pathologists but in 1967, an international panel was first assembled through the World Health Organization (WHO) to create a standard nomenclature for lung cancer. This classification with its periodic revisions has become the most widely used standard for diagnosis and treatment and is provided in Appendix A. The most recent edition of the WHO morphological classification was published in 2004 and is more comprehensive than previous editions' description of the classification, taking into account molecular data as well as morphology.[1] The purpose of this chapter is not so much to recapitulate the details of the WHO classification but rather to provide an understanding of the main categories of lung carcinoma, to highlight potential pitfalls in histopathological diagnosis of lung cancer, to summarize current information on molecular properties and cellular origin of individual lung tumor types, to relate pathology to biological behavior, and to provide review guidelines for reporting and pathological staging of lung cancer.

Nearly all lung cancers exhibit the morphological and molecular features of epithelial cells (described later) and are accordingly classified as carcinomas. The cells of origin of virtually all lung cancers reside in the epithelial lining of the airways. As more is learned about the origin of lung carcinoma, it is increasingly clear that the biology of lesions arising in the central airways is distinct from that of peripheral airway lesions. In addition, there are important distinctions between tumors from the two sites in histopathological appearances, molecular profiles, and diagnostic approaches. While the dichotomy between central and peripheral is not a sharp one, it is nevertheless useful to consider tumors of the central airways separately from peripheral tumors.

## TUMORS PREDOMINANTLY OF THE CENTRAL BRONCHI

In this chapter, we use the term *central airway lesions* to refer to tumors and premalignant conditions predominantly arising proximal to the terminal bronchiolar and alveolar epithelium. Surprisingly, little information is available on the cells from which central airway carcinomas arise. It might be expected that since the high risk posed by tobacco exposure has been known for many years, the earliest changes in the airway lining cells would by now be well known and the subject of interventional trials. That this is not the case is because of the macroscopic invisibility of early carcinoma and its precursor lesions, to the inaccessibility of the lower airway epithelium to direct inspection and serial sampling and to the great extent of the lower airway epithelial surfaces. It has nevertheless been known for many years that, in the central airways, a distinct series of changes of variable severity may be seen in the airways of smokers. Typically these lesions, described in detail later in the chapter, have been regarded as precursors of squamous carcinoma but there is evidence that they may also represent precursors of other histological types of central airway carcinoma, including undifferentiated large and small cell lung carcinomas (SCLC).

**Central Airway Precursor Lesions** Lung carcinoma, like tumors in other organs, is thought to arise from a stepwise series of molecular and cellular alterations in precursor cells. The first studies to demonstrate significant histological changes in the lower airways of the human population were the autopsy analyses of Auerbach and colleagues[2] performed over 50 years ago. These studies consisted of serial cross sectioning of tracheobronchial tissue removed at autopsy from 1522 adult

smokers and control nonsmoking patients without invasive carcinoma. Nearly 42,000 bronchial cross sections were evaluated and epithelial lesions consisting of *atypical cells* were found in 93% of sections from current smokers but in only 1.2% of sections from individuals who were never-smokers. Cellular abnormalities in smokers' lungs were often multifocal and were independent of age, sex, place of residence, and the presence of pneumonia. A significant number of individuals who were former smokers in this study also had cellular abnormalities, whereas they were rare in individuals who never smoked.[3]

### Sputum Cytology and Risk Assessment

Although these studies documented the prevalence of cellular lesions in the lower airways at a single time point in smokers who did not have carcinoma, prospective confirmation that these lesions represent precursor lesions for carcinoma has been problematic. A major difficulty is a lack of any creditable intervention strategy that can be offered to individuals who are found to have dysplasia. In other organs, preinvasive lesions can be excised and this has been a successful strategy in cervix and colon where screening has proven successful in reducing the incidence and mortality of invasive carcinoma.[4,5]

The most analogous studies in the lung are the lung cancer screening trials of the 1970s and 1980s. In these studies, the effectiveness of sputum cytology as a screening tool was evaluated in 21,000 subjects at Sloan-Kettering Medical Center and the Mayo Clinic. Spontaneous sputa were evaluated by conventional cytological criteria for the presence of carcinoma. Cytology proved to be an insensitive tool for detection of lung cancer. Only 41% of subjects were sputum positive among those who had carcinoma at an initial (*prevalence*) screen and 17% with carcinoma in subsequent (*incidence*) screenings. In the Mayo Clinic project, no effect on mortality could be demonstrated by chest radiograph or sputum cytology performed quarterly for 6 years. The only positive trend resulting from these interventions was a slightly improved median survival for screen-detected stage I carcinomas in comparison to those detected outside the screened group, a difference that was not statistically significant.[6]

The failure of sputum and radiograph screening to reduce mortality from lung cancer has largely been attributed to *overdiagnosis bias*.[7,8] Overdiagnosis bias refers to the detection of tumors through screening that, even if undetected, would not have affected mortality. It implies either that death may occur from other causes before any mortality effect from screened tumors can occur, or that the detected tumors were indolent and would not have affected survival. The lack of impact of screening on overall mortality has lead to the proposal that small screen-detected tumors are biologically distinct from advanced tumors that are responsible for the high mortality in lung cancer. Small screen-detected tumor are postulated to have lower growth rates and different epidemiological associations than those of advanced lethal tumors and, moreover, may not be precursors of advanced lesions,[9] as is widely believed. The morphological and biological features of screen-detected central airway tumors have been analyzed by Mayo pathologists.[10]

**FIGURE 22.1**   Dysplastic squamous cells in sputum. **A:** Mild dysplasia on the right consists of small rounded red cell with condensed nucleus and low N/C ratio. **B:** Moderately dysplastic orangophilic cell with large irregular nucleus and visible nucleolus. **C:** Carcinoma with large nucleus, high N/C ratio and visible nucleolus. Large cell appears to be ingesting smaller one. (See color plate.)

Only 86% of the screened tumors were unequivocally invasive with 14% regarded as preinvasive by one or more of the pathologists on the reviewing panel. Inclusion of preinvasive lesions in the outcome analysis may have contributed to overdiagnosis bias in the Mayo Lung Project and provides some biological basis for the outcome of the trial.

One crucial difference between the lung cancer screening trials and screening practices for colon and cervix is that the latter target preinvasive lesions rather than fully developed invasive carcinomas. A similar approach has not been fully explored in lung cancer. The significance of less than fully malignant cells in the sputum (Fig. 22.1) has recently been evaluated.[11,12] These studies have shown that cytologic atypia is a marker for increased lung cancer risk. The association of sputum atypia with lung cancer increases with the severity of the atypia, with short interval between sputum collection and with squamous tumor histology. Higher-grade cytological changes thus seem to arise from late events in the central airways. Whether sputum atypia can be a useful indicator for the presence of premalignant dysplasia in the central airways, whether the presence, grade, and extent of dysplasia predicts invasive carcinoma, and whether meaningful interruption or delay in neoplastic progression is possible when premalignant changes are identified are questions currently being investigated using new methods for visualizing and directly sampling bronchial mucosa for histological assessment.

## HISTOLOGY OF SQUAMOUS DYSPLASIA

Because premalignant lesions and early carcinomas are not easily recognized by white-light bronchoscopy, the stimulus for evaluating the lower airways to identify lower airway neoplasia by this method has not been great. Only recently has it been possible to detect premalignant lesions using fluorescence bronchoscopy as described in this volume and elsewhere.[13,14]

This technical advance has engendered a need for a reproducible and less descriptive classification of bronchial

premalignancy than that used in the earlier studies of Auerbach. The WHO pathology panel has recognized this need and has provided a suggested classification based largely on the earlier work of Saccomanno and illustrated in Figure 22.2. The classification is based on cellular changes that occur in the epithelium, which consist of a transformation of bilayered mucociliary epithelium to squamous epithelium that is associated with varying degrees of alteration in nuclear irregularity and mitotic activity. The classification includes seven categories including histologically normal epithelium, basal cell hyperplasia and squamous metaplasia, mild, moderate, and severe dysplasia, and carcinoma in situ (CIS). Independent studies have indicated that this classification is reproducible[15] and may be used in clinical trials targeting premalignant changes in the airways.

In addition to changes in the bronchial epithelium, changes in the stromal support tissues have also been described. Potentially, the most significant of these changes may be microscopic evidence neoangiogenesis that has been referred to as angiogenic squamous dysplasia (ASD).[16] ASD is characterized by the sprouting of capillaries into dysplastic squamous mucosa (Fig. 22.3). These lesions are frequently multifocal, may persist for several years at the same bronchial sites and are preferentially associated with squamous carcinoma.[17]

Although areas of squamous dysplasia are now more readily identified in the central airways, the risk posed by dysplastic lesions discovered at bronchoscopy has not been quantified. What is known is that CIS is associated with progression to

**FIGURE 22.2** Chronological sequences of cellular and molecular changes that may occur during central airway carcinogenesis. Although this sequence is rarely observed in a single individual, these changes are well described in the high-risk population and the sequence provides a useful way to conceptualize multistep carcinogenesis in the lung. At the cellular level, the earliest smoking-related changes may consist of mucous gland hyperplasia (shown), basal cell hyperplasia, or squamous metaplasia, which are not recognizably premalignant changes. The earliest cellular abnormalities that suggest premalignancy are squamous dysplastic changes that may range from mild-to-severe carcinoma in situ. The appearance of stromal invasion marks progression to fully established malignancy. (See color plate.)

**FIGURE 22.3** Premalignant changes in the bronchial epithelium. Mucociliary cells are converted to squamous cells and may elicit and angiogenic stromal response shown at low magnification (**top**) and high magnification (**bottom**). Nuclear irregularity with clearly visible nucleoli is present in the cells surrounding the vascular loop in the lower frame. (See color plate.)

invasive carcinoma in many cases[18] but not all and that CIS with aneuploidy in more likely to be associated in invasive carcinoma (discussed later).[19] One form of squamous CIS exhibits a horizontal pattern of spread that may extend a considerable distance along the airway mucosa without invasion or metastasis.[20] The prognosis in those few cases that have been reported has been excellent. The prognostic significance of lesser degrees of bronchoscopically detected dysplasia is not yet well defined but the association with invasive carcinoma is much weaker than with CIS.[19] It is likely that lesser degrees of dysplasia persist for many years before undergoing sufficient genetic alteration to progress to invasive tumor.

Finally, nonsquamous atypias of the respiratory mucosa have recently been reported.[21] In our experience, nonsquamous dysplasias of the central airways are less common and more difficult to recognize than squamous lesions. It will be important, however, to determine whether these lesions are significant predictors of nonsquamous carcinoma.

## Immunohistochemical Changes in Bronchial Dysplasia

Premalignant squamous lesions in the lower airways are associated with a constellation of changes in protein expression that can be demonstrated by immunohistochemical methods, including overexpression of cytokeratin 5/6 (CK5/6),[22] epidermal growth factor receptor (EGFR),[23,24] human epidermal growth factor receptor 2 (HER-2)/*neu*,[24–26] and the cell cycle–associated protein Ki-67,[24,27,28] fatty acid synthase,[29] and MCM2.[24,30] Loss of FHIT,[31] p16,[32] E-cadherin,[33] and catenin[33] has also been demonstrated. Nuclear p53 accumulation has been described in dysplasia[32,34] but is usually focal and immunostained cells rarely have the robust signal present in tumors with homozygous mutation. Most of these immunohistochemical changes are first visible when normal mucociliary epithelium changes to squamous epithelium and do not visibly

progress with the level of dysplasia. Exceptions to this rule are the biomarkers that are associated with cell proliferation. Generally, there is an increase in the level of expression of cell proliferation markers with increasing histological grade. Cyclin D1,[32,35,36] cyclin E,[37] PCNA,[38] Ki-67,[24,27,28] and MCM2[24,30] all increase with increasing grade of dysplasia, reflecting the increased proliferative capacity of more severely dysplastic cells. With the possible exception of proliferative immunohistochemical biomarkers, no single change in immunohistochemically demonstrable protein expression has to date added significantly to the information that can be gleaned from conventional histological examination.

**Genetics of Preneoplasia**  Underlying the morphological and immunohistochemical changes that occur in the airways is a multistep sequence of molecular and chromosomal events illustrated in Figures 22.4 and 22.5. The initial event in lung carcinogenesis is the formation of DNA adducts, the physical complexes between DNA, and the reactive metabolites in tobacco smoke and industrial pollutants.[39–41]

Among the most potent of the carcinogens are polycyclic aromatic hydrocarbons (PAH), aromatic amines, and metals. These compounds are largely metabolized to execrable products by cytochrome p450 and glutathione S transferase (GST). However, some small fraction of intermediates is highly reactive with DNA and forms bulky adducts with DNA in which the reactive metabolite is covalently bonded to specific DNA bases.[40]

DNA adducts activate complex DNA repair mechanisms, which are not completely effective in removing adducts from damaged DNA. Unrepaired DNA bases may be bypassed by DNA polymerase, creating mutations that are transmitted to daughter cells. Mutations formed in this way tend to favor GC→TA transversions. Many of the genetic changes that ultimately appear in lung carcinomas are thus thought to originate from misrepaired DNA adducts.

Among these changes are allelic losses, easily demonstrated by a simple molecular test based on the measurement of the length of polymorphic tandem repeat sequences that exist throughout the genome. In these tests, chromosomal loci that

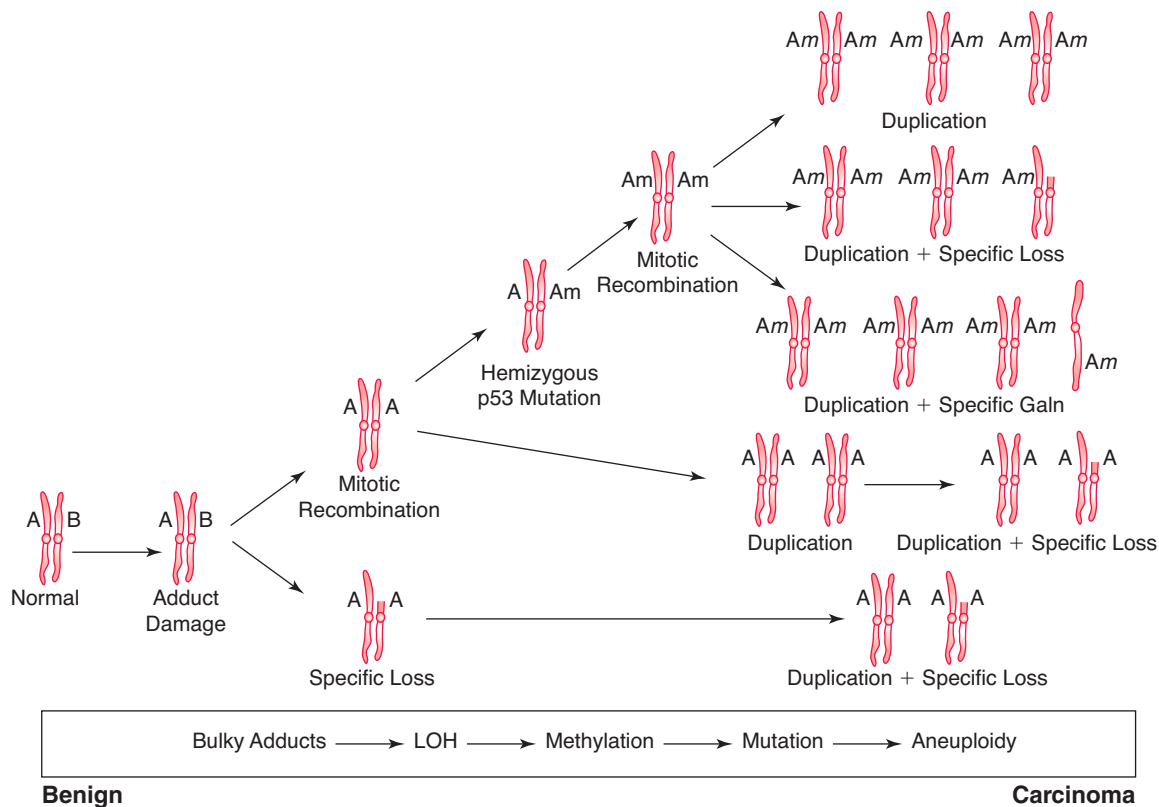

**FIGURE 22.4**  Lung carcinogenesis is thought to proceed through the accumulation of genetic and chromosomal abnormalities depicted in this diagram in approximate chronologic sequence. One of the earliest events is bulky DNA adduct formation as a result of exposure to carcinogens in tobacco smoke and which is not visible at the chromosomal level. Adducts may interfere with DNA repair and mitosis resulting in mitotic recombination or partial chromosomal loss. Recombination could explain the nearly ubiquitous occurrence of LOH that occurs early in lung carcinogenesis. Gene methylation, mutation, further mitotic recombination, and a high level of chromosomal rearrangement (chromosomal instability) may then occur resulting the high level of aneuploidy that is present in many lung carcinomas. *LOH*, loss of heterozygosity. (Reproduced from Franklin WA, Hirsch FR. Molecular and cell biology of lung carcinoma. In: Sculier JP, Fry WA, eds. *Malignant Tumors of the Lung*. New York: Springer-Verlag, 2003:3–17.)

**FIGURE 22.5** Chromosomal heterogeneity and instability. The high degree of chromosomal instability in lung carcinoma is reflected in numerous structural abnormalities that are visible through chromosomal imaging methods. Shown here is a spectral karyotype of a large cell undifferentiated carcinoma (H&E section). The SKY pseudocolor image of the karyotype provides a color code for each chromosome. In this figure, extra chromosomes 1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 12, 18, 19, 20, and 22 are visible. A reciprocal translocation, several nonreciprocal translocations, deletions, and marker chromosomes are also present. *FISH*, fluorescence in situ hybridization; *H&E*, hematoxylin and eosin; *SKY*, spectral karyotyping. (See color plate.)

normally harbor two different polymorphic alleles are assessed for loss of one (loss of heterozygosity [LOH]) or both of these alleles. Loss of both alleles (homozygous deletion) results in silencing of the gene while loss of a single allele (heterozygous loss) causes loss of gene expression if the retained allele is mutated or inactivated by methylation. Loss of genes that are important in controlling cell growth, apoptosis, or error DNA replication can impart a malignant phenotype to lung cells and much effort has been expended in trying to identify candidate tumor suppressor genes in dysplastic epithelium and invasive tumors.[42]

Allelic losses at loci throughout the genome have been demonstrated in premalignant bronchial mucosa and detailed consideration of specific allelic losses is reviewed elsewhere.[43,44] Several conclusions may be drawn from LOH studies performed so far. First, many regions of allelic loss have been demonstrated in smoking damaged airways but few studies have demonstrated any effect of LOH on corresponding gene expression. Second, many loci demonstrate loss from the earliest exposure to tobacco smoke but allelic loss does not occur in individuals who have never smoked.[45] Finally, no specific loss appears to be crucial for progress to malignancy but rather it is the accumulation of multiple losses that is most tied to malignant progression.[46]

The molecular mechanism responsible for allelic loss is not fully known. It has been suggested that bulky adducts resulting from DNA oxidation could affect repair of double-stranded DNA breaks and result in the recombination of homologous recombination of DNA strands during the repair process. Fluorescence in situ hybridization (FISH) studies have indicated an increase rather than a decrease in gene copy number occurs at sites of allelic loss,[47] suggesting that tumor cells harbor multiple

copies of the same allele and that gene dosage may in fact be increased. Allelic loss may result in functional loss of protein only when the retained allele is mutated or silenced by methylation.

A molecular property that distinguishes lung cancers and, to a lesser extent, premalignant lesions from normal bronchial cells is chromosomal instability, which is reflected as aneuploidy in tumor and premalignant cells. Aneuploidy is first detected in squamous dysplasia[48] and in one recent study, aneuploidy was found in cultured bronchial epithelial of 26% of high-risk smokers.[49] In invasive lung carcinomas, aneuploidy is nearly universal and involves multiple chromosomes.[50] Aneuploidy has been found in lung cancer by classical cytogenetics methods[51] but is more efficiently demonstrated by FISH. Numerical abnormalities have been demonstrated in every chromosome by FISH.[52–54]

New technologies such as spectral karyotyping (SKY) (Fig. 22.5) and comparative genomic hybridization indicate that not only are numerical chromosomal imbalances frequent but also structural chromosomal abnormalities such as translocations and amplifications are ubiquitous as well.[55] This high degree of chromosomal instability may explain the extreme molecular and cellular heterogeneity of lung cancers as well as their adaptability and resilience in the face of chemotherapeutic treatment.

Patients with squamous as well as large and SCLC frequently harbor dysplastic squamous lesions in the central airways although the precise frequency in which this occurs is not known. There is also increasing evidence of genomic and phenotypic plasticity in invasive carcinomas, and tumors of mixed histological type are a frequent finding in the lung suggesting that tumor cells of many histological types could arise from a common progenitor. Molecular evidence indicates that lung tumors recapitulate ontological development,[56,57] suggesting that central airway lesions of various histological types could represent arrested development at various stages in the same progenitor cells rather than origin from separate progenitor cell lineages.

## Invasive Squamous Carcinoma of the Bronchus

Squamous carcinomas are in the most common of the central airway tumors and are highly associated with smoking.[58] Invasive squamous tumors are characterized by extension of malignant squamous cells beyond the basement membrane of the airway lining. Approximately 29% of lung cancers are of this histological type (Table 22.1).[59] The diagnosis of

| TABLE 22.1 | Frequencies of Histological Types | |
|---|---|
| **Histological Type (Subtype)** | **% Total** |
| Squamous carcinoma | 29% |
| SCLC | 20% |
| LCLC | 9% |
| LNEC | 2% |
| Adenocarcinoma | 32% |
| -(Bronchioloalveolar) | 3% |
| Others | 12% |

squamous carcinoma and indeed of all non–small cell tumors has taken new importance with the recognition that new targeted agents may differentially affect non–small cell subtypes and it is therefore more important to recognize and report squamous lesions than in the past.

## HISTOLOGY OF SQUAMOUS CARCINOMA

The histological features of squamous carcinoma are summarized and compared with other forms of lung cancer in Table 22.2. Invasion is recognized as angulated nests or individual tumor cells that have broken away from the surface epithelium and become embedded in the stromal tissues as shown in Figure 22.6. The invasive cells may form keratin pearls (KP) and intercellular bridges[60] and may develop irregular areas of central necrosis described as geographic necrosis. Nuclear features include irregular nuclei and coarse

chromatin. The cytoplasm may show clearing, most clearly seen in clear cell variant of squamous cell carcinoma, which can resemble vacuolization as might be seen in adenocarcinomas. Squamous tumors also elicit a variable stromal response consisting of loose fibroblastic tissue with an inflammatory component that may include plasma cells, macrophages, and lymphocytes. In more poorly differentiated carcinomas, there is less keratinization and intercellular bridges may be difficult to identify. Here, the overall epithelioid architecture of the tumor cells is important for diagnosis. In these cases, there may be maturation of cells from a basilar zone to a central area where there is loss of the typical verticality of the epithelium.

Several variants of squamous cell carcinoma are described, which may mimic other tumors either clinically or histologically. A papillary variant of squamous cell carcinoma, for example, may present as an exophytic endobronchial mass and histologically show a prominent in situ pattern. While an

| TABLE 22.2 | Histological and Cytological Differences among Major Classes of Lung Cancer | | |
|---|---|---|---|
| **Type (Subtype)** | **Nucleus** | **Cytoplasm** | **Defining Feature(s)** |

| | | | Necrosis |
| LCNEC | Intermediated to fine granularity | Abundant | Lack of differentiated features |
| | Nucleoli inconspicuous | Basophilic/amphophilic | Large size (>21 mm) |
| | Mitotic rate >1/10 hpf | | |
| Adenocarcinoma | Intermediate clumping | Abundant | Mucin vacuoles (>10% of cells) |
| | Prominent nucleoli | Basophilic/amphophilic | Invasive glandlike nests and sheets |
| | Mitoses frequent | | Fibrotic stromal response |
| Bronchioloalveolar | Intermediate clumping | Abundant | Lepidic along alveolar septae |
| | Prominent nucleoli | Basophilic/amphophilic | |
| | Mitoses usually infrequent | | |
**FIGURE 22.6** Various morphological appearances of squamous carcinoma. Cytological examination reveals bright orange, irregularly cells with conspicuous nucleolus. Histology of squamous cancers visible in both biopsy and resection specimens are characterized by irregular nests of cells, often with central KP. Early stage resected tumors are frequently ulcerated as indicated by the area of mucosal roughening and erythema (*arrow*). The ulcer overlies white invasive tumor tissue that surrounds a black anthrocotic LN. *KL*, keratin pearl; *LN*, lymph node. (See color plate.)

invasive component is usually present, a superficial biopsy may not be diagnostic of invasive tumor.

A small cell variant of squamous cell carcinoma may mimic neuroendocrine tumors including small cell carcinoma. Differences in nuclear pattern and mitotic activity are helpful in distinguishing these two tumors, as are neuroendocrine immunohistochemical stains. If sampled sufficiently, diagnostic squamous features (i.e., keratin, intercellular bridges) can be identified focally in basaloid squamous carcinomas.

Another consideration in the differential diagnosis is the distinction of squamous cell carcinoma from SCLC (discussed later). The nuclear architecture of squamous carcinoma uniquely contains large and atypical nucleoli that are not present in small cell carcinoma. There is also clumping of nuclear chromatin that permits distinction from the chromatin of SCLC.

Typically, squamous carcinomas spread directly through and replace tissue at the interface between normal lung and carcinoma. Squamous carcinomas can frequently be found spreading through the alveolar septae rather than along the surfaces of the alveolar walls as is typically observed in bronchioloalveolar carcinomas described later. However, a minority of tumors may also spread through the alveoli.

## BRONCHIAL BIOPSIES AND THEIR PITFALLS

Endobronchial biopsy is the most commonly used procedure for obtaining a diagnosis in non–small cell carcinomas including squamous carcinoma and is described in detail elsewhere in this volume. In this procedure, a small fragment of bronchial mucosa is fixed in formalin and embedded in a block of paraffin wax for sectioning. Diagnostic tumor tissue my not be evenly distributed in the tissue and multiple sections of the block may be required to obtain a definitive histological result. Occasionally, squamous carcinomas may have an inaccessible endobronchial component and the easiest access to diagnostic material is through transbronchial biopsy. Here the same considerations of sampling artifact and representation of the tumor through all sections of the block are relevant.

**Cytology**   Cytological specimens may be obtained through transbronchial or transthoracic fine-needle aspiration or through expectoration of sputum, either spontaneous or induced. Cytological specimens are fixed in alcohol-based fixatives and typically stained by the Papanicolaou method, which incorporates orange G dye that produces an intense waxy red-orange staining of squamous cell cytoplasm (Fig. 22.6).[61] Elongated single cells (*tadpole cells* or *fiber cells*) are frequent. Nuclei are large, irregular shaped, and irregularly condensed. Less differentiated tumors contain sheets of cells with high nuclear/cytoplasmic (N/C) ratios with fewer differentiated squamous cells. Although sheets of cells with well-defined cell borders can be suggestive of squamous cell carcinoma, intercellular bridges cannot be easily visualized in cytological specimens and therefore are not a reliable criterion. The appearance of the aspirate can vary with the technique used to sample the tumor. In squamous cell carcinoma, for example, a sputum specimen will more likely sample better differentiated superficial tumor cells, whereas techniques such as bronchial brushing or fine-needle aspiration will sample more cells from within a tumor mass that may show more of the tumor sheets and less differentiated cells.[61]

The overall sensitivity and specificity of cytological specimens in a recent literature review of 16 studies by the Duke University Center for Clinical Health Policy Research were 0.66 and 0.99, respectively.[62] The sensitivity of sputum specimens is highest for squamous cell carcinoma and small cell carcinoma (the centrally located tumors),[62,63] and is most specific for squamous cell carcinoma.[61] The diagnostic yield is better with larger tumors, which are centrally located, and in patients who present with bloody sputum.[63]

**Differential Diagnosis**   A major differential diagnostic consideration in an endobronchial biopsy is the distinction between invasive squamous carcinoma and noninvasive squamous lesions in the respiratory mucosa. In some cases, in situ squamous carcinoma may exhibit considerable pleomorphism and may be difficult to distinguish from invasive carcinoma purely on the basis of the cytological appearances. An additional consideration is the extension of in situ tumor into the bronchial glands, which many mimic invasive carcinoma. Finally, the bronchial lining may respond to many different types of injury

such as pneumonia, infarcts, and radiation or chemotherapy by converting from mucociliary epithelium to squamous epithelium that can mimic squamous cell carcinoma. It is therefore important that a history of these conditions accompany requests for pathological examination. In order to be completely confident of a diagnosis of invasive carcinoma, unequivocal invasion with nests of cells or single cell infiltrates eliciting a stromal response in the underlying mucosa is required.

The diagnosis of squamous carcinoma is usually made by conventional light microscopic examination of small biopsy or cytology specimens. Diagnosis can be difficult or misleading when small numbers of tumor cells are available for study and in approximately 30% of these small specimens, distinction of cell type cannot be made or the specimen is misdiagnosed. This can be a critical issue since agents such as the vascular endothelial growth factor (VEGF) blocker, bevacizimab,[64] may cause cavitation in squamous tumors that can be life threatening while pemetrexed may be less effective against squamous tumors than against adenocarcinoma.[65]

## DIAGNOSTIC IMMUNOHISTOCHEMISTRY OF INVASIVE SQUAMOUS CARCINOMA

Immunohistochemical markers may be used for diagnosis, prognosis, or prediction of response to treatment with targeted agents. In this section, the focus is mainly on the diagnosis whereas in the next, molecular lesions that are important in squamous carcino-

genesis are discussed. Immunohistochemical predictors of response to targeted therapy are discussed elsewhere in this volume.

### Cytokeratin and Its Isotypes: Pan-CK, PCK5/6, CK7, and CK20
Immunohistochemical markers have been used in lung cancer largely to distinguish poorly differentiated metastatic tumors that may mimic the histological appearance of squamous carcinoma. Such tumors include large cell lymphoma, melanoma, germ cell malignancies, and sarcoma. The most helpful markers in this context are the cytokeratins (CKs). CK intermediate filaments are expressed in several different isotypic forms. Pan-CK antibodies recognize epitopes that are common to most of the CK isotypes. A pan-CK stain such as AE1/AE3 cocktail usually suffices to distinguish poorly differentiated squamous carcinomas from other poorly differentiated tumors. Occasionally, however, poorly differentiated tumors are pan-CK negative and these cases specific anti-CK isotypes such as CK5/6 may be positive and clarify the diagnosis.

A more complicated problem is the use of isotype-specific antikeratin antibodies to distinguish squamous carcinoma from other non–small cell lung carcinoma (NSCLC) types. With the emerging importance of squamous histology in predicting response to targeted agents, the question of whether immunohistochemical markers could be help to distinguish squamous from other non–small cell histologies has become more important. Several of the immunohistochemical markers useful for making this distinction are CKs (Table 22.3). The CKs form a large family of related proteins that associate to form mature filaments in

epithelial cells and tumors.[66–68] Central airway squamous tumors express different CKs than tumors originating from peripheral airways. Squamous carcinomas express CK5/6 at a frequency of >80%,[69–71] but adenocarcinomas express this protein at a lesser frequency.[70–73] However, there is so much overlap in the expression of CK5/6 among the tumor types, staining for CK5/6 by itself is not a reliable marker for squamous carcinoma.[74]

A second CK protein that has been suggested as a useful diagnostic aid is CK7. In squamous carcinoma, CK7 is notable by its absence with three quarters of squamous carcinomas negative for this marker.[70,75–77] Here again, however, the number of positive cases found among squamous carcinoma is sufficient to limit the utility of the protein as a diagnostic discriminant of squamous carcinoma.

**P63**    P63 is a transcription factor and homologue of p53 that is important in epithelial cell differentiation. It is expressed by myoepithelial and reserve support cells and has been proposed as a possible marker of squamous phenotype. The marker is frequently expressed at high level in the nuclei of squamous carcinoma cells and overexpression is associated with *p63* gene amplification.[78] Several studies have shown that the marker has high sensitivity for squamous carcinoma with >95% of tumors immunoreactive with anti-p63 antibody.[69,79–81] However, specificity is variable, with several studies reporting that 0% to 30% of adenocarcinomas express *p63*.[79–82]

Antibodies against p63 or CK5/6 or both have been paired with anti–thyroid transcription factor-1 (TTF-1) (discussed later) in a single immunohistochemical panel to distinguish squamous carcinoma from adenocarcinoma. Sensitivities and specificities for the double antibody test are high (80% to 100%) but the numbers of cases reported is small.[82,83] Double antibody testing may ultimately prove useful for poorly differentiated tumors where little tissue is available but this test will require further validation in specific clinical contexts.

## MOLECULAR PATHOLOGY OF SQUAMOUS CARCINOMA INCLUDING HIGH-THROUGHPUT GENE EXPRESSION ARRAYS

A variety of molecular abnormalities are present in squamous carcinoma that are not necessarily diagnostically useful but are part of the constellation of changes that accompany malignant transformation. Genetic changes in squamous tumors are numerous and can be grouped according to the molecular pathway they affect. Specific genetic lesions tend to group with specific histologies. To date, most mutations in squamous carcinoma are found to be associated with cell cycle genes and less frequently with tyrosine kinase pathway genes.[84,85] A list of the most common genetic abnormalities and their frequencies in specific tumor types is presented in Table 22.4 and discussed in the context of specific tumor types.

**Cell Cycle Genes**    Genes of the cell cycle were the first to be evaluated in lung cancer and are the most commonly mutated genes in squamous carcinoma.

**TP53**    TP53 is a multifunctional transcription factor that plays a complex role in a variety of processes including cell cycle regulation, DNA repair, and apoptosis. Of particular interest is its role as a cell cycle checkpoint in which TP53 interacts with DNA repair and recombination enzymes.[86] This allows the cell to correct DNA damage during replication and the frequency of mutation and chromosomal rearrangement transmitted to daughter cells is thereby reduced. TP53 mutation interferes with DNA repair and may thus result in chromosomal instability, a major factor in malignant progression and resistance to chemotherapy. TP53 is the most commonly mutated gene in all lung carcinomas including squamous carcinoma.[87] TP53 mutation does not appear to be associated with outcome in squamous carcinoma although it is associated with reduced survival in adenocarcinoma.[88]

**CDKN2A (p16)**    P16 protein inhibits cyclin-dependent kinase 4 (CDK4) and inactivation of this inhibitor removes a brake on cell proliferation, enhancing tumor growth. *P16* is one of the most frequently affected of the tumor suppressor genes and may be deleted[89,90] or methylated[91] in lung cancer. The gene is inactivated in approximately 60% squamous carcinoma.[92] Methylation of *p16* is an independent prognostic variable in NSCLC regardless of histological subtype.[93] By contrast, in SCLC *p16* is usually intact but the *RB1* gene, also affecting progression through the cell cycle, is almost universally inactivated (see succeeding discussion of SCLC). Immunohistochemical tests assessing cell cycle–related proteins have been of more limited prognostic value. In one recent

study, no single cell cycle protein (including p16) was of prognostic importance[94,95] and only with combinations of markers could statistical significance be achieved.[95] Prediction of outcome in individual tumors based on immunohistochemical testing of cycle proteins is unlikely to be accurate or reliable and it appears that only direct assessment of *p16* gene methylation provides prognostic information.

### Expression Microarrays other High-Throughput Technologies

Until recently, biomarkers have been measured singly but oligonucleotide expression microarrays have permitted simultaneous evaluation of virtually all expressed genes in a single analysis. This technology has not yet found its way to broad clinical application but several important observations regarding lung tumors in general and squamous carcinoma in particular have been made utilizing this technology. First, microarray profiles strongly correlate with histology and clinical samples of squamous carcinoma can be distinguished from adenocarcinoma with a high degree of statistical certainty.[56,96,97] Second, microarray data is reproducible[98] and much of the variation in the reported literature can be attributed to differences in data interpretation that may be a complex exercise. Third, individual biomarkers are discoverable through application of microarrays and some of these markers may have clinical application. MAGE genes stand out in microarray experiments as some of the most highly overexpressed genes in central airway tumors including squamous carcinomas[99] providing a target for ongoing immunotherapy trials.[100,101] Fourth, it is possible to identify prognostically important subsets of genes[102] that may predict response chemotherapeutic intervention[103–105] or response to targeted agents.[106] Whether gene expression profiles can be used to prospectively select appropriate therapy for individual patients is an important and to date unanswered question.

Additional high-throughput technologies are currently under investigation including proteomics[107] and rapid large-scale gene sequencing that will permit identification of all mutations within individual tumors (see succeeding discussion of adenocarcinoma). These technologies potentially could reach a level accuracy that will compel their use in the clinical management of squamous and other non–small cell carcinomas. However, they require accessing larger amounts of tumor for clinical study and changes in the way tissue is processed. These requirements could transform surgical tissue acquisition and pathology practices but will need careful validation and cost/benefit analysis before transfer from bench to bedside.

## LARGE CELL LUNG CARCINOMA

Large cell lung carcinoma (LCLC) is an undifferentiated malignancy without features of small cell carcinoma, squamous cell carcinoma, or adenocarcinoma.[60] Although the cell of origin of LCLC is not well defined, ultrastructural studies have revealed features of glandular or squamous differentiation that cannot be appreciated by light microscopy. LCLC thus represents an extremely poorly differentiated NSCLC without histological features that permit ready assignment to one of the more usual and better-differentiated forms of lung carcinoma. With loss of differentiating features comes extremely aggressive biological behavior. These tumors comprise approximately 9% of primary lung malignancies.[108]

### Histology of Large Cell Lung Carcinoma

LCLCs are composed of poorly differentiated large cells (>21 microns) with prominent nucleoli and abundant, clearly visible cytoplasm (Fig. 22.7). Cells and nuclei are usually separate and discrete and less prone to deformation than the cells of small cell carcinoma. Tumor cells are generally arranged in nests or sheets. Nuclei are large and N/C ratios may be high. Mitoses are numerous and areas of necrosis are common.

The category of LCLC is heterogeneous and several variants of this tumor type have been described based on histology and immunohistochemical properties. These include clear cell carcinoma, large cell carcinoma with rhabdoid phenotype (rhabdoid carcinoma), and lymphoepithelioma-like carcinoma as well as two variants discussed elsewhere in this chapter, basaloid carcinoma and large cell neuroendocrine carcinoma (LCNEC). Clear cell carcinoma and rhabdoid carcinoma are terms that convey the essential cytological appearances of these neoplasms. The rhabdoid type has a particularly poor prognosis.[109–112]

The lymphoepithelioma-like variant resembles the lymphoepithelial carcinoma seen in the nasopharynx (undifferentiated epithelial cells with an intermixed prominent lymphoid infiltrate); this rare variant that affects young, Asian, nonsmokers[113,114] is associated with Epstein-Barr virus (EBV). These tumors are Bcl-2 positive by immunohistochemistry (IHC) and express EBER-1 by in situ hybridization,[114] suggesting viral etiology. Surgery is the treatment for early stage tumors, while multimodality treatment is used in advanced cases. Although quick to metastasize, this variant shows a favorable response to chemotherapy.[114–118]

**FIGURE 22.7** Large cell undifferentiated lung carcinoma exhibits no differentiating features and is composed of large cells with coarsely clumped nuclei and prominent nucleoli. Mitoses are abundant. (See color plate.)

**Cytology**  Because the diagnosis of large cell carcinoma is made after the exclusion of squamous, glandular, or small cell components, it is often classified as a *non–small cell carcinoma* on small tissue specimens such as transbronchial biopsies and cytological specimens. Cytological smears show an undifferentiated carcinoma without squamous, glandular, or small cell features. Smears are usually cellular and composed of both single cells and syncytial aggregates. Cells are large with high N/C ratios, large nuclei with prominent or multiple nucleoli in a background of necrosis.

### Immunohistochemistry of Large Cell Lung Carcinoma

The immunohistochemical staining properties of LCLC are listed in Table 22.3. In general, they are similar to other forms of NSCLC with the exception of a higher level of expression of proliferation markers, reflecting the rapid growth of these tumors.

## UNCOMMON BUT SIGNIFICANT VARIANTS OF NON–SMALL CELL LUNG CARCINOMA

Several histological variants of NSCLC are significant because of their distinct morphology and prognosis. The most prominent among these variants are basaloid carcinoma and pleomorphic carcinoma.

**Basaloid Carcinoma**  This variant histology may be found admixed with other forms of non–small cell carcinoma or as the sole cell type in a subgroup of lung carcinomas. Basaloid histological features include lobular growth of relatively small cells with dense nuclei, inconspicuous nucleoli, scant cytoplasm, a high mitotic rate, and peripheral palisading.[119] Misinterpretation of these tumors as SCLC has been described in fine-needle aspirations.[120,121] Small cell variant of squamous carcinoma is also distinguished from undifferentiated small cell carcinoma by nuclear features including prominent nucleoli and a coarse clumping of the chromatin. In doubtful cases, immunohistochemical stains for neuroendocrine markers may be applied (see succeeding discussion).

The reported frequency is about 6% of all lung cancers.[119] The reported prognostic significance of basaloid histology has been inconsistent with one study finding reduced actuarial 5-year survival for basaloid tumors in comparison to poorly differentiated squamous tumors[122] but a second similar-sized study finding similar survival for the two tumor types.[123] Since these tumors are rare, additional studies, perhaps through a multicenter registry, will be necessary to better characterize their behavior.

**Carcinomas with Pleomorphic, Sarcomatoid, or Sarcomatous Elements**  These carcinomas have been recognized under various names for many years including spindle cell carcinoma, giant cell carcinoma, pleomorphic carcinoma, and carcinosarcoma. This category consists of tumors that are composed exclusively of sarcoma or pleomorphic tumor cells or of tumors that contain a component of sarcomatoid or pleomorphic cells along with tumor of a more usual histological type. In the most recent WHO classification,[1] these tumors are grouped in a single diagnostic category. These tumors are uncommon and usually reported as single cases but two larger series have also been published.[124,125] The median survival in these series is 10 months.

Sarcomatoid tumor histology is characterized by the presence of spindle areas that resemble sarcoma.[124,125] The sarcomatous element in this variant type may contain muscle, bone, or cartilage as well as undifferentiated spindle cells.[124,125] There also may be mixtures of epithelial tumor and sarcomatous components, referred to as carcinosarcoma. The giant cell variant of the category consists of highly pleomorphic cells that form multinucleated giant cells, usually accompanied by a heavy inflammatory infiltrate. In most cases, these tumors have biomarker profiles similar to those of other lung tumors, expressing CK7 and TTF-1.[125] However, in approximately 25%, either one or the other or both of these biomarkers is (are) absent and these negative tumors tend to be those with the most sarcomatous histological appearance.

The biological significance of this category of tumor has been emphasized by the recent description of the stromal molecular and cellular properties in tumors that are otherwise considered epithelial. This pattern of differentiation has been referred to as *epithelial mesenchymal transition* (EMT). Properties associated with EMT include change in cell culture characteristics from the sheetlike pattern of epithelial cells to a more single cell infiltrative stromal pattern of growth.[126] This morphological change is accompanied by increased expression of vimentin intermediate filament and the transcription factor ZEB1 and by reduced expression of the adhesion molecule E-cadherin, the transcription factor SNAIL, and EGFR.[127] Such molecular changes are most evident in tumors that exhibit elements of sarcomatoid differentiation but poorly differentiated tumors without sarcomatous elements may also lose expression of E-cadherin. Loss of E-cadherin imparts a poor prognosis independent of stage[128] and resistance to EGFR blockade.[77,106,127,129–131] It seems likely that the loss of E-cadherin represents part of a continuum of dedifferentiation that at its most extreme is reflected in the pleomorphic tumor category. This category will require unique therapeutic consideration, especially as targeted drugs become increasingly available for tumors with specific molecular phenotypes.

## SMALL CELL LUNG CARCINOMA

The separate and unique histological features of SCLC were first recognized in 1926 by Bernard who introduced the tumor as *oat cell sarcoma*.[132] This subcategory took on greater importance when it was shown that the response to chemotherapy in these tumors differed substantially from the response of other tumor types with the SCLC being particularly sensitive to mitotic inhibitors.[133] It is for this reason that the main dichotomy of clinical relevance

in lung cancer pathological diagnosis remains the distinction between SCLC and all other forms of lung carcinoma (NSCLC).

**Histology of Small Cell Lung Carcinoma**   SCLC is an invasive carcinoma composed of small (<21 microns or <3 lymphocyte diameters) cells with scanty cytoplasm (Fig. 22.8). Histologically, these tumors are distinguished by their finely granular nuclei (*salt and pepper* chromatin), by their small and relatively inconspicuous nucleoli, and by the tendency for the nuclei to become easily deformed by contact with other cells and other structures (*nuclear molding*). These tumors are highly proliferative and rarely is the mitotic rate less than 10 mitoses per 10 high-power fields (hpf) so that virtually every hpf contains one or more mitoses. The neoplastic cells in this tumor type are fragile, and crush artifact is common particularly in small biopsy samples. Lymphocytes and other inflammatory cells can also undergo crush artifact and it is therefore of some importance that definitive diagnosis be based on examination of well-preserved cells where nuclei are clearly visible. A unique feature of SCLC is the *Azzopardi effect* consisting of an accumulation of chromatin in the vascular walls supplying the tumor. In a great majority of cases, the diagnosis of SCLC is obvious by histological examination alone. However, in some cases, immunohistochemical studies can serve to buttress the diagnosis and provide confirmation of diagnosis.

Within the category of SCLC, there is considerable variation in cell size and cellular configuration. For several years, subsets

**FIGURE 22.8**   SCLC as found on cytology, histology, and IHC. On the upper left are clusters of small cells with scant cytoplasm, nuclear molding (*arrow*), and finely granular nuclei with inconspicuous nucleoli. Macrophage (*Mac*) provides size comparison. The frame on the upper right shows the histology of SCLC with closely packed cells with scanting cytoplasm with streaming nuclei. NCAM and TTF-1 stains are strongly positive along plasma membranes and in the nuclei. *Mac*, macrophage; *NCAM*, neural cell adhesion molecule; *TTF-1*, thyroid transcription factor-1. (See color plate.)

of SCLC were included in the SCLC category. The 1967 WHO classification included *oat cell* carcinoma and an intermediate cell variant that differed from classical oat cell carcinoma in cell size and amount of cytoplasm. These categories proved to be of no prognostic significance and the two categories were combined in the latest classification into a single small cell category. This tumor type comprises 15% to 20% of all lung cancers but its frequency may be decreasing.[59,134] Typically, small cell carcinomas present as an endophytic lesion in a central bronchus with mediastinal lymph node (LN) metastases.

**Cytology**   Success in identifying SCLC by cytological examination is partially dependent on the type of specimen available for examination. SCLC may be readily identified bronchial washings and brushings where the cells are well preserved and in these cases, cytology may be crucial in arriving at a definitive diagnosis. However, SCLC has been infrequently identified in screening trials[135,136] in part because SCLC is not well preserved in expectorated sputum and also perhaps because the disaggregation process may damage the fragile cell of SCLC. The cytological features of SCLC correspond to what is seen in well-preserved tissue sections. Single cells or small clusters of cells less than 21 microns in diameter have a high N/C ratio with only a thin sometimes barely visible rim of cytoplasm around and enlarged nucleus (Fig. 22.8). Nuclear fragmentation is often present in association with better-preserved cells. The nucleus again has finely granular (salt and pepper) chromatin and small, inconspicuous nuclei. In small clusters of cells, nuclei are often molded against one another. Nuclear features are crucial and excellent preservation of cells is required for diagnosis. Cells that may resemble SCLC are basilar cells of the respiratory mucosa that usually are smaller and more uniform that the cells of SCLC. Lymphocytes may also cause confusion but usually only in poorly preserved specimens.

**Diagnostic Immunohistochemisty of Small Cell Lung Carcinoma**   Immunohistochemical stains can be used to verify the neuroendocrine nature of the tumor or help distinguish SCLC from other NSCLC (Fig. 22.8). SCLC almost always expresses CK but the amount of this intermediate filament may be quite small, particularly in less than that optimally preserved specimens. CK expression serves to distinguish SCLC from other small blue cell tumors such as lymphoma, which occasionally can mimic SCLC. SCLC, like adenocarcinomas of the lung (see succeeding discussion), is usually positive for the primitive lung differentiation gene TTF-1 with several studies documenting expression rate in at least 85% of these tumors.[71,137–144] In specific contexts, TTF-1 may be useful in distinguishing SCLC from small cell tumors of other sites. For example, while this marker is expressed in a large percentage of SCLC, histologically similar Merkel cell tumor of dermal origin and small cell carcinoma of ovary are virtually always negative for this marker.[140–142,144–146] Small cell cervical and colon carcinomas are occasionally positive (10% to 15%[140,146,147]) but up to 50% of transitional carcinomas of bladder[140,147–149] and over 70% of esophageal small
cell tumors are reported positive.[150] Reported results for small cell prostate carcinomas have been variable with some studies indicating high frequency of expression[147] and other low frequency of expression.[140,151] The utility of TTF-1 in distinguishing site of origin of unknown primary is therefore highly context dependent.

A distinguishing feature of SCLC is its expression of neuroendocrine markers including neuron specific enolase, synaptophysin, neural cell adhesion molecule (NCAM) (CD56), and Leu-7 (CD57).[152–154] Approximately 50% of SCLCs also express chromogranin A in sufficient quantity to be detectable in conventional immunohistochemical tests so that in doubtful cases a negative chromogranin is uninformative. The quantity of chromogranin in SCLC is usually less than that present in carcinoid, so that in cases with strongly positive chromogranin stains carcinoid tumor should be excluded. A salient feature of SCLC is its high growth fraction; as determined by Ki-67 labeling procedures, the growth fraction usually exceeds 50%. Ki-67 may be helpful in distinguishing SCLC from other neuroendocrine tumors of the lung. A negative differentiating marker is EGFR, which is expressed in NSCLC but not in SCLC.[154] Finally, it has been reported that c-kit receptor (CD117) is nearly always expressed by high-grade neuroendocrine carcinomas including SCLC and LCNEC,[155–158] an observation that has been fully exploited neither diagnostically nor therapeutically. The expression of CD117 is apparently not associated with mutation of the c-kit receptor gene[159] and no relationship to survival or response to chemotherapy has been shown to date.[160]

The application of immunohistochemical staining procedures to lung tumors has revealed considerable overlap in staining properties. It is known for example that about 20% of adenocarcinomas are focally positive for NCAM, a molecule that otherwise is almost universally expressed by SCLC. This suggests a degree of phenotypic plasticity in lung tumors that is confirmed in gene profiling studies (see discussion that follows).

### Molecular Pathology in Small Cell Lung Carcinoma

The unique histological and immunohistochemical features of this tumor are a reflection of underlying genetic changes that are increasingly better defined. SCLC was among the first of the lung tumor types in which genetic changes were defined. These changes included structural chromosomal abnormalities (deletion [3p(14–23)[161]] and the mutations described and listed in Table 22.4. The pathways most frequently affected by mutation involve cell regulation and tyrosine kinase signaling genes including KRAS[84,162] and EGFR[84,163] are rarely mutated. In the succeeding discussion, genetic lesions are grouped by pathway as in the previous discussion of squamous carcinoma.

### Cell Cycle Genes

A number of the mutations and chromosomal rearrangements that affect cell cycle genes are present in SCLC.

### RB1/CDKN2A (p16)

*RB1* was first identified as a tumor suppressor gene in retinoblastoma. Knudson's "two-hit" model of carcinogenesis, whereby a dominant tumor suppressor gene is inactivated by two mutational events eliciting tumor formation, was formulated in 1971 to explain retinoblastoma tumorigenesis.[164] Fifteen years later, the retinoblastoma gene, *RB1*, was cloned[165] and the relevance of *RB1* to lung cancer was demonstrated.

*RB1* encodes a phosphoprotein that binds to the transcription factor E2F. Phosphorylation of RB1 releases E2F and transition from the G1 to S phase of the mitotic cycle occurs. *RB1* is therefore an important cell cycle regulator and tumor suppressor gene. Loss of *RB1* results in an increase in cell proliferation and more rapid tumor growth.

Structural changes in the *RB1* gene in SCLC lines and tumors have been reported and complete absence of RB1 protein has been reported to affect all SCLC.[166–168] The mechanism of *RB1* inactivation in human tumors is still not completely understood. Although RB protein is absent in SCLC, DNA sequencing has identified mutations in only a minority of tumors and these consist primarily of deletions resulting in frame shifts or stop codons.[169]

The mutational pattern evident in cell cycle genes in SCLC is distinct from that in NSCLC with the latter frequently affected by loss of p16 with and overexpression of cyclin D1 rather than the near universal loss of *RB1*[168] observed in SCLC.

### TP53

TP53 is more frequently mutated in SCLC than in the other non–small cell forms of lung cancer. Loss of TP53 function with associated loss of cell cycle checkpoint function and impairment of apoptotic pathways undoubtedly contributes to the aggressive growth and hypermutability that are features of this tumor.

### Gene Expression Profiles

In virtually all the nucleotide microarray analyses, small cell tumors emerge as a separate phenotypic category with numerous gene expression difference with the non–small cell tumors.[170] Available microarray data for SCLC has considerably expanded the number of potential biomarkers that may be useful in the differential diagnosis and detection of SCLC. Moreover, these studies have indicated that many of the genes expressed in SCLC are also found during lung differentiation (see succeeding discussions).

To date, however, the molecular features of SCLC have not been sufficiently definitive nor have they added sufficient independent information to histological diagnosis to justify the general application of diagnostic molecular testing in this tumor. The diagnosis of this neoplasm therefore continues to rest on histological examination supplemented by immunohistochemical studies in difficult cases.

## MIXED SMALL CELL AND NON–SMALL CELL CARCINOMA

It is of interest that a large proportion of small cell carcinomas contain a component of non–small cell tumor. These tumors include large cell carcinoma, adenocarcinoma, and squamous carcinoma. In a recent review of 100 small cell carcinomas,

Nicholson et al.[171] found 72 pure small cell carcinomas and 28 combined small cell carcinomas. Sixteen cases were combined with large cell carcinoma, nine with adenocarcinoma, and three with squamous cell carcinoma.

# BRONCHIAL CARCINOID, ATYPICAL CARCINOID AND LARGE CELL NEUROENDOCRINE CARCINOMA

The term *carcinoid* was originally coined in 1907 to describe a subset of gastrointestinal epithelial tumors that were less aggressive than the conventional gastrointestinal carcinoma and were therefore designated carcinoid tumors rather than *carcinoma*.[172] It was subsequently demonstrated that similar tumors existed in the lower respiratory tract.[173] Currently, these tumors together with SCLC and LCNEC are regarded as *neuroendocrine* and are considered part of a continuum. Carcinoid tumor is the lowest grade and least aggressive of this group and SCLC is the highest grade and most aggressive.[174,175] This category also includes atypical carcinoid, which characteristically has an elevated mitotic rate in comparison to typical carcinoid and behaves more aggressively with a metastatic rate of approximately 50%. Finally, LCNEC is an aggressive, high-grade tumor that was first described in 1991[175] as an undifferentiated tumor that is intermediate in morphological features and prognosis between atypical carcinoid and SCLC.

**Typical Carcinoid Tumor**   Typical carcinoid tumors may arise in the either central or peripheral airways. They usually have strikingly different macroscopic features in the two locations. The central airway tumors are relatively large (mean diameter 3 cm)[176] and grow as endobronchial masses that may obstruct the large bronchi (Fig. 22.9). The secretory products

**FIGURE 22.9**   Histological comparison of various forms of neuroendocrine tumor of the lung. On the left is a classical carcinoid tumor with a ribbonlike pattern of growth. The central image shows more sheetlike tumor growth with occasional mitotic figures (see text). This tumor type also is defined by the presence of focal areas of necrosis. The figure on the right shows the high level of mitotic activity (*arrows*) and areas of necrosis that characterize LCNEC. *LCNEC,* large cell neuroendocrine carcinoma. (See color plate.)

of these tumors also may induce swelling of adjacent tissues that augments the obstruction caused by the tumor itself. These tumors may extend into the bronchial wall but such infiltration does not necessarily imply aggressive growth and is not a criterion for atypical carcinoid. The sectioned surface of carcinoid tumor is usually gray and homogeneous. The histological features that distinguish carcinoid tumors from NSCLC are relative uniformity of the tumors cells, abundant grayish granular cytoplasm, lack of tumor cell necrosis, and round to oval nuclei with finely granular (salt and pepper) nuclear chromatin and inconspicuous nucleoli. Carcinoid cells form small clusters without true gland formation in a pattern that is variously described as organoid or insular. Cells and nuclei are frequently oriented perpendicularly to the basement membrane, forming palisading or rosettelike patterns. To distinguish slow-growing typical carcinoids from more aggressive tumors, the diagnosis is limited to those tumors with <2 mitoses per 2 mm$^2$ (<10 hpf) and no necrosis. [60]

Carcinoid tumors may also grow in the peripheral lung. Minute (<5 mm) peripheral carcinoid tumors, referred to as *tumorlets*,[177] are frequent incidental findings in lungs resected for other lung diseases and are benign. Larger carcinoid tumors may also occur in the peripheral lung. The uniform cellular appearances of the central airway tumors are recapitulated in the peripheral tumors with the exception that tumor cells are found in the bronchioles and in some cases, the tumors have a spindled appearance (spindle cell carcinoid tumor[178]).

Symptomatic carcinoid tumors represent 1% to 2% of all lung carcinomas and survival at both 5 and 10 years is 87%.[174,179]

**Atypical Carcinoid**   A mitotic rate of 2 to 10 per 2 mm$^2$ and foci of necrosis are the features that separate atypical from typical carcinoid (Fig. 22.9) as first defined by Arrigoni et al.[180]

In contrast to the low mortality of typical carcinoid, atypical carcinoid tumors have a survival rate of 50% to 60% at 5 years and 35% at 10 years, a mortality effect that remains significant in multivariate analysis.[174,181] Patients with atypical carcinoid are reported to have higher tobacco smoke exposure than the general population or patients with typical carcinoid.[182] A smoking association is supported by an increase in the prevalence of smoking-associated genetic changes including LOH and p53 mutation in atypical carcinoid in comparison to typical carcinoid.[183]

**Large Cell Neuroendocrine Carcinoma**   In the LCNEC, necrosis is also frequently present and mitotic rate exceeds 10 mitoses per 2 mm$^2$ areas. Cells often retain a neuroendocrine appearance with organoid nesting, trabeculae, rosettelike structures, and peripheral palisading[175] (Fig. 22.9). Nuclei may exhibit the fine granularity seen in SCLC but there are often more conspicuous nucleoli. Immunostains for neuroendocrine markers may or may not be positive and are not necessary for diagnosis when neuroendocrine differentiation is evident. Conversely, the diagnosis of LCNEC in an undifferentiated large tumor
may be based purely on immunohistochemical staining results (Table 22.3). LCNEC is distinguished from SCLC on the basis of the aforementioned features as well as cell size >21 microns (3 lymphocyte diameters).

The incidence of LCNEC carcinoma is approximately 3% of all primary pulmonary malignancies[184,185] and is strongly associated with smoking history.[186] It is generally thought that LCNEC carries a worse prognosis than other non–small cell carcinomas.[179,187] Five-year survival for this tumor from several studies varies from 15%[179] to 27%,[174,186] and 10-year survival is reported at 9%.[174,187] Another study of 87 cases of LCNEC reported significantly worse survival for stage I patients[185] but overall 5-year survival was not significantly different from an overall 5-year survival of or the NSCLC at 57%. Although currently treated as NSCLC, the prognosis for LCNEC approaches that of small cell carcinoma, and treatment options may change in the future.[188,189]

### Cytology of Carcinoid Tumor and Large Cell Neuroendocrine Carcinoma

Although most carcinoid tumors are centrally located, their cytologic features are better seen on fine-needle aspiration specimens than in sputum. Smears show small uniform cells with central to eccentric round nuclei with smooth nuclear outlines. There is no molding as seen with high-grade neuroendocrine carcinomas. A minority of carcinoid tumors can have spindle-shaped cells. Cytologically, atypical carcinoids show more pleomorphism, atypia, higher N/C ratios, more irregular membranes, and coarser chromatin than typical carcinoids. Cells are arranged as single cells and syncytial aggregates, and necrosis may be present[190]; however, these features are only suggestive and tissue is required for a definitive diagnosis.

Suggested cytological criteria for LCNEC include flattened three-dimensional groups of cells with peripheral palisading, moderate to large cells, some molding and crush artifact, prominent nucleoli, mitoses, necrosis, and positive neuroendocrine markers.[191,192] Distinction between SCLC and NSCLC may be difficult on cytological examination[193] unless enough material is available for a cell block to evaluate architectural features and immunohistochemical biomarker expression.

### Immunohistochemisty of Carcinoid Tumor and Large Cell Neuroendocrine Carcinoma

As mentioned previously, expression of immunohistochemical markers is currently one of the two defining criteria of neuroendocrine tumors. Table 22.3 lists antibodies that distinguish among neuroendocrine tumor types. Antibodies that are most generally useful in the evaluation of neuroendocrine tumors include NCAM, synaptophysin, and chromogranin.[194–201] LCNEC frequently expresses one or more neuroendocrine markers.[153,202] However, staining tends to be more focal and weaker than that observed with SCLC or carcinoid tumor (Table 22.3). In a small subset of LCNEC, immunostains for these markers are negative and diagnosis is made on the basis of histology alone.

Electron microscopy has, in the past, been useful in characterizing neuroendocrine tumors but has largely been replaced by less expensive and often more informative immunohistochemical tests.

### Cell of Origin: Small Cell Lung Carcinoma and the Neuroendocrine Tumor Hypothesis

Since the original description of SCLC, the cell of origin has been the subject of much speculation. In the 1960s, the hypothesis was advanced that these tumors were derived from Kulchitsky (K) cells that are scattered along the airway surfaces.[203] K cells were considered to be a part of a dispersed neuroendocrine system.[204] These cells were thought to be derived from neural crest and thus separately derived from the rest of the lung. However, the neuroendocrine cells were later shown to be derived locally.[205] Although K cells populate the bronchial epithelium at a density of approximately one cell per millimeter, these cells are infrequently observed in premalignant conditions. Moreover, SCLC arises in a milieu similar to that of non–small cell central airway lesions including widespread squamous metaplasia and dysplasia. This, together with the frequent combination of small cell and non–small cell elements in lung carcinomas, suggests that the small cell tumors may have the same progenitor cells of origin as NSCLC.

The hypothesis that tumors with neuroendocrine properties should be grouped into a single category is not universally accepted[206] for several reasons. First, a large proportion of lung carcinomas have mixed nonneuroendocrine and neuroendocrine properties. This is particularly evident in molecular profiling studies where otherwise unremarkable adenocarcinomas have been shown to express clusters of genes that are thought to reflect neuroendocrine differentiation.[96,97,207] Adenocarcinomas having this gene expression profile have a worse prognosis than other adenocarcinomas. Second, many of the markers that are regarded as neuroendocrine markers are expressed in a variety of cells in addition to neuroendocrine cells.[206] Third, neuroendocrine markers including NCAM are expressed during embryonic development of the lung.[208] For example,[209] gastrin-releasing peptide signaling has been to shown to determine airway branching in the embryonic mouse lung.[210] Expression of neuroendocrine biomarkers in LCNEC could be regarded as evidence of dedifferentiation to a more primitive developmental stage rather than neuroendocrine differentiation.

At the present time then, expression of neuroendocrine biomarkers may be regarded as an interesting but not yet fully understood property of lung carcinomas that may be prognostically important within specific histological categories. Moreover, expression of neuroendocrine-associated genes may provide therapeutic targets but does not necessarily indicate ontological relationships among tumors. The biological rationale for grouping diverse lung tumors into a single neuroendocrine diagnostic category is problematic and this grouping has not yet been unequivocally proven to be clinically relevant. It may yet prove to be more useful to annotate conventional histological categories with biomarker expression data rather

than retain the neuroendocrine designation to refer to such a divergent group of tumors.

## DIFFUSE IDIOPATHIC PULMONARY NEUROENDOCRINE CELL HYPERPLASIA: A POSSIBLE CARCINOID PRECURSOR

Neuroendocrine cells may also proliferate in the bronchiolar walls without forming tumors, a condition referred to as diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH).[211] Histologically, multifocal, patchy collections of neuroendocrine cells may involve the full circumference of the bronchiolar walls and form tumorlets or small carcinoid tumors. The proliferative cells in this condition are considered to be benign but because the disorder gives rise to carcinoid tumors, it is considered a premalignant condition. To date, more aggressive forms of lung carcinoma, including SCLC, have not been associated with DIPNECH. The condition may cause an obliterative bronchiolitis that is often a presenting symptom. It has also been described in association with hypoxic childhood pulmonary emphysema, tachypnea of infancy, and adult dyspnea.[212–214] There is currently no effective treatment.

### Peripheral Airway Lesions: Adenocarcinoma and Its Precursors
In this chapter, we use the term *peripheral airway lesions* to refer to tumors and premalignant conditions predominantly arising from airway epithelium distal to the terminal bronchiolar and alveolar epithelium. Most but not all adenocarcinomas of the lung arise in the peripheral airways and are divided into invasive adenocarcinoma, which is distinguished by a fibrous stromal response around individual tumor cell nests, bronchioloalveolar carcinoma, which grows exclusively along the alveolar surfaces and does not invade stromal tissues, and the putative adenocarcinoma precursor lesion atypical adenomatous hyperplasia (AAH).

The incidence of adenocarcinoma is rising.[108] This cell type now represents over 30% of primary lung malignancies. Although adenocarcinoma is associated with smoking, the association is weaker than for squamous cell carcinoma or small cell carcinoma and a large subset of adenocarcinomas occur in never-smokers. This histological type is the most common type seen in women and in nonsmokers.[215]

Emerging evidence suggests and indicates that peripheral adenocarcinomas may arise from different progenitor lesions than squamous carcinoma as discussed later. During the past 2 decades, the existence of stepwise sequential morphological changes corresponding to the progression from atypia to carcinoma has been described in the peripheral lung. The prognostic significance of histology in small early lesions is increasingly better understood. Moreover, the increasing sensitivity of imaging technology during the past several years has allowed for the detection of smaller lesions in previously inaccessible peripheral airways. All this has created a pressing need for accurate classification of the peripheral airway lesions.

## ATYPICAL ADENOMATOUS HYPERPLASIA AND THE ORIGIN OF PERIPHERAL LUNG ADENOCARCINOMA

AAH (also referred to as *atypical alveolar hyperplasia* or *bronchial adenoma*) is a small (<5 mm) proliferation of alveolar cells that was originally described in lungs resected for invasive adenocarcinoma.[216] Since its original description, a high frequency of AAH in patients with adenocarcinoma has been documented in many studies. AAH has been found in 14% to 57% of lungs with adenocarcinoma[217–223] and in 3% to 30% with squamous carcinoma.[218,220–223] It has also been found at autopsy in 2.8% of elderly Japanese population without carcinoma.[224] The frequent occurrence of AAH in association with adenocarcinoma and bronchioloalveolar carcinoma (BAC)[223] suggests that AAH may be a precursor of adenocarcinoma and BAC, and AAH has been defined as a preinvasive lesion of adenocarcinoma in the current WHO classification.[1] This hypothesis is supported by the similarity in molecular profiles between AAH and BAC.

### Histopathology of Atypical Adenomatous Hyperplasia
AAH can be recognized by careful examination of freshly resected lung, but is usually invisible to the naked eye and is detected only incidentally on microscopic examination. In hematoxylin and eosin (H&E)–stained sections, AAH (Fig. 22.10) is observed as well-circumscribed cluster of alveoli lined by a single uniform layer of well-formed type II pnuemocytes or Clara type (*hobnail*) cells without scarring or significant inflammation in the area. Involved alveoli are frequently clustered around a terminal bronchiole. The cells of AAH are sparsely concentrated along the alveoli and have dense nuclei with inconspicuous nucleoli.

AAH may be difficult to histologically discriminate from BAC. Histological evidence of malignancy includes

**FIGURE 22.10** Atypical adenomatous hyperplasia. On the left is a low magnification view showing the small overall size of the lesion. At higher magnification (*right*), a single layer of cuboidal cells covers the alveolar septae with minimal associated inflammation. (See color plate.)

cellular crowding, nuclear chromatin granularity and prominence of nucleoli, increase in cell height, and stratification of cells.[225] Lesions containing larger, more crowded cells with cytological atypia may be impossible to distinguish from BAC and some observers have suggested that lesions smaller than 5 mm be classified as AAH, while larger lesions be classified as BAC.

## Molecular Correlates of Atypical Adenomatous Hyperplasia

**Immunohistochemistry**　It has been difficult to characterize AAH immunohistochemically because it is usually detected incidentally after surgery as a very small lesion. However, several studies have reported an immunohistochemical relationship between AAH and BAC. AAH expresses high levels of several markers that are also upregulated in lung carcinomas including survivin,[227] Mre11 (telomere maintenance),[228] telomerase, Dicer (microRNA-related protein),[229] and matrix metalloproteinases.[230] Overexpression is consistent with a likely pathogenetic relationship among AAH (preinvasion lesion), BAC (in situ adenocarcinoma), and invasive adenocarcinoma.

**Genetic Changes**　That AAH represents a true neoplasm is also supported by morphometric and molecular studies. AAH has proven to be aneuploid by morphometric analysis[231–234] and flow cytometry,[235] is monoclonal, and may harbor the same genetic changes listed for adenocarcinoma in Table 22.4 including mutations of *KRAS*[236,237] and *EGFR*.[237] AAH also has demonstrated LOH at chromosomal sites of putative tumor suppressor genes including 3p,[238,239] 9p,[238,239] 9q,[240,241] 16p,[241] 17p,[239] 17q,[240] and chromosomal imbalance by comparative genomic hybridization.[242] One study[239] has shown that increasing frequency of LOH and *TP53* mutation correlates with increasing histological grade from AAH to invasive carcinoma, suggesting an increasing frequency of genetic abnormalities with progression from premalignant to invasive disease.

## Natural History of Atypical Adenomatous Hyperplasia

The evidence that AAH is a precursor lesion for peripheral adenocarcinoma is also supported by the coexistence AAH with non–small cell carcinoma, but because the lesion is rarely identified in patients without tumor, longitudinal studies have not been possible. Combined molecular and available epidemiological data support a stepwise sequence of changes in the peripheral airways similar to the adenomatous polyp/invasive carcinoma sequence that has been well described in the colon.[218] The lesion following AHH in sequential peripheral lung carcinogenesis is BAC.

## Bronchioloalveolar Carcinoma

BAC was described many years before AAH. Recently, there has been renewed interest in this tumor type for several reasons. First, BAC is unique among lung tumors in its capacity to spread through the airways without tissue destruction. Metastasis through the airways may result in nodular growths anywhere in the airways. Direct extension of tumor along the alveolar septae can result in a pneumonic pattern of growth that has a pneumonia-like appearance on imaging studies, the pneumonic form of BAC.[243] Second, the pathological definition of BAC has changed during the past 10 years and continues to evolve. Third, although 70% of BAC occurs in smokers, it is one of the few lung cancers in which a substantial minority of the affected population is nonsmoking.[244] Fourth, molecular mechanisms that drive tumor cells of this type have been dramatically elucidated through genetic analyses.[245,246] Finally, it is a tumor that is most frequently detected by new high-resolution computed tomography (CT) imaging methods.[247] The extension of tumor cells along the alveolar septae with retained aeration or low-density mucous production may provide BAC with a unique ground-glass appearance in CT imaging studies,[248–250] the so-called *ground glass opacity* (GGO). The small peripheral GGO is often a presenting feature of BAC. Its incidence has been increasing with the use of CT screening for lung cancer. An account of the development of the concept of BAC is provided in the succeeding discussion.

## Histology of Bronchioloalveolar Carcinoma: A Changing Concept

The notion that tumors may develop in the peripheral lung from alveolar epithelium is an old one that was first advanced in 1876.[251] The premise was in doubt for another three quarters century since it was not until 1953 that electron microscopic studies demonstrated a thin pneumocyte layer continuously lining the alveolar septae and abutting the bronchiolar epithelium.[252] During the intervening years, there was much speculation about the nature of the subset of well-differentiated peripheral lung cancers that grew by extending along the alveolar septae, that were frequently multicentric and that preserved the underlying architecture of the lung.[253] In the early 20th century, South African sheep suffering an endemic infectious disease (jaagsiekte) were found to have nonmetastasizing epithelial proliferations in the lungs,[254] microscopically similar to human alveolar tumors.[255] The term *adenomatosis* was proposed to refer to this disease. Jaagsiekte eventually proved to have a viral etiology and but to date, no causative viral agent has yet been confirmed in morphologically similar human tumors.[256] The term *adenomatous* was applied to human tumors as well but was not wholly satisfactory since sheep rarely developed metastases but that were frequent in the analogous human tumors.

By 1960, it had become clear that peripheral lung tumors that spread along the alveolar surfaces could resemble bronchiolar or alveolar epithelium. The term *bronchiolo-alveolar* carcinoma was introduced by Liebow[257] and quickly accepted to describe "…well-differentiated adenocarcinomas primary in the periphery of the lung beyond a grossly recognizable bronchus, with a tendency to spread chiefly within the confines of the lung by aerogenous and lymphatic routes…"

This definition persisted without change until 1980 when Shimosato et al.[258] recognized that peripheral adenocarcinomas <3.0 cm without fibrosis have a significantly longer mean survival

than those with a central scar. Noguchi et al.[259] later confirmed that the 5-year survival of patients with pure BAC with no fibroblastic foci is 100%, with no cancer-related death. Fibroblastic foci were presumed to indicate host response to invasion by tumor cells and the presence of fibroblastic foci reduced 5-year survival to 75%. This fibrosis of invasion was distinguished from *collapse* of alveolar walls with accumulation of residual elastic fibers and basement membrane into consolidated nodules.[259] The importance of fibrosis to predict outcome in early stage alveolar tumors has been supported by more recent studies from Japan that indicate fibrosis <5 to 10 mm in maximum diameter is a favorable prognostic indicator.[260,261] The WHO/International Association for the Study of Lung Cancer (IASLC) panel lung tumor recognized these observations in the most recent classification published in 2004.[1] By current definition, BAC is an in situ lesion that may spread through the alveolar spaces but exhibits no evidence of stromal invasion and does not metastasize to distant sites through the blood or lymphatics. To accommodate those numerous tumors with both BAC and invasive carcinoma components, the category of *adenocarcinoma, mixed subtype*, sometimes referred to as *adenocarcinoma*, mixed subtype with BAC features.

To determine whether or not fibroblastic foci are present in a peripheral nodule and whether vascular, lymphatic, or pleural invasion are present, it is necessary to carefully examine the entire tumor. Elastic staining is useful for distinguishing alveolar collapse from tumor invasion. If the lesion is small (<1 cm) the entire tumor should be embedded for microscopic examination. This is not possible when diagnosis is based on needle biopsy or aspiration.

BAC may be mucinous or nonmucinous (Fig. 22.11). Mucinous tumors are composed of mucus-producing goblet cells with large cytoplasmic mucous vacuoles that may compress and deform nuclei. These cells are often evenly distributed in single layers along alveoli. Nuclei are low grade but may be difficult to visualize well. Surrounding alveoli often contain pools of mucus. Nonmucinous cells may differentiate along the lines of Clara-type cells, type 2 pneumocytes, or a mixture of both. In the nonmucinous Clara-type tumor, cells are columnar and eosinophilic, with apical cytoplasmic extensions (*snout*) projecting above the level of adjacent epithelium. The less frequent tumors composed of nonmucinous, type II pneumocyte-like cells contain cuboidal or low columnar cells that may have foamy, vacuolated cytoplasm. Nuclei are located centrally in nonmucinous tumors, nuclear grade is usually low, and mitoses infrequent in both cell types. Rare mixtures of mucinous and nonmucinous types may coexist in the same tumor.[262]

### Cytology of Bronchioloalveolar Carcinoma

Fine-needle aspiration may be readily used to evaluate peripheral lung nodules and cytological specimens from these aspirates can be diagnostic of carcinoma. However, accurate distinction of BAC from invasive carcinoma is not possible without the view of lung architecture afforded by tissue sections. Athough BAC has been reported to have characteristic cytological features,[263–265] these features do not directly reflect the presence

**FIGURE 22.11**   Histology of various forms of BAC, BAC mixed with invasive carcinoma, and pure invasive carcinoma. **A:** Small nonmucinous BAC at low magnification without evidence of stromal invasion. **B:** High magnification of **A** shows lepidic spread of well-differentiated malignant pneumocytes along alveolar septae. **C:** Pink acellular mucus fills the alveoli of this mucinous BAC photographed at low magnification. **D:** At higher magnification of **C**, mucous vacuoles are present in apex of columnar cells lining alveoli. **E:** In this invasive adenocarcinoma, there is fibrosis at the center of a tumor that exhibits extension of tumor cells. **F:** High magnification of this tumor (**E**) reveals a sclerotic response to tumor cells with pink fibers aligned parallel to the elongated fibroblastic nuclei. (See color plate.)

or absence of stromal invasion and cannot be reliably used to make this important distinction.

Generally, the aspirate of BAC[266] is cellular with minimal inflammatory infiltrate and contains two-dimensional monolayer sheets of uniform cells.[263,264] In contrast, cytological features such as three-dimensional balls, papillary clusters, marked nuclear atypia, and background necrosis are characteristic of invasive adenocarcinoma, but not BAC, and it is important not to overlook these invasive signs. Nuclei are pale staining and round with nuclear grooves in cells from nonmucinous tumors. In mucinous tumors, extracellular mucin is visible.[267] These cytological features may also be evident in advanced and invasive adenocarcinomas and in part responsible for the 35% overall accuracy of FNA for specific diagnosis of adenocarcinoma.[268] It is currently recommended that a specific diagnosis of BAC not be made on a cytology specimen.[226]

**Immunohistochemisty of Bronchioloalveolar Carcinoma**   BAC is a relatively slow-growing tumor and difficult to culture in immunohistochemical studies support this biological behavior in vivo. Growth fraction estimated by Ki-67 labeling is reported to be 11% in pure BAC and increases to 35% in invasive adenocarcinoma.[269,270] These tumors often have proliferative margins but nonproliferating central zones. Otherwise, the immunohistochemical and other molecular features of BAC are similar to invasive carcinoma and are discussed later.

## INVASIVE ADENOCARCINOMA

Invasive adenocarcinoma, in contrast to BAC, destroys the alveolar septae rather than using them as a framework for spread and metastasizes through the lymphatics to LNs rather than through the airways. Invasive adenocarcinoma is now the most common form of lung carcinoma.[271] Metastatic rates for even small (stage I to II) peripheral adenocarcinomas overall is 17% and is higher (31%) in more poorly differentiated carcinomas.[272] Distant metastases are also common even in stage I tumors particularly those that are high grade.[273] The invasive adenocarcinoma category is quite heterogeneous in its both morphological and molecular features, as discussed later.

**Histology of Adenocarcinoma**   Invasive adenocarcinoma (Fig. 22.11) is distinguished from pure BAC by extension of nests of glandlike cells frequently containing mucus vacuoles into a proliferative, fibroblastic stroma with destruction of bronchi and alveolar walls. Tissue invasion permits cells to gain access to the lymphatic and vascular channels of the lung so that spread of invasive adenocarcinoma is typically by LN or hematogenous metastasis, in contrast to BAC with its exclusively intrapulmonary spread.

The scarring (desmoplasia) that occurs in invasive tumors is chemically and morphologically distinct from that occuring in response to infection or ischemia.[274–276] Rather than representing a preexisting focus from which tumor arises, as implied in the now-outmoded term *scar carcinoma*, scarring is thought to be stimulated directly by tumor. Scarring of invasive adenocarcinoma is also distinct from collapse of the stromal framework that occurs in BAC.[232]

The histological features that distinguish adenocarcinoma from other invasive carcinomas are glandular differentiation and mucin production. The glandular elements and mucin vacuoles of adenocarcinoma may be arranged in many different patterns and these various arrangements are the basis of the division of adenocarcinoma into several different subgroups. The most common pattern is the acinar pattern in which tumor cells form glandlike or tubular structures. More uncommon are the papillary, solid, and signet ring patterns of growth. Detailed discussion of the many different variants is contained in several excellent reviews and atlases.[1,60,271,277] The papillary and micropapillary subtypes are composed of tufts of cells projecting into alveolar spaces with central vascular cores in the

papillary variant and without vascular cores in the micropapillary variant. The significance of papillary and micropapillary patterns is their poor prognosis[278,279] and their relatively high EGFR mutation rate (approximately 35%).[280]

Demonstration of mucus vacuoles in mucicarmine or alcian blue stains may be crucial for the diagnosis of this tumor type. However, small amounts of mucin are also produced by other types of NSCLC and for this reason, the presence of mucin in 10% or more of tumor cells has been set as a threshold for the diagnosis of adenocarcinoma.[60]

Current grading of adenocarcinoma is based on the resemblance of tumor to normal lung tissue. Recent studies have suggested that tumor grade,[272] nuclear grade,[281] necrosis,[281] lymphatic invasion,[281,282] and the presence of >25% papillary growth component[282] have may be indicators of aggressive behavior. Even so, the predictive accuracy of these features is not sufficient to allow extrapolation to individual cases. Eight percent of small, well-differentiated adenocarcinoma is reported to have metastases at the time of surgery. The presence of an intratumoral fibrotic response may prove to be a valuable grading marker but is difficult to quantify in cross sections and impossible to evaluate in needle biopsies.

**Cytology of Adenocarcinoma**   The cytological appearances of adenocarcinoma are complicated by the heterogeneity of this group of tumors. Diagnosis is based on overall architecture and individual cellular details (Fig. 22.12). Cytological specimens may show groups of cells with glandular, papillary, or bronchioloalveolar patterns but as noted previously, diagnosis of specific subtypes of adenocarcinoma is not possible by cytological examination alone. Cell aggregates may form monolayer sheets, three-dimensional cell balls, papillary structures, or flat groups with a central lumen. Cytoplasm may

**FIGURE 22.12**   Cytology of adenocarcinoma showing Papanicolaou-stained cluster of adenocarcinoma cells. These are large cells with high N/C ratio and prominent nucleoli (dark circular structure in nucleus [Nucl]). Under the microscope, the cell cluster has a three-dimensional structure and a mucus vacuole (Muc) is present at one margin of the cluster. *MC* indicates smaller mucociliary cell. (See color plate.)

be vacuolization or may be granular and is usually translucent. Nuclei are eccentrically placed and have prominent nucleoli that may be misshapen rather that perfectly rounded. Micropapillary adenocarcinomas, a variant with poor prognosis and EGFR association reported by Miyoshi et al.[279] as mentioned previously, are recognizable in cytology preparation by their micropapillary structures. These are composed of tumor cell aggregates without central fibrovascular tufts. Adenocarcinomas are only infrequently detected in sputum and because the majority of adenocarcinomas are more peripheral tumors. Transthoracic FNA is most likely to yield a diagnosis especially in peripheral nodules >2.0 cm with a sensitivity and specificity of 0.9 and 0.97, respectively.[62]

### Diagnostic Immunohistochemistry of Adenocarcinoma

A major practical question facing the pathologist on discovery of adenocarcinoma in the lung is the organ site of origin since many adenocarcinomas found in the lung are metastatic. The detailed immunophenotypic characterization of lung adenocarcinoma has done much to address this question. Perhaps the most useful protein biomarker in this regard is TTF-1 (Fig. 22.13). This protein is one of the master regulatory genes for lung development. It is a transcription factor that regulates the expression of surfactant, Clara cell proteins, and several others that are important in lung development.[283,284] TTF-1 is first expressed in the laryngotracheal diverticulum, then, for the next few weeks, in the bronchial epithelium. Expression then shifts to the alveolar epithelium where it is found in the adult.[285] In lung cancers, this protein is expressed by many types of primary lung tumors including adenocarcinoma, SCLC, LCLC, and carcinoid but usually not by squamous carcinoma (Table 22.3). The *TTF1* gene has recently been shown to reside in a region of amplification.[286,287] Gene amplification is associated with overexpression of the protein, but overexpression may occur in the absence of amplification.[288]

A second marker set that addresses the question of tumor site of origin are the CKs. Well-differentiated lung adenocarcinoma has a CK profile that is distinct from squamous carcinoma and from metastasic adenocarcinomas arising below the diaphragm. Most pulmonary adenocarcinomas are CK5/6−/CK7+/p63−/CK20−, while squamous tumors are usually CK 5/6+/CK7−/p63/CK20−. Other primaries such as breast, ovary, pancreas, and endometrium may also be CK7+/CK20−.[289,290] Carcinomas of colon are usually CK7−/CK20+[291,292] and may, in addition, produce the gastrointestinal marker, caudal-related homeobox 2 (CDX2).[290,293,294] A CK7/CK20/CDX immunohistochemical panel may thus be useful in the distinction of pulmonary adenocarcinoma from tumors of the gastrointestinal tract metastatic to the lung.[295]

Other proteins that could reflect peripheral airway origin are the surfactant proteins including surfactant protein A (SPA) and surfactant protein C (SPC), which are expressed in more than half of adenocarcinomas.[296–299] The utility of these markers is limited by relatively low sensitivity[70,300–302] of the immunohistochemical assay and by expression of many of the surfactant proteins by nonpulmonary tumors.[303] TTF-1 and the CKs are generally the more specific and useful of the discriminators of pulmonary adenocarcinoma.

### Molecular Pathology of Adenocarcinoma

The rapid expansion of technologies available to examine adenocarcinomas during the past 2 decades has led to the deciphering of complex molecular pathology that drives growth and metastases of these tumors. The molecular abnormalities of adenocarcinoma are not only of intrinsic biological interest but also provide targets for therapeutic intervention and can be used to predict response to new targeted agents. Molecular pathology is probably better defined for adenocarcinoma than for other tumor types because of its high frequency, surgical accessibility, and heterogeneity and because of the early success in identifying clinically important molecular pathways in this tumor type.

### Gene Mutations in Adenocarcinoma

***KRAS***   Among the first of the molecular changes of clinical significance identified in pulmonary adenocarcinoma was point mutation in the *KRAS* gene. This gene encodes a

**FIGURE 22.13**   Immunohistochemical staining patterns for several biomarkers reported to be of diagnostic and prognostic significance in adenocarcinoma (see text). **A:** TTF-1, nuclear staining; **B:** CEA, cytoplasmic staining; **C:** p27, nuclear staining; **D:** p53; strong nuclear staining (mutant pattern); **E:** COX-2, cytoplasmic staining; **F:** MIB-1 (Ki67); nuclear staining. (See color plate.)

membrane-associated protein that is a key link in the tyrosine kinase signaling cascade in cancer cells. Mutation in this gene results in a constitutively active protein that enhances cell proliferation and induces malignant transformation.[304,305] In 1988, Rodenhuis et al.[306] reported that *KRAS* mutation was present in 9 of 35 clinical samples of adenocarcinoma and subsequently *KRAS* mutation prevalence has ranged from approximately 10% to 40%.[307–315] The frequency of *KRAS* mutation increases with disease stage,[316] ranging from 12.5% of single nodules to 40% of tumors with satellite nodules to 60% of cases of intrathoracic spread of tumor. Initially, *KRAS* mutation was reported as negative prognostic marker[307] but the prognostic significance of mutation was not initially confirmed. A recent analysis of available prognostic data concludes that *KRAS* is a weakly negative prognostic indicator.[317] There is a strong association between smoking and *KRAS* mutation in adenocarcinoma.[318–320]

**TP53**    Point mutation in the *TP53* gene is also common in lung adenocarcinomas, occurring in 35% of these tumors and has been associated with poor outcome.[321,322] Mutation is uncommon in pure BAC but is found in 11% of adenocarcinomas of mixed invasive/BAC subtype and in 48% of tumors that are purely invasive,[323] suggesting a role for *TP53* in progression to aggressive forms of invasive peripheral lung cancer. *TP53* mutation occurs in association with *KRAS* in a small proportion (<5%) of adenocarcinomas and appears to occur independently.[320,324]

**EGFR**    EGFR-blocking agents are now available that are most effective in *EGFR* mutant tumors and for this reason, the most clinically relevant of the mutations reported to date in lung cancer are point mutations and deletions of the EGFR gene. Reported independently by two Boston groups in 2004,[245,246] point mutations were found in exons 18 and 21 and deletions in exon 19, the coding region for the tyrosine kinase domain of EGFR. The mutations increase sensitivity of tumor cells to small molecule EGFR blockers, erlotinib (Tarceva) and gefitinib (Iressa). In a large series of tumors from Japan, Taiwan, Australia, and United States, EGFR mutation is closely correlated with gender (female), nonsmoker status, and Asian ethnicity.[84] Not all EGFR mutations are equally predictive of survival or response to EGFR blockers and mean survival in treated tumors with exon 19 deletion is longer than survival in treated tumors with point mutation.[325,326] Finally, resistance to EGFR blockade may be acquired during treatment and has been attributed to mutation in *EGFR* exon 20 (T790M) in half of the cases[327,328] and acquired amplification of the *c-met* gene in another 20%.[329,330] C-met amplification is present in <5% of untreated tumors.[330]

As indicated previously, adenocarcinoma is a histologically heterogeneous tumor with many different patterns of growth. The correlation between histological subtype and *EGFR* mutational status is not completely resolved. Initially, it was reported that mutations occurred predominantly in BAC.[246] Subsequent studies using strict noninvasive WHO criteria have

had conflicting results with some studies finding few if any tumors with pure or predominant BAC to be mutant,[84,280] while others find the frequency of *EGFR* mutation in pure nonmucinous BAC higher than in invasive adenocarcinoma[331] or mucinous BAC.[332] Recently, it has also been reported that adenocarcinomas with predominantly papillary or micropapillary morphology are more likely to be *EGFR* mutant[280] than nonpapillary tumors. In view of these complexities, it seems likely that direct mutational analysis of adenocarcinoma will continue to be required for accurate assessment of biological behavior and prediction of treatment outcome regardless of histological subtype.

Several studies have reported that there is a mutually exclusive relationship between EGFR mutation and Ki-RAS mutation and cases harboring both mutations are unusual.[84] While EGFR mutation is associated in nonmucinous tumors in nonsmokers, Ki-RAS mutation is often present in mucinous tumors and in smokers, suggesting different carcinogens may affect neoplastic development in tumors harboring the separate mutations.

**STK11 (LKB1)**    *STK11 (LKB1)* encodes a serine-theonine kinase that coordinates a variety of cellular processes including cell polarity, regulation of proliferation, and control of protein synthesis.[333] STK11 is mutated in the germline DNA of patients with Peutz-Jeghers syndrome,[334,335] an hereditary condition that includes melanocytic macules of the lips, multiple gastrointestinal hamartomatous polyps, and an increased risk for various neoplasms, including gastrointestinal cancer and is thus considered a tumor suppressor gene. Approximately 30% of lung adenocarcinomas harbor an inactivating mutation of STK1,[336–338] but mutation is rare in other lung tumor types. Mutations consist of nonsense point mutations and frame shifts all of which predict a truncated protein with an incomplete catalytic domain.[336] Mutational inactivation of SKT11 is frequently associated with mutation of *KRAS*,[337] suggesting synergy between the tumor SKT11 tumor suppressor gene and the *KRAS* oncogene. The full clinical relevance of mutated SKT11 is to be determined and it is not yet clear whether mutation can be a prognostic marker or predictor of response to targeted agents.

**EML4-ALK Fusion Gene**    A new oncogene has recently been discovered that is the result of a small inversion in chromosome 2p.[339] The inversion results in the fusion in opposite orientations of a gene called echinoderm microtubule-associated protein-like 4 (*EML4*) and anaplastic lymphoma kinase (*ALK*), a gene that is also a fusion partner in large cell lymphomas. The new gene was discovered in a complementary DNA (cDNA) expression library created from a patient with NSCLC and was shown to transform T3T fibroblasts. The gene has been detected in 4% of a large series of adenocarcinomas from Japan[340] but not in other tumor types. Emerging data indicates that the mutation is also present in Western tumors at approximately the same frequency and tumors harboring the mutation have a consistent invasive adenocarcinomatous morphology. It seems that oncogenes resulting from rearrangements of tumor

DNA are likely to be frequent and could present therapeutic targets in the future.

## High-Throughput Mutational Analysis

Finally, the mutations described previously were discovered separately over many years. Recent technical advances have made it possible to rapidly sequence the genome of separate tumors to provide a complete mutational profile of all expressed genes.[338] Recently, this technological approach has been employed to evaluate 188 adenocarcinomas for the presence of mutations in 623 genes with known or potential relationships to cancer. Over 1000 mutations were identified in 163 of the tumors. Mutations were found in 26 genes at a significant frequency. The four most commonly mutated genes unsurprisingly were *p53*, *KRAS*, *STK11*, and *EGFR*. Most of the remaining mutations were point mutations and were present in less than 10% of tumors. Notably, most tumors had more than one mutation and the number of mutations per tumor was significantly higher in smokers (maximum 49) than in nonsmokers (maximum 5) consistent with a higher degree of genetic instability in tumors of smokers. This project identified several new potential targets for therapeutic intervention that will take considerably more time to fully assess than it took to identify them. The relatively low frequency of the mutations suggests that in the future, sequencing of a large number of genes will be required to identify therapeutic targets and that sequencing of single genes may be replaced by high-throughput global sequencing of individual tumor genomes.

## Molecular Changes Detectable by In Situ Methods: Immunohistochemistry and Fluorescence In Situ Hybridization

IHC and FISH have been used to assess levels molecules that may be therapeutically useful or elucidate the biology of adenocarcinoma. IHC was applied in adenocarcinoma to demonstrate that the expression of the tyrosine kinase receptor, EGFR, is less frequent and more heterogeneous in adenocarcinoma than in squamous carcinoma.[25] EGFR is strongly expressed in nonmucinous BAC (Fig. 22.14) and early anecdotal reports of dramatic responses of tumors with nonmucinous BAC morphology suggested that expression levels of EGFR might predict response to EGFR blockade. However, large subsequent IHC studies have had mixed outcomes with some studies indicating no relationship between EGFR level[341,342] and effectiveness of anti-EGFR treatment but others suggesting improved response in EGFR *positive* non–small cell tumors regardless of histology type.[343,344] Whatever the explanation for this discrepancy, it seems unlikely that EGFR protein level by itself will be a reliable predictive marker but may provide added insight into the biology of adenocarcinoma and, in the proper context, could be of clinical use.

A mechanism for the overexpression of EGFR was elucidated when it was observed and subsequently confirmed that high EGFR gene copy number is associated with overexpression of EGFR protein[345,346] in NSCLC including adenocarcinoma.

**Non-mucinous BAC HER2/*neu* <150 and pMAPk <100**

**Non-mucinous BAC HER2/*neu* >150 or pMAPk >100**

**FIGURE 22.14** Immunohistochemical stains of two morphologically similar BAC. Both tumors strongly express EGFR but on the upper tumor sufficient levels of HER-2/*neu* to be visible in immunostains. Activation of intracellular signaling through the mitogen-activated protein (MAP) kinase pathway as reflected in phosphorylated MAPK (pMAPk) immunostaining levels is strongest in the lower tumor. *BAC*, bronchioloalveolar carcinoma; *EGFR*, epidermal growth factor receptor; *H&E*, hematoxylin and eosin; *pMAPk*, phosphorylated MAPK. (See color plate.)

However, EGFR protein overexpression may occur in the absence of high gene copy number and protein level does not therefore predict gene copy number. As reviewed elsewhere in this volume, high EGFR gene copy number has been found to independently predict outcome in patients treated by EGFR blockade.[343,344,347,348]

Many markers have been reported to be related to prognosis in adenocarcinoma including carcinoembryonic antigen (CEA),[349] p53,[331] p27,[350] cyclooxygenase-2 (COX-2),[351] and MIB-1 index (Ki67 labeling) (Fig. 22.13).[352] However, only two markers are significantly correlated with the prognosis of early stage adenocarcinomas including BAC and their clinical impact has been minor to date.

## High-Throughput Gene Expression Arrays

Heterogeneity in lung cancer histomorphology is now increasingly evident but the first studies to highlight the extent of this striking heterogeneity were molecular. Gene expression array analyses have demonstrated that adenocarcinomas can be divided into several groups, at least one of which has prognostic importance.[96,97,207,353–355] This prognostically important group expresses markers that have been previously associated with neuroendocrine differentiation and has a significantly worse prognosis than other forms of pulmonary adenocarcinoma.

## Histogenesis of Central Airway Adenocarcinoma

Many aspects of the histogenesis of invasive adenocarcinoma have been discussed under BAC. However, it should be pointed out here that a minority of adenocarcinomas

is thought to arise from the bronchial gland or mucosal epithelium. These are endobronchial or central airway lesions that grow as plaques or polyploid lesions frequently with preservation of the overlying epithelium.[356] Histologically, these tumors have acinar or cribriform patterns, such as salivary glandtype adenocarcinoma and occur about 10 years earlier than adenocarcinomas of the peripheral airways.[107] Tumor cells are mostly positive for lactoferrin. The frequency of central adenocarcinoma type is not entirely clear since, in many cases, growth to large size and destruction of tissue around the sites of origin of invasive carcinoma may result in underestimation of the true frequency of this tumor type. These tumors have not been well characterized as to cell of origin and it is possible that they arise from the same central respiratory mucosa as squamous carcinoma and large cell carcinoma.

## MESOTHELIOMA

Mesothelioma is a malignant tumor of cells lining the pleural cavity. It is a tumor that results from exposure to asbestos fibers, but other causative factors may be involved in its genesis including exposure to SV-40 virus and radiation. Most patients with mesothelioma present between the ages of 50 and 70 with chest pain and dyspnea and less often with weight loss, cough, or fever.[357] Eighty to ninety-five percent of patients have pleural effusion. The tumor may begin with multiple small lesions on the parietal pleura that later coalesce and encase the lung. Findings associated with a better prognosis include epithelial histology, younger age, absence of pain and weight loss, and good performance status.[358] Median survival in mesothelioma is less than 1 year.[359,360] The poor survival is due to uncontrolled growth of neoplastic mesothelial cells with spread of tumor over pleural surfaces and nodal metastases but distant metastases are infrequent. Death is usually due to respiratory failure and treatment is aimed at local control.

### Asbestos and Mesothelioma
Although interstitial lung disease caused by asbestos was recognized at the turn of the 20th century,[361] the carcinogenic properties of asbestos were not appreciated and it was another 60 years before an association between mesothelioma was established.[362]

Since that time, the risk posed by the various types of asbestos has been quantified.[357,363] Asbestos is a group of silicate minerals that form fibers with somewhat variable properties. There are two forms of asbestos, serpentine and amphibole. These two forms are further subdivided. The only form of serpentine asbestos is chrysotile fiber, which is long, curly, and pliable and is more easily broken down and removed from the lungs.[364] It is considered less hazardous than amphibole fibers. Amphibole asbestos is divided into several types including amosite, crocidolite, and anthophyllite, which form short, straight, and stiff fibers that are favored in commercial and industrial processes

for their chemical and physical stability. Several forms of nonindustrial asbestos are also found in soils including tremolite, actinolite, and zeolite. Asbestos fibers in lungs of patients with mesothelioma are over 95% amphibole[365] and amphibole exposure is much more likely to result in mesothelioma than chrysotile exposure.[363]

Asbestos exposure may result in several pleural changes that precede mesothelioma including pleural effusion and pleural plaque. Pleural effusion has a peak incidence in the 2nd decade after exposure and pleural plaque progressively increases in frequency from 10 to 50 years after exposure.[366] By contrast, the prevalence of mesothelioma begins to increase approximately 25 years after exposure and continues to increase indefinitely thereafter.[366,367] However, a direct relationship between the benign pleural lesions associated with asbestos exposure and the future occurrence of mesothelioma has not been established.[357]

The prevalence of mesothelioma has increased in parallel with increasing use of asbestos[367] and its occurrence is associated with cumulative exposure.[363] The incidence may be five times higher in heavily exposed workers[368] than in those with low to moderate exposure.[369] However, not all cases are associated with heavy asbestos exposure and the roll of radiation and SV-40 exposure in these patients is currently under study (see succeeding discussion).

### Histology of Mesothelioma
Mesothelioma is frequently difficult to diagnose, in part, because it is histologically heterogeneous and, in part, because in well, differentiated cases, it may resemble reactive pleural conditions or adenocarcinoma of lung (Fig. 22.15). Four subtypes of mesothelioma are recognized in the most recent WHO classification,[60] the epithelial, sarcomatoid, desmoplastic, and biphasic. Epithelial mesothelioma shows a pattern of tumor cell growth that resembles that of reactive mesothelium but includes formation

Mesothelioma        Adenocarcinoma

**FIGURE 22.15** Histological sections showing similarity between epithelial type mesothelioma and adenocarcinoma. (See color plate.)

of tubules, acini, papillae, or sheets. These tumors invade normal adjacent tissues including fat and skeletal muscle. Fifty percent of mesotheliomas are of this type.[359] Sarcomatoid mesothelioma is composed of malignant spindle cells that resemble sarcoma but may express CKs demonstrable in immunohistochemical tests. This type represents about 16% of mesotheliomas and carries a worse prognosis than the epithelial type.[370] Desmoplastic mesothelioma is defined as a bland-appearing sarcomatoid mesothelioma in which more than 50% of the tumor consists of hypocellular, dense collagenous stroma containing slitlike spaces.[371] Due to its bland appearance, this histological subtype may be a diagnostic challenge for the pathologist and may be misinterpreted as a reactive fibrosing process. The last histological subtype is biphasic mesothelioma, which contains both epithelial and sarcomatoid components and accounts for the remaining 34%.

### Cytology of Mesothelioma

Cytological specimens are cellular and composed of cells that resemble benign mesothelial cells, but show more atypia, nuclear enlargement, and large cell clusters. Cells show a range of atypia within the same specimen rather than two obvious populations of cells (normal mesothelial cells and malignant cells), as would be seen with involvement by carcinoma. Giant cells and signet ring forms can be seen. The differential diagnosis includes primary or metastatic carcinoma. Thus, a cell block preparation on which immunohistochemical stains can be performed is essential. In some cases, electron microscopy can be applied to cytologic specimens.[372]

### Immunohistochemistry of Mesothelioma

Mesothelioma may resemble lung carcinoma, especially adenocarcinoma. While in some cases, the clinical, radiographic, and histologic features point to the correct diagnosis, in many cases, mesothelioma cannot be distinguished from carcinoma on purely morphological grounds. The most common diagnostic problem in this regard is distinguishing mesothelioma from epithelial tumors, particularly adenocarcinoma. Several studies testing large numbers of cases with panels of antibodies against candidate markers to distinguish mesothelioma from carcinoma have been reported. In a study by Ordonez,[373] 19 candidate immunohistochemical biomarkers were evaluated on a set of 110 lung tumors including 60 mesotheliomas and 50 adenocarcinomas. Antibodies that proved most sensitive in identifying mesothelioma were those against calretinin (100% sensitivity, 92% specificity), CK5/6 (100% sensitivity, 98% specificity), and WT1 (93% sensitivity, 100% specificity). Antibodies most accurate for identifying adenocarcinoma were TTF-1 (74% sensitivity, 100% specificity), TAG72 (88% sensitivity, 100% specificity), CEA (88% sensitivity, 100% specificity), and CD15 (72% sensitivity, 100% specificity). Another candidate marker recently added to this list is podoplanin, which is recognized by monoclonal antibody D2-40.[374] This marker has nearly 90% sensitivity for epithelioid mesothelioma[375–377] but has low sensitivity for sarcomatoid mesothelioma and cross-reacts with metastatic 65% of serous carcinomas[375] and approximately 15% of squamous carcinomas.[378]

Thus, a substantial list of antibodies is now available with reasonable sensitivity and specificity for distinguishing mesothelioma from other tumors in tissue sections (Table 22.3). It is likely that no single panel will distinguish all mesotheliomas and a small number of poorly differentiated tumors will not be identifiable through IHC. Optimal panels for distinguishing mesothelioma from adenocarcinoma have been suggested[379–381] and most include a limited number of antibodies. Which antibodies are employed in these panels will ultimately depend not only on sensitivity and specificity but also on clinical context and local resources available for addressing this problem as well.

Electron microscopy can also be helpful in the diagnosis of mesothelioma. By electron microscopy, tumor cells have microvilli, which are longer and thinner than those seen in adenocarcinomas, and the length/diameter ratio can be used to favor one tumor versus the other. Of note, electron microscopy is less useful in poorly differentiated epithelial tumors and in sarcomatous tumors.[382]

### High-Throughput Gene Expression Arrays

Several studies utilizing gene expression microarray technology to evaluate mesothelioma have been published in the past few years.[383,384–387] A substantial gene expression database is available for mining the high-density data that is the product of these studies. The objectives of these studies have been to detect genes that are overexpressed and underexpressed in mesothelioma in comparison to normal tissue, to identify prognostic markers, and to define subsets of genes that predict response to treatment. These studies have constructed gene classifiers that are reported to predict outcome with an accuracy in the range of 68% to 88%.[384,386,387] However, there is little overlap in the genes incorporated into the various classifiers and when compared to clinical predictors such as stage, histology, and *p16* deletion status, no independent or additive predictive value is found.[387] At the present time, therefore, expression microarrays can be regarded as a valuable source of biological data that is not completely explored and does not yet have an established clinical role.

### Molecular Correlates

The mutations, gene copy number abnormalities, and patterns of protein expression that drive carcinogenesis in epithelial lung tumors are largely absent from mesothelioma. The underlying molecular lesions responsible for uncontrolled tumor cell growth in mesothelioma are not well understood. It is known that asbestos may induce phosphorylation of EGFR[388] stimulating tumor cell growth and spread but *EGFR* mutations commonly present in adenocarcinoma have not been found in mesothelioma.[389] Genes that are overexpressed and may represent activation of

growth signal transduction include *hepatocyte growth factor (HGF)*[390] and *notch*,[391] but mutations and structural alterations affecting these genes have not been explored to date. In fact, genomic alterations in mesothelioma are numerous[392] but consistent abnormalities affecting specific genes are not defined.

It has been proposed that reactive oxygen and nitrogen species produced in response to asbestos fibers directly induce DNA damage in mesothelial cells, causing adduct formation and ultimately mutation of important tumor suppressor genes inducing NF2, p15, and p16. In addition, SV-40 sequences have been identified in mesothelioma.[393] SV-40 large T antigen is able to bind RB and p53 protein. Binding of these proteins may result in tumor cell proliferation and chromosomal instability. The role of SV-40 in mesothelioma, however, has yet to be confirmed and clinical consequences of this possible association are not established.

## PATHOLOGICAL STAGING OF LUNG CANCER

Pathological staging remains a definitive means of quantifying extent of disease. Staging considerations differ for non–small cell carcinoma and small cell carcinoma and are discussed separately.

**Staging of Non–Small Cell Carcinoma** Revised staging definitions for NSCLC have recently been compiled by the IASLC and are summarized in Table 22.5. This revision is the result of an international effort involving 46 data sources from 19 countries that began in 1996.[394–398] Data from 67,725 NSCLC patients with 5-year follow-up and complete staging information were analyzed to arrive at the final revision. Changes made in the staging system include refinement of the T-stage criteria, revision of the classification of intrapulmonary multifocal tumor, and stratification of the M category as follows:

1. Analysis of T1 tumors indicated separation of Kaplan-Meier survival curves for tumors less than 2 cm (median survival 103 months) versus tumors between 2 and 3 cm (median survival 124 months). To accommodate this difference, the T stages 1a and 1b were introduced.
2. Analysis of outcome data prompted the reclassification of tumors with separate nodules in the same lobe from the T4 to T3, those with nodules in separate ipsilateral lobes as T4 and those with nodules in the contralateral lung as M1.
3. M1 disease was subdivided into an M1a category that consists of intrathoracic metastases to the contralateral lung or to either pleura and an M1b category that includes distant metastasis.

Details of the changes that are incorporated into the new staging scheme are provided elsewhere.[394–398]

An important component of staging is the assessment of pleural invasion. Assessment of pleural invasion is not always straightforward since tumors may abut the visceral pleura without invading it. Recent studies have indicated that elastic stains may be helpful and in some cases definitive in assessing whether true invasion of the pleura has occurred.[399–403]

If staging is based on pathologic evaluation of lung tissue and LNs, there is generally a migration from lower- to higher-stage disease (Table 22.6). Clinical staging tends to underestimate the extent of disease. It is important to note that the presence of enlarged LNs on CT scanning is not a reliable indicator of metastatic disease within those LNs. The specificity of this finding is only 70%. If enlarged size is taken as equivalent to metastatic disease, significant numbers of patients will be denied surgical therapy who might otherwise benefit. Mediastinoscopy can aid in the staging of these patients.

**Staging of Small Cell Carcinoma** SCLC is clinically staged as either limited or extensive disease. Limited stage generally refers to those tumors that are confined to the chest including supraclavicular LNs but without pleural effusion. Extensive stage refers to tumors that have metastasized beyond the chest and is equivalent to stage IV in the NSCLC staging system. Combination of chemotherapy and radiation is curative in approximately 10% of limited stage SCLC patients but is rarely curative in extensive stage disease. Limited stage SCLC therefore is initially treated with concurrent chemotherapy and radiation to the site of the primary lesion. This regimen results in more cures but may not be well tolerated. Patients with extensive-stage SCLC are initially treated with chemotherapy alone and radiation therapy is reserved for either resistant or symptomatic disease. It is therefore important for proper choice of treatment that SCLC be properly staged both clinically and pathologically.

## MICROMETASTATIC DISEASE

Despite apparently complete surgical resection, patients without detectable metastases have a 40% rate of relapse within 24 months. Furthermore, this group has an overall 5-year survival rate of roughly 60%. These numbers indicate that NSCLC disseminates early in its progression and causes significant mortality. Conventional histological sections may not be sufficiently sensitive to detect small numbers of tumor cells in regional LNs or distant tissue, such as bone marrow. By most accounts, a micrometastasis is defined as less than 0.2 cm in size, although many studies include much smaller cell clusters and even single tumor cells as micrometastasis. Several studies have suggested that micrometastatic disease may be efficiently detected by IHC. NSCLC tumor cells have been detected in up to 45%[404] of histologically negative LNs and 60% of histologically negative bone marrows.[405] Antibodies used tumor cell

**TABLE 22.5**  **Pathologic Tumor-Node-Metastasis Staging for Lung Cancer with Proposed Changes (*Italics*)**

| Descriptor | | | Definition |
|---|---|---|---|
| **Tumor (T)** | T0 | | No tumor |
| | TX | | Positive sputum or bronchial cytology, no apparent tumor |
| | TIS | | Carcinoma in situ |
| | T1 | | ≤3 cm in greatest dimension, surrounded by lung or visceral pleura, without bronchoscopic evidence of invasion more proximal than lobar bronchus (i.e., not in the main bronchus) |
| | | *T1a* | *Tumor ≤2 cm diameter; no visceral pleural or lobar bronchial involvement* |
| | | *T1b* | *Tumor ≤3 cm diameter; no visceral pleural or lobar bronchial involvement* |
| | T2 | | Tumor >3 cm but ≤7 cm or involve main bronchus ≥2 cm distal to carina or visceral pleura; or with hilar obstructive pneumonitis or atelectasis |
| | | *T2a* | *T2a Tumor >3 cm but ≤5 cm in greatest dimension* |
| | | *T2b* | *>5 cm but ≤7 cm in greatest dimension* |
| | T3 | | >7 cm or invades chest wall (including superior sulcus tumors), diaphragm, phrenic nerve, mediastinal pleura, parietal pericardium; or tumor in main bronchus <2 cm distal to the carina but without involvement of carina; or associated atelectasis or obstructive pneumonitis of entire lung; *or separate tumor nodule(s) in the same lobe* |
| | T4 | | Invades mediastinum, heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, carina, or vertebrae; or *separate tumor nodule(s) in different ipsilateral lobe* |
| **Nodes (N)** | NX | | Not assessed |
| | N0 | | No LN involvement |
| | N1 | | Ipsilateral peribronchial, hilar, or intrapulmonary node(s) |
| | N2 | | Ipsilateral mediastinal or subcarinal node(s) |
| | N3 | | Contralateral mediastinal or hilar nodes; any supraclavicular or scalene nodes |

| | V1 | | Vascular invasion present |

detection have included BerEP4, AE1/AE3, p53,[404,406] and CK2.[405,406] Patients with IHC detectable NSCLC in LNs and bone marrow show an increased risk for both relapse and shortened survival times.[404,407] However, whether IHC improves tumor cell detection sensitivity significantly beyond careful LN sectioning and thorough H&E evaluation is still debated.[408] Micrometastases do not have a specific designation in the current or revised staging systems.

Whether patients diagnosed with micrometastatic disease could benefit from postoperative adjuvant chemotherapy and/or immunotherapy therapy is yet to be determined.

Reverse transcriptase-polymerase chain reaction (RT-PCR) has also been evaluated as a method of detecting micrometastases and has been shown to be more sensitive than routine H&E.[409] However, both false-positive and false-negative results may occur. Correlation with histology to verify malignant

| TABLE 22.6 | Outcomes by Clinical Stage in Comparison to Pathology Stage | | |
|---|---|---|---|
| | | **5-Year Survival** | |

| | T4 Any N M0 | | |
| IV | Any T, Any N, M1 | ~1% | |

cytology, and use of more than one marker may be helpful.[409,410] In one study by Xi et al.,[411] 39 benign LNs and 38 tumor LNs were evaluated by screening for a panel of six markers by RT-PCR, resulting in a combination of three markers (SFTPB, TACSTD1, PVA), which provided the best classification of benign and malignant LNs. Such panels may increase the accuracy of this method.[411]

Micrometastatic tumor has been evaluated intraoperatively using intratumoral injections of color markers or radioactive isotope (technetium-99m) to detect grossly inapparent tumor in thoracic LNs (sentinel nodes). To date, results of these procedures have been promising[412–416] but controlled trials have not been reported, and clinical benefit has not been demonstrated. It is also not yet clear how positron emission tomography (PET) and PET/CT imaging, which improve the sensitivity of radiological staging procedures,[417–419] will affect the need to perform sentinel node sampling.

## MOLECULAR STAGING

Increasing understanding of the biology of specific tumor types and the availability of targeted therapies have prompted detailed molecular assessment of tumors and other biospecimens not only for diagnostic purposes but also to assess treatment strategies as well. Genomic analysis by gene expression array is already being used in the treatment of breast cancer, for example, and similar methods are being developed to assess recurrence or predict response to therapy of lung cancer patients. Potti et al.,[105] for example, studied 89 early stage NSCLC by Affymetrix microarray, using a lung metagene model to analyze numerous gene expression profiles that

predict recurrence. The gene expression data predicted recurrence better than clinical data.[105] More recently, Taguchi et al.[107] in a multi-institutional proteomic study discovered eight distinct mass/charge ratios that identified patients likely to respond to tyrosine kinase inhibitors (TKIs). The features were not predictive of response to standard chemotherapy. This is a promising study in that it was able to show reproducible results between institutions and suggests that it may not be necessary to directly sample tumor to predict response to targeted agents. Continued progress in this area of investigation could potentially alter the approach to treatment selection in lung carcinoma.

## THE PATHOLOGY REPORT

Despite the importance of the pathological diagnosis in lung cancer until recently, the surgical pathology report was not standardized and was left to the discretion of individual pathologists. The increasing standardization of diagnoses and requirements for specific information by clinicians, clinical trial administrators, billing personnel, and statistical/epidemiological workers has resulted in development of guidelines for the reporting of pathological diagnoses by several organizations.[420,421] A summary of the information that can be reasonably expected to appear on an adequate pathology report is listed in Table 22.7.

| TABLE 22.7 | Checklist for Lung Cancer Pathology Report |
|---|---|

1. Patient and specimen identifiers (forms, labels)
2. Type procedure performed to generate specimen
3. Fixation, processing (formalin, frozen, etc.)
4. Part of lung removed (bronchial site, lobe, lung)
5. Tumor size (preferably three dimensions)
6. Bronchus of origin
7. Distance from closest pleural margin
8. Pleural puckering
9. Distance from closest bronchial margin
10. Histological type (WHO classification)
11. Histological grade
12. Special procedures (immunohistochemistry, electron microscopy, etc.)
13. Other lesions in lung (2nd tumor, pneumonia, emphysema, clots, etc.)
14. LNs location
15. LNs positive
16. LNs negative
17. Invasion of other intrathoracic structures
18. Submitted metastasis
19. Pathology stage (pTNM, stage grouping)

## Appendix A. World Health Organization Classification of Lung Cancer

| Tumor Type | Code* | Tumor Type | Code* |
|---|---|---|---|
| **MALIGNANT EPITHELIAL TUMORS** | | **Carcinoid Tumor** | 8240/3 |
| **Squamous cell carcinoma** | 8070/3 | Typical carcinoid | 8240/3 |
| Variants: | | Atypical carcinoid | 8249/3 |
| Papillary | 8052/3 | | |
| Clear cell | 8084/3 | Salivary Gland Tumors | |
| Small cell | 8073/3 | Mucoepidermoid carcinoma | 8430/3 |
| Basaloid | 8083/3 | Adenoid cystic carcinoma | 8200/3 |
| | | Epithelial-myoepithelial carcinoma | 8562/3 |
| **Small cell carcinoma** | 8041/3 | | |
| Variant: | | PREINVASIVE LESIONS | |
| Combined small cell carcinoma | 8045/3 | Squamous carcinoma in situ | 8070/2 |
| | | Atypical adenomatous hyperplasia | |
| **Adenocarcinoma** | 8140/3 | Diffuse idiopathic pulmonary neuroendocrine cell | |
| Adenocarcinoma, mixed subtype | 8255/3 | Hyperplasia | |
| Acinar adenocarcinoma | 8550/3 | | |
| Papillary adenocarcinoma | 8260/3 | MESENCHYMAL TUMORS | |
| Bronchioloalveolar carcinoma | 8250/3 | Epithelioid hemangioendothelioma | 9133/1 |
| Nonmucinous | 8252/3 | /Angiosarcoma | 9120/3 |
| Mucinous | 8253/3 | Pleuropulmonary blastoma | 11012 |
| Mixed nonmucinous and mucinous or indeterminate | 8254/3 | Chondroma | 9220/0 |
| Solid adenocarcinoma with mucin production | 8230/3 | Congenital peribronchial myofibroblastic tumor | 8827/1 |
| | | Diffuse pulmonary lymphangiomatosis | |
| Variants: | | Inflammatory myofibroblastic tumor | 8825/1 |
| Fetal adenocarcinoma | 8333/3 | Lymphangioleiomyomatosis | 9174/1 |
| Mucinous ("colloid") carcinoma | 8480/3 | Synovial sarcoma | 9040/3 |
| Mucinous cystadenocarcinoma | 8470/3 | Monophasic | 9041/3 |
| Signet ring adenocarcinoma | 8490/3 | Biphasic | 9043/3 |
| Clear cell adenocarcinoma | 8310/3 | Pulmonary artery sarcoma | 8800/3 |
| | | Pulmonary vein sarcoma | 8800/3 |
| **Large cell carcinoma** | 8012/3 | | |
| Variants: | | **BENIGN EPITHELIAL TUMORS** | |
| Large cell neuroendocrine carcinoma | 8013/3 | **Papillomas** | |
| Combined large cell neuroendocrine carcinoma | 8013/3 | Squamous cell papilloma | 8052/0 |
| Basaloid carcinoma | 8123/3 | Exophytic | 8052/0 |
| Lymphoepithelioma-like carcinoma | 8082/3 | Inverted | 8053/0 |
| Clear cell carcinoma | 8310/3 | Glandular papillomas | 8260/0 |
| Large cell carcinoma with rhabdoid phenotype | 8014/3 | Mixed squamous cell and glandular papilloma | 8560/0 |
| | | | |
| **Adenosquamous carcinoma** | 8560/3 | **Adenomas** | |
| | | Alveolar adenoma | 8251/0 |
| **Sarcomatoid carcinoma** | 8033/3 | Papillary adenoma | 8260/0 |
| Pleomorphic carcinoma | 8022/3 | Adenomas of the salivary gland type | |
| Spindle cell carcinoma | 8032/3 | Mucous gland adenoma | 8140/0 |
| Giant cell carcinoma | 8031/3 | Pleomorphic adenoma | 8940/0 |
| Carcinosarcoma | 8980/3 | Others | |
| Pulmonary blastoma | 8972/3 | Mucinous cystadenoma | 8470/0 |

# Presentation, Diagnosis, and Staging

Antoinette J. Wozniak
Shirish M. Gadgeel

# Clinical Presentation of Non–Small Cell Carcinoma of the Lung

Lung cancer is a major cause of cancer-related mortality worldwide and is expected to remain a major health problem for the foreseeable future.[1] Although lung cancer remains predominantly a disease of men, the number of women diagnosed with the disease has risen dramatically over the last 2 decades. The median age at presentation in the United States is around 67 years old. However, about 10% of the cases occur in patients younger than the age of 50.[2]

The clinical manifestations of lung cancer are varied. Patients are usually asymptomatic in early stages of the disease. This is related to the sparse pain fiber innervation of the lungs and the significant respiratory reserve that both lungs provide. The lack of symptoms is particularly true for lung cancers that originate in the periphery of the lungs. Approximately 5% to 10 % of lung cancer patients are asymptomatic at presentation.[3,4] These cancers are often detected during evaluation for an unrelated medical problem or on a chest radiograph performed for preoperative evaluation. Screening to identify a greater proportion of lung cancer patients has been the focus of much effort over the last 3 decades, and this may lead to an increase in the percentage of lung cancer patients who are asymptomatic at diagnosis. In recent years, promising results have been reported with the use of high-resolution computed tomography (CT) scans. The applicability of CT scans or other methods as screening tools for lung cancer remains to be determined.

Most lung cancer patients who are symptomatic have advanced disease. In a series of more than 600 patients, 27% presented with symptoms related to the primary tumor.[5] Most of the patients had either symptoms related to metastatic disease (32%) or nonspecific constitutional symptoms such as anorexia, fatigue, and weight loss (Table 23.1). Outcomes of patients appeared to be better when they were asymptomatic at presentation, whereas patients who presented with symptoms related to metastatic disease fared the worst. Furthermore, patients with absence of symptoms and abnormalities on standard laboratory tests were very unlikely to have scan evidence of metastatic disease.[6,7]

A delay in reporting of new symptoms or change of existing symptoms by lung cancer patients has been observed. In a series from the United Kingdom, the median time between onset of symptoms and patients seeking medical attention was 12 months.[8] A further delay often occurs since primary care physicians may not consider lung cancer in the differential diagnosis.[9] Various reasons account for the delay in considering lung cancer as a diagnosis by physicians, including the nonspecific nature of lung cancer symptoms and the fact that common lung cancer symptoms are more often attributable to benign etiologies. The impact of this observed delay on patient prognosis is unclear.

## MANIFESTATIONS OF LOCAL DISEASE

**Cough**    Cough is the most common symptom reported at presentation by lung cancer patients. Cough is present at diagnosis in 50% or more of patients and eventually develops in nearly all patients who are not cured.[10,11] Cough in lung cancer may be related to many factors, including a central tumor, obstructive pneumonia, multiple parenchymal metastases, lymph node involvement, and pleural effusion. Even though cough is the most common symptom of lung cancer, it accounts as the only cause in about 2% of patients with chronic cough.[12]

Many lung cancer patients have underlying chronic obstructive pulmonary disease (COPD) and therefore may suffer from a chronic cough. Some smokers and former smokers also have a chronic cough referred to as *smoker's cough*. Hence, the patient or the patient's physician may ignore a gradual change in such a cough. A persistent change in the cough or acute exacerbation of COPD that fails to respond to therapy should prompt performance of a chest radiograph or even a CT scan. This evaluation is particularly important if the cough is not associated with fever or symptoms of upper respiratory tract infection or persists for longer than a week. Some of these patients are treated with multiple courses of antibiotics under the

| TABLE 23.1 | Symptoms at Diagnosis of Non–Small Cell Lung Cancer[3,53,87–89] |
|---|---|
| **Symptoms** | **Present at Diagnosis (%)** |
| Cough | 45–75 |
| Dyspnea | 40–60 |
| Weight loss | 20–70 |
| Chest pain | 30–45 |
| Hemoptysis | 25–35 |
| Bone pain | 6–25 |
| Fatigue | 0–20 |
| Dysphagia | 0–2 |
| Wheezing and stridor | 0–2 |
| None | 2–5 |

presumption of bronchitis or pneumonia, thereby delaying the diagnosis of lung cancer.

Treatment of cough is most successful if the underlying etiology can be addressed. Thus, tumor-specific therapy is most successful in relieving lung cancer–related cough. In patients with airway involvement by the tumor, patients may also benefit from the addition of beta$_2$-agonists such as albuterol.

Many lung cancer patients continue to suffer from a persistent, distressing cough despite appropriate tumor-specific therapy. It is important to evaluate and treat other potential causes of cough such as postnasal drip, gastroesophageal reflux, and bronchospasm. Opiates have been used with some success for their antitussive properties.[9] There is no evidence that one preparation of opiates is better than the other. Other antitussives such as guaifenesin, dextromethorphan, benzonatate, and levodropropizine may be tried, but they have had variable success in treating cancer-related cough.[13–16]

Inhaled lidocaine has been used to suppress cough.[13,17–19] A starting dose of 5 mL of 2% lidocaine solution, via a nebulizer, every 4 to 6 hours may be used. The dose may be increased if required. Generally, dosages greater than 15 mL of 2% lidocaine solution are avoided to decrease the risk of seizures, from systemic absorption of lidocaine through the airways. Patients should be warned about the potential for aspiration resulting from oropharyngeal anesthesia. Corticosteroids can also be helpful in treating cough, particularly when the cough is related to underlying bronchitis, radiation-induced lung damage, or lymphangitic metastases. In addition, inhaled sodium cromoglycate may help cough of lung cancer through the inhibition of afferent unmyelinated C-fiber activation. C-fibers are involved in cancer-related cough, probably from the release of bradykinin by cancer cells and from the stimulation of the C-fibers by the cancer.[20]

**Hemoptysis**   Hemoptysis in lung cancer varies in severity but commonly consists of blood-streaked sputum. The most common description by the patient is that of coughing up blood-tinged sputum for several days in succession.

Again, these patients are presumed to have bronchitis and are treated with antibiotics. The index of suspicion is raised if the symptom persists or recurs particularly in a patient who has a smoking history. It is prudent to initiate a workup immediately in a patient younger than 40 years with a smoking history who presents with hemoptysis. Although chest radiographs are usually abnormal in these patients, some may have a normal study. In these patients, further diagnostic studies such as sputum cytology, bronchoscopy,[21] and CT scans should be considered. Detailed history of hemoptysis is essential because presence of hemoptysis is a contraindication for the use of bevacizumab. In the clinical trial, Eastern Cooperative Oncology Group phase III trial (ECOG 4599) that evaluated the role of bevacizumab, presence of half a teaspoon of hemoptysis per episode was an exclusion criteria.[22]

The management of hemoptysis in lung cancer patients depends on the severity. Blood-streaked sputum does not require any specific therapy other than the therapy for lung cancer. More severe hemoptysis requires use of antitussives and advising the patient to sleep with the affected lung in the dependent position. In patients with advanced lung cancer, chest radiotherapy is the preferred treatment for moderate hemoptysis. In patients who have received prior radiotherapy, management of hemoptysis can be challenging.[23]

In certain cases, emergent thoracotomy with resection of the affected area could be considered. However, technical difficulties or the general condition of the patient may preclude such an approach. Endobronchial brachytherapy is another alternative for control of hemoptysis in patients who have received prior external beam radiotherapy. Selective embolization of bronchial arteries feeding the hemorrhagic area can also be considered in settings where such expertise exists.[24,25]

Massive hemoptysis, which is fairly uncommon in lung cancer patients, is immediately fatal in many cases. The initial management of these patients is securing the airway with intubation or emergent tracheostomy to allow efficient suctioning of the blood that floods the alveoli, leading to respiratory failure. Bronchoscopy can be performed for both diagnostic and therapeutic purposes. Bronchoscopic instillation of cold saline solution or vasoconstrictive agents and bronchial balloon tamponade are some of the therapeutic interventions that could be implemented.[26] Further management of hemorrhage should proceed based on the clinical condition of the patient. Management of hemoptysis in lung cancer patients requires sound clinical judgment. Many patients with this problem have a poor prognosis, and any interventions chosen for the hemoptysis must be consistent with the patient's prognosis.

**Chest Pain**   Chest pain or discomfort is a common symptom that may occur even in early stage lung cancer, without frank evidence of invasion of the pleura, chest wall, or mediastinum. The origin of such discomfort is unclear because the lung parenchyma is not supplied with pain fibers. Patients may develop retrosternal pain from hilar and mediastinal adenopathy or at times from pericardial involvement. Pain from pleural involvement or rib metastasis is usually more localized

and severe than the nonspecific chest pain associated with lung cancer. Appropriate analgesics, including narcotics, should be used along with definitive antitumor therapy.

It is not unusual for patients with chest pain to undergo evaluation for coronary artery disease, including cardiac catheterization. Given the prevalence of coronary artery disease among smokers, it is not surprising that such patients have been discovered to have lung cancer from a chest radiograph performed prior to or after coronary artery bypass surgery.

**Dyspnea** Dyspnea is a fairly common symptom in patients with lung cancer. Most lung cancer patients have dyspnea during the course of their disease.[27] Dyspnea could be from various causes, including the tumor itself or the underlying chronic lung disease, and/or could be multifactorial (Table 23.2). Patients could also experience dyspnea from the complications of radiation therapy administered with or without chemotherapy. Incidence of dyspnea is often higher when pain and anxiety are high.[28]

Management of dyspnea requires proper identification and treatment of the underlying etiology, with recognition that the tumor is not always the primary cause of the dyspnea. Symptomatic management of dyspnea includes judicious use of oxygen, opioids, and sedatives. Use of oxygen is clearly beneficial in the treatment of hypoxic patients with dyspnea.[29,30] The role of oxygen, in treating dyspnea in patients who are not hypoxic, is unclear. There are studies that suggest that oxygen may be helpful in patients with nonhypoxic dyspnea,[31,32] and based on this limited data, it is appropriate to offer a trial of oxygen in all cancer patients with dyspnea.

Opioids have been used to relieve dyspnea for many years. There is a concern about the potential of inducing respiratory failure with opioid use, particularly in patients with preexisting respiratory impairment.[33] However, studies in cancer patients suggest that opioids do not compromise respiratory function when titrated correctly.[34,35] Respiratory depression is more a function of rate of change of the dose of opioids and the

history of previous exposure to opioids.[36] Opioids administered through both parenteral and oral routes appear to be beneficial in relieving dyspnea.[37] Nebulized morphine was also assessed but was found to be no better than nebulized saline, when the data of randomized trials were analyzed.[37] Sedatives and tranquilizers have also been used to relieve dyspnea. Evidence supports the use of promethazine or chlorpromazine alone or in combination with morphine for the treatment of dyspnea, but the evidence for the use of benzodiazepines is lacking.[38–41] Systemic steroids should be considered in patients with acute exacerbation of COPD and in patients with treatment-related lung toxicity.

Dyspnea is an extremely distressing symptom for the patient and the family. Relief of dyspnea to the maximum extent possible should be a primary goal of the treating physician. Education regarding complimentary methods such as breathing and relaxation techniques has been shown to be helpful for patients dealing with dyspnea.[42] It is also important to educate the patient and the family about measures that can be taken to relieve dyspnea such as anticipatory administration of opioids, taking frequent rests during physical activities, and sitting near an open window or in front of a fan.

**Wheezing** Localized wheezing may be the presenting symptom in patients with disease in the major airways, particularly in the mainstem bronchi. This symptom should be distinguished from the generalized wheezing of bronchospasm. The patient is often able to tell from where the wheezing is emanating. This type of localized wheezing is often associated with cough.

Lesions that are primarily endobronchial, but are too proximal for resection, often require special management techniques. Newer techniques have improved the ability to control such cancers and thus the symptoms from these lesions. High-dose brachytherapy, either alone or in combination with external beam radiation, can be highly effective in palliating such lesions.[43] Photodynamic therapy techniques have improved recently with the development of better photosensitizing agents and can be effectively employed in this setting.[44] Laser therapy can also be useful for this problem, particularly when other treatments have failed.[45] Stents made of different materials have been used, following tumor debridement to relieve airway obstruction, primarily when the obstruction is in central airways.[46,47]

**Pneumonia** Pneumonia can be a common presentation of lung cancer. Patients may not have the classical symptoms of pneumonia such as high fever, pleuritic chest pain, cough, and dyspnea but may have more generalized symptoms such as fatigue. A chest x-ray performed for evaluation may reveal lobar consolidation or atelectasis. These patients may not necessarily have pneumonia but are treated for pneumonia based on chest x-ray findings and despite lack of resolution are continued on different antibiotics. It is essential that follow-up x-rays are performed for evaluating resolution of the original findings.

# MANIFESTATIONS OF LOCALLY ADVANCED DISEASE

**Hoarseness**   Hoarseness in lung cancer patients is almost always caused by the involvement of the left recurrent laryngeal nerve resulting in left vocal cord paralysis. Because the left recurrent laryngeal nerve passes under the arch of the aorta, it is susceptible to involvement by primary tumors or lymphadenopathy in the aortopulmonary window. It is not unusual for patients with hoarseness to have had laryngoscopy and CT scans of the neck performed and then told that they have vocal cord paralysis, without any chest evaluation. New-onset hoarseness caused by involvement of the left recurrent laryngeal nerve is usually indicative of surgically unresectable lung cancer. Hoarseness may also be observed after surgery for lung cancer, because the recurrent laryngeal nerve may have to be sacrificed for complete resection of the tumor.

Vocal cord paralysis leads to voice change, in addition to hoarseness, and could also cause aspiration, dyspnea, and/or dysphagia. Hoarseness may improve with treatment of lung cancer, but more often it is persistent because of inadequate control of the primary tumor or irreversible damage to the nerve. Management of vocal cord paralysis includes Teflon or Gore-Tex injection of the vocal cord or phonosurgery.[48,49] These procedures can improve the vocal quality, as well as improve other symptoms such as dysphagia and aspiration. Some patients may require feeding tubes to prevent aspiration pneumonia.

**Phrenic Nerve Paralysis**   The phrenic nerve courses along the pericardium bilaterally and is subject to injury caused by invasion from the primary tumor or bulky adenopathy. The left phrenic nerve is more commonly affected than the right, probably because of the relatively greater proximity of the left phrenic nerve to lymph nodes of the aortopulmonary window. Damage to the left phrenic nerve results in paralysis of the left hemidiaphragm, with consequent volume loss in the left hemithorax. Because the left hemidiaphragm is normally lower than the right, this condition has a rather characteristic x-ray appearance. The proximity of the left recurrent laryngeal nerve to the phrenic nerve in the aortopulmonary window occasionally results in coexisting hoarseness and left diaphragmatic paralysis. Phrenic nerve paralysis is always indicative of locally advanced disease. This condition is generally not reversible.

**Dysphagia**   Dysphagia can result from esophageal obstruction by bulky mediastinal adenopathy. Although bulky adenopathy is a relatively common occurrence, this symptom is surprisingly uncommon. Another potential cause of dysphagia is recurrent laryngeal nerve damage that can lead to dysfunction of the pharyngeal swallowing mechanism. This problem may be associated with aspiration as well (see preceding discussion under "Hoarseness"). Treatment of the mediastinal adenopathy with radiotherapy (with or without concurrent chemotherapy) may improve dysphagia caused by this mechanism. However, radiation-induced esophagitis could lead to acute odynophagia and dysphagia with a few patients developing chronic dysphagia from esophageal strictures. Selected patients may require nutritional support until effective swallowing is reestablished.

**Stridor**   Stridor results from compromise of the lumen of the trachea. It can be caused by invasion of the trachea by tumor, or less commonly, bilateral vocal cord paralysis. An aggressive approach to management of stridor is necessary, because this problem is life threatening and extremely distressing. Prompt initiation of treatment, including radiotherapy or brachytherapy, with or without chemotherapy, is essential. For lesions located high in the trachea, or stridor caused by vocal cord paralysis, a tracheostomy may permit placement of a rigid canula beyond the obstruction. Considerations could be given to treatments, such as photodynamic therapy or laser therapy, to improve the airways prior to proceeding with more definitive therapy. Because flow is related to diameter in an exponential fashion, a small increase in diameter can result in a dramatic improvement in symptoms. This increase can sometimes be accomplished via laser fulguration.[50,51]

Symptoms can be eased by the use of a helium–oxygen mixture (70:30), in place of room air or oxygen alone. Helium has a much lower viscosity than nitrogen, thus reducing obstruction to flow.[52] Patients whose disease progresses despite therapy may require significant doses of morphine for control of symptoms.

**Superior Vena Cava Syndrome**   Superior vena cava (SVC) syndrome is a relatively common complication of lung cancer.[53,54] It is generally a consequence of obstruction of the SVC by right paratracheal adenopathy or central extension of primary tumor in the right upper lobe. The syndrome is characterized by facial swelling, flushing, cough, and neck and chest wall vein distention. The extent and severity of symptoms greatly depends on how rapidly the obstruction progresses and on the speed and extent of the development of collateral circulation. Rapidly developing obstruction is most dangerous because it can result in central nervous system symptoms, including coma and death. Much more commonly, the onset is insidious, with swelling of the face, upper extremities, and breasts, causing the patient to seek medical attention.

In the undiagnosed patient, the principal differential diagnosis is between lung cancer and lymphoma. Approximately 80% of patients with SVC syndrome in the United States have an underlying diagnosis of lung cancer, divided approximately equally between small cell and non–small cell histologies. Once considered an emergency, current practice is to obtain a tissue diagnosis expeditiously prior to the initiation of appropriate therapy.[55] Bronchoscopy, mediastinoscopy, or mediastinotomy usually yield a diagnosis with little risk to the patient. Radiotherapy remains the preferred treatment for non–small cell lung cancer (NSCLC) and in selected situations, concurrent chemotherapy may be appropriate. Percutaneous stenting of the SVC is being increasingly used as the first treatment

modality.[56,57] Stents are also considered in patients who have not responded to other treatment modalities. In uncommon circumstances, surgery could be considered for bypass or replacement of the SVC.

## Pleural Effusion

Approximately 15% of lung cancer patients present with pleural effusion. Although most of these effusions are ultimately determined to be malignant, about one half are initially cytologically negative. Diagnostic thoracentesis should be performed to determine the origin of the effusion, with an adequate amount of fluid sent for cytology. The differential diagnosis for causes of effusion can include atelectasis, pneumonia, lymphatic obstruction from enlarged lymph nodes, and congestive heart failure, among others. It is important to identify malignant effusion if possible. Proper classification of an effusion can both prevent the application of ineffective local measures (i.e., surgery or radiotherapy) as well as ensure that resectable patients are not denied the benefits of surgery.

The management of malignant pleural effusion varies greatly, depending on the clinical situation. Patients with good performance status and reasonable life expectancy can benefit from aggressive interventions such as video-assisted thoracoscopy and talc insufflation. Traditional thoracostomy tube placement can also be beneficial to patients who are in good physical condition.[58,59] Patients with more advanced stages of disease are better served by placement of a flexible small-bore catheter, which does not require hospitalization. It is also important to understand that patients with trapped lung caused by parenchymal or pleural disease will not benefit from pleural fluid drainage.

Pleural effusions may resolve with effective chemotherapy, especially in patients with small cell lung cancer (SCLC). In NSCLC patients who are not symptomatic from the effusion and do not have a large effusion, chemotherapy may be tried as the initial management, but most patients in this category eventually require more aggressive local measures.

## Pericardial Effusion

Pericardial effusion develops in 5% to 10% of lung cancer patients. At autopsy, cardiac involvement occurs in approximately 15% of cases.[60,61] Pericardial effusion typically occurs in the setting of locally advanced disease. Patients usually have dyspnea and orthopnea as the initial symptoms. The other symptoms and signs associated with pericardial effusion are anxiety, substernal chest tightness, jugular venous distension, and hepatomegaly.

Pericardial effusion causing cardiac tamponade is missed in up to one third of patients. The symptoms can be only dyspnea and anxiety and are often attributed to progression of parenchymal lung disease. The finding of dyspnea without concurrent hypoxia in an anxious, dyspneic patient with locally advanced lung cancer should prompt an investigation for pericardial disease.

Management of pericardial disease is dependent on whether the patient has cardiac tamponade. Patients with tamponade require immediate intervention with the preferred treatment being pericardiotomy (pericardial window) via a subxiphoid approach.[62] Patients with very short expected survival or patients who do not have tamponade could be treated with pericardiocentesis. If appropriate expertise is available, placement of a small bore pericardial catheter can be effective. Such a catheter could be used to instill a sclerosing agent, which may help achieve long-term control of the effusion in many patients.[63]

Pericardial effusion can be a late complication of chest radiation therapy (with or without chemotherapy) when significant portions of the pericardium are included in the radiation field.[64] Therefore, occurrence of pericardial effusion in a patient who has received chest radiation should not be assumed to be tumor recurrence.

## Pancoast Syndrome

Pancoast syndrome is the occurrence of shoulder and upper chest wall pain caused by the presence of a tumor in the apex of the lung with invasion of adjacent structures. It could be accompanied by Horner syndrome, brachial plexopathy, and reflex sympathetic dystrophy. The chest pain is caused by direct invasion of the chest wall, the first and second ribs, and in some cases, the transverse processes and bodies of the upper thoracic vertebrae. Some of these patients develop spinal cord compression. Horner syndrome results from the involvement of the superior cervical ganglion, and consists of ipsilateral ptosis, meiosis, enophthalmos, and anhydrosis. When the upper sympathetic chain is also destroyed, autonomic innervation to the ipsilateral limb is lost, leading to reflex sympathetic dystrophy. This is characterized by pain and swelling, resulting from loss of vascular tone regulation. Involvement of the brachial plexus results in radiating pain to the arm and forearm.

The typical patient has symptoms for long periods and is often evaluated for local shoulder problems without attention to the chest. Treatment of patients with pancoast tumors is based on the stage of the disease. Patients with no mediastinal involvement are treated with preoperative chemotherapy and radiation followed by surgery.[65,66] Patients who have mediastinal involvement are treated usually with radiation and chemotherapy. Pain control can be problematic in these patients requiring large doses of long-acting narcotics. In patients who do not undergo surgery, radiation can achieve pain control. However, the pain control in many of these patients is transient, requiring further interventions such as placement of an epidural or intradural catheter.

## Lymphangitic Spread

Lymphangitic spread of the tumor through the lung parenchyma is an ominous development. This spread is characterized by progressive dyspnea, cough, and hypoxia associated with an expanding infiltrate. Fever may be observed with these developments.

Lymphangitic spread often presents a diagnostic dilemma. The nonspecific nature of the infiltrate often results in diagnostic uncertainty. The differential diagnosis typically includes infection and radiation pneumonitis. High-resolution

CT scanning might reveal characteristic changes associated with lymphangitic spread.[67] Bronchoscopy with bronchoalveolar lavage can also be useful in establishing a diagnosis. In many cases, empiric use of antibiotics and high-dose steroids may be preferable in many patients. High-dose steroids may be transiently beneficial in relieving dyspnea caused by lymphangitic spread.

## MANIFESTATIONS OF EXTRATHORACIC SPREAD

**Brain Metastases**   Lung cancer is the most common cause of brain metastases.[68] There are some data to suggest that with improved disease control in locally advanced disease increased incidence of brain metastases is being observed.[69,70] The manifestations of brain metastases are variable and depend on the location of the lesion and the amount of associated edema and/or hemorrhage. Patients may present with headache, nausea/emesis, focal weakness, seizures, confusion, ataxia, or visual disturbances. Leptomeningeal carcinomatosis may present as cranial nerve palsies. Patients with persistent headaches without any structural abnormalities on brain imaging should undergo spinal fluid evaluation for leptomeningeal carcinomatosis. A positive cytology is found on an initial lumbar puncture in 50% to 70% of the patients. In patients with clinical signs and symptoms suggestive of leptomeningeal metastases, repeat lumbar puncture is required if the first cytology evaluation is negative.

Magnetic resonance imaging (MRI) is clearly the gold standard for identifying brain metastases and is more sensitive than CT scanning.[71,72] MRI is particularly useful when resection of solitary brain metastases is being contemplated because an MRI scan with gadolinium contrast may reveal other smaller lesions missed on CT scans. MRI could also be useful in the diagnosis of leptomeningeal involvement.

Initial management of brain metastases consists of corticosteroids given intravenously or orally, based on the patient's condition.[73] Patients with seizures should be treated with antiseizure medications. However, prophylactic use of antiseizure medications is not essential and carries with it a high potential for adverse effects.[74] Subsequent management of brain metastases depends on size, number, location of the lesions as well as the status of the extracranial disease, and the general condition of the patient.[75]

Leptomeningeal carcinomatosis is a particularly difficult challenge in lung cancer patients. It is poorly responsive to therapy and generally occurs in the setting of progressive systemic disease. In selected patients, intrathecal chemotherapy can be beneficial, but in many patients, supportive care alone is optimal.[76]

**Bone Metastases**   Lung cancer can metastasize to almost any bone, although the axial skeleton and proximal long bones are most commonly involved. Bone pain is present in up to 25% of all lung cancer patients at presentation. In lung can-

cer, positron emission tomography (PET) scans have similar sensitivity to isotope bone scans although less specificity.[77] Therefore, patients with PET scans that do not show any abnormality in bones, and have no signs or symptoms suggestive of metastases, do not need an additional bone scan. In patients with bone metastases, radiograph evaluation of weight-bearing bones may be important to detect the risk of and prevent pathologic fractures. Most symptomatic bone metastases in lung cancer patients are treated with radiation therapy. In selected patients with weight-bearing bony metastases, surgical options could be considered.[78,79]

Patients with bone metastases may require significant pain medications. Pain related to bone metastases may respond well to nonsteroidal anti-inflammatory drugs (NSAIDs) and should be considered in addition to narcotic analgesics. Recent data suggests that the new generation nitrogen-containing bisphosphonate, zoledronic acid, has clinical benefits in solid tumor patients with bone metastases, including lung cancer patients. In a randomized study that included NSCLC patients, zoledronic acid significantly decreased the incidence of skeletal-related events and increased the time to the first skeletal-related event.[80] There are also data to suggest that the addition of bisphosphonates to radiation therapy for bone metastases was beneficial.[81]

**Liver, Adrenal Glands, and Intra-abdominal Lymph Node Metastases**   Liver involvement is fairly common in patients with lung cancer. Liver metastases most commonly cause fatigue, weight loss, epigastric discomfort, and nausea/emesis. Patients may have upper quadrant pain from large metastases. Liver function tests could be normal, and liver dysfunction occurs only in the presence of numerous metastases. Presence of liver metastases carries a poor prognosis.

Adrenal and intra-abdominal lymph node metastases are usually detected on CT scans performed to evaluate lung cancer. In most cases, these lesions are asymptomatic. Large adrenal metastases may cause pain. Adrenal insufficiency is usually not observed but should be considered in patients who present with appropriate clinical symptoms and laboratory abnormalities, with bilateral adrenal metastases. There have been reports of surgical resection of solitary adrenal metastases, particularly metachronous lesions.[82,83] However, many of these reports have demonstrated limited benefits from such a strategy.

**Other Metastatic Sites**   Since lung cancer is a common tumor, metastases are occasionally seen at a variety of other sites. These include skin, soft tissue, pancreas, bowel, ovary, and thyroid. Management of these other metastatic sites is primarily symptomatic.

**Constitutional Symptoms**   Several constitutional symptoms affect lung cancer patients. These symptoms include depression, fatigue, anxiety, and insomnia. Depression is fairly common in lung cancer patients.[84,85] Impaired functional status was the most important risk factor for presence of depression.[85] Inadequate recognition of depression has been observed

among cancer patients. Presence of depression and anxiety can worsen other symptoms such as pain and fatigue. Appropriate interventions, including use of drug therapy, have shown benefits in cancer patients.[86]

Fatigue is a frequent symptom in lung cancer patients and is commonly a result of multiple factors including anemia, dyspnea, cachexia, and therapy-related side effects. Identification of the factors contributing to fatigue in a particular patient is important for the management of the symptom. Similarly, multiple different factors cause and contribute to insomnia. Appropriate assessment of these symptoms and management of the causes can reduce the symptom burden of the patient, particularly in patients with advanced cancer.

## PARANEOPLASTIC SYNDROMES

Carcinomas of the lung most often present with symptoms related to the locoregional effects of the primary tumor or to the manifestation of extrathoracic spread. However, patients can also present with paraneoplastic syndromes, which are remote effects of the primary tumor that can result in organ dysfunction.[90] The development of paraneoplastic syndromes is not necessarily related to the extent of disease and can precede the clinical diagnosis of cancer. They can also occur later in the course of the disease or herald a cancer recurrence. The mechanistic etiology of these syndromes is not entirely understood but, in some instances, may be related to a humoral substance produced by the tumor or to an immunologic response to the cancer.[91] Several different paraneoplastic syndromes are clinically apparent in 10% to 20% of patients with bronchogenic carcinoma. These syndromes occur with more frequency in patients with SCLC. Table 23.3 lists the common and not-so-common paraneoplastic syndromes associated with thoracic malignancies.[92] This discussion will be devoted to those syndromes that occur in NSCLC patients.

**Cachexia**    Cancer cachexia syndrome is characterized by anorexia, weight loss, and weakness, resulting in impaired immune status, tissue wasting, and decline in performance status.[93] Cancer-associated anorexia and cachexia entails weight loss of more than 5% of baseline weight during the previous 2 to 6 months.

The syndrome of cancer cachexia occurs commonly in lung cancer patients but usually in the case of advanced disease. The origin of cancer cachexia is not totally understood but is probably multifactorial. Several cytokines, tumor factors, and hormones have been implicated, including tumor necrosis factor $\alpha$ (TNF-$\alpha$), interleukins (IL), proteoglycan, insulin, corticotropin, epinephrine, human growth factor, and insulin-like growth factor.[94,95] The cancer patient may also have a maladaptive metabolism, resulting in a poor utilization of nutrients, in addition to decreased caloric intake.[96] The abnormalities associated with cachexia include alterations in carbohydrate, lipid, and protein metabolism.[97] Anorexia can also be potentiated by pain, gastrointestinal involvement by

tumor, development of food aversions, and the systemic effect of cancer treatment.[98] Cachexia in lung cancer patients has been associated with reduction in performance status, quality of life, and poorer prognosis.

The cachexia syndrome is not easily managed. A careful assessment of the patient's symptoms, clinical condition, and the disease status is required to properly address the issues of anorexia and cachexia. It is important to detect and treat reversible causes such as dry mouth, stomatitis, severe constipation, pain, depression, and others. Simply increasing nutritional support even by central or parenteral means is not clinically efficacious.[99] Several pharmacologic agents have been utilized to improve anorexia in cancer patients.[100] The most commonly used agent is megestrol acetate. In a trial by Loprinzi et al.,[101] a positive dose–response effect on appetite resulted with increasing doses of megestrol acetate (no benefit beyond 800 mg/day), and a trend toward nonfluid weight gain was apparent. Steroids have limited benefit; tetrahydrocannabinol derivatives may be useful in improving appetite and symptoms of nausea. The treatment of cancer-related cachexia is a fertile area of research. Some novel approaches have included the use of ghrelin, melanocortin antagonists, and anticytokine strategies.[102] A better understanding of the mechanism of cancer-related anorexia/cachexia will clearly be needed before more advances can be made.

### Endocrinologic Syndromes

**Hypercalcemia**    Hypercalcemia is a fairly common metabolic problem associated with malignancies.[103] Several pathologic mechanisms have been proposed, including osteolytic bone metastases or humoral and cytokine factors such as parathyroid hormone–related protein (PTHrP), transforming growth factor-$\alpha$, IL-1, TNF, prostaglandins, and lymphotoxin.[104,105] Bender and Hansen[106] reviewed 200 consecutive cases of bronchogenic lung cancer and found a 12.5% incidence of hypercalcemia. Hypercalcemia associated with carcinoma of the lung can occur with bone metastases but often occurs in the absence of osseous involvement. Squamous cell carcinoma is the most common histology associated this paraneoplastic presentation, generally in advanced-stage disease.[107] Hypercalcemia rarely occurs in small cell carcinoma even though other paraneoplastic syndromes are common in this malignancy.[108] Benign conditions may be responsible for hypercalcemia in cancer patients. An example of this relationship would be coexistence of primary hyperparathyroidism with the malignancy.[109]

Calcium is controlled by the interaction of parathyroid hormone (PTH), 1,25-dihydroxyvitamin D, and calcitonin in the bone, kidney, and gastrointestinal tract. PTH stimulates bone resorption, renal calcium reabsorption in the distal renal tubules, and production of vitamin D by the kidney. Patients with cancer-related hypercalcemia can have increased PTH activity in their blood.[110] Immunoreactive PTH levels are usually low or normal; however, a PTHrP can be detected in the serum.[111] This protein product is homologous with PTH at the amino terminus, which is the portion that binds to the

*Associated with carcinoid tumors.

†No significant clinical syndrome.

PTH receptor.[112] The gene responsible for PTHrP expression is located on the short arm of chromosome 12. PTHrP acts as a hormone that stimulates bone resorption and renal phosphate wasting, resulting in hypercalcemia and hypophosphatemia. It has been suggested that lung cancer patients with hypercalcemia and elevated PTHrP levels may have a higher likelihood of bone metastases and a shorter survival.[113]

Clinical symptoms associated with hypercalcemia can be variable depending on the level of serum calcium and rapidity with which the level was achieved. Early manifestations can include nausea and vomiting, fatigue, lethargy, anorexia, muscle weakness, constipation, pruritus, polyuria, and polydipsia.

The symptoms may not be recognized because they can be related to the existing malignancy, treatment toxicities (i.e., chemotherapy, narcotics), and other comorbid conditions. If untreated, patients can become severely dehydrated, subsequently developing renal insufficiency. Glomerular filtration is decreased, and a reversible defect in the kidney can result in loss of urine-concentrating ability.[114] Neurologic manifestations can also be significantly worsened, resulting in confusion, obtundation, psychosis, seizures, and coma. Further effects on the gastrointestinal tract can lead to obstipation and ileus. Electrocardiographic changes can occur with a prolonged PR interval, shortened QT interval, and a

wide T wave. This can result in bradycardia and atrial or ventricular arrhythmias. Poor performance status, advanced age, and preexisting renal and hepatic dysfunction can add to the effects of hypercalcemia.

Patients who have serum calcium levels higher than 13 mg/dL or who exhibit symptoms related to hypercalcemia usually require treatment. Goals of treatment should include hydration, inhibition of bone resorption and/or promotion of calcium excretion, and treatment of the underlying malignancy.[115]

Because hypercalcemic patients are often dehydrated, rehydration has become the mainstay of treatment. Vigorous hydration with isotonic saline (200 to 400 mL/hr) can be used for several hours to restore intravascular volume and glomerular filtration to promote calcium excretion.[116] Care must be taken in the patient with cardiovascular compromise or renal insufficiency to avoid volume overload. In cases of renal failure, dialysis may have to be employed. Diuretics should be used judiciously once rehydration is achieved. Thiazide diuretics should be avoided because they can increase calcium resorption in the distal tubule. Furosemide is the diuretic of choice and can promote calcium excretion by interfering with calcium reabsorption in the ascending limb of Henle's loop. Diuretics should be primarily used to balance fluid intake and output. The use of saline hydration and forced diuresis for treatment of hypercalcemia is no longer recommended. Along with hydration, a pharmaceutical agent that helps decrease bone resorption should be employed.

The bisphosphonates are the safest and most effective agents used for the treatment of hypercalcemia. These compounds are structural analogues of pyrophosphate and by binding to hydroxyapatite are potent inhibitors of bone crystal dissolution and osteoclast reabsorption. Pamidronate and zoledronate are the drugs most commonly used for the treatment of hypercalcemia. In a randomized trial, zoledronate (4 and 8 mg) proved to be statistically superior to pamidronate (90 mg) in that it yielded a more rapid and sustained decrease in serum calcium.[117] The recommended dose of zoledronic acid is 4 mg by a 15-minute infusion. The drugs have an acceptable safety profile but should be administered with caution in patients with renal insufficiency.

Gallium nitrate is a potent inhibitor of bone resorption via inhibition of an ATPase-dependent pump in the osteoclast.[118] Gallium nitrate is usually administered at a dose of 100 to 200 mg/m$^2$/day by continuous infusion for up to 5 days, making it somewhat inconvenient. Urine output has to be maintained during administration and nephrotoxic drugs should be avoided because of a potential for renal toxicity. Calcitonin (4 to 8 IU/kg intramuscularly or subcutaneously every 12 hours) exerts its hypocalcemic effect by inhibiting bone resorption and promoting calcium excretion.[119] The main advantage is that it has a rapid onset of action and can be used in patients even if they have renal insufficiency. The main disadvantage of the drug is that the hypocalcemic effect is weak and transient. Plicamycin (Mithramycin) is an antineoplastic agent that is toxic to osteoclasts.[120] Its use is currently limited secondary to lack of availability and potential adverse side effects. Corticosteroids are useful agents in patients whose diseases are often treated with these drugs (i.e., hematologic malignancies, breast cancer). Steroids are not particularly useful in lung cancer–related hypercalcemia.

Ultimately, successful treatment of the malignancy controls hypercalcemia. This goal is particularly difficult in the case of advanced lung cancer. No effective oral agents are available for maintenance of a desired serum calcium level. Patients who have continued problems with symptomatic hypercalcemia may require intermittent treatment with a bisphosphonate, which can easily be given as an outpatient infusion.

**Other Endocrinologic Paraneoplastic Syndromes**    The syndrome of inappropriate antidiuretic hormone (SIADH) is most commonly associated with SCLC. Other cancers including NSCLC, prostate, adrenal cortex, esophageal, pancreas, colon, head and neck, thymoma, mesothelioma, bladder, carcinoid tumors, and hematologic malignancies have been associated with SIADH.[121] Nonmalignant conditions, such as an intracranial process (i.e., trauma, cerebral vascular accident, infection), pulmonary infection, or drug-related toxicity, can also be associated with SIADH. Chemotherapeutic agents (vincristine, cisplatin, cyclophosphamide), narcotics, chlorpropamide, thiazides, clofibrate, and carbamazepines have all been implicated.[122] Other causes for hyponatremia in the lung cancer patient include cardiac, liver and renal disease, adrenal insufficiency, hypothyroidism, and gastrointestinal and renal losses that are not SIADH related.

Most normal tumor tissues produce a precursor adrenocorticotropin hormone (ACTH) molecule, whereas carcinomas can produce this same precursor in much larger quantities. Some neoplasms convert the precursor ACTH to biologically active ACTH, resulting in clinically apparent Cushing syndrome.[123] The most common malignancy associated with ectopic Cushing syndrome is SCLC. Lung cancers other than SCLC tend to produce precursor ACTH that does not result in Cushing syndrome.[124] Other neoplasms associated with ectopic ACTH production include carcinoid tumors, thymic cancer, islet cell tumors, pheochromocytoma, neuroblastoma, medullary carcinoma of the thyroid, and various malignancies.[125]

Lung cancers, particularly SCLCs, can produce other hormone substances, but this process does not always result in a clinically significant paraneoplastic syndrome. Gonadotropin secretion can occur from bronchogenic carcinomas.[126] Production of the β-subunit of human chorionic gonadotropin (hCG) can result in the male patient presenting with gynecomastia. Other causes of β-hCG elevation, such as germ cell tumors, should be ruled out in this situation. Galactorrhea as a result of increased prolactin level has been reported.[127] Thyroid-stimulating hormone can be produced by tumors but rarely results in clinical hyperthyroidism. Acromegaly has been attributed to the release of a growth hormone–releasing factor by a bronchial carcinoid.[128] Hypoglycemia is rarely associated with non–islet cell malignancies. Mesothelioma is the most common neoplasm associated with hypoglycemia. The suspected cause is the tumor secretion of a nonsuppressible insulin-like substance.[129]

## Neurologic Syndromes

Neurologic paraneoplastic syndromes are relatively rare and can involve any portion of the nervous system.[130] Effects can be relatively focal or involve multiple levels of the nervous system. These syndromes may often develop before the actual diagnosis of the cancer. SCLC is the most common histologic type associated with neurologic paraneoplastic syndromes.

## Musculoskeletal Paraneoplastic Syndromes

Hypertrophic pulmonary osteoarthropathy (HPO) has long been associated with carcinoma of the lung. It is characterized by digital clubbing, painful arthralgias, and periostosis of the tubular bones.[131] Digital clubbing involves paronychial soft tissue expansion with loss of the angle between the base of the nail bed and cuticle and can involve both fingers and toes. Clubbing can present as an isolated finding. In one series, clubbing was present in 29% of the patients and was more common in women.[132] HPO is seen in less than 5% of patients with NSCLC.[133] Adenocarcinoma and squamous cell carcinoma are the most common histologies, with SCLC accounting for a small number of cases.[134] The origin of HPO is not really known. It has been suggested that a humoral mechanism, specifically growth hormone, may be involved.[135] An overexpression of vascular endothelial growth factor has recently been implicated in the pathogenesis of HPO and clubbing.[136] Diagnosis is made with radiographs of the long bones, which show periosteal elevation. A radioisotope bone scan can be very sensitive in detecting HPO before it is evident on radiographs. Treatment of the malignancy does not usually alleviate symptoms because patients often have advanced NSCLC. NSAIDs can be useful in treating the painful arthralgias.

Dermatomyositis and polymyositis are inflammatory conditions characterized by muscle weakness and tenderness, and skin changes, in the case of dermatomyositis. Breast and lung cancers are the most common associated malignancies. Most cases are idiopathic in nature and unrelated to cancer. Some controversy exists as to whether there is an actual increase in cancer risk in patients who have either disorder.[137,138] The course of these conditions may not parallel the course of the malignancy. Immunosuppressives, particularly steroids, have been used for treatment.

## Mucocutaneous Manifestations

Many cutaneous syndromes are associated with cancer. Many of these skin lesions are uncommon, and the association with malignancy is stronger. Some of the cutaneous findings are common and may be associated with benign conditions. It is beyond the scope of this review to describe all of these mucocutaneous manifestations. Table 23.4 shows a compilation of the syndromes associated with lung cancer.[122,139,140]

## Hematologic Syndromes and Vascular Manifestations

Anemia is a common problem in cancer patients, with many possible causes such as bleeding, nutritional defi-

ciencies, and bone marrow involvement by the malignancy. Anemias with no apparent cause can be termed *paraneoplastic*. Red blood cells are usually normochromic or slightly hypochromic, ferritin levels and iron stores are normal or increased, and erythropoietin levels and reticulocyte counts are inappropriately low. The anemia may be related to several cytokines that blunt erythropoietin response.[141] Rarely autoimmune hemolytic anemia, red cell aplasia, and microangiopathic hemolytic anemia have been associated with lung cancers.[142,143]

Leukocytosis is observed in some patients and may be related to the effects of IL-1 or granulocyte-stimulating factor.[144] Leukopenia is rare. Both eosinophilia and monocytosis can occur infrequently. Thrombocytosis is a fairly common occurrence and may be related to cytokine release of IL-6 or thrombopoetin.[145,146] An idiopathic thrombocytopenia purpura-like syndrome can rarely be seen in lung cancer.[147]

Trousseau syndrome is one of the earliest paraneoplastic syndromes described. It represents an association between thrombosis and malignancy. It is seen in several malignancies, including gastrointestinal, lung, breast, ovarian, and prostate cancers.[148] Deep vein thrombosis of the lower extremities and pulmonary embolism are the most common presentations, although unusual location of thromboses can occur. The origin is probably multifactorial and can include release of procoagulant materials (particularly from mucin), release of cytokines

that have procoagulant activity, platelet hyperactivity, and the release of tissue factors via abnormal tumor vasculature.[149] Therapy with heparin or warfarin may not provide satisfactory treatment.

Nonbacterial thrombotic endocarditis is associated with sterile verrucous fibrin platelet lesions in the left-sided heart valves. It is most commonly associated with adenocarcinoma of the lung.[150] This syndrome can cause tumor embolisms to the brain and other organs. Anticoagulants are usually not useful.

# Clinical Presentation of Small Cell Lung Cancer

The clinical presentation of small cell lung cancer (SCLC), including signs and symptoms of the disease, is important in the understanding of this disease to help make a proper diagnosis and ultimately decide on the best therapy. Various clinical factors can help predict outcome in patients with SCLC, including tumor-related factors and host-related factors. This chapter will discuss the clinical presentation of SCLC and paraneoplastic syndromes associated with this disease.

## INITIAL PRESENTATION: SYMPTOMS AND SIGNS

Nearly all patients with SCLC present with symptomatic disease, and less than 10% of lung cancer patients will be diagnosed prior to clinical presentation of symptoms.[1] More effective screening, including use of chest x-rays, and more recently, low-dose spiral computed tomography (CT) scanning, as well as more sensitive molecular or genomic techniques may allow for improvement in the ability to diagnose this disease at an earlier stage,[2] but SCLC will likely be the more difficult histologic subtype to find early because of its proclivity for early dissemination. Lung cancer also tends to affect the elderly population, and nearly half of all patients presenting with SCLC will be older than the age of 60 years.[3]

A thorough understanding of the symptoms associated with SCLC can help in the appropriate diagnostic workup and, ultimately, in more effective control of these symptoms in these patients. Clinical reports have identified the most common symptoms at the time of presentation.[4] Table 24.1[5] delineates the frequency of these various signs and symptoms.[6] These can be classified as localized symptoms from the primary tumor, regional spread of disease, and distant effects from metastatic disease, as well as general symptoms, which may be attributed to a paraneoplastic effect. Presenting symptoms can also help predict prognosis in this disease.[7] It has been shown that early presentation of lung cancer is often associated with a specific pattern of symptoms.[8] Limited versus extensive disease stage, the fewer sites of metastatic involvement, good performance status, and absence of weight loss are all consistently found to correlate with survival in this disease.[9]

**General Systemic Symptoms**   Most patients with lung cancer, and particularly SCLC, present with symptoms from their disease. Generalized systemic symptoms can include fatigue, anorexia, weight loss, and depression. These symptoms occur to a greater degree than would be expected for the extent of tumor spread.

Attempts have been made to investigate the etiology for the anorexia/cachexia syndrome associated with malignant disease, including lung cancer. This syndrome has been described as the most common cause of death in cancer patients.[10] Cachexia comes from Greek meaning "bad condition" and causes significant morbidity in lung cancer patients. No definite etiology has been determined, but loss of appetite and weight loss are commonly attributed to circulating cytokines.[11] Up to 40% of patients may experience anorexia and cachexia,[12] often requiring interventions to improve appetite and weight gain.

Fatigue is another presenting symptom commonly associated with lung cancer.[13] Commonly found at presentation, fatigue can be exacerbated by antineoplastic therapy including surgery, radiation, chemotherapy, and biologics. Evaluation for contributing secondary causes of fatigue, including anemia, endocrine dysfunction, and depression can identify readily treatable and reversible causes. Treatment of the primary tumor may be the most effective way to manage this symptom.

Depression can be another symptom in lung cancer patients.[14] With such a poor prognosis, reactive depression is a common initial reaction to a lung cancer diagnosis. Other factors may be involved in the development of depression in patients with lung cancer. Recent clinical trials have demonstrated that quality of life can be severely impacted by a diagnosis of lung cancer. Contributing to the depression are the specific symptoms from the disease as well as the psychosocial adjustment necessary with this diagnosis and its associated

| TABLE 24.1 | Signs and Symptoms of Small Cell Lung Cancer at Presentation |
|---|---|
| **Symptom/Sign** | **Frequency (%)** |
| Chest pain | 20–49 |
| Anorexia | 18–33 |
| Superior vena cava syndrome | 10–15 |
| Cough | 8–75 |
| Hemoptysis | 6–35 |
| Bone pain | 6–25 |
| Dyspnea | 3–60 |
| Hoarseness | 2–18 |
| Weight loss | 0–68 |
| Weakness | 0–42 |
| Clubbing | 0–20 |
| Fever | 0–20 |
| Dysphagia | 0–2 |
| Wheezing/stridor | 0–2 |

treatments.[15] Further refinement of quality of life analysis in lung cancer patients is being attempted by several groups.[16]

Paraneoplastic symptoms associated with SCLC will be discussed later in this chapter. These symptoms are characterized by a systemic manifestation of disease not explained by local tumor effects.

**Local Symptoms** SCLC frequently presents as a large central tumor, often with symptoms of bronchial obstruction. Therefore, many patients present with local symptoms at the time of diagnosis of lung cancer.[17] Most commonly observed are chest pain, cough, and shortness of breath.[18] Cough occurs in lung cancer patients when the tumor irritates bronchial nerve fibers or leads to increased sputum production or atelectasis. Obstruction of the airway may lead to postobstructive atelectasis and/or pneumonia. These symptoms are present in at least 50% of patients at the time of diagnosis and develop in many of the remaining patients.[19] Chest x-ray can identify sites of disease and evidence for postobstructive changes. A CT scan and possibly fiberoptic bronchoscopy are necessary to identify the exact location of the tumor and to help determine appropriate ways to manage respiratory symptoms.

Central tumors can erode into blood vessels, and cough can be associated with bleeding. Hemoptysis has been noted to occur in up to 35% of patients presenting with lung cancer.[20] Hemoptysis does not necessarily imply more advanced disease but can be associated with cavitation or local extension into blood vessels. In fact, hemoptysis does not in and of itself imply malignancy.[21] Hemoptysis at times can be mild or can lead to fatal hemorrhage in lung cancer patients. Therefore, management of hemoptysis depends on the severity and specific etiology of the process. Various techniques from surgical resection, to external beam radiation, to bronchoscopic techniques including laser treatment,

brachytherapy, cryotherapy, or photodynamic therapy can control symptoms effectively.[22]

Chest pain is another common symptom in SCLC, occurring in up to 49% of patients who present with primary lung cancer.[23] Pain is generally not caused by a primary tumor in the lung parenchyma, but it can be associated with chest wall involvement or local extension of disease affecting adjacent nerve fibers. Chest pain can also be attributed to unrelated causes, such as cardiac disease, esophageal disease, or vascular disease such as aortic dissection. Thus, careful evaluation of lung cancer patients with chest pain is crucial. Alternatively, lung cancer can be diagnosed serendipitously in patients presenting with acute chest pain of unrelated etiology when the chest radiograph or CT identifies a pulmonary nodule or mass.

Dyspnea or shortness of breath is also common in patients with SCLC.[24] Primary tumors are unlikely to directly result in true hypoxia. However, more advanced disease, such as obstructing tumors, lymphangitic cancer spread, or central lesions that produce significant sputum can be a cause of dyspnea in these patients. Evaluation of the differential diagnosis of shortness of breath is important to determine the underlying etiology, even in patients with malignancy. Patients may have underlying pulmonary pathology resulting from chronic obstructive pulmonary disease (COPD), and acute events such as pulmonary embolism, congestive heart failure, pneumonia, pneumothorax, and cardiac ischemia are also possibilities. In addition, regional extension and pleural effusion with compression of the remaining lung can lead to shortness of breath in this population. A thorough workup for other causes of dyspnea is necessary in lung cancer patients with worsening shortness of breath.

Lung cancer patients also present with wheezing, which can be wrongly attributed to reactive airway disease such as asthma or COPD. Obstructing pulmonary lesions can lead to wheezing in SCLC patients and should be thoroughly evaluated. Primary treatment techniques such as radiation and chemotherapy may be useful in controlling this symptom, as can standard medical therapy such as bronchodilators or corticosteroids.

Involvement of the heart or pericardium can result in tachyarrhythmias. These can present with palpitations or light-headedness. Unexplained tachycardia in lung cancer patients should be evaluated with an electrocardiogram and/or echocardiogram whenever pericardial involvement is suspected. Pericardial metastasis or effusion may be the offending etiology, and urgent attention may benefit this population.

Locally advanced SCLC can produce esophageal compression from the primary tumor or mediastinal lymphadenopathy. Patients may have dysphagia or odynophagia, and should be evaluated endoscopically or with upper gastrointestinal imaging to evaluate the etiology of the dysphagia. Local radiation provides appropriate palliation but occasionally stenting can be helpful.[25] Particularly in SCLC, chemotherapy may provide adequate tumor shrinkage for symptom relief.

Multimodality management of SCLC patients with significant pulmonary symptoms including a thoracic surgeon, pulmonologist, primary care physician, radiation oncologist,

radiologist, and medical oncologist leads to the most effective management of these local symptoms from lung cancer.

**Regional Metastasis**   SCLC is notorious for its regional symptoms from locally advanced disease. Growth to adjacent structures near the lung as well as involvement of regional lymph nodes lead to these symptoms in patients with locally advanced disease. Patients with right-sided tumors can develop superior vena cava (SVC) obstruction as a result of the primary cancer or involvement of lymph nodes in the right paratracheal area. This can lead to the clinical manifestation, SVC syndrome. This is typically characterized by swelling of the arms, neck, face, and head. This syndrome can also be associated with shortness of breath, cyanosis, headaches, nausea, blurred vision, and more serious neurological sequelae.[26] This syndrome can also be associated with distention or dilatation of the neck and chest wall veins because of collateral blood flow. SVC syndrome can appear indolently, delaying diagnosis because of the slow changes that occur. More rapidly growing tumors or thrombosis associated with SVC syndrome can lead to a more acute presentation with rapidly developing symptoms.

In SCLC, SVC syndrome occurs in 10% to 15% of patients, more commonly than in non–small cell carcinoma.[27] A careful differential diagnosis is important in patients with SVC syndrome. Other malignancies including breast cancer and lymphoma, as well as other mediastinal tumors and occasionally benign disease such as tuberculosis or other infections can cause SVC syndrome and need to be considered in the differential diagnosis.

For patients presenting with SCLC and SVC syndrome, chemotherapy is generally the standard treatment approach, and radiotherapy is used only when chemotherapy has failed or there is a need for more rapid tumor cell kill. More aggressive interventions may become necessary, including vascular stenting of the SVC, therapeutic anticoagulation, or corticosteroids to decrease vascular inflammation and obstruction and alleviate clinical symptoms. Invasive procedures may be more hazardous because of the extensive collateral vascularity commonly observed with this syndrome.

Hoarseness is another regional symptom associated with SCLC. This is most commonly attributed to mediastinal lymph node involvement and compression of the left recurrent laryngeal nerve. This is nearly always associated with pathologic involvement of the levels 4 and 5 left-sided mediastinal lymph nodes. Evaluation with laryngoscopy can help confirm the diagnosis of vocal cord paralysis. CT scanning of the neck and chest with intravenous contrast can help document involved nodes in this region. Occasionally, local treatment may be necessary to improve symptoms resulting from vocal cord paralysis from recurrent nerve involvement.[28] Hoarseness may improve with treatment of the underlying cancer, but this symptom is commonly irreversible because of permanent nerve injury or progressive cancer in this region.

Stridor can also develop because of tracheal compression with involvement of the upper airways or bilateral recurrent laryngeal nerve involvement. This may be a result of local tumor involvement or extrinsic compression from lymphadenopathy. This can be a life-threatening emergency in patients with malignancies of the lung and/or head and neck and requires urgent airway management, usually tracheostomy. Laryngoscopic therapy can be useful in controlling upper airway tumors, but more aggressive intervention is often required, including radiation, chemotherapy, or rarely in SCLC, surgical therapy.[29]

Patients with SCLC can present with malignant effusions in the pleural or pericardial space. These effusions are most commonly directly related to tumor involvement, either with direct invasion of the pleura or with hematologic spread to the pleura, but can also be a result of lymphatic obstruction from adenopathy or the primary tumor. Effusions can also be caused by late effects of prior therapy including surgery or radiation. Prompt management of pericardial effusions can prevent life-threatening consequences, including cardiac tamponade. Pericardial effusions, which become clinically symptomatic resulting from pressure on the ventricles, may require surgical intervention with a pericardial window or pericardial stripping, or can be managed less invasively with percutaneous catheter drainage.[30]

Malignant pleural effusions occur in up to 20% of patients with lung cancer[31] and may be the initial presenting sign of malignant disease.[32] Lung cancer is the most common cause of malignant pleural effusion.[33] The incidence of malignant effusions in SCLC is comparable to that of non–small cell lung cancers (NSCLC) in general but less than for the adenocarcinoma histologic subtype. Some authors have argued that patients with small cell with an isolated malignant effusion as the only site of metastatic disease may have a comparable outcome to patients with limited stage disease and should therefore be treated as such.[34] Nonetheless, this strategy has not gained widespread acceptance. Initial evaluation should be with diagnostic and therapeutic thoracentesis. Exudative effusions should be assumed to be malignant, unless a satisfactory benign etiology can be assigned.[35] These effusions may require chest tube drainage and pleurodesis for optimal management, although SCLC patients may be appropriately treated with chemotherapy alone. Less invasive options are becoming available in the management of malignant pleural effusions, such as smaller catheters and home drainage.

Horner syndrome can be observed in lung cancer patients with apical lung carcinoma in the superior sulcus because of involvement of the sympathetic chain of nerves. This syndrome, more commonly associated with NSCLC, is often associated with Pancoast syndrome. SCLC more commonly is a central mass with bulky mediastinal lymphadenopathy, and therefore is not commonly involving the lung apex.[36] Horner syndrome is characterized by ptosis, myosis, and anhydrosis of the affected side most commonly from apical lung tumors. Pancoast syndrome is characterized by Horner syndrome plus the additional local–regional effects of involvement of the brachial plexus, chest wall, ribs, and thoracic spine.[37] Again,

chemotherapy often provides rapid symptomatic relief from this syndrome in SCLC, and the cancer is managed according to clinical stage.

**Systemic Metastasis** SCLC can spread at a rapid rate, and early diagnosis before regional or metastatic spread is rare. Nearly two thirds of patients with small cell present with systemic disease at the time of initial diagnosis. Involved sites affected by metastatic disease can cause significant symptoms. The most commonly involved sites with metastatic lung cancer include the brain, contralateral lung, liver, adrenals, and bones.[38] Other less common sites can also be affected, including visceral organs, skin and subcutaneous tissues, kidneys, pancreas, and spinal cord and meninges. Specific symptoms related to each of these sites of disease can appear at the time of initial diagnosis or may develop as the disease progresses. Symptomatic patients should be further evaluated with the appropriate diagnostic test (CT, magnetic resonance imaging [MRI], or radionuclide scan) to exclude additional sites of disease. Asymptomatic patients, however, may not need full evaluation for metastatic disease in the absence of clinical findings.[39]

Optimal evaluation of patients with SCLC for evidence of metastasis generally includes a CT scan of the chest to include adrenals and liver, and consideration of brain imaging with CT or MRI, bone scanning, and possibly bone marrow biopsy. This procedure became part of standard staging of SCLC because of the frequent involvement of bone marrow by metastatic disease. More recent evidence suggests that having marrow involvement as the sole site of metastasis occurs in less than 5% of patients and may not have the prognostic significance previously thought.[40] In fact, these patients were found to have no difference in overall survival compared with patients with extensive disease without marrow involvement. Newer imaging techniques including positron emission tomography (PET) are still being evaluated in SCLC, but may play a role in defining disease stage in some patients.[41]

Brain metastasis is common in SCLC, occurring in 50% of patients in one autopsy series.[42] Symptomatic patients presenting with brain metastasis from SCLC may develop headaches, nausea, fatigue, weakness, seizures, visual change, or ataxia. These symptoms can often be the presenting symptoms of the cancer and are generally controlled with treatment. Patients may also harbor metastatic disease to the brain in the absence of symptoms. Some have debated the roll of screening asymptomatic patients with brain scanning. One study found that 63% of SCLC patients with any neurologic symptoms had brain metastases on CT scan, whereas only 18% of patients with no neurologic symptoms had evidence for brain metastasis.[43] The more sensitive technique of MRI scanning may have picked up additional patients with small volume metastases, but the clinical implications of this are unclear, especially given the chemosensitivity of this tumor.

Options for treatment of brain metastasis include surgery, radiation, chemotherapy, or some combination. More recent data suggests that some patients with SCLC may have control of central nervous system (CNS) disease with chemotherapy alone.[44] Leptomeningeal metastasis carries a particularly grave prognosis[45] and may produce the similar neurological symptoms, changes in mental status, or the signs of meningeal irritation including stiff neck and photophobia.

Bony metastasis is another common site of metastasis and can lead to significant problems with pain. Aggressive management of symptomatic bone metastasis is necessary in this disease. Patients who present with bony pain should be evaluated with whole body bone scanning, and specific sites of involvement can be further evaluated with plain x-rays and CT or MRI scanning. Sites of symptomatic metastasis should be considered for palliative radiotherapy. Weight-bearing regions in the hip, epidural spinal cord compression, or proximal humerus lesions should also be considered for surgical evaluation and possible prophylactic fixation. However, the role of aggressive local therapy for metastatic disease must be weighed carefully with the need for systemic therapy in this aggressive neoplasm. Data has emerged suggesting that bisphosphonates may be effective in reducing bony complications and discomfort caused by metastatic tumor to bone.[46] Definitive clinical trials are not yet available in SCLC patients.

Patients presenting with metastatic SCLC to the adrenal gland are generally those with systemic manifestations of their disease.[47] It is relatively uncommon for patients with adrenal metastasis to develop clinical hypoadrenalism, but bilateral metastases can produce adrenal insufficiency.[48]

Patients with liver metastasis may present with abdominal pain, asymptomatic hepatomegaly, or jaundice. Evaluation with ultrasound, CT scan, or MRI is often useful in evaluating for metastases to the liver. Generally, chemotherapy is the treatment of choice, but in unique cases, radiation, surgery, or other local treatment modalities such as chemoembolization, cryotherapy or radiofrequency ablation may play a role.[49]

## THE ROLE OF CLINICAL EXAMINATION DURING DISEASE EVALUATION

As in all cancer patients, the clinical examination is a crucial component of the initial evaluation of patients presenting with SCLC. A thorough patient history is important to evaluate for local, regional, and systemic symptoms of cancer as listed in the previous sections. The clinical examination may reveal additional abnormal findings in these patients who most often present with advanced disease at the time of diagnosis. The initial approach to the physical examination in SCLC patients includes a general assessment of the patient and his or her overall well-being and performance status. Most patients with SCLC do present with physical symptoms, which often lead to a change in a patient's general appearance. The general examination may reveal cachexia associated with weight loss, and may also reveal changes in skin tone or color characteristic of the

anemia often present in patients with advanced disease (or the plethora seen in patients with emphysema). Vital signs are another important element of the examination because patients may have developed abnormal heart rates or rhythms based on systemic illness or involvement of the cardiopulmonary system. Specifically, resting tachycardia is common in patients with underlying hypoxia. Patients may also exhibit postural hypotension related to poor oral intake leading to dehydration. Fever can be associated with postobstructive pneumonia, and tachypnea is a typical finding because many patients have pulmonary compromise from their cancer or underlying pulmonary disease.

The physical examination of the head and neck region in patients with SCLC can help detect spread to this region and associated abnormalities. Subcutaneous metastasis can occur in the scalp, and these can be demonstrated on physical examination by observation and palpation. In addition, cervical or supraclavicular, or even occipital lymphadenopathy can be associated with locally advanced or metastatic SCLC. SVC syndrome may reveal neck vein distension or facial or periorbital swelling in this region as well. Cranial nerve abnormalities can be associated with CNS disease, meningeal carcinomatosis, or sympathetic nerve involvement with the occasional small cell cancer affecting the superior sulcus producing Horner syndrome.

The pulmonary examination is crucial in evaluating patients with lung cancer. Local consolidation from mass effect or atelectasis can occur and often shows other specific findings such as pneumonia leading to crackles, rhonchi, wheezing, or dullness to percussion. SCLC can also produce pleural effusions demonstrated by dullness to percussion and decreased breath sounds. Pleural involvement may lead to a pleural friction rub. Most patients with SCLC have a history of heavy tobacco exposure and may therefore demonstrate changes associated with COPD such as wheezing and decreased air movement.

Cardiac examination in SCLC patients may reveal tachyarrhythmias such as sinus tachycardia or atrial fibrillation if pericardial disease (or pulmonary hypertension) is present. The cardiac examination may reveal a friction rub consistent with pericarditis or a pericardial effusion. Pulmonary artery hypertension can also accompany lung cancer, and a right ventricular heave may be identified on physical examination.

Examination of the bones including spine may reveal areas of tenderness consistent with bony metastatic disease. Less often observed in small cell histology is digital clubbing or hypertrophic pulmonary osteoarthropathy (HPOA), with tenderness of the bones of the lower extremities, more characteristic of non–small cell carcinoma.

Careful examination of all lymph node stations is important in patients with SCLC because of the proclivity of this disease to metastasize to lymph nodes. The palpable regions most commonly involved are the cervical and supraclavicular lymph node chains. Enlarged axillary lymph nodes may also be detected. Inguinal lymph nodes are less commonly involved, but when present, they indicate disseminated stage IV disease.

The abdominal examination may demonstrate liver, adrenal, or intraperitoneal metastases. Small cell carcinoma can also spread to the periportal or pancreatic region. Examination may show hepatomegaly or abdominal fullness consistent with abdominal metastasis. Ascites can develop in patients with metastatic SCLC related to intra-abdominal tumor or liver disease and produce abdominal distension.

The extremity examination in patients with NSCLC can show digital clubbing, but this occurs less commonly in small cell histology. Other abnormalities in the extremity examination can include wasting of the muscles, fingernail changes, or cyanosis in these patients.

Skin examination may show changes in patients with SCLC, including pallor associated with anemia, skin rashes that may be paraneoplastic in nature, or jaundice associated with liver dysfunction (or occasionally hemolysis). Small cell carcinoma can also spread to the skin or subcutaneous tissues, producing symptomatic or asymptomatic nodules.

The neurologic examination requires particularly careful attention in SCLC patients. Various manifestations can include dementia, changes in mental status, weakness (focal or diffuse), loss of sensation, cerebellar findings such as ataxia, loss of coordination and gait disturbances, and cranial nerve abnormalities. These findings need to be viewed in the context of the overall clinical situation to make an appropriate diagnosis and direct further evaluation and treatment. A careful neurologic examination helps to evaluate for CNS involvement from metastatic tumor or paraneoplastic neurologic effects. Neurologic consultation is often helpful as are imaging studies such as CT or MRI scans, and electromyogram (EMG)/nerve conduction velocity (NCV) studies in localizing the lesion and narrowing down the differential diagnosis of neurologic abnormalities. Serum and cerebrospinal fluid antibodies may be helpful in suspected paraneoplastic syndromes.

## PARANEOPLASTIC SYNDROMES

Paraneoplastic syndromes are associated with malignancy, but are not directly related to the primary tumor, regional spread, or distant metastasis. Paraneoplastic syndromes are particularly common in SCLC patients, occurring in up to 50% of patients with SCLC, but in only about 10% of patients with NSCLC.[50] Paraneoplastic syndromes may precede the diagnosis of malignancy, or at any time during the course of the disease, but worsening of these symptoms generally signals disease progression. The extent of symptoms from paraneoplastic syndromes may be unrelated to the size of the primary tumor or bulk of metastatic disease, and may, in fact, be the dominant cause for a patient to seek medical attention.[51] These syndromes are clinically important because of the disabling effect on patients. Clinical improvement may result from treating the underlying malignancy, leading to improvement in quality of life. Paraneoplastic syndromes can be useful markers of tumor activity and may also carry prognostic value (Table 24.2).

| TABLE 24.2 | The Paraneoplastic Syndromes Associated with Small Cell Lung Cancer | |
|---|---|---|
| **Category** | **Syndrome** | **Predominant Cell Type** |
| General | Cachexia/anorexia | Any |
| | Depression | Any |
| Endocrinologic | Hypercalcemia | Squamous cell |
| | Cushing syndrome | Small cell |
| | SIADH | Small cell |
| Neurologic | LEMS | Small cell |
| | Cerebellar degeneration | Small cell |
| | Peripheral neuropathy | Small cell |
| | Myotonia | Small cell |
| | Retinopathy | Small cell |
| | Optic neuropathies | Small cell |
| Hematologic | Anemia | Any |
| | Thrombocytosis | Any |

| Musculoskeletal | Digital clubbing | Adenocarcinoma |
| | HPOA | Adenocarcinoma |
| | Polymyositis | Any |
| Dermatologic | Dermatomyositis | Any |
| | Acquired tylosis | Small cell |
| | Trip palms | Small cell |
| | Erythema gyratum repens | Small cell |
| Renal | Nephrotic syndrome | Any |
| | Glomerulonephritis | Any |

**General**    Patients with SCLC can present with a wasting syndrome characterized by anorexia, cachexia, weight loss, weakness, and fatigue that is unresponsive to increased caloric intake. The etiology of such paraneoplastic cachexia is not known but is likely multifactorial, involving cytokines and hormonal factors.[52] The increased metabolic needs of an increasing tumor burden, and failure to efficiently incorporate nutrients may explain the difficulty in gaining or even maintaining weight despite adequate caloric intake. Patients appear to have a syndrome of maladaptive metabolism that results in decreased nutrient intake, increased hepatic gluconeogenesis, failure to efficiently use glucose, and increased proteolysis and lipolysis. Neuropeptides produced in the hypothalamus stimulate appetite in a normal individual[53]; whether qualitative or quantitative abnormalities of these peptides play a role in the anorexia of cancer is not clear. Other mediators may be involved in the pathophysiology of the wasting syndrome including cytokines such as tumor necrosis factor $\alpha$ (TNF-$\alpha$), hormones (insulin, corticotropin, epinephrine, growth hormone), and other tumor-related factors.[54] Retrospective studies have consistently found that patients experiencing weight loss have an inferior survival compared with those who have maintained their weight.[55]

**Endocrine**    Paraneoplastic endocrine syndromes commonly associated with SCLC are caused by the production of protein hormones or precursors to these hormones. Two potential mechanisms may explain the production of these hormones. One hypothesis states that cancers producing ectopic endocrine syndromes are derived from amine precursor uptake and deamination (APUD) cells.[56,57] Another more recent hypothesis states that these hormones are not produced ectopically, but rather represent an increased expression of a normal cell function.[58] The most common endocrine syndromes associated with SCLC are Cushing syndrome and syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Other paraneoplastic abnormalities can include hyperglycemia, hypoglycemia, hypercalcemia, and gynecomastia.

Ectopic adrenocorticotropic hormone (ACTH) can produce Cushing syndrome. This syndrome is seen in up to half of the patients with lung cancer[59] and is most commonly associated with SCLC. Studies have shown that normal tissues can produce small amounts of the precursor pro-ACTH.[34] Carcinomas seem to produce a greater amount. SCLC cells can convert pro-ACTH to the biologically active ACTH, and therefore produce the clinical syndrome of weakness, muscle wasting, drowsiness, confusion, edema, hypokalemic alkalosis, and hyperglycemia. However, severe symptoms develop in less

than 5% of patients with SCLC.[60] These patients may have a worse prognosis than SCLC patients who do not demonstrate ectopic ACTH production. One study found a response rate of only 46% to chemotherapy in these patients, with a median survival of only 3.6 months.[61]

Paraneoplastic Cushing syndrome can be differentiated from pituitary-dependent Cushing disease by five factors: (a) both the serum and urine cortisol levels are markedly elevated in cancer-related Cushing syndrome, but only moderately increased in Cushing disease; (b) serum ACTH levels are markedly higher in cancer-related Cushing syndrome compared with Cushing disease; (c) hypokalemia is more commonly seen in cancer-related Cushing syndrome; (d) the elevated levels of ACTH and cortisol are generally not suppressed by high doses of dexamethasone in cancer-related Cushing syndrome in contrast to Cushing disease; (e) corticotropin-releasing hormone (CRH) increases ACTH and cortisol secretion in Cushing disease but not in cancer-related Cushing syndrome.[62] Effective therapy of the underlying disease in SCLC can often improve the paraneoplastic Cushing syndrome.

Lung cancer is the most common malignancy associated with SIADH, and SIADH can be seen in 40% of patients with small cell carcinoma.[63] This syndrome produces hyponatremia, hypervolemia, increased loss of renal sodium, and inappropriately high urine osmolality. This clinical syndrome was first described in cancer patients by Vorherr et al.[64] in 1968. Increased levels of antidiuretic hormone (ADH) were found in these patients. Despite the laboratory abnormality, not all of these patients have symptoms attributed to SIADH. In order to develop symptoms, increased water intake is also needed.[65,66] Symptomatic patients can present with confusion, somnolence, and may lead to seizures. SIADH does not seem to lead to a worse prognosis in these patients, and often resolves with effective treatment of the cancer,[67] but tends to recur with tumor recurrence or progression.

**Neurologic**   Paraneoplastic syndromes of the nervous system are rare, affecting less than 1% of cancer patients.[68] These syndromes can be caused by a systemic autoimmune reaction to an "onconeural" antigen shared by both the cancer and the nervous system.[69] Specific autoantibodies have been identified in some patients with paraneoplastic syndromes of the nervous system, and these can be associated with specific tumors. Treatment of neurologic paraneoplastic syndromes consists of (a) treatment of the underlying cancer, which has been shown to diminish the neurologic impairment in some cases,[70] and (b) suppression of the antibody with steroids, cyclophosphamide, plasma exchange, and intravenous immune globulin (IVIG). Such immunosuppression may also lead to significant clinical improvement.[71]

Lambert-Eaton myasthenic syndrome (LEMS) can affect up to 3% of patients with SCLC.[72] LEMS provides strong support for the autoimmune basis for neurologic paraneoplastic syndromes. Patients develop immunoglobulin G (IgG) antibodies against voltage-gated calcium channels (VGCC) in the presynaptic neurons. Decreased calcium entry leads to decreased acetylcholine release, leading to a pure motor neuropathy characterized by muscular weakness. Patients present with muscle weakness preferentially affecting the lower limbs and proximal muscles. Commonly associated is autonomic dysfunction such as dry mouth, impotence, constipation, and blurred vision. On physical examination, deep tendon reflexes in lower extremities are diminished or absent, and patients have increased strength after repeated contraction of the involved muscles, differentiating LEMS from typical myasthenia. Treatment of the underlying tumor usually results in improvement of LEMS, and plasma exchange or IVIG may also improve the clinical symptoms.[73] One case-control report suggested that these patients affected by LEMS may actually have a better survival outcome than SCLC patients who are not affected.[74] The authors hypothesized that these patients with LEMS may have a slower rate of tumor growth in part related to tumor macrophage infiltration.

Paraneoplastic cerebellar degeneration (PCD) may have an indolent or a more sudden onset, often evolves rapidly, and can lead to ataxia, dysarthria, and dysphagia. Symptoms may be purely cerebellar, or they can also be associated with other neurologic manifestations. The disease course for this effect may be independent of that of the underlying tumor. This syndrome has been shown to result from autoantibodies against the Purkinje cells of the cerebellum.[75] In half the patients of PCD associated with SCLC, circulating anti-Hu antibodies are found.[76] Limbic encephalitis is a paraneoplastic effect consisting of memory failure, seizures, and agitation.[77] Most of these patients also have detectable anti-Hu antibodies in both the serum and cerebrospinal fluid.

Peripheral neuropathies in SCLC patients may indicate a paraneoplastic syndrome. Four types of paraneoplastic peripheral neuropathies can occur: pure motor, pure sensory, sensorimotor, and autonomic.[75] SCLC is most strongly associated with peripheral sensory neuropathy, a rapidly developing severe disorder in which patients lose sensory modalities in all four extremities. Symptoms usually start proximally and progress distally. Neurologic symptoms usually precede the diagnosis of cancer, and anti-Hu antibodies are often present in high titers.[78] Autonomic neuropathy can also develop in patients with the anti-Hu antibody. These patients can have the entire autonomic nervous system affected or may present with isolated dysfunction, involving the sympathetic or the parasympathetic nervous system. These patients may develop gastroparesis and intestinal pseudo-obstruction resulting from dysfunction of autonomic innervation to the gastrointestinal tract as well.

SCLC can be associated with myotonia. In neuromyotonia, spontaneous and continuous muscle fiber activity causes stiffness and cramping. The muscle activity continues during sleep, general anesthesia, and peripheral nerve block, but can be inhibited by blocking the neuromuscular junction. This condition is differentiated from the stiff-man syndrome in which muscle activity goes into quiescence during sleep and general anesthesia.[79] In stiff-man syndrome, the axial lower extremity muscles are affected most, causing such severe spasms that bone deformities and fractures have been reported.

Cancer-associated retinopathy (CAR) is a rare complication of SCLC. Patients present with night blindness, photosensitivity, and impaired color vision. Symptoms often develop prior to the detection of cancer, and the disease usually progresses to painless visual loss. Visual field testing reveals peripheral and ring scotomata and loss of visual acuity. The electroretinogram is abnormal and establishes the diagnosis. This paraneoplastic phenomenon is thought to be caused by autoimmune destruction of photoreceptors with preservation of the rest of the optic pathway. Steroids, plasmapheresis, or intravenous IgG (IVIgG) can reduce antibody titer and stabilize vision in some cases, but progressive total loss of vision is more the rule.[80] Paraneoplastic optic neuropathies can also occur in SCLC.[81] These are characterized by visual loss, as well as other neurologic changes, and may respond to immunosuppressive therapy.

### Hematologic

Cancer-related anemia is generally characterized by a normochromic to slightly hypochromic morphology and a low serum iron, but with increased bone marrow iron stores and ferritin. Other causes of anemia must be ruled out such as nutritional deficiencies, bleeding, concurrent inflammatory disorders or other causes of chronic disease, and bone marrow suppression from treatment such as chemotherapy or radiation. Treatment of the underlying malignancy may occasionally reverse the anemia, but more commonly, transfusion or recombinant erythropoietin may be required because of suppressed erythropoietin levels. Paraneoplastic anemia may be related to cytokines such as the tumor necrosis factor and interleukin-1.[82]

Thrombocytosis can be observed as a paraneoplastic effect in SCLC patients. Up to 35% of patients with platelet counts greater than $400,000/\mu$L will have an underlying malignancy, and thrombocytosis is present in 40% of patients with lung cancer.[83] Interleukin-6 (IL-6) has been shown to stimulate production of platelets in vivo and in vitro, and patients with cancer have been observed to possess elevated serum levels of IL-6.[84] Thrombopoietin simulates megakaryocyte proliferation and may play a role in platelet overproduction; however, the definitive cause of thrombocytosis in cancer patients has not yet been determined.

There is no clear link between thrombocytosis and the elevated risk of venous thrombosis, or Trousseau syndrome, in patients with cancer.[85] As many as 17% of patients with recurrent venous thromboembolism have an underlying malignancy.[86] Clotting may be caused by the release of procoagulants or cytokines from tumor cells, inappropriately initiating the coagulation cascade and activating platelet aggregation.[87] Patients who develop deep venous thrombosis and do not have a contraindication to systemic anticoagulation should receive intravenous heparin or low–molecular weight heparin, and anticoagulation should be continued for a minimum of 6 months.[88] Patients with a documented deep venous thrombosis or pulmonary embolism with a contraindication to anticoagulation should be considered for placement of an inferior venous cava filter.

### Musculoskeletal

Digital clubbing and HPOA can be associated with many types of lung disease. With bronchogenic carcinoma, this association is strongest with adenocarcinoma histology and least common with small cell cancer. The mechanism for these paraneoplastic disorders is unknown, but may involve neurogenic, hormonal, and vascular mechanisms. Circulating vasodilators have been postulated as one underlying mechanism of this condition.[89] In a study of 111 patients with lung cancer, clubbing was present in 29%.[90] Clubbing is more commonly observed in women than men (40% vs. 19%). About 10% to 20% of patients also have HPOA. HPOA is characterized by digital clubbing as well as pain, swelling, and tenderness of distal extremities with or without joint effusions, and periosteal new bone formation along the shafts of long bones. Lower extremity involvement predominates. In patients who present with HPOA, malignancy and NSCLC in particular are found in 90% of patients.[91]

Polymyositis, an inflammatory myopathy, can represent a paraneoplastic effect in SCLC patients. Characterized by muscle pain, weakness, and inflammation, this condition may predate the diagnosis of malignancy by up to 5 to 10 years.[92] In one retrospective study of polymyositis, the relative risk of cancer in patients diagnosed with this condition was 1.8, and 14% of these patients ultimately died of cancer. It remains a rare condition, however, and may be difficult to recognize and diagnose in lung cancer patients with a host of other ailments.

### Dermatologic

Many dermatologic manifestations can be associated with malignancy. Most commonly associated with lung cancer are dermatomyositis, acquired tylosis, tripe palms, and erythema gyratum repens.[93] Dermatomyositis is identified by a bluish purple "heliotrope" rash on the upper eyelids, a flat rash on the face and trunk, and erythema and scaling of the knuckles that often precede muscle weakness.[94] Acquired tylosis presents with keratoderma in palmar and plantar areas. Tripe palms are thickened palms with the fingers acquiring a velvety texture. This condition can occur independently or can be found in association with acanthosis nigricans. More than 90% of patients with tripe palms have an underlying or associated malignancy.[95] Erythema gyratum repens is a reactive erythema presenting with lesions that produce a "wood-grain" appearance of the affected skin, especially on the trunk and proximal extremities. Pruritus can become debilitating. An associated malignancy is usually present with erythema gyratum repens, with lung cancer observed most frequently.

### Renal

An association has been made between the development of nephrotic syndrome and glomerulonephritis and malignancy.[96] This paraneoplastic effect is rare, however, occurring in less than 1% of lung cancer patients. Nonetheless, smokers who develop an otherwise idiopathic renal disorder should be evaluated for an underlying malignancy.

## CONCLUSION

In summary, the clinical presentation of patients with SCLC, including paraneoplastic syndromes often begins with new or changing symptoms of pulmonary origin, but may be characterized by a host of regional or systemic complaints. The vast majority of this population will present with significant symptoms at the time of initial diagnosis, and generally, they have abnormal findings on the physical examination. This stresses the importance of the basic technique of a thorough medical history and physical examination in the population of SCLC patients. A careful and detailed discussion with patients will assist in the proper diagnosis and staging of such patients. This can also help guide further evaluation and management decisions to determine the appropriate interventions to maximize treatment efficacy and improve quality of life, and ultimately prevent future complications from this disease.

The clinician must be particularly aware of the diverse signs and symptoms of patients presenting with SCLC, including those related to the local tumor, regional spread of disease to the surrounding structures, distant spread of cancer, and general symptoms or paraneoplastic syndromes that affect these patients. It is crucial to establish the baseline condition of these patients to differentiate new or progressive symptoms related to the cancer itself versus toxicities arising from diagnostic or therapeutic interventions and therapy.

The careful clinical evaluation of lung cancer patients can help determine an individual patient's stage of disease as well as help address the need for interventions to maximize symptom control, provide effective curative treatment when possible, and individualize palliative measures for the maximum improvement of overall quality of life and survival. Measuring symptom control and quality of life may also ultimately lead to better monitoring and evaluation of the effectiveness of our treatments.

CHAPTER **25**

# Gender-Related Differences in Lung Cancer

For several decades, lung cancer has been mainly viewed as a malignant disease affecting men; however, over the past 30 years, as a consequence of the dramatic increase in tobacco consumption in women, there has been an exponential increase in the incidence of the disease among women.[1] Starting from 1990 to 1995, in many parts of the western world, the incidence of lung cancer in men has progressively declined as a consequence of antitobacco campaigns. If the worldwide sharp increase in women continues, the incidence of this malignancy is projected to be identical for women and men over the next decade.[2] Overall, lung cancer causes the death of more women than the other three most common female cancers (breast, colorectal, and ovarian cancer) combined.

Sex differences in terms of susceptibility to carcinogens and natural history of the disease have been observed. When compared with men, women are more likely to develop adenocarcinoma and small cell carcinoma than squamous cell carcinoma, are more likely to be younger (<50 years old) at the time of diagnosis, are less likely to have a positive smoking history, and have a better survival at any stage (Table 25.1).[3–6]

## EPIDEMIOLOGY

Internationally, lung cancer is the most often diagnosed cancer and is the leading cause of cancer-related deaths in men and women.[7] In the United States, prostate cancer has the highest incidence in men, and in women, breast cancer has the highest incidence.[8]

Tobacco smoking became popular among women at the end of World War II, and the number of lung cancer cases and deaths in women started to increase around the 1960s and 1970s. The prevalence of smoking is extremely epidemic especially in high school girls: the percentage of American high school girls who smoke rose from 17.9% in 1991 to 27.7% in 2001.[9]

**United States Data**  In the United States, the lung cancer incidence and mortality are different between men and women. The incidence rate is higher in men than in women regardless of age.[3] In 2006, among new lung cancer cases, it has been estimated that 92,700 men (53% of the lung cancer cases) were diagnosed with lung cancer and 90,330 died of their disease. For women, 81,770 (47% of lung cancer cases) were diagnosed with lung cancer and 72,130 died of their disease.[8] Lung cancer is the leading cause of cancer-related death in both sexes. Although the lung cancer incidence and mortality have been decreasing, since the early 1990s, in men, the incidence and mortality from lung cancer in women has been rising until just recently.[10,11] The incidence in women peaked in 1991 at 33.1 per 100,000 person-years and has leveled off at 30.2 to 32.3 per 100,000 person-years between 1992 and 1999.[3]

Several other epidemiologic differences exist between the sexes. Utilizing the National Surveillance, Epidemiology, and End Results (SEER) database from 1975 to 1999, Fu et al.[3] found that the median age at the time of diagnosis was 66 years for both men and women. However, more women were diagnosed at an age younger than 50 compared to men (8.6% vs. 6.9%, respectively; $p = 0.0001$). Overall incidence rates in both men and women younger than 50 years old have decreased. In those patients older than 50 years, the incidence of lung cancer decreased by 13.5% in men but increased by 37.3% in women from 1975 to 1987 and from 1988 to 1999. Lung cancer rates in women older than the age of 50 continue to rise.[4–6,12,13] Among 228,572 patients with lung cancer registered in the SEER database, and diagnosed from 1975 to 1999, 35.8% were women. Women accounted for 40.9% of patients who were younger than 50 years of age.

The proportional occurrence of histologic subtypes also differed significantly between men and women ($p < 0.0001$): in women, adenocarcinoma (44.7%) was the most common histologic subtypes, followed by small cell carcinoma (22.6%) and squamous cell carcinoma (21.4%).[3] The incidence rate of adenocarcinoma increased in both men and women from 1975 to 1987, with an

increase seen in women of 40.5% versus 9.3% in men. In the same period, incidence rates for squamous cell and small cell carcinoma decreased in men, while increasing in women (Fig. 25.1). In the previously mentioned group of patients registered in SEER, the sex-related survival difference was greatest in patients with local disease and declined as the extent of disease increased.[3]

**European Data**    Data from European cancer registries are slightly different than the U.S. statistics. In Europe, lung cancer accounts for 10% of cancer deaths in women compared to 28% in the United States.[14] Lung cancer is not the most common cause of cancer-related deaths in women.[15] Lung cancer ranks third behind breast and colon cancer in European women

**FIGURE 25.1**    Age-adjusted, gender-specific incidence rates of histologic subtypes of lung cancer, from 1975 to 1999. (From Fu JB, Kau TY, Severson RK, et al. Lung cancer in women: analysis of the national Surveillance, Epidemiology, and End Results database. *Chest* 2005;127:768–777.)
**FIGURE 25.2**    Estimated incidence of cancer **(A)** and estimated mortality from cancer **(B)** in Europe in 2006. (Data from Ferlay J, Autier P, Boniol M, et al. Estimates of the cancer incidence and mortality in Europe in 2006. *Ann Oncol* 2007 Mar;18[3]:581–592.)

(Fig. 25.2). Of course these data vary from country to country; the lung cancer–related deaths have increased in the United Kingdom and northern European countries, where lung cancer is now the leading cause of cancer-related deaths in women. The risk of lung cancer for women is highest in Denmark and Iceland. Data published from a Polish community-based cancer registry revealed that the age at diagnosis was younger for women compared to men (60.02 vs. 62.18 years, respectively; $p < 0.001$).[4] Squamous cell cancer was the most common type of lung cancer in both sexes in Poland. Similarly to U.S. data, more women were diagnosed at an age younger than 50 years compared to men (23% vs. 12%, respectively). Also, women were more frequently nonsmokers (18.8%) than men (2.4%).

**Asian Data**    In Asia, the lung cancer mortality rates for women are lower than in the United States and Europe. However, the lung cancer mortality rates are increasing across several Asian countries including China, South Korea, and Japan.[16–18] Adenocarcinoma tends to be the most common histology in women in Asia, and this proportion continues to increase over time.[19–24] Although tobacco smoke is the most common cause of lung cancer in women throughout the rest of the world, the cause of lung cancer in the Asian woman is more complex. The proportion of female lung cancer patients who are never-smokers is 61% to 83%.[25,26] In fact, only Filipino and Japanese women have a smoking rate higher than 10%.[27] In comparison, the smoking prevalence is 22% in U.S. women.[27] Environmental tobacco smoke and indoor pollutants, including cooking oil fumes and burning coal, have been implicated in increasing risks of lung cancer in nonsmoking Asian women.[28–39]

## SUSCEPTIBILITY

**Never-Smokers**    The risk of lung cancer is 2.5 times more common in female lifetime nonsmokers compared to male nonsmokers.[40] Several studies have shown an association of increased risk of lung cancer, particularly adenocarcinoma, in never-smoking women with smoking husbands.[41] Reasons for this are unclear; however, hormonal factors may play a role.[42,43]

Thun et al.[44] investigated lung cancer death rates in lifelong nonsmokers. The age-standardized lung cancer death rate was 17.1 for men and 14.7 for women per 100,000 person-years. A small increase in death rate was seen between the periods of 1959 to 1972 and 1982 to 2000 in white and African American women, but not for men. The increase in death rate was only significant in women aged 70 to 84 years ($p < 0.001$).

**Smokers**    Epidemiologic studies demonstrate mixed results regarding female smokers and their susceptibility to develop lung cancer. Some studies note an increased risk of developing lung cancer in women compared to men (Fig. 25.3). Other

**FIGURE 25.3**    Age-adjusted incidence rates for men and women, 1975 to 2004. The decline in the incidence of lung cancer in men has not been seen in the female population. (From SEER program, Fast Stats: Lung and Bronchus Cancer, 9 registries, Age-adjusted incidence rates, 1975–2004. Available at: http://seer.cancer.gov/faststats/sites.php?site = Lung%20and%20Bronchus%20Cancer&stat = Incidence .Accessed September 10, 2009.)

trials found similar risks between the sexes when controlling for smoking exposure.[45–48] One trial concluded that smoking women had a 1.5-fold higher relative risk (RR) of lung cancer compared to men.[49] Another study noted an odds ratio (OR) for developing lung cancer in a 40–pack-year smoker compared to a never-smoker of 27.9 in women versus 9.6 in men.[50] In 2004, Henschke and Miettinen[51] reported an increased risk of lung cancer of 2.7 (prevalence OR with 95% interval estimate of 1.6 to 4.7) in women versus men, controlled for age and smoking history, in a regression analysis done among smokers undergoing screening by computed tomography (CT) in the Early Lung Cancer Action Project.

## GENETIC/FAMILIAL FACTORS

Polymorphisms of genes that encode for enzymes, important in the breakdown of tobacco-derived carcinogens, may play a role in the development of lung cancer in female smokers and never-smokers. N-acetyltransferase (NAT2) activity can modify risk as well as cytochrome P450 (CYP) CYP1A2 activity (see Chapter 4). In Chinese female nonsmokers, low NAT2 activity and fast CYP1A2 activity had an adjusted OR of 6.9 compared to high NAT2 activity and slow CYP1A2 activity, making them at higher risk of developing lung cancer. Also, CYP1A1 is associated with an increased risk of lung cancer in female nonsmokers (OR = 3.97; 95% confidence interval [CI], 1.85 to 7.28).[52] CYP1A1 is important in converting tobacco carcinogens into DNA-binding metabolites important in DNA adduct formation. Glutathione S-transferase M1 (GSTM1) and T1 (GSTT1) are important for detoxification of carcinogens. GSTM1 null genotype is associated with an increased risk of lung cancer in some series but not in others.[52–55] One study conducted among Japanese women demonstrated an association between GSTM1 null genotype and the increased risk of lung cancer particularly in lifetime nonsmoking women with the null genotype and the increased risk of lung cancer in never-smoker women with the null genotype and significant environmental tobacco smoke exposure (OR = 2.27; 95% CI, 1.13 to 2.7) compared with women without the null genotype and no significant environmental tobacco smoke (ETS) exposure.[56] Similar to GSTM1, the null genotype of GSTT1 has shown an increased risk for the development of lung cancer in never-smokers.[57]

Nitadori et al.[58] evaluated the association of lung cancer incidence and family history in the Japanese population. The study found that women had higher risks of lung cancer if a first-degree relative was diagnosed with lung cancer with a hazard ratio (HR) of 2.65 compared to similar men with an HR of 1.69. Other case-control studies found similar findings.[59]

## VIRAL FACTORS

Human papillomavirus (HPV) may play a role in the development of lung cancer. In lung cancer, one study reported that female lung cancer patients who were never-smokers and older than 60 years of age had a higher prevalence of infection with HPV-16 and HPV-18.[60,61] However, other studies have not demonstrated this same result in similar populations.[62]

## DIET, RADON, OCCUPATIONAL EXPOSURES, AND PREEXISTING LUNG DISEASE

Sex differences have not been well studied regarding the risk of developing lung cancer related to occupational exposures independent of smoking (asbestosis, radiation, and other chemicals), diet, and radon. In one study of never-smoking women, researchers found that women exposed to asbestos (OR = 3.5; 95% CI, 1.2 to 10) and pesticides (OR = 2.4; 95% CI, 1.1 to 5.6) had an increased risk for developing lung cancer.[63] Dry-cleaning workers were also found to have an elevated risk (OR = 1.8; 95% CI, 1.1 to 3.0). Exposure to radiation in the workplace or for treatment of other malignancies has been linked to the development of lung cancer. A recent study reported that breast cancer radiotherapy increased the risk of developing lung cancer particularly in smokers. Adjusted OR for smokers who received postmastectomy radiation was 18.9 (95% CI, 7.9 to 45.4). Nonsmokers in this study, who received postmastectomy radiation, did not have an increased risk for the development of lung cancer.[64]

Exposure to high levels of radon is also associated with an increased risk for developing lung cancer particularly in smokers or those with exposure to secondhand smoke.[65] Bonner et al.[66] studied women pooled from several case-control studies that measured exposure to secondhand smoke and radon. The researchers also looked at the GSTM1 status of the person and found that in individuals exposed to residential radon who had GSTM1 null genotype, the risk of lung cancer was threefold higher than GSTM1 carriers (OR = 3.41; 95% CI, 1.10 to 10.61) even when adjusting for age, smoking status, and secondhand smoke exposure. In case-control and cohort studies, high dietary intake of fruits and vegetables decrease the risk of developing lung cancer.[67] Of the fruits and vegetables studied, tomatoes and cruciferous have been associated with decreased risk for lung cancer.[68–70]

Other potential risk factors for lung cancer include preexisting lung diseases such as asthma and chronic obstructive pulmonary diseases. Several case-control studies demonstrate an increased risk for developing lung cancer in both men and women affected of these lung diseases.[71] Even when controlling for active and passive tobacco exposure, some studies show an increased risk for lung cancer.[72] Wu et al.[73] studied nonsmoking women with previous lung disease and demonstrated an increased risk for lung cancer (adjusted OR = 1.56; 95% CI, 1.2 to 2.0).

## STEROID HORMONES IN LUNG CANCER

Classical steroid hormone pathways have been successfully targeted in the treatment of breast and prostate cancer, where

hormone-dependent growth has been well established. Steroid hormone receptors are known to be expressed in tissues outside the reproductive tract and to have biological effects in nonreproductive tumors. Some effects mediated by steroid receptors appear to be independent of steroid ligands and result from activation of steroid receptors by phosphorylation pathways. Steroid hormone receptors could thus have biological activity via steroid-induced signaling or steroid-independent signaling. Because estrogen receptor (ER) signaling pathways that induce proliferation have been repeatedly found in non–small cell lung cancer (NSCLC), the ER is a promising target for lung cancer therapy. The progesterone receptor (PR) may play a role in lung cancer biology as well.

## ESTROGEN RECEPTORS IN LUNG CANCER

Studies of sex differences in lung cancer risk and disease presentation suggest that estrogens may be involved in the aetiology of this disease.[74] For example, female patients are more likely to present with adenocarcinoma of the lung and to be never-smokers compared to male patients.[75] As detailed previously, data have recently emerged that the rate of diagnosis of lung cancer in never-smoking women is higher than in never-smoking men.[76] ERs, members of the nuclear steroid receptor superfamily, mediate cellular response to estrogen. Two forms of the ER have been identified, ER$\alpha$ and ER$\beta$, which are encoded by separate genes and display different tissue distributions. These proteins function either as ligand-activated transcription factors or can be activated by phosphorylation independent of ligand (Fig. 25.4).[77]

There have been inconsistent results reported concerning the presence of ERs in lung tumors. With the identification of antibodies that distinguish between ER$\alpha$ and ER$\beta$ and more standard immunohistochemical procedures, it is now clear that ER$\beta$ is expressed and functional in most human NSCLC cell lines and is present in primary specimens of human NSCLCs from both men and women.[78–82] There is less consensus on the expression of ER$\alpha$ in the lung. ER$\alpha$ was mainly found in the cytoplasm and membrane in immunohistochemical studies and was found to be comprised of mostly alternatively spliced variants based on immunoblot and RNA analysis.[78] This nonnuclear ER$\alpha$ pool may be comprised of a variant isoform that lacks the amino-terminus, because it is differentially detected

**Nuclear Estrogen Receptor Mechanisms**
**FIGURE 25.4** Classic nuclear estrogenic effects in the lung. Nuclear estrogen receptors can be activated in a ligand-dependent manner by 17-$\beta$-estradiol binding to nuclear ERs at either estrogen responsive elements (ERE) or AP1 sites utilizing the fos (F) and jun (J) transcription factors in the promoters of estrogen-regulated genes. Alternatively, nuclear ERs can be activated in a ligand-independent manner such as through growth factor–mediated estrogen receptor phosphorylation. Epidermal growth factor receptor activation is an example of such a pathway. *AP1*, activator protein 1; *CBP*, calcium binding protein; *EGF*, epidermal growth factor; *EGFR*, epidermal growth factor receptor; *ER*, estrogen receptor; *ERE*, estrogen responsive elements; *ERK*, extracellular regulated MAP kinase; *ER-regulated gene*, estrogen receptor–regulated gene; *F*, fos; *Grb2/SOS*, growth factor receptor bound protein 2/son of sevenless; *GRIP-1*, glutamate receptor interacting protein 1; *J*, jun; *JNK*, c-jun N-terminal kinase; *MEK*, MAP kinase-ERK kinase; *P-ER*, phosphorylated estrogen receptor; *PO$_4$*, phosphate; *Raf*, cellular homolog of viral raf gene (v-raf); *Ras*, rat sarcoma; *Src*, Rous sarcoma oncogene.

by antibodies that recognize the ER$\alpha$ amino- and carboxy-terminal.[79] ER$\beta$, on the other hand, was found mainly localized to the nucleus with some cytoplasmic staining also observed and to be comprised of mainly full-length protein in addition to some variants.[78] ER-mediated RNA transcription and proliferation in lung tumor cell lines support the hypothesis that at least some forms of ER are functional.[78]

Several reports relating ER status to NSCLC patient survival have been completed. Nuclear localization of ER$\beta$ was observed in 45.8% to 69% of lung cancer cases[79–82] and found to be a favorable prognostic indicator in all studies. In some cases, the prognostic significance was only observed in male patients. Nuclear ER$\alpha$ expression is either never detected or rarely detected in NSCLC patient tumors.[79–83] Prognostic significance of ER$\alpha$ was shown to have either no effect on survival or to correlate with poor prognosis.[79,80] Kawai et al.[79] reported that the presence of cytoplasmic ER$\alpha$ and the absence of ER$\beta$ is associated with worse prognosis among NSCLC patients. Patients at higher risk at histopathologic stage I were those with no ER$\beta$ expression.[79] These results are opposite of what has been demonstrated for ER status and prognosis of breast cancer patients.[84,85] Whether or not this relationship is observed in other patient populations is not known at the present time, and the specificity of some ER$\beta$ antibodies has been disputed. Clearly, both nuclear and cytoplasmic ERs are important, and each component should be assessed separately and together, when examining patient tissue specimens for clinical evaluation.

Several studies have shown that women with advanced NSCLC live longer than men.[4,86,87] A population study examining lung cancer presentation and survival in premenopausal versus postmenopausal women revealed that the premenopausal women presented with more advanced disease including poorly differentiated tumors with less favorable histologies.[88] However, in this study, there was not a significant survival difference between premenopausal and postmenopausal women. In a more recent study, women older than the age of 60 had a statistically significant survival advantage over both men and younger women; the difference compared to younger women is potentially caused by higher levels of circulating estrogens in the younger population.[89] Men did not show a survival difference by age.

Hormone replacement therapy (HRT) has also been examined in relation to lung cancer risk and survival and has yielded conflicting results. Ganti et al.[90] have reported that in almost 500 female lung cancer patients examined, a significant association between both a lower median age at lung cancer diagnosis and a shorter median survival time in women who used HRT around the time of diagnosis versus those who did not. This effect was more pronounced in smoking women versus nonsmokers, suggesting an interaction between estrogens and tobacco carcinogens. However, other reports suggest that HRT use prior to diagnosis could actually protect women from developing lung cancer, especially if they smoked.[91] An inverse relationship was also observed between HRT use and NSCLC risk in postmenopausal women with ER-positive lung tumors, but not ER-negative lung tumors.[92] This may suggest that there are different effects on the balance between induction

of cell differentiation and cell proliferation by estrogen in normal lung epithelium compared to malignant epithelium. Because lung tumors are also known to produce aromatase (see discussion that follows), it is possible that exogenous hormone use reduced local estrogen production by inhibiting aromatase expression. Exact HRT used, duration of use and timing of use, is critical information needed to elucidate the exact role of HRT on lung cancer risk and survival of lung cancer patients in future studies.

Although epidemiologic studies evaluating the effects of estrogen on lung cancer risk have yielded varying results, preclinical evidence clearly shows that estrogen acts to induce cell proliferation of NSCLC cells in vitro and in vivo and can modulate expression of genes in NSCLC cell lines that are important for inducing cell proliferation.[78,83,93] Genomic estrogen signaling has been demonstrated to occur mainly through ER$\beta$ in NSCLC cells.[94] Furthermore, fulvestrant, an ER antagonist with no agonist effects, inhibits cell proliferation in vitro and lung tumor xenograft growth in severe combined immunodeficient mice by ~40%.[78] Thus, preclinical evidence strongly suggests that targeting the estrogen signaling pathway may have therapeutic value to treat or prevent lung cancer.

There are currently three available strategies to target the estrogen signaling pathway in cancer cells: (a) antagonists of ER function through drugs such as tamoxifen and raloxifene; (b) downregulation of ER function through agents such as fulvestrant; and (c) reduction of estrogen levels through aromatase inhibitors, such as the reversible nonsteroidal agents letrozole and anastrozole and the irreversible steroidal inactivator exemestane.[95,96] Tamoxifen and raloxifene have partial agonist effects in certain tissues, such as endometrium. Tamoxifen has been shown to increase lung tumor xenograft growth and is not an appropriate choice of therapy for NSCLC.[94] Additionally, results from the Tamoxifen Breast Cancer Prevention trial as part of the National Surgical Adjuvant Breast and Bowel Project did not show any decreased risk of lung cancer.[97] Seventeen tumors of the lung, trachea, and bronchus were reported among the placebo group and 20 in the women who had received tamoxifen therapy. Although not statistically significant, these results suggest that tamoxifen could have some agonist effects in the lung.

**Aromatase in Lung Cancer**    Lung cancer cells can also produce their own estrogen.[98] The aromatase enzyme, a member of the CYP family, catalyzes the conversion of the androgens androstenedione and testosterone to estrone and estradiol, respectively, and is expressed in the lung.[99,100] Aromatase protein was expressed in lung tumor cell lines and tumor tissue and was demonstrated to be functional.[98] Additionally, a large decrease in growth of lung tumor xenografts treated with anastrozole was observed.[98] Aromatase inhibitor therapy in lung cancer is further supported by Coombes et al.,[101] who reported a decreased incidence of primary lung cancer in breast. Preclinical work suggests that aromatase inhibitors are also potential inhibitors for lung cancer therapy. Cancer patients treated with exemestane after 2 to 3 years of tamoxifen therapy (4 cases) compared with continued tamoxifen treatment (12 cases).

Mah et al.[102] have recently identified aromatase as an early stage predictive biomarker of lung cancer survival. In this regard, in women older than the age of 65, lower levels of aromatase in tumor tissue predicted a greater chance of survival compared to women with higher aromatase expression levels. Furthermore, the prognostic value of aromatase expression was greatest in early stage lung cancer patients (stages I and II). In this population of patients where circulating estrogen levels are low because of decreased production by the ovaries, tumor cells could compensate for this loss by producing estrogen through aromatase. These results strongly suggest the use of aromatase inhibitors, already approved for breast cancer treatment, to treat or possibly prevent lung cancer in women whose lung cancers have high levels of aromatase and may give clinicians a new tool to predict survival at an early stage of disease where more treatment options are available.

### Nongenomic Estrogen Signaling and Interactions with the Epidermal Growth Factor Receptor Signaling Pathway

In addition to the nuclear mechanisms of ER action such as increased cell proliferation and gene transcription, estrogens can also rapidly activate signaling in seconds to minutes. These rapid signaling effects are often referred to as nongenomic effects and are thought to occur via ERs located in the membrane (Fig. 25.5). In human breast cancer cells, this membrane receptor was identified as a G-protein–coupled receptor called GPR30.[103,104] In NSCLC cells, extranuclear ERs have been identified in plasma membrane fractions and have been shown to promote rapid stimulation of signaling pathways.[105] These effects can be inhibited by the addition of fulvestrant. Current work is focusing on the role of GPR30 in NSCLC.

Nongenomic ER signaling acts in concert with growth factor signaling pathways, such as the epidermal growth factor receptor (EGFR/HER-1). EGFR is a member of the tyrosine kinase receptor family that also includes HER-2, HER-3, and HER-4.[106] These receptors have been implicated in proliferation, cell motility,

angiogenesis, cell survival, and differentiation.[107] Clinically, overexpression of EGFR correlates with poor prognosis in NSCLC patients.[79,108] Furthermore, combined overexpression of EGFR and ERα correlates was demonstrated to be an independent indicator of poorer prognosis in lung cancer, consistent with cross talk between these two pathways.[79]

An interaction between the ER and EGFR has been demonstrated in lung cancer cells.[94,109] In this regard, estrogen can rapidly activate the EGFR in lung cancer cell lines (ligand-dependent signaling) and the combination of fulvestrant and gefitinib, an EGFR tyrosine kinase inhibitor (TKI), in NSCLC can maximally inhibit cell proliferation, induce apoptosis and affect downstream signaling pathways both in vitro and in vivo.[94] The more clinically relevant EGFR TKI, erlotinib, also gave superior antitumor activity in NSCLC tumor xenograft experiments when used in combination with fulvestrant compared to single-agent therapy.[109] Furthermore, membrane ERs were found to be colocalized with EGFR in lung tumors.[105] Ligand-independent nongenomic signaling can also occur. In this regard, EGFR could directly phosphorylate ER at specific serine residues.[110] These residues were found to be phosphorylated in 87.5% of ER-positive lung tumors examined.[109]

A reciprocal control mechanism was also observed between ER and EGFR in lung cancer cells. In this respect, EGFR protein expression was downregulated in response to estrogen and upregulated in response to fulvestrant in vitro, suggesting that the EGFR pathway is activated when estrogen is depleted.[94] Conversely, ERβ protein expression was downregulated in response to EGF and upregulated in response to gefitinib providing a rationale to target these two pathways simultaneously.[94]

Targeting the EGFR through small molecule TKIs is of limited use in the absence of an EGFR mutation, which only occurs in a minority of patients. Interestingly, the patients who respond to EGFR TKIs are mainly women and never-smokers.[111] Recently, a phase I clinical trial using drugs that target these two signaling pathways was performed to assess the

**FIGURE 25.5** Non-nuclear mechanism of estrogen action in the lung through rapid activation of EGFR in the cell membrane. Estrogen can bind to the ER and activate G-proteins, which can activate Src and cause matrix metalloproteinases (MMPs) to cleave EGFR ligands (amphiregulin, HB-EGF, TGF-α) to allow them to bind to EGFR. The ERK downstream signaling pathway is then activated, which ultimately leads to cell proliferation and survival. *EGFR*, epidermal growth factor receptor; *ER*, estrogen receptor; *G*, G protein subunits; *GDP*, guanosine diphosphate; *GTP*, guanosine triphosphate; *HB-EGF*, heparin-binding epidermal growth factor; *MAPK/ERK1/2*, mitogen-activated kinase-like protein/elk-related tyrosine kinase; *MEK*, MAP kinse-ERK kinase; *MMP-2*, matrix metallopeptidase 2; *MMP-9*, matrix metallopeptidase 9; *PO₄*, phosphate; *Raf*, cellular homolog of viral raf gene (v-raf); *Ras*, rat sarcoma; *Src*, Rous sarcoma oncogene; *TGF-α*, transforming growth factor alpha.

**Non-Genomic Mechanism of Estrogen Action Through Rapid Activation of EGFR**
toxicity of combined treatment of gefitinib with fulvestrant in 22 postmenopausal women.[112] Targeting both pathways was found to be safe and have antitumor activity in women with stage IIIB/IV NSCLC. Additionally, immunohistochemical staining of nuclear ER$\beta$ was correlated with improved patient survival. Phase II trials examining the combination of erlotinib with fulvestrant are also underway. Targeting the estrogen signaling pathway via both nuclear and extranuclear receptors in conjunction with the EGFR signaling pathway should have increased beneficial antitumor effects in NSCLC as has been observed in breast cancer cells.[113] Combination therapy may increase the duration of response in patients whose tumors harbor an EGFR mutation as well as an improved response in patients whose tumors do not contain an EGFR mutation.

## Progesterone Receptors in Lung Cancer

Progesterone mediates cell differentiation through the PR. Presence of PR in breast cancer is, in general, an indication of a more differentiated tumor that is responsive to antiestrogen therapy, and PR is a known estrogen-responsive gene. There are several reports of expression of PR by primary NSCLC, although there is a great deal of variability in the reported frequency of expression.[114,115] One report found no PR in NSCLC.[116] A recent report used a monoclonal antibody that recognizes both the A and B forms of PR and found positive PR expression in 46% of cases, with a preponderance of positive PR expression in tumors from women.[117] Enzymes capable of synthesizing progesterone were also detected in many NSCLC, and a positive correlation was observed between intratumoral levels of progesterone and the presence of three enzymes that participate in progesterone synthesis. Exposure of NSCLCs to progesterone led to growth inhibition of tumor xenografts and concomitant induction of apoptosis, in agreement with clinical data, suggesting that the presence of PR was correlated with longer overall survival in NSCLC patients.

Progesterone derivatives have been useful in the treatment of both endometrial cancer and breast cancer.[118,119] Agents such as medroxyprogesterone acetate, which can be given orally, have a potential role in the treatment of lung cancer, perhaps in combination with agents that suppress either the ER pathway or act on growth factor pathways such as EGFR, mesenchymal–epithelial transition factor (c-Met), or other TKIs. Long-term progesterone treatment might even be feasible for chemoprevention of lung cancer.

## Implications for Lung Cancer Therapy

Research on estrogen in lung cancer is likely to benefit both men and women. Because lung tumors from both men and women express ERs and aromatase and cell lines derived from both sexes respond to estrogens, antiestrogens, and aromatase inhibitors, these types of therapeutic treatments may be beneficial for both populations, not solely women. However, data are strongest for aromatase and estrogen levels playing an important role in survival of female lung cancer patients. Further understanding of the role of estrogen, estrogen synthesis and ERs in lung cancer will provide rationale for future targeting of this pathway for

therapy earlier in the course of disease and possibly for lung cancer prevention. Additional understanding of the role of non-nuclear versus nuclear ERs as well as PRs in lung cancer and which drugs affect which receptors will be important for designing new effective treatments.

## Sex as a Prognostic Factor in Early Stage Lung Cancer

Several authors have reported a more favorable prognosis of lung cancer in women than in men and this regardless of a longer life expectancy or the influence of other prognostic factors (Fig. 25.6). In a large population-based analysis conducted in patients with local disease, more women underwent surgery than men (64% vs. 56%; $p$ <0.001), and men were more frequently treated with radiotherapy (23% vs. 18%; $p$ <0.001). A similar trend, although to a lesser extent, was also reported for patients with locoregional extent of the disease.[4] In a Polish cancer registry information, about 20,561 patients diagnosed from 1995 to 1998 were collected and women had an RR of death of 1 compared to 1.21 ($p = 0.001$) for men at univariate analysis.[4] In a French cohort of 208 patients, when the data were adjusted for stage, women lived significantly longer in each stage of the disease.[13] Similarly, in a retrospective review of 7553 patients treated for NSCLC between 1974 and 1998, the overall median survival was 12.4 months for women and 10.3 months for men ($p$ <0.001) and the survival advantage was uniformly detected across all stages ($p$ <0.001).[120] In all the previously mentioned studies, the lack of information about smoking status and cause-specific mortality does not allow any definitive conclusion about the prognostic influence of sex.

In a prospective cohort of 4618 patients diagnosed with NSCLC, sex was found at the multivariate analysis to be an independent prognostic factor after adjusting for age at diagnosis, tumor histology and grade, stage, pack-years smoked, and treatment received (resection, radiation, or chemotherapy). Stage of the disease, at diagnosis and treatment received, did not differ between men and women. The estimated 1- and 5-year survival

**FIGURE 25.6** Lung cancer–specific survival curves by sex and type of treatment. Women had a statistically significant survival benefit compared with men regardless of the type of treatment received.

time in men was 51% (95% CI, 49%, 53%) and 15% (95% CI, 12%, 17%), respectively, whereas in women, the 1- and 5-year survival time was 60% (95% CI, 58%, 62%) and 19% (95% CI, 16%, 22%). Men were at a significantly increased risk of mortality compared to women, following a diagnosis of NSCLC (adjusted RR = 1.20; 95% CI, 1.11, 1.30), particularly for patients with stage III/IV disease or adenocarcinoma.[2]

These data have been confirmed in other prospective studies. Cerfolio et al.[121] analyzed a cohort of 1085 patients and detected an overall age-adjusted and stage-adjusted 5-year survival rate favoring women (60% vs. 50%; $p$ <0.001). Women had better stage-specific 5-year survival rates (stage I disease, 69% vs. 64%, [$p$ = 0.034]; stage II disease, 60% vs. 50%, [$p$ = 0.042]; and stage III disease, 46% vs. 37%, respectively [$p$ = 0.024]). Women who received neoadjuvant chemotherapy were more likely to achieve a complete or partial response compared to men ($p$ = 0.025).

In a single institution study in completely resected NSCLC, it was found that pathological stage, female sex, and squamous cell type were independent predictors of survival. According to stage, women had a significant survival advantage at pathological stage I ($p$ = 0.01) and a moderately better survival at stage II and stage III disease ($p$ = 0.3)[122] (Table 25.2). A similar survival trend according to stage with a more pronounced survival difference in stage I and II was also confirmed in two other studies,[5,123] and the impact of sex on survival independent from smoking status was also reported in a large Japanese cohort, which studied 12,703 cases of resected NSCLC.[124]

Survival advantage by female sex is also maintained among elderly patient population. In a population-based analysis from the SEER database, 18,967 elderly patients (<65 years old) with stage I and II NSCLC, diagnosed between 1991 and 1999, were considered. Patients were grouped into three categories according to the treatment received: surgery, radiation or chemotherapy, and untreated

cases. Survival data were controlled for competing risks, including lung cancer–specific survival, overall survival adjusting for comorbidities, and relative survival. Women in all treatment groups had better lung cancer–specific, overall, and relative survival than men ($p$ <.0001), and this benefit was retained with multivariate analysis. Sensitivity analyses demonstrated that these survival differences were not related to a different smoking behavior. Sex differences were also observed among untreated patients, and this may suggest that lung cancer in women has a different natural history.[125] An ongoing South Western Oncology Group (SWOG) trial is investigating molecular epidemiology of NSCLC in smoking and never-smoking men and women, evaluating the influence of hormonal and reproductive factors in 720 stage I to III lung cancer patients.

The epidemiological findings from population-based studies indicate that more women are diagnosed at earlier stages. A higher adherence rate among women in ongoing early detection studies raises the issue of whether or not the survival advantage by sex may be attributable only to a more frequent medical consultation and radiological assessment rather than related to differences in genetic predisposition and natural history of the neoplastic disease.

As previously described, the ELCAP screening project gave insights into women and lung cancer.[51] In the International Early Lung Cancer Action Program (I-ELCAP), 14,435 asymptomatic volunteers with no previous history of cancer and fit to undergo thoracic surgery (6296 women), at least 40 years of age, and past or current cigarette smokers underwent baseline CT screening for lung cancer. Lung cancer was diagnosed in 111 of 6296 women and 93 of 8139 men: in terms of prevalence, the women-to-men OR was 1.6 ($p$ = .001). Women diagnosed with lung cancer were at a comparable age to men (67 vs. 68 years) but had a significantly reduced tobacco exposure (47 vs. 64 pack-years, respectively). Additionally, women were more frequently diagnosed in clinical stage I disease (89% vs. 80%), but the resection rate in stage I was only slightly higher than men (90% vs. 88%). The proportion of adenocarcinoma subtype among women and men was 73% versus 59%, respectively.[126]

From this study, the hypothesis that women may be more susceptible to tobacco carcinogens appears biologically plausible: if lung cancer risk for women who smoke is indeed higher than the risk for men of the same age who smoke, this suggests that antismoking efforts directed toward girls and women need to be even more serious than those directed toward boys and men. For the same reason, in consideration that early detection programs are conducted among smokers, female sex calls for screening at lower levels of tobacco exposure than the corresponding indication threshold in men.

Overall, the evidence suggests that women with lung cancer survive longer than men and that this difference is more pronounced in very early stages. Cancer stage at diagnosis, cell type, or treatment do not appear to be entirely explanatory of this difference, and it is not clear whether this survival difference is because lung cancer in women tends to be more commonly curable or less malignant.

| TABLE 25.2 | Five-Year Survival in Women and Men with Early Stage Non–Small Cell Lung Cancer, in Different Studies | | |
|---|---|---|---|
| First Author | Ouellette[13] | Cerfolio[121] | Alexiou[122] |
| No. of subjects | 208 | 1085 | 833 |
| Women (%) | 104 (50%) | 414 (38%) | 252 (30%) |
| 5-year survival | | | |
| Stage I | 47.2% | 69% | 56% |
| II | 63.1% | 60% | 41% |
| III | 14.5% | 46% | 21% |
