Table of Contents

Preface XXVII
Committees XXIX

1. Keynote lectures

Insights and advances in the analysis of structures 3
K.J. Bathe

Recent studies on long-span bridges: Vibration control, seismic retrofit and monitoring in Japan 9
Y. Fujino & D.M. Siringoringo

Local-distortional interaction in cold-formed steel columns: Non-linear behaviour, ultimate strength and DSM design 17
D. Camotim, P.B. Dinis, B. Young & N. Silvestre

Simulation of multi-physical processes in solar updraft power generation 23
W.B. Krätzig

Mechanics of interfaces and evolving discontinuities 29
R. de Borst, J.J.C. Remmers, C.V. Verhoosel & A. Needleman

Recent controversies and new challenges in structural topology optimization 35
G.I.N. Rozvany

2. Dynamic response, vibration analysis, vibration control

General conditions for instantaneous system inversion in structural dynamics 43
K. Maes, E. Lourens, G. De Roeck & G. Lombaert

Determination of aerodynamic damping of twin cables in wet conditions through passive-dynamic wind tunnel tests 49
M.B. Eriksen, E. Mattiello & C.T. Georgakis

Frequency domain stochastic response of structural systems with uncertain parameters: Closed-form sensitivity 55
G. Muscolino, R. Santoro & A. Sofi

Semi-active control of structural systems with uncertainties using an unscented Kalman filter 61
M.S. Miah, E.N. Chatzi & F. Weber

Guided waves for stress identification 67
A. Pau, G. Ruta & F. Vestroni

Unscented Kalman Filter for the identification of passive control devices 69
R. Ceravolo, A. De Stefano, E. Matta, A. Quattrone & L. Zanotti Fragonara

Vibration elimination analysis of simply-supported bridge under moving loads based on Laplace-Carson integral transform 75
K. Wang, H. Xia & W. Guo

Dynamic identification of Palazzo Marchesale in S. Giuliano di Puglia 81
G. Bongiovanni, G. Buffarini, P. Clemente, D. Rinaldis, F. Saitta, M. Nicoletti, A. De Sortis & G. Rossi

A suspended mass damper for torsional and translational vibration control 87
M. Carlisle & K. Li

Status quo and critical review of PPV safe limits for subsurface construction blasting close to low-rise buildings 93
E.Y. Sayed-Ahmed & K.K. Naji

Dynamic response of rigid pavement under moving traffic load with variable velocity 99
Y. Zhong & M.J. Xu

Assessment of bridge behavior due to the passage of high speed trains 105
A. Graça, L. Guerreiro & F. Virtuoso

Dynamic response of airport building structure due to construction machinery effects 111
J. Benčat & D. Papán

3. Vibration serviceability, human-induced vibrations, human-structure interaction

Data-driven model of random lateral pedestrian excitation 119
V. Racic, J.M.W. Brownjohn & A. Pavic

Simultaneous registration of walking behaviour and structural response 125
K. Van Nimmen, P. Van den Broeck, G. Lombaert & G. De Roeck

Vibrations in a multi-storey lightweight building structure: Influence of connections and nonstructural mass 131
L.V. Andersen & P.H. Kirkegaard

Direct velocity feedback versus a geometric controller design of remotely located vibration control systems 137
D.S. Nyawako, U. Ubaid, P. Reynolds & M.J. Hudson

Sensitivity analysis of coupled crowd-structure system dynamics to walking crowd properties 143
E. Shahabpoor, A. Pavic & V. Racic

Experimental study of the human ability to deliberately excite a flexible floor 149
C. Schwartz, A. Berger, O. Brüls, J.-L. Croisier, B. Forthomme & V. Denoël

4. Non-linear dynamics

Dynamics of structural components subjected to large rotations using a flexible multibody approach (Invited Paper) 157
J. Ambrósio & M.A. Neto

Nonlinear dynamics of a rotating SD oscillator 163
Q. Cao, N. Han & M. Wiercigroch

A hybrid time-frequency procedure for the solution of nonlinear dynamic problems 169
F.N. Correa & B.P. Jacob

Nonplanar vibration and dynamics instability of slender cruciform columns 175
E.C. Carvalho, P.B. Gonçalves, Z.J.G.N. Del Prado & G. Rega

Bifurcation analysis of a Jeffcott rotor with a bearing clearance: Numerics and experiments (Invited Paper) 181
J. Páez Chávez, M. Wiercigroch & S.V. Vaziri Hamaneh

A computational study of the upper Lyapunov exponent and the uniform persistence for monotone skew-product semiflows 183
J.A. Calzada & R. Obaya

Vibrations of cables with bending stiffness by an asymptotic approach 189
T. Canor & V. Denoël

Singularities that induce a breakdown of determinism in mechanics 195
M.R. Jeffrey

On the dynamics of stacks of rigid blocks 201
F. Saitta, P. Clemente & D. Rinaldis

Numerical bifurcation analysis of an impact oscillator with drift 207
J. Páez Chávez, M. Wiercigroch & E.E. Pavlovskaia

5. Seismic response, seismic analysis, earthquake-resistant design

Seismic behaviour and earthquake resistant design of long period structures (Invited Paper) 211
A. Astaneh-Asl

Thinking outside the box: Integrated seismic system evolution in high rises 217
M. Sarkisian, N. Mathias & E. Long

Yokohama-Bay cable-stayed bridge seismic response analysis during the 2011 Great East Japan Earthquake 223
Y. Fujino & D.M. Siringoringo

Large natural draft cooling towers under earthquake excitation 229
M. Andres, R. Woermann & D. Casucci

Future development of the European seismic code, Eurocode 8 235
E.D. Booth

Dynamic shakedown design of structures under repeated seismic loads 241
S. Benfratello, L. Palizzolo & P. Tabbuso

Performance of buildings and other structures during the Tohoku Tsunami 247
I.N. Robertson & G. Chock

Numerical investigation of the cyclic response of CHS braces 253
T. Sheehan, T.M. Chan, J.H. Xing & L. Gardner

Parametric identification of building structures with seismic recordings 259
R. Zhang & L.O. Gargab

Generation of spectrum compatible site-dependent earthquake load histories by evolutionary approach 265
F. Carli & C. Carino

Large-scale dual shake tables testing: An experimental approach to study the non-uniform excitation effects on long span bridges 271
M.M.S. Cheung, C.-Y. Yang, Y. Pan & F. Xiong

Seismic design of the self anchored suspension bridge: San Francisco Oakland Bay Bridge 277
M. Nader & B. Maroney

Seismic performance of an asymmetric base-isolated building in the 2011 Great East Japan Earthquake 283
Y. Fujino & D.M. Siringoringo

Assessment of evaluation methods of dynamic response of multi-span bridge to mining tremor 289
J.M. Dulinska & M. Fabijanska-Kopacz

Characterization of the seismic behaviour of steel pallet racks in cross-aisle direction 295
C. Braham & H. Degée

Passive energy dissipation characteristics of yielding shear panel device produced from steel and stainless steel 301
M. Ashraf & M.R. Hossain

Seismic behaviour of exposed column bases in buckling restrained braced frames 307
Y. Cui, S. Kishiki & S. Yamada

Multi-story steel structures: Seismic energy modal distribution 313
O. Prodan, I. Ladar & N. Chira

Effect of basement rigidity on seismic response of RC buildings 319
A. Koçak, M. Borekci, E.C. Ekinci & A. Kalyoncuoglu

Bidirectional pushover analysis of irregular structures 323
G.P. Cimellaro, D. Lopez-García & T. Giovine

Seismic collapsing response analysis of wooden house retrofitted by ACM braces 329
T. Takatani & H. Nishikawa

Nonlinear behaviour of submerged floating tunnels accounting for seaquake effects 335
C.X. Shi, M. Domaneschi & L. Martinelli

An innovative solution for earthquake resistant hybrid steel-concrete systems with replaceable dissipative steel links 341
A. Zona, G. Leoni, A. Dall'Asta, T. Bogdan, C. Braham & H. Degée

Effectiveness of seismic protection by added damping: An energy approach 347
I. Ladar, O. Prodan & N. Chira

Seismic Safety Screening Method (SSSM) for slum clearance 353
P.O. Caglayan

Experimental study on the performance of hollow reinforced concrete bridge piers subjected to lateral seismic loads 357
O. Lopez-Batiz, R. Gomez-Martinez, J.A. Escobar-Sanchez, F. De la Serna-Hernandez & G. Aguilar-Ramos

Evaluating the seismic performance of RCC dams, subjected to near-field and far-field earthquakes via FEA approach 363
M.R.A. Ala, H.R. Vosoughifar, N. Hasani & S.K.S. Shokouhi

6. Material modelling, composite materials, functionally-graded materials

Some advances in functionally graded materials (Invited Paper) 369
L. Nunziante

Numerical implementation of the Hoek-Brown material model with strain hardening 375
E.S. Sørensen, J. Clausen & L. Damkilde

Simulation of the mechanical behaviour of W/Cu composites containing FGM related interpenetrating microstructures under consideration of phase dependent damage limits 381
S. Schmauder & U. Weber

Determination of effective elastic constants of two phase composites 387
O. Bulut, N. Kadioglu, S. Ataoglu, M. Yuksek & E. Sancak

Strain induced product properties of magneto-electric composites 393
J. Schröder, M.-A. Keip, M. Labusch & D.C. Lupascu

Microstructural image-based modelling of weld failure 399
O. Barrera, A.C.F. Cocks & E. Tarleton

Flame straightening application on structural steels: Effects on mechanical and fracture properties 405
R. Lacalle, J.A. Álvarez, D. Ferreño, J. Portilla, E. Ruiz, B. Arroyo & F. Gutiérrez-Solana

Statistically similar RVE construction based on 3D dual-phase steel microstructures 411
L. Scheunemann, D. Balzani, D. Brands, J. Schröder & D. Raabe

A study of local mechanical properties of 304L SS welded joints subjected to cyclic straining using depth-sensing instrumented indentation 417
D. Ye, F. Mi & X. Yin

Biological tissue mechanics with fibres modelled as one-dimensional Cosserat continua: Applications to cardiac tissue in healthy and diseased states 423
K. Sack, S. Skatulla & C. Sansour

Buckling analysis of thin composite plates reinforced by carbon nanotubes (CNTs) using finite strip methods (F.S.M) 429
M. Pazoki, M. Azhari & A. Heidarpour

Identification of nonlinear hyperelastic material parameters for healthy myocardial tissue via an inverse method based on modelling the passive filling stage of the cardiac cycle 435
M. Essack & S. Skatulla

Numerical properties of second order integration algorithms for plasticity models 443
M. Jahanshahi

7. Numerical modelling, FEM modelling

A layered shell element for the thermal analysis of plates exposed to non-uniform heating 451
A.E. Jeffers

Co-rotational FEM for fast geometrically nonlinear static and dynamic algorithms 457
D. Marinkovic & M.W. Zehn

Finite element modelling of shear tab connections including damage simulation 463
A. Mirzaei, C.A. Rogers & R. Tremblay

Nonlinear static and dynamic analysis of an electrically-actuated microbeam modelled by means of the strain gradient elasticity theory 469
P. Belardinelli & S. Lenci

Peak shear stress distribution in finite element models of concrete slabs 475
E.O.L. Lantsoght, C. van der Veen, J.C. Walraven & A. de Boer

Elimination of slip-locking in composite beam analysis by using a meshfree method 481
R.E. Erkmen

Nonlinear analysis of semi-rigid steel frames subjected to blast or fire 487
A. Heidarpour

Coupling different FE-models for the calculation of the thermo-mechanical behavior of ultra high performance concrete components under high temperature load 493
M. Siemon, D. Hosser & J. Zehfuß

FE modelling of semi-rigid flush end plate joints with concrete-filled steel tubular columns 499
A. Ataei & M.A. Bradford

Development and testing of a technique for the simulation of the rock cutting process 505
M.J. Mikl, R. Tichy, W. Ecker, T. Antretter & G. Pittino

Material influence on the strength of aluminium column web in tension 511
G. Sarracco, G. Brando & G. De Matteis

8. Impact, blast, damage mechanics, damage modelling

Interaction forces between huge cargo vessels and quay walls 519
M. Bahr & V. Sigrist

Response of a building envelope system to near field blast events 525
H.D. Hidallana-Gamage, D.P. Thambiratnam & N.J. Perera

Impact velocity and initial length influence on the crushing behaviour of TWCF open section members under axial impact 531
M. Kotełko, R.J. Mania & M. Jankowski

Computational modelling of reinforced concrete wall subjected to transformer tank rupture 537
M.A. Seman, M.A. Nasly, Y.T. Feng & Z.M. Jaini

Blast test and numerical simulation of point-supported laminated glass curtain wall 541
S. Chen, C.G. Zhu, G.Q. Li & Y. Lu

Thermodynamics-based constitutive modeling of coupled dissipative phenomena in engineering materials 547
H. Egner, W. Egner & M. Ryś

Heterogeneous structures studied by an interphase elasto-plastic damage model 553
G. Giambanco, G. Fileccia Scimemi & A. Spada

A coupled local-nonlocal framework for modeling hydraulic fracturing in the Karoo 559
D.Z. Turner

Tensile and compressive buckling of shear deformable damaged beams 565
S. Caddemi, I. Caliò & F. Cannizzaro

9. Fracture, fatigue

The use of the theory of critical distances in fracture and structural integrity assessments 573
S. Cicero, V. Madrazo, I. Carrascal & T. García

Fracture mechanics as an improvement of fatigue life assessment in orthotropic bridge decks 579
W. Nagy, H. De Backer & Ph. Van Bogaert

Analogies in the fracture mechanisms of concrete and ice 585
B. Chiaia, A.P. Fantilli & B. Frigo

An investigation of the double torsion geometry using peridynamics 591
T.H. Becker & D.Z. Turner

Propagation of non-planar pressurized cracks from a borehole 597
J.A.L. Napier & E. Detournay

Hydraulic fracture simulation: Comparison with exact solutions 603
C. Detournay, P.A. Cundall & B. Damjanac

Optimisation of the Double Torsion geometry 609
S.P. Goqo, S. Skatulla & T.H. Becker

An experimental validation of residual stresses in weld clad pipelines 613
G. Schnier, J. Wood & A. Galloway

Assessment of fracture toughness in strain hardening cement-based composite (SHCC) made from fine and coarse sand 619
S.C. Paul & G.P.A.G. van Zijl

Polymeric facades: Fatigue performance of pultruded panel connections 625
P.T. Gates, T.J. Ibell, A.P. Darby & M. Evernden

Experimental evaluation of the fretting fatigue behaviour of high-strength steel monostrands 631
J. Winkler, C.T. Georgakis & G. Fischer

10. Wind loading, robustness, progressive collapse, tall buildings

Revised wind loading for linear and non-linear design of cooling towers (Invited Paper) 639
H.-J. Niemann & W. Hubert

Wind-tunnel investigations of pressure distribution over high-rise buildings 645
M. Cwik, M.A. Gizejowski & A.M. Goliger

Probabilistic models for design of structures against wind loads 651
J.V. Retief, C. Barnardo-Viljoen & M. Holicky

Computational fluid dynamics simulations and validation of results 657
M.A. Sitek, M. Cwik, M.A. Gizejowski & A.M. Goliger

Equivalent static wind loads for structures with non-proportional damping 663
N. Blaise, V. Denoël & T. Canor

Robustness of structures: State of art 669
Seema, N. Baldassino & R. Zandonini

Performance-based plastic design of earthquake resistant tall building frames 675
W.-C. Liao, M.R. Bayat & S.C. Goel

Parametric study of pyramid-like tubular structure 681
G.S. Liou & H.-C. Kuo

More optimal seismic design of highrise structures using nonlinear analysis techniques 687
S.A. Ashrafi

Progressive collapse prevention of drive-in steel storage racks 693
S. Yadwad & L.H. Teh

Assessment of column removal time for progressive collapse evaluation of high rise structures 699
O.D. Stephen, D. Lam & V.V. Toropov

Rotational capacity of concrete slabs and its influence on tensile membrane action in the framework of robustness analysis 705
D. Gouverneur, R. Caspeele & L. Taerwe

The impact of fire scenario to the collapse of a tall structure 711
S. Selamet

Behaviour of tall buildings under blast loading with direct simulation method 717
F. Fu

A modal property analysis of linked tall buildings using a matrix model 721
K.T. Tse & J. Song

11. Bridge engineering, bridge girders

Composite steel-concrete cable-stayed bridges: Developments and future trends 729
J.J. Oliveira Pedro & A.J. Reis

Analysis of steel and steel-concrete bridge girders through a higher order beam model (Invited Paper) 735
R.F. Vieira, F.B. Virtuoso & E.B.R. Pereira

Full-scale testing of concrete deck slabs under fatigue-causing axle loads 741
G. Borkowski, K. Thoma & P. Roos

Cable stressing sequence of an asymmetrical cable stayed bridge 747
J.R.B. Anderson

Design curves for stiffened flanges used in steel box girder bridges 751
P.S. Ferreira & F. Virtuoso

Fatigue life assessment of existing motorway bridge 757
L. D'Angelo, A. Nussbaumer, M.A. Fenart & A.-G. Dumont

Comparing two types of fatigue and tsunami resisting medium span bridges 763
Ph. Van Bogaert

Are short span reinforced concrete bridge girders cost effective? 769
T.N. Haas & D. Smith

Effect of constraint in-plane displacement conditions for the unloaded edges of stiffened flanges used in steel box girder bridges 775
P.S. Ferreira & F. Virtuoso

Buckling resistance with combined shear of steel curved bridge girder webs 781
Ph. Van Bogaert

The weathering steel bridges maintenance practice in Poland 787
M. Łagoda & T. Wierzbicki

Study on high speed railway prestressed continuous rigid frame bridges 793
J.Q. Lei & K. Zhang

Experimental study on hybrid FRP-concrete bridge superstructure 799
Y.L. Wang, J.H. Ran, Y.Y. Li & M.M. Cao

12. Lightweight structures, roof systems, membranes, cables, bars, rods, struts

Design of tension components according to Eurocode 3 Part 1-11 (Invited Paper) 807
K. Kathage

Extraordinary possibilities using fabric to form concrete structures (Invited Paper) 813
J.J. Orr, T.J. Ibell, A.P. Darby & M. Evernden

The Porsche Pavilion in the Autostadt Wolfsburg, Germany (Invited Paper) 819
H. Pasternak & T. Krausche

Computational model for simulation of rigid foldable origami structures 823
J.D. van der Woerd, R. Chudoba & J. Hegger

Performance analysis of a membrane roof project 829
E.F. Nunes, J.B.M. de Sousa Jr, B. Baier & A.M.S. de Freitas

Collapse behaviour of double-layer grid structures in steel 835
J.M. Adams & A. Zingoni

Behaviour of composite bar structures: Theory and examples (Invited Paper) 841
J.B. Obrębski

A method for reconstructing the shape of highly flexible, slender objects from distributed strain measurements 847
M.D. Todd, C.J. Stull & M. Dickerson

Rod-in-tube buckling – Comparative analysis of numerical and test results 853
V.S. Tikhonov & O.S. Bukashkina

On load drop phenomenon in axially compressed elasto-plastic columns 859
L. Kwasniewski

Eulerian formulation for an extensible elastic rod 865
A. Huynen, E. Detournay & V. Denoël

Some results of experimental investigations of thin-walled bars 871
J.B. Obrębski

13. Plates, shells, laminated composite structures, sandwich structures

Bending and buckling of circular sandwich orthotropic plates with corrugated cores (Invited Paper) 879
K. Magnucki, M. Walachowski & E. Magnucka-Blandzi

Modeling and simulation of large amplitude vibrations of layered composite and smart structures 885
R. Schmidt, M.N. Rao & T.D. Vu

Simplified modelling of stiffened panels for simultaneous static and dynamic optimisation 891
L. Weiß, H. Köke & C. Hühne

Finite element vibration analysis of pole structures made of advanced composite materials 897
G.-D. Kim & S.-Y. Lee

Experiments on fatigue behaviour of sandwich panels 901
H. Nelke & J. Lange

Modelling and nonlinear FE analysis of composite shells at finite rotations (Invited Paper) 907
R. Schmidt, M.N. Rao & T.D. Vu

Using the polynomial annihilation edge detection for locating delamination in laminated composite plates 911
C. Surace, H. Darwich & M. Gherlone

On the design of plates and stiffeners of rectangular industrial ducts 917
T. Thanga, K.S. Sivakumaran & B. Halabieh

Structural behaviour of flexible straws 923
B. Zhang & Z. You

A strain gradient Reissner-Mindlin micro-plate model obtained through an asymptotic analysis 929
M. Serpilli

Inelastic buckling of annular plates in shear 933
J. Becque

A novel analytical solution of orthotropic rectangular thick plate 939
B. Pan & H. Liu

14. Renewable energy structures

Wind loading on solar chimneys: From wind tunnel experiments to CFD simulation 947
F. Lupi, C. Borri & H.-J. Niemann

Stability and nonlinear behaviour of RC solar updraft towers 953
R. Harte

An analysis of an optimised solar thermal chimney for desert deployment 959
P. Cottam, P. Duffour & P. Fromme

Solar energy systems under impact of aeolian sand and dust 965
C. Kalender-Wevers, U. Winkelmann & R. Höffer

Constructability-aspects for reinforced concrete solar updraft power plants chimneys: From construction technology and logistics to schedules and costs – data-requirements for economical evaluation 971
L. Laußat, N. Warkus & M. Helmus

SHM strategies, application and measurements on tripod offshore wind energy converters within the German offshore park Alpha Ventus 977
W. Rücker, S. Thöns, S. Said & W. Schmid

A comparative study about the effects of linear, weakly and fully nonlinear wave models on the dynamic response of offshore wind turbines 983
E. Marino, G. Stabile, C. Borri & C. Lugni

Structural health monitoring for life-cyle estimation of on-shore wind energy converters 989
R. Höffer, D. Hartmann, S. Lachmann, X. Liu & K.R. Leimbach

15. Cold-formed steel structures, thin-walled sections

Analysis and design of perforated cold-formed steel members in compression (Invited Paper) 997
Z. Yao & K.J.R. Rasmussen

A semi-discretized thin-walled beam element including distortion 1003
M.J. Andreassen & J. Jönsson

Generalised Beam Theory (GBT) for stiffened sections 1009
G. Taig, G. Ranzi, G. Piccardo & A. Luongo

Cold-formed steel design and research assisted by testing (Invited Paper) 1015
D. Dubina

On the response of cold-formed steel sections under compression 1023
N. Baldassino, G. Torresani, R. Zandonini, G. Manzini & F. Scavazza

Local and global vibration analysis of thin-walled steel frames using Generalised Beam Theory (GBT) 1029
C. Basaglia, D. Camotim & H.B. Coda

Moment redistribution in cold-formed steel continuous beams 1035
C. Hui, L. Gardner & D.A. Nethercot

Shear strengths of lipped channel beams with stiffened web openings using numerical studies 1041
P. Keerthan & M. Mahendran

Coupled instability behaviour of members with thin-walled welded box sections loaded in bending and compression 1047
A. Taras, H. Unterweger & S. Hafner

Performance of reinforced web openings of cold-formed steel joists 1053
K.S. Sivakumaran

A linear one-dimensional model for the flexural-torsional vibrations of tapered thin-walled bars with open cross-sections 1059
A. Andrade, P. Providência & D. Camotim

Design models for the bolted joints of cold-formed steel pitched roof portal frames 1065
D. Dubina, V. Ungureanu & P. Perneş

Tests of cold-formed steel lipped channel columns undergoing local-distortional-global interaction 1071
B. Young, D. Camotim & P.B. Dinis

Shear design of cold-formed steel beams using direct strength method 1077
P. Keerthan & M. Mahendran

Influence of cross-section geometry on the distortional post-buckling strength of cold-formed steel columns 1083
A. Landesmann, D. Camotim & C. Basaglia

Cold-formed steel beams of corrugated web 1089
D. Dubina, V. Ungureanu & L. Gîlia

Post-buckling behaviour and strength of cold-formed steel lipped channel columns: When is local-distortional interaction relevant? 1095
P.B. Dinis, D. Camotim & A.D. Martins

Design of Z-section purlins under combined axial compression and bending 1101
J. Becque & K.J.R. Rasmussen

Buckling of cold-formed lipped-channel stub columns 1107
M. Dundu & J. Lim

Continuous beam tests on aluminium alloy SHS and RHS with internal stiffeners 1113
M. Su, B. Young & L. Gardner

Rational DSM design of thin-walled cruciform and angle columns 1119
P.B. Dinis & D. Camotim

Flexural-torsional analysis of shear-deformable monosymmetric thin-walled open members – I. Closed-form solution 1125
M.A. Hjaji & M. Mohareb

Flexural-torsional analysis of shear-deformable monosymmetric thin-walled open members – II. Finite element formulation 1131
M.A. Hjaji & M. Mohareb

Flexural strength of single channels restrained by angle cleats 1137
G.M. Bukasa & M. Dundu

Single shear screwed connection tests of thin sheet steel at elevated temperatures 1143
S. Yan & B. Young

Finite element simulation of perforated rack section columns 1149
A.M. Sarmanho Freitas, M.S.R. Freitas & F.T. Souza

16. Steel structures: Stability, strength, design

Inelastic post-buckling GBT analysis of tubular thin-walled metal members 1157
M. Abambres, D. Camotim & N. Silvestre

Direct stability analysis of steel beam-column with an elastic restraints 1165
I. Misiunaite & A. Juozapaitis

Stabilization of members with I-sections against flexural torsional buckling 1171
R. Stroetmann

Lateral-distortional buckling formulae for hollow tubular flange plate girders with slender unstiffened webs 1177
M.F. Hassanein & N. Silvestre

Modeling of force deformation characteristic of angle bracing members (Invited Paper) 1183
M.A. Gizejowski & A.M. Barszcz

Experimental and numerical research on longitudinally stiffened tapered steel plate girders subjected to shear 1189
A. Bedynek, E. Mirambell & E. Real

A new design methodology for steel hollow sections: The Overall Interaction Concept 1195
J. Nseir, E. Saloumi & N. Boissonnade

Use of the Overall Interaction Concept for the practical design of steel sections and members 1201
N. Boissonnade, J. Nseir & E. Saloumi

Influence of imperfections and geometrical discontinuities on the behavior of the steel towers 1207
A.I. Dogariu & D. Dubina

Nonlinear finite element modelling of castellated steel beams lateral torsional bucking 1213
F.O.M. da Gama, L.R.O. Lima, J.G.S. Silva, P.C.G.S. Vellasco & M.M.B.R. Vellasco

Buckling mode decomposition of thin-walled members with holes 1219
M. Nedelcu, N. Chira, H.L. Cucu & A.G. Popa

Resistance assessment of the sinusoidal openings in cellular beams 1225
S. Durif & A. Bouchaïr

GBT buckling analysis of I-section steel girders under concentrated loads 1231
P. Natário, N. Silvestre & D. Camotim

Design by inelastic analysis – 2010 AISC specification 1237
R.D. Ziemian

Three-dimensional joist member design using equivalent beam theory 1243
S.J. Kilber & A.E. Surovek

Behaviour of I-section columns experiencing local–global mode interaction: Analytical and finite element modelling 1249
M.A. Wadee, L. Bai, D. Camotim & C. Basaglia

Influence of the cross section slenderness on the buckling behaviour of steel welded tapered beam-column 1255
I.M. Cristutiu & D.L. Nunes

Analyzing portal frames using rotational springs 1261
T.N. Haas, H.L. Albertyn & P.E. Dunaiski

Behaviour of pitched-roof portal frames with tapered web and flange members considering lateral restraints 1267
I.M. Cristutiu & D.L. Nunes

Compressive resistance of circular hollow sections with squashed ends 1273
M. Dundu & J. Tumkou

The influence of pallets on the behaviour and design of drive-in steel storage racks – Part I: Behaviour 1279
B.P. Gilbert, L.H. Teh, R.X. Badet & K.J.R. Rasmussen

The influence of pallets on the behaviour and design of drive-in steel storage racks – Part II: Design 1285
B.P. Gilbert, L.H. Teh, R.X. Badet & K.J.R. Rasmussen

Extension of the DSM to welded H profile cross-sections 1291
B. Rossi & Y. Li

On the strength of T-section columns 1297
F. Sena Cardoso & K.J.R. Rasmussen

Stability, failure and design of I-section steel beams subjected to tension 1303
J. Tomás, J. Nseir, D. Camotim & N. Boissonnade

17. Steel joints, steel connections

Lateral-torsional buckling behaviour of members in steel structures with hanging-profile connections 1311
D. Liu & J. Lange

Design bearing stresses for injection bolts with short and long duration high loads 1317
A.M. Gresnigt & D. Beg

On evaluation of a unified moment-rotation characteristic of steel and steel-concrete composite joints 1323
M.A. Gizejowski, W. Barcewicz, J. Uziak & A.A.K. Saleh

The influence of the bolt grade on its behaviour under combined tension and shear 1329
A. Renner & J. Lange

Finite element modeling of CHS T-joints strengthened using through bolts 1335
M.A. Mohamed, A.A. Shaat & E.Y. Sayed-Ahmed

In-plane shear flexibility evaluation of fastened steel flat plate by numerical simulation considering the interaction between connectors and thin plate 1341
F. Bakhti, R. Tremblay & C.A. Rogers

New experimental method for determining the stiffness and strength of steel storage rack floor connections 1347
F. Roure, M.M. Pastor, M.R. Somalo & M. Casafont

Seismic behaviour of welded and bolted I-beam to box column connections 1353
Q.Y. Song, A. Heidarpour & X.L. Zhao

Analytical approach for the determination of the strength and stiffness of the T-stub with four rows of bolts 1359
N. Mehidi, F.Z. Mimoune, M. Mimoune & A. Bouchaïr

Axial capacity of transverse branch plate-to-CHS T-joints 1365
A.A. Shaat

18. Steel-concrete composite construction

Sustainable composite beams with deconstructable bolted shear connectors 1373
S.S.M. Lee & M.A. Bradford

Numerical simulations of concrete-composite-slabs with perforated metal sheets 1379
S. Pirringer & J. Kollegger

A computer method for design and M-N-Φ analysis of composite steel-concrete cross-sections 1385
C.G. Chiorean, A. Chira & M. Buru

Load-carrying capacity of steel and high-strength concrete composite columns 1391
M. Karmazínová & J.J. Melcher

Behaviour of multi-span composite steel-concrete beams subjected to combined flexure and torsion 1397
E.L. Tan, B. Uy & G. Hummam

Considerations on the long-term behaviour of composite steel-concrete bridges 1403
G. Ranzi, G. Leoni, L. Dezi & R. Zandonini

Nonlinear inelastic analysis of 3D composite steel-concrete frameworks 1409
C.G. Chiorean, M. Buru, A. Chira & I. Marchis

Square concrete filled steel hollow columns 1415
M. Dundu

Study on the loading transferring efficiency of large dimension CFT column in joint zone with internal stiff ring 1421
Y. Chen, X.Z. Zhao, N.N. Yan & S.Y. Wu

Connections by adherence – A numerical analysis of preliminary push-out tests 1427
H.J.F. Diógenes, A.L.H.C. El Debs & M.K. El Debs

19. Stainless steel structures

Constitutive equations for stainless steels: Experimental tests and new proposal 1435
I. Arrayago, E. Real & E. Mirambell

Direct strength method and continuous strength method for cold-formed lean duplex stainless steel columns 1441
Y. Huang & B. Young

Numerical study of lean duplex stainless steel plate girders with stocky flanges and slender unstiffened webs under bending 1447
M.F. Hassanein & N. Silvestre

Structural response of stainless steel cross-sections under combined compression and biaxial bending 1453
M. Theofanous, L. Gardner & E. Koltsakis

Investigating the role of gradual yielding in stainless steel columns and beams by virtual testing 1459
P. Hradil & A. Talja

Experiments on ferritic stainless steel columns in fire 1465
B. Rossi, J.M. Franssen & N. Tondini

Buckling response of ferritic stainless steel columns at elevated temperatures 1471
S. Afshan, L. Gardner & N.R. Baddoo

Interaction effects of constituent plate elements on cold-formed high strength stainless steel cross-section behaviour in compression 1477
F. Zhou, Y. Chen & B. Young

Mechanical properties of austenitic stainless steel after exposure to fire 1483
X.Q. Wang, Z. Tao, T.Y. Song & L.H. Han

Study on ferritic stainless steel and its application on architecture structure 1489
M. Li & W. Dong

20. Concrete structures, concrete design

Assessing the reliability of existing concrete bridges in terms of shear strength 1497
D. Busse, L. Eckfeldt & M. Empelmann

Dismantleable joints of load-bearing reinforced concrete units of prefabricated concrete building system with controlled stiffness (Invited Paper) 1503
J. Witzany, T. Čejka & R. Zigler

Numerical investigations on the shear capacity of reinforced concrete slabs under concentrated loads 1507
K. Reissen & J. Hegger

Analysis of the structural behaviour of shear-critical prestressed and reinforced concrete beams using digital image correlation 1513
K. De Wilder, G. De Roeck, L. Vandewalle, P. Lava, D. Debruyne & Y. Wang

The effect of steel fibres on the compressive ductility in lightweight aggregate concrete structures 1519
J.A. Øverli & T.M. Jensen

Full-range behavior of FRP-to-concrete bonded joints with trilinear bond-slip law 1525
H. Yuan & L. Wu

A comparison of the variable strut inclination and alternative stirrup design methods 1531
K.K. Mensah, C. Barnardo-Viljoen & J.V. Retief

Shear strength of reinforced concrete plastic hinges subjected to seismic action 1537
R.V. Mehrabani & V. Sigrist

Experimental and numerical investigations on punching behaviour of thick footings with and without shear reinforcement 1543
D. Kueres, C. Siburg, K. Reissen & J. Hegger

Reliability of EN1992 crack model applied to South African water retaining structures 1549
C.H. McLeod, J.V. Retief & J.A. Wium

New design approach for crack width calculation in reinforced concrete structures 1555
H.A. Elgohary & M.M. Assas

21. Fibre-reinforced concrete, polymer-reinforced concrete, cement composites

Multi-functional fiber reinforced concrete for sustainable structures (Invited Paper) 1561
N. Banthia

Comparison of strain measurement techniques for the characterization of brittle, cementitious matrix composites 1567
D. Arboleda, S. Yuan, J. Giancaspro & A. Nanni

Strut and tie models for disturbed regions: Steel fibre reinforced concrete dapped end beams 1573
J.M. Hisdal, G. Zirgulis, E.V. Sarmiento & T. Kanstad

Study of the properties of hybrid fibre reinforced concretes 1579
T. Zych

A review of the shear behaviour of reinforced steel fibre concrete 1587
S. Zeranka & G.P.A.G. van Zijl

Time-dependent behaviour of pre-cracked polypropylene fibre reinforced concrete (PFRC) under sustained loading 1593
A.J. Babafemi & W.P. Boshoff

Effect of temperature on the behaviour of polymer reinforced concrete façade 1599
J.O. Akinyele

Flexural behaviour of normal and high strength concrete beams reinforced with GFRP rods 1603
N.F.O. Evbuomwan

Flexural behaviour of GFRP prismatic beams in composite action with concrete 1611
N.F.O. Evbuomwan

22. High strength concrete, high performance concrete

UHPC – a challenging material for innovative structures (Invited Paper) 1619
E. Fehling

Modular constructions made of UHPC 1625
N.V. Tue & M. Reichel

Development of ultra-high performance concrete and applications to bridges in Korea 1631
C. Joh, S.Y. Park, K.T. Koh, S.W. Kim, Y.J. Kim & B.S. Kim

Behaviour of hybrid PVA-steel fibre reinforced ultra high performance concrete at high temperature 1637
S. Sanchayan & S.J. Foster

Sustainable building with ultra-high performance concrete (UHPC) – coordinated research program in Germany 1643
M. Schmidt

Composite structures of steel and filigree UHPC-elements – experimental and numerical investigations 1649
T. Lechner, O. Fischer & G. Seidl

Optimization process for thin-walled high performance concrete sandwich panels 1655
K. Hodicky, T. Hulin, J.W. Schmidt & H. Stang

Quality control of UHPC by using non-destructive ultrasonic testing methods 1661
B. Middendorf & A. Glaubitt

Statistical model for compressive strength prediction of high-performance concrete 1667
A. Kapelko, M. Kapelko & R. Kapelko

Experimental tests and analytical modeling of UHPC beams subjected to torsion 1673
E. Fehling, M. Ismail & T. Leutbecher

Compressive strength of high-performance concrete with absorption capacity of Super-Absorbing-Polymers (SAP) 1679
B.J. Olawuyi & W.P. Boshoff

A model for spalling of HPC thin plates exposed to fire 1685
T. Hulin, K. Hodicky, J.W. Schmidt, J.H. Nielsen & H. Stang

Micro structural optimization of high strength performance air hardened foam concrete 1691
B. Middendorf & A. Just

The anchorage of rebars in UHPC 1697
P. Lorenz & E. Fehling

Next generation nano-based carbon concrete 1703
P.S. Nagaraja, F.A. Khan, K.N.N. Gowda, S.A.K. Zai & H.R. Srinivas

Evaluation of behaviour and ductility of polymer modified steel fiber reinforced high performance concrete beams 1709
S.A.K. Zai, N. Munirudrappa, K. Muthumani, R. Naveen & H.R. Srinivas

Structural behaviour of high performance fibre-reinforced flowable concrete beams and plates 1715
S.G. Ladkany & A.T. Berhe

Influence of fiber orientation on the properties of strain hardening Ultra-High Performance Fiber Reinforced Concrete (UHPFRC) under direct tensile loading 1721
C. Hollmann & K. Wille

23. Durability, creep, shrinkage, transport processes in concrete

The origin of plastic settlement cracking and the effect of re-vibration 1729
R. Combrinck & W.P. Boshoff

Composite material under influence of moisture 1735
J. Skramlik, M. Novotny & K. Suhajda

Chimney cracked reinforced concrete walls as a problem of durability exploitation 1739
M. Kaminski, M. Maj & A. Ubysz

Water transport in surface layer of fair-face concrete 1745
P. Reiterman, F. Vogel, O. Holčapek, K. Kolář, P. Konvalinka, M. Keppert, M. Čáchová & E. Vejmelková

Creep influence on concrete slabs, pre-stressed in both directions 1749
G. Sossou

Frost resistance property of concrete doped with scrap rubber powder 1755
B.M. Wang, Y. Han & S. Liu

24. Construction materials, construction technology, building performance

Determination of the relation between the content of used reclaimed asphalt material and deformation characteristics of asphalt concretes 1763
K. Miláčková, P. Mondschein & J. Valentin

Feasibility of lightweight aggregate concrete for structural and non-structural works in Tanzania 1769
A.L. Mrema & H.A. Mboya

Mechanical properties of aluminous cement paste at high temperature 1775
O. Holčapek, P. Reiterman, F. Vogel, P. Konvalinka & E. Vejmelková

The influence of percentage replacement from coarse recycled concrete aggregate 1779
D.W. Immelman & W. de Villiers

Full-scale model of road structure 1785
M. Varaus, P. Hyzl & D. Stehlik

Monitoring of experimental sections with recycled waste materials 1789
D. Stehlik, M. Varaus & P. Hyzl

Experience with experimental designs and performance assessment of cold asphalt mixtures – New type of pavement structure in the Czech Republic 1795
J. Suda, J. Valentin, J. Žák, J. Šedina & K. Miláčková

Knowledge sharing and constructability in structural design 1801
V. Kuo & J. Wium

Processes of ID-based linking of structural relevant construction phase data to planning phase data using auto-ID techniques 1807
L. Laußat, A. Kelm, A. Meins-Becker & M. Helmus

Verification of MZELWE module in ESP-r programme with experimental confrontation 1813
A.M. Čekon, M. Kalousek & B.J. Hraška

Thermal comfort of the rooms in the designing of commercial buildings 1819
K. Nowak, K. Nowak-Dzieszko & M. Rojewska-Warchał

25. Timber structures

Behaviour of steel to timber connections in fire and normal conditions (Invited Paper) 1827
A. Bouchaïr, P. Racher & D. Dhima

Shaking table tests on a large scale moment resistant timber frame with post-tensioning and energy dissipating system 1833
F.C. Ponzo, A. Di Cesare, M. Simonetti, D. Nigro, T. Smith & S. Pampanin

Fracture process under moisture content variation in timber structures 1839
R. Moutou Pitti, F. Dubois, E. Fournely & B. Mbangagoye

The resilience of timber buildings 1845
G. Faller

Numerical modeling of a post-tensioned timber frame building with hysteretic energy dissipation 1851
A. Di Cesare, F.C. Ponzo, M. Simonetti, T. Smith & S. Pampanin

26. Masonry structures

In situ full-scale tests for old masonry elements: The out-of-plane response 1859
A. Borri, M. Candela & R. Fonti

Seismic behaviour of masonry walls with soft-layer wall bearings 1865
N. Mojsilović, B. Stojadinović, A. Barandun & C. Vögeli

Application of sequentially linear analysis to the seismic assessment of slender masonry towers 1871
V. Mariani, A.T. Slobbe, M.A.N. Hendriks & J.G. Rots

Experimental evaluation of the response of ferrocement strengthened lightweight masonry walls to impact loads 1877
M.A.N. Abdel-Mooty

Externally applied retrofit system for existing masonry buildings subject to progressive collapse 1883
A. Kousgaard & E. Erdogmus

Non-linear static analysis of masonry-infilled RC frames 1889
A. Koçak, B. Doran, A. Kalyoncuoglu & B. Zengin

Sisal reinforced cement-based masonry units 1895
G. Coetzee, W.P. Boshoff & R.D. Toledo Filho

Structural design for earth buildings 1901
A.C. Heath & P.J. Walker

Affordable, sustainable and resilient tornado shelter design using compressed stabilized earth block construction 1907
B. Wagner, E. Erdogmus & A. Schwer

27. Performance of structures in fire, design for fire resistance

Global structural behaviour in fire and consolidated testing of steel structures (Invited Paper) 1915
M. Fontana, M. Knobloch & A. Frangi

Structures in fire or fires in structures? Assessing the true performance of structures in fire (Invited Paper) 1919
J.L. Torero

Numerical simulation of thin RC structures exposed to fire (Invited Paper) 1925
R. Harte

Shear capacity of steel plate girders with slender webs in fire 1931
T. Ohtsuka, M. Knobloch & M. Fontana

Modeling and assessment of the response of super-light elements to fire 1937
K.D. Hertz, B.M. Campeanu, M. Giraudo & L. Giuliani

Composite floors with steel fibre reinforced concrete slabs exposed to fire 1943
J. Bednář, F. Wald, J. Vodička & A. Kohoutková

Engineering solutions for structures in fire: Should concrete care? 1947
L.A. Bisby

The application of fire engineering methods for the design of open steel car parks 1953
G. Woźniak & R. Obiała

Numerical study on structural behaviour of cold-formed steel columns under fire conditions 1959
S.J.C. Almeida, J.M. Neto & J.P.C. Rodrigues

An analytical method for determining the loading on connections in heating and cooling during a fire 1965
D. Lange & J. Albrektsson

Fire protection of multi-storey straw bale buildings 1971
J. Wachtling, D. Hosser & J. Zehfuß

Structural analysis at the fire limit state: Practical applications 1977
A. Jowsey & P. Scott

Fire design of wooden box floors 1981
D. Dhima & R. Blondeau-Patissier

No-sway collapse of steel frames under fire conditions: A parametric investigation 1987
A. Monti, T. Pariciani, F. Gentili & F. Petrini

Numerical studies of load bearing LSF walls under realistic design fire conditions 1993
P. Keerthan, A. Ariyanayagam & M. Mahendran

Numerical study of travelling fire in full-scale experimental building 1999
K. Horová & F. Wald

Numerical and experimental investigation of the toxicity and light extinction of fire smoke using experimental data from fire tests of polymers 2003
A. Löhnert, N. Monreal, C. Knaust & U. Krause

Development of a simplified design method to predict the fire rating of LSF walls 2009
S. Gunalan & M. Mahendran

Fire resistance assessment of steel structure exposed to fire for differentiated safety requirements 2015
M. Maślak

Numerical experimental design approach to evaluate the fire resistance of timber connections 2021
M. Audebert, D. Dhima & A. Bouchaïr

Performance of reinforced concrete structures in post-earthquake fire 2027
B. Behnam, H. Ronagh & M. Ashraf

Behaviour of structural steel subjected to post-earthquake fire 2033
S. Sinaie, A. Heidarpour & X.L. Zhao

28. Structural safety, structural reliability, risk assessment

Target reliability for engineering structures (Invited Paper) 2041
M. Holický

Reliability evaluation and design of steel frames with BRBs under severe earthquakes 2047
Y.S. Liu, G.Q. Li & X.K. Guo

Reliability analysis of corroding pipelines by enhanced Monte Carlo simulation 2053
B.J. Leira, A. Naess & O.E. Brandrud Næss

Some practical aspects of statistics methods of estimation reliability computed for existing silo constructions 2059
M. Kaminski & M. Maj

Model uncertainties in reliability analysis of reinforced concrete structures 2065
M. Holický, M. Sykora, C. Barnardo-Viljoen, K.K. Mensah & J.V. Retief

Safety in design for industrial and mining structures 2071
T. Langbecker & S. Loganathan

Risk-based design in mining structures 2077
M. Mmusi & A. Masarira

Simulated virtual portfolio for masonry buildings 2081
A. Mühlhausen, U.E. Dorka, F. Obón Santacana, A. Smolka & M. Stupazzini

29. Structural optimisation, manufacturing processes

Effective lightweight design of a rocket interstage ring through mixed-integer optimization 2089
H. Köke, L. Weiß & C. Hühne

Topology optimization with local stress contraints in a simultaneous analysis and design setting 2095
D.P. Munro & A.A. Groenwold

Reliability-based robust optimization using variance based methods 2101
G. Karaki

Designing adaptive structures for whole life energy savings 2105
G. Senatore, P. Duffour, S. Hanna, P. Winslow & C. Wise

Softening some effects of the no free lunch (NFL) theorems in optimization via parallel computing 2111
S.S. van Huyssteen & A.A. Groenwold

Exploring the domain of application of adaptive structures 2117
G. Senatore, P. Duffour, P. Winslow, S. Hanna & C. Wise

Effect of serviceability limits on optimal design of steel portal frames 2123
T.D. Phan, J.H. Lim, J.B.P. Lim, W. Sha, T.T. Tanyimboh & M. Dundu

Optimization of the injection molding processes using the Moldflow simulation program on the example of electrical connectors 2129
M. Szostak & R. Staniek

Comparison of simulation results of injection molding process obtained by Moldflow and Moldex3D programs 2133
M. Szostak & R. Staniek

The use of modified three axes forging to strengthen Nb for superconducting radio frequency cavities 2137
P.N. Kalu, N. Bembridge & I. Dagwa

Biomass in materials processing: Using cassava leaves to case-harden mild steel 2143
R. Gordon, K.J. Akinluwade, A.R. Adetunji, P.N. Kalu & O.O. Adewoye

30. Structural health monitoring, damage detection, non-destructive evaluation

Non-destructive evaluation (NDE) practice for concrete bridges in USA (Invited Paper) 2151
A. Ghorbanpoor & S. Boone

Rapid and economical condition assessment of concrete bridge decks through automation of NDE data collection, analysis and interpretation 2157
N. Gucunski, A. Maher, H. Ghasemi & F.S. Ibrahim

Making sense of bridge monitoring: Vision for the future (Invited Paper) 2163
A. Pavic & J.M.W. Brownjohn

Structural model updating using combined global mode and local primary frequency 2169
J.L. Hou, J.P. Ou & Ł. Jankowski

On the application of artificial boundary condition frequencies in structural identification (Invited Paper) 2175
Y. Lu, L. Mao & Z.G. Tu

A novel two-step method for localization and assessment of cracks in beams 2181
G.R. Gillich & Z.I. Praisach

Model updating of strategic building structures under real earthquake loading 2187
R. Ceravolo, A. De Stefano, E. Matta, A. Quattrone & L. Zanotti Fragonara

A frequency analysis applied to force identification 2193
M. Thiene, U. Galvanetto, M. Ghajari & M.H. Aliabadi

Influence of multiple cracks upon the dynamic behaviour of beams 2199
Z.I. Praisach & G.R. Gillich

Structural health monitoring of continuously welded underground pipelines based on quasi-distributed wireless inclinometers 2205
S. Li, M. Zhao & N. Gao

Cable break detection in pre-stressed bridges, parking decks and girders 2211
B. Hillemeier & S. Knapp

Detection of damage due to salt crystallization through the Scaling Subtraction Method 2217
P. Antonaci, P.G. Bocca, A.S. Gliozzi & M. Scalerandi

A damage evaluation method for bridge substructures using longitudinal impact dynamic responses 2223
J.W. Zhan, H. Xia & N. Zhang

Structural damage identification in small scale models of bridge decks 2229
R. Carrazedo & T.M. Juliani

An application of the local flexibility method to hyper-static beams using non-local virtual forces 2235
T.Y. Hsu, S.Y. Shiao, W.I. Liao & C.H. Loh

Effect of load redistribution of a steel truss bridge due to fracture of a truss member on vibration-based fault detection 2239
C.W. Kim, S. Kitauchi, K. Hashimoto, K. Sugiura & M. Kawatani

A system model for lifecycle monitoring of bridges 2247
M. Wild, O. Fischer, G. Dori & A. Borrmann

The opportunities of blind source separation techniques in the automation of modal identification for vibration based SHM 2253
C. Rainieri & G. Fabbrocino

Transducers frequency influence on ultrasonic velocity measurements in concrete specimens 2259
G. Concu, B. De Nicolo, N. Trulli & M. Valdés

Application of SHM system based on modal filtration to the truss structure 2263
K. Mendrok, T. Uhl & W. Maj

System identification of masonry buildings in Vienna 2269
F. Kopf, D. Schäfer, M. Pietsch & H. Wenzel

Shear wave travel times in multi-story buildings for system identification and damage detection 2275
E. Şafak, E. Çaktı & E. Zengin

Application and developments of the infrared thermography in the building construction sector 2281
S. Knapp & B. Hillemeier

Automated devices for inspection and maintenance 2285
E. Kuhn & C. Zimmermann

Structural health monitoring of the Basilica S. Maria di Collemaggio 2291
V. Gattulli, F. Graziosi, F. Federici, F. Potenza, A. Colarieti & M. Lepidi

Experimental study on bridge damage identification based on wavelet packet energy curvature difference method 2297
Z. Yu, H. Xia & J. Zhan

Damage detection on reinforced concrete framed structures using a band-variable filter 2303
F.C. Ponzo, R. Ditommaso, G. Auletta & A. De Muro

Damage identification in the mistuned bladed system utilizing the outlier analysis 2309
A.U. Rehman, F.H. Shah, K. Worden & J.A. Rongong

Modal characteristics-based damage identification in repeating structures 2315
A.U. Rehman, F.H. Shah, S. Nazar, C.E. Lord & A. Javed

Research on corrosion monitoring for steel-reinforced concrete structures using fiber optic sensing technique 2321
X.F. Zhao, L. Wang, Q. Liu, S.J. Shan, H. Dong, Y.F. Zhu, Y.H. Jiang & Y. Yu

Steel reinforced concrete structures dynamic damage monitoring using guided wave testing technique 2327
D.S. Li, J.H. Yuan, W. Yang & W.Y. Zhang

Structural condition assessment based on modal flexibility from operational modal analysis and model updating 2333
L.-M. Zhang, T. Wang & X.-K. Lin

31. Structural assessment, damage assessment, failure analysis, forensic engineering, disaster management

The art of the forensic engineer 2341
D. Charrett

Lessons for structural engineers: The Hillsborough disaster (Invited Paper) 2347
R.A. Smith

Causal models for the forensic investigation of structural failures 2353
S. Arangio, C. Crosti & F. Bontempi

Capacity assessment of damaged school buildings after 2011 Van earthquake 2359
R.A. Oyguc

Structural failures and monitoring of structural health with use of WiSeNe^{MONIT} system 2365
S. Wierzbicki, M.A. Gizejowski & Z. Stachura

Approaches to quantify the safety gain for existing concrete bridges due to surveillance 2371
C. Siegert, L. Eckfeldt & M. Empelmann

An investigation on the collapse sequence of an RC frame during L'Aquila 2009 earthquake 2377
M.G. Mulas, L. Martinelli & F. Perotti

Structural assessment during the demolition of an arch bridge by advanced modal techniques 2383
K. Islami & R. Betti

EQvis: A consequence based risk management software tool 2389
D. Schäfer, M. Pietsch & H. Wenzel

Measuring degree of interdependencies at the infrastructure level during emergencies 2395
D. Solari, G.P. Cimellaro & A.M. Reinhorn

Back-analysis of the collapse of a metal truss structure 2401
C. Crosti & F. Bontempi

FE models for evaluating damages in churches hit by L'Aquila earthquake 2407
G. Brando, E. Criber & G. De Matteis

32. Repair, strengthening, retrofitting, sustainable construction

The strengthening and widening of the Okavango River Bridge in Northern Namibia 2415
W. Martin

CFRP strengthening of steel I-beam against local web buckling: A numerical analysis 2421
M.A. Ghareeb, M.A. Khedr & E.Y. Sayed-Ahmed

Timber beams with external strengthening based on CFRP and GFRP composites 2427
M. Karmazínová

Bond characterization between historical concrete substrate and SRG/SRP strengthening systems 2433
E. Stievanin, F. da Porto, M. Panizza, E. Garbin & C. Modena

Methods of silo strengthening walls in practice 2439
M. Kaminski & M. Maj

Study on mechanical behaviour of circular concrete columns confined by HFRP under axial compressive load 2445
L.J. Li, S.D. Xu, L. Zeng & Y.-C. Guo

Research on concrete repair materials 2451
G. Lagoda & T. Gajda

Energy harvesting for the sustainability of structures and infrastructures 2457
K. Gkoumas, F. Petrini, S. Arangio & C. Crosti

Sustainability considerations for tunnel projects 2463
J. Sauer & O. Fischer

Challenges in rehabilitation techniques in strengthening cracked concrete beams 2467
M.K. Murthy, N. Munirudrappa, S.A.K. Zai, J. Guruswamy & S. Krishnan

33. Soil-structure interaction, foundations, geotechnical engineering

The second order solution of Boussinesq's problem 2473
E. Ferretti

Upper and lower bound calculations of the bearing capacity of strip footings near slopes in cohesionless soil 2479
S. Krabbenhoft, L. Damkilde & K. Krabbenhoft

Stress state of massive foundation slabs – Measurements and simulation 2485

Preface

The International Conference on Structural Engineering, Mechanics and Computation (SEMC) was inaugurated in 2001 with the aim of "bringing together from around the world academics, researchers and practitioners in the broad fields of structural mechanics, associated computation and structural engineering, to review recent achievements in the advancement of knowledge and understanding in these areas, share the latest developments, and address the challenges that the present and the future pose". Held every 3 years since then, SEMC has attracted an ever-increasing level of participation from all over the world. The fifth conference in the series, SEMC 2013, was held in Cape Town (South Africa) from 2 to 4 September 2013. Well over 400 participants from 60 countries worldwide attended the conference.

These Proceedings contain over 420 papers that were presented at the Fifth International Conference on Structural Engineering, Mechanics and Computation. The Proceedings are divided into 34 sections for ease of reading. The six keynote lectures delivered at the Conference have been collected together into Section 1, while the rest of the papers have been classified under the most appropriate topics, and appear in Sections 2 to 34 of the Proceedings. As expected, many papers have subject matter that spans more than one topic, and could equally have been placed in any one of two or more sections of the Proceedings. In trying to access papers on a particular subject, readers should therefore be mindful of the overlapping nature of the topics, and make sure they look through all relevant sections of the Proceedings.

Every contribution that was submitted for the Conference was prepared as a full paper of length 6 pages, and a shortened version of the paper of length 2 pages. The Proceedings have been published in the form of a printed book containing the short papers, and a CD-ROM containing the full papers. All papers were reviewed by members of the International Scientific Advisory Board and other identified experts acting independently, and only those papers that were accepted have been included in the Proceedings. The editor would like to thank all reviewers for their input in enhancing the quality of the Proceedings.

The SEMC 2013 International Conference was wide in scope, and on opening the Proceedings, one immediately sees this in the diversity of the subject matter treated by the six keynote papers, from analytical and computational considerations to practical issues of design and monitoring. The first section is followed by a cluster of sections covering the topics of vibration, dynamics, vibration control and seismic design. Immediately after these appear papers on the mechanics of materials and modelling in general, and these specifically cover material modelling, composite materials, numerical modelling, finite-element modelling, damage mechanics, fracture, fatigue and other problems. The more design-oriented considerations of robustness, progressive collapse, tall buildings and bridge engineering are dealt with next, followed by a series of papers on lightweight structures, roofing solutions, plates, shells, laminated and sandwich construction, and the growing area of renewable energy structures (solar chimneys, wind-turbine structures, and the like).

Not unexpectedly, the Proceedings feature several sections devoted to various aspects of steel structures (thin-walled sections, cold-formed steel construction, stainless-steel structures, steel joints and connections, steel-concrete composite construction) as well as concrete structures (reinforced-concrete design, prestressed concrete, fibre-reinforced concrete, high-strength concrete, high-performance concrete, properties of concrete, creep, shrinkage and durability). There is also a significant number of contributions on masonry and timber structures. Performance of structures in fire, and design for fire resistance, are topics which are attracting the attention of many researchers worldwide, and this is reflected in the large number of papers making up the section on fire. There is also a healthy number of papers dealing with more general issues of structural safety and reliability, as well as the important topic of optimization in structural design.

Towards the end of the Proceedings, one finds papers related to the integrity and long-term performance of structures. The large section on structural health monitoring, damage detection and non-destructive evaluation reflects the intensity of global research activity in these areas. This is followed by sections on the related topics of structural assessment, damage assessment, failure analysis, forensic engineering, repair, strengthening and retrofitting of structures. Papers on soil-structure interaction and foundation design have been collected together in the second-last section of the Proceedings. The last section features papers on structural-engineering education.

The editor is most grateful to all the many authors who contributed to these Proceedings. It is hoped that this rich collection of research and technical papers will serve as an enduring resource for all researchers and practitioners working in various fields, and also provide direction for future activity in these areas.

The financial support of the following organisations, who were the offical sponsors of the SEMC 2013 International Conference, is gratefully acknowledged:

- The National Research Foundation of South Africa
- The South African National Roads Agency Limited
- Anglo American Corporation
- ADINA (USA)

In his capacity as Conference chair, the editor is also grateful to colleagues and postgraduate students who assisted with various aspects of the organisation of the Conference, and to all session chairs for managing the oral presentations so competently. Last but not least, the editor wishes to acknowledge the support of his wife Lydia and children Ratidzo, Tafadzwa and Simbarashe, for their patience and understanding in giving him the space required to accomplish this work.

Insights and advances in the analysis of structures

Klaus-Jürgen Bathe
Massachusetts Institute of Technology, Cambridge, Massachusetts, USA

ABSTRACT: The objective in this presentation is to survey our recent research accomplishments to advance the state of computational simulations in engineering and the sciences. We present our novel insights and recent advances in the analysis of transient and wave propagation problems, the simulation of large strain conditions of shells, the prediction of more accurate solutions using low-order elements, and the coupling of structures to general fluid flows and electromagnetic effects. At the conference, applications are given in the analysis of traditional structures and in the modeling of nano-structures, specifically, proteins and DNA assemblies. Also, major challenges are outlined for further advances in the field.

1 INTRODUCTION

Although the analysis of solids and structures has been much researched during the recent decades, and finite element methods are nowadays used abundantly, there are many analysis areas where further advances are still much needed. These areas primarily pertain to the solution of dynamic, nonlinear, and multiphysics problems. The objective in this paper is to briefly present some advances that we have recently accomplished. Due to space limitations, we mention only our books and papers, and refer the reader to the many references given therein.

When considering research achievements in the field, it is important to realize the philosophy that a research group adheres to in its research on computational methods. Our philosophy – as pursued for about 40 years now – is to focus on the development of methods that are general, reliable and efficient, and advance the current state of the art as practiced in industry and the sciences (Bathe 1996, Bathe 2009, Bathe 2012a).

The ultimate test as to whether a computational scheme is of value is, indeed, whether the scheme, once published, is used widely in industry and scientific investigations. Since there is a keen interest in engineering and the sciences to solve ever more complex and difficult physical problems, significant new, reliable and effective analysis procedures are quickly adopted.

Our research focus is on the conception of novel and general methods, their mathematical analyses and their testing to establish the generality, reliability and efficiency.

A finite element method is *general* if it is applicable to many varied problems in a certain problem area; for example, a general shell element can be used for all shell problems described by a general mathematical model like the 'basic shell model' identified in references (Chapelle & Bathe 2000, 2011).

A finite element method is *reliable* and *efficient* if identified as such; for example, a finite element discretization is reliable and efficient if the ellipticity and inf-sup conditions are satisfied without the use of any artificial factors, and the scheme shows optimal convergence at a low computational cost (Bathe 1996, Chapelle & Bathe 2011).

In the next sections, we present our recent developments, according to the above research aims, regarding the analysis of wave propagations, large strains in shells, prediction of more accurate solutions when using low-order elements, and the simulation of fluid-structure interactions including electro-magnetic effects. These schemes are widely applicable in traditional areas of analysis and also in novel areas, like the analysis of proteins and DNA structures.

2 INSIGHTS AND ADVANCES

We briefly focus in the following sections on some of the research we have pursued.

2.1 *Wave propagation problems*

The accurate analysis of transient wave propagations and the accurate solution of time harmonic problems at high frequencies have remained a significant challenge. The essential difficulties are that the waves need to be captured accurately by the mesh and the time integration scheme used. If high frequency waves are to be simulated, very fine meshes of conventional finite elements may be needed. However, even with such very fine meshes, to calculate a transient response accurately, the numerical dispersion and dissipation of waves due to the spatial and temporal discretizations must be small. To address these solution difficulties, spectral methods, spectral element methods, and spectral finite element methods have been proposed, for the solution of specific problems.

We have developed a finite element method 'enriched for wave propagation problems' (Ham & Bathe 2012). In this method the standard low-order Lagrangian finite element interpolations are simply enriched with harmonic functions, governed, as usual, by nodal degrees of freedom. An important point is that the usual fundamental theory of finite element methods is applicable.

For two-dimensional solutions, the basic displacement interpolations for a typical solution variable $u(r,s)$ are

$$
\begin{aligned}
&u(r,s)= \\
&\sum_{\alpha} h_\alpha(r,s) \\
&\left[U_{(\alpha,0,0)} + \sum_{k_x=1}^{n} \left\{ \cos\left(\frac{2\pi k_x x}{\Lambda_x}\right) U^{C}_{(\alpha,k_x,0)} + \sin\left(\frac{2\pi k_x x}{\Lambda_x}\right) U^{S}_{(\alpha,k_x,0)} \right\} \right. \\
&+ \sum_{k_y=1}^{m} \left\{ \cos\left(\frac{2\pi k_y y}{\Lambda_y}\right) U^{C}_{(\alpha,0,k_y)} + \sin\left(\frac{2\pi k_y y}{\Lambda_y}\right) U^{S}_{(\alpha,0,k_y)} \right\} \\
&+ \sum_{k_x=1}^{n}\sum_{k_y=1}^{m} \left\{ \cos\left(\frac{2\pi k_x x}{\Lambda_x}+\frac{2\pi k_y y}{\Lambda_y}\right) U^{C+}_{(\alpha,k_x,k_y)} + \sin\left(\frac{2\pi k_x x}{\Lambda_x}+\frac{2\pi k_y y}{\Lambda_y}\right) U^{S+}_{(\alpha,k_x,k_y)} \right. \\
&\left. \left. + \cos\left(\frac{2\pi k_x x}{\Lambda_x}-\frac{2\pi k_y y}{\Lambda_y}\right) U^{C-}_{(\alpha,k_x,k_y)} + \sin\left(\frac{2\pi k_x x}{\Lambda_x}-\frac{2\pi k_y y}{\Lambda_y}\right) U^{S-}_{(\alpha,k_x,k_y)} \right\} \right]
\end{aligned}
$$

where the $U_{(\alpha,k_x,k_y)}$ with superscripts are the nodal degrees of freedom, α is the local element node, with h_α the conventional finite element interpolation function, and the S, C, and $+$ and $-$ are used in the superscripts to correspond to the harmonic expressions. The interpolations for one- and three-dimensional analyses directly follow from the above equation. Here, the two fundamental wavelengths Λ_x and Λ_y, typically equal to twice the element lengths, and the wave cut-off numbers n and m with $1 \le k_x \le n$, $1 \le k_y \le m$, typically $n, m \le 3$, need to be chosen by the analyst.

These functions can directly be used to solve time harmonic and transient problems. Figure 1 shows the finite element solution of the Helmholtz equation corresponding to a 2D planar pressure wave

$$
\begin{aligned}
&\nabla^2 P + k^2 P = 0 && \text{in } V \\
&\frac{\partial P}{\partial n} = g(x,y) && \text{on } S_f \\
&\lim_{r\to\infty} \sqrt{r}\left(\frac{\partial P}{\partial r} - ikP\right) = 0
\end{aligned}
$$

Here good accuracy is seen, although a very coarse mesh is used (Ham & Bathe 2012).

For transient analysis also an effective time integration scheme needs to be employed. Considering implicit schemes, we use the Bathe method (available in ADINA) which shows good cut-off characteristics of waves that can spatially not be resolved (Bathe 2007, Bathe & Noh 2012, Noh, Ham & Bathe, In Press).

Figure 2 gives the relative wave speed errors when traditional 2-node elements are used to solve a 1D wave propagation problem, here the CFL number is defined as $\mathrm{CFL} = c_0 \Delta t / \Delta x$. The key point to note is that for

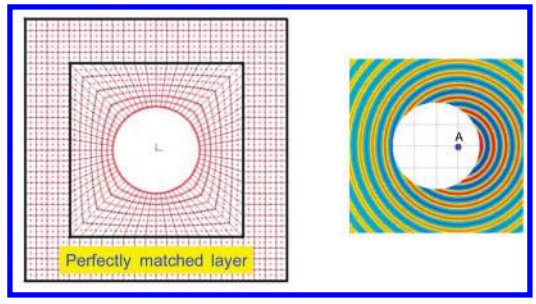

Figure 1. Solution of Helmholtz problem; 9-node elements and $\mathrm{n} = m = 2$; S_f = surface of the cylinder; point A is the pole.

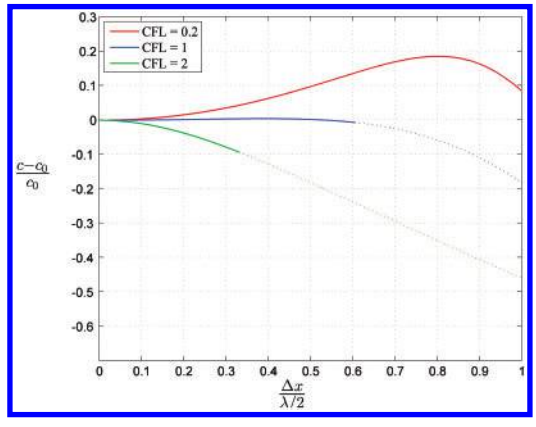

Figure 2. Relative wave speed errors of the Bathe method for various CFL numbers; results for discarded wave modes are given by dotted lines.

CFL = 1.0, the wave speed error is very small for reasonable spatial discretizations – hence the dispersion error is small for those waves that can be represented spatially – and waves of lengths less than 3 elements are 'cut-out' of the response.

The corresponding behavior of the widely-used trapezoidal rule of the Newmark method is given in Figure 3, here the property of cutting out the high-frequency modes is not present.

Figure 4 describes an illustrative 1D problem solved using standard 2-node elements. The response is given in Figure 5 using the Bathe method with CFL = 1.0 and the trapezoidal rule with CFL = 0.65, these being the optimal numbers to use. Less oscillations are seen when using the Bathe method. This better response prediction is due to cutting out those waves that cannot be accurately captured.

For further solutions, see Ham & Bathe 2012, Bathe & Noh 2012, Noh, Ham & Bathe, In Press, and Kazancı & Bathe 2012. Also, using the Bathe method, an added benefit is that the load at the half-step can be selected for optimal accuracy, like for rapidly varying loads, the mean value of the loads at times t and $t + \Delta t$ is best used. An explicit time integration scheme with

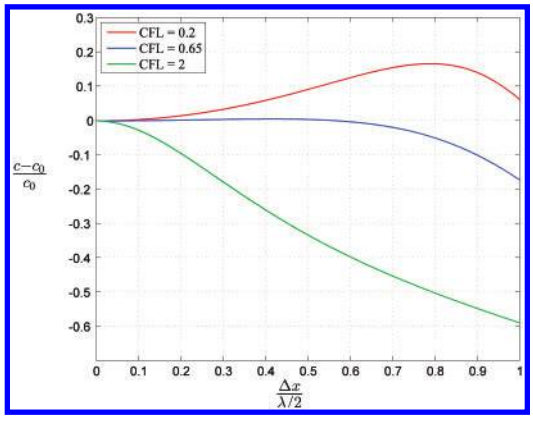

Figure 3. Relative wave speed errors of the trapezoidal rule for various CFL numbers.

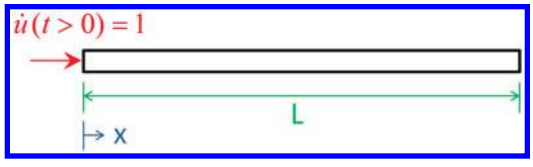

Figure 4. 1D bar impact problem, initial velocity = 0.

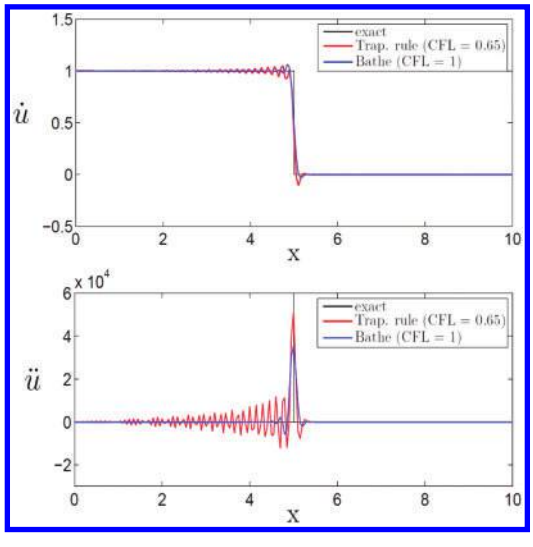

Figure 5. 1D bar impact problem, 200 2-node elements.

the property of 'cutting out' undesirable frequencies, as in the Bathe method, is given in Noh & Bathe 201x.

2.2 *3D-shell elements for large strain analysis*

Significant research efforts over many decades have focused on the analysis of shells, but there are still many outstanding challenges in the field (Chapelle & Bathe 2011); one such is the analysis of large strain behaviors. The 3- and 4-node MITC 3D-shell elements build upon the classical MITC shell elements but include important three-dimensional effects (Kim & Bathe 2008, Sussman & Bathe, In Press). The elements (available in ADINA) can be used to model very large deformations with large elastic or plastic strains. They are employed like the conventional MITC shell elements with 5 or 6 degrees of freedom at each mid-surface node and additional nodal degrees of freedom to represent through-the-thickness straining and warping of the transverse fibers. In the formulations, MITC interpolations are used on the transverse fiber motions to preserve the volume and prevent shear locking, and in incompressible analysis the u/p formulation is employed (Chapelle & Bathe 2011, Sussman & Bathe, In Press).

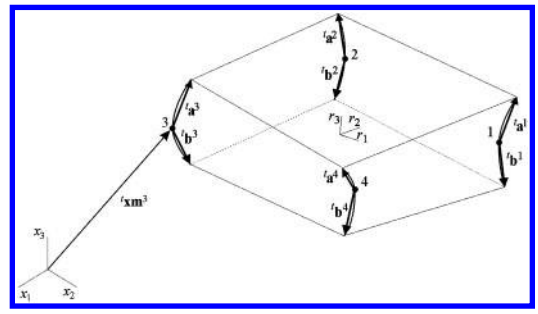

Figure 6. Nodes and control vectors of the 4-node 3D-shell element.

Figure 6 shows schematically a 4-node element. The important point is that at each node two control vectors are used to describe the deformations. To eliminate shear locking, the motions of the transverse fibers are described by a tying rule that represents an extension of the rule used for the classical MITC shell elements (Chapelle & Bathe 2011), namely we employ

$$\begin{bmatrix} \frac{\partial {}^t x_1}{\partial r_1} & \frac{\partial {}^t x_2}{\partial r_1} & \frac{\partial {}^t x_3}{\partial r_1} \\ \frac{\partial {}^t x_1}{\partial r_2} & \frac{\partial {}^t x_2}{\partial r_2} & \frac{\partial {}^t x_3}{\partial r_2} \\ \left(\frac{\partial {}^t \mathbf{x}}{\partial r_1}\times\frac{\partial {}^t \mathbf{x}}{\partial r_2}\right)_1 & \left(\frac{\partial {}^t \mathbf{x}}{\partial r_1}\times\frac{\partial {}^t \mathbf{x}}{\partial r_2}\right)_2 & \left(\frac{\partial {}^t \mathbf{x}}{\partial r_1}\times\frac{\partial {}^t \mathbf{x}}{\partial r_2}\right)_3 \end{bmatrix} \begin{bmatrix} \left(\frac{\partial {}^t x_1}{\partial r_3}\right)^{AS} \\ \left(\frac{\partial {}^t x_2}{\partial r_3}\right)^{AS} \\ \left(\frac{\partial {}^t x_3}{\partial r_3}\right)^{AS} \end{bmatrix} = \begin{bmatrix} {}^t_r C_{13}^{AS} \\ {}^t_r C_{23}^{AS} \\ \det {}^t_r \mathbf{X}^{DI} \end{bmatrix}$$

where ${}^t x_i, i = 1, 2, 3$ are the components of ${}^t\mathbf{x}$, $\partial {}^t\mathbf{x}/\partial r_i$ are the covariant base vectors, ${}^t_r C_{ij}$ are the components of the Cauchy-Green deformation tensor referred to the isoparametric description, $\det {}^t_r \mathbf{X}^{DI}$ is the determinant of the deformation gradient directly calculated, the superscript t denotes at time t, and the superscript AS denotes "assumed".

Figure 7 shows a large strain solution obtained with the MITC4 3D-shell element. Here the large strains in the structure result into a significant downward shifting of the midsurface nodes during the response.

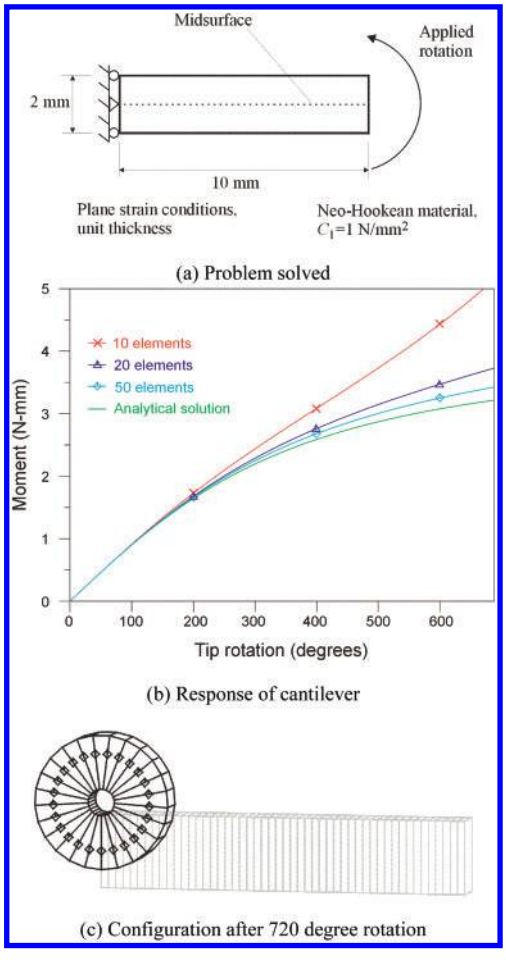

Figure 7. Large strain analysis of thick plane strain cantilever.

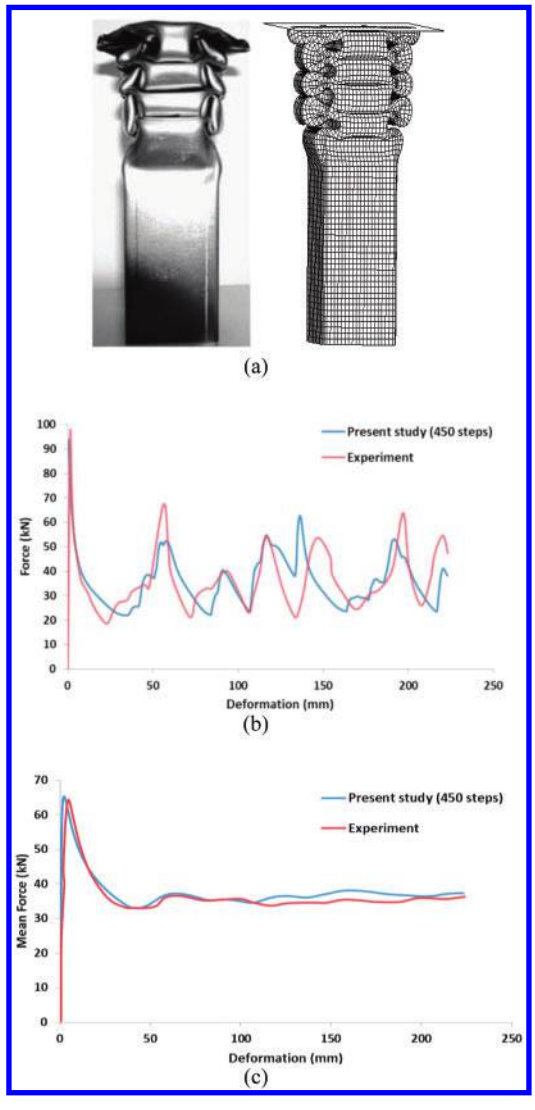

Figure 8. Quasi-static crushing of a square-section tube, length of tube is 310 mm; (a) experimental and computed results in final configuration; (b) force–displacement curves; (c) mean crushing force–displacement curves.

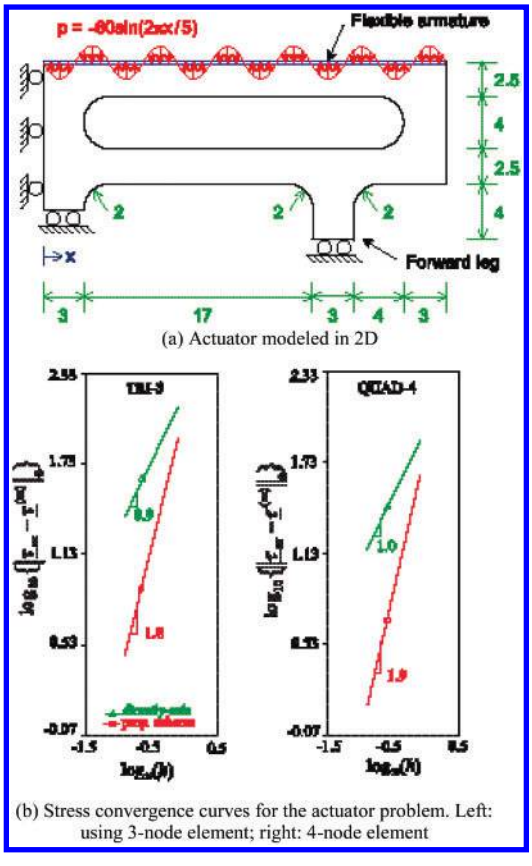
Figure 8 shows some analysis results obtained in a slow crush analysis of a square tube using the MITC4 3D-shell element and the Bathe time integration scheme; for details and also crash solution results see Kazancı & Bathe 2012.

2.3 *Procedures for solution improvements*

As well known, the 3-node triangular and 4-node quadrilateral elements in 2D solutions and 4-node tetrahedral and 8-node brick elements in 3D solutions lead to well-conditioned small bandwidth assembled matrices, they are robust but are not effective in predicting stresses accurately. Very fine meshes are needed in practice. Hence, it is of much interest to increase the order of stress convergence of these elements.



We have developed schemes to improve the predictions of stresses (Payen & Bathe 2012) and, both, displacements and stresses (Kim & Bathe 2013). To establish more accurate stresses from calculated displacements, we use two projection equations over the patch of elements that contains the element, for which improved stresses are sought, and those surrounding it (Payen & Bathe 2012)

$$\sum_{m=1}^{N_P}\left(\int_{V^{(m)}}\delta\underline{\bar{\tau}}^{(m)T}\left\{\underline{\tau}^{(m)}-\underline{\tau}_h^{(m)}\right\}dV\right)=0\quad\forall\,\underline{\bar{\tau}}^{(m)}\in\bar{\mathbf{V}}^{\tau}$$

$$\sum_{m=1}^{N_P}\left(\int_{V^{(m)}}\delta\underline{\zeta}^{(m)T}\left\{div\left[\underline{\tau}^{(m)}\right]+\underline{f}^{B}\right\}dV\right)=0$$

$$\forall\;\underline{\zeta}^{(m)}\in P_1$$

where P_k denotes the kth order polynomial, $\underline{\tau}^{(m)}$ represents the enhanced stresses to be calculated in P_2, $\underline{\tau}_h^{(m)}$ are the directly-calculated stresses, $\underline{\bar{\tau}}^{(m)}$ is an element in $\bar{\mathbf{V}}^{\tau}$, the subspace of P_2 in which all stress

(a) Actuator modeled in 2D

(b) Stress convergence curves for the actuator problem. Left: using 3-node element; right: 4-node element

Figure 9. Analysis of actuator subjected to Lorentz force.

functions satisfy the equilibrium equations $div\,[\,\underline{\bar{\tau}}^{(m)}] = \underline{0}$, and N_P is the number of finite elements in the patch considered.

The scheme is effective, needs to only be applied in certain critical stress areas, and can be used in linear and nonlinear, static and dynamic analyses.

Figure 9 shows an actuator analyzed and the results obtained. It is seen that with the scheme used the stresses converge with almost second order, i.e. with the same order as the displacements.

This scheme only improves the stresses. We have also researched another approach in order to improve all solution variables when using 3-node 2D triangular and 4-node 3D tetrahedral elements through 'enriching the finite element method by interpolation covers' (Kim & Bathe 2013). These covers are also applied only in those regions where higher accuracy is sought in the solution.

Considering a patch of 2D 3-node elements, the essence of the enrichment scheme is to interpolate the solution variable using

$$u_h = \sum_{i=1}^{3} h_i u_i + \sum_{i=1}^{3} \underline{\tilde{H}}_i\, \underline{\tilde{a}}_i \qquad \text{in the } \textit{element}$$

where u_i is the usual nodal degree of freedom and $\tilde{a}_i$ lists additional degrees of freedom with

$$\underline{\tilde{H}}_i = h_i \left[\bar{x}_i \quad \bar{y}_i \quad \bar{x}_i^2 \quad \bar{x}_i\bar{y}_i \quad \bar{y}_i^2 \quad \cdots \quad \bar{y}_i^p \right]$$

Here, the $(\bar{x}_i, \bar{y}_i)$ are coordinates measured from the node i,and p is the cover order used.Important considerations pertain to choosing computationally effective covers and having a well-conditioned coefficient matrix (Kim & Bathe 2013).

2.4 *Coupling of structures to fluid flows and electromagnetic effects*

Separate solutions of solids, structures, fluid flows, and electromagnetics have been obtained for decades. However, the solution of multiphysics problems involving fully coupled fluid-structure interactions with temperature and electromagnetic effects has hardly been tackled and presents special difficulties. Such fully coupled problems need to be solved, for example, in biomedical engineering, metal processing, and plasma physics.

We have developed a novel finite element scheme for the solution of the general Maxwell's equations to simulate fluid flows, solids, and structures coupled with electromagnetic effects (Bathe 2012a, Bathe, Zhang & Yan 201x). The finite elements used are similar to those we proposed for the solution of the Navier-Stokes equations (Bathe & Zhang 2009).

The basic equations we solve are, considering Faraday's law and Ampere's law with the Maxwell term, in the E-H form

$$\nabla\Box\left(\left(p + \rho_0/\varepsilon^*\right)\mathbf{I} - \nabla\mathbf{E} + \mathbf{I}\times\mathbf{K}\right) = \mathbf{0} \quad in\ \Omega_e$$

and

$$\nabla\Box\left(q\mathbf{I} - \nabla\mathbf{H} - \mathbf{I}\times\mathbf{J}\right) = \mathbf{0} \quad in\ \Omega_m$$

where Ω_e and Ω_m denote the domains of electric and magnetic fields, resp., $\mathbf{K}$ and $\mathbf{J}$ are source terms for the electric and magnetic field intensities, ρ_0 is the charge density, ε^* is the effective permittivity (for static and harmonic solutions), $\mathbf{I}$ is the identity tensor, and we introduced

$$p = \nabla\Box\mathbf{E} - \rho_0/\varepsilon^*$$

$$q = \nabla\Box\mathbf{H}$$

Of course, these equations specialize to specific cases by omitting certain terms, and the equations must be used with appropriate boundary and interface conditions.

However, for certain problems, a potential formulation can be more effective, in which the electric and magnetic potentials, ϕ and $\mathbf{A}$, are used

$$\mathbf{E} = -\nabla\phi - \frac{\partial\mathbf{A}}{\partial t}; \qquad \mathbf{B} = \nabla\times\mathbf{A}$$

with $\nabla\cdot\mathbf{A} = g_A$ and g_A a gauge condition. Solutions using these formulations in ADINA are shown at www.adina.com.

3 CONCLUDING REMARKS

In this paper we briefly summarized some of the research we have pursued during the recent years, with our research philosophy adhered to in these developments.

Significant advances in many areas are still to be accomplished – in particular when the actual *practice* of simulations in engineering and the sciences is focused upon. Here the reliability and efficiency of procedures is very important. Major challenges exist in solving multiphysics problems, at small and large scales, and in multiscale conditions.

In all applications, the endeavor is, in essence, to 'understand nature and try to predict the future through analysis'. This endeavor will be of increasing interest and value throughout the sciences and engineering, and the hierarchical process of analysis will be of particular value, see references (Bathe 1996, Bucalem & Bathe 2011). However, while novel areas of simulations will attract exciting attention, it is also important to continuously increase the efficiency of methods in traditional areas of analysis, like for the analysis of shells and for the solution of large finite element systems (Chapelle & Bathe 2011, Bathe 2012b).

Recent studies on long-span bridges: Vibration control, seismic retrofit and monitoring in Japan

Y. Fujino & D.M. Siringoringo
Bridge & Structure Lab., Department of Civil Engineering University of Tokyo, Japan

ABSTRACT: The paper describes three important issues on the long-span bridges, namely, vibration problem and control, seismic retrofit and vibration-based structural health monitoring. Specific studies on these topics are discussed based on recent experiences and practices in Japan.

1 INTRODUCTION

Dynamic performance is an important consideration in bridge designs especially the long-span ones. Various types of vibration from various sources of excitation such as wind, earthquake, vehicle movement, and human motion could occur during a lifetime of a long-span bridge. They can have several levels of consequence, from a potentially hazardous effect such as causing immediate structural failure; to a more subtle but have more extended effect such as structural fatigues. Vibration can also affect users' safety and comfort and limit bridge serviceability. Extensive research and development has been carried out to understand bridge vibration mechanisms. Some vibration mechanisms are now well understood and results of the research have been adopted in bridge design codes and put into practices by specifying methodologies and guidelines for countermeasures, or by introducing new structural elements or devices as vibration control.

Vibration problems are not only considered when designing new bridges but also when improving safety, durability and long-term performance of existing bridges. Seismic retrofit, for example is an important effort to improve seismic safety of existing bridges against foreseeable earthquakes in the future. Durability and long-term performance of existing bridges are also important issues nowadays and more efforts are now being devoted to enhance the implementation of technologies and methodologies for structural health monitoring (SHM) of bridges.

In this paper, we describe recent studies and developments on bridge vibration and control, seismic retrofit and vibration-based monitoring in Japan. We discuss specific cases involving the author and some important lessons from structural engineering viewpoints. New development, implementation of passive, and control of stay cable of the cable-stayed bridges in Japan are described. The paper also discusses case-studies on seismic retrofit of large bridges and vibration monitoring of long-span bridges under wind and seismic excitation.

2 VIBRATION AND CONTROL OF LONG-SPAN BRIDGES

2.1 *Wind-induced vibration and control of bridge structure*

Wind-induced vibration is the most critical among various types of dynamic excitation for long-span bridges. Type and level of vibration depend on bridge structural properties (i.e. mass, stiffness and damping), wind force condition and interaction between wind and bridge. The wind-induced vibration mechanisms on a bridge can be classified based on force excitation into four mechanisms: forced vibration, self-excited vibration, combination of forced and self-excited vibration and random vibration.

The bluff body of bridge components such as deck, pylon and cable immersed in a wind flow can move and create a motion that in turn affects the wind flow around the body. Vibration created by this interaction is known as the *self-excited* vibration and the resulted aerodynamic force is known as *motion-dependent* force. A phenomenon wherein structural motion and aerodynamic force interact significantly is called aeroelastic phenomenon. The aeroelastic phenomena commonly observed on long-span bridges are the galloping, torsional flutter, coupled flutter and vortex-induced vibration.

Long-span bridge girders are susceptible to torsional flutter. It is generally recognized now that the dramatic collapse of the Tacoma Narrows Bridge was due to torsional flutter. The weak torsional rigidity and aerodynamically unstable cross-section of the girder are two main factors responsible for the collapse. Since the Tacoma Narrows Bridge incident, flutter instability had become the most important issue in the design of long-span bridges. To avoid this instability

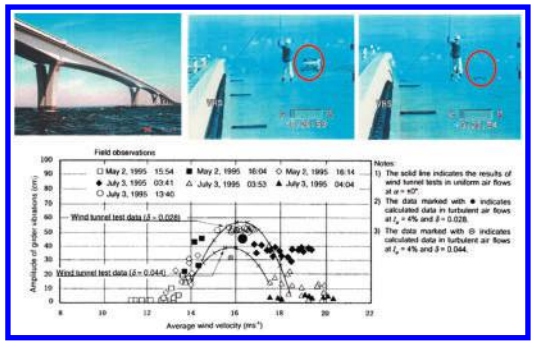
two different design approaches have been proposed; one is by streamlining the girder using box section that was promoted in UK such as Severn Bridge and Humber Bridge; and another one is using the truss-stiffened girder, which was promoted in the US, such as New Tacoma Narrows Bridge, Mackinac Bridge and Verrazano Narrows. Pressure difference between the girder upper and lower surface is considered as the main mechanism that induces flutter instability. To reduce such pressure difference, part of the deck floor can be made open using grating, or in case of box girder, by applying the central slot concept. For truss girder bridge, the use of vertical stabilizer and center barrier are effective to reduce the possibility of flutter instabilities. Such countermeasures are adopted in the Akashi-Kaikyo Bridge.

Vortex-induced vibration (VIV) is one of major issues in long-span bridge vibration. Although the vibration is self-limited and does not create divergent type of motion; maximum amplitude, fatigue problem and serviceability of the bridge associated with VIV are the main concern. VIV mainly occurs on bridge girder and pylon. VIV on cables of cable-supported bridge is also common; but the amplitude is usually small and can be suppressed completely by adding a small amount of damping. VIV on bridge deck is more serious and usually affects the girder vertical or torsional mode. Modern long-span bridges usually use box girder deck in the trapezoid form. This form has superior aerodynamic instability performance that is higher critical wind speed for flutter, but may suffer from VIV at low wind speed. Amplitude of VIV depends on wind turbulence, where larger turbulence intensity creates smaller vibration amplitude, shape of girder and structural damping.

A notable example of VIV problem in the girder of long-span bridge in Japan is the one that occurred on the Trans-Tokyo Bay Bridge (Fujino and Yoshida 2002). The Trans-Tokyo Bay Highway Crossing is a combination of tunnel and multiple bridge sea-crossing highways, completed in 1997, with total length of 11 km. The bridge section includes a ten-span continuous steel box-girder bridge with a total length of 1630 m. The two longest spans of this bridge are of 240 m. Significant vibration due to vortex shedding occurred under prevailing winds almost transverse to the bridge axis during construction stage. The vortex-induced first-mode vibration peaked at a wind velocity around 16–17 m/s, with maximum amplitude exceeding 50 cm (Figure 1).

Extensive wind tunnel testing using sectional models as well as three dimensional models had been conducted in the design stage and the VIV was indeed observed in the experiments. As countermeasures, 16 units of TMD were installed inside the box girder and aerodynamic flaps were added on deck side before opening the bridge to traffic. These countermeasures significantly reduced the vibration.

The VIV is also commonly observed on the long-span bridge pylons, especially during construction. During the free-standing construction period, the



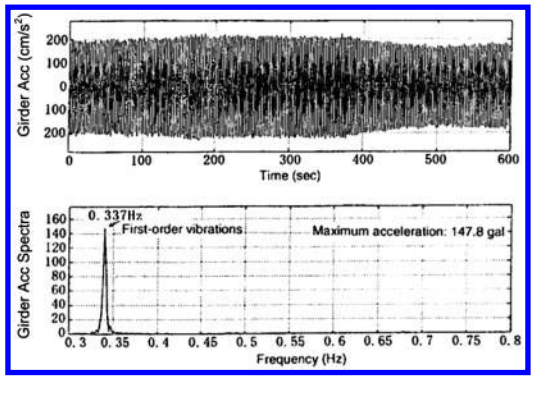


Figure 1. Observed 1st Mode Vortex-Induced Vibration at the Trans-Tokyo Bay Bridge. Note the disappearance of a car in the circle (After Fujino & Yoshida 2002).

pylons have low natural frequency and their bluff body would normally cause the out-of-plane VIV. Vibration could be excessive and obstruct the construction process, especially for pylons made of low-damped steel. Such vibration was observed during construction of Akashi-Kaikyo Bridge (Hata & Katsumi 1998), the Kurushima-Kaikyo Bridges (Suzuki et al. 1996). The excessive level of vibration obstructed construction process so that vibration control is required. Recently a unique in-line vortex combined with interference type of vibration has been observed on tower of Hakucho suspension bridge in Hokkaido Japan. Wind under certain velocity range and direction created vortices behind the windward tower leg and induced an in-line vibration on the leeward tower leg (Figure 2).

Two countermeasure strategies commonly employed are aerodynamic and mechanical counter measures. Aerodynamic countermeasures include cutting off the corners or making slits, and attaching the aerodynamic appendages such as deflectors or side-plates. Cutting the corner of bridge pylon reduces drag force and crosswind vibration at low wind speed. This approach was implemented in Higashi Kobe Bridge and Akashi-Kaikyo Bridge pylon. Mechanical countermeasures such as tuned mass damper (TMD), tuned liquid damper (TLD), tuned sloshing damper (TSD) and tuned liquid column damper (TLCD) (Fujino et al. 1992) are also commonly used in recent bridges in Japan. The first application of TMD scan be found

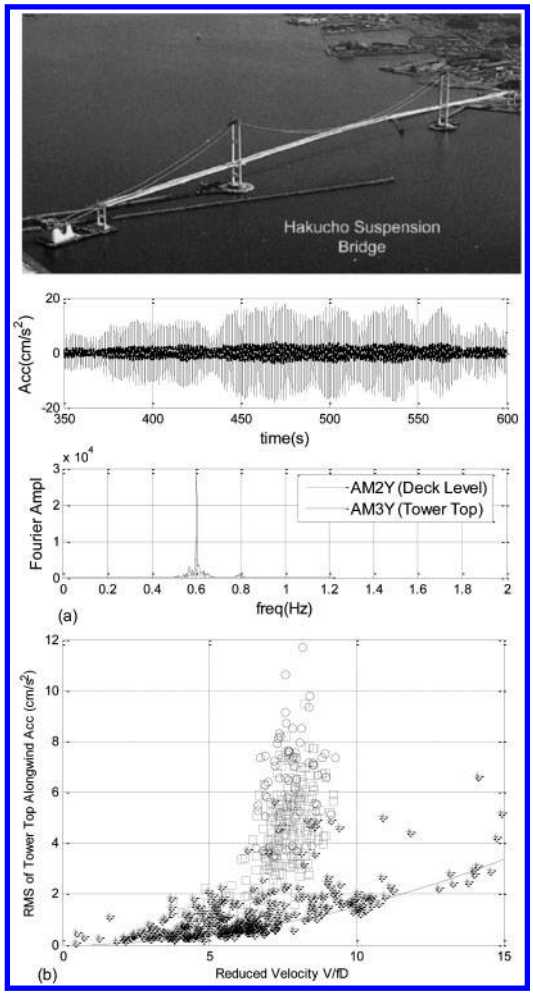

Figure 2. Hakucho Suspension Bridge and observed in-line VIV of the tower (After Siringoringo & Fujino 2012).

in the Meiko Bridge. TLD is used in Higashi Kobe Bridge and Toda Bridge. It should be noted that during construction, changes in pylon height lead to the changes in natural frequency, so that tuning frequency should be adjusted accordingly. This means several mass dampers of different natural frequencies should be prepared. To overcome this inefficiency, actively controlled mass dampers have been developed and this technology has been applied. One example of such application is the Hybrid-Mass Damper (HMD) used during construction of the Akashi-Kaikyo Bridge pylons (Fujino et al. 2012).

2.2 *Cable vibration and control*

Cables are essential component of long-span bridges and they are prone to vibrate because of their large flexibility, small mass and low mechanical damping. Main cable of suspension bridge, stay cables of cable-stayed bridge and hangers are generally very flexible

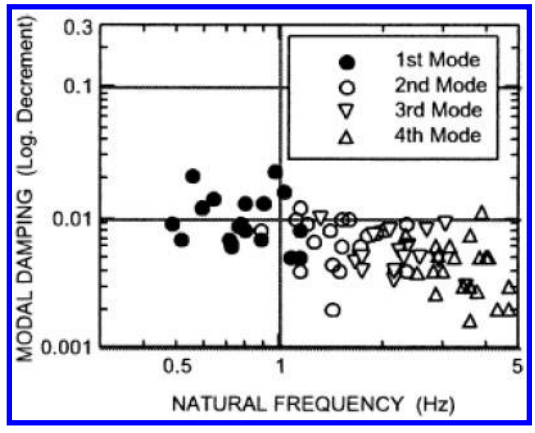

Figure 3. Relationship between modal damping and natural frequency of stay cable (After Yamaguchi & Fujino 1998).

compared to other bridge components, and therefore prone to vibrate. In long-span cable-stayed bridges, stay cable can be as long as 500 m, resulting in low natural frequencies of about 0.2–0.3 Hz in the lowest mode. A survey on inherent damping of stayed cables of cable-stayed bridges in Japan show that structural damping could reach as low as 0.1% critical damping ratio (Yamaguchi & Fujino 1998, Figure 3). Occurrences of large cable oscillation may cause damage to the anchorage and fatigue of the cable.

Vibration of objects caused by interference due to certain arrangements and proximities are very complex in nature. In the case of long-span cable-supported bridges, wake interference has been observed on the stay cables of cable-stayed bridge. It is observed in the range of $-2 < y/d < 2$ and $1 < x/d < 4$, where x and y denote the longitudinal and lateral spacing between cables, respectively and d is cable diameter (Matsumoto et al. 1989). The oscillation starts at the critical reduced velocity of around 40, which typically corresponds to the wind speed of 5–20 m/s, and generally produces an elliptical trajectory with the maximum amplitude of less than $3d$. The motion is known to be sensitive to the Scruton number (Sc), and becomes hardly recognizable at $Sc > 50$. Stay cables of Yobuko Bridge in Japan (Yoshimura 1992) and the parallel suspender cables of Akashi-Kaikyo Bridge (Furuya & Miyazaki 1998) were reported to have experienced the wake-flutter.

Rain-and-wind-induced (RWIV) cable vibration is probably the most well-known vibration problem of stay cable. It was firstly observed by Hikami on the stay-cables of the Meiko-Nishi Bridge in Japan (Hikami & Shiraishi 1998). The vibration occurs under certain wind velocity range but only during the raining condition. It occurs only on the inclined cables and the vibration amplitude on vertical plane is visible and can reach up to ten times cable diameter. The occurrence of RWIV was observed in many cable-stayed bridges around the world; such as Tempozan and Aratsu Bridge in Japan

Vibration with instability characteristics similar to RWIV has been reported on inclined stay-cables in tunnel tests during in dry (without rain) condition. It was shown that if the wind is in an oblique direction against the cable plane, the cable could have similar response characteristics as galloping instability. The instability phenomenon has been observed on several wind tunnel investigations and it appears to share the characteristics, namely, occurring on dry inclined cable at specific Reynolds number range and on the few specific geometrical cable positions. Dry galloping vibration would pose a very serious problem if it takes place as predicted in wind tunnel tests. However, unlike the RWIV, incident related to this type of cable motion has been rarely observed in real bridges. Perhaps a clear indication of dry galloping on stay cable was reported only recently in Japan (Matsumoto et al. 2005), where a 187 m length stay cable showed intense vibration with amplitude up to 1.5 m at the wind speed of 18 m/s.

In case of long-span cable-stayed bridge, natural frequency of the stay cables in local horizontal vibration (f_y) can be almost equal to the natural frequency of the girder global horizontal vibration (f_h), a condition that leads to the linear interaction known as parametric vibration. Since the cable is much lighter compared to girder and pylons, its vibration can develop easily in large amplitude so that the geometrical non-linearity of the cable cannot be ignored. This creates the *nonlinear interaction*. The linear internal resonance occurs when the natural frequency ratio of the local cable motion to the girder- or pylon-dominant global mode is 1:1. In the forced excitation experiment of cable-stayed bridges, cable local vibration is often excited and this is mostly due to the linear internal resonance. Mechanisms and estimation of the maximum amplitude of vibration interaction between pylon, girder and cables in the parametric and auto-parametric excitations are explained in the studies by Fujino et al. (1993).

Cable vibration can be controlled by aerodynamic, structural and mechanical countermeasures. For RWIV, the aerodynamic countermeasures aim at breaking up formation of the upper water rivulet on cable surface. This can be achieved by whirling helical wire on the cable surface, adding dimples to cable surface, or using axially protuberated surface (Figure 4). To suppress wake interference vibration, structural countermeasures by installing spacer and cable crossties between cables are commonly applied in an attempt to increase cable stiffness. This, however, may not be effective for very long cables.

Currently, mechanical countermeasure is the most widely used method. Main purpose of this approach is to increase cable damping by installing various types of dampers near the anchorage points or between cables. The relative motion between the cables and between cable and girder generate damping force. This method, however, has a limited performance and adequate damping force cannot be provided for extremely long stay cables. The damper has customarily been designed by neglecting several influencing factors; one

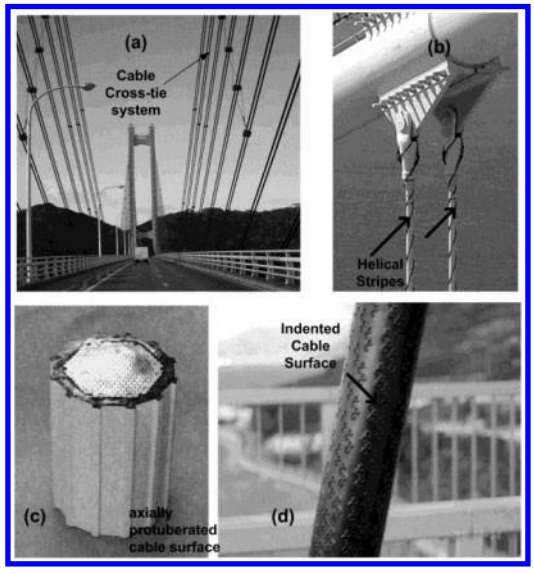

Figure 4. Aerodynamic countermeasures for cable vibration control at (a) Yobuko Bridge (Cross-tie), (b) Akashi-Kaikyo Bridge (Helical stripes), (c) Higashi-Kobe Bridge (axially protuberated surface) and (d) Tatara Bridge (indented surface).

of which is the cable flexural rigidity. It can be anticipated that the small flexural rigidity possessed by real cable systems affects performance of the damper since it is usually installed near the anchorage. As a result, additional damping given to the cable may not be as high as designed. Recent studies by author (Fujino & Hoang 2007, 2008) on the theoretical aspects have provided deeper understanding on the effects of sag, bending stiffness of cable and the flexibility of damper supports on the optimal performance of the dampers.

3 SEISMIC RETROFIT OF LARGE BRIDGES

Vibration problems are not only considered in the designing of new bridges but also when improving safety, durability and long-term performance of existing bridges. Seismic retrofit, for example, is an important effort to improve safety of existing bridges against foreseeable earthquakes in the future. In Japan, many bridges including the long-spanones were designed and constructed before the 1995 Hyogo-ken Nanbu (Kobe) Earthquake. Experience and lessons learned from the earthquake are very valuable and incorporated in the new seismic design code in 1997. According to the new code bridges must be designed for two levels of ground motions; one is a moderate ground motion with a return period of several tens year and the other is one for the maximum credible earthquakes with a return period of 500 to 2000 years. For the level 1 ground motion, the bridge is expected to receive no damage or very mild damage after the earthquake. For the level 2 ground motion, damage to

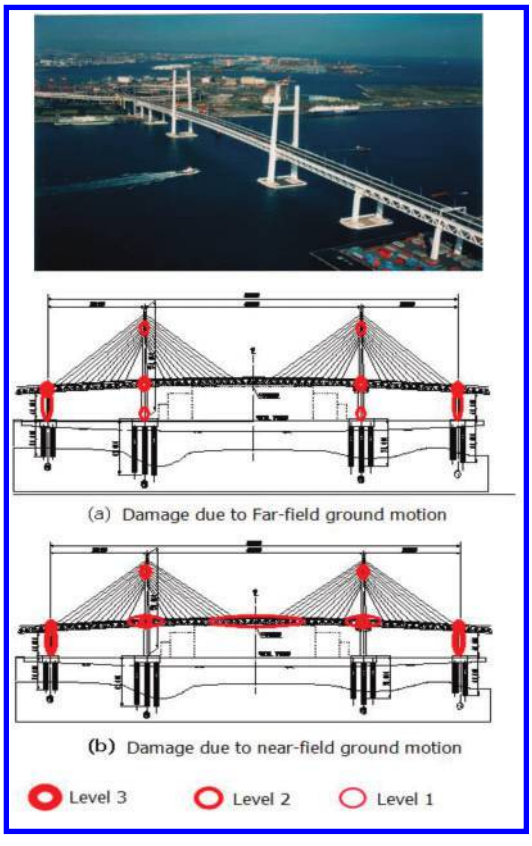

Figure 5. Yokohama-Bay Bridge. Several damage locations and levels due to simulated ground motions in retrofit program.

bridge after the earthquake is explicitly permitted, but functionality should be maintained after very severe ground motion.

Seismic performances for two levels of ground motions prescribed in new code must be evaluated and necessary retrofit strategies must be taken for existing bridges. Two case-studies on seismic retrofit of long-span bridges namely the Yokohama-Bay Bridge and Minato Truss Bridge are described in this section.

3.1 *Seismic retrofit of Yokohama-Bay Bridge*

Yokohama Bay Bridge (Figure 5), completed in 1988 is a double deck cable-stayed steel truss-box bridge with a central span of 460 m and two side spans of 200 m in length. It is located at the mouth of the Yokohama harbor. In 2005 a seismic retrofit program for safety assurance of level-2 earthquake according to Japan's bridge seismic code was conducted. The retrofit program considered two types of maximum credible earthquakes: magnitude 8 far-field or moderately far-field large earthquakes taking place in subduction zone of the Pacific plate with and near-field inland earthquake occurring beneath the site or close to the site.

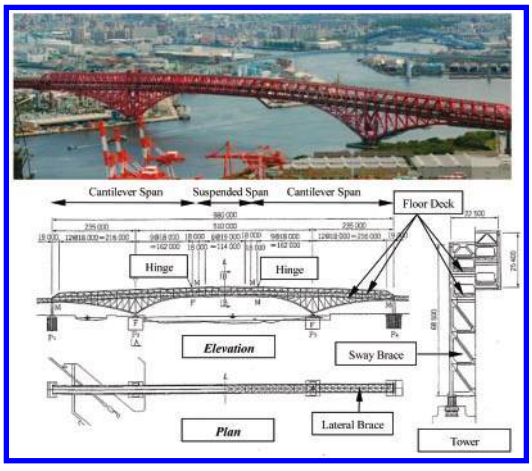

Figure 6. Minato Truss Bridge and its structural characteristics.

Based on seismological model, the ground motions were simulated assuming seven scenarios with fault geometry that resembles the 1923 Kanto Great earthquake (Fujino et al. 2008). Simulations identified potential damages for both types of ground motion and concluded that significant damage would occur on the towers and bearings under such excitations (Figure 5 (a),(b)). Furthermore, the far-field ground motion would create more damage and induce 1.5 m longitudinal displacement of the girder. Accordingly, a fail-safe design concept was introduced and the following strategies for major structural elements were implemented:

1) Providing adequate seating on the approach span to avoid unseating during a large earthquake.
2) Constructing additional cables connecting girder and end-piers in case that large transverse excitation damages the two link-bearing connections (LBC) at the end-piers.
3) Adding stiffeners inside the towers and piers to increase the ultimate strength and ductility in case a large longitudinal excitation damages the edge of steel frame.
4) Installing cable inside the lateral upper-beam near the top of tower to prevent the beam from falling in case of large deformation.
5) Providing additional seats on the lateral beam under the girder to prevent impact force from girder in case a large transverse excitation damages the tower links and stay cables near the towers.

3.2 *Seismic retrofit of Minato Truss Bridge*

The Minato Truss Bridge, completed in 1974 is located in Osaka, Japan. It is a 980 m-long cantilever-truss bridge and currently the third longest truss bridge in the world (Figure 6). Application of conventional retrofitting methods by strengthening the existing members is considered ineffective for this bridge for the concerns of low ductility, additional weight, large

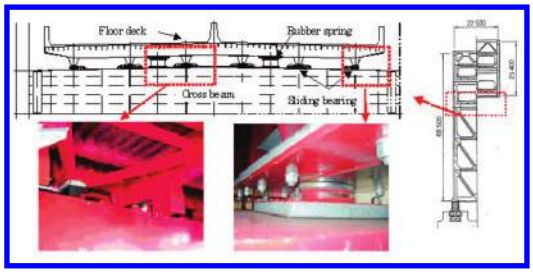

Figure 7. Floor deck seismic isolation system using sliding bearings (After).

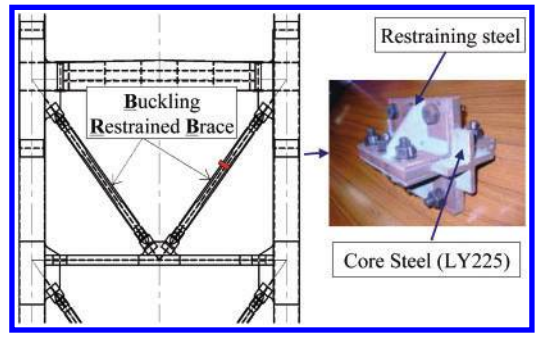

Figure 8. Buckling restrained brace (BRB) to give adequate damping to the entire bridge and also to avoid buckling. In transverse direction.

response force, working difficulties, and huge cost. Therefore it was decided to perform seismic retrofit by modifying and controlling seismic response (Kanaji et al. 2008).

Response spectrum analysis as well as time history analysis using the site-specific earthquake motions is carried out. Response spectrum analysis revealed that acceleration for the first mode in the longitudinal direction is larger than that of the original design acceleration, which implies that the 1st natural period should be shifted so that retrofit would be effective. On the other hand, the natural period of the 1st mode in the transverse direction is adequate, while for the 2nd mode the retrofit by increasing the damping would be effective.

Evaluation of *Demand/Capacity* ratio of each structural member under the site-specific prescribed ground motion is conducted. The results show that response in the longitudinal direction causes yielding ($R < -1.0$) or buckling ($R > 1.0$) in chord members located near the edges of side-spans, and around hinges between the cantilever span and the suspended span. On the other hand, the response in the transverse direction causes inelastic behavior in chord members located near the edges of the bridge, as well as, in lower chord members, diagonal or vertical members of the side-spans near the towers, and also in towers' diagonal members.

The retrofitting strategy applied herein considers the damage control concept in which damage is allowed only in sub members supporting lateral forces. These sub-members are expected to behave elasto-plastically and to generate adequate hysteretic damping. On the other hand, the main members supporting vertical forces such as dead load and live load should remain almost elastic.

To realize the retrofit concept, several strategies were examined using dynamic analysis. Among them, it was confirmed that floor deck isolation for the longitudinal direction (Figure 7) and buckling restrained braces (BRB) for the transverse direction (Figure 8) is the most effective way considering their cost. Parametric study for the floor isolation properties gives the relationship between the bearing displacement and the response ratio of chord member force and shows that the optimal combination of the vibration period, 3.0 secs and the friction coefficient, 0.05. BRBs of lower lateral braces and sway braces of towers are extremely effective to provide large damping. The test of the frame incorporating BRBs shows the stable hysteretic curve with the equivalent damping coefficients is 32%.

4 BASED STRUCTURAL HEALTH MONITORING OF LONG-SPAN BRIDGES

A large number of long-span bridges were constructed in Japan in the past decades. These bridges, especially the cable-supported ones, are expensive to inspect and maintain. They have long service periods of over 100 years, during which they inevitably suffer from environmental long-term loads effects such as fatigue, material deterioration and other extreme load effects. To this end, structural health monitoring (SHM) becomes important, and more concerted efforts are now being devoted to enhance our understanding in implementation of both monitoring technologies and methodologies.

Structural health monitoring using vibration data is recommended for global assessment of bridges. The system consists of bridge instrumentation, signal processing, data transmission and storage, and the most important part is data analysis and interpretation. Many large bridges such as long-span cable-supported bridges are now instrumented in Japan. Some of them are continually monitored using vibration response recorded from normal traffic, wind, typhoon and seismic responses (see examples of continuously monitored bridges in Tokyo metropolitan area Figure 9). The objectives of vibration-based SHM can be broadly categorized in two: environment and disaster prevention, and stock management.

Monitoring for seismic response has been widely employed especially for structures with special features such as long span bridges (Siringoringo & Fujino 2008a, 2008b), and bridges with new technology such as base-isolated bridges (Chaudhary et al. 2000). One example is dense monitoring system installed on the Yokohama-Bay Bridge (Figure 9a) (Siringoringo & Fujino 2006, 2008a). The study shows that by employing a system identification technique, dynamic characteristics of the bridge can be evaluated and global

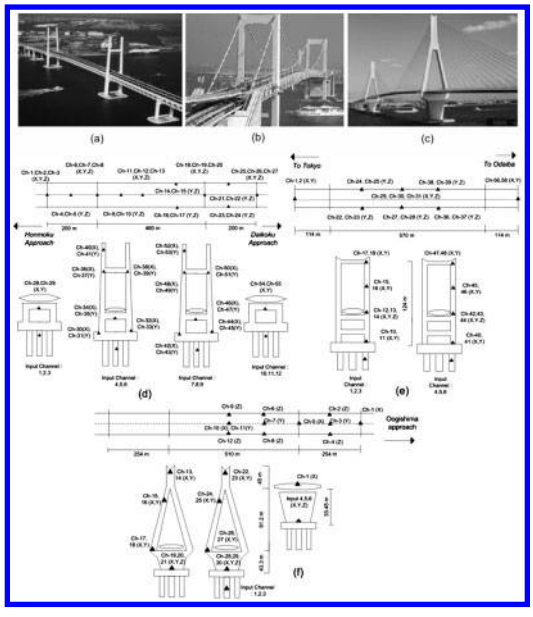

Figure 9. Three permanently instrumented long-span cable-supported bridges in Japan (a&d) Yokohama-Bay Bridge, (b&e) Rainbow Bridge, (c&f) Tsurumi-Tsubasa Bridge.

structural behavior under various levels of earthquake can be investigated. In addition to global behavior such as amplitude dependency of damping ratios, variations of local components were also observed. This variation was a result of non-linear response of link-bearing connection – a seismic isolation device between girder and tower.

Another popular method of monitoring of long-span bridges is ambient vibration measurement. Ambient vibration measurement uses loading from wind, waves, vehicular or pedestrian traffic or any combination of service loading. This offers economical advantage since it eliminates the need for loading testing devices and also does not re-quire the suspension of structure services during measurement. One of such analysis in conducted in Hakucho Suspension Bridge (Siringoringo & Fujino 2008). During ambient tests the bridge response was monitored by densely distributed vibration measurement system.

To estimate dynamic characteristics of the bridge system identification using random response is implemented. In this approach, dynamic signatures that have the characteristics of free vibration responses were extracted from random response. Using these dynamic signatures, effect of randomness and transient can be eliminated to obtain the dynamic characteristics such as natural frequencies, damping ratios and mode shape vectors. Important results of wind-induced monitoring are evaluation of influence of aerodynamic damping, bearing rotational stiffness on the girder vibration characteristics. It was found that the contribution of aerodynamic force was smaller than the effect of friction force from the bearing. These results are consistent with the expected increase in equivalent stiffness and decrease in damping when the amplitude level is small enough to suppress any relative movement at the bearing or extension devices (Nagayama et al. 2005).

5 CONCLUSIONS AND FUTURE CHALLENGES

Vibration mechanisms and control are critical factors in the design and construction of long-span bridges. In this paper, we present several studies on vibration mechanisms commonly observed for long-span bridges in Japan, especially cable-supported ones. Countermeasures against vibration problems have been developed based on the present understanding of vibration mechanisms. Performance improvement for these engineering countermeasures is still a subject for further study, especially for bridge with longer spans and taller pylons. One particular aspect of the countermeasures is the use of control technology for long-span bridge vibration problems. While passive control strategies have been widely applied, active control strategies have yet to reach a mature state to be directly applied to solve long-span bridge vibration problems, which provides both challenges and opportunities for bridge researchers and engineers in the future.

The recent advancement on computer technology has provided us with strong simulation tool to investigate vibration problems. Computational fluid dynamics (CFD) technique, for example, has been developed and used extensively as a supplement in recent years. Rapid development of CFD is expected to become a strong tool, although it may take some time to become a complete replacement for wind tunnel testing because of the high complexity of the geometry of the bridge section and the three-dimensional nature of the bridge.

For seismic-induced vibration analysis, the use of computer simulation and site-specific ground motions have improved our understanding on the behavior of bridge components under specific earthquakes, which is essential in the performance-based design and seismic retrofit of existing bridge.

We note also recent advancement in sensing and monitoring technologies applied in long-span bridges. Such monitoring systems have provided data that is useful for improving our understanding of bridge vibration problems. Furthermore, monitoring data will be essential for validation of structural model and providing feedback on the performance of current vibration countermeasures. Newly observed vibration phenomenon in authors' experience are the results of continuous monitoring of long-span bridges. One direction in bridge structural health monitoring is toward realizing a low-cost, smart, continuous and reliable monitoring system using wireless sensor network. The objective is to combine bridge engineering knowledge with developments in sensor technology and network/information management in order to provide a solution that is a robust and significantly lower-cost as an alternative to traditional wired monitoring systems.

ABSTRACT: This paper provides an overview of the most recent research activity concerning the (i) non-linear behaviour (elastic and elastic-plastic), (ii) ultimate strength and (iii) Direct Strength Method (DSM) design of cold-formed steel columns experiencing local-distortional (L-D) interaction. After briefly introducing and illustrating this mode coupling phenomenon, both numerical (ABAQUS 4-node shell finite element analysis) and experimental results are presented, compared and discussed. The numerical investigation make it possible to characterise the L-D interactive behaviour and failure of columns with different cross-section shapes (lipped channels, hats, zeds and racks) and includes fairly extensive parametric studies, carried out in order to (i) assess how the relevance of the L-D interaction effects varies with the ratios between the competing (local and distortional) critical buckling stresses and the steel yield stress, and (ii) gather a substantial ultimate strength data bank. Then, the experimental tests, dealing with lipped-channel and rack-section columns, provides experimental (i) evidence of the occurrence of clear L-D interaction and (ii) failure loads and collapse mechanisms. Next, after showing the inadequacy of the current DSM local and distortional column strength curves to predict L-D interactive failures, the paper presents and assesses the merits of recently developed DSM-based design procedures against such interactive column failures. Finally, the paper closes with some concluding remarks and a few comments on developments planned for the near-to-intermediate future.

1 INTRODUCTION

Most cold-formed steel members display very slender thin-walled open cross-sections, making them highly susceptible to instability phenomena involving cross-section in-plane deformations: local (L) and distortional (D) buckling. Moreover, since commonly used members exhibit cross-section geometries (shape and dimensions) that may be associated with close local and distortional critical buckling stresses, their post-buckling behaviour (elastic or elastic-plastic), ultimate strength and failure mode are bound to be heavily affected by the coupling between these two buckling modes.

A fair amount of research has been recently devoted to L-D interaction, involving mostly lipped channel columns and consisting of numerical simulations, experimental investigations and design proposals (e.g., Yang & Hancock 2004, Yap & Hancock 2011, Kwon *et al* 2009). The aim of this paper is to present a unified overview of the authors' recent research on the (i) non-linear behaviour (elastic and elastic-plastic), (ii) ultimate strength and (iii) Direct Strength Method (DSM – Schafer 2008) design of cold-formed steel columns affected by L-D interaction – this is part of an ongoing investigation on coupled instabilities involving distortional buckling (e.g., Camotim & Dinis 2011). Both numerical and experimental research was carried out, concerning pin-ended and fixed-ended columns with various geometries ensuring close L and D critical buckling stresses. The numerical simulations, carried out at the Technical University of Lisbon, employed ABAQUS shell finite element analyses (SFEA) and dealt with the elastic and elastic-plastic non-linear behaviour and strength of lipped channel (C), hat (H), zed (Z) and rack-section (R) columns. They involved the identification of key mechanical features concerning the member response, such as the most detrimental initial imperfection shapes and elastic-plastic failure modes (Dinis *et al* 2007, 2013a). These findings were then included in extensive parametric studies aimed at determining failure loads of imperfect columns with various geometries, support conditions and yield stresses (covering wide slenderness ranges). The experimental investigation, performed at The University of Hong Kong, clear evidenced the occurrence of L-D interaction in C (Young *et al* 2013) and R (Dinis *et al* 2012a) fixed-ended columns and provided the failure loads of the tested specimens. The numerical and experimental ultimate strength "data bank" gathered was the starting point to develop and validate DSM-based approaches to predict failure loads of columns influenced by L-D interaction (Silvestre *et al* 2009, 2012, Dinis *et al*

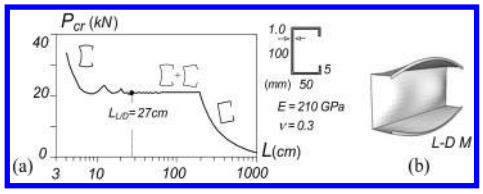

Figure 1. (a) Column critical buckling curve and (b) "combined" L-D buckling mode shape – $L_{L\text{-}D} = 27$ cm column.

2013a, Young *et al* 2013). This paper aims at providing an overview of the above research effort, namely the numerical simulations, experimental studies and quest for an efficient DSM design against L-D interactive failures.

2 NUMERICAL SIMULATIONS

Following a brief presentation of the most relevant issues concerning the buckling, post-buckling and strength behaviour of columns with $P_{crL}/P_{crD} = 1.0$, the performance of parametric studies, intended to gather a extensive failure load data bank involving mostly fixed-ended columns under strong L-D interaction and covering a wide slenderness range, is addressed. The numerical simulations were carried out by means of ABAQUS SFEA, using an existing model: (i) columns discretised into fine 4-node isoparametric element meshes (length-to-width ratio ≈1.0), (ii) fixed-ended conditions modelled by attaching rigid plates to the column end sections and (iii) steel material behaviour described by Prandtl-Reuss's elastic-perfectly model – details to be found in Dinis *et al*. (2007, 2013a).

2.1 *Buckling behaviour*

The column geometry (cross-section dimensions, length) selection, ensuring different levels of L-D interaction, was made by trial-and-error buckling analysis sequences. Figure 1 illustrates this procedure for a simply supported C column: while Figure 1(a) provides the P_{cr} vs. L (logarithmic scale) curve, Figure 1(b) shows the "combined" L-D buckling mode shape of the selected $L_{L\text{-}D}$ column ($P_{cr.L\text{-}D} = 21.1$ kN): 3 local and 1 distortional half-waves.

2.2 *Initial geometrical imperfections*

The initial geometrical imperfection shape plays a crucial role in mode interaction investigations, as its choice may alter considerably the column post-buckling behaviour and strength. Therefore, it is necessary to study the post-buckling behaviour of members with various critical-mode initial shapes, combining arbitrarily the competing L and D buckling modes and sharing the same amplitude (Dinis *et al* 2007) – the outcome of this study is the most detrimental imperfection shape (lowest column strength). Figure 2 illustrates the methodology adopted, for the $L_{L\text{-}D}$ column in section 2.1. The initial shapes are linear combinations of 3 half-wave local and 1 half-wave distortional buckling modes, normalised to exhibit amplitudes equal to 10% of the wall thickness t (0.1 mm). The coefficients $C_{L.0}$ and $C_{D.0}$ satisfy $(C_{L.0})^2 + (C_{D.0})^2 = 1$

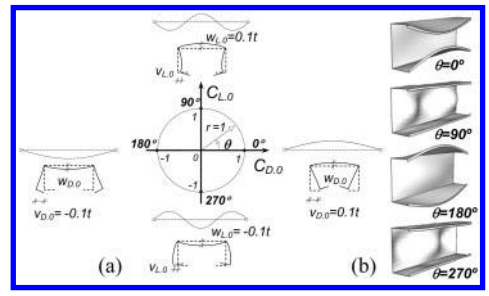

Figure 2. (a) Initial imperfection representation in the $C_{L.0}-C_{D.0}$ plane and (b) $\theta = 0°$, 90°, 180° and 270° column initial imperfection shapes.

and the initial imperfection is defined by an angle θ, such that $C_{L.0} = \sin\theta$ and $D_{D.0} = \cos\theta$ in Figure 2(a). Figure 2(b) shows the pure L ($\theta = 90°$ or 270° – inward-outward mid-span web bending) and D ($\theta = 0°$ or 180° – inward-outward mid-span flange-stiffener motion) initial imperfections.

2.3 *Post-buckling behaviour*

The influence of L-D interaction on the column elastic and elastic-plastic post-buckling behaviour is shown through the previous C $L_{L\text{-}D}$ column, with (i) 8 initial imperfection shapes ($\theta = 0°$, 45°, 90°, 135°, 180°, 225°, 270°, 315°) and (ii) 4 yield-to-critical stress ratios ($f_y/f_{cr} \approx 1.2$, 2.0, 3.5, $\infty - f_y = 120$, 200, 355 MPa and elastic behaviour). Figure 3(a) shows, for $P/P_{cr} > 0.6$, the P/P_{cr} *vs.* v/t elastic equilibrium paths (v: mid-span flange-lip corner vertical displacement) of the $\theta = 0°$, 180° and $\theta = 90°$, 270° columns (pure distortional and local imperfections). Figure 3(b) shows the evolution, along the equilibrium paths, of the mode coupling ratio C_L/C_D (for all columns). The following conclusions can be drawn from these results:

(i) All equilibrium paths merge into 2 common curves, associated with inward or outward flange-lip motions – the initial imperfection shape determines which curve is joined by a given equilibrium path.

(ii) The two straight lines in Figure 3(b), with slightly different slopes ($C_L \approx -0.34C_D$ and $C_L \approx -0.25C_D$, for outward and inward flange-lip motions), define the coupled buckling modes, combining distortional and local deformations (opposite mid-span web flexure).

(iii) The pure distortional outward imperfections ($\theta = 180°$) are the most *detrimental*, as they lead to the lowest strength. Similar studies involving H and R columns showed that the $\theta = 0°$ imperfections (inward mid-span flange-lip motions) are the most detrimental (Dinis *et al* 2013a) – in Z columns, both the $\theta = 0°$ and $\theta = 180°$ imperfections are equally detrimental (the associated post-buckling behaviours are identical).

In order to illustrate the elastic-plastic post-buckling behaviour and strength of columns experiencing strong L-D interaction, Figure 4(a) shows the upper portions ($P/P_{cr} > 0.6$) of the P/P_{cr} *vs.* v/t paths concerning the previous C $L_{L\text{-}D}$ columns with (i) $\theta = 180°$ imperfections and (ii) three yield-to-critical

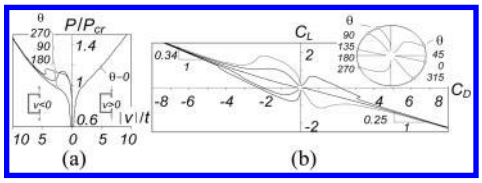

Figure 3. (a) Column critical buckling curve and (b) "combined" L-D buckling mode shape – $L_{L\text{-}D} = 27$ cm column.

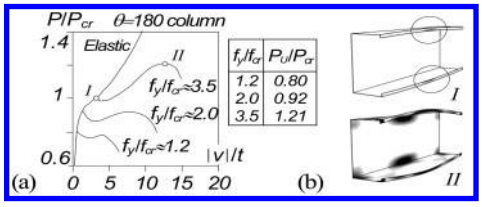

Figure 4. (a) Elastic-plastic P/P_{cr} *vs.* v/t paths ($\theta = 180° + f_y/f_{cr} \approx 1.2; 2.0; 3.5; \infty$) and (b) configurations and plastic strains ($\theta = 180° + f_y/f_{cr} \approx 3.5$).

stress ratios: $f_y/f_{cr} \approx 1.2; 2.0; 3.5$. Figure 4(b) concerns the $f_y/f_{cr} \approx 3.5$ column and displays the plastic strain diagrams at the equilibrium states shown on the equilibrium path (including the failure mode). This investigation led to the following conclusions:

(i) The nature and characteristics of the column elastic-plastic post-buckling behaviours and failure mode clearly depend on the f_y/f_{cr} value.

(ii) For f_y/f_{cr} close to 1.0 (e.g., $f_y/f_{cr} \approx 1.2$), yielding starts when the normal stresses are still fairly uniform and, therefore, precipitates a rather abrupt collapse.

(iii) For higher f_y/f_{cr} values (e.g., $f_y/f_{cr} = 3.5$), yielding starts when the normal stresses are already heavily non-uniform and, thus, collapse is not immediate (it only occurs after a mild snap-through phenomenon, followed by a further strength increase up to a limit point). The elastic-plastic strength reserve increases with f_y/f_{cr}, but the erosion due to L-D interaction is considerable (e.g., for $f_y/f_{cr} \approx 1.2; 2.0; 3.5$, the column ultimate load ratios are $P_U/P_{cr} = 0.80; 0.92; 1.21$).

(iv) Plasticity appears first at the mid-span section lip free ends and failure occurs after the full yielding of the column central zones located around the web-flange corners (see Fig. 5(b)).

2.4 *Parametric studies – failure load data*

ABAQUS SFEA parametric studies were performed to obtain numerical failure loads of imperfect C, H, Z and R columns with geometries leading to strong L-D interaction (Silvestre *et al* 2009, 2012, Dinis *et al* 2013a). These data were then used to (i) assess the merits of the current DSM design curves in predicting L-D interactive failures and (ii) to guide/validate the search for DSM-based design approaches able to capture this interaction.

The column cross-section geometries were selected to control the closeness between the critical buckling loads P_{crL} and P_{crD}. This was achieved by slightly altering a dimension of previously identified "base cross-sections" with identical P_{crL} and P_{crD} (see Fig. 2). This procedure led to several columns with close (but not coincident) P_{crL} and P_{crD} – the changes ensured $0.9 \leq P_{crL}/P_{crD} \leq 1.1$. Furthermore, to cover a wide distortional slenderness $\lambda = (f_y/f_{crD})^{0.5}$ range, various yield stresses were considered for each column. Failure loads of (i) 111 pin-ended C columns, (ii) 210 fixed-ended C, H and Z column triplets, and (iii) 234 fixed-ended R columns were obtained.

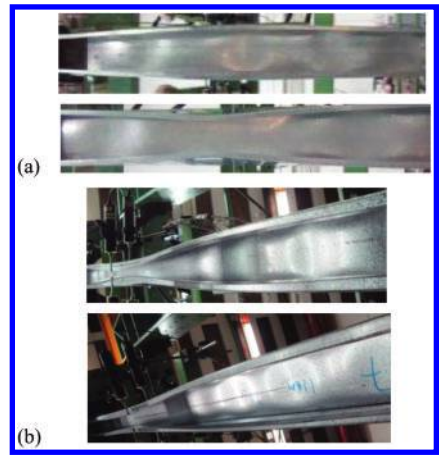

Figure 5. Experimental evidence of the occurrence of L-D interaction in the UHK (a) lipped channel and (b) rack-section column tests.

3 EXPERIMENTAL INVESTIGATIONS

Concerning C, H, Z and R columns, the occurrence of L-D interaction and ensuing ultimate strength erosion had only been experimentally observed by Kwon *et al* (2009) at Yeungnam University (YU – 6 C column tests) – note however, that these authors, and also Yang & Hancock (2004) and Yap & Hancock (2011) from the University of Sydney, reported experimental evidence on L-D interaction in web and/or flange-stiffened lipped channel columns (outside the scope of this study). Thus, it was decided to perform an experimental investigation at The University of Hong Kong (UHK), involving (i) 16 fixed-ended C (Young *et al* 2013) and (ii) 10 fixed-ended R (Dinis *et al* 2012a) columns with geometries selected to ensure strong L-D interaction. Although the specimens tested at YU and UHK showed sheer evidence of L-D interaction (see Fig. 5(a)–(b)), it was subsequently found that their P_{crL} and P_{crD} values were not that close (clearly not in the $0.9 \leq P_{crD}/f_{crL} \leq 1.1$ interval). Indeed, numerical calculations, based on the actual/measured specimen geometries (different from the requested ones) showed that local buckling always preceded distortional buckling – the P_{crD}/P_{crL} ratio varied from 1.34 to 3.23 (YU Cs), 1.73 to 2.71 (UHK Cs) and 1.31 to 1.46 (UHK Rs).

In order to explain this somewhat surprising feature, Figures 6(a)–(b) display the elastic equilibrium paths and four cross-section buckled configurations of C columns with P_{crD}/P_{crL} equal to 1.05 (Fig. 6(a)) and 1.4 (Fig. 6(b)): while the former concerns a "true interaction" (L-D coupling starts at the early loading stages),

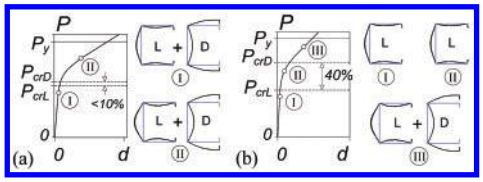

Figure 6. *P vs. d* equilibrium paths and cross-section buckled shapes for lipped channel columns with P_{crD}/P_{crL} equal to (a) 1.05 and (b) 1.4.

R10	98.8	72.2	17.2	20.8	2501	1.175	500	1.36	2.57	74.3

the latter deals with a "secondary bifurcation" – L-D interaction only starts close to the distortional buckling load level and it will cause ultimate strength erosion provided that the squash load P_y is "high enough" ($P_y > P_{crD}$) to allow for it – all the YU and UHK tests fell into this category.

3.1 *The University of Hong Kong test programme*

The UHK test programme is briefly addressed in this sub-section – more details in Young *et al* (2013) and Dinis *et al* (2012a). It comprised 16 C and 10 R fixed-ended cold-formed steel specimens brake-pressed from high strength and mild steel zinc-coated structural steel sheets – the zinc coating was removed by acid etching. Table 1 provides the various specimen geometries, yield stresses, P_{crD}/P_{crL} and P_y/P_{crD} ratios, and failure loads P_U. The specimens were cut to specified lengths, ranging from (i) 1026 to 2500 mm (Cs) and (ii) 1300 to 2500 mm (Rs), and their ends were milled flat electronically and welded to 25 mm thick steel plates, ensuring full contact with the test machine end bearings and contributing to achieve fully fixed end supports.

The specimen material properties were obtained by means of tensile coupon tests. Moreover, initial geometrical imperfection measurements were made at the column mid-height cross-section prior to testing, providing information on the local and distortional imperfections ("combined" with torsional rotation and minor-axis flexural information, in the case of the R column tests).

A servo-controlled hydraulic testing machine was used to apply the compressive axial force to the column specimen (with steel plates welded to their ends), whose top end plate was bolted to its bearing plate, which was restrained against warping, twist and major and/or minor axis flexural rotations – this setting may be said to correspond to a fully fixed-ended support condition. A data acquisition system recorded the readings of the applied load cell and displacement transducers (located at the top and mid-span cross-sections) at regular intervals during the tests.

All the C and R specimens failed in local-distortional interactive modes – Figures 5(a)–(b) show the deformed configurations near collapse of two C (Fig. 5(a)) and two R (Fig. 5(b)) specimens, exhibiting a very clear combination of local and distortional deformations. As mentioned earlier, these L-D interaction effects do not stem from the closeness of P_{crL} and P_{crD} – instead, the interaction takes place because $P_{cr.L} < P_{cr.D}$ and P_y is sufficiently larger than $P_{crD.}$: the $P_y/P_{cr.D}$ ratio varies from (i) 1.09 to 6.01 (Cs) and (ii) 1.83 to 2.88 (Rs).

4 DIRECT STRENGTH METHOD (DSM) DESIGN

The current DSM column strength curves are defined by "Winter-type" expressions that (i) were calibrated against fairly large numbers of experimental and/or numerical failure loads and (ii) predict efficiently the ultimate loads of columns failing in local (f_{NL}), distortional (f_{ND}), global (f_{NE}) and local-global (f_{NLE}) interactive modes, on the sole basis of yield and elastic buckling stresses – the expressions providing the above DSM nominal strengths can be found in Schafer (2008).

4.1 *L-D interaction – $P_{crL} \approx P_{crD}$*

Two distinct (but similar) DSM strategies to estimate the failure loads of columns experiencing L-D interaction were originally proposed by Schafer (2002): replace f_y either (i) by f_{ND} in the f_{NL} equations (NLD approach – f_{NLD}) or (ii) by f_{NL} in the f_{ND} equations (NDL approach – f_{NDL}). Then, the nominal strength against L-D interactive failure can be estimated by the equations

$$f_{NLD} = \begin{cases} f_{ND} & \text{if} \quad \lambda_{LD} \le 0.776 \\ f_{ND}\left(\frac{f_{crL}}{f_{ND}}\right)^{0.4}\left[1-0.15\left(\frac{f_{crD}}{f_{ND}}\right)^{0.4}\right] & \text{if} \quad \lambda_{LD} > 0.776 \end{cases}, \tag{1}$$

$$f_{NDL} = \begin{cases} f_{NL} & \text{if} \quad \lambda_{DL} \le 0.561 \\ f_{NL}\left(\frac{f_{crD}}{f_{NL}}\right)^{0.6}\left[1-0.25\left(\frac{f_{crD}}{f_{NL}}\right)^{0.6}\right] & \text{if} \quad \lambda_{DL} > 0.561 \end{cases}, \tag{2}$$

where $\lambda_{LD} = (f_{ND}/f_{crL})^{0.5}$ and $\lambda_{DL} = (f_{NL}/f_{crD})^{0.5}$ – local-distortional and distortional-local slenderness.

Later, Silvestre *et al.* (2009) used numerical failure load data to assess the performance of these two approaches for C columns and concluded that they provide similar predictions, even if the quality of the f_{NDL} estimates was marginally higher. Moreover, these authors showed that (i) regardless of the column end support conditions, the f_{ND} values predict the ultimate strength quite accurately in the low-to-moderate distortional slenderness range ($\lambda_D < 1.5$), but perform much worse for the more slender columns ($\lambda_D \geq 1.5$), and (ii) the f_{NDL} values only provide reasonably accurate failure load predictions for simply supported columns with moderate-to-high distortional slenderness ($1.4 \leq \lambda_D \leq 2.6$). Then, Silvestre *et al* (2012) went a step further and, on the basis of a larger numerical failure data bank, proposed a novel DSM approach for fixed-ended C columns: the NL-D approach – $f_{NL\text{-}D}$. It adopts the current DSM distortional strength curve for $\lambda_D < 1.5$ (i.e., $f_{NL\text{-}D} = f_{ND}$ – no relevant L-D interaction) and, for $\lambda_D \geq 1.5$, proposes a modified local strength f_{NL}^*, which (i) depends on the critical half-wave length ratio L_{crD}/L_{crL} (obtained from simply supported column signature curves), and (ii) provides ultimate strength estimates by replacing f_{NL} with f_{NL}^* in the NDL equations (2) – the f_{NL}^* values are given by the expressions

$$f_{NL}^* = \begin{cases} f_y & \text{if} \quad \frac{L_{crD}}{L_{crL}} \leq 4 \\ f_y + \left(1 - 0.25\frac{L_{crD}}{L_{crL}}\right)\left(f_y - f_{NL}\right) & \text{if} \quad 4 < \frac{L_{crD}}{L_{crL}} < 8 \\ f_{NL} & \text{if} \quad \frac{L_{crD}}{L_{crL}} \geq 8 \end{cases} . \qquad (3)$$

Note that these equations lead to the f_{ND} and f_{NDL} values for $L_{crD}/L_{crL} \leq 4$ and $L_{crD}/L_{crL} \geq 8$, respectively.

The above findings were very recently extended to columns with other cross-section shapes, in order to assess their generality and pave the way for the codification of a DSM-based design approach for columns undergoing L-D interaction. The authors (Dinis *et al.* 2013a) performed numerical simulations on (i) H and Z columns with cross-section dimensions equal to those exhibited by the C columns analysed previously (which implies the same local and distortional critical buckling loads), and (ii) R columns. It was found that (i) the C, H and Z column triplets behave quite similarly, and (ii) the L-D interactive failure loads of the four column sets exhibit similar f_U/f_y distributions/"clouds" – see Figures 7(a)–(d), which also show the DSM strength curves providing the f_{NL}/f_y, f_{ND}/f_y and f_{NDL}/f_y values (assuming $f_{crL} = f_{crD}$).

It may then be concluded that the $f_{NL\text{-}D}$ DSM design approach developed by Silvestre *et al.* (2012), in the context of C columns, predicts the L-D interactive failure loads of C, H, Z and R columns with equal efficiency. Its merits can be assessed in Figures 8(a)–(b), providing the variation of f_U/f_{NDL} (Fig. 8(a)) and $f_U/f_{NL\text{-}D}$ (Fig. 8(b)) with λ_D for the four column sets. It is clearly shown that the novel $f_{NL\text{-}D}$ failure load predictions exhibit higher quality than the f_{NDL} ones – the associated ultimate-to-predicted load ratios have an average closer to 1.0 (1.05 *vs.* 1.25), a smaller standard deviation (0.07 *vs.* 0.16) and a lower maximum value (1.26 *vs.* 1.81), with an expected "trade-off": higher underestimations (minimum 0.84 *vs.* 0.96).

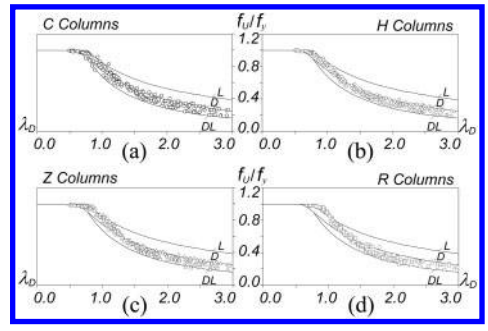

Figure 7. f_U/f_y *vs.* λ_D for the (a) C, (b) H, (c) Z and (d) R columns.

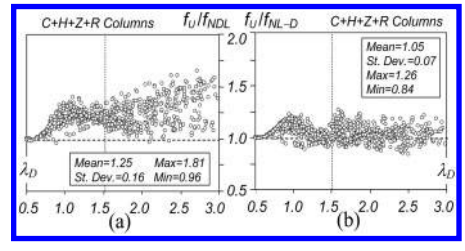

Figure 8. Variation of (a) f_U/f_{NDL} and (b) $f_U/f_{NL\text{-}D}$ with λ_D for the C, H, Z and R columns.

4.2 *L-D interaction* – $P_{crL} < P_{crD}$

As mentioned in section 3, it was found that all the available C, H, Z and R column experimental failure load data (Kwon et *al* 2009, Young *et al* 2013 and Dinis *et al* 2012a) concerns specimen geometries for which (i) P_{crL} always precedes P_{crD} by a substantial amount and (ii) P_y is almost always considerably larger than P_{crD} – the exceptions are a few test with $P_y/P_{cr.D}$ values close to 1.10. Since no numerical failure loads were obtained for columns exhibiting these mechanical characteristics, unveiled by the experimental investigations, it is not possible to assess adequately the merits of the novel DSM approach presented in the previous sub-section – this will be done in the near future, after concluding an ongoing investigation on the relevance of L-D interaction with respect to the P_{crD}/P_{crL} ratio (Dinis *et al* 2013b). Therefore, the available experimental failure loads are compared with their estimates provided by the DSM design approach proposed by Young *et al* (2013) on the basis of the YU and UHK fixed-ended lipped channel column tests – they suggested that, regardless of the closeness between P_{crD} and P_{crL}, the fixed-ended column ultimate strength can be fairly well predicted by the f_{NLD} estimates obtained from Eq. (1) and that had already been used by Yang & Hancock (2004), Kwon *et al* (2009) and Yap & Hancock (2011) to predict failure loads of lipped channel columns with web and/or flange intermediate stiffeners.

Figure 9(a) shows that (i) the C and R column sets exhibit similar f_U/f_y value distributions/"clouds", particularly for $\lambda_D > 1.0$, and (ii) all the experimental failure loads test ultimate loads are clearly below the DSM distortional strength curve, thus confirming

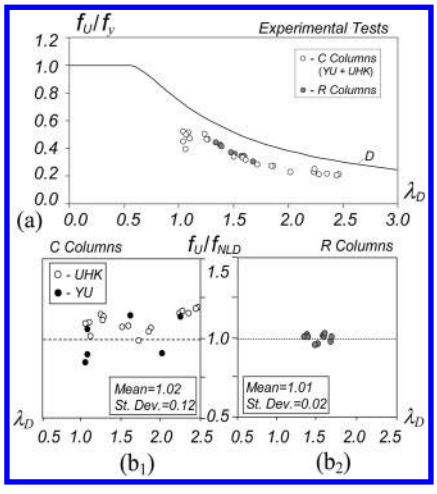

Figure 9. Variation with λ_D of the experimental (a) f_U/f_y values (C and R columns), and (b) f_U/f_{NLD} values for the (b_1) C and (b_2) R columns.

the ultimate strength erosion due to L-D interaction. The merits of the proposed DSM approach, which provides lower estimates that the $f_{NL\text{-}D}$ values defined in sub-section 4.1, can be assessed by looking at Figures 9(b), showing the variation of f_U/f_{NLD} with λ_D for the C (Fig. 9(b_1)) and R columns (Fig. 9(b_2)) – also given are the associated averages and standard deviations. These results make it possible to conclude that f_{NLD} provides mostly safe and accurate failure load estimates (higher overestimations for 3 YU tests): f_U/f_{NLD} averages and standard deviations of 1.01–0.02 (Rs) and 1.02–0.12 (Cs: 1.10–0.06 and 0.94–0.11 for the UHK and YU tests, respectively).

5 CONCLUDING REMARKS

The paper provided an overview of the most recent research activity on the non-linear behaviour, ultimate strength and DSM design of cold-formed steel columns with four cross-section shapes and experiencing L-D interaction. After illustrating this coupling phenomenon and providing its mechanical characterisation, numerical and experimental results were presented, compared and discussed – in particular, two types of L-D interaction were identified, corresponding to P_{crD}/P_{crL} values close to and clearly above 1.0, respectively. Next, after showing the inadequacy of the current DSM local and distortional strength curves to predict column L-D interactive failures, the paper presented and assessed the merits of recently developed DSM-based design procedures against such failures. The first one, more accurate and intended for columns with P_{crD}/P_{crL} close to 1.0, was compared against extensive numerical failure load data. The merits of the second one, less accurate (more conservative) and intended for columns with P_{crD}/P_{crL} above 1.0.

Research planned for the near future includes (i) continuing the work of Dinis *et al* (2013b), by further assessing how the relevance of L-D interaction varies with the P_{crD}/P_{crL} ratio, as well as its impact on the DSM design, and (ii) investigating L-D interaction in lipped channel columns with web and/or flange intermediate stiffeners, particularly when local buckling is triggered by the flanges, following the very recent numerical and experimental studies carried out by Dinis *et al* (2012b) and taking advantage of the available test results, which have been reported by Yang & Hancock (2004), Kwon *et al* (2009) and Yap & Hancock (2011).

Simulation of multi-physical processes in solar updraft power generation

W.B. Krätzig
Department of Civil and Environmental Engineering, Ruhr-University Bochum, Germany
Krätzig & Partner Civil Engineering Consultants, Bochum, Germany

ABSTRACT: After elucidating Schlaich's classical evaluation of the generated electricity of solar updraft power plants, the paper derives and discusses the numerical simulation concept for the thermo-fluid-mechanical processes of the airflow therein. This then will be supplemented by the description of the capture of solar irradiation through the collector glazing in the absorber soil and further the internal air, leading to a highly nonlinear simulation. A special fast solution concept is explained, and illustrated by few typical properties of physical variables of the plant. Finally, simulated results for the generated electricity are presented.

1 INTRODUCTION INTO SUPPS

Solar updraft power plants (SUPPs) form a rather modern and highly efficient concept of generating electricity from solar irradiation. SUPPs consist of large glass-covered collector areas (CA), huge central solar chimneys (SC), and turbo-generators as power conversion units (PCUs), see Figure 1.

The solar irradiation penetrates through the CA glass cover, heats the absorber soil which then warms up the internal collector air. This air expands and moves towards the elevated CA centre, where it is released into the ambience via the SC. This high stack acts as the engine of a SUPP, since the buoyancy of the heated air leads to a continuous airflow through the SUPP, drawing permanently fresh cold air into the CA from its rim. Parts of the kinetic energy of this airflow are extracted by the turbines and transformed into electricity by the coupled generators of the PCUs (Schlaich 1995).

Such power generation concept had been proposed first in 1903 by the Spanish Army Officer I. Cabanyes. In the years 1979 to 1982 J. Schlaich constructed the first pilot SUPP in Manzana-res/Spain which he and his team operated very successfully for more than 7 years. All data which are presently used for SUPP-designs stem from this prototype (Krätzig et al. 2009; Schlaich et al. 2005).

2 GLOBAL SUPP MODELS

2.1 *Schlaich's classical SUPP model*

In (Schlaich 1995) the author derived a clear, simple and evident concept for the determination of the maximum electric power of a SUPP. This concept, re-organized in Equation 1, catches all essential parameters correctly. It has been derived to determine

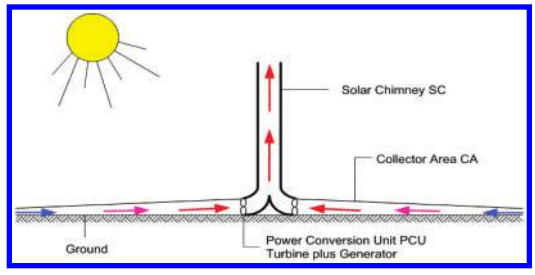

Figure 1. Working scheme of a solar updraft power plant.

the actual power P_{el}, G represents the actual solar irradiation in kW/m^2. But it serves also for estimates of the annually harvested electric energy E_{el}, in this case G stands for the annually irradiated energy:

$$P_{el} = 2/3\ \eta_{turb}\ \frac{g \times h_c}{c_p \times T_0}\ \eta_c\ \eta_{coll}\ A_{coll}\ G. \qquad (1)$$

In formula (1) we used the following abbreviations:

η_{turb} Degree of efficiency of the turbo-generators,
$g = 9.81$ m/s^2 Acceleration due to gravity,
h_c Effective height of the chimney in m,
$c_p = 1005$ J/kg K Specific heat capacity of the air,
T_0 Ambient temperature in K,
η_c Influence of mean chimney diameter d_c on P_{el},
η_{coll} Degree of efficiency of the collector in P_{el},
A_{coll} Effective ground area of the collector m^2,
G Solar irradiation in W/m^2 (or kWh/m^2 a).

At the time of the Manzanares pilot plant the designers had only single glazing of the collector in mind. Thus for this case of collector efficiency η_{coll} (Schlaich 1995) proposed the following expression:

$$\eta_{coll} = \alpha - \beta \times \Delta T/G. \qquad (2)$$

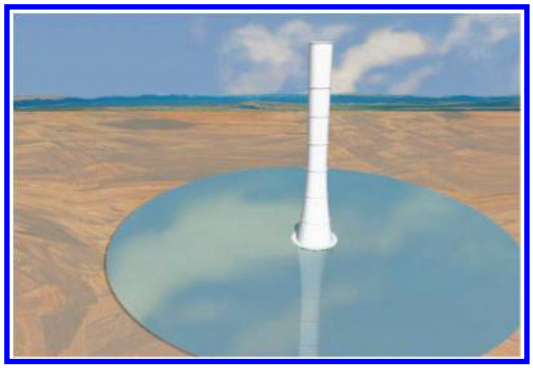

Figure 2. Computer vision of a solar updraft power plant.

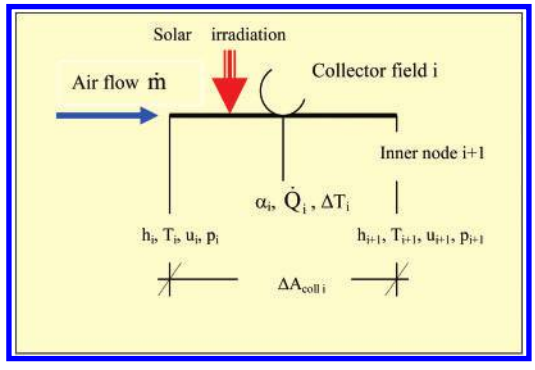

Figure 3. ith collector volume element.

Herein $\alpha = 0.75 \div 0.80$ denotes the heat absorption coefficient, and $\beta = 5 \div 6\,\mathrm{W/m^2K}$ a heat-loss coefficient for consideration of the collector size.

2.2 *Improvement of the model*

The expressions η_{coll} and η_c, the latter in SCHLAICH's concept equals 1, can be improved by use of computer simulated results. In P_{el} the collector efficiency η_{coll} follows the interpolation relation:

$$\eta_{coll} = 0.680\ (\ 1 - 0.229\ \sqrt{d_{coll} - 2.000}\ ), \qquad (3)$$

in which the diameter of the collector is measured in [km]. The influence of the mean chimney diameter d_c on P_{el} has been evaluated to:

$$\eta_c = 1 + 0.420\ f_c\ \frac{d_c - 200.0}{200.0} - 0.400\ f_c \left(\frac{d_c - 200.0}{200.0}\right)^2,$$
$$\text{with} \qquad f_c = 1 + 0.250\sqrt{d_{coll} - 2.000}\,. \qquad (4)$$

In f_c the effective diameter d_{coll} of the collector is again measured in [km]. These expressions fit well with examples taken from (Pretorius 2007).

This improvement changes the classical model to a rather comfortable instrument for pre-designs of SUPPs. However, desired modifications of the collector roof or of the absorber require mathematically much more rigor models which shall be treated now.

3 THERMO-FLUIDMECHANICAL MODEL OF THE ENTIRE SUPP

3.1 *Pre-requisites*

Overlooking Chapter 2 we observe a SUPP-model which has hidden all thermo-physical and fluid-mechanical knowledge in the efficiency parameters η_{coll}, η_c, and η_{turb}. For extensions of MANZANARES SUPP designs this might be sufficient. But for advanced designs a deeper insight into the thermo-fluid-radiation-mechanics is advantageous, as now based on the following pre-requisites:

- The collector bottom is horizontal with equal ambient air pressure everywhere.
- The thermo-fluiddynamics is modeled within one-dimensional flow-tube theory.
- Air is assumed as an ideal gas.
- The entire model is approximated as stationary.

3.2 *Collector model*

The collector is discretized into a number of i ring-shaped finite volumes:

- $\Delta A_{colli} = \pi(r_{i+1}^2 - r_i^2)$ denote ground/top surfaces,
- h_i, h_{i+1} are the respective collector heights,
- r_i, r_{i+1} stand for radial distances from the centre,
- $A_i = 2\pi r_i h_i$ are circular boundaries at i's inflow,
- $A_{i+1} = 2\pi r_{i+1} h_{i+1}$ boundaries at i's outflow.

The following conditions describe the thermo-fluidmechanical processes in the collector:

Conservation of mass: $\dot{m} = \text{const.}$, (5)

Conservation of momentum:

$$\dot{m}u_i - \dot{m}u_{i+1} + p_i A_{colli} - p_{i+1} A_{coll.i+1} = 0\,, \qquad (6)$$

Conservation of energy: $\Delta\dot{Q}_i = \dot{m}\, c_p\, \Delta T_i\,.$ (7)

Herein $\dot{m}$ abbreviates the rate of air mass flow (kg/s) in the plant, u the air velocity (m/s), p the air pressure (N/m^2), ΔQ_i the specific heat flux increase (W), and ΔT_i the temperature increase of the airflow (K). Again c_p stands for the specific heat capacity (J/kg K). The solar irradiance G (W/m^2) is coupled with the collector heat power by the relations:

$$\Delta\dot{Q}_i = \alpha_i\, G\, \Delta A_{coll.i} \ldots \Rightarrow \ldots \dot{Q}_i = \Sigma_i \Delta\dot{Q}_i\,, \qquad (8)$$

in which α_i denotes the efficiencies of the collector ring surface $\Delta A_{coll.i}$ in transforming G into heat increase ΔQ of the collector airflow, see Figure 3.

The initial conditions: $p = p_0$, $u = 0$ along the rim outside the CA are coupled to those corresponding values on the inflow border of the 1st finite volume by BERNOULLI's equation

$$p_0 = p_{i+1} + 0.5\rho_{i+1} u_{i+1}^2\,. \qquad (9)$$

Assuming further air as an ideal gas, the gas law

$$\rho_i = p_i / R\, T_i, \tag{10}$$

with R as general gas constant (J/kg K) and T_i as absolute temperature, couples the fluid-mechanic Equations (5, 6, 9) with the thermodynamic ones (7, 8, 10). All these equations formulate an initial value problem, nonlinear because of Equation 10. Its final values: u_{turb}, p_{turb} have to be coupled at the turbines' exits with the corresponding values of the chimney.

3.3 *Solar chimney model*

On the turbines' exits, the chimney's start, the heated air inside has smaller mass density ρ_{i0} as ρ_{o0} the colder air outside. So in the chimney there exists an updraft, which serves as the engine of the SUPP:

$$\Delta p = g \int_0^H \{\rho_o(h) - \rho_i(h)\}\, dh. \tag{11}$$

From this equation we receive with standard approximations expressions for the maximum pressure

$$\Delta p_{max} = g\, \rho_0\, H\ \ \Delta T / (T_0 + \Delta T) \tag{12}$$

of the airflow or for its maximum velocity:

$$u_{max} = \sqrt{2 g\, H\ \ \Delta T / (T_0 + \Delta T)}. \tag{13}$$

Because of the square-root in Equation (11), the above mentioned coupling to the collector airflow increase the initial nonlinearity.

Both density profiles $\rho_i(h)$, $\rho_o(h)$ in Equation (11) influence the buoyancy of the solar chimney. At least the outside profile $\rho_o(h)$ as meteorological variable is unknown at the design state. Thus intensive studies have been carried out proving that Equations (12, 13) give excellent approximations, if $\rho_o(h)$ describe a standard (polytrophic, $\kappa = 1.235$, $\Delta T = 6.5$ K/km) atmosphere, and $\rho_i(h)$ a special polytrophic one, with the following parameters ($\kappa = 1.100$, $\Delta T = 3.0$ K/km).

3.4 *Turbine model*

The turbines are pressure-staged, so they withdraw parts of the pressure out of the airflow, and transform them into electric power. With the pressure withdrawal factor κ of the turbine, and the maximum airflow velocity u_{max} from Equation (13) we receive:

$$\Delta p_{turb} = \kappa\, \Delta p_{tot} : u_{turb} = \sqrt{1-\kappa}\ \ u_{max}. \tag{14}$$

Δp_{turb} and u_{turb} stand for the average pressure jump and air velocity in the turbines, respectively. From the kinetic power of the airflow, $P_{tot} = m u_{max}^2/2$, the harvested effective power P_{eleff} is gained, introducing η_{turb} for the turbines' degrees of efficiency:

$$P_{el\,eff} = \eta_{turb}\, \Delta p_{turb}\ \dot{m}/\rho = \eta_{turb}\, \kappa\ \dot{m}\, u_{max}^2/2. \tag{15}$$

For more details see (Gannon & Backström 2003).

3.5 *Flow losses and initial value problem*

For simplicity, all equations (5) until (13) have been derived without any consideration of flow losses of the airflux, which reduce the flow pressures, and so the efficiency of the SUPP. Their integration is straight forward and will not be detailed here.

From all given fluid-thermodynamic conditions a (moderately) nonlinear initial value problem in the air mass flow $\dot{m}$ can be formulated. Its numerical solution by incremental-iterative techniques delivers all design parameters of the SUPP, provided, the collector efficiencies α_i introduced in Equation (8) are known. This is not the case, so their rigor determination shall now be elaborated.

4 SOLAR RADIATION INPUT

4.1 *Collector: Thermodynamics of radiation*

This determination of the collector efficiencies α_i requires the modeling of the complicated physical transformation process of solar irradiation G into heat increase ΔQ of the airflow $\dot{m}$. If further SUPPs shall be optimized, the collector turns out to be the most important component for its economy, because the convective/radiation heat power transfers determine largely the plant efficiency. At this point many specific properties of the collector design come into play which were not considered up to now, e.g. double glazing. Interactions of the heat power transfers and the flow velocity of the air will be neglected.

All essentials of this thermodynamics of radiation can be found in the monograph (Duffie & Beckman 2006) Bases of our modeling of the solar heat input are first the convective heat transfers (qc)

$$qc_i = hc_i\ \ T_i \tag{16}$$

with the convective heat power transfer coefficients hc_i, qc depending on absolute temperature T_i. Second, there are the radiation heat power transfers (qr) due to Boltzmann's radiation law. This reads for the radiation between two parallel plates

$$qr_1 = qr_2 = \frac{Q_r}{A} = \frac{\sigma(T_2^4 - T_1^4)}{1/\varepsilon_1 + 1/\varepsilon_2 - 1}, \tag{17}$$

or for the radiation between one plate and the sky

$$qr_1 = \varepsilon\sigma(T_1^4 - T_{sky}^4). \tag{18}$$

In these conditions, the ε-values abbreviate optical emittances of opaque bodies, T always absolute temperatures, and σ the Stefan-Boltzmann constant equal to 5.6697×10^{-8} (W/m^2 K^4). Necessary emittances ε can be found in (Duffie & Beckman 2006), convective heat power transfer coefficient hc in the standard literature.

4.2 *Heat transfers*

In each collector volume element the convective/ radiation heat power transfers now shall be modeled. To

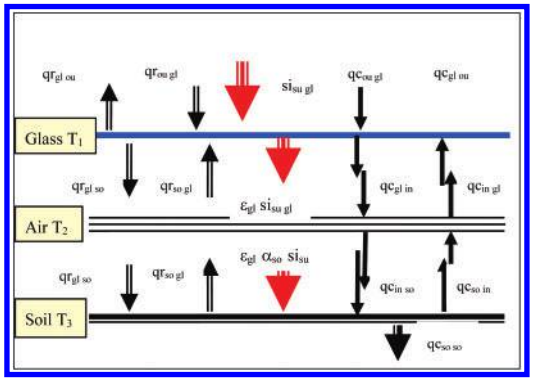

Figure 4. Heat transfers for glass/air/soil collector construction.

introduce our reader into this and to prepare the later formulation of the heat power balance equations of the collector, we select due to Figure 4 the simplest collector construction consisting of one panel of glass (temperature T_1), the heated airflow (T_2) and the soil-absorber (T_3). We consider a unit cell of the collector and distinguish therein the following thermal transfers qr due to radiation and qc due to heat convection. As emphasized in connection with Equations (16) to (18), they all are assumed to depend on their respective absolute temperatures T_i:

- $qr_{ou\,gl}$ thermal transfer by radiation (qr) from outer air (ou) into glass sheet (gl),
- $qr_{gl\,ou}$ thermal transfer by radiation (qr) from glass sheet (gl) into outer air (ou),
- $qr_{gl\,so}$ thermal transfer by radiation from glass sheet into soil, and analog for further transfers (qr),
- $qc_{ou\,gl}$ thermal transfer by convection (qc) from outer air (ou) into glass sheet (gl),
- $qc_{gl\,ou}$ thermal transfer by convection (qc) from glass sheet (gl) into outer air (ou),
- $qc_{gl\,in}$ thermal transfer by convection from glass sheet into inner air, and analog for further (qc),
- $si_{su\,gl}$ solar irradiance from the sun into glass sheet.

The solar irradiation penetrates through the glazing and then into the absorber soil. All this and further details can be seen from Figure 4.

4.3 *Heat balance conditions*

The stationarity condition of the solar radiation input process requires, that the vector sum of all heat transfers each into/from the glass, the inner air flow, and the soil absorber have to vanish. This leads to three coupled heat balance conditions, nonlinear equations in the temperatures T_1, T_2, T_3:

$$\begin{aligned}
\text{glass:}\quad & qr_{ou\,gl} - qr_{gl\,ou} - qr_{gl\,so} + qr_{so\,gl} + qc_{ou\,gl} \\
& - qc_{gl\,ou} - qc_{gl\,in} + qc_{in\,gl} + (1-\varepsilon_{gl})\, si_{su\,gl} = 0, \\
\text{air:}\quad & qc_{gl\,in} - qc_{in\,gl} + qc_{so\,in} + qc_{in\,so} = \alpha_i\, si_{su\,gl}, \\
\text{soil:}\quad & qr_{gl\,so} - qr_{so\,gl} + qc_{in\,so} - qc_{so\,in} - qc_{so\,so} \\
& + \varepsilon_{gl}\, \alpha_{so}\, si_{su\,gl} = 0. \qquad (19)
\end{aligned}$$

In these heat power balance equations, α_{so} denotes the broadband absorptance of the absorbing soil. Obviously, for this simplest collector construction with the first and last Equations (19) two coupled algebraic conditions have been received, depending on forth (qr) and first (qc) power of temperatures T_1, T_2 and T_3. The centered Equation (19), also algebraic and coupled to the other two, is written in such a way, that the heat flux increase

$$\Delta\dot{Q}_i = \alpha_i\, si_{su\,gl} \qquad (20)$$

in the i-th collector element stands on the right, and determines directly the desired efficiency parameter α_i, related to the solar irradiance input $si_{sugl} = G$. Nonlinear algebraic conditions like (19) have to be formulated for each collector ring element $\Delta A_{coll.i}$. For more complicated collector constructions (double glazing, water heat reservoirs, double air compartments), these conditions increase in number.

4.4 *Simulation concept for the entire SUPP*

In Chapter 3 we have established the initial value problem describing the thermo-fluiddynamics of the entire SUPP. This problem is now supplemented by one heat balance condition for each collector cell. These heat balance conditions are highly nonlinear.

If we just add them to the original initial value problem, e.g. in the form of so-called thermal networks (Bernardes 2004), and use an arbitrary nonlinear solver algorithm, we would run into endless automatic iterations.

It seems to be much more suitable to solve each heat balance condition i separately by a fast nonlinear solver for the corresponding α_i, and correct the initial value problem iteratively.

So the repeatedly mentioned nonlinear initial value problem from Chapter 3 is solved for a first guess of the efficiencies $\alpha_{i\,(1)}$ in all collector ring elements. This leads to a first approximation $\dot{m}_1$ for the airflow, and vice versa for the harvested electrical power $P_{eleff(1)}$. For each of the i collector elements we further find a 1^{st} approximation of the air temperatures $T_{int.air(1)}$, which then are inserted into the respective power balance conditions. Solution of all of these (highly nonlinear) conditions leads to a new set of collector efficiencies $\alpha_{i\,(2)}$, with which the computing process of the initial value problem has to be repeated. Introducing all new air temperatures $T_{int.air\,(2)}$ into the heat balance conditions with solutions lead to a new improved set of $\alpha_{i\,(3)}$. This iteration process is continued until the desired exactness for P_{eleff} has been achieved, see (Krätzig 2012b).

This analysis process is fast and extremely stable. It leads to unique solutions in rather short computing times, as has been proven in intensive theoretical studies and in many program runs.

5 ENERGY OUTPUT OF SUPPS

Up to now we have in great detail elucidated our simulation concept for day hours with solar irradiation.

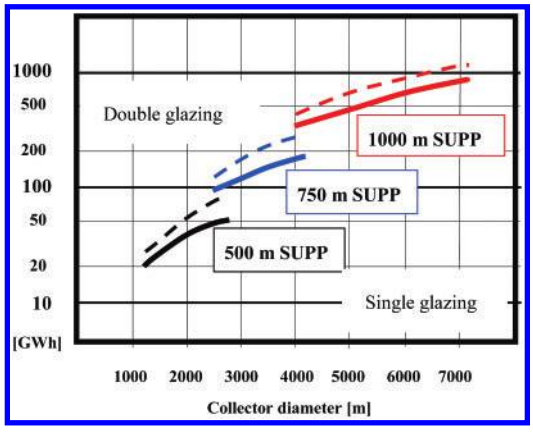

Figure 5. Annually harvested solar energy for different SUPPs.

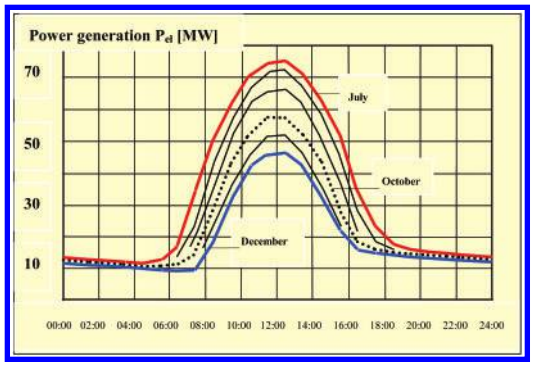

Figure 6. Power generation of 750/3500 SUPP over solar day.

Table 1. Results of an optimization study for 2 SUPP families.

	500/2000	750/3500
SUPP DIMENSIONS		
Chimney height [m]:	500.00	750.00
Throat diameter of chimney [m]:	45.00	67.50
Top diameter of chimney [m]:	50.00	75.00
Outer collector diameter [m]:	2 000.00	3 500.00
SERVICE PARAMETERS		
Total annual energy harvest [GWh/a]:	54.9	219.7
Max.electric power $P_{el\,max}$ at $G = 1088$ W/m^2 [MW]:	18.5	74.3
Values for max. solar irradiance of 1088 W/m^2:		
Maximum air mass flow [kg/s]:	37 501	106 705
Air temperature increase Δ_{turb} for $T_0 = 24°C$ [K]:	57.80	61.16
Medium air velocity u_{turb} [m/s]:	37.04	43.97
INVESTMENTS		
Chimney [M€]:	23.9	60.5
Double glazed collector (22.25 €/m^2) [M€]:	69.5	213.3
Turbo-generators (0.65 M€/MW of $P_{el\,max}$) [M€]:	12.2	48.8
Additionals + Engineering + Tests [M€]:	5.4	15.0
Total investments [M€]:	111.0	337.6
FINANCIAL AND SERVICE RESULTS		
Annuity including annual insurance [M€]:	7.4	22.8
Levelled electricity costs LECs (33 years) [€/kWh]:	0.131	0.099

This procedure has to be supplemented by a similar concept for night times, in which no solar irradiation can feed the SUPP with energy. Then the required heat has to be taken from the absorber soil, in which it had been stored automatically from the solar irradiance for night uses.

If we so have a simulation tool at hand applicable for 24 hours of a solar day, we can evaluate with hourly values of the solar irradiation and the actual temperatures the daily harvested energy, from which we compute the entire annually produced energy of a certain SUPP. Figure 5 shows such simulation results for SUPPs with suitably coated double glazing, an artificially blackened soil absorber, and for a location with annual solar energy irradiation of 2.20 MW/m^{2}a (logarithmic scale in the vertical).

Basis of such an annual energy evaluation of a SUPP are the courses of generated power over a typical solar day. Such a plot is shown in Figure 6 for different months of the last two seasons of a year. One clearly recognizes the strong influence of the sun shine during day hours, but also over different months. Very interesting is the fact, that the SUPP technology – in contrast to concentrating solar techniques CSP and PVT – the solar updraft concept possesses a natural storage component due to the heat storage property of the absorber soil.

Starting with such a simulation tool we are able to carry out optimization studies for SUPP families, to systematically find those plant alternatives with minimum levelled electricity cost LECs. Some results of such studies are presented in Table 1. The reader may observe the enormously low LECs, namely 0.131 €/kWh for MINI-SUPPs with 500 m SC, and 0.099 €/kWh for those ones with 750 m SC. Independent from this, (Bergermann & Weinrebe 2010) came to rather identical LECs for SUPPs with 1000 m SC.

Comparing these values e.g. with LECs for parabolic trough plants, central receiver works or photovoltaic installations, we observe the high economic efficiency of the solar updraft technology. In addition, this technology requires only water for glass cleaning, neither for steam formation nor for re-condensation, a great advantage in deserts with high solar irradiance (Backström et al. 2008).

Finally, Figure 7 shows the computer vision of a SUPP arrangement with solar chimneys of 1000 m of elevation and 6000 m of collector diameter. The maximum power is of the order of 300 MW, and the annual electric energy close to 900 GWh.

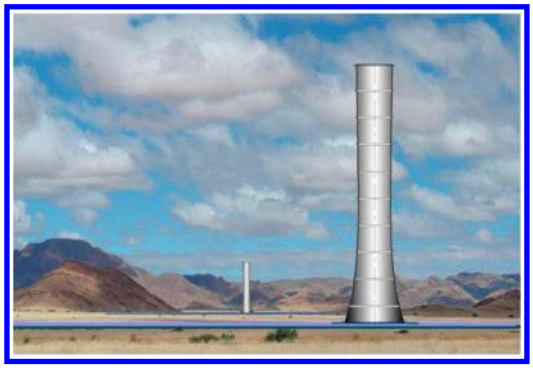

Figure 7. Computervision of 1000 m/6000 m SUPPs.

6 CONCLUSIONS

SUPPs are at the very beginning of their technical existence as an extremely sustainable electricity generation concept for countries with high solar irradiation. Many improvements are in discussion, as can be observed from the proceedings of the last two international conferences on this matter, see (Bottenbruch et al. 2010) and (Zhou 2012). Clearly one has to solve the problem of praiseworthy storing the solar energy at least for several hours after sundown when power is demanded. Many improvements in this direction are under discussion, e.g. storage of low-concentrated heat in water-filled basins under the CA (Schlaich 1995) or the storage of the generated electricity in modern devices. But all this is beyond the scope of this manuscript, and thus it is left for more deeply interested readers (Krätzig 2012a).

ABSTRACT: The two main approaches to the modelling of discontinuities are reviewed concisely, followed by a discussion of cohesive models for fracture. Emphasis is put on a novel approach to incorporate triaxiality into cohesive-zone models, and on the representation of cohesive crack models by phase-field models.

1 INTRODUCTION

The modelling of discontinuities, including interfaces, is of a growing importance in the mechanics of materials. Basically, two methods exist to capture discontinuities: one can either distribute them over a finite width, or handle them as true discontinuities, i.e. in a discrete sense.

When a discontinuity has a stationary character, such as in grain boundaries, it is fairly straightforward to describe it in a discrete manner, since it is then possible to make the discretisation such that the discontinuity, either in displacements or in displacement gradients, is modelled explicitly. An evolving or moving discontinuity, however, is more difficult to describe. A possibility is to adapt the mesh upon every change in the topology, as was done by Ingraffea and co-workers in the context of linear elastic fracture mechanics (Ingraffea & Saouma 1985), and later for cohesive fracture (Camacho & Ortiz 1996).

Another approach is to model fracture within the framework of continuum mechanics. A fundamental problem then emerges, namely that standard continuum models do not furnish a *length scale* which is indispensible for describing fracture. More pre- cisely, they result in a zero length scale. Since the energy dissipated in the failure process is given per unit area of material that has completely degraded, and since a zero internal length scale implies that the volume in which failure occurs goes to zero, the energy dissipated in the failure process also tends to zero. Two approaches have been followed to avoid this physically unrealistic situation, namely via discretisation and via regularisation of the continuum.

Along the first line, researchers have let the spacing of the discretisation take over the role of the missing internal length scale. The idea is then to choose the discretisation such that the spacing of the discretisation coincides with the internal length scale that derives from the physics of the process. Evidently, a good knowledge of the problem is required and solutions, including the proper choice for the discretisation, are dependent on the problem and the numerical method. Nevertheless, this approach has been used successfully to obtain insight in various issues in materials science (Ruggieri et al. 1996).

Yet, this approach cannot be called a proper solution in the sense that the mathematical setting of the initial value problem remains unchanged. Indeed, the introduction of degradation of the material properties in a standard, rate-independent continuum model – and therefore, the introduction of a stress-strain curve with a descending slope – can locally cause the governing differential equations to change character. Without special provisions such as the application of special interface conditions between both domains at which different types of differential equations hold, the initial value problem becomes ill-posed. Numerically, this has the consequence that the solution becomes fully dependent upon the discretisation (Bažant 1976).

As a more rigorous solution, various regularisation methods have been proposed, including non-local averaging, the addition of viscosity or rate dependency, or the inclusion of couple stresses or higher-order strain gradients (de Borst et al. 1993). The effect of these strategies is that the discontinuity is transformed into a continuous displacement distribution. The internal length scale is now set by the constitutive model, and for a sufficiently fine discretisation, the numerically calculated results only change in a sense that is normally expected upon mesh refinement.

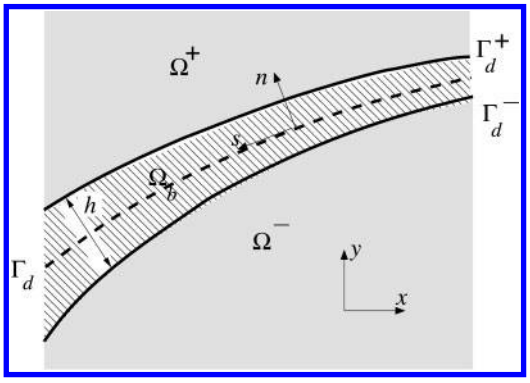

Figure 1. Cohesive surfaces at an internal discontinuity Γ_d.

2 COHESIVE SURFACE MODELS

Most engineering materials are not perfectly brittle in the Griffith sense, but display some ductility after reaching the strength limit. In fact, there exists a zone ahead of the crack tip, in which small-scale yielding, micro-cracking and void initiation, growth and coalescence take place. If this fracture process zone is sufficiently small compared to the structural dimensions, linear-elastic fracture mechanics concepts can apply. However, if this is not the case, the cohesive forces that exist in this fracture process zone must be taken into account. The most powerful and natural way is to use cohesive surface models, which were introduced by Dugdale (1960) and by Barenblatt (1962).

2.1 *General formulation*

We consider a volume Ω with an internal discontinuity boundary Γ_d as shown in Figure 1. As a starting point we consider the potential energy for the case of a discrete description of brittle fracture (Francfort & Marigo 1998):

$$\Psi_{\text{pot}} = \int_{\Omega} \psi^e(\boldsymbol{\varepsilon})\,\mathrm{d}V + \int_{\Gamma_d} \mathcal{G}_c\,\mathrm{d}A \tag{1}$$

with the elastic energy density ψ^e a function of the infinitesimal strain tensor ε. The elastic energy density is expressed by Hooke's law for an isotropic linear elastic material as $\psi^e(\varepsilon) = \frac{1}{2}\lambda\varepsilon_{ii}\varepsilon_{jj} + \mu\varepsilon_{ij}\varepsilon_{ij}$ with λ and μ the Lam'e constants. In Equation (1) the fracture energy, i.e. the amount of energy dissipated upon the creation of a unit of fracture surface) is denoted by $\mathcal{G}_c$. The potential energy Ψ_{pot} governs the balance between elastic energy in the bulk material and the fracture energy.

An essential difference between brittle and cohesive fracture models is the dependence of the fracture energy on the crack opening in the latter case, as the fracture energy is released only gradually, and energy dissipation is governed by a *fracture energy function*:

$$\mathcal{G} = \mathcal{G}(\llbracket \boldsymbol{u} \rrbracket, \kappa) \tag{2}$$

which depends on the jump of the displacement field $[\![u]\!]$ across the discontinuity Γ_d and on a history parameter κ, which obeys the Kuhn-Tucker loading/unloading conditions. The potential energy now takes the form:

$$\Psi_{\text{pot}} = \int_{\Omega} \psi^e(\boldsymbol{\varepsilon})\mathrm{d}V + \int_{\Gamma_d} \mathcal{G}(\llbracket \mathbf{u} \rrbracket, \kappa)\mathrm{d}A \tag{3}$$

and the cohesive tractions are obtained through differentiation of the fracture energy function with respect to the crack opening:

$$\boldsymbol{t} = \frac{\partial \mathcal{G}}{\partial \llbracket \boldsymbol{u} \rrbracket} \quad \rightarrow \quad \boldsymbol{t} = \boldsymbol{t}(\llbracket \boldsymbol{u} \rrbracket, \kappa) \tag{4}$$

2.2 *An extension: the cohesive-band model*

The cohesive surface model as outlined in the preceding section is a two-dimensional model embedded in a three-dimensional continuum, and only the crack opening and the crack sliding modes are available. The normal strain parallel to the cohesive surfaces is absent, and so is the normal stress in this direction. This hampers the accurate computation of failure modes in metals where stress triaxiality plays a role, but also prevents the prediction of splitting cracks in concrete or masonry structures where a large compressive stress induces cracks that are aligned with the normal stress (Rots 1991). To circumvent this deficiency of the cohesive surface model it has been proposed to take the normal stress from a neighbouring integration point in the continuum and to insert this stress component in the failure criterion for the cohesive surface model (Keller et al. 1999, Tijssens et al. 2000).

A more rigorous solution is to define a small band with a thickness h_0, which can be conceived as the value of the crack opening, h, in a reference state (Remmers et al. 2013), see Figure 1. In this cohesive band we define a strain tensor expressed in the n, s, t local frame of reference:

$$\bar{\boldsymbol{\mathcal{E}}} = \begin{bmatrix} \mathcal{E}_{nn} & \mathcal{E}_{ns} & \mathcal{E}_{nt} \\ \mathcal{E}_{sn} & \mathcal{E}_{ss} & \mathcal{E}_{st} \\ \mathcal{E}_{tn} & \mathcal{E}_{ts} & \mathcal{E}_{tt} \end{bmatrix} \qquad \forall\ \mathbf{x} \in \Omega_b \tag{5}$$

Under the assumption that the normal strain component ε_{nn}, and the shear strain components ε_{ns} and ε_{nt} are completely determined by the crack opening v_n, and the crack sliding components v_s and v_t, respectively, we can define:

$$\mathcal{E}_{nn} = \frac{v_n}{h_0} \tag{6}$$

and

$$\mathcal{E}_{ns} = \frac{v_s}{2h_0} \quad \text{and} \quad \mathcal{E}_{nt} = \frac{v_t}{2h_0} \tag{7}$$

The in-plane terms of the strain tensor in the band, ε_{ss}, ε_{tt} and $\varepsilon_{st} = \varepsilon_{ts}$ are independent of the magnitude

of the displacement jump. They represent the normal strain components in the s- and t-directions, respectively, and the in-plane shear strain. In view of the assumption that the strains in the band are piecewise constant at either side of the discontinuity Γ_d in the n-direction, and enforcing continuity for the in-plane strain components across Γ_d^- and Γ_d^+ these strain components are defined as:

$$\begin{aligned}\mathcal{E}_{ss} &= \frac{1}{2}\left(\mathcal{E}_{ss}|_{\Gamma_d^-} + \mathcal{E}_{ss}|_{\Gamma_d^+}\right)\\ \mathcal{E}_{tt} &= \frac{1}{2}\left(\mathcal{E}_{tt}|_{\Gamma_d^-} + \mathcal{E}_{tt}|_{\Gamma_d^+}\right)\\ \mathcal{E}_{st} &= \frac{1}{2}\left(\mathcal{E}_{st}|_{\Gamma_d^-} + \mathcal{E}_{st}|_{\Gamma_d^+}\right)\end{aligned} \tag{8}$$

Allowing for a wide range of cohesive relations, we postulate a tangential relation between the stress rate in the band $\dot{\boldsymbol{\mathcal{S}}}^{\mathrm{T}} = (\dot{\mathcal{S}}_{nn}, \dot{\mathcal{S}}_{ss}, \dot{\mathcal{S}}_{tt}, \dot{\mathcal{S}}_{ns}, \dot{\mathcal{S}}_{yt}, \dot{\mathcal{S}}_{st})$ and the strain rate in the band, $\boldsymbol{\varepsilon}$:

$$\dot{\boldsymbol{\mathcal{S}}} = \mathbf{D}_b \dot{\boldsymbol{\mathcal{E}}} \tag{9}$$

We assume that the tangential stiffness matrix $\mathbf{D}_b$ in the band has a transversely isotropic structure, and is obtained by differentiating the cohesive relation $\boldsymbol{\mathcal{S}} = \boldsymbol{\mathcal{S}}(\boldsymbol{\varepsilon}, \kappa, E_b, \nu_b)$, with κ an array of one or more internal variables, and E_b and ν_b the Young's modulus and the Poisson's ratio in the band, respectively. For the general three-dimensional case, a closed-form expression for $\mathbf{D}_b$ can be rather complicated. For this reason, a compliance format is sometimes preferred:

$$\mathbf{D}_b^{-1} = \begin{bmatrix} \frac{1}{k_n} & -\frac{\nu_b}{E_b} & -\frac{\nu_b}{E_b} & 0 & 0 & 0 \\ -\frac{\nu_b}{E_b} & \frac{1}{E_b} & -\frac{\nu_b}{E_b} & 0 & 0 & 0 \\ -\frac{\nu_b}{E_b} & -\frac{\nu_b}{E_b} & \frac{1}{E_b} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{k_s} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{k_t} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{2(1+\nu_b)}{E_b} \end{bmatrix} \tag{10}$$

with

$$k_n = \frac{\partial \mathcal{S}_{nn}}{\partial \mathcal{E}_{nn}}$$

the stiffness that derives from the cohesive relation for mode-I behaviour, and with

$$k_s = \frac{\partial \mathcal{S}_{ns}}{\partial \mathcal{E}_{ns}} \quad \text{and} \quad k_t = \frac{\partial \mathcal{S}_{nt}}{\partial \mathcal{E}_{nt}}$$

the tangential shear stiffnesses in the s- and t-directions, respectively.

We observe that the standard cohesive stiffnesses between the tractions and the relative displacements are incorporated, but that the matrix also includes the in-plane stiffness and the coupling between the normal relative displacement and the stretching of the fracture plane via the Poisson ratio ν_b in the band. The assumed transversely isotropic structure of equation (10) has limitations, in particular when ductile fracture processes are considered which involve metals, ductile polymers, or adhesives. An appropriate band constitutive relation could then involve a significant shear-normal stress/strain coupling and the response cannot be characterised by an isotropic constitutive relation.

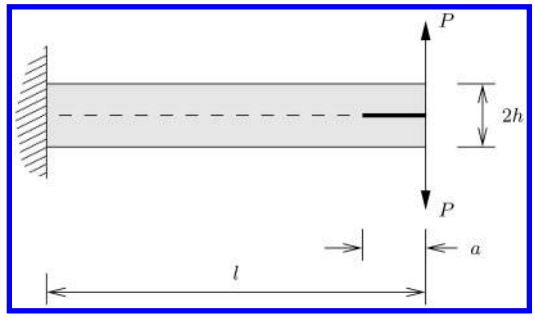

Figure 2. Geometry and boundary conditions of a double cantilever peel test.

2.3 *Double cantilever peel test*

We next consider the double cantilever test shown in Figure 2. The structure with length $l = 10$ mm consists of two layers with the same thickness $h = 0.5$ mm and with the same (isotropic) material properties: a Young's modulus $E = 100$ MPa and a Poisson ratio $\nu = 0.3$. The two layers are connected through an adhesive with a tensile strength $t_{\max} = 1$ MPa and an interfacial fracture toughness $\mathcal{G}_c = 0.1$ N/mm. The initial delamination extends over $\alpha = 1$ mm. An external load P is applied at the tip of both layers.

The specimen has been analysed with four-noded quadrilateral elements: 100 elements in the horizontal direction and 11 elements in the vertical direction. The elements in the centre of the specimen, i.e. the elements that are crossed by the discontinuity, are square with dimensions $l_e \times l_e = 0.1 \times 0.1$ mm. The solutions have been obtained using the energy dissipation arc-length method (de Borst et al. 2012).

The constitutive behaviour of the cohesive band is governed by an isotropic, plane-strain continuum damage relation:

$$\boldsymbol{\mathcal{S}} = (1 - \omega)\mathbf{D}_b^e \boldsymbol{\mathcal{E}} \tag{11}$$

where $\mathbf{D}_b^e$ is the plane-strain elastic stiffness matrix, that is constructed using the Young's modulus E_b and the Poisson's ratio ν_b in the band. The damage parameter ω is function of the history parameter κ, such that prior to reaching the tensile strength there is no accumulation of damage, while the residual strength decreases linearly thereafter. The relation between the classical, interfacial fracture toughness $\mathcal{G}_c$ and the volumetric fracture toughness is:

$$g_c = \frac{\mathcal{G}_c}{h_0} \tag{12}$$

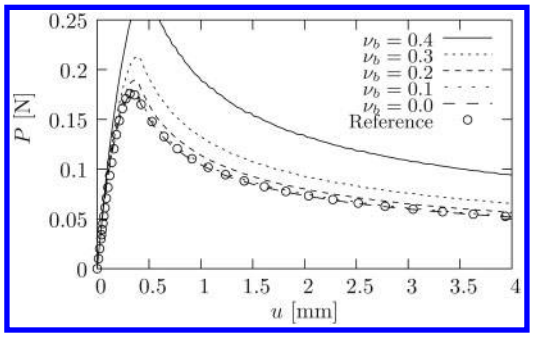

Figure 3. Effect of the Poisson ratio in the band, ν_b, on the strength and the ductility of a double-cantilever beam.

The results of the simulations for different values of the Poisson's ratio in the band, ν_b, are compared with a standard cohesive surface model in Figure 3. We clearly observe the effect of the in-plane strains, which are generated through the coupling to the crack opening displacement through ν_b, the Poisson ratio in the band. The additional strains and ensuing stresses give rise to an additional term in the internal virtual work, thus resulting in a higher peak load and a more ductile behaviour. Evidently, the effect diminishes for smaller values of the Poisson's ratio, and disappears for $\nu_b = 0$, when the results of the standard cohesive surface model are retrieved.

3 CONTINUUM REPRESENTATIONS OF THE COHESIVE MODEL

The cohesive-zone model is essentially a discrete concept. However, it can be transformed into a continuum formulation by distributing the fracture energy $\mathcal{G}_c$ over the thickness w of the volume in which the crack localises (Bažant & Oh 1983). The disadvantages of the formulation are that a pseudosoftening modulus is introduced which is inversely proportional to the number of elements, and, more importantly, that the boundary-value problem becomes ill-posed, implying a dependence on the discretisation. As discussed before, this anomaly is inherent in all smeared formulations without proper regularisation. A smeared formulation that is properly regularised, and therefore exhibits no mesh dependence, can be obtained using the phase-field concept, and will be outlined below.

3.1 *Cohesive fracture and phase fields*

As the starting point of the derivation of the phase field approximation to cohesive fracture we take the potential energy, equation (3) and we define $x_n = (\mathbf{x} - \mathbf{x}_c) \cdot \mathbf{n}(\mathbf{x}_c)$, with $\mathbf{n}(\mathbf{x})$ the unit vector normal to the fracture surface and $\mathbf{x}_c$ the position vector of a point on the fracture surface. The Dirac function δ can then be used to relate the infinitesimal surface area $\mathrm{d}A$ to the infinitesimal volume $\mathrm{d}V$ of the surrounding body:

$$\mathrm{d}A(\mathbf{x}_c) = \int_{-\infty}^{\infty} \delta\,(x_n)\ \mathrm{d}V \tag{13}$$

Equation (13) allows for smeared descriptions of the fracture surface by an approximation of the Dirac function. As in (Miehe, Welschinger, & Welschinger 2010, Miehe, Hofacker, & Welschinger 2010) we consider the approximated Dirac function

$$\delta_\epsilon(x_n) = \frac{1}{2\epsilon}\exp\left(-\frac{|x_n|}{\epsilon}\right) \tag{14}$$

with $\varepsilon > 0$ a length scale parameter. Evidently

$$\int_{-\infty}^{\infty} \delta_\epsilon(x_n)\mathrm{d}x_n = 1 \tag{15}$$

for arbitrary ϵ. Clearly, the fracture surface is distributed over a larger volume for higher values of ϵ. The corresponding infinitesimal fracture surface area then follows from

$$\mathrm{d}A_\epsilon(\mathbf{x}_c) = \int_{-\infty}^{\infty} \delta_\epsilon\,(x_n)\ \mathrm{d}V \tag{16}$$

Using the approximation to the Dirac function expressed in equation (14), the internal energy, equation (3), is approximated by

$$\Phi_{\mathrm{pot},\epsilon} = \int_\Omega \left(\psi^e(\boldsymbol{\varepsilon}^e) + \mathcal{G}(\mathbf{v},\kappa)\delta_\epsilon\right)\mathrm{d}V \tag{17}$$

Note that, compared to equation (3), we have replaced the infinitesimal strain tensor ε by the "elastic" infinitesimal strain tensor ε^e, and the jump in the displacement field $[\![\mathbf{u}]\!](\mathbf{x}_c)$ by an auxiliary field $\mathbf{v}(\mathbf{x})$. This is necessary since in the phase-field formulation, the crack only exists in a smeared sense. Hence, the clear distinction between the bulk and interface kinematics, i.e. between the strain tensor ε^e and the crack opening $[\![\mathbf{u}]\!]$, is lost.

In the phase-field formulation for cohesive fracture it is crucial to derive kinematic relations that are consistent with the discrete problem, in the sense that as the length scale parameter o approaches zero, the kinematics of the discrete problem are recovered. In order to arrive at such relations, we first introduce the distributed internal discontinuity

$$\Gamma_\epsilon = \{\mathbf{x} \in \Omega | d(\mathbf{x}) > \mathrm{tol}\} \tag{18}$$

with $\mathrm{tol} \ll 1$ being a small tolerance that truncates the support of the smeared crack, which provides the support for the auxiliary field $\mathbf{v}(\mathbf{x})$. Hence, the auxiliary

field is only present at the smeared crack, and the kinematics away from the crack are governed by the displacement field $\mathbf{u}(\mathbf{x})$. Next, we define the normal to the smeared crack based on the point closest to the discrete boundary Γ_d, denoted by $\mathbf{x}_c$, as

$$\mathbf{n}_c(\mathbf{x}) = \mathbf{n}(\mathbf{x}_c) \quad , \quad \mathbf{x}_c(\mathbf{x}) = \underset{\mathbf{y}\in\Gamma_d}{\operatorname{argmin}} \left(\|\mathbf{y}-\mathbf{x}\|\right) \tag{19}$$

In the discrete formulation, the displacement jump is strictly defined at the internal discontinuity Γ_d. In the phase-field approach the crack exists in smeared sense, and so does the crack opening. Therefore, we approximate the discrete displacement jump at $\mathbf{x}_c$ in terms of the auxiliary jump field $\mathbf{v}(\mathbf{x})$ as

$$[\![\mathbf{u}]\!](\mathbf{x}_c) \approx \int_{-\infty}^{\infty} \mathbf{v}(\mathbf{x})\delta_\epsilon \mathrm{d}x_n \tag{20}$$

Under the condition that the auxiliary field is constant in the direction normal to the fracture, i.e. $\frac{\partial v}{\partial x_n} = 0$, we have

$$\mathbf{v}(\mathbf{x}) = \mathbf{v}(\mathbf{x}_c + \zeta\mathbf{n}) = \mathbf{v}(\mathbf{x}_c) \tag{21}$$

with $\mathbf{n}$ the vector normal to the crack, and ζ the coordinate along $\mathbf{n}$. Back-substitution into equation (20) shows that $\mathbf{v}(\mathbf{x})$ reflects the crack opening at the closest point x_c on the discrete internal boundary. Consequently, in equation (17) the crack opening $[\![\mathrm{u}]\!]$ that appears as an argument of the fracture energy is directly replaced by the auxiliary field $\mathbf{b}(\mathbf{x})$. In the limiting case that the length scale parameter ϵ goes to zero, the smeared crack Γ_ϵ coincides with the discrete crack Γ_d and the auxiliary displacement field consides with the discrete displacement jump. The requirement that the auxiliary jump field is constant in the direction normal to the crack is now enforced weakly through an additional term in the internal energy functional:

$$\Phi_{\mathrm{pot},\epsilon} = \int_\Omega \left(\psi^e(\varepsilon^e) + \mathcal{G}(\mathbf{v},\kappa)\delta_\epsilon + \frac{1}{2}\alpha \left\| \frac{\partial \mathbf{v}}{\partial x_n} \right\|^2 \right) \mathrm{d}V \tag{22}$$

with α a positive constant parameter.

With the discontinuity kinematics determined through the auxiliary jump field, the elastic strain tensor ε^e can be derived by requiring the auxiliary field not to exert any external power on the problem, such that the balance of power is given by

$$\int_\Omega \left(\sigma^e_{ij}\dot{\varepsilon}^e_{ij} + t_i(\boldsymbol{v},\kappa)\delta_\epsilon \dot{v}_i \right) \mathrm{d}V = \int_{\partial\Omega} t_i \dot{u}_i \mathrm{d}A \tag{23}$$

Application of Gauss' theorem to the right-hand side of this equation, and requiring the traction to be in equilibrium with the elastic stress, $\sigma^e_{ij}n_j = t_i$, yields

$$\int_\Omega \sigma^e_{ij} \left(\dot{\varepsilon}^e_{ij} + \delta_\epsilon \,\mathrm{sym}\left(\dot{v}_i n_j\right) \right) \mathrm{d}V = \int_\Omega \sigma^e_{ij} \dot{u}_{(i,j)} \mathrm{d}V \tag{24}$$

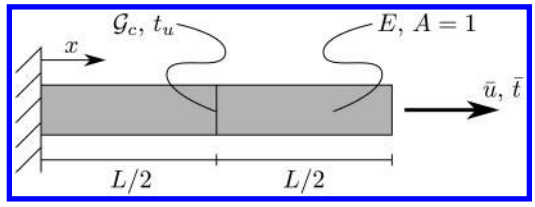

Figure 4. Schematic representation of a uniaxial rod with a cohesive interface.

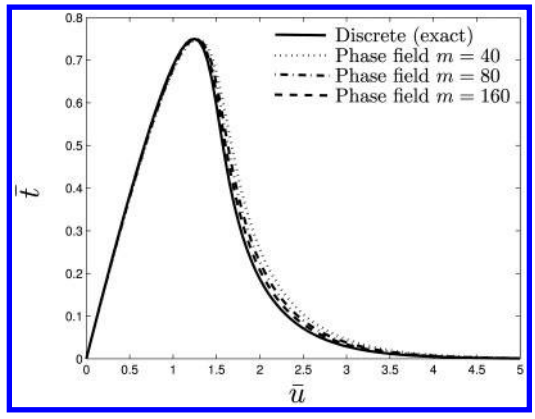

Figure 5. Force-displacement curve for the one-dimensional cohesive zone problem.

From the balance of power it is directly observed that the elastic infinitesimal strain tensor is related to the displacement field $\boldsymbol{u}(\boldsymbol{x})$ and auxiliary field $\boldsymbol{v}(\boldsymbol{x})$ as

$$\varepsilon^e_{ij} = u_{(i,j)} - \mathrm{sym}\left(v_i n_j\right)\delta_\epsilon \tag{25}$$

In this expression the first part is the symmetric part of the gradient of the displacement field. The second part can be interpreted as the strain caused by the displacement jump. Hence the elastic strain is defined as the symmetric gradient of the displacment field, minus the strain caused by the crack opening. We note from equation (25) that away from the crack, i.e. for $\boldsymbol{x} \notin \Gamma_\epsilon$, the continuum expression is recovered. In the limiting case that ϵ goes to zero, the elastic equivalent strain is equal to the symmetric gradient of the displacement field at every point in the interior of the domain. The unbounded strain term at the discontinuity is caused by the jump of the displacement field over this internal boundary.

3.2 *Cohesive fracture of a rod*

As an example we consider the one-dimensional bar loaded in tension as shown in Figure 4. The bar has a unit length and also the modulus of elasticity equals unity. The fracture toughness and fracture strength are taken as $\mathcal{G}_c = 1$ and $f_t = 0.75$, respectively. Figure 5 shows the response obtained using various mesh sizes for the phase-field model and compares it with the

exact solution to the discrete problem. It is observed that upon mesh refinement the phase-field model converges to the discrete solution.

4 CONCLUSIONS

The cohesive approach to fracture is simple, flexible, yet very powerful, and capable of capturing a wide range of fracture phenomena. A shortcoming of existing cohesive surface models is that the inplane strains, and therefore the in-plane stresses, are absent in the formulation, which makes it difficult, if not impossible to capture fracture phenomena like splitting cracks in reinforced concrete, or crazing in polymers. A simple and elegant extension of the classical cohesive surface methodology has been proposed Remmers et al. (2013), which can be incorporated straightforwardly in numerical methods, such as interface elements, partition-of-unity finite methods, and isogeometric analysis.

Another issue is the implementation of cohesive surface models in finite element methods. Since a cohesive surface represents an evolving, two-dimensional body in a three-dimensional continuum, this necessarily involves remeshing, or the use of another discretisation method that involves the addition of degrees of freedom during the computation, e.g. the finite element methods that exploit the partition-of-unity property of finite element shape functions. Smeared (or continuum) approaches avoid this, but tend to result in ill-posed boundary value problems when the damage exceeds a certain threshold. Herein, we have suggested that a phase-field approach to cohesive fracture can be a possible solution, since it operates on a fixed grid, but does not result in an ill-posed boundary value problem.

Recent controversies and new challenges in structural topology optimization

G.I.N. Rozvany
Department of Structural Mechanics, Budapest University of Technology and Economics, Budapest, Hungary

ABSTRACT: This keynote lecture deals with structural topology optimization, a relatively new but rapidly expanding field of structural mechanics. After discussing its fundamental features and defining its subfields (layout optimization and generalized shape optimization), we review the early history of both exact and discretized topology optimization and show extensive applications in the car, machine and aerospace industries, as well as in architecture and medicine. . Then a brief summary of both theoretical developments and numerical methods is given, and computational difficulties and quality control in topology optimization discussed. This includes a detailed review of basic features of optimal structural topologies, including some recent controversies in basic theory and numerical techniques. Finally, some new challenges and future perspectives are outlined.

1 INTRODUCTION

Structural topology optimization is becoming an extremely popular field of structural mechanics, because it results in substantial savings in industrial applications and has interesting theoretical implications in mathematics, mechanics, multi-physics and computer science.

Various theoretical aspects, as well as a great variety of numerical methods and applications are discussed extensively in the literature. At the ISSMO world congress in Seoul, over 160 papers dealt with topology optimization (out of some 400 papers). In this keynote lecture, we review basic features, history, applications, current status, recent controversies and future perspectives of structural topology optimization.

2 FUNDAMENTAL FEATURES OF STRUCTURAL TOPOLOGY OPTIMIZATION

As explained earlier (e.g. Rozvany et al. 1995), structural topology optimization consists of two main subfields.

Layout optimization deals with grid-like (low volume fraction) structures (trusses, grillages, shell-grids, and dense systems of intersecting shells), optimizing simultaneously the topology (connectivity of the members), geometry (location of the joints) and sizing (cross-sectional dimensions).

Generalized shape optimization finds the best topology of the internal boundaries and the optimal shape of both internal and external boundaries of perforated or composite continua.

In **layout optimization (LO)**, we start off with a 'ground structure', which contains all potential members ('ground elements'). During the optimization procedure, we remove non-optimal ground elements and determine the optimal sizes of the optimal ones.

In discretized LO, the number of ground elements is finite. In exact LO, it is infinite. A ground structure with an infinite number of elements is sometimes called 'structural universe' (Rozvany et al. 1995). Alternatively, a structural universe may be replaced by a 'design domain', at all points of which members may run in any direction.

The simplest form of structural topology optimization concerns so-called **ISE topologies** (with **I**sotropic **S**olid or **E**mpty elements).

In **generalized shape optimization** (GSO) the structural domain is divided into a finite number of ground elements. For ISE topologies, the thickness or density of each ground element may only take on a zero value ('white element') or a pre-assigned other value ('black element'). In a normalized formulation, the pre-assigned value is unity, and then we have a 0–1 problem.

In discretized GSO, we have a finite number of ground elements. In exact GSO, we have an infinite number of ground elements, which shrink to points. In other words, exact GSO consists of assigning optimally either 'material' or 'no material' to each point of the design domain.

GSO can be generalized into **multi-material optimization**, in which for each ground element (or at each point of the design domain) we may chose one out of several given materials or no material.

Structural topology optimization may consist of minimizing an objective function (typically the total structural volume, weight or cost) within **constraints** on the structural response (e.g. stresses, displacements, buckling load, natural frequency, etc.). Alternatively, we may maximize or minimize some structural responses or their combination for given volume, weight or cost.

In the following two sections, we review briefly the history of exact and numerical branches of structural topology optimization.

3 BRIEF HISTORY OF EXACT (ANALYTICAL) STRUCTURAL TOPOLOGY OPTIMIZATION

The first paper on exact structural topology optimization was published more than a century ago by the ingenious Australian inventor A. G. M. ('George') Michell (1904). It dealt with the **least-volume topology of trusses** with a single load condition and a stress constraint. This pioneering effort was completely ignored for over a half a century, when it was re-discovered by Cox (1958), who applied Michell's criteria to new load conditions. Later Hemp worked on Michell structures most of his professional life. His and his coworkers' results were summarized in his book (Hemp 1973).

The theory of the **optimal topology of grillages** (beam systems) actually preceded the development of the optimal layout theory (Prager and Rozvany 1977a). The grillage theory (e.g. Rozvany 1972a and b) was developed by the author's research group, but it has some elements of Morley's (1966) theory for optimal reinforcement in concrete slabs. Reviews of the grillage theory may be found in several texts (e.g. Rozvany and Hill 1976, Prager and Rozvany 1977b, Rozvany 1989 and Rozvany, Bendsoe and Kirsch 1995).

Exact optimal grillage topologies should actually be used more often as benchmarks, because they have the following advantages.

(i) The optimal grillage theory has advanced much further than the truss theory, because exact optimal grillage topologies are available for almost all possible support and load conditions, and these analytical solutions can even be generated by computer (see e.g. Fig. 38, Rozvany et al. 1995).
(ii) Michell trusses ignore buckling, which plays a much more important role for trusses than for grillages.
(iii) Grillages may have three types of boundary conditions (clamped and simply supported boundaries, and free edges), whilst trusses may only have two (support or no support).
(iv) A large number of extensions of the grillage theory exist (see Rozvany 1992, pp. 125–127)
(v) Whilst most Michell trusses are mechanisms, most optimal grillages are stable structures.

3.1 *The Prager-Rozvany (1977a) optimal layout theory*

The **first general theory of exact topology optimization** was introduced in effect in the author's first book (Rozvany 1976) for flexural systems (e.g. grillages, shells), and formulated in a more concise form later (Prager and Rozvany 1977a). It is based on the Prager-Shield (1967) optimality condition for plastic design and its extensions (Charrett and Rozvany 1972). However, the new element in the layout theory is, that it also gives optimality conditions for 'vanishing' members (of zero cross-sectional area) in terms of 'adjoint' strains along these members. In other words, optimal layout theory starts off with a ground structure or structural universe of all potential members, and selects the optimal members (of non-zero cross-sectional area) out of those.

In the Prager-Rozvany (1977a) layout theory, it is necessary to find a

(i) kinematically admissible 'adjoint' displacement/strain fields (satisfying kinematic continuity and boundary conditions),
(ii) statically admissible stress fields (satisfying equilibrium and statical boundary conditions),
(iii) such that certain ('static-kinematic') optimality criteria are also fulfilled.

In these optimality criteria, the adjoint strains are given by the subgradient of the 'specific cost function' with respect to stresses or stress resultants (e.g. member forces F or beam moments M).

The subgradient of a function is the usual gradient, but at discontinuities of the gradient any convex combination of the adjacent gradients can be taken.

For sign-independent stress-based design of trusses and grillages of given depth, for example, the 'specific cost functions' (representing in this text cross sectional areas A) are, respectively

$$A = k|F| \text{ and } A = k|M|, \tag{1}$$

where k is a constant, F is the member force and M is the beam bending moment. Then, e.g. for trusses, the optimality conditions reduce to those of Michell (1904)

$$\bar{\varepsilon} = k \operatorname{sgn} F \text{ (for } F \neq 0), \; |\bar{\varepsilon}| \leq k \text{ (for } F = 0), \tag{2}$$

where $\bar{\varepsilon}$ is the adjoint strain (see Fig. 1a). For a prescribed minimum cross section with equal and unequal permissible stresses in tension and compression the optimality criteria are shown in Figs. 1b and c, respectively.

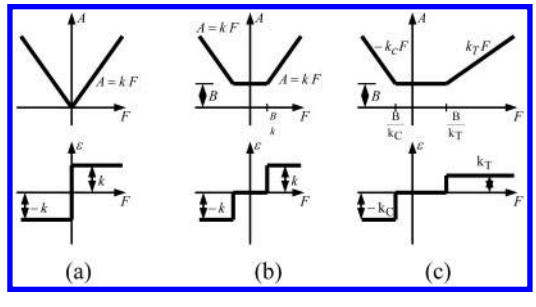

Figure 1. Optimality criteria for various types of trusses.

3.2 *Optimal regions in Michell trusses and grillages*

It follows from (2) that in Michell trusses, the members are in the direction of the adjoint principal strains of a constant magnitude (k), and the absolute value of adjoint strains may nowhere exceed this value. The optimal topology usually consists of several 'regions'. Denoting the principal adjoint strains by $(\bar{\varepsilon}_1, \bar{\varepsilon}_2)$, at any point of a 2D truss, *for equal permissible stresses in tension and compression* we may have the following **optimal regions**.

T-region with a tensile and a compression member at right angles, $\bar{\varepsilon}_1 = \bar{\varepsilon}_2 = k$,

S-region with members having forces of the same sign in any direction, $\bar{\varepsilon}_1 = \bar{\varepsilon}_2, |\bar{\varepsilon}_i| = k (i = 1, 2)$,

R-regions with only one member at any point, $|\bar{\varepsilon}_1| = k, |\bar{\varepsilon}_2| \le k$, or

O-region with no members $|\bar{\varepsilon}_1|, \le k, |\bar{\varepsilon}_2| \le k$ with $k = 1/\sigma^{(p)}$, where $\sigma^{(p)}$ is the permissible stress in both tension and compression.

Within O-regions we may have Z-regions with $\bar{\varepsilon}_1 = \bar{\varepsilon}_2 = 0$ and V-regions with $|\bar{\varepsilon}_1| \le k, \bar{\varepsilon}_2 = 0$

Most of the Michell literature deals with T-regions, because of the link with slip-lines (Hencky-Prandtl nets).

The symbols for optimal regions are shown in Fig. 2a. We have similar optimal regions for grillages of given depth.

3.3 *Example of determining an optimal truss topology*

In Fig. 2b we show some optimal topologies and in Fig. 2c the corresponding optimal adjoint displacement fields. The boundary conditions consist of two line supports at right angles. We use a normalized formulation with $k = 1$.

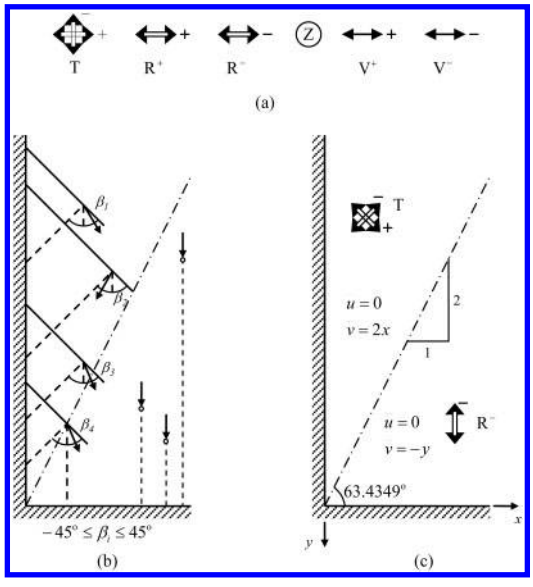

Figure 2. (a) optimal regions for Michell trusses and (b,c) example of determining an optimal truss topology.

Elementary calculations show that in the upper region we have the principal adjoint strains

$$\bar{\varepsilon}_1 = -\bar{\varepsilon}_2 = 1 \tag{3}$$

at ±45° to the horizontal. This corresponds to a T-region, denoted by an arrow cross in Fig. 2c. In the lower region we have

$$\bar{\varepsilon}_1 = 0, \ \bar{\varepsilon}_2 = -1, \tag{4}$$

which signifies an R^- region denoted by a double arrow. Both (3) and (4) *satisfy the optimality conditions* in (2).

It can be readily seen that along the line supports with $x = 0$ and $y = 0$ we have $u = v = 0$, satisfying the *kinematic boundary conditions*. Moreover, along the region boundary with $y = -2x$ both adjoint displacement fields in Fig. 2c give

$$\bar{u} = 0, \ \bar{v} = -2x \tag{5}$$

satisfying *kinematic continuity*.

3.4 *Shortcomings of Michell's truss theory*

One of the controversies discussed in this lecture concerns the limited range of validity of Michell's optimality criteria.

After re-examining Michell's proof, the author concluded (Rozvany 1996) that Michell's original optimality criteria are valid only if one or both of the following two conditions are satisfied:

(a) the structural domain is subject to prescribed external forces only, or equivalently, to 'statically determinate supports' (supports in which the reactions can be uniquely determined from equilibrium), or

(b) the permissible stresses in tension and compression are the same.

3.5 *Extension of Michell's theory to unequal permissible stresses and statically indeterminate support conditions*

If neither of the conditions (a) or (b) under Section 3.4 are satisfied, then Michell's optimality conditions are not valid, and must be modified.

For different permissible stresses σ_T, σ_C in tension and compression, and statically indeterminate support conditions, one must use the following optimality criteria (for proofs see Rozvany 1996).

$$\begin{aligned} &\bar{\varepsilon} = -1/\sigma_C \ (\text{for } F < 0), \ \bar{\varepsilon} = 1/\sigma_T \ (\text{for } F > 0), \\ &-1/\sigma_C \le \bar{\varepsilon} \le 1/\sigma_T \ (\text{for } F = 0), \end{aligned} \tag{6}$$

in which $\bar{\boldsymbol{\varepsilon}}$ represents a fictitious strain-field termed 'adjoint' strain field. We sometimes use the shorter notation

$$1/\sigma_C = k_C, \ 1/\sigma_T = k_T. \tag{7}$$

For $\sigma_T = \sigma_C = \sigma^{(p)}$ we have

$$k_T = k_C = k = 1/\sigma^{(p)}, \tag{8}$$

and then (6) reduces to (2). Relations (2) or (6) are necessary and sufficient conditions of optimality for the relevant class of problems if a feasible solution exists, the adjoint strains $\bar{\varepsilon}$ are kinematically admissible, and the member forces F statically admissible (i.e. satisfying equilibrium).

3.6 *More recent developments in Michell's truss theory*

New classes of solutions using the classical theory (relation (2)) were derived in papers by Rozvany and Gollub (1990) Lewinski et al (1994a and b), Rozvany et al. (1997), Lewinski and Rozvany (2007, 2008a and b), Sokol and Lewinski (2010, 2011), Sokol and Rorvany (2012).

Using the extended theory (relation (6)), a number of new solutions were derived by Graczykowski and Lewinski (2006a and b, 2007a and b), Rozvany and Sokol (2012), Sokol and Rozvany (2013), and Pichugin et al. (2012).

4 NUMERICAL METHODS IN STRUCTURAL TOPOLOGY OPTIMIZATION

4.1 *The origins of the SIMP algorithm*

The idea of FE-based topology optimization is due to Rossow and Taylor (1973), who used an unpenalized density-stiffness relation (continuous line in Fig. 3) and therefore obtained solutions with intermediate thicknesses In a pioneering publication, Bendsoe and Kikuchi (1988) suggested homogenization based on square or rectangular holes, which also produced some degree of penalization (dotted line in Fig. 3).

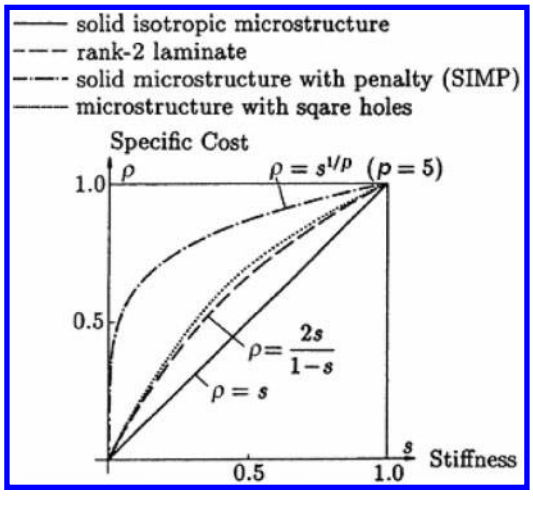

Figure 3. Normalized stiffness (s) – specific cost or density (ρ) relations in topology optimization methods (after Fig. 81 in Rozvany et al. 1995).

A year later Bendsoe (1989), in another milestone paper, considered a SIMP-like method based on the power-law relation

$$\rho = s^{1/p} \tag{9}$$

(see Fig. 2), but expressed as yet preference for homogenization with square holes. This he justified by referring to mesh dependence and fictitiousness of material properties in (9), which was quite reasonable from his viewpoint. Mlejnek (e.g. 1992) proposed later an independently conceived SIMP-like procedure.

The author and Zhou based the relation (9) on combined cost of material and manufacturing, assuming that only one plate thickness is available originally, and other thicknesses must be obtained by a machining process. Zhou developed the computational details of the SIMP method, with suitable re-design formulae for thicknesses (densities) and Lagrange multipliers. At a Karlsruhe conference in 1990, Zhou and the author presented already advanced solutions (Zhou and Rozvany 1991). The term 'SIMP' was coined by Rozvany et al. (1992).

Zhou and the author initially applied the DCOC optimality criteria method (Zhou and Rozvany 1992/1993) to solve the optimization problem under SIMP formulation. While DCOC offers unique capability in the handling of stress constraints, general optimization codes such as CONLIN and MMA (Fleury 1989, Svanberg 1987) based on dual method of convex programming offer robust black-box solutions to multiply constrained optimization problems.

SIMP was gradually accepted by other topology groups as well, particularly after Sigmund, who started working in the author's research group in Essen on topology optimization, moved back to Denmark and contributed much to explaining SIMP to the optimization community. Sigmund's (2001) educational article with a 99-line SIMP-code played an important role in SIMP's general acceptance. Moreover, Bendsoe and Sigmund (1999) generated microstructures corresponding to the power law in (9) above. The complete acceptance of SIMP can be seen also from the fact that the second edition of Bendsoe's trendsetting book (Bendsoe and Sigmund 2003) uses almost exclusively SIMP for its main part (on what we call here ISE topologies), whilst its earlier edition (Bendsoe 1995) mentioned the "penalized variable thickness approach" only in one sentence under "Bibliographical notes" (p. 230) .

4.2 *Application of SIMP in commercial software*

The author's former co-worker Ming Zhou moved from Essen University to the Altair software company in California, where he is currently the Vice President for research and development. He has incorporated the SIMP algorithm into the OptiStruct software, which is now used most extensively by the aerospace, car and machine industries, but also for very tall buildings in architecture. In the lecture, several examples of these

industrial applications will be shown. But other commercial software is also using exclusively the SIMP method for structural topology optimization.

4.3 *Other numerical methods of structural toplogy optimization*

Earlier the **homogenization method** was also used, in which in each element the dimensions and orientation of square or rectangular holes were optimized, and such elements were homogenized for the subsequent FE analysis in each iteration. Other investigators used earlier **optimal microstructures** in each element, and subsequently penalized intermediate densities. However, currently SIMP is used in preference to the latter two methods.

Moreover, Fleury and Beckers used **discrete dual programming** successfully for topology optimization (e.g. Beckers 1999).

More recent methods are the **topological derivative and level set methods**, which have very much promise, but have not reached as yet the stage of industrial applications.

Rather controversial are the completely heuristic '**sudden death**' or '**hard kill**' methods, in which in each iteration elements with some low response function values are taken out. The most publicized of these methods is the '**ESO**' (**E**volutionary **S**tructural **O**ptimization) method, which is not used currently in commercial software. A comprehensive review of established methods in structural topology optimization was published by the author four years ago (Rozvany 2009).

4.4 *Computational difficulties in structural topology optimization*

Some of these difficulties are the checkerboard (discretization) error, singular optima, local optima and special difficulties with local and global buckling constraints. These will be discussed in greater detail in the lecture, together with a review of the most recent research, particularly by Sigmund's research school in multi-physics applications.

5 CONCLUDING REMARKS

In the lecture we will also examine such controversial issues as the relative importance of gradient (e.g. SIMP) and non-gradient (e.g. nature-inspired) methods in topology optimization. It has been suggested recently in a paper by Sigmund (2011), that publication of the latter should be severely restricted in topology optimization, because the efficiency and resolving power of the former is several orders of magnitude higher. Moreover, it is not correct that we call non-gradient methods in general 'global methods', because there exists no proof of convergence to a global optimum for most of them. In fact in many examples in the literature they produce a highly non-optimal solution. It is true that gradient methods find the nearest local optimum only, but they are just as likely to locate the global optimum if we use several starting points in the design space.

Another issue to be discussed is the importance of exact analytical solutions in topology optimization, pointing out that they can be used (a) as benchmarks for checking on numerical methods, (b) for establishing fundamental properties of optimal topologies, and (c) for deriving non-heuristic numerical algorithms by discretization. On the other hand, new numerical methods (e.g. Sokol 2011a and b, Pichugin et al. 2012) can optimize problems with billions of variables for checking accurately on analytically derived optimal topologies.

General conditions for instantaneous system inversion in structural dynamics

K. Maes, E. Lourens, G. De Roeck & G. Lombaert
KU Leuven, Department of Civil Engineering, Leuven, Belgium

ABSTRACT: In structural dynamics, the forces acting on a structure are in many cases not well known. System inversion techniques may then be used to estimate these forces from the measured response of the structure. This paper presents conditions for the invertibility of linear system models, that apply generally to any instantaneous input estimation algorithm. The conditions ensure the identifiability of the dynamic forces, the stability of the system inversion and the uniqueness of the identified quantities. For the specific case of modally reduced order models, which can be obtained either from first principle models or from experimental data using system identification techniques, the conditions can be directly expressed in terms of the modal properties of the structure. This physical insight can then be used to design vibration experiments that aim for system inversion. Each of the conditions is derived and illustrated by a conceptual example.

1 INTRODUCTION

The dynamic forces acting on a structure are of great importance to many engineering applications. Often, however, the dynamic forces cannot be obtained by direct measurements, e.g. for wind loads, and have to be determined indirectly from dynamic measurements of the system response.

Force identification problems were initially solved off-line in a deterministic setting. Many methods were proposed, most of them based on the frequency response function (Guillaume et al. 2002, Liu and Shepard 2005, Parloo et al. 2003) or making use of a time domain approach (Klinkov and Fritzen 2007, Nordström and Nordberg 2002, Jacquelin et al. 2003, Adams and Doyle 2002). A recursive deterministic method was presented by Klinkov and Fritzen (2006), estimating both the input and system states from a set of output measurements. Currently, the attention is shifted to the development of recursive combined deterministic-stochastic approaches (Hwang et al. 2009, Ma et al. 2003). These methods do not only account for measurement errors, but also for modelling errors and additional unknown vibration sources. An algorithm was proposed by Gillijns and De Moor (2007), where the input estimation is performed separately from the state estimation step. The algorithm was applied in structural dynamics by Lourens et al. (2012). A similar approach was proposed by Niu et al. (2011). Alternatively, the dynamic forces and system states can be jointly estimated using a classical Kalman filter, hereby including the unknown forces in an augmented state vector (Lourens et al. 2012).

This paper focuses on instantaneous system inversion, i.e. inversion without any time delay, covering the majority of inversion algorithms applied in structural dynamics. The invertibility of a system in general requires three conditions. Firstly, the dynamic forces must be identifiable from the given set of response measurements. Secondly, the system inversion must be stable, such that small perturbations on the measurement data do not give rise to unbounded errors on the identified quantities. Thirdly, if the dynamic forces can be identified in a stable way, the estimates obtained must be uniquely defined by the measurement data. In the literature, the main requirements on the system description for instantaneous invertibility are extensively documented for the general case of linear systems (Antsaklis 1978, Massey and Sain 1968, Moylan 1977). For the specific case of linear modally reduced order models, as often used in structural dynamics, the general conditions can be directly translated into a number of requirements on the output vector, i.e. sensor types, sensor locations, and number of sensors. These requirements are important for the design of vibration experiments that aim for input estimation.

Starting from the general conditions on system invertibility, as given in the literature, the requirements on the output vector are derived. A conceptual example is used to illustrate the theoretical derivation.

2 PROBLEM FORMULATION

In structural dynamics, first principle models, e.g. finite element (FE) models, are widely used. In many cases, modally reduced order models are applied, constructed from a limited number of structural modes. When proportional damping is assumed, the

continuous-time decoupled equations of motion for modally reduced order models are given by:

$$\ddot{\mathbf{z}}(t) + \mathbf{\Gamma}\dot{\mathbf{z}}(t) + \mathbf{\Omega}^2\mathbf{z}(t) = \mathbf{\Phi}^{\mathrm{T}}\mathbf{S}_{\mathrm{p}}(t)\mathbf{p}(t) \tag{1}$$

where $\mathbf{z}(t) \in \mathbb{R}^{n_{\mathrm{m}}}$ is the vector of modal coordinates, with n_{m} the number of modes taken into account in the model. The excitation force is written as the product of a selection matrix $\mathbf{S}_{\mathrm{p}}(t) \in \mathbb{R}^{n_{\mathrm{dof}} \times n_{\mathrm{p}}}$, specifying the force locations, and a time history vector $\mathbf{p}(t) \in \mathbb{R}^{n_{\mathrm{p}}}$, with n_{p} the number of forces. For the remainder of this paper, the selection matrix $\mathbf{S}_{\mathrm{p}}(t)$ is assumed to be time-invariant. The results, however, can be readily extended to the case where $\mathbf{S}_{\mathrm{p}}(t)$ is varying over time. The number of degrees of freedom is indicated by n_{dof}. $\mathbf{\Gamma} \in \mathbb{R}^{n_{\mathrm{m}} \times n_{\mathrm{m}}}$ is a diagonal matrix containing the terms $2\xi_j\omega_j$ on its diagonal, where ω_j and ξ_j are the natural frequency and modal damping ratio corresponding to mode j, respectively. $\mathbf{\Omega} \in \mathbb{R}^{n_{\mathrm{m}} \times n_{\mathrm{m}}}$ is a diagonal matrix as well, containing the natural frequencies ω_j on its diagonal, and $\mathbf{\Phi} \in \mathbb{R}^{n_{\mathrm{dof}} \times n_{\mathrm{m}}}$ is a matrix containing the eigenvectors $\boldsymbol{\phi}_j$ as columns.

The decoupled governing equations can be written into state-space form, which after time discretization yields:

$$\mathbf{x}_{[k+1]} = \mathbf{A}\mathbf{x}_{[k]} + \mathbf{B}\mathbf{p}_{[k]} \tag{2}$$

The state vector $\mathbf{x}_{[k]} \in \mathbb{R}^{n_{\mathrm{s}}}$ consists of the modal displacements and velocities:

$$\mathbf{x}_{[k]} = \begin{bmatrix} \mathbf{z}_{[k]} \\ \dot{\mathbf{z}}_{[k]} \end{bmatrix} \tag{3}$$

The specific form of $\mathbf{A}$ and $\mathbf{B}$ depends on the time discretization scheme and will not be further considered. The reader is referred to Franklin et al. (1998) for a detailed overview of common time discretization schemes. As an alternative to models based on first principles, models can be directly identified from experimental data using system identification techniques, e.g. Reynders and De Roeck (2008).

The output vector is generally written as

$$\mathbf{d}(t) = \mathbf{S}_{\mathrm{d,a}}\mathbf{\Phi}\ddot{\mathbf{z}}(t) + \mathbf{S}_{\mathrm{d,v}}\mathbf{\Phi}\dot{\mathbf{z}}(t) + \mathbf{S}_{\mathrm{d,d}}\mathbf{\Phi}\mathbf{z}(t) \tag{4}$$

where $\mathbf{S}_{\mathrm{d,a}}$, $\mathbf{S}_{\mathrm{d,v}}$, and $\mathbf{S}_{\mathrm{d,d}} \in \mathbb{R}^{n_{\mathrm{d}} \times n_{\mathrm{dof}}}$ are selection matrices indicating the degrees of freedom corresponding to the acceleration, velocity and displacement measurements, respectively. The output vector is composed of $n_{\mathrm{d,d}}$ displacement or strain measurements, $n_{\mathrm{d,v}}$ velocity measurements and $n_{\mathrm{d,a}}$ acceleration measurements, where n_{d} is the sum of $n_{\mathrm{d,d}}$, $n_{\mathrm{d,v}}$, and $n_{\mathrm{d,a}}$.

Eq. (4) is transformed into its state-space form, using Eq. (1):

$$\mathbf{d}_{[k]} = \mathbf{G}\mathbf{x}_{[k]} + \mathbf{J}\mathbf{p}_{[k]} \tag{5}$$

The expression for the state-output matrix $\mathbf{G}$ and the direct transmission matrix $\mathbf{J}$, in general, does not depend on the discretization scheme and is given by Eq. (6) and Eq. (7), respectively.

$$\mathbf{G} = \begin{bmatrix} \mathbf{S}_{\mathrm{d,d}}\mathbf{\Phi} - \mathbf{S}_{\mathrm{d,a}}\mathbf{\Phi}\mathbf{\Omega}^2 & \mathbf{S}_{\mathrm{d,v}}\mathbf{\Phi} - \mathbf{S}_{\mathrm{d,a}}\mathbf{\Phi}\mathbf{\Gamma} \end{bmatrix} \tag{6}$$

$$\mathbf{J} = \begin{bmatrix} \mathbf{S}_{\mathrm{d,a}}\mathbf{\Phi}\mathbf{\Phi}^{\mathrm{T}}\mathbf{S}_{\mathrm{p}} \end{bmatrix} \tag{7}$$

When process noise and measurement noise are added to Eq. (2) and Eq. (5), respectively, the following discrete-time combined deterministic-stochastic state space description of the system is obtained:

$$\mathbf{x}_{[k+1]} = \mathbf{A}\mathbf{x}_{[k]} + \mathbf{B}\mathbf{p}_{[k]} + \mathbf{w}_{[k]} \tag{8}$$

$$\mathbf{d}_{[k]} = \mathbf{G}\mathbf{x}_{[k]} + \mathbf{J}\mathbf{p}_{[k]} + \mathbf{v}_{[k]} \tag{9}$$

where $\mathbf{x}_{[k]} \in \mathbb{R}^{n_{\mathrm{s}}}$ is the state vector, $\mathbf{d}_{[k]} \in \mathbb{R}^{n_{\mathrm{d}}}$ is the output vector, assumed to be measured, and $\mathbf{p}_{[k]} \in \mathbb{R}^{n_{\mathrm{p}}}$ is the unknown input vector. The deterministic system behaviour is described by the system matrices $\mathbf{A}$, $\mathbf{B}$, $\mathbf{G}$ and $\mathbf{J}$. The process noise $\mathbf{w}_{[k]} \in \mathbb{R}^{n_{\mathrm{s}}}$ and measurement noise $\mathbf{v}_{[k]} \in \mathbb{R}^{n_{\mathrm{d}}}$ are of no importance for the invertibility of the system, and will not be considered in the following theoretical derivation. When the optimal sensor configuration is to be determined, i.e. the configuration of sensors giving rise to the smallest error on the identified forces, the noise statistics will, however, be important.

In structural dynamics, the problem of input estimation consists of estimating the excitation forces $\mathbf{p}_{[k]}$, acting on a structure at known locations, from a set of response measurements.

3 IDENTIFIABILITY CONDITIONS

System identifiability requires that the measured output contains information on the estimated system input. This condition can be subdivided in two separate requirements, the observability requirement and the direct invertibility requirement.

3.1 *Observability*

System observability requires that all states are represented in the system output. The following definition holds (Kalman 1960).

Definition 3.1. *A system described by Eq. (8) and Eq. (9) is called observable if, in the absence of noise, the knowledge of the input* $\mathbf{p}_{[k]}$ *and the output* $\mathbf{d}_{[k]}$ *over a finite interval* $(k = 0, \ldots, n)$ *is sufficient to determine the state vector* $\mathbf{x}_{[0]}$.

In general, system observability is tested by means of the rank of the observability matrix $\mathcal{O}$:

$$\mathcal{O} \equiv \begin{bmatrix} \mathbf{G} \\ \mathbf{GA} \\ \vdots \\ \mathbf{GA}^{n_{\mathrm{s}}-1} \end{bmatrix} \tag{10}$$

Theorem 3.1. *The system described by Eq. (8) and Eq. (9) is observable if and only if* $\text{rank}(\mathcal{O}) = n_s$*, with* n_s *the number of system states.*

When a modally reduced order model is used, system observability requires that all structural modes contribute to the measured output. From the definition of the observability matrix in Eq. (10), and the definition of the output vector in Eq. (4), the observability test can be formulated in a more straightforward and comprehensible way.

Theorem 3.2. *The modally reduced order system described by Eq. (8) and Eq. (9) is observable if and only if the matrix*

$$\begin{bmatrix} \mathbf{S}_d\boldsymbol{\Phi} \end{bmatrix} = \begin{bmatrix} \mathbf{S}_{d,d}\boldsymbol{\Phi} \\ \mathbf{S}_{d,v}\boldsymbol{\Phi} \\ \mathbf{S}_{d,a}\boldsymbol{\Phi} \end{bmatrix} \tag{11}$$

does not contain any zero columns.

Proof. Theorem 3.2 directly follows from the expression of the matrix **G** and the structure of the matrix **A** for the case of modally reduced order models. The full proof is omitted here for the sake of brevity. □

The observability requirements in Theorem 3.1 and Theorem 3.2 hold for continuous-time systems and discrete-time systems. The observability of a discrete-time system in addition depends on the sampling frequency. On the one hand, the sampling frequency has to be chosen, in accordance to the Nyquist theorem (Franklin, Powell, & Workman 1998), taking into account the largest natural frequency of the model. When the sampling frequency becomes too large, on the other hand, the observability matrix becomes numerically rank-deficient. The influence of the sampling frequency is, however, not further considered in this paper.

When only force identification is aimed at and the system states as such are not of interest, the observability requirement can be relaxed, as not all n_m modes have to be observable. For the identifiability of the forces, it suffices that at least n_p modes, which are excited by these forces, contribute to the given set of output measurements. This requirement is referred to as relaxed observability hereafter. Relaxed observability can be ascertained, based on the system description.

Theorem 3.3. *Relaxed observability holds for the reduced order system described by Eq. (8) and Eq. (9) if and only if the matrices*

$$\begin{bmatrix} \mathbf{S}_d\boldsymbol{\Phi} \end{bmatrix} \text{and} \begin{bmatrix} \mathbf{S}_p^T\boldsymbol{\Phi} \end{bmatrix}$$

have at least n_p *non-zero columns in common.*

The concept of relaxed observability is illustrated by means of a conceptual example.

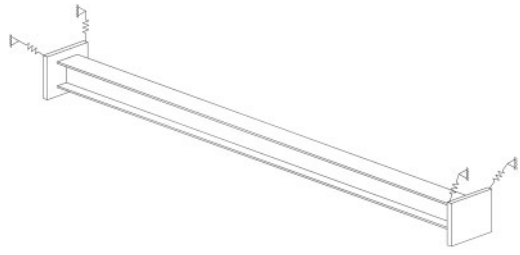

Figure 1. Structure as considered for the illustration of the theoretical derivation, three dimensional view.

Figure 2. Force and sensor locations as considered for Example 3.1, (a) side view and (b) top view.

Example 3.1. The structure under consideration is a steel beam with I-shaped cross section. The structure, as constructed at the laboratory, is shown in figure 1. The beam has steel plates welded to its ends and is connected to the environment by springs. In this way, free-free boundary conditions are obtained. Details on the structure and its modal characteristics, though not required for the remainder of this paper, can be found in Lourens et al. (2012).

Assume a modally reduced order model constructed from two modes of the beam, one torsional mode (mode T1) and one vertical bending mode (mode B1). A single vertical force, indicated as p_1, is acting eccentrically on the beam (figure 2). The response of the structure is measured using one accelerometer, a_1, placed on the beam axis. The force and sensor locations are shown in figure 2.

The force p_1 excites both the vertical bending mode and the torsional mode. The matrix $\mathbf{S}_p^T\boldsymbol{\Phi}$ becomes

$$\begin{bmatrix} \mathbf{S}_p^T\boldsymbol{\Phi} \end{bmatrix} = \begin{bmatrix} \overset{\text{T1}}{*} & \overset{\text{B1}}{*} \end{bmatrix} \tag{12}$$

where $*$ indicates a generally non-zero number. Since only bending of the beam contributes to the measured acceleration response, it is clear that in general

$$\begin{bmatrix} \mathbf{S}_{d,d}\boldsymbol{\Phi} \\ \mathbf{S}_{d,v}\boldsymbol{\Phi} \\ \mathbf{S}_{d,a}\boldsymbol{\Phi} \end{bmatrix} = \begin{bmatrix} \overset{\text{T1}}{0} & \overset{\text{B1}}{0} \\ 0 & 0 \\ 0 & * \end{bmatrix} \tag{13}$$

Since mode T1 is not observed by the sensor, the system is not observable and, consequently, the observation matrix $\mathcal{O}$ will not have rank n_s $(= 2n_m = 4)$. Relaxed observability holds, however, as there is only one force to be identified.

3.2 *Direct invertibility*

Direct invertibility requires that the system input can be estimated from the output without a time delay, which is called instantaneous inversion. The necessary and sufficient condition for direct invertibility is extensively documented in the literature (Massey and Sain 1968, Moylan 1977), and is given by the following theorem.

Theorem 3.4. *The system described by Eq. (8) and Eq. (9) is instantaneously invertible if and only if* $\text{rank}(\mathbf{J}) = n_\text{p}$.

For modally reduced order models, this condition results in two important requirements which have to be taken into account when performing instantaneous system inversion.

1. The number of forces n_p cannot become larger than the number of modes excited by these forces, which not necessarily equals the total number of modes. This has to hold for each subset of forces. The underlying physical explanation directly follows from the assumption of an uncoupled reduced order model. The forces must be able to control at least n_p modes independently, in order to be distinguishable. This requirement is referred to as relaxed controllability hereafter.

If requirement 1. holds, the matrix $\mathbf{\Phi}^\text{T}\mathbf{S}_\text{p}$ will be of rank n_p. An illustration is found in Example 3.2.

2. The contribution from at least n_p modes excited by the forces must be distinguishable from the measured acceleration signals. This has to hold for each subset of forces. This conclusion ensures a direct coupling between the measured acceleration responses and the estimated forces through at least n_p modes composing the model.

If requirements 1. and 2. hold, the matrix $\mathbf{J}$ will be of rank n_p and the system will be instantaneously invertible. The required number of independent acceleration measurements depends on the particular force and sensor locations, but can never become smaller than the number of forces n_p. An illustration is found in Example 3.3. From the direct coupling between the acceleration responses and the forces, it is clear that direct invertibility of the system also implies relaxed observability (see Theorem 3.3).

Example 3.2. Assume a modally reduced order model constructed from three modes of the beam, two torsional modes (modes T1 and T2) and one vertical bending mode (mode B1). Three vertical forces are acting on the beam, one of them eccentrically, two others centrically, indicated as p_1, p_2, and p_3, respectively. The force locations are shown in figure 3.

Force p_1 excites the torsional modes and the bending mode, whereas forces p_2 and p_3 only excite the bending mode. The matrix $\mathbf{S}_\text{p}^\text{T}\mathbf{\Phi}$ becomes

$$\left[\ \mathbf{S}_\text{p}^\text{T}\mathbf{\Phi}\ \right] = \begin{matrix}\text{T1} & \text{T2} & \text{B1}\end{matrix}\begin{bmatrix} * & * & * \\ 0 & 0 & * \\ 0 & 0 & * \end{bmatrix}\begin{matrix}p_1\\ p_2\\ p_3\end{matrix}$$

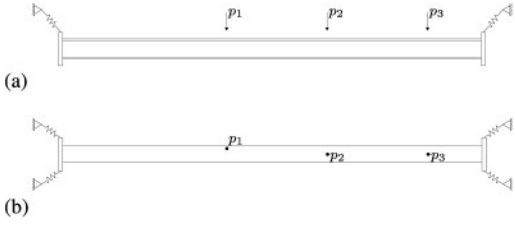

Figure 3. Force locations as considered for Example 3.2, (a) side view and (b) top view.

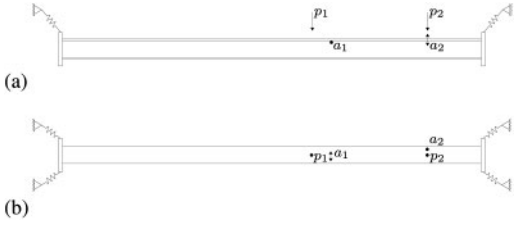

Figure 4. Force and sensor locations as considered for Example 3.3, (a) side view and (b) top view.

All modes are excited by the forces and, in general, the three forces are independent. However, $\mathbf{S}_\text{p}^\text{T}\mathbf{\Phi}$ is not of rank n_p, since the two torsional modes cannot be controlled independently by the forces assumed.

Example 3.3. Assume a modally reduced order model constructed from three modes of the beam, one torsional mode (modes T1) and two vertical bending modes (modes B1 and B2). Two vertical forces are acting centrically on the beam, indicated as p_1 and p_2. The response of the structure is measured using two accelerometers. The first accelerometer, a_1, measuring the horizontal accelerations, is placed at the web plate, right below the upper beam flange. The second accelerometer, a_2, measuring the vertical accelerations, is placed eccentrically. The force and sensor locations are shown in figure 4.

Forces p_1 and p_2 excite the bending modes of the beam. The torsional mode is not excited. The matrix $\mathbf{S}_\text{p}^\text{T}\mathbf{\Phi}$ becomes

$$\left[\ \mathbf{S}_\text{p}^\text{T}\mathbf{\Phi}\ \right] = \begin{matrix}\text{T1} & \text{B1} & \text{B2}\end{matrix}\begin{bmatrix} 0 & * & * \\ 0 & * & * \end{bmatrix}\begin{matrix}p_1\\ p_2\end{matrix}$$

Acceleration a_1 only contains a contribution from the torsional mode, whereas acceleration a_2 contains a contribution from all modes. The matrix $\mathbf{S}_{\text{d,a}}\mathbf{\Phi}$ becomes

$$\left[\ \mathbf{S}_{\text{d,a}}\mathbf{\Phi}\ \right] = \begin{matrix}\text{T1} & \text{B1} & \text{B2}\end{matrix}\begin{bmatrix} * & 0 & 0 \\ * & * & * \end{bmatrix}\begin{matrix}a_1\\ a_2\end{matrix}$$

The two forces excite the two bending modes independently. The system will, however, not be instantaneously invertible, since there is not a direct coupling between acceleration a_1 and the excitation forces. Consequently, matrix $\mathbf{J}$ ($= \mathbf{S}_{\mathrm{d,a}} \boldsymbol{\Phi} \boldsymbol{\Phi}^{\mathrm{T}} \mathbf{S}_{\mathrm{p}}$) will not be of rank n_{p}.

4 STABILITY CONDITIONS

Stability of system inversion is mainly an issue for recursive inversion algorithms, and is defined by the following definition:

Definition 4.1. *The inversion of a system is stable if, starting from an arbitrary initial state estimate* $\hat{\mathbf{x}}_{[0]}$*, the force estimates* $\hat{\mathbf{p}}_{[k]}$ *and/or state estimates* $\hat{\mathbf{x}}_{[k]}$ *converge to the true input and system state values,* $\mathbf{p}_{[k]}$ *and* $\mathbf{x}_{[k]}$*, respectively (in the absence of modelling errors and noise processes).*

The stability of the system inversion depends on the conditions under which the poles of the inverse system can be assigned. These conditions are directly related to the transmission zeros λ_j of the original system (Moylan 1977).

Theorem 4.1. *If all transmission zeros of the system described by Eq. (8) and Eq. (9) are located at the center of the unit circle* ($\lambda_j = 0$, $j = 1, \ldots, n_{\mathrm{s}}$)*, there exists a system inverse for which the poles can be arbitrarily assigned. If the system has no unstable transmission zeros* ($|\lambda_j| < 1$, $j = 1, \ldots, n_{\mathrm{s}}$)*, the poles of the system inverse can be chosen such that the system inversion is stable.*

Theorem 4.1 holds for instantaneous system inversion, as well as for time delayed inversion (e.g. Hsieh (2009)). If the system contains any unstable zeros ($|\lambda_j| \geq 1$), there does not exist a stable instantaneous inverse. By applying a time delay in the inversion process, the inverse system can stabilized. The issue of time delayed inversion is not further considered in this paper, however.

The transmission zeros of a system depend on all four system matrices $\mathbf{A}$, $\mathbf{B}$, $\mathbf{G}$ and $\mathbf{J}$ and are found by solving a generalized eigenvalue problem (Emami-Naeini and Van Dooren 1982). When a modally reduced order model is used, not only the mode shapes ϕ_j but also the natural frequencies ω_j and the modal damping ratios ξ_j determine the location of the system transmission zeros. In addition, the system zeros depend on the type and number of sensors used to measure the response (i.e. on the selection matrices $\mathbf{S}_{\mathrm{d,d}}$, $\mathbf{S}_{\mathrm{d,v}}$, and $\mathbf{S}_{\mathrm{d,a}}$), on whether these measurements are collocated with the forces (i.e. the relation between $\mathbf{S}_{\mathrm{d,d}}$, $\mathbf{S}_{\mathrm{d,v}}$, $\mathbf{S}_{\mathrm{d,a}}$ and $\mathbf{S}_{\mathrm{p}}$), on the time discretization scheme used, etc. For these reasons, a direct relation between the output vector and the occurrence of systems zeros cannot be derived and the system transmission zeros have to be checked systematically for each experiment design. Based on the physical background of system transmission zeros, however, a few rules of thumb can be drawn. Firstly, for collocated response measurements, i.e. when for each force a coinciding response measurement is available, the system will not have any unstable transmission zeros. Secondly, if only acceleration or velocity measurements are used, which are insensitive to static excitation, there will always be at least one transmission zero $\lambda_j = 1$, located at the unit circle. This transmission zero corresponds to excitation at a frequency of 0 Hz. If none of the other system zeros is unstable, the instantaneous inversion will be marginally stable. In structural dynamics, however, acceleration measurements are used extensively, as they can be obtained in a reliable way and at an acceptable cost. The problem of marginal stability of the system inversion can be resolved by including displacement and/or strain measurements, in accordance to the following theorem.

Theorem 4.2. *Transmission zeros of the system described by Eq. (8) and Eq. (9), corresponding to a frequency of* 0 Hz*, can be resolved by including displacement and/or strain measurements, such that* rank $(\mathbf{S}_{\mathrm{d,d}} \boldsymbol{\Phi} \boldsymbol{\Phi}^{\mathrm{T}} \mathbf{S}_{\mathrm{p}}) = n_{\mathrm{p}}$.

If the system is instantaneously invertible (see Theorem 3.4), the matrix $\mathbf{S}_{\mathrm{p}}^{\mathrm{T}} \boldsymbol{\Phi}$ is of rank n_{p}, and one additional requirement needs to be drawn, in order to ensure that the rank criterion, as stated in Theorem 4.2, holds:

1. The contribution from at least n_{p} modes excited by the forces must be distinguishable from the measured displacement and/or strain signals. This has to hold for each subset of forces. This conclusion ensures a direct coupling between the measured displacement and/or strain responses and the estimated forces through at least n_{p} modes composing the model.

If requirement 1. holds, $\mathbf{S}_{\mathrm{d,d}} \boldsymbol{\Phi} \boldsymbol{\Phi}^{\mathrm{T}} \mathbf{S}_{\mathrm{p}}$ will be of rank n_{p} and all transmission zeros corresponding to a frequency of 0 Hz are resolved. The required number of independent displacement and strain measurements depends on the particular force and sensor locations, but can never become smaller than the number of forces n_{p}. The choice of displacement or strain measurements (number of measurements, measurement locations and directions) is based on the same principles as the choice of acceleration measurements, needed for system invertibility (section 3.2). The reader is referred to Example 3.3 for an illustration of the concept.

5 UNIQUENESS CONDITIONS

The uniqueness of the identified forces depends on the system transmission zeros, as stated in the following theorem:

Theorem 5.1. *The input of a system with at least one transmission zero cannot be uniquely reconstructed.*

This follows directly from the definition of a system transmission zero: there exists an input and an initial state for which the system output is zero. As a consequence, the input cannot be uniquely reconstructed from the measured output.

Example 5.1. When the system output only consists of acceleration measurements, the static component of both the identified forces and system states cannot be retrieved from the measurements. By adding displacement and/or strain measurements, in accordance to Theorem 4.2, the static component is retained from the identification procedure as well.

6 CONCLUSIONS

In this paper, general conditions on the invertibility of linear system models have been presented. The conditions apply generally to any instantaneous input estimation algorithm. The main focus is on the identifiability of the dynamic forces, as well as the stability and the uniqueness of the identified quantities. It is shown that, for the specific case of modally reduced order models, the general invertibility conditions can be ascertained based on the knowledge of the modal characteristics of the structure. The resulting set of simplified requirements can then be used to design a measurement setup in a very straightforward and comprehensible way.

Determination of aerodynamic damping of twin cables in wet conditions through passive-dynamic wind tunnel tests

M.B. Eriksen & E. Mattiello
FORCE Technology, Hydro- and Aerodynamics, Kgs. Lyngby, Denmark

C.T. Georgakis
Department of Civil Engineering, Technical University of Denmark, Kgs. Lyngby, Denmark

ABSTRACT: Moderate amplitude cable vibrations continue to be reported on the cable-stayed Øresund Bridge, despite the presence of helical fillets and dampers. The vibrations are particularly notable in wet conditions, which would suggest a form of rain-wind induced vibrations (RWIV). A statistical operational modal analysis of the monitored vibrations revealed, in certain conditions and for specific wind velocities, the presence of negative aerodynamic damping. To investigate the observed aerodynamic damping of the twin cable arrangement further, a series of 1:2.3 scale passive-dynamic wind tunnel tests was performed at the DTU/FORCE Technology Climatic Wind Tunnel facility in Kgs. Lyngby, Denmark. Tests were performed for both dry and wet conditions, with and without helical fillets. The specific relative cable-wind angle tested was identified as critical from the aforementioned full-scale monitoring of the bridge cables. For the wet tests, the twin cable surfaces were treated in order to obtain uniform upper and lower water rivulets. The interaction between water rivulets, surface properties and the flow was found to govern the activation of the RWIV mechanism. The resulting aerodynamic damping from wet passive-dynamic wind tunnel tests showed the effect of the helical fillets in preventing the occurrence of negative aerodynamic damping, contrary to the plain cables.

1 INTRODUCTION

Bridge cable vibrations remain a problem for bridge designers and operators notwithstanding the wide research efforts spent in the last couple of decades. Two approaches have generally been followed so far to minimize these vibrations and their effects: application of fillets or dimples onto the cable surface to improve the aeroelastic behaviour, and addition of mechanical dampers to increase energy dissipation. The cable-stayed Øresund Bridge, linking Denmark and Sweden, was one of the first bridges to incorporate this dual approach. Nevertheless, vibrations of the cables have been observed since before its opening in 2000.

More recently, Acampora & Georgakis (2011) reported moderate vibration incidences in both dry and wet conditions and for a narrow range of cable-wind angles. Various mechanisms may be responsible for the reported vibrations, including dry inclined galloping and forms of rain-wind-cable interaction. In the wet case, water rivulets form on the cable surface interacting with the flow. An equilibrium between rain intensity, droplet size, wettability, aerodynamic and gravitational forces is required for the water rivulets to form and be sustained (de Sá Caetano 2007, Lemaitre et al. 2010). The subsequent non-symmetric cross-section of a cable with rivulets, does not completely describe the RWIV mechanism (Matsumoto et al. 1995). In fact, RWIV occur in a restricted range of wind velocities, as the water rivulets oscillate on the cable surface (Hikami & Shiraishi 1998). A possible explanation for the restricted velocity range is the resonance between the natural frequencies of the rivulets and of the cable, as proposed by Hikami & Shiraishi (1998). Furthermore, for a cable declining in the wind, the rivulets interact with the axial flow, and with three-dimensional vortex shedding (Matsumoto et al. 2001). Cosentino et al. (2003) reported that the thin water layer acts as an added roughness close to the separation line. It obstructs the separation-reattachment mechanism allowing for changes in the flow regime, and an enhanced vortex shedding may be observed (Matteoni & Georgakis 2012). These changes depend on the relative cable-wind angle and the wind angle of attack. In specific cases, the unfavourable changes of aerodynamic forces may lead to the formation of positive velocity-proportional forces corresponding to negative aerodynamic damping.

The specific twin-cable arrangement of the Øresund Bridge cables may further influence the aerodynamic and/or aeroelastic behaviour of the stays. The cable spacing to diameter ratio of the Øresund Bride cables, $S/D = 2.68$, generates a flow pattern with two wakes equal in size, leading to synchronised vortex shedding (Zdravkovich 2003). The Øresund Bridge cable arrangement was originally studied by Larose & Smitt

(1999), and its aerodynamic damping was recently estimated from full-scale measurements using an Operational Modal Analysis (OMA) technique (Georgakis & Acampora 2011) as well as an Eigenvalue Realisation Algorithm (ERA), as reported by Acampora et al. (2012). Negative aerodynamic damping was found from the monitoring of specific stays of the Øresund Bridge in wet condition for specific cable wind-angle orientations (Georgakis & Acampora 2011).

To further investigate the aerodynamics of the Øresund Bridge twin cables, a series of passive-dynamic wind tunnel tests has been undertaken in both dry and simulated rain conditions on a scaled model of the twin stays. The present paper details the investigations in wet conditions.

2 EXPERIMENTAL WORK

2.1 *Test facility*

The experimental work was carried out in the closed-circuit DTU/FORCE Technology Climatic Wind Tunnel (Georgakis et al. 2009). The tests were performed in the $2\,m \times 2\,m \times 5\,m$ test section with turbulence intensity $I_u \approx 1\%$ in the flow direction in the test section with local increases up to 3% at the wall panel openings, as described in section 2.3.

2.2 *Cable model preparation*

A 1:2.3 scale section model was produced using PVC piping of diameter $D = 110\,mm$, and thickness $t = 6\,mm$. Two 3 m long pipes were rigidly connected to each other at the ends to form the twin cable arrangement as shown in Figure 2.1. The pipes were sanded to reproduce the surface roughness and a scaled double helical fillet was added.

The surface properties of a prototype cable change over time due to the effects of various agents including ageing, sun, sea water and pollutants (Larose & Smitt 1999). In particular the wettability, described as the contact angle between a water droplet and the surface, increases (contact angle decreases). Therefore a polyvinyl coating was applied to the surface of the PVC pipes with a soft brush to achieve similar surface properties as the prototype cable. The applied solution consisted of 5% weight Gohsenol KP-08R dissolved in water at 70–75°C.

2.3 *Test set-up*

The cable configuration with inclination $\theta = 30°$ and horizontal yaw angle $\beta = 70°$ (see Figure 2.2) was identified as critical from full-scale monitoring of the bridge cables and thus chosen for the tests. The axial component of the model weight was carried by a steel wire.

A 1-DoF dynamic rig was designed to restrict the motion of the cable model to the in-plane degree of freedom, i.e. direction of motion in the plane containing the two cable axes. Two linear elastic springs per

Figure 2.1. Wind tunnel twin cable set-up.

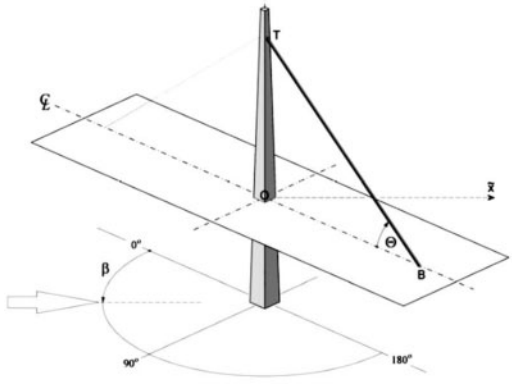

Figure 2.2. Cable-wind angle convention.

end were mounted perpendicular to the axes of the PVC pipes. The springs were chosen and adjusted to match the 1st in-plane natural frequency $f = 1.1\,Hz$ (model scale) of the bridge cables, identified as problematic from full-scale monitoring. The dynamic rig was designed to minimize the structural damping, which was measured to be $\zeta_s = 0.2\%$. In order to improve the likelihood for RVIW to occur, the Scruton number, was set to $Sc = m\zeta_s/(\rho D^2) = 1.35$, (FHWA 2007).

The blockage coefficient estimated as the ratio between the model frontal area inside the test section and the tunnel cross section was $S/A = 12.7\%$. No blockage corrections were made on aerodynamic damping or lift force coefficients though.

To allow attachment to the rig and movement of the model, the test section was partially open ($0.3\,m \times 0.9\,m$) at the cable ends. The influence of panel openings on flow velocity and turbulence intensity was investigated through flow profile measurements conducted along the model axis position and along the wall openings, respectively.

2.4 *Rain simulation system*

A rain simulation system was built inside the test section to provide the cable model with enough water to

form both upper and lower water rivulets. The water flow was optimized to obtain the biggest rivulets. The flow rate was measured to be 4.2 l/m for the filleted cable tests and 3.2 l/min for the plain cable tests (without fillets). More water was sprayed in the first case because the presence of the fillets redirected some of the water off the cables. The system was not designed to reproduce natural rain, but to form the rivulets on the cables.

Ten nozzles were fixed on two piano wires perpendicular to the flow and inclined as the model. The wires were positioned 0.8 m and 1.35 m upstream the upper and lower end of the model respectively. The wires were spaced from each other in order for the nozzles to direct the spray onto the cables. Five tubes channelling the water were led along the floor and vertically up to the wire where each of them was split in two to feed all the nozzles.

A balanced wettability was found to be necessary for the water rivulets to form, sustain and eventually cause vibrations. The model was subjected to a pre-wash prior to test in order to remove the excessive polyvinyl coating from the PVC surface. A water film was then formed on the windward side of the treated cables and upper and lower rivulets built up and oscillated near the separation lines.

2.5 *Test programme*

The wet tests were conducted on the twin cable model in two states: filleted and plain i.e. without helical fillets.

The model was manually excited to approximately 1D in amplitude and the free decay monitored by laser displacement transducers at both the upper and lower end. The model was also left steady to be excited only by the wind in the velocity range where the previous tests showed slow or zero decay. The free growth was logged with the same measuring technique. Five repetitions were made for every velocity tested from approximately 2 m/s to 30 m/s in steps of 1 m/s.

3 RESULTS AND DISCUSSION

The objective of the tests was to investigate the aerodynamic damping for the specific cable configuration described above. The negative aerodynamic damping reported from full-scale monitoring by (Georgakis & Acampora 2011) was of particular interest and the attempt to reproduce a situation leading to negative aerodynamic damping was emphasised.

The results were described as a function of Reynolds number, $\mathrm{Re} = \mathrm{UD}/\nu$, where U is the flow velocity, D is the single cable diameter and ν is the kinematic viscosity of the air.

3.1 *Formation of water rivulets*

The upper water rivulets started to form at velocities corresponding to $\mathrm{Re} \approx 0.2\text{–}0.25 \cdot 10^5$ and both

Figure 3.1. Filleted twin cable with lower water rivulet.

upper and lower rivulets were fully formed at velocities with $\mathrm{Re} \approx 0.5 \cdot 10^5$, see Figure 3.2. For flow velocities $\mathrm{Re} > 1.5 \cdot 10^5$, the rivulets were no longer continuous, but were partly blown off the cable surface.

3.2 *Aerodynamic damping*

The aerodynamic damping ratio of the cable model ζ_a was determined by subtracting the damping of the rig measured at zero wind velocity ζ_s from the total measured damping ζ and scaled to represent full-scale values. Following Macdonald & Larose (2006). aerodynamic damping can be described with the form:

$$\zeta_a = \frac{\mu Re}{4m\omega} f(Re, C_D, C_L, \alpha, \phi) \tag{1}$$

For cylinders with similar aerodynamic properties, such as a full-scale bridge cable and a scaled cable model, only mass m and natural frequency ω vary. This requires that flow characteristics and fluid dynamic behaviour are the same, i.e. Reynolds number and dynamic viscosity of air have to remain unchanged. Hence, the resulting scaling factor depends on the mass-frequency ratio between the full-scale cable and the scaled model, such that:

$$\lambda_{\zeta a} = \frac{\zeta_{a,model}}{\zeta_{a,full}} = \frac{m_{full}\omega_{full}}{m_{model}\omega_{model}} \tag{2}$$

The main results in terms of aerodynamic damping for in-plane motion are presented in Figure 3.2 as the mean value (solid lines) plus/minus the standard deviation (dashed lines). The aerodynamic damping ratio is given as a function of Re.

The figure shows the aerodynamic damping for the tests with and without helical fillets (plain). The black curve (◁) representing the filleted cables shows that the aerodynamic damping increased following an approximately linear trend until it reached the maximum value of $\zeta_a = 0.37\%$ for $\mathrm{Re} = 1.65 \cdot 10^5$.

The aerodynamic damping for the plain cables is represented by the dark grey curve (○). At low

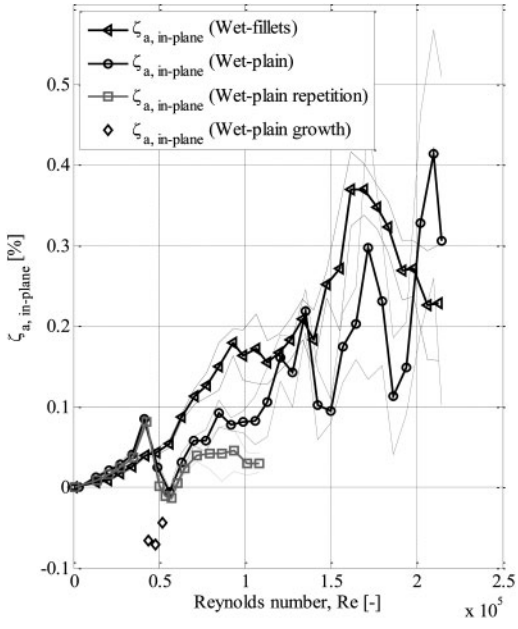

Figure 3.2. Aerodynamic damping ratios for in-plane motion.

flow velocities up to $\mathrm{Re} = 0.35 \cdot 10^5$ it followed a trend similar to the filleted cables, but after a rapid and short increase, a drop to negative values for $\mathrm{Re} \approx 0.5\text{–}0.6 \cdot 10^5$ was observed. The minimum value $\zeta_a \approx -0.01\%$ was observed for $\mathrm{Re} = 0.56 \cdot 10^5$. Hereafter the damping increased and remained positive in the tested flow velocity range. In general the aerodynamic damping for the filleted cables was found to be larger than for the plain cables.

The drop in aerodynamic damping to negative values for the plain cables was further investigated in two steps: first the free decay test was repeated and then a growth test was performed.

The repeated decay test represented in Figure 3.2 by the light gray curve (□) was performed as before, but with steps in velocity of 0.5 m/s in the range of interest until 15 m/s. This resulted in values similar to the first test.

Representative displacement time histories are illustrated in Figure 3.3 and Figure 3.4 for flow velocities of 8 m/s ($\mathrm{Re} = 0.56 \cdot 10^5$) and 11 m/s ($\mathrm{Re} = 0.77 \cdot 10^5$), respectively. The lines at the curve envelope represent the logarithmic fittings for the damping estimation. It is seen that the damping was lower at 8 m/s ($\mathrm{Re} = 0.56 \cdot 10^5$). Note that negative aerodynamic damping may still be achieved despite a total positive damping, when the structural damping is subtracted.

For the plain cables limited amplitude vibrations were observed in a narrow velocity range $\mathrm{Re} = 0.44\text{–}0.52 \cdot 10^5$ without any manual excitation of the model. This agrees with the incidences of RWIV documented in literature (Matsumoto et al. 1995; Cosentino et al. 2003). The damping determined from the growth tests is represented by the ◇-shaped points in Figure 3.2. Figure 3.5 shows a displacement time history for the growth at $\mathrm{Re} = 0.52 \cdot 10^5$. Again, the logarithmic fitting was used to determine the damping.

The aerodynamic damping determined from the increasing response was significantly larger in absolute value compared to the values determined from the free decay tests at the same flow velocities. The minimum value $\zeta_a \approx -0.07\%$ was observed for $\mathrm{Re} = 0.48 \cdot 10^5$.

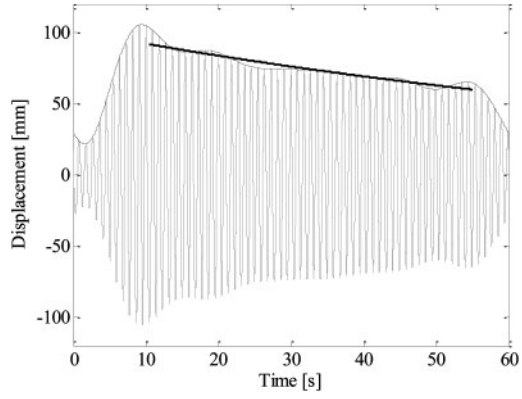

Figure 3.3. Time history, $\mathrm{Re} = 0.56 \cdot 10^5$ – decay test.

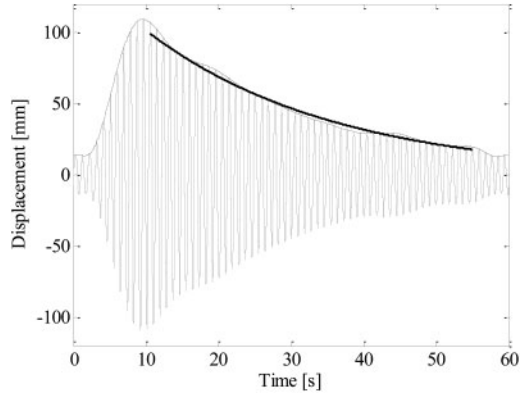

Figure 3.4. Time history, $\mathrm{Re} = 0.77 \cdot 10^5$ – decay test.

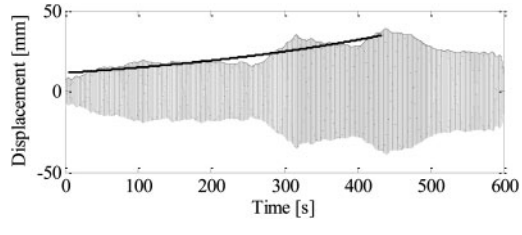

Figure 3.5. Time history, $\mathrm{Re} = 0.52 \cdot 10^5$ – growth test.

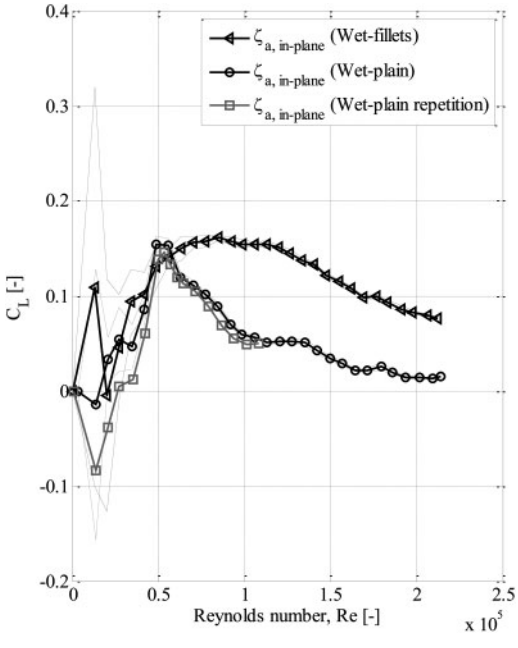

Figure 3.6. Lift force coefficients.

The excitation mechanism may have been triggered differently, generating diverse extreme values of negative aerodynamic damping for the two different tests. From Figure 3.5 it is seen that the growth continued to build up over a period of 450 s. The decay tests were carried out with sample time of 60 s. The excitation mechanism may require some interaction between flow and cable motion, which could be hardly obtained when the model was excited manually. Furthermore the amplitude levels (1D for the free decay test and 1/3D for growth test) were different.

Nevertheless, negative aerodynamic damping was observed for the plain cables, which may lead to undesired moderate amplitude vibrations. It was noticed that the drop in aerodynamic damping for the plain cable coincided with the complete formation of the rivulets, though at higher velocities the aerodynamic damping reached positive values in the presence of rivulets. The filleted cables did not suffer from instability and negative aerodynamic damping contrary to what had been monitored and observed for the Øresund Bridge cables.

3.3 *Lift force coefficients*

The mean lift forces were derived from the mean displacement and the stiffness of the system in the in-plane direction. Lift coefficients C_L for the wet tests are shown in Figure 3.6 as a function of Re.

It should be noted that the curve gradient for the plain cable (○) changes sign in the same range where the negative aerodynamic damping was found i.e. $Re = 0.5 \cdot 10^5$. At flow velocities $Re < 0.5 \cdot 10^5$ the standard deviations (dashed lines) in lift are significantly larger then for the higher flow velocities. This may be linked to the non-fully formed water rivulets at lower velocities. For flow velocities $Re > 0.6 \cdot 10^5$ the lift was observed to be higher for the filleted (◇) than for the plain cables (○).

4 CONCLUSIONS

A series of passive-dynamic wind tunnel tests was conducted on a scaled model of the twin stayed cables of the Øresund Bridge, to investigate the aerodynamics of this particular cable arrangement, for the critical conditions, i.e. weather precipitation and cable-wind angle, as shown by monitoring. Aerodynamic damping results showed no evidence of instability for the filleted cables in wet conditions. In the case of the plain cables, a region of instability zone with negative aerodynamic damping ratio was found between $Re \approx 0.4–0.6 \cdot 10^5$. This critical range could also be observed from the lift curve in correspondence to its abrupt change in gradient. This suggested the activation of a RWIV mechanism in the reported Re range. The results of the test campaign were consistent with the observation of RWIV incidences on the full-scale bridge cables.

Frequency domain stochastic response of structural systems with uncertain parameters: closed-form sensitivity

G. Muscolino & R. Santoro
Department of Civil, Information, Building, Environmental Engineering and Applied Mathematics, Messina, Italy

A. Sofi
Department of Civil, Energy, Environmental and Materials Engineering, Reggio Calabria, Italy

ABSTRACT: This study deals with the sensitivity analysis of the response of linear discretized structures with uncertain stiffness parameters subjected to stationary multi-correlated Gaussian random excitation. The proposed procedure relies on the use of the so-called *rational series expansion* (*RSE*), recently proposed by the authors as an alternative explicit form of the Neumann series expansion of the inverse of an invertible matrix with a modification of rank r. The *RSE* allows to derive approximate explicit expressions of the sensitivities of the probabilistic characteristics of the stationary stochastic response in the frequency domain by direct differentiation. The accuracy of the proposed procedure and computational issues related to sensitivity analysis are scrutinized through numerical results.

1 INTRODUCTION

Sensitivity plays an important role to evaluate the performance of structures subject to changes of model parameters.

From a mathematical point of view, sensitivity analysis involves computation of derivatives of the structural response quantities with respect to desired design variables (see e.g. Elishakoff & Ohsaki 2010). Within the context of structural applications, sensitivity derivatives are useful for performing optimization, structural health monitoring, identification, reliability etc.

There has been a great interest in developing methods for computing structural response sensitivities (Haftka & Adelman 1989). The approaches proposed for evaluating the partial derivatives of a performance measure can be classified in numerical, analytical and semi-analytical (Jensen 1995).

The availability of the exact or approximate explicit dependence of the response on the structural parameters allows an efficient sensitivity analysis.

The evaluation of the sensitivities of response statistics to variations of the design variables is of great interest for design purposes (Bhattacharyya & Chakraborty 2002, Chaudhuri & Chakraborty 2004) when the random nature of the main excitation sources, such as earthquake, wind etc., is taken into account besides the inevitable occurrence of uncertainty due to variation of design variables.

The present paper concerns the stochastic sensitivity analysis of linear discretized structures with uncertain structural parameters subjected to stationary multi-correlated Gaussian random excitation. The formulation is provided in the frequency domain. The proposed approach relies on approximate closed-form expressions of the mean-value and power spectral density (*PSD*) function of the stationary response obtained by applying the so-called *rational series expansion* (*RSE*) (Muscolino & Sofi 2012a, Muscolino & Sofi 2012b, Muscolino et al. 2012). Direct differentiation of these expressions allows to determine the sensitivities of response statistics in closed-form. Sensitivity information may be exploited to improve the computational efficiency of the *RSE* by eliminating the series terms associated to the design parameters whose variation has negligible influence on the response.

For validation purposes, the proposed procedure has been applied to a seismic-excited portal frame subject to variations of the Young's moduli.

2 PROBLEM FORMULATION

2.1 *Equations of motion*

The present study deals with the analysis of a quiescent n – DOF linear structural system with uncertain stiffness properties subjected to a stationary multi-correlated Gaussian stochastic process $\mathbf{f}(t)$. The equations of motion can be cast in the form:

$$\mathbf{M}\ddot{\mathbf{u}}(\boldsymbol{\alpha},t)+\mathbf{C}\dot{\mathbf{u}}(\boldsymbol{\alpha},t)+\mathbf{K}(\boldsymbol{\alpha})\mathbf{u}(\boldsymbol{\alpha},t)=\mathbf{f}(t) \tag{1}$$

where $\mathbf{M}$ and $\mathbf{C}$ are the $n\times n$ mass and damping matrices of the structure; $\mathbf{K}(\boldsymbol{\alpha})$ is the $n\times n$ stiffness

matrix depending on the vector $\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \ldots, \alpha_r]^{\mathrm{T}}$ which collects the r dimensionless fluctuations of the uncertain parameters, α_i, around their nominal values; $u(\alpha, t)$ is the stationary Gaussian vector process of displacements; a dot over a variable denotes differentiation with respect to time r.

In structural engineering problems, the uncertainties affecting the geometrical and mechanical properties are usually small, so that it can be reasonably assumed that $|\alpha_i| \ll 1$, where the symbol $|\bullet|$ means absolute value. Under this assumption, the classical modal analysis can be applied by introducing the following coordinate transformation:

$$\mathbf{u}(\boldsymbol{\alpha}, t) = \boldsymbol{\Phi}_0 \, \mathbf{q}(\boldsymbol{\alpha}, t) \tag{2}$$

where $q(\alpha, t)$ is the vector gathering the first m modal coordinates $q_j(\alpha, t)$ $(j = 1, 2, \ldots, m \leq n)$; Φ_0 is the nominal modal matrix of order $n \times m$, solution of the following eigenproblem:

$$\mathbf{K}_0 \boldsymbol{\Phi}_0 = \mathbf{M} \boldsymbol{\Phi}_0 \boldsymbol{\Omega}_0^2; \quad \boldsymbol{\Phi}_0^{\mathrm{T}} \mathbf{M} \boldsymbol{\Phi}_0 = \mathbf{I}_m \tag{3a,b}$$

where $\mathbf{I}_m$ denotes the identity matrix of order m; $\mathbf{K}_0 = \mathbf{K}(\boldsymbol{\alpha}_0)$ is the stiffness matrix pertaining to the nominal configuration where the uncertain parameters are set equal to their nominal values, i.e. $\boldsymbol{\alpha} = \boldsymbol{\alpha}_0$; $\boldsymbol{\Omega}_0^2 = \boldsymbol{\Phi}_0^{\mathrm{T}} \mathbf{K}_0 \boldsymbol{\Phi}_0$ is the spectral matrix of the nominal structural system, say a diagonal matrix listing the squares of the natural circular frequencies of the structure, $\omega_{0,i}$, for $\boldsymbol{\alpha} = \boldsymbol{\alpha}_0$. According to Eq. (2), the modal matrix of the structural system with uncertain parameters is approximated by the nominal one, i.e. $\boldsymbol{\Phi}(\boldsymbol{\alpha}) \approx \boldsymbol{\Phi}_0$, being $|\alpha_i| \ll 1$.

By applying the coordinate transformation (2), the equations of motion in the modal subspace are obtained:

$$\ddot{\mathbf{q}}(\boldsymbol{\alpha}, t) + \boldsymbol{\Xi} \, \dot{\mathbf{q}}(\boldsymbol{\alpha}, t) + \boldsymbol{\Omega}^2(\boldsymbol{\alpha}) \, \mathbf{q}(\boldsymbol{\alpha}, t) = \mathbf{p}(t) \tag{4}$$

where $\boldsymbol{\Omega}_2(\boldsymbol{\alpha}) = \boldsymbol{\Phi}_0^{\mathrm{T}} \mathbf{K}(\boldsymbol{\alpha}) \boldsymbol{\Phi}_0$; $\boldsymbol{\Xi} = \boldsymbol{\Phi}_0^{\mathrm{T}} \mathbf{C} \boldsymbol{\Phi}_0$ is assumed to be a diagonal matrix; $\mathbf{p}(t) = \boldsymbol{\Phi}_0^{\mathrm{T}} \mathbf{f}(t)$ is the modal forcing vector. It is worth mentioning that, due to the assumption $\boldsymbol{\Phi}(\boldsymbol{\alpha}) \approx \boldsymbol{\Phi}_0$, the spectral matrix $\boldsymbol{\Omega}^2(\boldsymbol{\alpha})$ is not diagonal and the modal equations of motion in Eq. (4) are always coupled.

The external load vector $\mathbf{f}(t)$ in Eq. (1) is modelled as a stationary multi-correlated Gaussian random process fully characterized from a probabilistic point of view by the mean-value vector, $\boldsymbol{\mu}_{\mathbf{f}}$, and the correlation function matrix, $\mathbf{R}_{\mathbf{ff}}(t_1, t_2) \equiv \mathbf{R}_{\mathbf{ff}}(t_2 - t_1)$, given, respectively, by:

$$\begin{aligned} &\boldsymbol{\mu}_{\mathbf{f}} = \mathrm{E}\left\langle \mathbf{f}(t) \right\rangle; \\ &\mathbf{R}_{\mathbf{ff}}(t_2 - t_1) = \mathbf{R}_{\mathbf{ff}}(\tau) = \mathrm{E}\left\langle \mathbf{f}(t_1) \mathbf{f}^T(t_2) \right\rangle - \boldsymbol{\mu}_{\mathbf{f}} \, \boldsymbol{\mu}_{\mathbf{f}}^T \end{aligned} \tag{5a,b}$$

where t_1 and t_2 are two generic time instants and $E\langle \cdot \rangle$ denotes the stochastic average operator.

The input process $\mathbf{f}(t)$ can be conveniently split as sum of two terms, i.e.:

$$\mathbf{f}(t) = \boldsymbol{\mu}_{\mathbf{f}} + \tilde{\mathbf{X}}_{\mathbf{f}}(t) \tag{6}$$

where $\boldsymbol{\mu}_{\mathbf{f}} = \mathrm{E}\langle \mathbf{f}(t) \rangle$ is a deterministic vector denoting the mean-value of the excitation, whereas $\tilde{\mathbf{X}}_{\mathbf{f}}(t)$ is a zero-mean stationary multi-correlated Gaussian random process. Since the addition of a deterministic function has no influence on the autocorrelation function of a stochastic process, the following relationship holds:

$$\mathbf{R}_{\tilde{\mathbf{X}}_{\mathbf{f}} \tilde{\mathbf{X}}_{\mathbf{f}}}(\tau) = \mathrm{E}\left\langle \tilde{\mathbf{X}}_{\mathbf{f}}(t_1) \tilde{\mathbf{X}}_{\mathbf{f}}^T(t_2) \right\rangle \equiv \mathbf{R}_{\mathbf{ff}}(\tau). \tag{7}$$

The zero-mean stationary multi-correlated Gaussian random process $\tilde{\mathbf{X}}_{\mathbf{f}}(t)$ is completely characterized by the correlation function matrix $R_{\tilde{\mathbf{X}}_{\mathbf{f}} \tilde{\mathbf{X}}_f}(\tau)$ or, alternatively, by the power spectral density (*PSD*) function matrix:

$$\mathbf{S}_{\tilde{\mathbf{X}}_{\mathbf{f}} \tilde{\mathbf{X}}_{\mathbf{f}}}(\omega) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(-\mathrm{i}\omega\tau) \, \mathbf{R}_{\tilde{\mathbf{X}}_{\mathbf{f}} \tilde{\mathbf{X}}_{\mathbf{f}}}(\tau) \, \mathrm{d}\tau \tag{8}$$

where $i = (-1)^{1/2}$ denotes the imaginary unit.

2.2 *Stationary stochastic response in the frequency domain*

In view of the linearity of the structural system, the stochastic response to the stationary multi-correlated Gaussian random process $\mathbf{f}(t)$ is Gaussian too (Lutes & Sarkani 1997).

Based on the decomposition (6) of the input vector process $\mathbf{f}(t)$, the stochastic response can be split as follows:

$$\mathbf{u}(\boldsymbol{\alpha}, t) = \boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha}) + \tilde{\mathbf{U}}_{\mathbf{u}}(\boldsymbol{\alpha}, t) \tag{9}$$

where $\boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha}) = E\langle \mathbf{u}(\boldsymbol{\alpha}, t) \rangle$ denotes the mean-value vector; $\tilde{\mathbf{U}}_{\mathbf{u}}(\boldsymbol{\alpha}, t)$ is the zero-mean stationary Gaussian stochastic response vector process due to the random excitation $\tilde{\mathbf{X}}_{\mathbf{f}}(t)$.

The mean-value of the stationary response process is given by:

$$\boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha}) = \mathbf{K}^{-1}(\boldsymbol{\alpha}) \boldsymbol{\mu}_{\mathbf{f}} \tag{10}$$

where $\boldsymbol{\mu}_{\mathbf{f}}$ is the mean-value of the input process.

The correlation and *PSD* function matrices of the vector $\tilde{\mathbf{U}}_{\mathbf{u}}(\boldsymbol{\alpha}, t)$ coincide with those pertaining to the response vector process $\mathbf{u}(\boldsymbol{\alpha}, t)$. Furthermore, it is well-known that, after performing the projection into the modal subspace through Eq. (2), the *PSD* function matrix of the response, is related to the *PSD* function matrix of the zero-mean stationary Gaussian stochastic input, $\mathbf{S}_{\tilde{\mathbf{X}}_{\mathbf{f}} \tilde{\mathbf{X}}_{\mathbf{f}}}(\omega)$, by means of the following relationship (Lutes & Sarkani 1997):

$$\mathbf{S}_{\mathbf{uu}}(\boldsymbol{\alpha}, \omega) = \boldsymbol{\Phi}_0 \, \mathbf{H}^*(\boldsymbol{\alpha}, \omega) \mathbf{S}_{\tilde{\mathbf{X}}_{\mathbf{p}} \tilde{\mathbf{X}}_{\mathbf{p}}}(\omega) \mathbf{H}^T(\boldsymbol{\alpha}, \omega) \boldsymbol{\Phi}_0^T \tag{11}$$

where the asterisk means complex conjugate; $\mathbf{\Phi}_0$ is the modal matrix of the nominal structural system obtained by solving the eigenproblem (3); $S_{\tilde{\mathbf{X}}_p\tilde{\mathbf{X}}_p}(\omega)=\mathbf{\Phi}_0^{\mathrm{T}}\,S_{\tilde{\mathbf{X}}_\mathbf{f}\tilde{\mathbf{X}}_\mathbf{f}}(\omega)\,\mathbf{\Phi}_0$ is the *PSD* function matrix of the modal input vector process $\mathbf{p}(t)=\mathbf{\Phi}_0^{\mathrm{T}}\mathbf{f}(t)$ and $H(\alpha,\omega)$ is the modal *frequency response function* (*FRF*) matrix also referred to as *transfer function*, defined as:

$$\mathbf{H}(\boldsymbol{\alpha},\omega)=\left[-\omega^2\,\mathbf{I}_m+\mathrm{i}\omega\mathbf{\Xi}+\mathbf{\Omega}^2(\boldsymbol{\alpha})\right]^{-1}. \tag{12}$$

Once, the *PSD* function matrix, $\mathbf{S_{uu}}(\boldsymbol{\alpha},\boldsymbol{\omega})$, is known (see Eq. (11)), the covariance matrix of the random response can be evaluated as:

$$\mathbf{\Sigma_{uu}}(\boldsymbol{\alpha})=\int_{-\infty}^{\infty}\mathbf{S_{uu}}(\boldsymbol{\alpha},\omega)\,\mathrm{d}\omega. \tag{13}$$

In conclusion, the probabilistic characterization of the stationary Gaussian random response process in the frequency domain involves the inverse of the parametric stiffness matrix (see Eq. (10)) and the modal *FRF* matrix (see Eq. (12)) which in turn requires the inversion of a parametric frequency-dependent matrix.

3 RATIONAL SERIES EXPANSION

3.1 *Approximate inverse of the stiffness matrix*

It is assumed that the stiffness matrix $\mathbf{K}(\boldsymbol{\alpha})$ of a linearly-elastic structure can be expressed as a linear function of the uncertain parameters:

$$\mathbf{K}(\boldsymbol{\alpha})=\mathbf{K}_0+\Delta\mathbf{K}(\boldsymbol{\alpha})=\mathbf{K}_0+\sum_{i=1}^{r}\mathbf{K}_i\,\alpha_i \tag{14}$$

where $\mathbf{K}_0=\mathbf{K}(\boldsymbol{\alpha}_0)$ is a positive definite symmetric matrix representing the stiffness matrix of the nominal system introduced in the previous section; $\mathbf{K}_i=\partial\mathbf{K}(\boldsymbol{\alpha})/\partial\alpha_i|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0}$ denotes a $n\times n$ semi-positive symmetric matrix of rank p_i. According to Eq. (14), the stiffness matrix $\mathbf{K}(\boldsymbol{\alpha})$ results from a rank-r modification $\Delta\mathbf{K}(\boldsymbol{\alpha})$ of the nominal matrix $\mathbf{K}_0$.

The computation of the inverse of modified matrices is a crucial step in the solution of various engineering problems involving changes in the design parameters. By properly modifying the Neumann series expansion, recently the authors derived a novel series expansion, called *rational series expansion* (*RSE*), which provides an approximate explicit expression of the inverse of an invertible matrix with a rank-r modification. The starting point to derive the *RSE* is the decomposition of the $n\times n$ matrix $\mathbf{K}_i$ in Eq. (14) as sum of n rank-one matrices, i.e.:

$$\mathbf{K}_i=\sum_{\ell=1}^{n}\mathbf{k}_i^{(\ell)}\mathbf{i}^{(\ell)\mathrm{T}},\quad(i=1,2\cdots r) \tag{15}$$

where $\mathbf{k}_i^{(\ell)}$ is the ℓ-th column of $\mathbf{K}_i$ and $\mathbf{i}^{(\ell)}$ is a vector of order n containing zeros except the ℓ-th entry which is equal to 1. Then, the stiffness matrix of the structural system with r uncertain parameters (Eq. (14)) can be recast as:

$$\mathbf{K}(\boldsymbol{\alpha})=\mathbf{K}_0+\sum_{i=1}^{r}\alpha_i\left[\sum_{\ell=1}^{n}\mathbf{k}_i^{(\ell)}\mathbf{i}^{(\ell)\mathrm{T}}\right]. \tag{16}$$

Based on Eq. (16) and modifying the Neumann series expansion, the authors derived the *RSE* which yields the following approximate explicit expression of the inverse of the stiffness matrix (Muscolino & Sofi 2012a, Muscolino & Sofi 2012b, Muscolino et al. 2012):

$$\begin{aligned}\mathbf{K}^{-1}(\boldsymbol{\alpha})&=\left[\mathbf{K}_0+\sum_{i=1}^{r}\sum_{\ell=1}^{n}\alpha_i\,\mathbf{k}_i^{(\ell)}\mathbf{i}^{(\ell)T}\right]^{-1}\\&\approx\mathbf{K}_0^{-1}-\sum_{i=1}^{r}\sum_{\ell=1}^{n}\frac{\alpha_i}{1+\alpha_i\,d_{i\ell}}\mathbf{D}_{i\ell}\end{aligned} \tag{17}$$

where only first-order terms are retained being $|\alpha_i|\ll 1$. In Eq. (17), the following quantities appear:

$$d_{i\ell}=\mathbf{i}^{(\ell)T}\mathbf{K}_0^{-1}\mathbf{k}_i^{(\ell)};\quad\mathbf{D}_{i\ell}=\mathbf{K}_0^{-1}\mathbf{k}_i^{(\ell)}\mathbf{i}^{(\ell)T}\mathbf{K}_0^{-1}. \tag{18a,b}$$

Notice that Eq. (17) holds if and only if the following conditions are satisfied $|\alpha_i d_{i\ell}|<1$.

3.2 *Modal frequency response function matrix*

Upon substitution of the decomposition of the stiffness matrix given by Eq. (16), the spectral matrix of the structural system with uncertain parameters takes the following form:

$$\mathbf{\Omega}^2(\boldsymbol{\alpha})=\mathbf{\Omega}_0^2+\sum_{i=1}^{r}\alpha_i\left[\sum_{\ell=1}^{n}\mathbf{w}_i^{(\ell)}\,\mathbf{v}^{(\ell)\mathrm{T}}\right] \tag{19}$$

where

$$\mathbf{w}_i^{(\ell)}=\mathbf{\Phi}_0^{\mathrm{T}}\mathbf{k}_i^{(\ell)};\quad\mathbf{v}^{(\ell)\mathrm{T}}=\mathbf{i}^{(\ell)\mathrm{T}}\mathbf{\Phi}_0. \tag{20a,b}$$

Introducing Eq. (19) into Eq. (12), the *FRF* matrix can be recast as:

$$\mathbf{H}(\boldsymbol{\alpha},\omega)=\left[\mathbf{H}_0^{-1}(\omega)+\sum_{i=1}^{r}\sum_{\ell=1}^{n}\alpha_i\,\mathbf{w}_i^{(\ell)}\mathbf{v}^{(\ell)T}\right]^{-1} \tag{21}$$

where $\mathbf{H}_0(\omega)$ is the *FRF* matrix of the nominal structural system, given by:

$$\mathbf{H}_0(\omega)=\left[-\omega^2\,\mathbf{I}_m+\mathrm{i}\,\omega\mathbf{\Xi}+\mathbf{\Omega}_0^2\right]^{-1}. \tag{22}$$

For the nominal systems here studied the matrix $\mathbf{H}_0(\omega)$ is diagonal. Conversely, the *FRF* matrix $\mathbf{H}(\boldsymbol{\alpha},\omega)$ in Eq. (21) (or Eq. (12)) is not diagonal since, as already mentioned, the spectral matrix $\mathbf{\Omega}^2(\boldsymbol{\alpha})$ in Eq. (19) is a full matrix. This implies that in

order to determine the matrix $\mathbf{H}(\boldsymbol{\alpha},\omega)$, the inverse of a frequency-dependent parametric matrix has to be performed.

In this regard, it is useful to observe that the decomposition (16) of the stiffness matrix allows to express the deviation of the *FRF* matrix with respect to the nominal value as sum of $r \times n$ modifications of rank one, as shown in Eq.(21). Thus, by applying the *RSE* (Muscolino & Sofi 2012a, Muscolino & Sofi 2012b, Muscolino et al. 2012), the following approximate explicit expression of the *FRF* matrix is obtained:

$$\mathbf{H}(\boldsymbol{\alpha},\omega) = \mathbf{H}_0(\omega) - \sum_{i=1}^{r}\sum_{\ell=1}^{n} \frac{\alpha_i}{1+\alpha_i\, b_{i\ell}(\omega)}\, \mathbf{B}_{i\ell}(\omega) \tag{23}$$

where the following complex quantities have been introduced:

$$\begin{aligned} b_{i\ell}(\omega) &= \mathbf{v}^{(\ell)T}\mathbf{H}_0(\omega)\,\mathbf{w}_i^{(\ell)}; \\ \mathbf{B}_{i\ell}(\omega) &= \mathbf{H}_0(\omega)\,\mathbf{w}_i^{(\ell)}\mathbf{v}^{(\ell)T}\mathbf{H}_0(\omega). \end{aligned} \tag{24a,b}$$

Equation (23) holds if and only if the following conditions are satisfied:

$$\left\| \alpha_i\, b_{i\ell}(\omega) \right\| < 1 \tag{25}$$

where the symbol $||\bullet||$ means modulus of $\bullet$.

4 SENSITIVITY ANALYSIS OF THE STATIONARY STOCHASTIC RESPONSE

The main aim of the present study is to perform a sensitivity analysis of the probabilistic characteristics of the random response of structures with uncertain stiffness properties under stationary Gaussian random excitation in the frequency domain.

The sensitivity of the generic scalar response quantity $R(\boldsymbol{\alpha})$ to the i-th structural parameter α_i is expressed, by definition, as the partial derivative of $R(\boldsymbol{\alpha})$ with respect to α_i evaluated at $\boldsymbol{\alpha} = \boldsymbol{\alpha}_0$, i.e. $\partial R(\boldsymbol{\alpha})/\partial \alpha_i | = \boldsymbol{\alpha}_0$.

In this section, the sensitivities of both the mean-value and *PSD* of the random response to the uncertain parameters α_i are derived in closed-form by direct differentiation of the explicit expressions of $\boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha})$ and $\mathbf{S}_{\mathbf{uu}}(\boldsymbol{\alpha},\omega)$ obtained by applying the *RSE*.

The closed-form approximate inverse of the stiffness matrix $\mathbf{K}(\alpha)$ and *FRF* matrix $\mathbf{H}(\boldsymbol{\alpha},\omega)$ obtained in the previous sections by applying the *RSE* allow to derive explicit expressions of the mean–value, $\boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha})$, and *PSD* matrix, $\mathbf{S}_{\mathbf{uu}}(\boldsymbol{\alpha},\omega)$, of the stationary random response (see Eqs. (10) and (11)). Indeed, substituting Eq. (17) into Eq. (10), the following explicit approximate expression of the mean value vector is obtained

$$\boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha}) = \mathbf{K}^{-1}(\boldsymbol{\alpha})\,\boldsymbol{\mu}_{\mathbf{f}} \approx \boldsymbol{\mu}_{\mathbf{u},\mathbf{0}} - \sum_{i=1}^{r}\sum_{\ell=1}^{n} \frac{\alpha_i}{1+\alpha_i\, d_{i\ell}}\, \mathbf{D}_{i\ell}\,\boldsymbol{\mu}_{\mathbf{f}} \tag{26}$$

where $\boldsymbol{\mu}_{\mathbf{u},\mathbf{0}} = \boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha})|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} = \mathbf{K}_0^{-1}\boldsymbol{\mu}_{\mathbf{f}}$ is the nominal mean-value vector.

The influence of the i-th uncertain parameter α_i on the mean-value of the response can be investigated by evaluating the sensitivity of $\boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha})$ to α_i $(i = 1,2,\ldots,r)$ through direct differentiation of Eq. (26) which yields the following explicit expression:

$$\left.\frac{\partial \boldsymbol{\mu}_{\mathbf{u}}(\boldsymbol{\alpha})}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} = -\sum_{\ell=1}^{n}\left[\frac{1}{\left(1+\alpha_i d_{i\ell}\right)^2}\right]_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} \mathbf{D}_{i\ell}\,\boldsymbol{\mu}_{\mathbf{f}}. \tag{27}$$

Similarly, substituting Equation (23) into Eq. (11) the *PSD* matrix of the random response process $\mathbf{S}_{\mathbf{uu}}(\boldsymbol{\alpha},\omega)$ is obtained in closed-form and the explicit expression of the sensitivity to the i-th uncertain parameter α_i $(i = 1,2,\ldots,r)$ can be derived analytically by direct differentiation, i.e.:

$$\begin{aligned} &\left.\frac{\partial \mathbf{S}_{\mathbf{uu}}(\boldsymbol{\alpha},\omega)}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} = \\ &= \boldsymbol{\Phi}_0 \left.\frac{\partial \mathbf{H}^*(\boldsymbol{\alpha},\omega)}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} \mathbf{S}_{\hat{\mathbf{X}}_p\hat{\mathbf{X}}_p}(\omega)\,\mathbf{H}^T(\boldsymbol{\alpha},\omega)\boldsymbol{\Phi}_0^T \\ &+\boldsymbol{\Phi}_0\mathbf{H}^*(\boldsymbol{\alpha},\omega)\mathbf{S}_{\hat{\mathbf{X}}_p\hat{\mathbf{X}}_p}(\omega) \left.\frac{\partial \mathbf{H}^T(\boldsymbol{\alpha},\omega)}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} \boldsymbol{\Phi}_0^T \end{aligned} \tag{28}$$

where $\mathbf{H}(\boldsymbol{\alpha},\omega)$ is given by Eq. (23) and

$$\left.\frac{\partial \mathbf{H}(\boldsymbol{\alpha},\omega)}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} = -\sum_{\ell=1}^{n}\left[\frac{1}{\left(1+\alpha_i b_{i\ell}(\omega)\right)^2}\right]_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} \mathbf{B}_{i\ell}(\omega). \tag{29}$$

Finally, the sensitivities of the covariance matrix of the random response, $\boldsymbol{\Sigma}_{\mathbf{uu}}(\boldsymbol{\alpha})$, to the uncertain parameters can be determined straightforwardly from Eq. (28) as:

$$\left.\frac{\partial \boldsymbol{\Sigma}_{\mathbf{uu}}(\boldsymbol{\alpha})}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} = \int_{-\infty}^{\infty} \left.\frac{\partial \mathbf{S}_{\mathbf{uu}}(\boldsymbol{\alpha},\omega)}{\partial \alpha_i}\right|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} \mathrm{d}\omega. \tag{30}$$

The above explicit expressions of the sensitivities enable designers to gain a deeper insight into the effects and relative importance of each stiffness parameter on structure's performance. Specifically, we may determine how the statistics of the random response change due to a given change in the stiffness parameters.

5 NUMERICAL APPLICATION

A very simple reasoning, based on the knowledge of sensitivities to the various uncertain parameters, allows to reduce the number of series terms in the *RSE* (23). Specifically, if for a given degree-of-freedom, sensitivity analysis shows that the variability of some

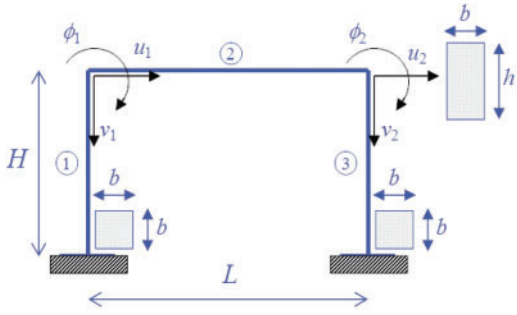

Figure 1. Portal frame with uncertain Young's moduli.

Table 1. Sensitivities of the variances of the nodal horizontal displacements with respect to α_i $(i = 1, 2, 3)$.

$\|\|\partial\sigma^2_{u_s}/\partial\sigma_i\|_{\alpha=\alpha_0}\|\|$	μ_1	μ_2
α_1	3.06809×10^{-7}	3.06809×10^{-7}
α_2	5.30716×10^{-8}	5.30716×10^{-8}
α_2	3.06809×10^{-7}	3.06809×10^{-7}

stiffness parameters does not affect the response, then the corresponding terms can be dropped from the *RSE*. This provides substantial computational savings especially when a large number of uncertain parameters is involved.

As an application, a portal frame with uncertain Young's moduli is considered (see Fig. 1). It is assumed that the elastic moduli of the beam and columns exhibit fluctuations $|\alpha_i| < 1$ around the nominal value $E_0 = 2.85 \times 10^7$ kN/m^2, i.e. $E_i = E_0(1 + \alpha_i)(i = 1, 2, 3)$. The geometrical properties of the portal frame are indicated in Figure 1, where $b = 0.30$ m, $h = 0.60$ m, $L = 3$ m and $H = 2$ m. Furthermore, each node possesses a lumped mass $M = 500$ kg. The modal damping ratio is set equal to $\xi = 0.05$.

The ground acceleration is modelled as a Tajimi Kanai process with *PSD* given by:

$$S(\omega) = S_W \frac{4\zeta_g^2\omega_g^2\omega^2 + \omega_g^4}{\left(\omega_g^2 - \omega^2\right) + 4\zeta_g^2\omega_g^2\omega^2} \tag{31}$$

where $S_W = 0.05$ m^2/s^3, $\zeta_g = 0.6$ and $\omega_g = 4\pi$ rad/s.

The sensitivity analysis provides information on response variability due to changes of Young's moduli in the beam and columns. The analysis is performed here by evaluating the sensitivities of the covariance matrix given by Eq. (30). In Table 1, the values of the sensitivities of the variances, $\sigma^2_{u_s}(\boldsymbol{\alpha})$, of the horizontal displacements, u_1 and u_2, with respect to the parameters α_1, α_2 and α_3 are reported.

Any response variable depending on the uncertain parameters can be expanded in the Taylor series about its nominal value. For small uncertainties, the first-order term of this expansion turns out to be the most significant contribution to the deviation of the response from the nominal value due to the variability of the model parameters. Such term is given by the summation of the first-order partial derivatives of the response with respect to the uncertain parameters multiplied by the uncertainties. Then, a percentage measure of the influence of a generic design variable on the response can be defined by introducing the so-called *coefficient of sensitivity* that measures the global variability of the response with respect to its nominal value. In particular, for the variance of the s-th DOF the *coefficient of sensitivity* with respect to the i-th uncertain parameter can be defined as:

$$\varepsilon_{i,\sigma^2_{u_s}}\% = \frac{1}{\sigma^2_{u_s}(\boldsymbol{\alpha}_0)}\left(\frac{\partial\sigma^2_{u_s}(\boldsymbol{\alpha})}{\partial\alpha_i}\right)\Bigg|_{\boldsymbol{\alpha}=\boldsymbol{\alpha}_0} \Delta\alpha_i \times 100. \tag{31}$$

Table 2. Coefficients of sensitivity of the variances of the horizontal displacements with respect to α_i $(i = 1, 2, 3)$.

$\varepsilon_{i,\sigma^2_{u_s}}$ %	u_1	u_2
α_1	4.6%	4.6%
α_2	0.8%	0.8%
α_3	4.6%	4.6%

In Table 2, the coefficients of sensitivity for the variances of the horizontal displacements u_1 and u_2 with respect to the uncertain parameters α_i $(i = 1, 2, 3)$ are reported.

As expected, the variances of the horizontal displacements are sensitive to variations of the parameters α_1 and α_3, while they are almost unaffected by the variation of the parameter α_2.

The results provided by sensitivity analysis allow an efficient evaluation of the approximate *PSD* of the response by the *RSE* (see Eq. (11) and Eq. (23)). To assess the validity of sensitivity analysis outcomes, comparisons in terms of *PSD* function of the nodal horizontal displacement u_1, $S_{u_1}(\omega)$, are reported in Figures 2a–c.

In Figure 2a, the proposed estimate of the *PSD*, obtained by retaining all terms in the *RSE*, is contrasted with the exact one for $\alpha_i = \alpha = 0.05$ $(i = 1, 2, 3)$. For completeness, in the same plot the nominal *PSD* is also depicted.

Figure 2b shows a similar comparison where the proposed *PSD* is estimated by retaining in the *RSE* (see Eq. (23)) only the terms associated to the parameters resulting as the most influential for the selected response quantity from the preliminary sensitivity analysis (see Table 1), namely the parameters α_1 and α_3. By inspection of Figure 2b, it can be seen how the accuracy of the estimated *PSD* is not affected by neglecting the term associated to the parameter α_2. Further validation of the sensitivity analysis is provided considering another comparison among the *PSD* functions as reported in Figure 2c.

The proposed *PSD* of the horizontal displacement u_1 plotted in Figure 2c is evaluated by neglecting the

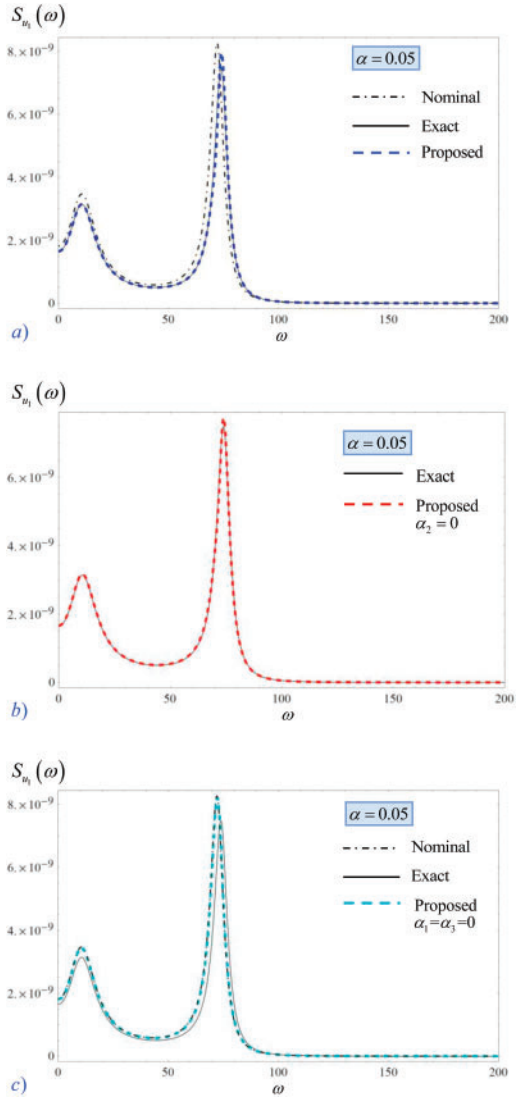

Figure 2. Comparison between the proposed estimate of the *PSD* function of u_1 and the exact one: a) retaining all terms in the *RSE* (see Eq. (23)); b) neglecting the term associated to α_2; c) neglecting the terms associated to α_1 and α_3.

terms associated to the parameters α_1 and α_3. Notice that the estimated *PSD* matches the nominal one, thus confirming the negligible influence of the parameter α_2 on the *PSD*, detected via sensitivity analysis.

6 CONCLUSIONS

Sensitivities give information about the variability of the response due to a change in a given design parameter and play an important role also in structural identification, optimization and anti-optimization problems.

In the paper, a novel procedure for deriving approximate explicit expressions of the sensitivities of the mean-value and covariance matrix of the stationary response of randomly excited structures subject to variations of the stiffness parameters has been presented. The proposed approach relies on the use of the so-called *RSE*, recently proposed by the authors for evaluating in approximate closed-form the inverse of an invertible matrix with a modification of rank r.

The present study has also focused on the usefulness of sensitivity analysis to improve the computational efficiency of the *RSE* which involves a summation over the fluctuating properties.

The accuracy and efficiency of the proposed procedure for sensitivity analysis of randomly excited structures has been demonstrated through numerical results concerning a frame structure with variability of the Young's moduli.

Semi-active control of structural systems with uncertainties using an unscented Kalman filter

M.S. Miah & E.N. Chatzi
Institute of Structural Engineering, ETH Zurich, Zurich, Switzerland

F. Weber
Empa, Structural Engineering Research Laboratory, Duebendorf, Switzerland

ABSTRACT: This work presents a novel semi-active control approach for the mitigation of vibrational response of structures. As is often the case for structural systems, the underlying mathematical/simulation model is not entirely deterministic due to uncertainties related to both the system properties as well as the noise content of the measured information. Therefore, in order to successfully monitor the system, it is essential to develop suitable algorithms that can incorporate dynamic feedback into the computation. In order to meet the aforementioned challenges, in the approach introduced herein a nonlinear joint state and parameter estimation algorithm is employed. The combination of an LQR controller with a linear Kalman Filter is already well established and is commonly known as Linear-Quadratic-Gaussian (LQG) control. In what follows the combination of a nonlinear filter equivalent, namely the Unscented Kalman Filter (UKF) with a Linear Quadratic Regulator (LQR) semi-active controller is numerically investigated. The proposed methodology is validated through two numerical applications, a first one assuming uncertain structural parameters, and a second one employing online tuning of the design parameter R.

1 INTRODUCTION

Over the past few decades smart materials, intelligent structures and emerging associated technologies have led to increasingly complex structural systems. As a result, the efficient design and precise monitoring of such systems are non-trivial tasks. Several techniques have in fact been developed involving the use of control strategies for the mitigation of vibrations (Weber & Boston 2011, Weber & Maslanka 2012, Preumont 2004). One of the inherent difficulties in the field of structural control is that in most cases the anticipated extreme event forces are not entirely known. Therefore, even though a controller might be optimally designed for some predefined type of input forces, in effect it may not be capable of handling a wider range of uncertain inputs. In order to eliminate such a drawback, this study investigates the applicability of an online system identification technique for the real-time updating of the control scheme. As shown later on, this leads to a nonlinear identification problem of joint state and parameter estimation (Chatzi et al. 2009). A novel structural control approach is proposed, combining the Unscented Kalman Filter (UKF) with an LQR controller. The UKF surfaced through the work of Julier & Uhlmann (1997) who introduced the Unscented Transform. Later on Merwe & Wan (2004) introduced the sigma-point Kalman filters (SPKF), a special class of which is the UKF, as an upgraded version of the Extended Kalman Filter (EKF). The performance of the UKF algorithm in real-time nonlinear identification problems has been verified by several studies (Chatzi & Smyth 2010, Xie & Feng 2011, Wu & Smyth 2007, Mariani & Ghisi 2007) noting its robustness against available alternatives.

In a previous study, Araki & Okada (2005) firstly perform parameter identification of an Acrobot system using the UKF, and an energy based control approach is proposed in a second, separate step. Bisgaard et al. (2010) have also employed a UKF filter for estimating the slung load states of a helicopter system. Marafioti (2010) explores the efficacy of the UKF and EKF within the context of Model Predictive Control (MPC) where simulation-based results prove the advantages of using the UKF as an alternative to the EKF. Rigatos (2011) demonstrates the use of Particle Filter and other nonlinear state estimation algorithms for industrial control applications using a reduced number of sensors. Aiming to achieve optimal control Wang (2011) combines nonlinear estimators with fuzzy control of nonlinear systems with general performance criteria.

Concerning the control approach utilized herein, the LQR controller is employed as one of the most commonly used and robust algorithms for mitigating structural vibration (Johnson & Erkus 2002, Rajamohan et al. 2011). However, the LQR controller is associated with two significant drawbacks. One concerns the full observation of the state vector. When this is

not possible, as is frequently the case due to a limited number of sensors, the LQR is combined with a Kalman Filter state estimator yielding the LQG control (Athans 1971). This is commonly performed for the case of linear systems, however not much work has dealt with combining the LQR with nonlinear filters (Jimenez et al. 2011, Gawronski 2008). An additional drawback is the selection of optimal weight matrices $\boldsymbol{Q}$ and $\boldsymbol{R}$. Conventionally, this is performed based on designer experience or the trial and error method. Several studies have tried to overcome this limitation and proposed an automated design usually based on evolutionary processes (Mobaieen et al. 2012, Coelingh et al. 1997). Li et al. (2008) propose a multi-objective evolutionary algorithm for selecting the optimal weight matrices. More interestingly Oral et al. (2010) propose an approach that is based on a mathematical formulation relying on the knowledge of the characteristics of the particular system. In the work presented herein, the online identification problem is appropriately formulated in order to regulate the optimal weight matrices in an online regime.

2 THE SHEAR FRAME SETUP

In order devise the envisioned control scheme, an online approach is devised based on feedback from measurements of structural response. A 5-storey shear frame is considered as the case study, relying on an actual experimental setup assembled on the uniaxial shaking table of the Structural Engineering laboratory in EMPA. The experimental setup (without controller) is shown in Figure 1. Each floor is assumed to have a mass of 5.95 kg. A non parametric simulation has been performed yielding the natural frequencies ($f_1 = 1.33$ Hz, $f_2 = 3.94$ Hz, $f_3 = 6.23$ Hz, $f_4 = 8.04$ Hz, $f_5 = 9.28$ Hz) and modal shapes of this test structure as well as the estimated damping. By synthesizing the results, an analytical model is additionally put together (physical model of the system). In formulating the simple model of only five degrees of freedom (dof), symmetry is taken into account. Additionally no rotation is considered for horizontal sections at the floor levels, i.e., the simplified model corresponds to a shear-type frame. The physical model is essentially the representation of the dynamic equation of motion of this 5 dof system.

$$\boldsymbol{M}_{sf}\ddot{x}(t)+\boldsymbol{C}_{sf}\dot{x}(t)+\boldsymbol{K}_{sf}x(t)=F(t) \tag{2.1}$$

where $\boldsymbol{M}_{sf}$ (5×5) is the mass matrix and $\boldsymbol{K}_{sf}$,$\boldsymbol{C}_{sf}$ are the associated stiffness and damping matrices. Due to the nature of the considered system, the mass matrix is assumed to be diagonal and the stiffness and damping matrices contain non-diagonal terms only in the case of consecutive storey dofs. It is clear that due to the number of simplifying assumptions the system matrices are not idealized. Nonetheless, the numerical simulation of the system using the identified matrices agrees well with the experimentally measured response.

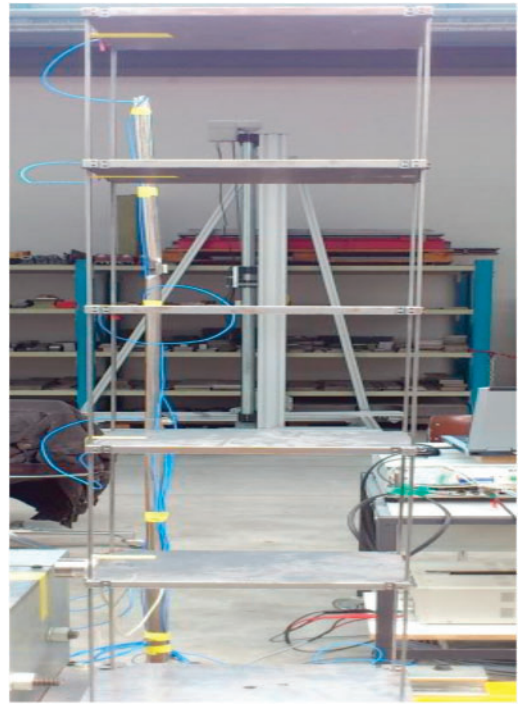

Figure 1. Experimental setup of 5-storey shear frame at EMPA.

In order to apply the framework proposed herein the system is brought into a state-space formulation. Equations 2.2 are known as the process (or system) and measurement (or observation) equations of the continuous system and can be easily derived from Equation 2.1.

$$\dot{x}(t)=A_c x(t)+B_c u(t) \;\;\&\;\; y(t)=C_c x(t)+D_c u(t) \tag{2.2}$$

where in the general case: $A_c[.]$ = system matrix $(n \times n)$, $B_c[.]$ = input matrix $(n \times p)$, $C_c[.]$ = output matrix $(m \times n)$, $D_c[.]$ = feed-forward matrix $(m \times p)$, $x(.)$ = state vector (R^n), $y(.)$ = output vector (R^m), $u(.)$ = input vector (R^p). The input vector $u(.)$ holds the exogenous input (ground excitation) and the actuator control force as appears in Equation 2.3.

$$u(t)=\begin{bmatrix} f_{cont}(t) \\ a_g(t) \end{bmatrix} \tag{2.3}$$

where $f_{cont}(t)$ = control force, $a_g(t)$ = exogenous input. In this study a_g is a harmonic excitation with a frequency chosen exactly equal to the first resonant frequency of the shear frame, $f_1 = 1.33$ Hz. The control force is provided by means of an actuator assumed to act horizontally on the first floor level. In order to calculate the control force, the full-state vector (displacement & velocity) needs to be fed to the controller. Using an appropriate integration algorithm,

the continuous system can be brought to its discrete equivalent:

$$x_{k+1} = Ax_k + Bu_k \quad \& \quad y_k = Cx_k + Du_k \tag{2.4}$$

3 THE LQR CONTROL STRATEGY

Complex structures such as bridges or high-rise buildings often incorporate systems for their monitoring and control. However, most real world structures come with inherent uncertainties related to their structural properties or even to the lack of knowledge concerning the loading involved. This renders the control task non trivial.

In this study, a semi-active control strategy based on the LQR is deployed for the shear frame presented earlier. A detailed concept of semi-active control, employing clipping of the active force, and its applications are studied by Weber & Boston (2011) and Lazar et al. (2012). Active control comes with several drawbacks. The most significant one is associated with the possibility of electrical power loss during an emergency event (i.e. earthquake, significant wind, etc.) in which case the control scheme is non-operational. In order to tackle this limitation, semi-active control strategies can be implemented.

The LQR is a well-known full-state feedback control algorithm, frequently met in the fields of structural dynamics and mechanical control. For reasons of completeness we provide here the basic form of the discrete-time quadratic strategy for a discrete LTI system of the form of Equation (2.4). This control strategy minimizes the cost-to-go function J defined in Equation 3.2.

$$J = \sum_{k=0}^{\infty} (x_k^T Q x_k + u_k^T R u_k) \tag{3.2}$$

The first part of this equation corresponds to the state response contribution whereas the second part reflects the contribution of the control force.

$$u_k = -K_{opt} x_k \tag{2.3}$$

where K_{opt} is the optimal closed-loop gain of the control law, which minimizes the performance index J by feeding in the state response. The minimization strictly depends on the optimal set of weight matrices $\boldsymbol{Q}$ & $\boldsymbol{R}$. The selected weight matrices must satisfy the following conditions; $\boldsymbol{Q}$ must be positive semi-definitive, $x_k^T Q x_k \geq 0$; $\boldsymbol{R}$ must be positive definitive, $u_k^T R u_k > 0$; and both must be symmetric. As already mentioned in section 1, the choice of optimal weight matrices $\boldsymbol{Q}$ & $\boldsymbol{R}$ is conventionally performed by trial and error or relying on the designer's experience. In this study a novel online approach is demonstrated for optimal tuning of the weight matrices based on the measured structural response. For further information on the LQR, the interested reader is referred to Anderson & Moore (1989).

4 THE UKF FOR NONLINEAR SYSTEM ESTIMATION

As aforementioned, the UKF algorithm was introduced in an effort to eliminate the computational drawbacks of the EKF, associated with linearizations and the calculation of Jacobians. The UKF models the state as a Gaussian random variable whose distribution can be approximated by a carefully chosen set of deterministic points (sigma points). These points capture the prior mean and covariance of the state and when propagated through the nonlinear function, provide the estimation of the posterior/transformed state. This process is known as the Unscented Transformation (UT) (Julier & Uhlmann 1997).The assumed process and observation functions are shown in Equations 4.1 and 4.2 where functions f, h can be nonlinear.

$$x_k = f(x_{k-1}, u_{k-1}) + w_{k-1} \tag{4.1}$$

$$y_k = h(x_k) + v_k \tag{4.2}$$

where w_{k-1} = process noise, v_{k-1} = measurement noise, assumed white, Gaussian.

The sigma points are calculated as follows:

$$x_k^a = \left[\hat{x}_{k-1}^a \quad \hat{x}_{k-1}^a + \sqrt{(L+\lambda)P_{k-1}^a} \quad \hat{x}_{k-1}^a - \sqrt{(L+\lambda)P_{k-1}^a} \right] \tag{4.3}$$

where L = state dimension, x_k^a = sigma point vector, augmented to account for the process noise dimension, λ = scaling parameter indicating the spread of the sigma points, P_{k-1}^a = covariance of the state. The sigma points are propagated through the process/system equation in a prediction step and, subsequently, the weighted estimate is updated in a correction step. The estimation of the posterior is performed by minimizing the error between the estimated and actually measured quantities. At this point, it is important to note for what follows, that the observations do not need to correspond to the full system state. In other words a limited number of sensors can be employed. For a deeper insight into the UKF, the interested reader is referred to Wan & Merwe (2001); Julier & Uhlmann (1997).

5 APPLICATIONS

5.1 *Calibration of "**Q**" and "**R**"*

The initial task of this work is to design an optimal LQR controller. As a preliminary step, and in order to obtain a better understanding of the problem at hand, the optimal selection of the weight matrices Q & R is numerically performed, by employing a number of different nonlinear optimization techniques in place of trial and error. These include (i) the Genetic Algorithm (GA) and (ii) Particle Swarm Optimization (PSO) (Kennedy & Eberhart 1995) which constitute evolutionary methods, and (iii) a gradient/algebraic

Table 1. Summary of the optimization techniques.

Algorithm	GA	PSO	CNO
Q/R	1082	1042	1097
Fitness Value	39.15	38.57	38.03
Time (sec)	2414.25	5822.24	29.64

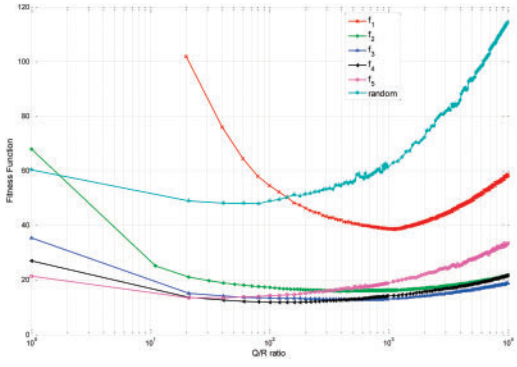

Figure 2. Fitness Function plot for a range of Q/R ratios.

approach for Constrained Nonlinear Optimization (CNO).

The test structure and the assumed loading is already described in Section 2. The fitness function f to be optimized aims at the minimization of the amplitude of response quantities for all five stories:

$$f = \sum_{i=1}^{5} \left\{ w_1 |x_i|_{\max} + w_2 |\dot{x}_i|_{\max} + w_3 |\ddot{x}_i|_{\max} \right\} \tag{5.1}$$

where w_1, w_2, w_3, are appropriate scaling factors. A summary of the results of the different optimization techniques and the corresponding calculation times are presented in Table 1. As noted in the figure, and is well established in the literature, the optimal pair depends only on the ratio Q/R since scaling the LQR cost function does not change the optimal control law. Additionally, it is obvious that the gradient based method requires considerably less computational effort than the GA and PSO schemes.

In Figure 2 the fitness function value is plotted for a range of plausible Q/R ratios given harmonic excitations of frequency equal to the structure's natural frequencies, as well as one random input. As is evident, the optimum lies in a valley-like space which clearly explains the faster convergence of the gradient based method against evolutionary ones.

It is obvious that as the nature of the simulated ground motion varies, the optimal point can be shifted, yielding different optimal Q & R configurations. This, in combination with the fact that the actual extreme event loading is generally unknown a-priori, confirms the need for the weight parameters to be tuned online. In Section 5.2 predefined values of the Q & R parameters are utilized for the controller, assuming an uncertain system, whereas in Section 5.3 the structure is assumed known and the Q & R are tuned online. In both cases limited sensor information is assumed. The required algorithms are programmed in MATLAB®/Simulink and the sampling frequency for the simulations is set to 200 Hz.

5.2 *Joint states and parameter estimation*

In this application the system's stiffness characteristics are assumed to be unknown. The goal is therefore the joint state & parameter estimation of the system based on limited sensor measurements, i.e. the state vector is only partially observed. Therefore in order to conduct the LQR control, a state estimator is required. When introducing the stiffnesses as unknowns, the problem becomes nonlinear. We therefore utilize the UKF as the state observer. The state vector is augmented to include all floor stiffnesses $k_1 \ldots k_5$, and the dimension of the state vector size is now 15:

$$x = \begin{bmatrix} x_1 & \ldots & x_5 & \dot{x} & \ldots & \dot{x}_5 & k_1 & \ldots & k_5 \end{bmatrix}^T \tag{5.2}$$

where, x = state vector, $x_1 \ldots x_5$ = 1st–5th floor displacement, $\dot{x}_1 \ldots \dot{x}_5$ = 1st–5th floor velocity, and $k_1 \ldots k_5$ = 1st–5th floor stiffness.

$$A = \begin{bmatrix} 0_{5\times5} & \mathrm{I}_{5\times5} & 0_{5\times5} \\ -M_{sf}^{-1}K_{ident} & -M_{sf}^{-1}C_{sf} & 0_{5\times5} \\ 0_{5\times5} & 0_{5\times5} & 0_{5\times5} \end{bmatrix} \tag{5.3}$$

where $0_{5\times5}$ = null matrix, $\mathrm{I}_{5\times5}$ = unit matrix.

$$B = \begin{bmatrix} 0_{1\times5} & m_1^{-1} & 0 & 0 & 0 & 0 & 0_{1\times5} \\ 0_{1\times5} & -1 & -1 & -1 & -1 & -1 & 0_{1\times5} \end{bmatrix}^T \tag{5.4}$$

where $0_{1\times5}$ = null matrix (1×5).

The need for an online update of the stiffness matrix stems not only from a possible incomplete knowledge of the properties, but also from changes that might occur during the life of a structure owing to deterioration, damage, loosening of bearings, etc. The analysis is performed for a duration of 10sec for a harmonic input of 1.33 Hz (1st natural frequency). In this example, the weight matrices Q & R are considered preselected and set equal to Q = 5e-8, R = 7.5e-10. We assume that only acceleration signals from floors 1, 3 and 5 are observed, and the UKF is able to reconstruct the full state estimate. A process noise of 0.5% RMS noise to signal ratio is set, indicating confidence in the physical state-space model and a measurement noise of 7% RMS is added to the simulated, "clean" response signal which is generated using an accurate 4th order Runge-Kutta scheme. The discrete state space formulation is carried out using a 2nd order Taylor expansion approximation

Table 2. Summary of the identified stiffness.

Parameters	Original	Identified	Error (%)
k_1	481.30	491.10	2.00
k_2	545.50	514.90	5.93
k_3	554.10	558.40	0.77
k_4	544.70	571.90	4.76
k_5	553.00	541.60	2.10

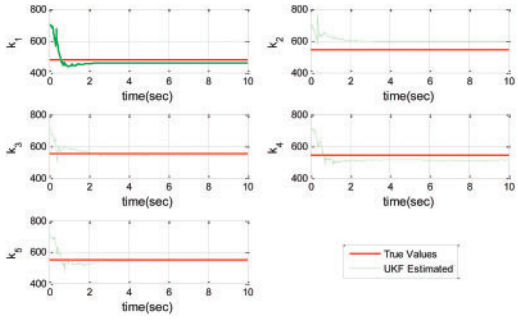

Figure 3. Identified/estimated stiffness vs. the true values.

for the matrix exponential formula applied on $A_c dt$, where dt is the sampling time & $A_c\,dt$ is convergent. This simplified assumption keeps the process online.

The summary of the converged identified stiffness values is presented in Table 2. Also a graphical representation over time is provided in Figure 3. The method seems to effectively estimate the unknown parameters despite an initial guess of 700 units, which is about 30% off the actual values. It is worth noting that even as the order of the system increases (for more dofs), the sigma point evaluation can be carried out in parallel computations and it is hence possible to maintain the computational time to a low.

It should be stated, that convergence is affected by the assumed levels of measurement noise and by the initial choice of covariance for the state. As the problem is nonlinear, the choice of initial covariance for the constant parameters has to lie within a reasonable range or the algorithm might be disoriented early on in the estimation process.

Additionally, Figure 4 displays the results for the first floor displacement. The blue line is the real response from the online control (stiffness unknown a-priori), the red line is the UKF estimate (quite close), and the green line is what the controlled response would be if the stiffness was known a-priori (fixed k value).

The nature of observations is an important factor. For instance in this example additional displacement info would improve the estimation by mitigating integration issues stemming from the analog to digital system conversion. These issues will be the topic of more extended research.

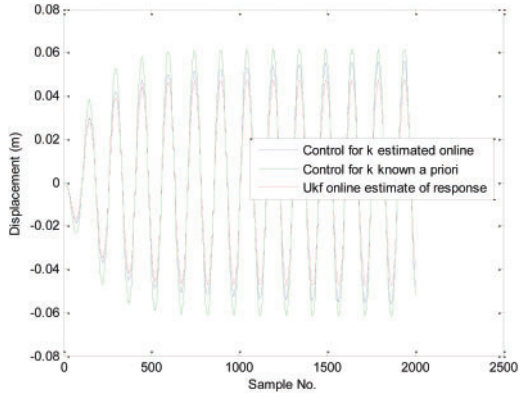

Figure 4. The top floor online response i) as would actually occur for online control, ii) as would occur is k was known a-priori and iii) as is estimated from the UKF in an online manner.

5.3 *Online Estimation of weight factor "**R**" assuming known properties*

As a next step, it is now assumed that the structural characteristics are this time known a-priori, while the optimal control force weight factor R is unknown. As already mentioned Q & R are linearly dependent and therefore only one of the two needs to be defined as a parameter, otherwise the system would become unobservable. The aim is to tune the control force in an online manner. For this purpose, the state vector is augmented to a dimension of 11, so as to include the weight factor.

$$x = \left[x_1 \quad . \quad . \quad . \quad x_5 \quad \dot{x}_1 \quad . \quad . \quad . \quad \dot{x}_5 \quad R\right]^T$$

The system matrices are again appropriately formulated. The estimation of R is achieved by defining an additional set of observations, other than the floor accelerations. These are "*artificial, zero observations*" of the five first states, requiring that the corresponding floor displacements are minimized, i.e., $x_i(t) = 0, i = 1 \ldots 5$. For these artificial observations a relatively sizeable measurement noise is assumed; namely 30% RMS noise to signal ratio. The remaining noise levels are the same as before, as is the input ground excitation. Since R is now a design variable, the control loop has to be checked for stability in every update of its value. Therefore, the computational time now increases and, unless this process is carried out in parallel, the control scheme is not online. It could however become near-online by enforcing the update of R at intervals scarcer than the time step. Further research will investigate this.

As shown in Figure 5, the proposed approach indeed yields a reduced vibration response as compared to the empirically calibrated equivalent.

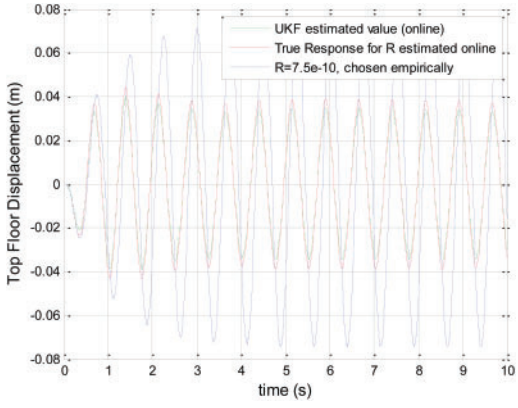

Figure 5. The top floor online response as would actually occur for online control (red), as would occur is R was empirically chosen a-priori (blue) and as is estimated from the UKF in an online manner (green).

6 CONCLUSION

This paper proposes a framework for the online tuning of an LQR controller by employing a nonlinear filter, namely the UKF, as the state estimation algorithm. Three main applications are presented; firstly the weight matrices *Q & R* are calibrated in an offline mode; then joint state and parameter estimation is achieved, corresponding to a system with uncertainties; and finally the control parameter *R* is tuned in an online manner. The overall results of the simulated performance of the shear frame confirm that the proposed approach provides a promising adaptive control scheme. In future work, the sensitivity of system to noise and the coupling of joint state & parameter estimation with the tuning of the control parameter *R* will be explored.

Guided waves for stress identification

A. Pau, G. Ruta & F. Vestroni
Department of Structural and Geotechnical Engineering, "Sapienza" University, Rome, Italy

ABSTRACT: The measurement of stress in structural components would be of great value in engineering. Here, a numerical model is set up to expound experimental tests on a prestressed plate in the light of acoustoelasticity and in view of the formulation of an inverse problem, in which response is measured and stress is identified. The theory of acoustoelasticity is used to describe wave propagation in a prestressed guided wave, accounting for selected sources of nonlinearities. In particular, finite strains are used, and energy is written as a third-order function of the strains. The experiments are performed on a rectangular plate held by a machine, inducing prestress in the plate and applying in-plane impulsive loadings by an instrumented hammer. The time histories of both loading and dynamic response are recorded and the variation of the relevant dynamic response quantities are investigated. The aim of the experimental tests is to observe the transmission of waves in the plate, relating the prestress to the variation of the propagation speed of waves.

1 INTRODUCTION

This study aims at developing techniques of stress evaluation in structural elements. The starting point for a numerical and experimental analysis is that the speed of wave propagation varies as a function of the stress in the material. Acoustoelasticity (Murnaghan 1951, Cantrell 2004) is the basic theory relating the change of wave speed to the initial stress in the medium. The early studies on this phenomenon assume that the body is hyperelastic, and finite strain acting on the natural (unstressed and unstrained) state causes prestress. Waves of small amplitude are then superimposed on the strained initial state (Hughes & Kelly 1953, Egle & Bray 1976, Pao & Gamer 1985). The velocity of waves changes as a function of both the state of stress and the kind of propagating wave, e.g. plane, shear, Rayleigh, Lamb waves (Chen & Wilcox 2007, Gokhale 2007). Here, acoustoelasticity is applied to investigate the phenomenon in the case of a plane strip of solid (Figure 1) acting as a waveguide for waves propagating in longitudinal direction. The same problem is examined also with experimental tests.

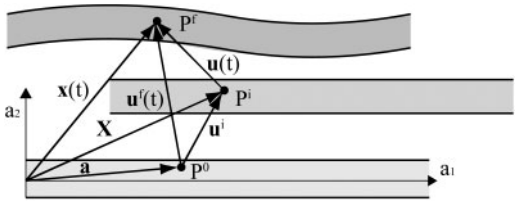

Figure 1. Natural (0), initial (i) and final (f) configurations.

2 ANALYTICAL MODEL

A longitudinally unbounded strip with two free surfaces reaches its initial state by stretching the solid parallel to its length. Three different configurations are considered (Figure 1). In the natural configuration, free of stress and strain, the material point P is retrieved by the vector **a**, with components a_1 and a_2. Physical quantities in this configuration are referred to by the superscript "0". The initial configuration is stressed and strained, and the vector **X**, with components X_1 and X_2, defines the position of P as follows:

$$\mathbf{X} = \mathbf{a} + \mathbf{u}^i \tag{1}$$

In (1) $\mathbf{u}^i$ is the displacement vector from the natural to the initial state. The physical quantities of the latter are referred to by the superscript "*i*". We assume that this initial state is attained by a static homogeneous transformation $\mathbf{u}^i = \mathbf{A}\mathbf{a}$. The final configuration is due to a dynamic disturbance superimposed on the initial state. The vector **x**, with components x_1 and x_2, defines the position of P as follows:

$$\mathbf{x}(t) = \mathbf{a} + \mathbf{u}^i + \mathbf{u}(t) = \mathbf{X} + \mathbf{u}(t) \tag{2}$$

In (2) $\mathbf{u}(t)$ represents the displacement from the initial to the final state, the physical quantities of which are referred to by the superscript "*f*". We may write:

$$\mathbf{u}(t) = \mathbf{u}^f(t) - \mathbf{u}^i \tag{3}$$

The tensor of finite strains is:

$$\mathbf{E}^f = \frac{1}{2}\left(\nabla_a \mathbf{u}^{f\,T} + \nabla_a \mathbf{u}^f + \nabla_a \mathbf{u}^{f\,T} \nabla_a \mathbf{u}^f\right) \tag{4}$$

In (4) the derivatives are calculated with respect to the position **a** in the natural configuration.

Let us denote by **S** the first Piola-Kirchhoff stress tensor. In the initial frame of reference, and in the absence of body forces, the equations of motion are:

$$\mathrm{div}_{\mathbf{a}}\mathbf{S} = \rho^{i}\ddot{\mathbf{u}} \tag{6}$$

since $\mathbf{u}^i$ is a static displacement. The strain energy Φ of a hyperelastic and isotropic material can be written as a power series of the invariants I_1, I_2 and I_3 of the strain tensor $\mathbf{E}^f$. Neglecting infinitesimals of order higher than three in Φ, it is:

$$\Phi = \frac{1}{2}(\lambda + 2\mu)I_1^2 + 2\mu I_2^2 + \frac{l+2m}{3}I_1^3 + 2mI_1I_2 + nI_3 \tag{7}$$

where λ and μ are the Lamé constants and l, m, n are the Murnaghan constants. Since in a plane state of strain $I_3 = 0$, the constitutive relation expressing the first Piola-Kirchhoff stress tensor as a derivative of the strain energy (7) is:

$$\mathbf{S} = \mathbf{F}\frac{\partial\Phi}{\partial\mathbf{E}^f} = \mathbf{F}\{[\lambda I_1 + lI_1^2 + (2m\text{-}n)I_2]\mathbf{I} + \\ + [2\mu + (2m-n)I_1]\mathbf{E}^f + n\ co(\mathbf{E}^f)\} \tag{8}$$

where *co* stands for the cofactor of the indicated matrix and $\mathbf{F} = \nabla_{\mathbf{a}}\mathbf{x}$. To obtain a displacement formulation of the equations of motion in the initial frame of reference, equation (8) is substituted into (6). The speed of wave propagation is then obtained by substituting a given harmonic wave for $\mathbf{u}(t)$ in the equation of motion (6), which gives an expression depending on the initial state of prestress and on Lamé and Murnaghan constitutive constants.

3 EXPERIMENTAL TESTS

The experimental tests have been performed on a steel plate 1 m in length, 10 cm in height and 1 cm in thickness. As a first step, the constitutive relationship for the material was determined by performing a static stress-strain test on a specimen cut from the plate. The elastic range was defined on the basis of the amplitude of the unloading branch (about up to 500 N/mm^2). A curve fitting of the experimental stress-strain relationship to straight lines in four strain ranges enables to evaluate the percent variations of the elastic modulus in the related elastic range (2, 5, 15, 43%). Two kinds of dynamic tests were performed on the plate, according to the sketches of Figure 2. The time-history of the

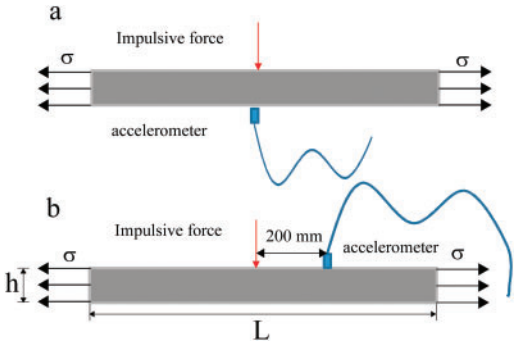

Figure 2. Sketch of the dynamic tests.

dynamic response to an impulsive force was measured on the opposite side of the plate with respect to the excitation (test a) and on the same side of the plate (test b). The impulsive force was applied by means of an instrumented hammer, the time-history of which was also measured, revealing a frequency range extending up to 15 kHz. Both tests were repeated in three different states of prestress, corresponding to tensile stresses of 200, 300 and 400 N/mm^2, respectively, and the related wave speed was observed. These tests showed that, while it is difficult to observe the variation of *p* wave speed within this range of prestress and frequency band (tests a), the transverse waves measured in tests b are more sensitive to a variation in the state of stress. These results are in agreement with the results of the developed analytical model (Gokhale, 2007) and provide a basis for the development of techniques for the measurement of stress in structural elements.

Unscented Kalman Filter for the identification of passive control devices

R. Ceravolo, A. De Stefano, E. Matta, A. Quattrone & L. Zanotti Fragonara
Department of Structural, Geotechnical and Building Engineering, Politecnico di Torino, Torino, Italy

ABSTRACT: The Unscented Kalman Filter (UKF) is a technique which allows dealing with nonlinear systems and it is able to handle any type of non-linearity. In detail, differently from Extended Kalman Filter (EKF), UKF does not require the computation of the Jacobian of the non-linear function. Estimation of parameters through the UKF approach is an indirect procedure, consisting of transforming the parameter estimation problem into a state estimation problem. This is done by augmenting the system state vector by artificially defining the unknown parameters as additional state variables. In the present study the UKF is proposed to the purpose of the nonlinear identification of rolling-pendulum tuned vibration absorbers.

1 INTRODUCTION

In the field of nonlinear system identification several methods have been proposed in the past (Kerschen et al. 2006; Bursi et al. 2012). In the field of on-line methods the most promising are probably those belonging to the family of Kalman Filter algorithms. Though the Kalman Filter (1960) has been originally proposed for linear applications, different extensions of the method to the nonlinear field have been proposed.

The first group descends from the Extended Kalman Filter (EKF) (Jazwinski, 1966). The EKF allows applying the Kalman Filter to nonlinear optimal filtering. It forms a Gaussian approximation to the joint distribution of state and measurements by resorting to a Taylor series based transformation. When working with nonlinear processes the optimality of the estimation is lost and, even worst, the estimate may diverge (Stengel 1994). The EKF has some flaws: (i) it is not an optimal estimator; (ii) it may diverge due to its linearization approach if the initial estimate of the state vector is wrong or the process is modelled incorrectly; (iii) its estimated covariance matrix tends to underestimate the true covariance matrix so that it risks becoming inconsistent in the statistical sense without the addition of a "stabilising noise".

State-Dependent Riccati Equation Filter (SDRE) overcomes the EKF flaws, since it does not involve the Jacobian evaluations, but it entails direct parameterization (Beikzadeh & Taghirad 2009). Briefly, it fully captures the nonlinearities of the system and brings the nonlinear system into a nonunique linear structure having state-dependent coefficients (SDCs). This nonuniqueness of the SDC form provides design flexibility which can be exploited to overcome serious difficulties such as singularities and loss of observability in traditional filtering methods.

Among the family of Particle Filters the most widely used and applied is the Unscented Kalman Filter (UKF). This technique has been recently proposed by Julier and Uhlman (2000) having the advantage, with respect to the canonical filters, of being able to treat any type of nonlinearity. In detail, UKF does not require the computation of the Jacobian of the nonlinear function; in fact it does not approximate the measurement equation of the system but it approximates the posterior probability density by a Gaussian density, by using a set of deterministic points (the so-called Sigma points). This allows dealing with also non differentiable nonlinear systems. When the Sigma points are propagated through the nonlinear transform, they capture the true mean and covariance of the Gaussian random variables, and the posterior mean and covariance accurately to the 3rd order Taylor series expansion for any nonlinearity.

In the last few years, the UKF has been successfully applied for the identification of nonlinear mechanical systems in several numerical case studies, e.g. (Wu & Smyth, 2008; Ceravolo et al. 2012). Due to the uncertainty in the dissipation laws of real dynamic systems (nonlinear damping, hysteresis, friction, etc.), very few experimental applications to real case studies are known. As a consequence, any experimental applications should be previously validated through extensive numerical simulations.

The capability of UKF to deal with the nonlinear identification of system parameters has been tested on a numerical model aimed to describe the dynamic behaviour of a new prototype of vibro-protective control device recently proposed by Matta et al. (2009). The device consists of an innovative type of rolling-pendulum tuned vibration absorber which, relying on an optimal three-dimensional guiding receptacle, can simultaneously control the response of the supporting structure along two orthogonal horizontal directions.

Through preliminary numerical simulations, the effectiveness of the UKF in identifying the structural parameters of the new device is investigated for different alternative descriptions of the nonlinear dissipation model introduced to simulate rolling friction at the interface between the ball bearing and the rolling surface.

2 THE NEW BIDIRECTIONAL PENDULUM VIBRATION ABSORBER

In recent years, many vibration control strategies have been developed for enhancing serviceability and safety of Civil Engineering structures against natural and manmade hazards. Among them, tuned vibration absorbers have been extensively studied and widely applied because of their simplicity, efficiency and low maintenance cost.

In its basic configuration, a tuned vibration absorber merely consists of a viscously damped single-degree-of-freedom (SDOF) auxiliary system attached to the main structure. By properly tuning its natural frequency to that of the selected target mode of the main structure, part of the vibratory energy of that mode is transferred to the auxiliary system and dissipated through its damping (Warburton & Ayorinde, 1982).

Tuned absorbers have found through the years a variety of technological implementations (Matta & De Stefano, 2009). Among them, the rocking pendulum, the ball pendulum and the rolling pendulum share the same idea of using curved rolling surfaces to derive the necessary restoring force, which makes them more compact and durable than hanging pendulums as well as more suitable to tuning to low-period structures for seismic applications. Several variants of rolling pendulum vibration absorbers are described in the literature (Legeza, 2005; Pirner, 2002), however arranged either in a planar configuration (constrained to move in a vertical plane) or in an axial-symmetrical configuration (constrained on a spherical cavity).

In order to simultaneously achieve bidirectional tuning to two distinct in-plan orthogonal structural modes, a new bidirectional pendulum vibration absorber was proposed by the first author in (Matta et al. 2009), based on an innovative non-axial-symmetrical rolling guide. An analytical non-linear dynamic model was first derived using Appell's nonholonomic mechanics, and then a laboratory scaled prototype was tested which eventually demonstrated the bidirectional tuning capability and validated the mathematical model. Yet, the nonlinear dissipation law governing the rolling problem was outside the scope of the analytical model and therefore was only roughly identified from the experiments.

Aiming at more accurately characterizing the dissipative term, the same prototype absorber is here reconsidered. This consists of two identical plexiglass plates having dimensions $400 \times 300 \times 25\ mm^3$, each carved with five identical toroidal concavities (Fig. 1).

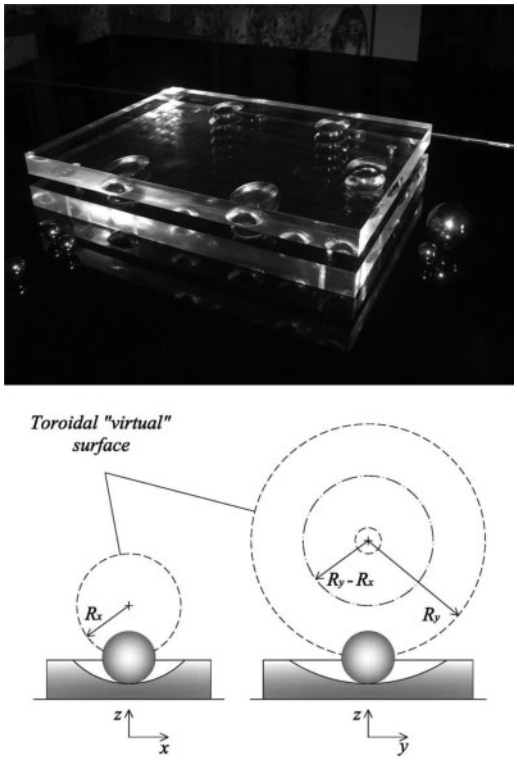

Figure 1. The prototype: (left) the test assembly; (right) a scheme of the toroidal concavities.

The plates are deployed with their concavities symmetrically facing each other, with three out of the five pairs of concavities sandwiching a stainless steel ball of radius $R = 10$ mm. The mass of each plate is $m = 3.42$ kg. The "physical" concavities have radii of curvature $R_{xp} = 29.9$ mm and $R_{yp} = 54.7$ mm, and are 9 mm deep. Correspondingly, being $R = 10$ mm, the "virtual" radii are $R_x = 19.9$ mm and $R_y = 44.7$ mm.

In (Matta et al. 2009), with four accelerometers attached to each plate along the lateral faces (two in the x direction and two in the y direction), two kinds of experimental tests were conducted: fixed-base free motion tests, through imparting an initial non-zero relative displacement of the upper plate; and base shaking tests, through imparting a (non-stationary) random bidirectional translational motion to the lower plate. In the present paper, as an intermediate step towards using the UKF for the experimental identification of the dissipative rolling mechanism from those tests, the latter are preliminary replaced with numerical simulations, for simplicity circumscribed to unidirectional motions in the yz vertical plane only.

3 THE NONLINEAR MODEL

The thorough nonlinear model describing the three-dimensional rolling-without-slipping motion of each ball with respect to both the lower and the upper plates,

and therefore of the upper plate with respect to the lower plate, is given in (Matta et al. 2009). As long as ball bearings' inertia is neglected and motion is restrained to the yz plane, that model reduces to the following nonlinear SDOF one (Matta & De Stefano, 2009):

$$\ddot{\theta} + c_1 \left|\dot{\theta}\right|^{c_2} \operatorname{sgn}(\dot{\theta}) + \frac{g}{R}\sin\theta = -\frac{1}{R}\ddot{x}_g \cos\theta \qquad (1)$$

where θ is the pendulum angular deflection, is the absolute acceleration of the lower plate, $R = 2R_y$ is the effective pendulum radius, g is the gravity constant, c_1 and c_2 are the two parameters governing the dissipation mechanism, here assumed to be velocity-dependent and someway intermediate between dry friction ($c_2 = 0$) and linear viscous damping ($c_2 = 1$), as suggested by experiments (Matta et al. 2009). Notice that, for the assigned value of R_y, the undamped linearized natural period, defined as $T = 2\pi/\omega = 2\pi\sqrt{(R/g)}$, happens to be exactly equal to 0.60 s.

4 UKF WITH BOUNDARIES

The equations of a general dynamic system in discrete form can be defined by resorting to the state-space equation and its measurement equation as follows:

$$\begin{aligned} \mathbf{X}_k &= f\left(\mathbf{X}_{k-1}, u_{k-1}\right) + \mathbf{q}_k \\ \mathbf{Y}_k &= h\left(\mathbf{X}_k\right) + \mathbf{r}_k \end{aligned} \qquad (2)$$

where $\mathbf{X}$ is the state vector in its augmented form, $\mathbf{Y}$ is the output vector, u is the input whilst $\mathbf{q}$ and $\mathbf{r}$ are the process and measurement noises, respectively.

In this paper the UKF algorithm (see Table 1 or, for further information, (Julier et al. 2000)) is applied to the system described in Equation 1 using a modified version which allows for interval constraints on the state vector:

$$\mathbf{X}_L \le \mathbf{X}_k \le \mathbf{X}_U \qquad (3)$$

In (Kolas et al. 2009) several steps were identified in the original UKF algorithm where constrains can be introduced: on the sigma points (step 1 and 2), on the state vector prediction (step 3), on the output Sigma points (step 5), on the output (step 6) or on the updated state vector (step 10).

The bounds used in this paper have been applied according to the methods proposed in (Teixera et al. 2010) and in (Vachani et al. 2006). It has been chosen to deal with this problem by using both constraints on the unscented transform, on the predicted and updated state vector. In order to generate Sigma points satisfying Equation 3 one can use the following equations:

$$\mathcal{X}_k^- = \mathbf{X}_k + \begin{bmatrix} \mathbf{0}_{nx1} & \theta_{1,k}\,\mathrm{col}_1\left[\left(\mathbf{P}_{XX_k}\right)^{1/2}\right] & \dots \\ \dots & \theta_{n,k}\,\mathrm{col}_n\left[\left(\mathbf{P}_{XX_k}\right)^{1/2}\right] & \dots \\ \dots & -\theta_{n+1,k}\,\mathrm{col}_{n+1}\left[\left(\mathbf{P}_{XX_k}\right)^{1/2}\right] & \dots \\ \dots & -\theta_{2n,k}\,\mathrm{col}_{2n}\left[\left(\mathbf{P}_{XX_k}\right)^{1/2}\right] & \end{bmatrix} \qquad (4)$$

where n is the length of the state vector and θ is defined as follows:

$$\theta_{j,k} = \min\left(\mathrm{col}_j\left(\Theta\right)\right) \qquad (5)$$

Table 1. The UKF algorithm as proposed by Julier and Ulhmann (Julier et al. 2000).

1. Unscented transform and computation of sigma points

$$\mathcal{X}_{k-1}^- = \left[\hat{\mathbf{X}}_{k-1} \quad \hat{\mathbf{X}}_{k-1} + \sqrt{(n+\lambda)\mathbf{P}_{XX_{k-1}}} \quad \dots \quad \dots \hat{\mathbf{X}}_{k-1} - \sqrt{(n+\lambda)\mathbf{P}_{XX_{k-1}}}\right]$$

2. Nonlinear propagation of sigma points

$$\mathcal{X}_{k,i}^{-\mathcal{X}} = f\left(\mathcal{X}_{k-1}^-, u_{k-1}\right)$$

3. State vector prediction

$$\hat{\mathbf{X}}_k^- = \sum_{i=0}^{2n} W_i^{(m)} \cdot \mathcal{X}_{k,i}^{-\mathcal{X}}$$

4. State covariance matrix prediction

$$\mathbf{P}_{XX_k}^- = \sum_{i=0}^{2n} W_i^{(c)} \left[\mathcal{X}_{k,i}^{-\mathcal{X}} - \hat{\mathbf{X}}_k^-\right]\left[\mathcal{X}_{k,i}^{-\mathcal{X}} - \hat{\mathbf{X}}_k^-\right]^T + \mathbf{Q}_k$$

5. Propagation of sigma points through measure equation

$$\mathcal{Y}_{k,i} = h\left(\mathcal{X}_{k,i}^{-\mathcal{X}}\right)$$

6. Measurement prediction

$$\hat{\mathbf{Y}}_k^- = \sum_{i=0}^{2n} W_i^{(m)} \cdot \mathcal{Y}_{k,i}$$

7. Measurement covariance matrix prediction

$$\mathbf{P}_{YY_k}^- = \sum_{i=0}^{2n} W_i^{(c)} \left[\mathcal{Y}_{k,i} - \hat{\mathbf{Y}}_k^-\right]\left[\mathcal{Y}_{k,i} - \hat{\mathbf{Y}}_k^-\right]^T + \mathbf{R}_k$$

8. Cross covariance matrix prediction

$$\mathbf{P}_{XY_k}^- = \sum_{i=0}^{2n} W_i^{(c)} \left[\mathcal{X}_{k,i}^{-\mathcal{X}} - \hat{\mathbf{X}}_k^-\right]\left[\mathcal{Y}_{k,i} - \hat{\mathbf{Y}}_k^-\right]^T$$

9. Kalman gain

$$\mathbf{K}_k = \mathbf{P}_{xy}^- \left(\mathbf{P}_{yy}^-\right)^{-1}$$

10. State vector update

$$\hat{\mathbf{X}}_k = \hat{\mathbf{X}}_k^- + \mathbf{K}_k\left(\mathbf{Y}_k - \hat{\mathbf{Y}}_k^-\right)$$

11. State covariance matrix update

$$\mathbf{P}_{XX_k} = \mathbf{P}_{XX_k}^- - \mathbf{K}_k \mathbf{P}_{YY_k} \mathbf{K}_k^t$$

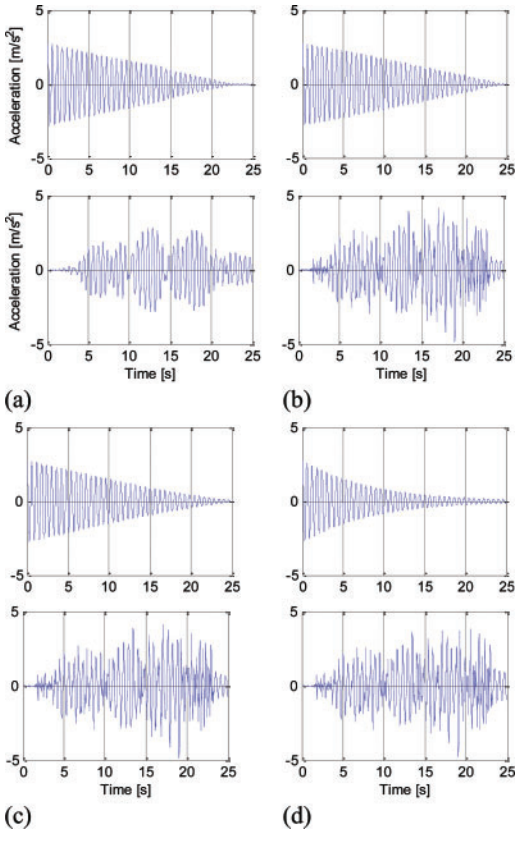

Figure 2. The free decay (above) and random shaking (bottom) responses of: (a) the real test device; (b) the model with $c_1 = 0.2$ and $c_2 = 0.0$; (c) the model with $c_1 = 0.2$ and $c_2 = 0.3$; (d) the model with $c_1 = 0.25$ and $c_2 = 1.0$.

$$\Theta_{(i,j)} = \begin{cases} \sqrt{n+\lambda} & \text{if } \mathbf{S}_{(i,j)} = 0 \\ \min\left(\sqrt{n+\lambda}, \dfrac{\mathbf{X}_{U,i} - \hat{\mathbf{X}}_k}{\mathbf{S}_{(i,j)}}\right) & \text{if } \mathbf{S}_{(i,j)} > 0 \\ \min\left(\sqrt{n+\lambda}, \dfrac{\mathbf{X}_{L,i} - \hat{\mathbf{X}}_k}{\mathbf{S}_{(i,j)}}\right) & \text{if } \mathbf{S}_{(i,j)} < 0 \end{cases} \quad (6)$$

$$\mathbf{S} = \left[\left(\mathbf{P}_{XX_k}\right)^{1/2} \quad -\left(\mathbf{P}_{XX_k}\right)^{1/2} \right] \quad (7)$$

Weights applied to the Sigma points are given by $W_i = [W_{0,k} W_{1,k} \ldots W_{2n,k}]$ satisfying $\sum_{j=0}^{2n} W_{1,k} = 1$ where:

$$W_{0,k} = b_k, \quad W_{j,k} = a_k \cdot \theta_{j,k} + b_k \quad (8)$$

with a_k and b_k determined using the equation proposed by Teixera (2010). Furthermore, in order to apply the constraints on step 3 and 10, a simple clipping procedure on the vector $\mathbf{X}_k$ is performed. It is worth noticing that the clipping procedure, even if it is rough, is the optimal solution in most of the usual problems (see (Vachani et al. 2006)) and without doubt the most computationally efficient.

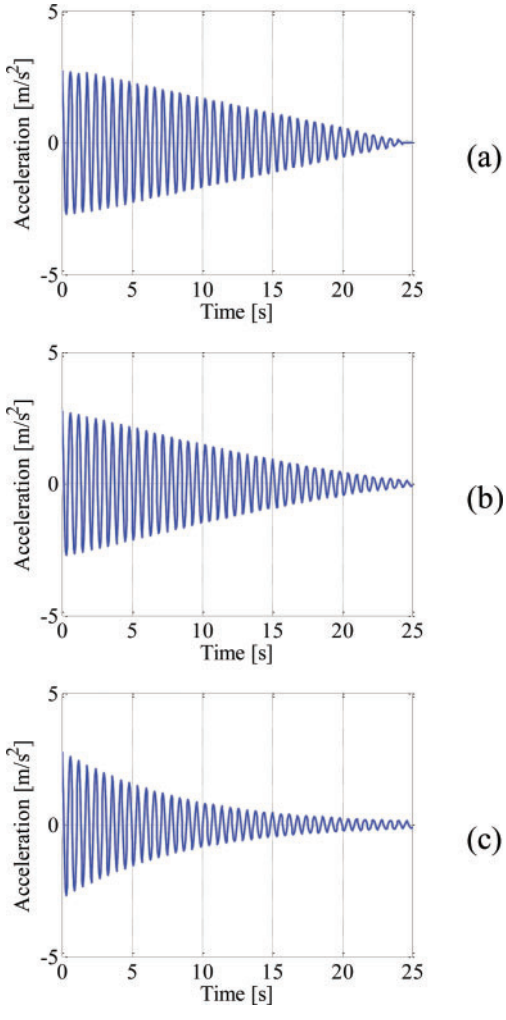

Figure 3. UKF matching of the free decay response for: (a) $c_1 = 0.2$ and $c_2 = 0.0$; (b) $c_1 = 0.2$ and $c_2 = 0.3$; (c) $c_1 = 0.25$ and $c_2 = 1.0$ – Simulated model (thick grey line) vs. estimated model (thin blue line).

5 NUMERICAL EXAMPLES

The UKF is here applied to estimate the two states and the two dissipation coefficients c_1 and c_2 of the nonlinear model defined by Equation 1, i.e. to identify the following joint state vector:

$$\mathbf{X} = [x_1, x_2, x_3, x_4] = [x, \dot{x}, c_1, c_2] \quad (9)$$

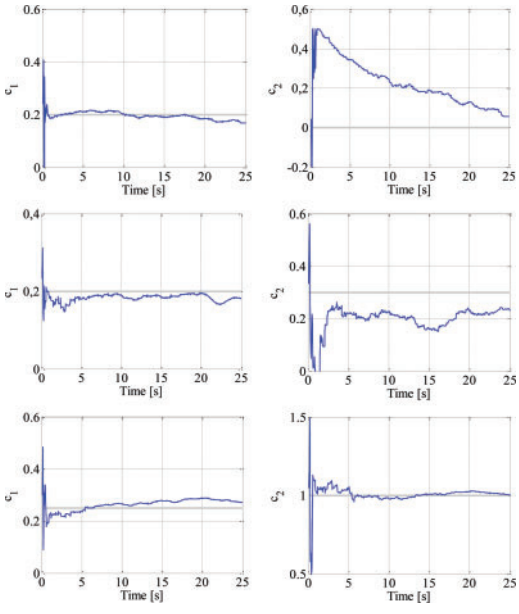

Figure 4. UKF esteems from the free decay response for: (above) $c_1 = 0.2$ and $c_2 = 0.0$; (middle) $c_1 = 0.2$ and $c_2 = 0.3$; (bottom) $c_1 = 0.25$ and $c_2 = 1.0$ – Simulated model (thick grey line) vs. estimated model (thin blue line).

while the two remaining parameters, g and R, are assumed to be exactly known. For the sake of validation, the identification is repeated for a number of simulated scenarios, chosen to roughly reproduce the two experimental test cases, i.e. the free decay oscillation and the random base shaking. Namely, three distinct models are simulated, each described by a different pair $[c_1, c_2]$ of the model parameters, and each responding to the experimental inputs in nearly the same way as the real device, as can be appreciated from Figure 2. For each model, the UKF identification is then repeatedly run for different additive measurement noise levels and different initial estimation errors.

Some of the results obtained for the free decay input scenario are exemplified in Figure 3.

One example of the results obtained for the random shaking input scenario is reported in Figure 4.

For both the free decay and the random shaking scenarios, a satisfactory performance of the UKF estimation can be generally appreciated. The simulated response can be tracked with good accuracy and the estimated parameters tend to rapidly converge to the assumed numerical values in nearly all cases. This is a promising result in view of the application to the real experimental data, which is left for future work.

6 CONCLUSIONS

In the present work, a preliminary numerical investigation is reported in order to assess the viability of UKF for the nonlinear identification of a new prototype of vibro-protective control device. The device

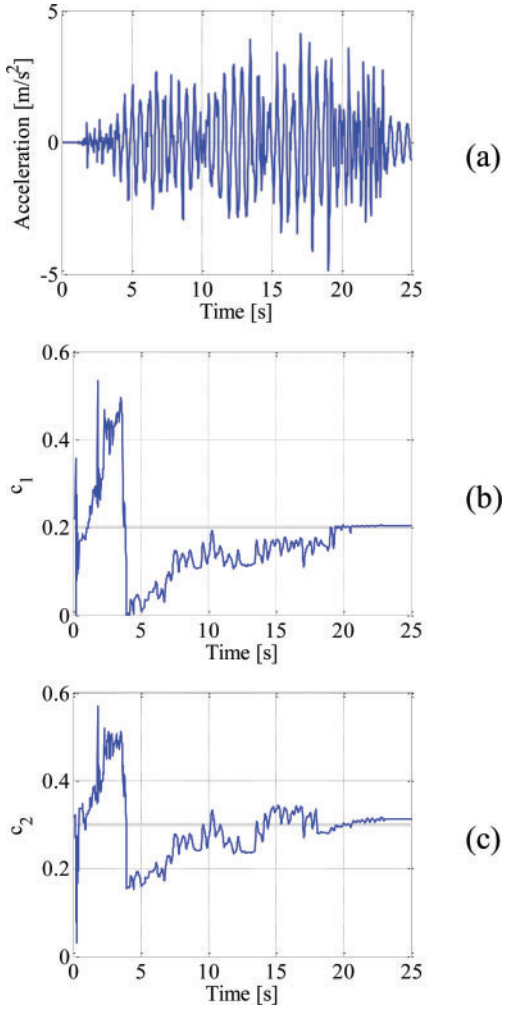

Figure 5. UKF applied to the random shaking response for $c_1 = 0.2$ and $c_2 = 0.3$ – Simulated model (thick grey line) vs. estimated model (thin blue line).

consists of an innovative type of rolling-pendulum tuned vibration absorber which, relying on an optimal three-dimensional guiding receptacle, can simultaneously control the response of the supporting structure along two orthogonal horizontal directions.

Through preliminary numerical simulations, the effectiveness of the UKF in identifying the structural parameters of the new device is investigated for different alternative descriptions of the nonlinear dissipation model introduced to simulate rolling friction at the interface between the ball bearing and the rolling surface. The experimental characterization of the real test prototype is left for future work.

Vibration elimination analysis of simply-supported bridge under moving loads based on Laplace-Carson integral transform

Kunpeng Wang, He Xia & Weiwei Guo
School of Civil Engineering, Beijing Jiaotong University, Beijing, China

ABSTRACT: The displacement solution for dynamic equation of simply-supported bridge under moving loads is derived using the method of Laplace-Carson integral transform. By introducing two non-dimensional parameters to describe the influence of load speed and damping of bridge respectively, the moving load induced vibration elimination phenomenon is studied. The result shows that the phenomenon of vibration elimination will appear, i.e. the displacement and velocity of bridges become zero when the load leaves the bridge at a certain speed. The elimination speed and resonance speed obtained in case of no damping also are applicable to case of light damping.

1 INTRODUCTION

With the raise of trains speed, the vehicle has a higher demand on the quality of railway lines. To increase the quality of the line, more bridges are built in high-speed railways in China, which has accounted for a large part of the line. Take Beijing-Shanghai High-speed Railway as example, the rate of bridge length is 86.5%. Therefore, it is necessary to study the problem of train going through the bridges. In studying the resonance and elimination of train-bridge system, the vehicle load is usually simplified as moving load series (Xia et al. 2011).

The problem of moving load going through simply supported bridge is a basic problem, which has been studied in many references, where the dynamic equation of the bridge is solved by numerical integration methods (Cao et al. 1987, Gao et al. 2005 & Garinei et al. 2008), such as the Duhamel integral method. Numerical integration method is applicable. However, it only gives us an integral expression, but not shows the influence of load speed nor bridge damping. In this paper, the displacement solution for dynamic equation of the simply supported bridge under moving loads is derived using the method of Laplace-Carson integral transform, and the vibration elimination of the bridge is analyzed.

2 ANALYSIS MODEL AND SOLUTION

2.1 *Problem*

Assumed the simply supported beam has a constant section (EI is a constant), a uniform the mass ($\bar{m}$ is a constant), the moving load $P(t)$ goes through the beam from left to right at a constant speed V, and zero initial deflection and velocity are assumed for the beam vibration. The model is shown in Fig. 1.

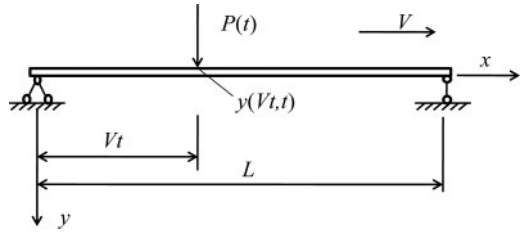

Figure 1. Moving load passing the simply supported beam.

Assume the beam remains small deformation and has a viscous damping coefficient c, the forced vibration equation of the beam can be expressed as

$$EI\frac{\partial^4 y(x,t)}{\partial x^4}+\bar{m}\frac{\partial^2 y(x,t)}{\partial t^2}+c\frac{\partial y(x,t)}{\partial t}=\delta(x-Vt)P(t) \quad (1)$$

and the initial condition is

$$y(x,0)=0;\quad \left.\frac{\partial y(x,0)}{\partial t}\right|_{t=0}=0 \quad (2)$$

where $y(x,t)$ is the vertical displacement of the beam; and δ is Dirac function.

2.2 *Solution*

Equation (1) can be solved by the modal superposition method. Thus, the displacement of the beam can be expressed as

$$y(x,t)=\sum_{i=1}^{\infty}\phi_i(x)\cdot q_i(t) \quad (3)$$

where $\phi_i(x)$ is the i-th vibration mode of the beam; $q_i(t)$ is the generalized coordinate of the i-th mode. For an ideal simply supported beam, $\phi_i(x)=\sin(i\pi x/L)$ (Clough, et al. 2003).

Substitute Eq. (3) into (1), multiply $\phi_n(x)$ on both sides of the equation, and then integrate both sides of the equation along the beam. Basing the orthogonality of mode shapes, the motion equation of the generalized coordinate of the n-th vibration mode can be obtained as

$$\ddot{q}_n(t)+2\omega_b\dot{q}_n(t)+\omega_n^2 q_n(t)=\frac{2}{\bar{m}L}P(t)\sin n\omega t \tag{4}$$

where ω_n is the n-th circular frequency of the beam; $\xi_n=c/2\bar{m}\omega_n$ is the damping ratio of the n-th mode of the beam; $\omega_b=\xi_n\omega_n$ is the critical circular frequency of the beam with damping; and $\omega=\pi V/L$ is the circular frequency expressing the load motion.

Equation (4) is usually solved by Duhamel integral method, but in this paper, it is solved by the Laplace-Carson integral transform method. The basic relations of this transform are as follows:

$$\begin{cases} F(s)=s\int_0^\infty f(t)\mathrm{e}^{-st}\mathrm{d}t \\ f(t)=\dfrac{1}{2\pi\mathrm{i}}\int_{a_0-\mathrm{i}\infty}^{a_0+\mathrm{i}\infty}\mathrm{e}^{st}\dfrac{F(s)}{s}\mathrm{d}s \end{cases} \tag{5}$$

where s is a complex variable.

In view of the initial condition Eq. (2), we only solve the displacement of the beam induced by the moving load. After transform using Eq. (5), Eq. (4) becomes

$$\begin{aligned} &s^2Q_n(s)+2\omega_b sQ_n(s)+\omega_n^2Q_n(s) \\ &=\frac{2}{\bar{m}L}\frac{s}{2\mathrm{i}}\left[\frac{P^*(s-\mathrm{i}n\omega)}{s-\mathrm{i}n\omega}-\frac{P^*(s+\mathrm{i}n\omega)}{s+\mathrm{i}n\omega}\right] \end{aligned} \tag{6}$$

$$\begin{cases} Q_n(s)=s\int_0^\infty q_n(t)\mathrm{e}^{-st}\mathrm{d}t \\ P^*(s)=s\int_0^\infty P(t)\mathrm{e}^{-st}\mathrm{d}t \end{cases} \tag{7}$$

Using Eq. (6), it is not difficult to computer the transformed solution as

$$\begin{aligned} Q_n(s)=&\frac{2}{\bar{m}L}\frac{1}{(s+\omega_b)^2+\omega_D^{n2}} \\ &\times\frac{s}{2\mathrm{i}}\left[\frac{P^*(s-\mathrm{i}n\omega)}{s-\mathrm{i}n\omega}-\frac{P^*(s+\mathrm{i}n\omega)}{s+\mathrm{i}n\omega}\right] \end{aligned} \tag{8}$$

where $\omega_D^{n2}=\omega_n^2-\omega_b^2$ is the circular frequency of a beam with light damping.

The integral transform can be realized by means of the tables (Frýba 1999). Using the table, the inverse Fourier transform $q_n(t)$ of the original $Q_n(s)$ shown in Eq. (8) can be easily obtained as

$$q_n(t)=\frac{2\int_0^t P(\tau)\sin n\omega\tau\mathrm{e}^{-\omega_b(t-\tau)}\sin\omega_D^n(t-\tau)\mathrm{d}\tau}{\bar{m}L\omega_D^n} \tag{9}$$

where $\omega_D^n=\omega_n(1-\xi_n^2)^{0.5}$ is the n-th circular frequency of the beam with damping.

Using the generalized coordinate $q_n(t)$ obtained in Eq. (9) and the modal superposition method, the displacement of the beam induced by the moving load can be obtained as

$$\begin{aligned} y(x,t)=&\frac{2}{\bar{m}L}\sum_{n=1}^\infty\frac{1}{\omega_D^n}\sin\frac{n\pi x}{L} \\ &\times\int_0^t P(\tau)\sin n\omega\tau\mathrm{e}^{-\omega_b(t-\tau)}\sin\omega_D^n(t-\tau)\mathrm{d}\tau \end{aligned} \tag{10}$$

In Eq. (10), the load $P(t)$ can be in various forms. When the vehicle is simplified as moving load series for simplified analysis, two special condition are studied, i.e. $P(t)=P$ and $P\sin\bar{\omega}t$.

To discuss more easily the effect of different factors on the dynamic responses of the beam, two dimensionless parameters α and β are herein introduced, to represent the effect of load speed and beam damping, respectively.

$$\begin{cases} \alpha=\dfrac{\omega}{\omega_1}=\dfrac{VL}{\pi}\left(\dfrac{\bar{m}}{EI}\right)^{1/2}=\dfrac{V}{V_{cr}} \\ \beta=\dfrac{\omega_b}{\omega_1}=\dfrac{\omega_b L^2}{\pi}\left(\dfrac{\bar{m}}{EI}\right)^{1/2}=n^2\xi_n \end{cases} \tag{11}$$

where $V_{cr}=2f_nL/n^2=\pi(EI/\bar{m})^{1/2}(n=1,2,3,\dots)$ is the critical speed of beam under the moving load.

3 SOLUTION AND DISCUSSION OF SPECIAL CASES

3.1 *Case of* $p(t)=p$

If moving load $P(t)$ equals to P, the Laplace-Carson integral transform of $P(t)$ is shown below

$$P^*(s)=s\int_0^\infty P\mathrm{e}^{-st}\mathrm{d}t=P \tag{12}$$

Accordingly, Eq. (8) can be transformed into

$$Q_n(s)=\frac{2Pn\omega}{\bar{m}L}\frac{s}{s^2+n^2\omega^2}\frac{1}{(s+\omega_b)^2+\omega_D^{n2}} \tag{13}$$

Ditto, the inverse Fourier transform $q_n(t)$ of original $Q_n(s)$ in Eq. (13) can be obtained. The displacement of the beam induced by the moving load P can be obtained as

$$\begin{aligned} y(x,t)=v_0\sum_{n=1}^\infty&\frac{1}{n^2\left[n^2(n^2-\alpha^2)^2+4\alpha^2\beta^2\right]} \\ &\times\Big\{n^2(n^2-\alpha^2)\sin n\omega t \\ &-\frac{n\alpha\left[n^2(n^2-\alpha^2)-2\beta^2\right]}{(n^4-\beta^2)^{1/2}}\mathrm{e}^{-\omega_b t}\sin\omega_D^n t \\ &-2n\alpha\beta(\cos n\omega t-\mathrm{e}^{-\omega_b t}\cos\omega_D^n t)\Big\}\sin\frac{n\pi v}{L} \end{aligned} \tag{14}$$

where $v_0=PL^3/48EI\approx 2PL^3/\pi^4EI=2P/\bar{m}L\omega_1^2$ is the deflection at mid-span of a simply supported

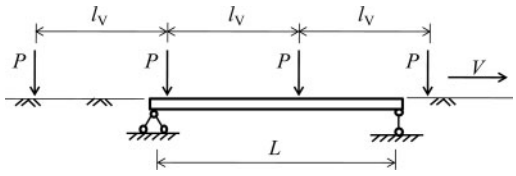

Figure 2. Moving train load passing through beam.

beam loaded with static force P at point $x = L/2$; $\omega_b = \beta\omega_1 = \beta\omega/\alpha$; $\omega_D^n = \sqrt{n^4 - \beta^2}\omega/\alpha$. The zero time in Eq. (14) is the instant of force arrival, and the range of time t is $0 \le t \le L/V$.

Equation (14) is the displacement of the beam induced by one moving load P. Usually, the vehicle is simplified as moving load series with equal load spacing l_v, which is equal to the length of the vehicle, as shown in Fig. 2. Based on the small deformation theory, the displacement of the beam under moving load series is the superposition of all displacement components induced by each single load P, which can be expressed as

$$y(x,t) = \sum_{i=0}^{N-1} y_i\left[x, (t - \frac{i \cdot l_V}{V})\right] \tag{15}$$

where $y_i(x,t)$ is the displacement component of beam induced by the i-th moving load P. When the i-th moving load P is on the beam, $y_i(x,t)$ is calculated by Eq. (14), while after the i-th moving load P leaves the beam, $y_i(x,t)$ is the free vibration induced by the i-th moving load P, which is calculated by Eq. (21).

In this paper, based on Eq. (14), three special cases are discussed detailed.

3.1.1 *Static case ($\alpha = 0$)*

If the load is static, i.e. $\alpha = 0$, Eq. (14) can be converted to

$$y(x,t) = v_0 \sum_{n=1}^{\infty} \frac{1}{n^4} \sin\frac{n\pi x}{L} \sin\frac{n\pi Vt}{L} \tag{16}$$

In this case, Eq. (16) is the static deflection of the beam at point x, if the beam loaded with force P at point Vt. Herein, Vt is considered as a combined variable to express the location of load P.

When it is divided by v_0, Eq. (16) can be considered as the influence line of the beam deflection at point x expanded in the Fourier series, which can also be considered as the deflection of the beam induced by force P at point Vt, expanded in the Fourier series.

3.1.2 *Case with no damping ($\beta = 0$) — analysis of elimination and resonance*

3.1.2.1 α is not an integer, $\beta = 0$

In this case, Eq. (17) can be obtained from Eq. (14)

$$y(x,t) = v_0 \sum_{n=1}^{\infty} \sin\frac{n\pi x}{L} \frac{1}{n^2(n^2 - \alpha^2)} \left(\sin n\omega t - \frac{\alpha}{n} \sin\omega_n t\right) \tag{17}$$

From Eq. (17), it can be seen that the first vibration mode has the largest contribution to the displacement of the beam. Shen et al. (1996) and Yang et al. (2004) indicated that using the first vibration mode of the beam to calculate the dynamic response of the beam could achieve high solution precision. In this case, Eq. (17) can be simplified as

$$y(x,t) = \frac{v_0}{1-\alpha^2} \sin\frac{\pi x}{L} \left(\sin\omega t - \alpha \sin\omega_1 t\right) \tag{18}$$

Assumed the part in the parentheses of Eq. (18) equal to zero at the instant of moving load P leaves the beam (i.e. $t = L/V$), will give us

$$\begin{aligned} \left(\sin\omega t - \alpha \sin\omega_1 t\right)\Big|_{t=\frac{L}{V}} &= \sin\pi - \alpha \sin\frac{\pi}{\alpha} = 0 \\ \Rightarrow \alpha &= \frac{1}{k};\ (k = 2, 3, \cdots) \end{aligned} \tag{19}$$

From Eq. (19), it can be seen that when $\alpha = 1/k$, the displacement component of the beam contributed by the first vibration mode of the beam will be zero at the instant of moving load P leave the beam. In this condition, the displacement of the beam will approaches zero, for the first vibration mode has the largest contribution to the displacement of the beam. In this paper, the speed $V_D = 2f_1 L/k$ expressed in Eq. (19) is named elimination speed (f_1 is the first natural frequency of the beam).

At the instant of moving load P leaves the beam, the velocity of beam is expressed as

$$\dot{y}(x,t)\Big|_{t=\frac{L}{V}} = \frac{v_0\omega}{1-\alpha^2} \sin\frac{\pi x}{L} \left(\cos\pi - \cos\frac{\pi}{\alpha}\right) \tag{20}$$

After the moving load P leaves the beam (i.e. $t > L/V$), the free vibration of beam can be expressed as

$$y(x,t) = \frac{\dot{y}_0}{\omega_1} \sin\omega_1 t + y_0 \cos\omega_1 t \tag{21}$$

If the moving load P pass through the beam at speed V_D, at the instant of moving load P leaves the beam, the velocity of the beam is expressed as

$$\dot{y}(x,t)\Big|_{t=\frac{L}{V}} = \frac{v_0\omega}{1-\alpha^2} \sin\frac{\pi x}{L} \left(\cos\pi - \cos k\pi\right) \tag{22}$$

where y_0 and is the displacement and velocity of the beam, at the instant of moving load P leaves the beam, respectively.

In order to keep the beam still after the moving load P leaves the beam, according to Eq. (21), the displacement and velocity of the beam should be zero at the instant of moving load P leaves the beam. From Eq. (22), it can be seen that the velocity of the beam may not be zero at the instant of the moving load P leaves the beam at speed V_D.

When k is an odd, Eq. (22) is equal to zero, i.e. both displacement and velocity of the beam are zero at the instant of the moving load P leaves the beam. According to Eq. (21), the beam will keep still after the moving load P leaves the beam. In this paper the speed $V_{D1} = 2f_1 L/2i - -1)$ (i is an integer) is named true elimination speed.

When k is an even, Eq. (22) is not equal to zero, only displacement of the beam is zero at the instant of the moving load P leaves the beam. In this case, the beam will continue vibrate after the moving load P leaves the beam. In this paper the speed $V_{D2} = 2f_1 L/(2i)$ is named false elimination speed.

When moving load series pass through the beam at true elimination speed V_{D1}, the displacement component of the beam induced by one of the moving load series will be zero at the instant of this load leaves the beam. The beam will keep still at this condition, for the displacement of the beam under moving load series is the superposition of displacement components induced by single load P, which is useful for determining the operation speed of the vehicle on the bridge. True elimination speed V_{D1} is also applicable to moving load series with unequal load spacing and load values.

3.1.2.2 α is an integer, $\beta = 0$

If α is equal to one of the number $i = 1, 2, 3, \ldots$, say to number k, in this case $\alpha = \omega/\omega_1 = k$, $\omega_k^2 = k^4\omega_1^2 = k^2\omega^2$. The Laplace-Carson integral transform of generalized coordinate $q_k(t)$ of k-th vibration mode will be Eq. (23) rather than Eq. (13), whereas for the remaining ones, $i = 1, 2, \ldots, k--1, k+1, \ldots$ there hold the preceding solution of Eq. (13) as

$$Q_k(s) = \frac{2Pk\omega}{\bar{m}L}\frac{s}{(s^2 + k^2\omega^2)^2} \tag{23}$$

Similarly, using Eq. (13) and Eq. (23), the displacement of the beam can be obtained, which consists of two parts as

$$\begin{aligned} y(x,t) &= v_0 \frac{1}{2k^4}(\sin k\omega t - k\omega t \cos k\omega t)\sin\frac{k\pi x}{L} \\ &+ v_0 \sum_{n=1,n\neq k}^{\infty} \sin\frac{n\pi x}{L}\frac{1}{n^2(n^2-\alpha^2)}\left(\sin n\omega t - \frac{\alpha}{n}\sin\omega_n t\right) \end{aligned} \tag{24}$$

The first part in Eq. (24) can be considered as the limit values of the k-th term in Eq. (17) for $\alpha \to k$. It can be seen from Eq. (24) that the displacement of the beam is increased with the time t, the maximum of which is appeared at the instant of moving load P leaves the beam. This can be considered the resonance of the beam induced by a single moving load P. The resonance of the beam can also be induced by moving load series at a special speed for the cyclic loading (Gao et al. 2005 & Xia et al. 2006).

When the circular frequency expressing the load motion ω is k times of the first circular frequency of the beam, in this case $\sin(k\pi Vt/L) = \sin k^2\omega_1 t$, the resonance of the k-th vibration mode of the beam will be induced by the moving load. In this paper, the speed $V_R = 2kf_1 L$ is named resonance speed. If k is equal to 1, the resonance of the beam is strongest. Take $L = 32$ m, $f_1 = 4.5$Hz, $k = 1$ as example, in this case the critical speed of beam V_R equal to 1036.8 (km/h), which is far more than the actual train speed, so resonance speed resonance speed V_R only has meaning in mathematics.

3.1.3 *Case with light damping ($\beta << 1$)*

3.1.3.1 α is not an integer, $\beta << 1$

When the beam damping is very light, terms contain β or β^2 can be neglected in Eq. (14), approximately, the expression of the displacement of the beam can be given as

$$\begin{aligned} y(x,t) \approx v_0 \sum_{n=1}^{\infty} \sin\frac{n\pi x}{L}\frac{1}{n^2(n^2-\alpha^2)} \\ \cdot\left(\sin n\omega t - \frac{\alpha}{n}\mathrm{e}^{-\omega_b t}\sin\omega_n t\right) \end{aligned} \tag{25}$$

For $\alpha \to k$, the calculation error of Eq. (25) will be too large to be applicable. Because the actual operation speed of the vehicle cannot reach the critical speed V_R and the damping of actual bridge is very light, so Eq. (25) is very practicable in engineering practice. If the speed of the vehicle is very low, i.e. $\alpha << 1$, and using the first vibration mode of the beam to express the displacement of the beam, Eq. (25) can be simplified as

$$y(x,t) \approx v_0 \sin\frac{\pi x}{L}\sin\omega t \tag{26}$$

3.1.3.2 α is an integer, $\beta << 1$

This case is similar to the case in Section 3.1.2.2, the expression of the displacement of the beam is given directly as

$$\begin{aligned} y(x,t) \approx \frac{v_0}{2k^4}\left[\mathrm{e}^{-\omega_b t}\sin k\omega t - \frac{k^2}{\beta}\cos k\omega t(1-\mathrm{e}^{-\omega_b t})\right] \\ \cdot\sin\frac{k\pi x}{L} + v_0\sum_{n=1,n\neq k}^{\infty}\sin\frac{n\pi x}{L}\frac{1}{n^2(n^2-\alpha^2)} \\ \cdot\left(\sin n\omega t - \frac{\alpha}{n}\mathrm{e}^{-\omega_b t}\sin\omega_n t\right) \end{aligned} \tag{27}$$

The cases of light damping ($\beta << 1$)and no damping ($\beta = 0$) are very similar, the elimination speed V_D and resonance speed V_R obtained in case of no damping also are applicable to the case of light damping, the error induced by the damping of the beam within the acceptable range.

3.2 *Case of $p(t) = P\sin\bar{\omega}t$*

One dimensionless parameter γ is herein introduced, to represent the effect of circular frequency of moving load $P\sin\bar{\omega}t$.

$$\gamma = \frac{\bar{\omega}}{\omega_1} \tag{28}$$

If moving load $P(t)$ equals $P\sin\bar{\omega}t$, the Laplace-Carson integral transform of $P(t)$ is shown as

$$P^*(s) = s\int_0^{\infty} P\sin\bar{\omega}t\mathrm{e}^{-st}\mathrm{d}t = \frac{P\bar{\omega}s}{s^2+\bar{\omega}^2} \tag{29}$$

Accordingly, Eq. (8) can be transformed into

$$Q_n(s) = \frac{P}{\bar{m}L}\left(\frac{1}{s^2+r_2^2} - \frac{1}{s^2+r_1^2}\right)\frac{s^2}{(s+\omega_b)^2+\omega_D^{n2}} \tag{30}$$

where $r_1 = \bar{\omega} + n\omega$; $r_2 = \bar{\omega} - n\omega$

Ditto, the inverse Fourier transform $q_n(t)$ of original $Q_n(s)$ in Eq. (30) can be obtained. In this case, the displacement of the beam induced by the moving load $P\sin\bar{\omega}t$ can be obtained as

$$y(x,t)=\frac{v_0}{2}\sum_{n=1}^{\infty}\left\{\frac{\omega_1^2}{(\omega_n^2-r_2^2)^2+4\omega_b^2r_2^2}\left[(\omega_n^2-r_2^2)\right.\right.$$
$$\cdot\left(\cos r_2t-\mathrm{e}^{-\omega_bt}\cos\omega_D^nt\right)+2\omega_br_2\sin r_2t$$
$$\left.-\frac{\omega_b}{\omega_D^n}(\omega_n^2+r_2^2)\mathrm{e}^{-\omega_bt}\sin\omega_D^nt\right]-\frac{\omega_1^2}{(\omega_n^2-r_1^2)^2+4\omega_b^2r_1^2}\quad(31)$$
$$\cdot\left[(\omega_n^2-r_1^2)\left(\cos r_1t-\mathrm{e}^{-\omega_bt}\cos\omega_D^nt\right)+2\omega_br_1\sin r_1t\right.$$
$$\left.\left.-\frac{\omega_b}{\omega_D^n}(\omega_n^2+r_1^2)\mathrm{e}^{-\omega_bt}\sin\omega_D^nt\right]\right\}\sin\frac{n\pi x}{L}$$

If $\alpha<<1$, $\beta<<1$ and using the first vibration mode of the beam to calculate the dynamic response of the beam, in this case, Eq. (31) can be simplified as (Frýba 1999)

$$y(x,t)=v_0\frac{1}{\gamma^2}\frac{1}{\left(\frac{1}{\gamma^2}-1\right)^2+4\left(\frac{\alpha^2}{\gamma^2}+\frac{\beta^2}{\gamma^2}\right)}$$
$$\cdot\left\{\left[\left(\frac{1}{\gamma^2}-1\right)^2+4\frac{\beta^2}{\gamma^2}\right]^{1/2}\sin\left(\frac{\gamma\omega t}{\alpha}+\varphi\right)\sin\omega t\right.\quad(32)$$
$$\left.+2\frac{\alpha}{\gamma}\left(\cos\frac{\gamma\omega t}{\alpha}\cos\omega t-\mathrm{e}^{-\omega_bt}\cos\frac{\omega t}{\alpha}\right)\right\}\sin\frac{\pi x}{L}$$

where $\tan\varphi=-\dfrac{2\omega_b/\bar{\omega}}{\omega_1^2/\bar{\omega}^2-1}=-\dfrac{2\beta\gamma}{1-\gamma^2}$

When the circular frequency $\bar{\omega}$ of moving load is closed to the first circular frequency ω_1 of the beam, the displacement of the beam is very large. In this case, Eq. (32) can be simplified as

$$y(x,t)=\frac{v_0}{2}\frac{\cos\omega_1t}{\alpha^2+\beta^2}\sin\frac{\pi x}{L}\quad(33)$$
$$\cdot\left[\alpha(\cos\omega t-\mathrm{e}^{-\omega_bt})-\beta\sin\omega t\right]$$

4 NUMERICAL RESULTS

4.1 *Model parameters*

According to the theory above, the displacement of the beam induced by moving load P or $P\sin\bar{\omega}t$ is calculated and analyzed.

Model parameters of the beam: the span of the beam $L=32$ m. The first natural frequency of the beam $f_1=4.5$ Hz, which is a composite reflection of section stiffness EI and mass $\bar{m}$ of the beam. The damping ratio of the first vibration mode $\xi_1=0.0$ or 0.1, i.e. the damping factor $\beta=0.0$ or 0.1. In engineering practice, the damping ratio of concrete bridge and steel bridge

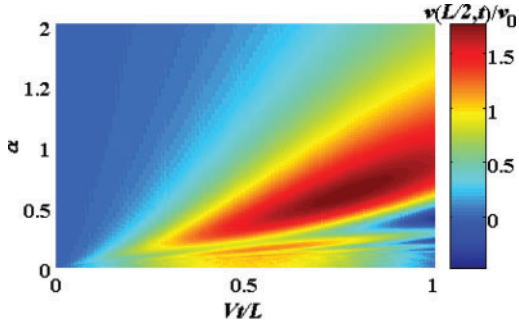

Figure 3. Mid-span displacements *vs* time and load speed ($\beta=0$).

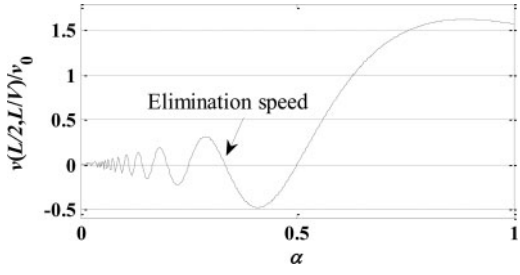

Figure 4. Mid-span displacement *vs* load speed as load leaves the beam ($\beta=0$).

are taken as 0.05 and 0.03, respectively, which is much lesser than 0.1. In this case, the critical speed of beam $V_R=1036.8$ (km/h), while the actual operation speed of the vehicle is 0∼300 km/h, i.e. $\alpha=0.0$∼0.3.

4.2 *Displacement of the beam induced by moving load*

Figure 3 is the displacement of the beam, induced by moving load P at different velocities, in no damping case. From Fig. 3, it can be seen that the maximum mid-span displacement will appear when moving load located near the mid-span of the beam when load speed is low. With the load speed increased, the maximum mid-span displacement will appear when moving load located near the right support of the beam. The phenomenon shown in Fig. 3 is applicable to the beam with different section stiffness EI.

Figure 4 is the mid-span displacement of the beam at the instant of moving load leaves the beam, i.e. $t=L/V$, induced by moving load P at different velocities. As the preceding discussion, the displacement of the beam becomes zero when the load leaves the beam at an elimination speed V_D, i.e. $\alpha=1/k$.

Figure 5 is the relationship between displacement of the beam and speed factor α, and the range of α is 0.0∼0.3 in no damping case. From Fig. 5, it can be seen that the maximum mid-span displacement increases in sinusoidal way with gradually increasing amplitude, instead of in monotonous way, which is also indicated by Wang et al. (2010), by studying the sprung mass through the simply supported bridge. The damping of

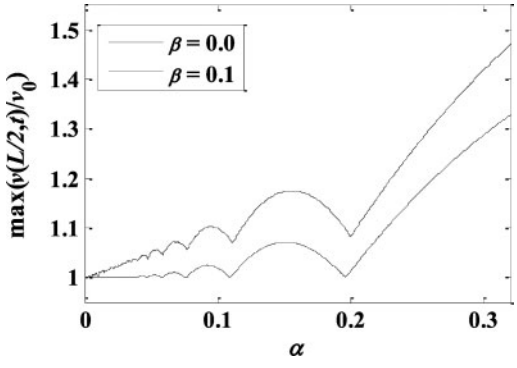

Figure 5. Maximum mid-span displacement *vs* load speed.

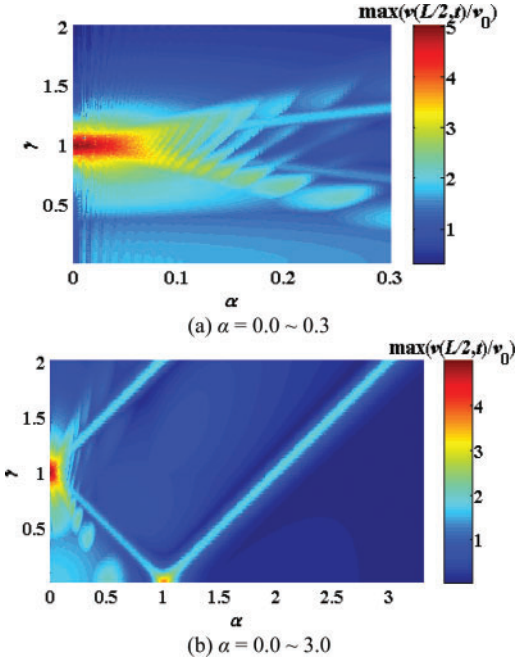

Figure 6. Dynamic amplification factor vs load frequency and speed ($\beta = 0.1$).

the beam can reduce the maximum mid-span displacement of the beam and the elimination speed V_D, but the difference of elimination speed V_D is within the acceptable range. If the damping factor β equals to 0.05, the difference can be smaller, which indicates the elimination speed V_D obtained in case of no damping also are applicable to case of light damping.

From Figs. 4 and 5, it is seen that when the speed factor α equals to 0.2, i.e. $k = 5$, the maximum mid-span displacement of the beam is small, and the beam keeps still after the moving load P leaves the beam. Therefore, in the design, the section stiffness EI, mass $\bar{m}$ and span L of the bridge should be carefully selected.

Figure 6 is the displacement of the beam, induced by the moving load $P \sin \bar{\omega} t$ at different speeds and circular frequencies, in case of low damping. The displacement of the beam is affected by circular frequencies $\bar{\omega}$ and ω. When speed factor α is low, the displacement of the beam is the largest on condition of γ equal to 1. With the increase of speed factor α, the displacement of the beam becomes smaller on condition of γ equal to 1, and the maximum displacement of the beam appears on condition of γ equal to other value. From Fig. 6, an interesting phenomenon is found that if consider coordinate planes as mirror surfaces, the form of maximum displacement of the beam looks like the incidence light at angle of 45° reflected by mirror surfaces, which is named generic-light reflection effect phenomenon in this paper.

5 CONCLUSIONS

The following conclusions can be summarized up from this paper:

(1) There are special speeds $V_{D1} = 2f_1 L/(2i-1)$ (i is an integer), when moving load P through the beam at speeds V_D, the beam will keep stationary after the moving load P leaves the beam.
(2) The maximum mid-span displacement increases with load speed in sinusoidal way with gradually increasing amplitude, instead of in monotonous way.
(3) The elimination speed V_D and resonance speed V_R obtained in case of no damping also are applicable to case of light damping, the error induced by the damping of the beam within the acceptable range.

Office for the reconstruction of San Giuliano di Puglia, Italy

ABSTRACT: Palazzo Marchesale in San Giuliano di Puglia (Italy) is an old masonry structure hosting the new City Hall. It is quite complex and is characterized by several parts with different height and foundation levels, and includes an internal court. After the earthquake of October 31st ($M_L = 5.4$) and November 1st, 2002, ($M_L = 5.3$), the building was retrofitted and seismic joints were realized between the different buildings, in order to regularize the dynamic behaviour. The structure has been considered for seismic monitoring in the framework of a research project funded by the Office for the reconstruction of San Giuliano di Puglia. Therefore a permanent accelerometric array has been designed and installed. It was tested by deploying also a temporary array in different configurations and recording ambient vibrations and weak motion effects. The experimental results were compared with those obtained by means of a finite element model. Thus, linear and nonlinear analysis allowed to evaluate the seismic safety of the structure. Modal identification and model updating are shown in the paper.

1 INTRODUCTION

Identification of dynamic characteristics of historical buildings is an important step that is necessary for two basic reasons: to assess possible dynamic behaviour of such complex structures during strong events and to gain experience on the dynamic behavior of historical buildings such that the experience and data base can be used in future design and analyses.

Past efforts in determination of dynamic behaviour of historical buildings allowed the development of data bases, which in turn have been used in design codes. Actually, data on dynamic behaviour of complex structures such as historical buildings are scarce.

The data bases are in general obtained from dynamic testing of structures (forced vibration, ambient vibration, etc.), and from analyses of data from instrumented structures. With this purpose, ENEA, the Italian Civil Protection and the Municipality of San Giuliano di Puglia organized a research project for seismic monitoring of relevant structures in the framework of the reconstruction of San Giuliano di Puglia, Italy. A permanent accelerometric array was designed and installed as part of the Seismic Observatory of Structures (OSS) of the Italian Civil Protection. The OSS (Spina et al., 2011) is the Italian State permanent network that monitors the seismic response of public structures, including 133 buildings (schools, city halls, hospitals, etc.), 7 bridges and 1 dam. The array was designed after a detailed study of the expected dynamic behavior of the structure and then installed and tested by recording ambient vibrations and weak motion effects also using a temporary array. The experimental results were compared with those obtained by means of a finite element model. Thus, linear and nonlinear analysis allowed to evaluate the seismic safety of the structure. All the steps of the modal identification, the model updating and the seismic analysis are summarized in the paper.

2 THE BUILDING

The Palace, located in the historical center of San Giuliano di Puglia, is composed of a series of masonry buildings, arranged around a central courtyard. They spreads over several levels, two completely above the ground emerging from the courtyard (level 0 and level 1), two below (level -1 and level -2) and then partially buried by the presence of a slope, which affects the site. In more detail four buildings can be distinguished, which are structurally separated (Fig. 1). For the seismic monitoring the following buildings have been considered:

- building A, developed from level -1 to level 1; a little room on level -2 is present in the left corner in Fig. 1;
- building B, which includes levels 0 and 1 but also levels -1 and -2 in some parts;
- the tower T, which starts from level 0 and presents levels 1, 2 and 3.

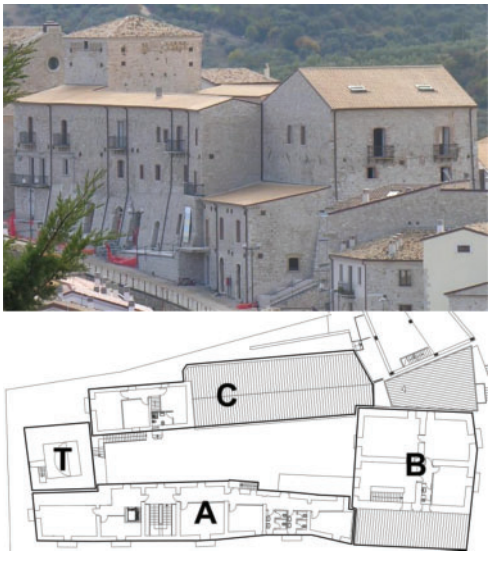

Figure 1. View and plan of Palazzo Marchesale.

Seismic improving interventions have recently been done. These consisted in mortar injections in masonry, substitution of some floors with new ones having laminated wood structure, and retrofit of vaulted roofs by means of FRP. Furthermore, the Palace was divided into buildings of regular shape (T, A, B and C), with seismic joints between them. Therefore, the tower, at the entrance of the courtyard is separated structurally and so are the buildings A and B, where the municipal offices are placed. In these buildings, which belong to the local municipality, an accelerometric network has been installed.

3 ACCELEROMETRIC NETWORK

The accelerometric network was designed on the basis of previous dynamic tests carried out on Palazzo Marchesale (Fig. 2). It is composed by 26 sensors, 4 of them are triaxial, 8 are biaxial sensors and 14 are uniaxial accelerometers. The total number of channel is 48. In more details, in building A three sensor (A1) were deployed on the floor and two sensor (A4) under the ceiling at level −1. Three other sensor (A9) were put on level 0 as well as two sensor respectively on the floor (A6) and under the ceiling (A7). On level 1, five accelerometers are on the floor and six under the ceiling. This deployment should be able to record both longitudinal and transversal movements of building A, in which one size is much higher than the other.

In building B three accelerometers (A2) were put on level −1, three (A10) on level 0 and three (A16 and A17) on level 1. The latest should be able to analyze both the translational and torsional modes of building B. The tower was instrumented by means of four accelerometers (A21, A22, A23 and A24) on level 2, four on the floor of level 3 (A8 and A19) and four under the ceiling of level 3 (A24, A25, A26 and A27).

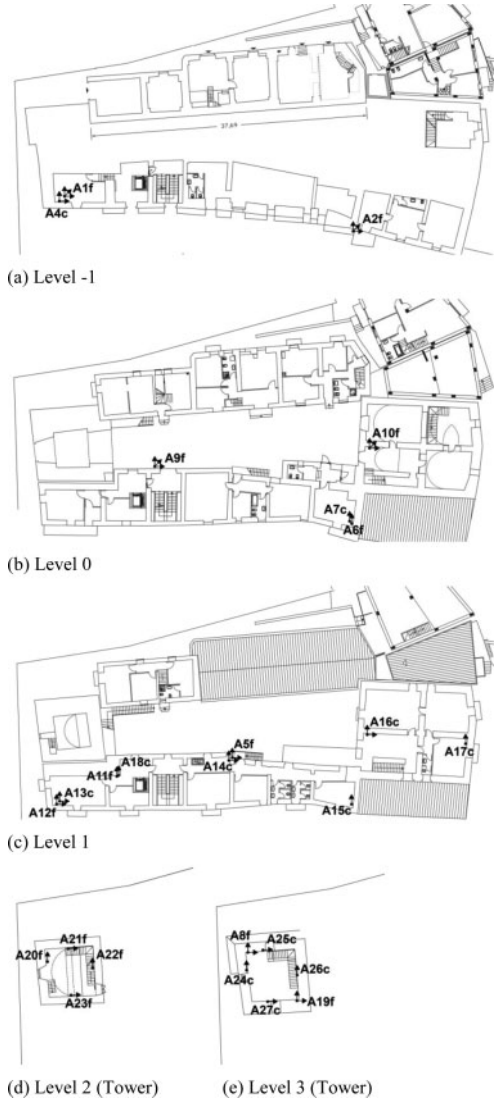

Figure 2. Accelerometric network (f = floor, c = ceiling).

Another triaxial accelerometer is in the courtyard, about 10 m below the ground level. This should record the seismic input to the building.

4 AMBIENT VIBRATION ANALYSIS

The ambient vibration analysis were carried out by using a Granite acquisition system and seismometers SS-1. Sensors were deployed in 2 configurations. In the first one 15 seismometers were deployed in the tower T (Fig. 3), in the second 17 seismometers were positioned in buildings A and B (Fig. 4). In both cases sensors positions were very close to the accelerometers of the fixed network. In the case of accelerometers placed at the top of the level, seismometers were positioned on the above floor. In Tab. 1 each seismometer in

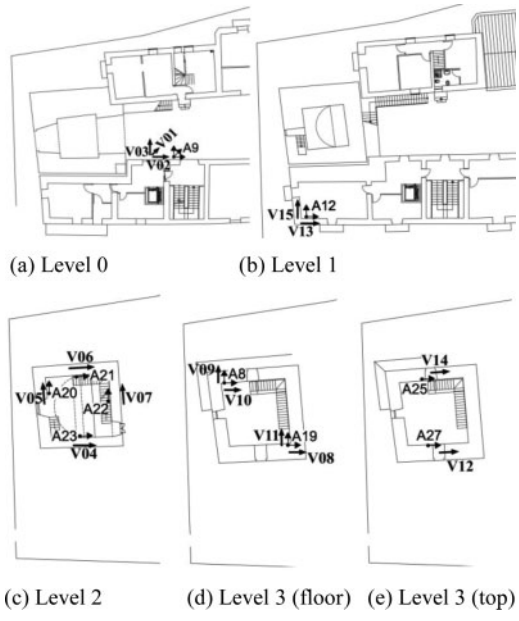

Figure 3. Configuration 1 – Tower.

the two configuratons is associated to the corresponding accelerometer in the tower T and in buildings A and B. Also the direction is associated to each sensor, x being the longitudinal, y the transversal and z the vertical one.

Several test for each configurations were carried out, each lasting 5 minutes, with the sampling rate of 250 samples/sec ($\Delta t = 0.004$ sec) in analogy to the sampling rate of the fixed accelerometric network (Clemente et al., 2012).

For all recordings the analysis was performed in the time and frequency domains. The velocimetric data were first derived in order to obtain accelerations. Then the corresponding auto- and the cross-spectral densities were compared with those of the accelerometric recordings. All recordings gave similar results. So only one test for each configuration was reported here in detail.

4.1 *Ambient vibration of the tower*

The resonance frequencies and the dynamic behavior of the tower, which is taller than the other portion, are apparent from the first configuration.

The main peak in the X direction is at 6.59 Hz, while in the Y direction the main peak is at 5.73 Hz. A resonance frequency is also at 10.10 Hz, apparent in all sensors, which is associated to a torsional mode, as demonstrated by the phase factors.

To assess the degree of connection of the tower T with building A, sensors V13x and V15y were placed just beyond the joint. The transversal sensor V15y followed the behavior of the sensors in the tower, while the longitudinal sensor V13x recorded the presence of the tower but also other peaks typical of building A, which will be analyzed later. For low levels

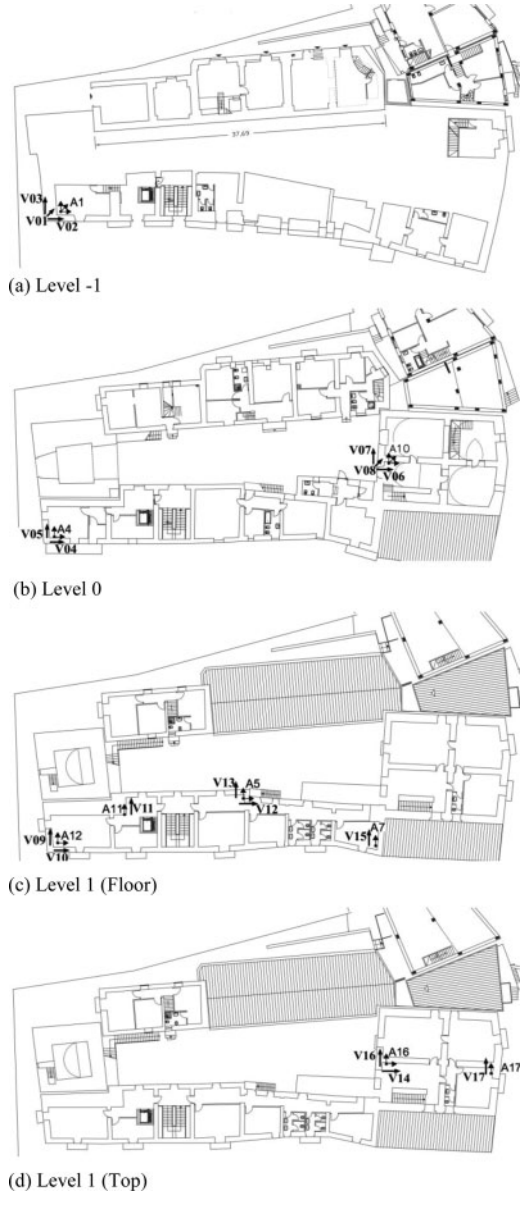

Figure 4. Configuration 2 – Buildings A and B.

of excitation the links with non-structural elements across the joint form a continuous link in the direction perpendicular to the joint (V15y).

Other resonance frequencies apparent in the spectra can be attributed to the local modes present in such complex structure. These make difficult the interpretation of the global behavior but have less importance in the interpretation of the general dynamics of this part of the building. The frequencies recorded by seismometers in the tower are shown in Table 2, while the first and second modal shapes obtained with accelerometric recordings are in Figs. 5a and 5b with the associated frequencies.

Table 1. Correspondence between seismometers and accelerometers in the tower and in buildings A and B (configuration 1 and 2, respectively).

Seismometers	Accelerometers in Tower	Accelerometers in buildings A and B
V01z	A9z	A1z
V02x	A9x	A1x

Freq. (Hz)	Modal shape
5.73	Transversal Traslation Y
6.59	Longitudinal Translation X
10.10	Torsional

4.2 *Comparison with the accelerometric recordings*

To perform the comparison the operation of derivation of the velocity recordings was performed, in order to make the data consistent to accelerations recorded from the fixed network. For these comparisons the frequency range was expanded up to 30 Hz. Then the comparison was performed in the frequency domain, through the auto-spectra and cross-spectra and the difference between the auto-spectra of the corresponding sensors.

The analysis of the diagrams showed significant values of the coherence function in the studied frequency range, while the phase factor assumes almost everywhere values around $\pi/2$, consistent with the derivation operation performed in the frequency domain.

Particularly significant is also the difference between the auto-spectra of the two measuring systems. Actually, the spectral shapes of the velocimeter recordings are always in agreement with the accelerometer ones while the amplitudes of velocimeters at the foundation level are not very similar to the corresponding accelerometric recordings (A9x, A9y, A9z). Proceeding to the positions at the upper levels of the structure a good compliance between the amplitudes is apparent. The presence of a low frequency component in the recording of A20y is apparent, which does not influence the spectrum but could affect the peak in the time domain.

Table 3. Experimental frequencies of buildings A and B.

Freq. (Hz)	Building	Modal shape
8.17	A	Transversal Y
9.88	A	Longitudinal X
6.22	B	Transversal Y
8.54	B	Longitudinal X

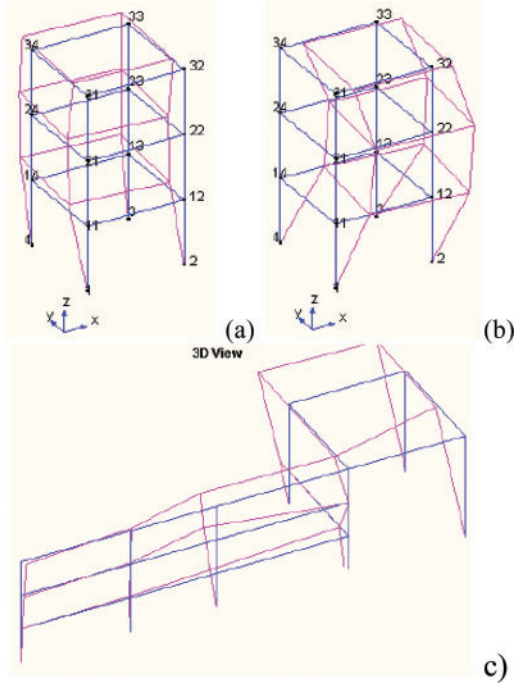

Figure 5. Experimental modal shapes with accelerometric data: (a) f = 5.6 Hz (Translational Y Tower), (b) $f = 6.7$ Hz (Translational X Tower), (c) $f = 6.2$ Hz (Translational Y building B).

4.3 *Ambient vibration of buildings A and B*

In the second configuration seismometers were deployed in buildings A and B. The complexity of the structures made the interpretation of the dynamic behaviour very hard. In the records of sensors in the transversal direction in the central portion of building A (V13y) the prevalent resonance frequency is at 8.17 Hz. This is associated to a bending modal shape with maximum amplitude in the central portion. In the records of sensors close to the tower (V05, V09) the same resonance of the tower, 5.73 Hz, was found. In the longitudinal direction (V04, V10 and V12) the main resonance is at 9.88 Hz.

With reference to building B, records of sensors in transversal direction (V16 and V17) showed an apparent peak at 6.22 Hz. Only V16 presents peaks at higher frequencies, between 10 and 11 Hz. In the longitudinal direction the record of sensor V14 has the main peak at 8.54 Hz. Both 6.22 Hz in the transversal direction and 8.54 Hz in the longitudinal one, can

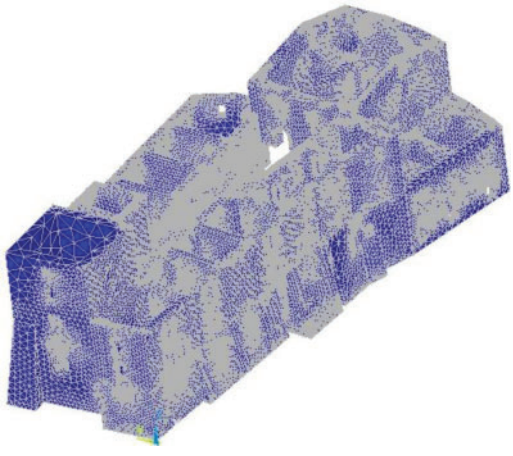

Figure 6. Mesh with solid elements.

be assumed as structural resonances. In Tab. 3 the structural resonances and the corresponding modal shapes are listed. The modal shape obtained with accelerometric recordings is in Fig. 5c.

4.4 *Comparison with the accelerometric recordings*

The low level of excitation and the stiffness of the structure determine a higher influence of the noise in both accelerometric and velocimetric recordings. The analysis showed significant values of the coherence function, while the phase factor is always equal to about $\pi/2$, due to the derivation in the frequency domain. The power spectral densities have very similar shape but some differences in the amplitudes are apparent. These could be related to the distance between accelerometers, which are often just below the floor or at the vault springing, and the velocimeters, which are above the corresponding floor.

5 FINITE ELEMENT MODEL

A finite element model was set up by using the code ANSYS. The elastic modulus was equal to 2120 N/mm^2 and was obtained by matching the first frequency with the experimental value. The model has 189236 nodes, and a total of 567 708 degrees of freedom. Finite element SOLID45 of prismatic or tetrahedral shape were used.

The mesh with solid elements is shown in Fig. 6. In the first step, here reported, the building was considered as a whole, without seismic joints. This hypothesis could be useful to analyze the behaviour under very low vibrations, such as the ambient vibrations. Then the mesh was generated obtaining. The frequencies of vibrations and the corresponding modal shapes were extracted by mean of the *subspace iteration method*. The first eleven modes were found, whose frequencies are listed in Tab. 4.

The first and second modal shapes are associated to a transversal and to a longitudinal movement of

Table 4. Numerical frequencies.

Mode	Freq. (Hz)	Building
1	5.73	T
2	6.50	T
3	6.74	B
4	6.96	C
5	7.43	A
6	7.87	A
7	8.20	All
8	8.36	All
9	8.43	All
10	8.62	All
11	9.08	All

the tower, respectively (Figs. 7 and 8). The portion around the tower is also involved in the modes. The third modal shape consists in the transversal movement (Y direction) of building B (Fig. 9), while the fourth mode interests building C, not considered in

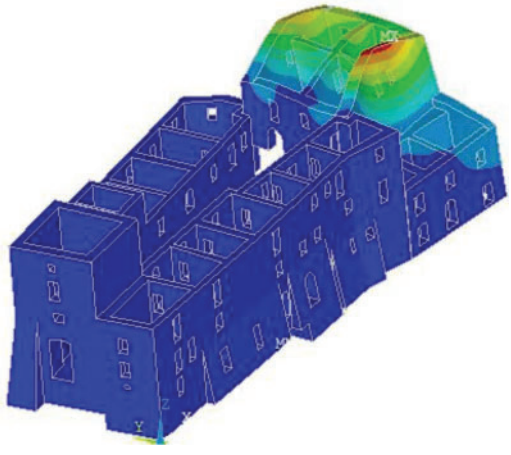

Figure 9. Mode 3 ($f = 6.74$ Hz).

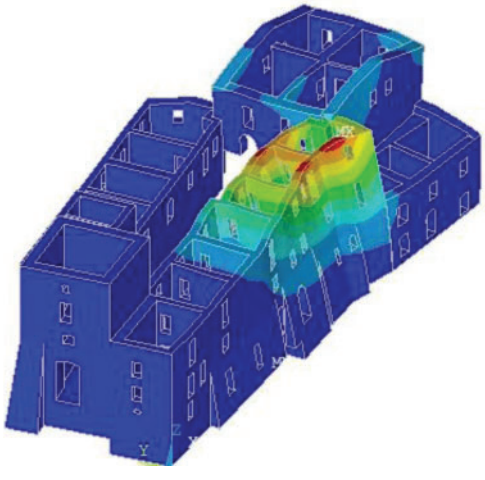

Figure 10. Mode 5 ($f = 7.43$ Hz).

the seismic monitoring. Modes 5 and 6 are relative to the longitudinal building A (Figs. 10 and 11).

The model was updated in order to obtain the coincidence between the first experimental and numerical frequencies. The comparison with the other frequencies gave quite good results (Tab. 5) and the same conclusion can be gathered in terms of modal shapes (Fig. 5 with Figs. 7–10). The comparison between the higher frequencies and the corresponding modal shapes is quite hard, especially for building *A*. Further recordings, including seismic events, could be useful.

6 CONCLUSIONS

The experimental campaign on Palazzo Marchesale by using both a temporary array, composed by velocimeter sensors, and a permanent array, composed by accelerometer sensors, gave the following results:

- the first three resonance frequencies of the tower were found; due to its slenderness its vibrations were detected using ambient noise only, which was quite hard for the other portions;
- the resonance frequencies of building B were also found but the modal shapes are not very clear;
- the longitudinal building A requires more data and a more detailed analysis;
- the comparison between accelerometric and velocimetric recordings gave good results.

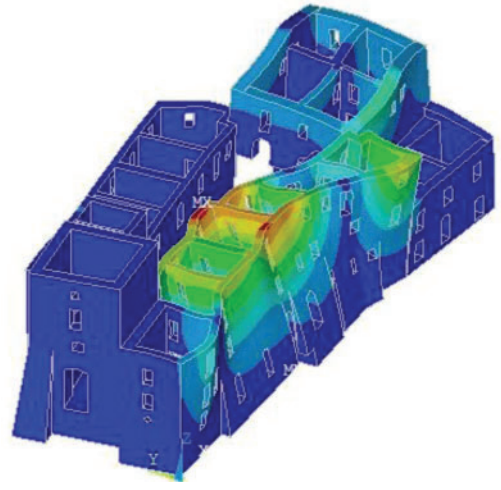

Figure 11. Mode 6 ($f = 7.78$ Hz).

Table 5. Comparison between experimental and numerical frequencies.

Num. Freq. (Hz)	Exp. Freq. (Hz)	Modal shape	Building
5.73	5.73	Translational Y	T
6.50	6.59	Translational X	T
6.74	6.22	Translational Y	B

The numerical model seams to interpret very good the experimental results. Anyway, further analyses will be very useful, especially in case of seismic recordings.

ACKNOWLEDGEMENTS

The activities here described are part of a research project funded by the Office for the reconstruction of San Giuliano di Puglia.

A suspended mass damper for torsional and translational vibration control

M. Carlisle & K. Li
The University of the Witwatersrand, Johannesburg, South Africa

ABSTRACT: A Suspended Mass Damper (SMD) is a passive vibration control device consisting of a mass which is suspended in the top region of a structure and is forced into motion, due to inertia, when the structure is excited. A test structure is used to carry out this experimental investigation. The damper mass is connected to the structure to be controlled by a group of inelastic ropes. It moves relative to the structure, utilising and dissipating energy as it swings, and in this way, the vibrational energy of the structure is absorbed and the vibrations are controlled. Free vibration tests are carried out on the test model to determine the damping effects of the SMD. The results reveal that a SMD, without tuning or specific adjustment, can provide significant control on translational, torsional and coupled vibration of the structure, making it versatile, uncomplicated and therefore ideal for engineering applications.

1 INTRODUCTION

The control of the dynamic response of structures to certain loads is an important focus of study in Civil Engineering. It aims to eliminate unwanted vibrations and to maintain a safe and comfortable environment for the inhabitants of a structure. Vibrations can occur in floor systems of tall, flexible buildings due, most commonly, to excitation from human activity, wind, and seismic activity. The dynamic nature of these loads causes vibrations which are not usually a safety concern but rather a serviceability issue, causing discomfort to the occupants. In relatively recent years, the research of vibration control on Civil Engineering structures has increased with the development of active and passive control devices. Passive control devices are those which are activated by the excitation of the structure and possess no feedback capability. They seem to be favoured due to the fact that they do not require power for their use as well as their mechanical simplicity and efficiency. A common passive control device which is frequently featured in the literature is the Tuned Mass Damper (TMD). A TMD is, in its basic configuration, a SDOF auxiliary mechanism consisting of a mass, spring and a dashpot which is connected to the main structure. The TMD's natural frequency is tuned to the natural frequency of the fundamental mode of the structure and therefore, under excitation, the damper will resonate out of phase with the structure's motion due to inertia. In this way, a portion of the structure's vibratory energy is transferred to the TMD and is dissipated. The World Trade Center Towers (1973) in New York and the John Hancock Tower (1976) in Boston were among the first practical applications of this type of control device.

It is obvious from observing the results of TMD applications that this system of vibration control for the protection of Civil Engineering structures has been widely successful and accepted. Although TMDs have achieved a great amount of success, the main shortfall of their use is their need to be tuned to a particular modal frequency of the structure and the fact that their efficiency depends strictly on this frequency. Unfortunately, a structure's fundamental frequency can change with time due to changes in building use or occupancy and changes to non-structural elements. These modifications may adjust the building's mass or stiffness and therefore alter its modal frequencies. Research has been conducted into other types of dampers, including multiple tuned mass dampers (Xu & Igusa 1992), active mass dampers (Scheller & Starossek 2011) and semi-active tuned mass dampers (Nagarajaiah & Sonmez 2007), with the aim of increasing the robustness of the TMD to mistuning. Attempts have also been made to produce a damper which can control the vibration in more than one direction, such as the rolling pendulum vibration absorber proposed by Matta *et al.* (2009) and the bidirectional and homogenous tuned mass damper proposed by Almazan *et al.* (2007). However, these devices need to be tuned and are therefore also subject to mistuning.

Although the research and application of the control of translational vibrations in structures has become more common, the control of torsional vibrations is significantly more challenging. A small amount of research has been done into reducing the torsionally coupled response of irregular structures (Lynch 1998, Lin *et al*. 1999, Yoshida & Dyke 2005). The control devices which have been studied for torsional control are mainly semi-active or active, and often multiple dampers are required in order for them to be effective.

The purpose of this investigation is to attempt to come up with an effective yet simplistic way of controlling torsional vibrations on buildings, as well as

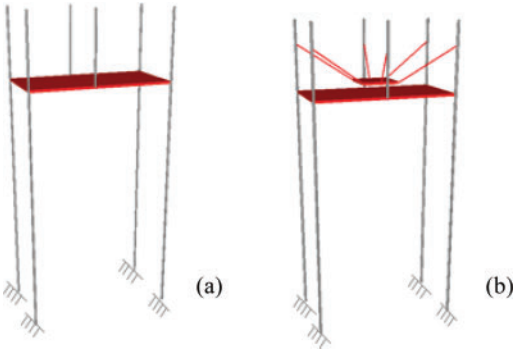

Figure 1. (a) The primary test model (b) The test model containing the SMD.

bidirectional translational vibrations, using only one control device, whilst also eliminating the problem of mistuning. The proposed SMD is completely passive and does not require any tuning to be effective. The inelastic ropes tighten and loosen as the damper moves during excitation, and in this way, the stiffness of the system can vary passively from zero to infinity as required. The proposed system effectively controls torsional and coupled vibrations of the structure. Furthermore, the translational vibrations of the structure, in two orthogonal directions, can be controlled. This paper uses experimental results to demonstrate the performance of an SMD.

2 EXPERIMENTS

2.1 *Experimental structure and setup*

Experimental tests were carried out on a tall, flexible test model. The primary, undamped model is illustrated in Figure 1a, whilst the model containing the SMD is shown in Figure 1b. The primary model consists of four 1.3 m high, 12 mm threaded rods and a 300 mm × 600 mm × 10 mm thick steel plate. The plate is secured at a height of 1m using nuts. The columns are bolted rigidly to the base such that the ends are rotationally fixed, and the base is fixed to a unidirectional shaking table. Prokon was used to simulate the behavior of the primary model, and to determine its first three natural frequencies and associated mode shapes. It was ensured that the values obtained during the Prokon simulation closely matched those which would be expected for a real-life tall, flexible structure. A number of model dimensions were entered and simulated until suitable frequency values were obtained, and therefore the suitable model dimensions were decided. The simulated model's first three natural frequencies, corresponding to the first three mode shapes are $f_{n1} = 2.66$ Hz, $f_{n2} = 2.69$ Hz and $f_{n3} = 4.24$ Hz.

The suspended mass damper, shown attached to the primary model in Figure 1b, is a 15 cm square metal plate with a thickness of 10 mm. It has a mass of 0.75 kg which is about 5% of the primary model's mass of 14.13 kg. It is tied, with inelastic ropes, to the threaded rod at a height of 20 cm above the plate. The damper mass sits 5 cm above the plate.

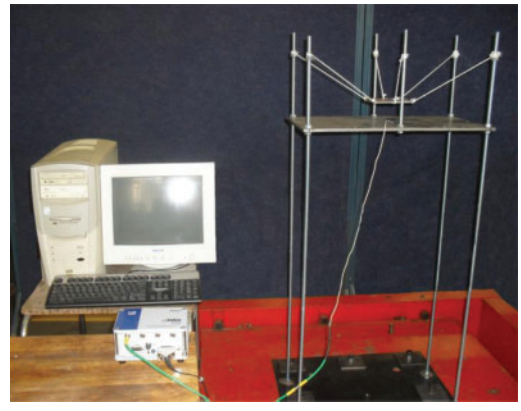

Figure 2. The experimental setup showing the test model, accelerometer, data logger and computer.

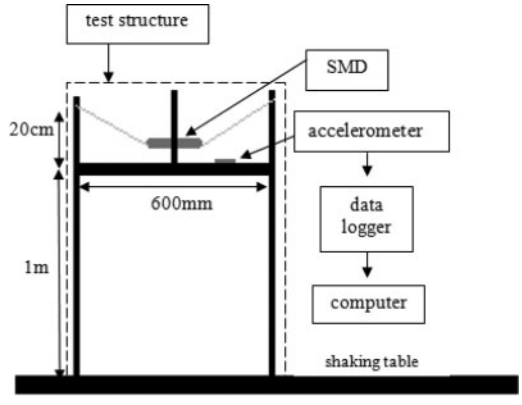

Figure 3. A schematic diagram of the experimental setup.

The test setup is shown in a photograph in Figure 2 and in a schematic diagram in Figure 3. An accelerometer is attached to the primary model in order to measure the accelerations after excitation. The accelerometer is connected to a data logger which records the acceleration readings over time. The data logger is connected to a computer so that the data acquired during the test can be viewed, analysed and processed using the programs TCE Build and Matlab.

2.2 *Experimental procedure*

2.2.1 *Free vibration tests*

Free vibration tests were carried out on the primary test model. The model was excited by giving it an initial displacement, which was measured using a dial gauge, and then releasing it. The tests were done for five different excitations of the test structure – it was excited in two translational directions; torsion; and lastly it was given two coupled excitations. The two translational directions were the orthogonal x and y-directions,

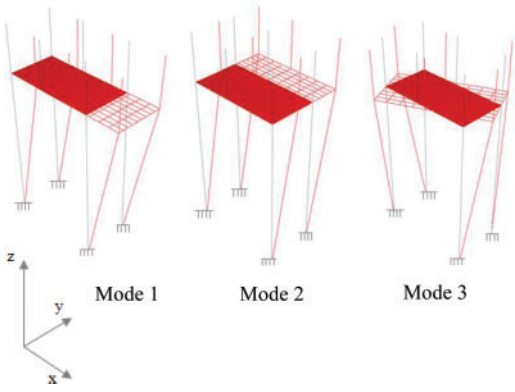

Figure 4. The model's first three mode shapes.

depicted by mode shapes 1 and 2 respectively in Figure 4 below. It was excited torsionally, as shown by mode 3 in Figure 4, by applying an initial twist to the model and then releasing it. Lastly, the model was subjected to two coupled excitations which were achieved by giving it initial torsional as well as translational displacements simultaneously.

The SMD was then added to the primary structure and the tests described above were repeated. The sampling frequency chosen for these experiments was 250 Hz, meaning that 250 acceleration readings were collected by the data logger per second.

3 RESULTS AND COMPARISON

3.1 *Translational vibration in the x-direction*

In the first test, an initial displacement of 30 mm was given to the undamped and damped models in the x-direction before releasing them. Figure 5 below shows a high peak at 2.36 Hz which is the model's first natural frequency, with a smaller peak at half of this value, 1.18 Hz. It is observed that the natural frequencies obtained by simulation (2.66 Hz) and by experimentation (2.36 Hz) do not match up exactly, however they are close in value. This is to be expected as the simulation results represent the results of an 'ideal' test and were merely obtained in order to get a basic idea of what could be expected during experimentation. Figure 5 shows that the SMD provides a high level of attenuation at both of the peaks, with the peaks of the damped model being reduced almost to zero. The time history of acceleration response for the first 25 seconds of the test can be seen in Figure 6. Near the beginning of the test, as the SMD starts moving, the acceleration peaks generated in the damped model are very high, exceeding those generated in the undamped model. These high accelerations subside and the accelerations rapidly become less than those found in the undamped model; however these initial high accelerations are undesirable. It was discovered by doing some further testing, that by making the inelastic ropes tighter i.e. reducing the height at which they are tied

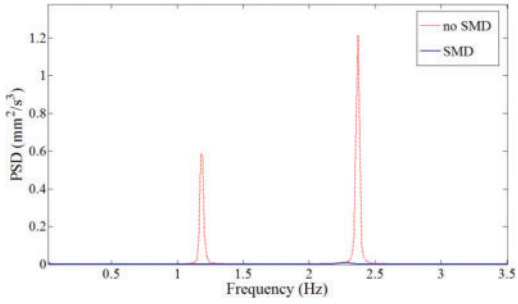

Figure 5. Power spectral density (PSD) of the acceleration response in the x-direction.

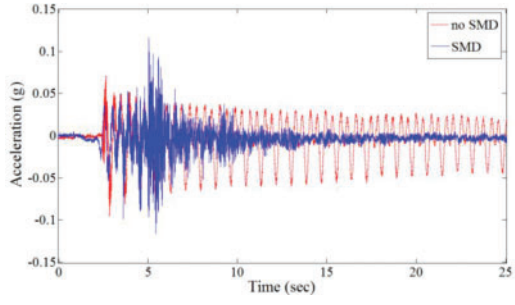

Figure 6. Time-history of acceleration response in the x-direction.

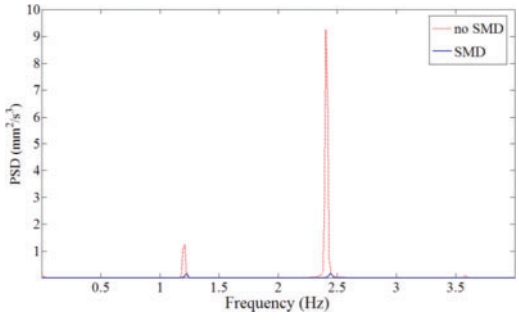

Figure 7. Power spectral density (PSD) of the acceleration response in the y-direction.

onto the threaded columns from 20 cm to 15 cm, the high accelerations decrease in value, becoming equal to or less than the undamped peaks. However, regardless of this small modification, the positive damping effects of the SMD evident in Figures 5 and 6 are still significant.

3.2 *Translational vibration in the y-direction*

Next, the damped and undamped models were given an initial displacement of 30 mm in the y-direction before being released. The PSD graph shows a high peak at 2.4 Hz, which is the model's natural frequency in that direction. Again, this is slightly different to the simulated result of 2.69 Hz, which is to be expected.

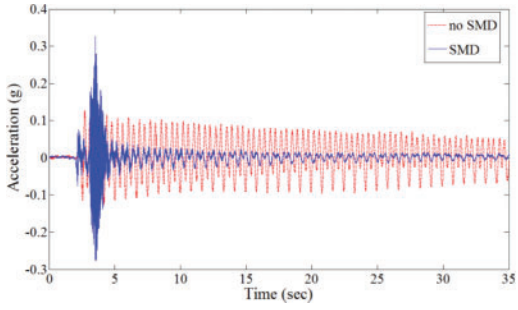

Figure 8. Time-history of acceleration response in the y-direction.

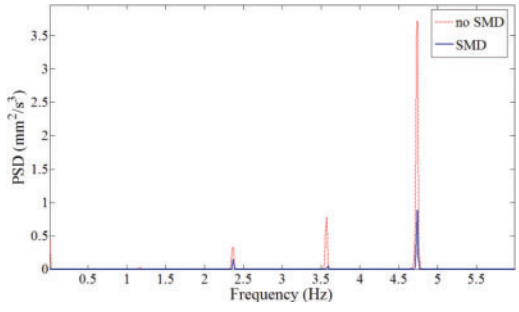

Figure 9. Power spectral density (PSD) of the acceleration response for torsional vibration.

A smaller peak can be seen at half of this value, 1.2 Hz. Again, the peaks are reduced as the structure is controlled by the addition of the SMD. The time history of acceleration response, shown in Figure 8, also contains high acceleration peaks for the damped model as the SMD starts moving, with these peaks rapidly decreasing to well below those of the undamped model as time progresses. Again, these initial high accelerations can be controlled by the slight tightening of the inelastic ropes of the SMD, which does not affect the positive damping results.

3.3 *Torsional vibration*

The damped and undamped models were then given a torsional displacement of 30 mm which was measured using dial gauges. The PSD graph below shows a high peak at 4.75 Hz, the torsional frequency of the model, as well as smaller peaks at 1.2 Hz, 2.4 Hz and 3.6 Hz. The torsional frequency obtained during simulation was 4.24 Hz, which is relatively close to the experimental value. The fact that there is a peak at 2.4 Hz means that although the model was excited in torsion, it had some movement in the y-direction as well. Once again, all of the peaks are reduced by the addition of the SMD. The time history of acceleration response for the damped model shows a more gradual decrease in accelerations as opposed to the translational time history graphs. However, the effect of the SMD is still obvious as time passes.

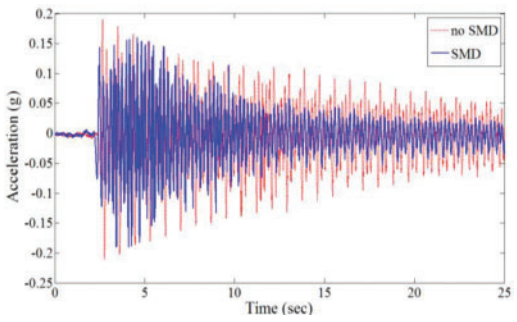

Figure 10. Time-history of acceleration response for torsional vibration.

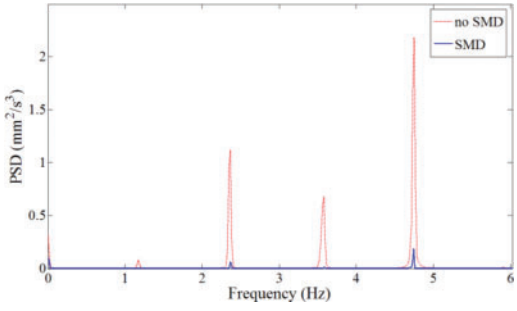

Figure 11. Power spectral density (PSD) of the acceleration response for coupled vibration (x-direction and torsion).

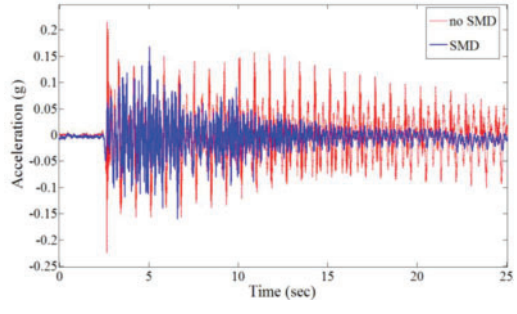

Figure 12. Time-history of acceleration response for coupled excitation (x-direction and torsion).

3.4 *Coupled vibration (translation in x-direction and torsion)*

Next, the model was subjected to a coupled excitation. It was given initial translational and torsional displacements simultaneously and then released. In Figures 11 and 12, the model was displaced in the x-direction as well as twisted. As can be seen, there are peaks at the torsional natural frequency, 4.75 Hz and at the natural frequency of translation in the x-direction, 2.35 Hz as well as smaller peaks at 1.2 Hz and 3.6 Hz. All of these peaks are decreased substantially by the addition of a SMD, indicating its control effect. This control is also obvious in the time history of acceleration response where the acceleration peaks generated in the damped

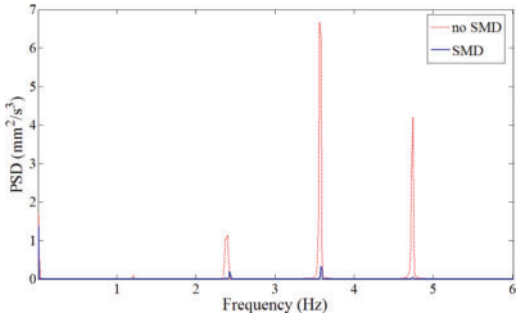

Figure 13. Power spectral density (PSD) of the acceleration response for coupled excitation (y-direction and torsion).

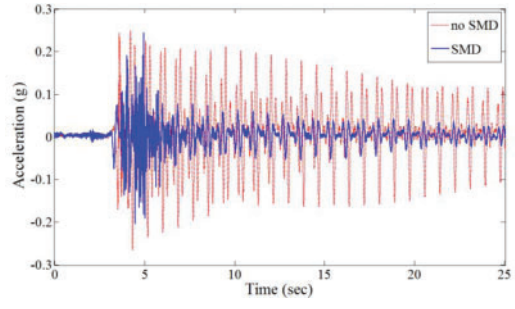

Figure 14. Time-history of acceleration response for coupled excitation (y-direction and torsion).

test decrease much more rapidly than those generated in the undamped test.

3.5 *Coupled vibration (translation in y-direction and torsion)*

Lastly, the model was subjected to a second coupled excitation. It was given a translational displacement in the y-direction and a torsional displacement simultaneously. The PSD shows peaks at the natural frequency for torsion, 4.75 Hz and the natural frequency for translation in the y-direction, 2.4 Hz, as well as a peak at 3.6 Hz. The control effect of the SMD is obvious for all peaks in the PSD graph and in the time history of acceleration response.

4 CONCLUSIONS

The proposed control device is effective, yet also simple and versatile. The free vibration tests which have been carried out, demonstrate the proposed SMD's capability of providing considerable vibration control to structures such as the tall, flexible test structure. The SMD did not need to be tuned during the tests and no specific adjustment took place. This is a significant advantage over traditional TMDs which are often the subject of mistuning due to changes in the structure's mass or stiffness and therefore changes in its natural frequency, which can render the TMD ineffective. The SMD's stiffness varies, as needed, during excitation by virtue of inelastic ropes, making it an uncomplicated yet efficient passive control device.

A further advantage of the proposed SMD is its ability to significantly control torsional and coupled vibrations, which has previously proven to be considerably more difficult than the control of translational vibrations. Moreover, the translational vibrations in the two principle, orthogonal directions, direction x and direction y were controlled effectively in the free vibration tests. High acceleration peaks were seen to occur in the damped model soon after the SMD was excited; however these were reduced by the slight tightening of the inelastic ropes connecting the damper to the structure. This modification does not reduce the positive damping effects which are obvious in all of the tests.

Status quo and critical review of PPV safe limits for subsurface construction blasting close to low-rise buildings

E.Y. Sayed-Ahmed

K.K. Naji
Facilities and IT, Qatar University, Qatar

ABSTRACT: Subsurface construction blasting may result sever man-made ground vibrations. Waves generated due to detonating a charge in a solid medium like rock generate particle movement and travel at different wave velocities. As such, ground-borne vibrations have effects on nearby buildings that range from disturbing the occupants to causing severe threshold "cosmetic" or structural damage. The said ground vibrations are usually monitored to assess their impact on nearby structures. Currently, codes of practice adopt safe limit criteria which are mainly based on field observations where the structural damage is correlated to the soil Peak Particle Velocity (PPV) produced on the ground surface close to the structure. For example, the criteria limit the PPV of the ground vibration to 51 mm/s at the nearest "non-owned" structure to the blasting site. On the contrary, it is not the soil PPV that matter but it is the structural response to the ground vibration which causes the damage: all the blast-vibration complaints are actually due to the structure vibration not the ground vibration. In this paper, some of the currently adopted safe limit criteria of ground vibration generated by subsurface construction blasting are reviewed. Two real case studies have been performed on low rise buildings (houses) located nearby an excavation performed by blasting in rock. The PPV and the vibration frequency due to excavation by blasting measured close to these low-rise buildings satisfied the existing safe limit criteria for subsurface blasting ground vibration. Despite this fact, both buildings suffered threshold cracks and one of them even had structural cracks. Thus, it is argued that the current safe limit criteria ignore a very important factor which is the structural response to the ground vibration. It is also argued that ground vibrations with low level frequencies affected the structural response of the two houses may have caused resonance and wall rattling. These, in turn, caused threshold, and even structural, cracks beside the severe disturbance to the residents. So, as an urgent modification, it is recommended that the PPV for low level frequency vibrations (4–30 Hz) should be multiplied by a magnification factor before comparing them to the current safe limits of the codes of practice. This would simulate the resonance or wall rattling which may occur to low rise buildings subjected to ground-born vibrations with low level frequencies.

1 INTRODUCTION

Rock excavation is commonly adopted by blasting which generates a family of waves that travel at different wave velocities. Approximately 15% of the total blast energy is utilized for actual breakage and mass displacement with the reminder spent on undesirable activities Niclson (2005). Among these are the ground-borne vibrations which may have an effect on residential buildings ranging from disturbing the occupants to causing severe threshold "cosmetic" or structural damage. Problems may occur as a result of large amplitude (low frequency) vibrations, repeated occurrence of smaller amplitude vibrations, or from differential settlement induced by soil particles rearrangement. Classifying ground vibrations types, monitoring their effects and establishing their severity were investigated (Dowding1985; Franfield 1996; Dowding 1996; Massarsch 1993; Wiss 1981; Skip 1984). The level of ground vibration resulting from subsurface blasting and the structural response depends on the explosive type and weight, delay time, blasting technology, soil properties, distance between the structure and the blasting centre, susceptibility ratings of the adjacent and remote structures, and the age and type of the structure. A simple equation estimating the PPV in terms of distance from the blasting location (D in m) and the charge weight per delay (W in kg) is:

$$PPV = 1725 \cdot \left(D/\sqrt{W}\right)^{-1.6} \quad (1)$$

Many attempts have been made to relate the vibration parameters (displacement, velocity, acceleration and frequency) with the observed human annoying, disturbance of sensitive devices and structural damage (Medearis 1976; Siskind et al. 1980; Wiss 1981; Svinkin 1993; Dowding 1996). Currently, codes of

practice adopt safe limit criteria which are mainly based on field observation (Svinkin 2004; ISEE 1998). Most of these criteria correlate the structural damage to the soil Peak Particle Velocity (PPV) produced on the ground surface and limit the PPV to 51 mm/s at the nearest "non-owned" structure to the blasting site. Three factors of ground vibration affect the structural response: ground vibration amplitude defined via the PPV, ground vibration duration (which is not the same as the blast duration), and ground vibration frequency. Usually seismographs report the PPV and the frequency and often ignore the duration. Reducing ground vibration duration would reduce the structure response but increase the perception of the occupants to the ground vibration.

This paper shows that it is not the soil PPV that matter but it is the structural response to the ground vibration: all the blast-vibration complaints are actually due to the structure vibration not the ground vibration. Thus, the currently adopted criteria cannot define reliable and acceptable safe limits for subsurface construction blasting. Two case studies have been performed and discussed for two residential houses (one- and two-storeys) located adjacent to an excavation where blasting was to be used for excavating the rock. Data recorded during blasting are compared to currently adopted ground vibration safe limit criteria: PPV and the vibration frequency due to excavation by blasting measured close to these houses satisfied the existing safe limits criteria. Despite this fact, both houses suffered threshold cracks and one of them had some structural cracks. Thus, a new approach that is based on relating the PPV and the ground vibration frequency to the structural response is proposed and a safe limit criterion for sub-surface construction blasting is developed.

2 CURRENT SAFE LIMIT CRITERIA

The International Standards ISO 4866-1990 lists some major regulations of ground vibrations for different types of buildings. Further, it was continuously argued that damage could be related to the PPV of the ground vibration (Duvall and Fogelgon 1962; Wiss 1968; ISEE 1998).

A 10-year research programme of the United States Bureau of Mines (USBM) led to the widely adopted criterion for the safe-limit vibration against structural and threshold damage of buildings resulting from ground vibrations generated by blasting (Nichollas et al. 1971). The safe limit for the resulting PPV was set at 51 mm/s in the frequency range of 3–100 Hz. This limit could not prevent the frequent residents' complaints from construction blasting. To take into account the effect of the dominant vibration frequency to assess the ground vibration effect on structures, an alternative USBM frequency-based safe limit was proposed (Siskind et al. 1980). This criterion is known as USMB-RI 8507 (Figure 1) for providing safety against ground vibrations resulting from blasting.

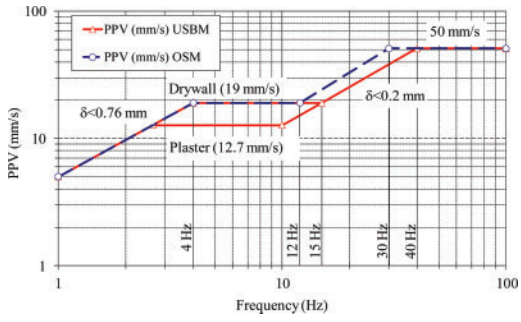

Figure 1. USBM and OSM safe limit criteria against ground-born vibrations due to subsurface blasting.

Table 1. PPV and Scaled Distance (US-OSM).

Distance m	PPV mm	Scaled Distance m
0∼91	31.8	22.6
92∼1524	25.4	24.9
>1524	19.1	29.4

The USMB-RI 8507 criterion was modified by US Office of Surface Mining (OSM). It is shown graphically in Figure 1 and compared to the previously mentioned USMB-RI 8707 criterion.

The OSM adopted two other methods. In the first method, the PPV is limited to the values shown in Table 1 without the need for monitoring the vibration frequency. In the second method, the amount of explosive is designed based on a scaled distance (SD) using the following Equation:

$$W = (D / SD)^2 \quad (2)$$

where W is the allowable charge per delay (kg), D is the distance (m) and SD is the scaled distance given in Table 1 (m). The scaled distance method is very conservative and there is no need to fit seismograph to measure the PPV or the vibration frequency during the blasting operation.

The British Standard BS 7385 criterion for safe limit against ground vibrations due to blasting is plotted in Figure 2 and compared to the OSM criterion. It is very close to both USBM-RI 8507 and OSM criteria. The BS 7385 adopts two lines for the safe limit depending on the building type: line 1 (independent of the vibrations' frequency) is used for commercial large buildings and line 2 (frequency based) is used for residential or small buildings.

The DIN 4150 and the Swiss Standards criteria for safe limits against ground vibrations resulting from blasting are also plotted in Figure 2. It is evident that these two criteria are significantly conservative. It is argued that the DIN 4150 criterion is not damage-based; it is intended to minimize the perceptions and complaints of housing residents who live adjacent to blasting sites.

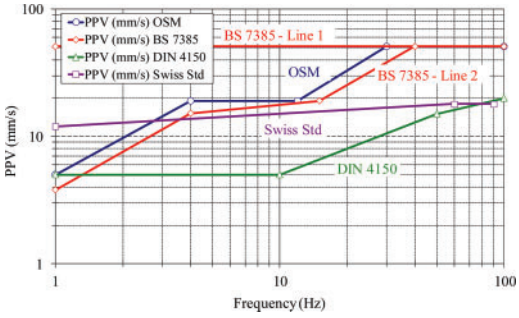

Figure 2. OSM versus other safe limit criteria against construction vibrations.

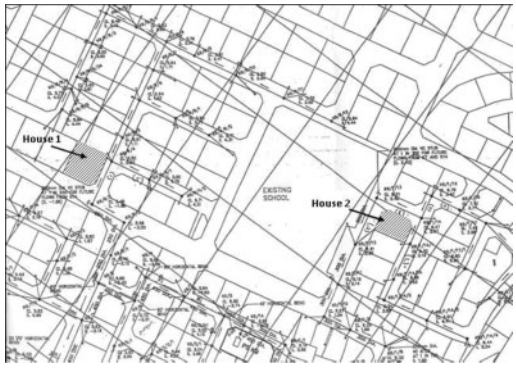

Figure 3. The two houses outlined on the layout of the sewerage system project (Blast locations are along the solid lines representing the sanitary sewer of the city).

3 PROPOSED DAMAGE CRITERIA

The current safe limit criteria make no distinction for the type, age or stress history of the structure; all of which considerably affect the safe limits. The y are all based on the PPV and frequency of the ground vibrations and thus, they fail in many situations (ISEE 1998; Quesne 2001). A major drawback is in the concept of the safe limit criteria itself: they only correlate the structural damage to the intensity of the ground vibration. However, a safe limit criterion against ground-born vibrations due to blasting should be based on the structure vibration/response not the ground vibration. In other words, the 51 mm/s safe-level criterion should be applied to the PPV of the structural vibration due to blasting not to the soil vibration.

The intensity of the vibration depends on the soil-structure interaction that determines the structure responses to the ground excitation. A ground vibration frequency which is 40% (or more) greater than the fundamental frequency of the structure introduces a structure PPV that is less than the PPV of the ground vibration. On the other hand, a ground vibration with a frequency below the fundamental frequency of the structure causes the structure to vibrate at least as much as the ground. If the ground vibration frequency is close to the structural natural frequency, a state of resonance may be generated and the PPV of the structure will increase considerably beyond the PPV of the ground vibration. This phenomenon is totally disregarded in all the currently adopted safe limit criteria against ground-born vibrations due to subsurface blasting.

Low-rise buildings have a natural frequency in the order of 4～12 Hz (Medearis 1977; Siskind 1980; ISEE 1998). The structures and their parts (e.g. floor, walls, etc.) respond differently to ground vibration as they have different natural frequencies. For example, the natural frequencies are 12～20 Hz for interior walls' horizontal vibrations and 8～30 Hz for floors vertical vibrations. Mid-walls' vibrations cause residential buildings to "rattle" making vibration more noticeable and aggravate human response to annoyance from ground vibration. It is difficult, if not impossible, to follow a uniform vibration standard to reduce the human perception of vibration due to subsurface blasting (Baliktsis 2001).

For the currently adopted safe limit criteria which are based on threshold/structure damage prevention, it is proposed to apply an amplification factor ranging between 2 and 4.5 to the soil PPV in the frequencies range of 4 Hz to 30 Hz as a modification to these criteria in order to consider the structure's resonance effect (Svinkin 2004).

4 PROPOSED CRITERIA VERFICATION

A project for sewerage system was executed in rock soil; part of the project layout plan is shown in Figure 3. The excavation was performed using subsurface blasting. The blasting events were officially supervised and the resulting soil PPVs and vibration frequencies were recorded using seismograph.

All the safe limits criteria for ground vibration resulting from the subsurface blasting, particularly those of the USBM and OSM, were accurately followed. The readings recorded by the seismographs for all the blasting events were well below the 51 mm/s limit. However, complaints were reported from many residents who blamed the blasting operation for causing threshold cracks to their houses. The readings of the seismographs recorded nearby two houses are compared to the currently adopted safe limit ground vibration criteria. The proposed safe limit criterion is also applied to these two houses to investigate the effect of the ground vibration resulting from the excavation by blasting on the two houses.

4.1 *House 1*

The first investigated house is a two-storey residential building which was newly built. When excavation by blasting started the house was almost one year old. It is a common reinforced concrete skeletal structure (solid slabs, beams and columns). The foundation of the house is composed of isolated footings constructed

Table 2. PPVs recorded for some blasting events – House 1.

Event No.	281	282	280	283	177	185	288
PPV mm/s	14.7	22.7	23.2	20.8	14.9	27.5	20.1
Event No.	294	287	219	218	220	284	285
PPV mm/s	15.7	19.8	25.5	28.8	20.5	19.3	12.4
Event No.	279	147	163				
PPV mm/s	14.2	24.8	23.3				

1.20 m below the lowest ground level and tied together with strong ground beams. The mid-wall partitions of the house consist of concrete block masonry walls. The house contains one stair case joining its two storeys.

After the excavation by blasting, many cracks appeared inside and outside the house (Figure 4). Most of the thresholds cracks started from the window frames, propagated vertically for a short distance then continue to propagate diagonally at an angle ranging between 30° and 60°. One structural crack was visible in the beam carrying the reinforced concrete slab of the second storey over the stair case.

Samples of ground PPV measured during the excavation by the blasting process around the house are listed in Table 2. The date of the event and its position with respect to the house were eliminated from the table. The seismographs also recorded the blasting event frequency in the vertical, radial and circumferential directions. These frequencies are plotted against the PPV for every blasting event in Figure 5 and compared to some of the currently available safe limit ground vibration criteria. The PPV of the low frequency vibrations (between 10–20 Hz) are magnified, as recommended by the proposed safe limit criterion, and also plotted in Figure 5: these events are enclosed by the dotted line in the figure to highlight their sever effects.

4.2 *House 2*

The second investigated case study is a one-storey residential house which was about twenty years old when the excavation by blasting started. The house had been renovated about two years before the start of the excavation work. It is an ordinary reinforced concrete structure with solid slabs carried by reinforced concrete beams which are supported over columns. The foundation of the house consists of isolated footings. The partitions of the house consist of concrete block masonry walls. Some of the cracks which appeared in this house after excavation are shown in Figure 6. Samples of ground PPV measured during the excavation by blasting process are list in Table 3. The vertical, radial and circumferential frequencies recorded by the seismographs are plotted against the PPV for every blasting event in Figure 7 and compared to some of the currently available safe limit ground vibration criteria. Ground PPV which have low frequency vibrations are magnified and plotted in Figure 7.

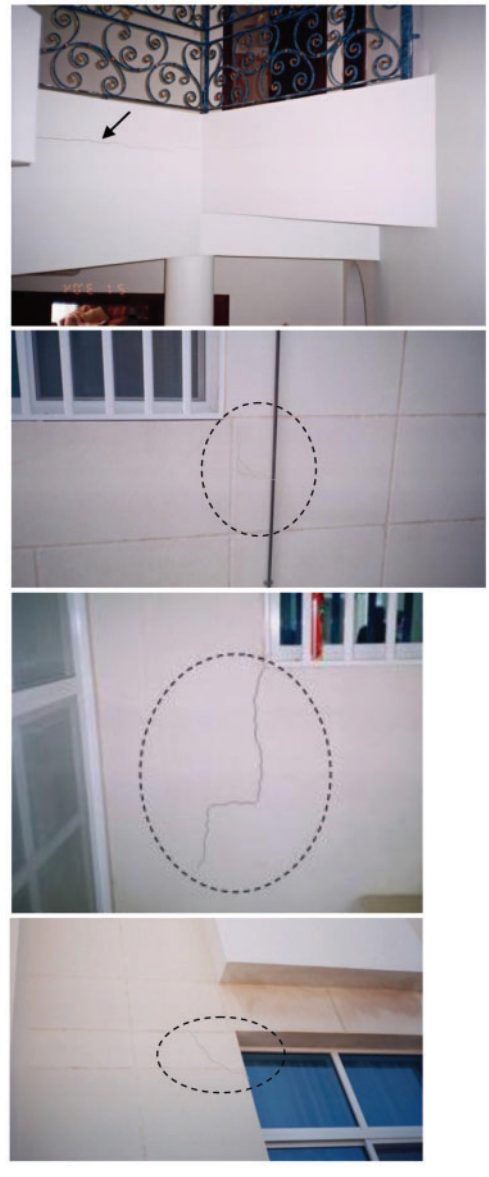

Figure 4. Examples of cracks appeared on House 1 after excavation by blasting (Cracks circled by dotted lines have been enhanced by plotting grey lines on top of them).

4.3 *Discussion*

Data recorded for the two case studies of houses located nearby subsurface blasting were examined. It is evident form the readings of the seismographs (samples of them are summarized in Tables 2 and 3) that the PPVs recorded for all blasting events were well below 51 mm/s; the limit defined in most of the available safe limit criteria. Furthermore, plotting the relations between the PPVs and the frequencies of the ground vibrations for these events (Figures 5 and 7) reveals that the ground vibrations satisfy the safe limit criteria set by the USBM, the OSM and the BS 7385. Some

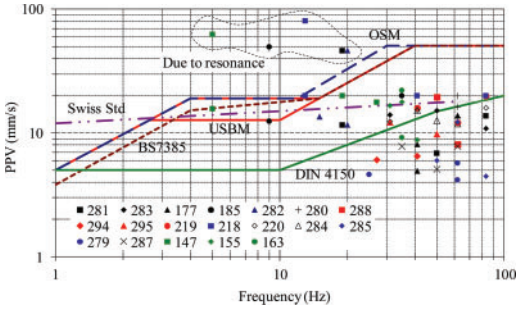

Figure 5. Ground PPVs and vibration frequencies of the blasting events recorded for House 1.

Figure 6. Examples of cracks appeared on House 2 after excavation by blasting (Cracks circled by dotted lines have been enhanced by plotting grey lines on top of them).

the events do not satisfy the Swiss Standards and most of them are unsafe compared to the DIN 4150 specifications. However, these two standards are human annoyance driven as opposed to structural damage driven criteria.

Table 3. PPVs recorded for some blasting events – House 2.

Event No.	269	270	175	176	266	267	182
PPV mm/s	18.8	22.3	23.0	12.7	21.9	15.7	22.4
Event No.	183						
PPV mm/s	16.9						

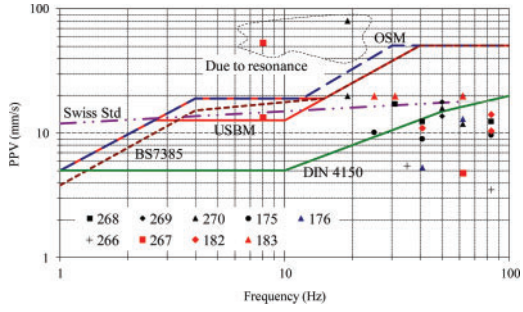

Figure 7. Ground PPVs and vibration frequencies of the blasting events recorded for House 2.

Despite satisfying all these criteria, threshold cracks, and even structural cracks, appeared in these houses after the excavation by blasting. Furthermore, the residents complained that the blasting effects were significantly pronounced.

It is evident that the currently adopted safe limit criteria ignore a very important factor which is the structural response to the ground vibration. It is argued that ground vibrations with low level frequencies affected the structural response of these two houses causing resonance and wall rattling. These, in turn, caused threshold, and even structural, cracks beside the severe disturbance to the residents.

So, as a modification, the PPVs of the low level frequency vibrations (4–30 Hz) should be magnified by a certain factor (estimated as 4.0 in the current investigation) before comparing them to the currently adopted safe limit criteria. This would simulate the resonance or wall rattling which may occur to the houses subjected to ground-born vibrations with low level frequencies. With this modification, Figures 5 and 7 reveal that some of the ground vibrations are significantly outside the safe limit defined by the safe limit criteria and would cause damage to the structures.

Gad *et al*. (2005) presented an investigation which agrees with the reached conclusion of this paper. They investigated the effects of blast vibrations on a single storey brick veneer house, which was monitored for over 1 year and was subjected to 43 blasts with ground PPV ranging from 1.5 to 222 mm/s. They recommended an amplification factor ranging between 2.0 and 4.0 for the ground PPV depending on the PPV value where:

$$\begin{aligned} \lambda &= 4.0 \quad for\ PPV \le 5\ mm/s \\ \lambda &= 2.0 \quad for\ 5\ mm/s < PPV \le 100\ mm/s \end{aligned} \tag{3}$$

No evidence was clear for this stepped function and further research is required to investigate if a smoother function for the magnification factor.

The amplification factor was adopted in calculating the wall shear strain γ resulting from ground vibration (Gad *et al*. 2005) where:

$$\gamma = \frac{PPV_{hl}}{2\pi f}\frac{\lambda}{H} \quad (4)$$

where PPV_{hl} is the horizontal ground peak component velocity, H is the floor height and f is the natural frequency of the structure. It is evident from equation 4 that the shear strain (causing structural/threshold damage) is dependent on both the PPV and the dynamic properties of the building.

Other data collected by Niclson (2005) for residential houses located nearby subsurface blasting had PPVs ranged between 0.06 mm/s and 11.5 mm/s which were well below the 51 mm/s defined by common safe limit criteria. Despite this fact, many complaints of structural/threshold damages were reported which also confirm the conclusions reached in this work.

5 CONCLUSIONS

The currently adopted safe limit criteria for ground-born vibrations resulting from subsurface blasting were discussed. All these criteria do not focus on resonance or wall rattling which may occur to a residential building if it is subjected to low-level frequency ground vibrations.

Data recorded for two houses located nearby subsurface blasting were examined. The two houses suffered cracking despite satisfying the current safe limit criteria required for subsurface blasting. It is argued that ground vibrations with low level frequencies affected the structural response of these two houses causing resonance and wall rattling. These, in turn, caused threshold, and even structural cracks in addition to causing severe disturbance to the residents.

Thus, it is recommended that the PPV for low level frequencies (4–30 Hz) be multiplied by a certain magnification factor before comparing them to the current safe limits. The magnification factor adopted in the current investigation was 4.0; however, the value of this factor should be refined to include the ratio between the ground vibration frequency and the natural frequency of the nearby structure. Furthermore, this proposed concept still needs to be explicitly verified using more data.

Dynamic response of rigid pavement under moving traffic load with variable velocity

Yang Zhong & Mei-Jie Xu
School of Civil and Hydraulic Engineering, Dalian University of Technology, Dalian, Liaoning, China

ABSTRACT: In this paper, the dynamic response of an infinity plate resting on an elastic foundation subjected to moving traffic load with variable velocity (accelerating or decelerating) is investigated by using a triple Fourier transform in time and space. The effects of the load moving velocity, acceleration and deceleration are discussed respectively. The numerical results indicate that the main affecting parameters are initial velocity, acceleration or deceleration. Numerical examples are presented to compare the results of static analysis and those of dynamic analysis with a constant moving velocity. The results show that the dynamic response of rigid pavement under a moving traffic load with variable velocity is not only different from that caused by static load, but also different from that generated by load with a constant moving speed. Displacement of the plate is reduced with increasing of moving velocity and acceleration. But, stresses of the plate increase with the moving velocity at given acceleration. Both the velocity and acceleration of a moving vehicle shall be considered in the analysis of rigid pavement.

1 INTRODUCTION

In the analysis of pavements of highway and airport, a rigid pavement structure is usually regarded as a plate resting on an elastic foundation, which is often modeled as a Winkle foundation. In general, the loads exerted on the plate are moving traffic load such as wheel loads from moving vehicles and from air planes. When a vehicle accelerates or decelerates or a plane takes off or lands, the loads applied to the plate structure are moving loads with acceleration or deceleration. Therefore, the investigation of dynamic response of the plate resting on an elastic foundation subjected moving traffic loads is interesting and important, as the results can be applied to understand the dynamic behaviors of pavements of highway and airport.

Many research works have appeared in the literature on the dynamic response of a beam resting on the foundation subjected to moving loads and free vibration of plate. In comparison, plates on an elastic foundation subjected to moving loads have only attracted the attentions of few researchers. Sun el at studied the effects of initial stress on the dynamic response of infinity long and simply supported composite plate under cylindrical bending by means of model superposition approach. Wu et al. used the finite element method to study the dynamic response under moving loads. Lin and Gbadeyan discussed the dynamic behavior of a beam and a rectangular plate under moving loads, paying more attention to moving mass. Takabataka investigated the dynamic response of rectangular plate with stepped thickness subjected to moving loads, including moving mass. Existing research on dynamic analysis of plates on elastic foundation pertains to analytical models with simple and regular boundary conditions. Gbadeyan and Oni gave a closed-form solution by using double Fourier sine integral transformation to analyze a simply supported rectangular plate resting on elastic Pasternak foundation traversed by an arbitrary number of moving concentrated masses. Kim and Roesset investigated an infinite plate resting on an elastic Winkler foundation subjected to moving loads with transformed field domain analyses using Fourier transform. The response to moving loads with acceleration (or deceleration) has not been well studied before. Existing research on response to accelerated moving loads can only be found for plate and beam structures without an elastic foundation. Suzuki investigated the influence of the acceleration of the traveling load on the response of a finite beam. Wu et al. used the finite element method to investigate the response of flat plate structures and studied the effects of eccentricity, span length, acceleration and initial velocity of moving load. Lin and Trethway used the finite element method to analyze response of elastic beams to a moving load, which could be specified as a general excitation force. This paper studies the dynamic response of an infinity plate resting on an elastic foundation. The effects of acceleration, initial moving velocity and initial position are investigated and discussed. In order to prove the correctness of formulations derived in the paper, the numerical results are presented and compared with results for the same problem with a constant velocity. The dynamic response of a plate resting on an

elastic foundation subjected moving traffic loads is interesting and important. The results can be applied to understand the dynamic behaviors of pavements of highway and airport.

2 GOVERNING EQUATIONS AND SOLUTION ANALYSIS

The governing differential equation for the dynamic vertical displacements $w(x,y,t)$ in a Cartesian coordinate system $\{x,y\}$, based on the Kirchhoff small deflection plate theory, can be written as

$$D\left[\frac{\partial^4 w}{\partial x^4}+\frac{\partial^4 w}{\partial x^2\partial y^2}+\frac{\partial^4 w}{\partial y^4}\right]+Kw +C\frac{\partial w}{\partial t}+\rho h\frac{\partial^2 w}{\partial t^2}=F \tag{1}$$

where D is the flexural rigidity of the plate defined by $D=Eh^3/12(1-\mu^2)$, the parameters ρ, h, E, μ and C are the unit density, thickness, modulus, damping coefficient and Poisson's ratio of the plate respectively. K is the reaction modulus of the foundation. F is external dynamic load acting on the surface plate. The plate is assumed to extend to infinity in the horizontal plane. The load pressure within the contact area is assumed to uniformly distribute in a rectangular area.

When the loads moving along the x direction are considered and the loads, for this case, can be expressed as:

$$F(x,y,t)=F_0\{U[x+a-X(t)]U[y+b] -U[x-a-X(t)]U[y-b]\} \tag{2}$$

where U is the unit step function and X(x) denotes a function describing the motion of the force at time t defined

$$X(t)=x_0+Vt+\frac{1}{2}at^2 \tag{3}$$

where F_0 is the amplitude function of the load. x_0 is the load positions, V is the initial speed, and a, is the constant acceleration. The uniform velocity type of motion, of course, is given by

$$X(t)=x_0+Vt \tag{3'}$$

Equations (1), (2) and (3) are total formulations for the analytical model of the plate on elastic foundation, subjected to moving concentrated loads.

In order to solve the problem described above double dimensions Fourier transform is adopted as defined by following:

$$\bar{f}(\varsigma,\eta,t)=\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(x,y,t)e^{-i(\varsigma x+\gamma\eta)}dxdy \tag{4}$$

The inverse Fourier transform is

$$f(x,y,t)=\frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} f(\varsigma,\eta,t)e^{i(\varsigma x+y\eta)}d\varsigma d\eta \tag{5}$$

Using the Fourier transform defined as Eq. (4), the Eq. (1) can be presented as

$$\frac{d^2\bar{w}}{dt^2}+\frac{C}{\rho h}\frac{d\bar{w}}{dt}+\frac{1}{\rho h}\left[D(\xi^2+\eta^2)^2+K\right]\bar{w}=\frac{\bar{F}}{\rho h} \tag{6}$$

Fourier transforming equation (3) gives

$$\bar{F}=F_0\frac{4\sin\xi b}{\xi}\frac{\sin\eta c}{\eta}e^{i\xi[x_0+t(V+\frac{1}{2}at)]} \tag{7}$$

Substituting Eq. (7) into Eq. (6) and using Duhamel Integration and the inverse Fourier transform, the solution for Eq. (1) in temporal domain can be obtained as

$$w=\frac{F_0}{\rho h\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\int_0^t\frac{\sin\xi b\sin\eta c}{\xi\eta}e^{i\xi[x_0+\tau(V+\frac{1}{2}a\tau)]-B(t-\tau)} \frac{\sin A(t-\tau)}{A}e^{i(\varsigma x+\eta y)}d\xi d\eta d\tau \tag{8}$$

where $B=\frac{\rho hC}{2}$; $A=\sqrt{D(\xi^2+\eta^2)^2/\rho h-B^2}$.

Using Mathematica and integrating for τ in Eg. (8), gives

$$w=\frac{(-1)^{1/4}F_0}{\rho h\pi^2\sqrt{2a\pi}}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{e^{i\{\xi(x+x_0)+\eta y+\frac{(A+iB-\xi B)^2}{2a\xi}\}-pt}}{A} \frac{\sin\xi b\sin\eta c}{\xi\eta}\left\{e^{A(\frac{2B}{a\xi}-it)}\left[erf(Z_1)-erf(Z_2)\right]\right. \left.e^{iA(\frac{2V+at}{a})}\left[erf(Z_3)-erf(Z_4)\right]\right\}d\xi d\eta \tag{9}$$

where $erf(x)=\frac{2}{\sqrt{\pi}}\int_0^x e^{-t^2}dt$ is the error function

$$Z_2=\frac{(1+i)(\xi V-A+iB)}{2\sqrt{a\xi}};\quad Z_1=\frac{(1+i)[\xi(V+at)-A+iB]}{2\sqrt{a\xi}}$$

$$Z_3=\frac{(1+i)(\xi V+A+iB)}{2\sqrt{a\xi}};\quad Z_4=\frac{(1+i)[\xi(V+at)+A+iB]}{2\sqrt{a\xi}}$$

The transverse stresses are the longitudinal stresses at the bottom of the plate can be obtained respectively.

$$\sigma_x=\frac{Eh}{(1-\mu^2)}\left(\frac{\partial^2 w}{\partial x^2}+\mu\frac{\partial^2 w}{\partial y^2}\right) \tag{10}$$

$$\sigma_y=\frac{-Eh}{(1-\mu^2)}\left(\frac{\partial^2 w}{\partial y^2}+\mu\frac{\partial^2 w}{\partial x^2}\right) \tag{11}$$

The stresses considered in this study are tensile stresses in the longitudinal direction at the bottom of the plate because the transverse stresses are smaller than the longitudinal stresses.

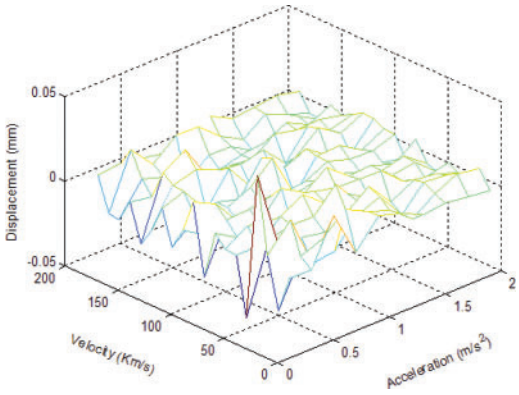

Figure 1. Displacements of the plate with different accelerations and velocities.

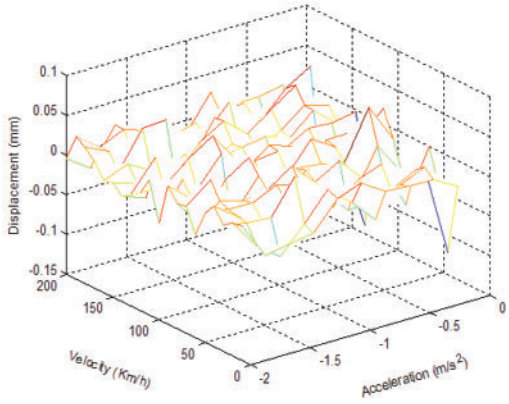

Figure 2. Displacements of the plate with different decelerations and velocities.

3 DYNAMIC RESPONSE TO MOVING ACCELERATED OR DECELERATION LOAD

An infinity plate resting on the elastic Winker foundation subjected to moving traffic load with variable velocity (accelerating or decelerating) is considered in this and the following sections. The data for the plate and load amplitude used in the all the numerical examples are

$E = 3.45 \times 10^4$MPa, $\mu = 0.15$, $K = 1.36$ MN/m^3, $C = 2.0 \times 10^5$Ns/m^3, $b = 0.35$ m, $F_0 = 1.0 \times 10^5$N; $h = 0.30$ m, c $= 0.25$ m, $t = 1.0$ s, $x_0 = 0.0$.

A range of acceleration and velocity values are considered in the numerical examples treated in order to study the effect of acceleration and velocity on the dynamic response of the plate.

Fig. 1 and Fig. 2 show the deflected shapes of the plate with different acceleration, deceleration and velocity at time of 1s and at load positions of 0.5 m respectively. Fig. 3 shows stresses of the plate with different acceleration and velocity at time of 1 second and at load positions of 0.5 m. It can be seen that the deflected shapes and the stresses of the plate and the

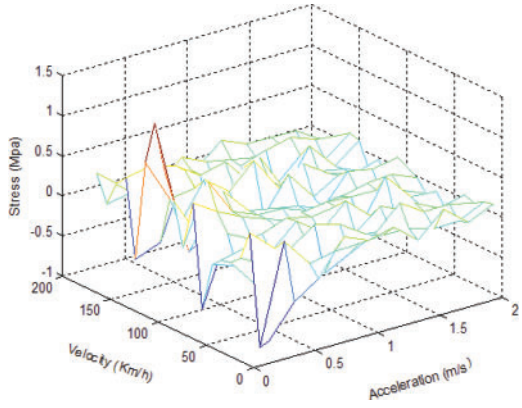

Figure 3. Stress of the plate with different accelerations and velocities.

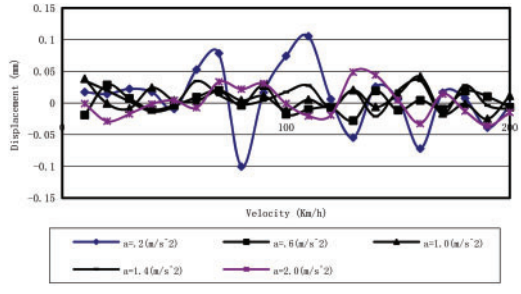

Figure 4. Displacement of the plate with different velocities and given acceleration.

change with the load moving acceleration, deceleration and velocity and occur different maximum values. This feature can also be seen from Fig. 4 to Fig. 9 which illustrates the dynamic deflections and stresses of the plate under the different moving load acceleration, deceleration and velocity when one of them is given.

From Fig. 4, it can be seen that when the load acceleration is given, the deflection of the plate increases with the load moving velocity and appear peak values. At the acceleration of 0.2 m/s^2 and velocity of 100 km/h the displacement occurs maximum value. When acceleration is given 2 m/s^2 the displacement will have a peak value at the velocity of 130 km/h.

Fig. 5 shows the results of displacement with different velocities when the deceleration is given. It can be seen that there are same results as shown in Fig. 4, the deflection of the plate increases with the load moving velocity addition and appear peak values. But the increasing speed is larger than that when the load moves with acceleration. Also, at the deceleration of -0.2 m/s^2 and velocity of 100 km/h the displacement occurs maximum value. But when deceleration is given -2 m/s^2 the displacement has a peak value at the velocity of 190 km/h. Fig. 6 and Fig. 7 illustrates the results of displacement with different acceleration and deceleration when the load moving velocity is given. It can be seen that the displacement reduces with the

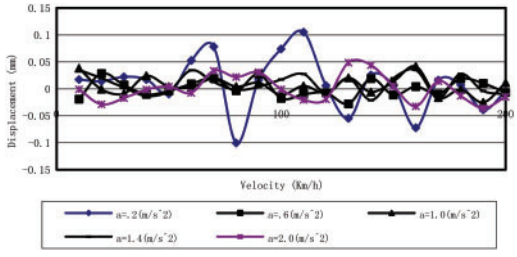

Figure 5. Displacement of the plate with different velocities and given deceleration.

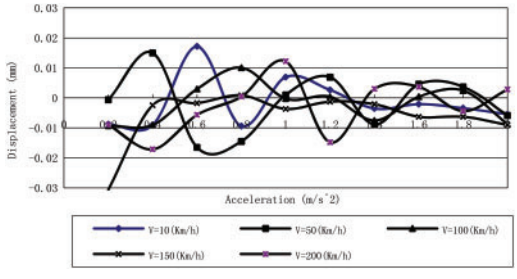

Figure 6. Displacement of the plate with different accelerations and given velocity.

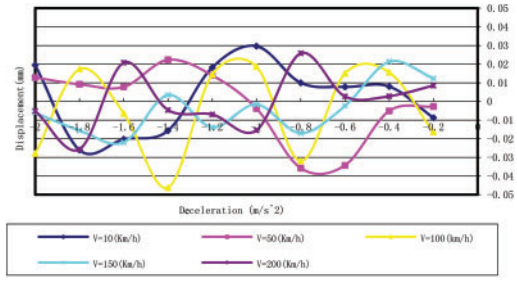

Figure 7. Displacement of the plate with different decelerations and given velocity.

acceleration and deceleration increasing when the load moving velocity is given.

Fig. 8 presents the results of the stresses of the plate with different acceleration when the load moving velocity is given. It can be seen that the stresses of the plate reduces with the acceleration and deceleration increasing when the load moving velocity is given. At small values of velocity (less than 50 km/h) the reducing is slowly. At large values of velocity the reducing is rapidly.

Fig. 9 is the results of the stresses of the plate with different velocity when the load moving acceleration is given. It can be seen that the stresses of the plate increase with the acceleration increasing when the load moving velocity is given. At the acceleration of 0.2 m/s^2 and velocity of 140 km/h the stresses of the plate reaches the maximum value. When aceleration is given 2 m/s^2 the plate stresses appear a peak value at the velocity of 170 km/h.

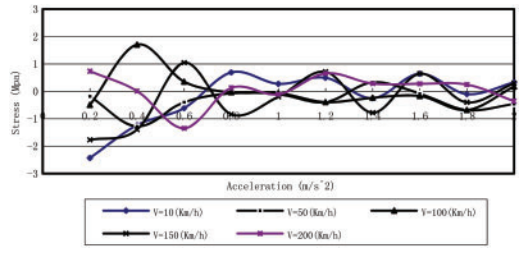

Figure 8. Stresses of the plate with different accelerations and given velocity.

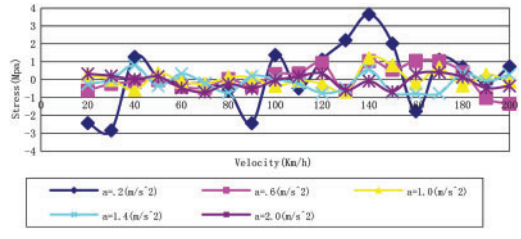

Figure 9. Stresses of the plate with different velocities and given acceleration.

4 CONCLUSION

In this paper, the dynamic response of an infinity plate resting on an elastic foundation subjected to moving traffic load with variable velocity (acelerating or decelerating) is investigated by using a triple Fourier transform. The effects of the load moving velocity, acceleration and deceleration are discussed respectively. The numerical results illustrate that the deflected shapes and the stresses of the plate change with the load moving acceleration, deceleration and velocity. Both the deflection and the stresses reach different maximum values. The dynamic displacements and stresses of the plate increase with the load moving velocity and decrease with the load moving acceleration and deceleration. This phenomenon indicts that the design of the rigid pavement shall consider the effect of the dynamic load caused by variable moving vehicles.

Assessment of bridge behavior due to the passage of high speed trains

A. Graça
Grid S.A.,Lisboa, Portugal

L. Guerreiro & F. Virtuoso
Instituto Superior Técnico, Lisboa, Portugal

ABSTRACT: The railway bridges, due to the passage of high speed trains, can suffer high resonance phenomena that cause, for example, ballast instability, endangering the railway line. Therefore, the main goal of this paper was to develop a simplified but efficient MATLAB model able to reproduce and analyze the dynamic response of bridges to the passage of high speed trains, in order to obtain static (bending moments, shear forces and reactions) and cinematic (accelerations, displacements and rotations) envelopes along the bridge. The implementation of this methodology took place using a continuous beam model subjected to moving point loads, which was based on the determination of the free vibration modes, generated semi-analytically, considering simple supports model, or by finite elements, using spring supports model. Extensive parametric studies were performed, which contributed to raise the sensibility to results, particularly for continuous bridges, the less studied type.

1 INTRODUCTION

In modern societies, transports play a crucial role in economic growth and globalization. Among the other transports, High speed trains can be more competitive for distances about 100/200 km and 400/600 km, comparing with terrestrial and aero transportation, respectively (Ureña, 2010). With the increase of high speed trains usage, some resonance problems were identified (e.g. ballast liquefaction due to high accelerations produced by the passage of the trains (Gustafsson, 2008)), being essential to evaluate the bridge response due to their passage. Bridge's safety studies should be performed through dynamic analyses.

Full dynamic analyses gives more accurate results, which are important if the designer intends to compare model with experimental results, evaluate the passenger comfort or have a more sophisticated analysis of an important bridge. The dynamic analysis are complex and time consuming because of the large amount of information required to define the input and the difficulty in solving the equilibrium equations, which lead to slow computational models (Wilberg, 2009) (Azevedo et al., 2007).

The goal of this work was to study the bridge response with simple models, by using the moving load beam model. This model, implemented in MATLAB, although less accurate than the more complex models (Barbero, 2001), is able to quick reproduce a large amount of different structural solutions. As the objective of this work was to perform extensive parametric studies, it was important to have a reliable and simplified model with capacity to reproduce any train and several dynamic parameters of the bridge. All the studies were done for the set of HSLM-A trains, presented in EN1991-2. Velocities between 40 and 120 m/s were considered.

2 THEORETICAL BACKGROUND – BRIEF REVIEW

As shown in Fig. 1, the bridge superstructure is modeled as a continuous beam with a total length L, constant flexural stiffness EI, constant mass per unit length m and viscous proportional damping C. The beam is assumed to be a Bernoulli-Euler beam, in which the effects of shear deformation and rotary inertia are not taken into account.

Considering the group of forces p_j moving from left to right at a constant speed, the equation of motion is given as

$$m\,\frac{\partial^2 u(x,t)}{\partial t^2} + C\,\frac{\partial u(x,t)}{\partial t} + EI\,\frac{\partial^4 u(x,t)}{dx^4} = p(x,t) \quad (1)$$

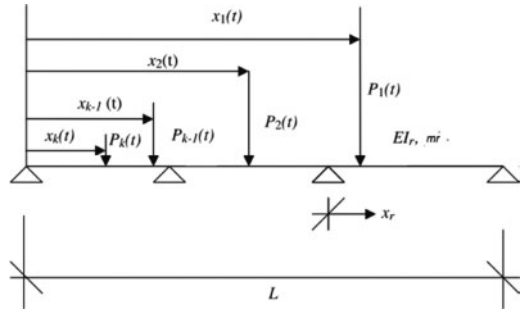

Figure 1. Bridge model.

Based on modal superposition, the solution of Eq. (1) can then be expressed as

$$u(x,t) = \sum_{n=1}^{\infty} \emptyset_n(x) q_n(t) \quad (2)$$

where $q_n(t)$ is the nth modal amplitude and $\Phi_n(x)$ is the nth mode shape function of the beam. Substituting Eq. (2) into (1), the result leads to an equation in terms of modal amplitude (Yang & Lin, 2004)

$$\frac{d^2 q_n(t)}{dt^2} + 2\xi_n \omega_n \frac{d\, q_n(t)}{dt} + \omega_n^2 q_n(t) = \\ = \frac{1}{M_n} \sum_{j=1}^{N_l} f_j(x,t)\, \varepsilon_j(t) \quad (3)$$

where ω_n, ξ_n are modal frequency and damping ratio of the nth mode, respectively, and

$$M_n = \int_0^L m\, \emptyset_n^2(x) dx \quad (4)$$

$$\varepsilon_j(t) = H\left(t - t_j^{in}\right) - H\left(t - t_j^{out}\right) \quad (5)$$

$$f_j(x,t) = \emptyset_n\left(x_j(t)\right) p_j \quad (6)$$

where M_n, H(t), $\Phi_n(x)$ and $t_j^{in/out}$ are the modal mass, Heaviside function, nth mode shape and the time instant when the jth force enter and leave the bridge.

To solve the problem it is only necessary to calculate the mode shapes, since they are responsible to define the modal participation. Therefore, after the computation of mode shape $\Phi_n(x)$ a numerical integration of Eq. (3) should be done. It was used the Newmark-β method (Newmark, 1959) to perform this integration. The analysis was not restrained to the first vibration mode. A mode superposition model using the resonant modes resented a good fit on the studied cases.

In this paper, a semi-analytical method to obtain frequencies and modal amplitudes were used. For the rth span of the general case, shown in Fig. 1, the analytical solution of the problem is given by

$$\emptyset_{nr}(x) = A_{nr} \cos(\lambda_n x) + B \cos h(\lambda_n x) + \\ C_{nr} \sinh(\lambda_n x) + D_{nr} \sin(\lambda_n x) \quad (7)$$

where $\Phi_{nr}(x)$ is the nth modal shape function of the rth span and the constants A_{nr}, B_{nr}, C_{nr}, D_{nr} and λ_n are the problem unknowns of the span r and nth eigenvalue.

The constants (Eq. (7)) are determined from the boundary and initial conditions. The calculation of eigenfunctions is just a matter of substituting the appropriate boundary conditions in Eq. (7). The complete development of the equations and solution of the problem are presented in (Graça, 2011).

3 COMPUTATIONAL IMPLEMENTATION

In order to apply the theoretical background, a MATLAB program and three routines were implemented.

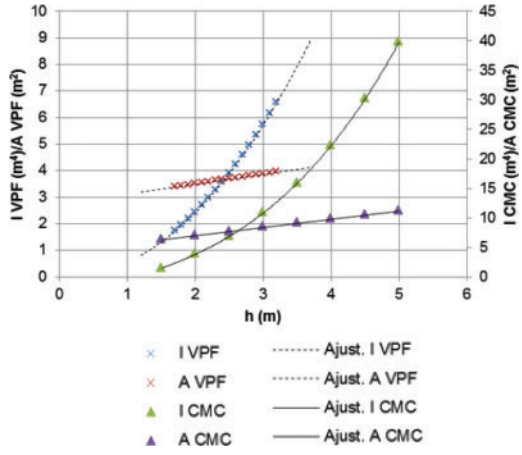

Figure 2. Moment of inertia and area versus section height (VPF – prefabricated box girder, CMC – one cell box girder).

The main program computes, for a defined velocity and train, the accelerations and displacements time response. In addition, the routines perform: (i) computation of general envelopes, for a defined interval of passage velocities, (ii) parametric studies, function of transversal section slenderness ($\lambda = h/L$), and (iii) analysis of foundation flexibility on the final response, in terms of acceleration and vertical reaction.

Fig. 2 shows the moment of inertia and area, functions of section height. It defines the domain of validity of the parametric studies carried out.

4 SUITABILITY OF EN1991-2 ACCELERATION PEAK CRITERION

A set of rules and limitations are prescribed in EN 1991-2 and EN1990-A2. One of them is the limitation of peak acceleration to 3.5 m/s^2 (ballasted bridges) and 5 m/s^2 (non-ballasted bridges). Some authors (Zacher & Baessler, 2005) consider that the implementation of a different criterion leads to a more economical design, without compromise the bridge safety. They state that the peak criterion should be replaced by a 5 peak criterion. So, the new proposed criterion is:

1) Ballasted bridges – 5 successive peaks are allowed (with the same signal) surpassing 3.5 m/s^2 with a maximum peak of 5.5 m/s^2;
2) Non-ballasted bridges – 5 successive peaks are allowed (with the same signal) surpassing the 5.0 m/s^2 with a maximum peak of 5.5 m/s^2.

The present section intends to analyze the dynamic response characteristics, particularly the difference between criterions, of a vast group of structural solutions – simple supported and continuous bridges. Consequently, conclusions about the suitability of the new criteria can be drawn, with the premise that, the smaller the difference between criterions, the more adjusted the code limits are.

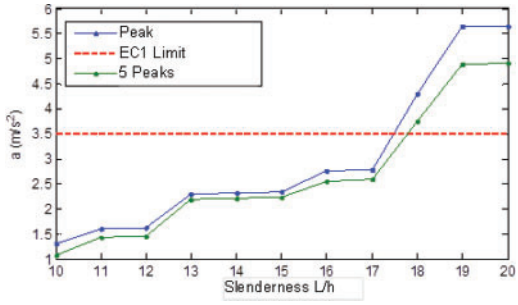

Figure 3. Evolution of the two peak criterion with the slenderness of the bridge.

4.1 *Case studied*

In order to illustrate the differences between criterions, only one geometrical example was used (a continuous bridge with 5 spans – 35 m long inner-spans and 28 m long end-spans) with different cross section slenderness (λ = span/height), varying from 10 to 20. Additional death load of 100 kN/m, a modulus of elasticity of 34 GPa and 1% damping were considered. Fig. 3 the differences for the set of HLSM-A trains are presented.

The analysis of the results presented on Fig. 3 prompts the following remarks:

1) Both acceleration values grow with the increase of slenderness. The evolution is made by steps. Each step is caused only by one determined critical train (Graça, 2011).
2) Differences between criterions are very small, smaller than 0.5 m/s^2, for slenderness's inferior to 17, and increases (not much) for $\lambda > 17$ (very high slenderness).
3) Differences similar to 2 m/s^2 (difference between 3.5 and 5.5 m/s^2) were never registered.

4.2 *Simple supported bridges*

The existence of any appreciative differences in simple supported bridges was also evaluated. In terms of geometric examples, Fig. 4 and 5 show the results for bridges with lengths varying from L = 20 m to 40 m, and slenderness's between 8 and 14.

After analyzing both figures, the following comments, for simple supported bridges, are appropriate:

1) Fig. 4 shows that all the differences between criteria are lower than 2 m/s^2. A higher difference only exists for more slender specimens and spans length equal or lower than 30 m. Spans of 35 m and 40 m do not suffer much difference with slenderness increasing;
2) To confirm the acceleration scale factor argument, which leads to higher differences, Fig. 5 illustrates the absolute accelerations registered for peak criterion. It is clearly visible that upper differences are related with large accelerations, much higher than the limits;

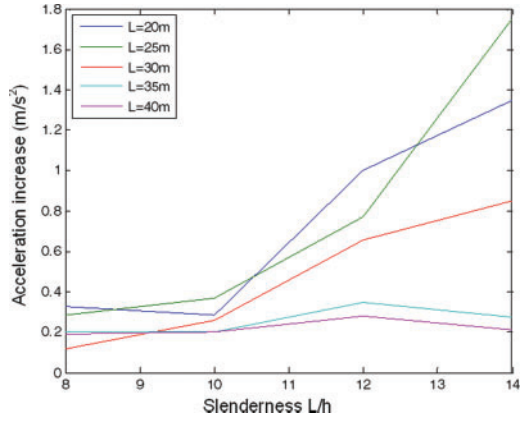

Figure 4. Evolution of the two peak criterion differences $\Delta a = (a_{peak} - a_{5\,peak})$ with the slenderness of the bridge.

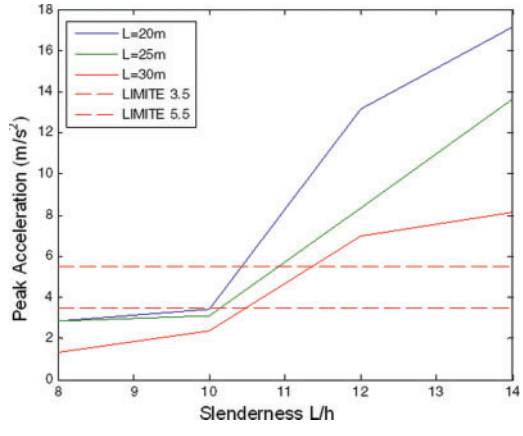

Figure 5. Evolution of the two accelerations with the slenderness of the bridge.

Table 1. Key parameters for the continuous bridge analysis.

Parameter	Variation Domain
Slenderness	10, 12, 14 and 16
Number of inner spans	1, 2 and 3
Length of inner span (m)	30, 35 and 40

3) Results show that if a solution does not verify the peak criterion, will also not check the 5 peak one.

4.3 *Continuous bridges*

Additionally, the continuous bridge analysis was made with a vaster group of geometrical examples. It was used cross sections bridges with end/inner span relationship of 0.75. While Table 1 shows the varying key parameters, Table 2 presents the results for differences in peak criterion for all the different tested parameters.

Table 2. Difference between peak criteria ($\Delta a = a_{peak} - a_{5\,peak}$) for continuous bridges.

Span	Slenderness	Δa (m/s^2) Number of inner spans 1	2	3
30 m	10	0.25	0.25	0.20
	12	0.41	0.35	0.29
	14	0.55	0.61	0.30
	16	1.63	0.53	0.35
35 m	10	0.35	0.16	0.08
	12	0.74	0.49	0.25
	14	0.75	0.45	0.40
	16	0.35	0.54	0.30
40 m	10	0.45	0.21	0.21
	12	0.70	0.15	0.37
	14	0.35	0.15	0.20
	16	0.28	0.35	0.14

The conclusions that can be drawn from the analysis of Table 2 are:

1) The maximum registered difference was 1.63 m/s^2 for the solution with slenderness of 16, inner span length of 30 m and one inner span only. This solution presents an acceleration of 6.39 m/s^2 with peak criterion and 4.77 m/s^2 with 5 peak criterion, both values higher than the limits;
2) Differences tend to diminish with the increasing of the number of inner spans (except for $\lambda = 16/L = 35$ m and $\lambda = 12/L = 45$ m);
3) Once again, results show that if a solution does not verify the peak criterion, will also not check the 5 peak one.

5 PARAMETRIC STUDIES

In this section the results concerning the parametric studies for vertical acceleration behavior of bridges are presented and discussed.

5.1 *Influence of inner span number – N*

To analyze the influence of inner spans number N, models with slenderness from 10 to 17, span lengths of 30 m, 35 m and 40 m, additional death load of 100 kN/m, and end/inner span length relationship $\beta = 0.75$ were used. Fig. 6 depicts the acceleration evolution with N. To explain some of the results, Fig. 7 presents the curve decomposition in critical trains, for L = 30 m and $\lambda = 0.14$, which leaded to envelope one.

From the observation of Fig. 6, the following remarks can be drawn:

1) Higher slenderness produces always larger accelerations than lower slenderness;
2) N = 1 gives the response maximum;
3) On average, acceleration decrease with N. However, it is clearly visible local maxima and minima. Acceleration fluctuates around a straight line between points N = 1 and N = 8. It can be explain

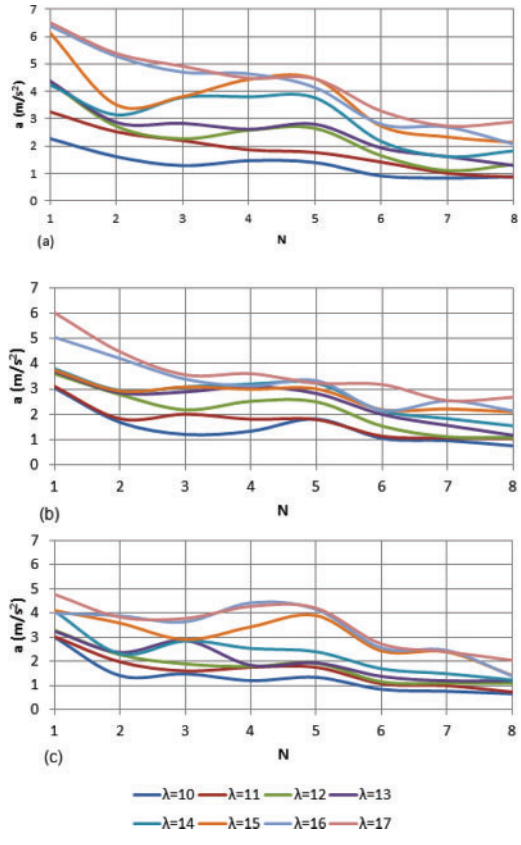

Figure 6. Evolution of bridge acceleration with the number of inner spans N for (a) L = 30 m, (b) L = 35 m and (c) L = 40 m.

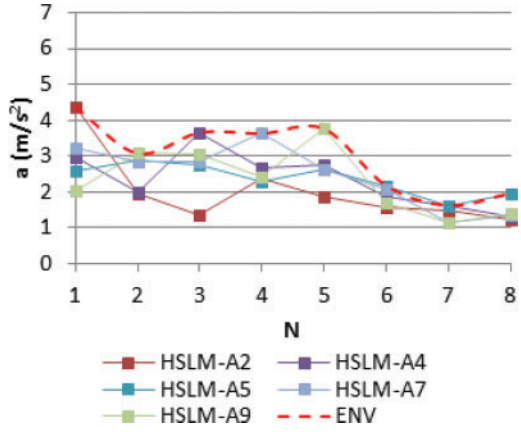

Figure 7. Decomposition in critical trains for L = 30 and $\lambda = 14$.

by the observation of Fig. 7, where is shown that local maximums come from resonances of a particular HSLM-A train. Local minimums appear when there is no train with a clear resonance;
4) For this reason, it does not seem to exist a simple mathematical explanation to the results. In truth,

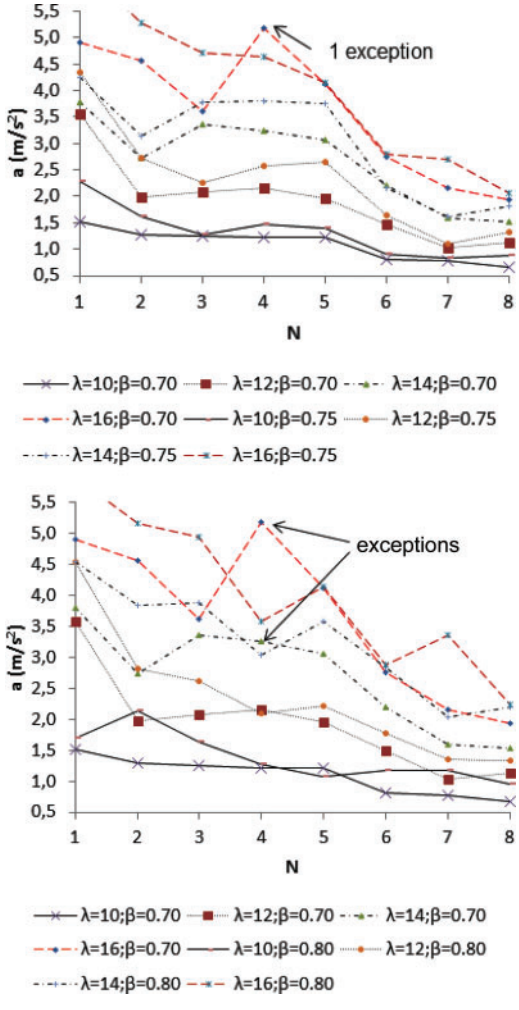

Figure 8. Comparison between $\beta = 0.70/\beta = 0.75$ (top) and $\beta = 0.70/\beta = 0.80$ (bottom) for L = 30 m.

there are 10 times 7 (critical trains times used frequencies) possibilities to create resonance;

5) The usage of L = 35 m gives smoother curves. The same can be said for $\lambda \leq 13$. Those slenderness's have much better performance, both in terms of it regularity as in acceleration greatness;
6) Finally, for $N \geq 5$ the acceleration is always lower than the one registered for $N < 5$. From $N \geq 6$, it can be considered as constant.

5.2 *Influence of end/inner span length relationship*

In order to evaluate the influence of end/inner span length relationship the presented in Fig. 8 were obtained. It was only compared relations of 0.70, 0.75 and 0.80, typical in design situation.

Analysis of Fig. 8 results prompts the following observations:

1) For inner span length of 30 m, over 90% of analyzed situations show that the usage of $\beta = 0.70$ produces lower accelerations than the usage of $\beta = 0.75$ and $\beta = 0.80$;
2) On the other hand, for spans of L = 35 and 40 m, using the same relationship, guarantee 70% of the cases (lower value);
3) Thus, one can consider that in design situation preference should be given for $\beta = 0.70$.

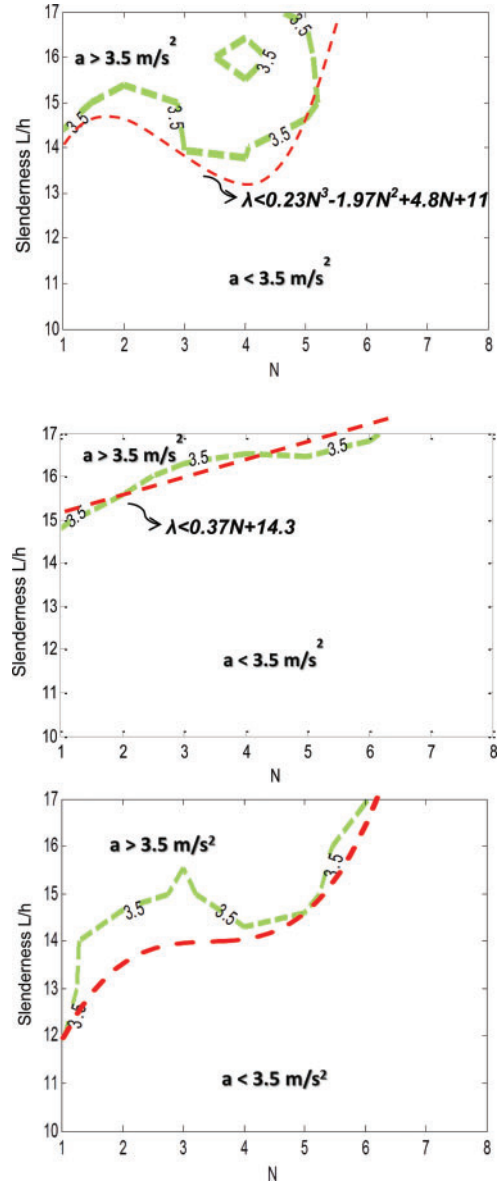

Figure 9. Peak criterion verification curves for L = 30 m (top), L = 35 m (middle), L = 40 m (bottom).

5.3 *Criterion verification curves for* $\beta = 0.70$

Taking into account the conclusions made in de last section, a relation N versus λ curves were produced, which guarantee the peak criterion verification. Fig. 9

displays the results and includes criterion verification formulas. Some conclusion from their analysis:

1) For $L = 30$ m, acceleration is only restrictive with $N = 1$, where the curve indicates $\lambda = 12$. For higher N values, slenderness raises to 14, which is considered current and for $N > 6$ it's completely non-restrictive;
2) Bridges with $L = 35$ m only have problems with $N = 4$;
3) In longer span bridges ($L = 40$ m) acceleration restrictions don't put much limitations to design, because designer can use slenderness's equal or higher than 15.

6 CONCLUSION

This paper dealt with the use of a simplified but efficient computational implementation, in order to assess the effect of high speed trains on bridges. Hence, several studies were made.

Focusing on the results about the suitability of code acceleration peak criterion, one showed that, apparently, there is no reason to change the existing rules. It should be noted that, conclusion is based only on the present paper structural analysis model.

Relatively to parametric studies, one can prompt the following general conclusions:

1) About influence of N parameter, analysis showed a tendency to acceleration decrease with several local minima and maxima. The usage of less slender cross sections leads to a smoother decrement and lower accelerations. For $N \geq 6$, acceleration can be considered constant and with inferior values;
2) Usually, the most convenient end/inner span length relationship, which cover over 70% of the cases, is $\beta = 0.70$.

Dynamic response of airport building structure due to construction machinery effects

J. Benčat & D. Papán
University of Žilina, Žilina, Slovakia

ABSTRACT: In spite of the wide use of driven piles and sheet piles and the increasing awareness of the public and authorities for environmental problems, little progress has been made in the understanding of ground vibrations caused by vibration pile driving. The construction vibrations can be reduced by planned and controlled use of construction machinery. We studied the effect of the construction vibration on the Bratislava Airport buildings caused by sheet piledriving during the construction works near present operating Airport buildings.

1 INTRODUCTION

Construction activity such as driving piles, vibrating compaction of earth materials, and driving heavy construction machinery, can result in varying degrees of ground vibration, depending on the equipment and methods employed. Operation of construction equipment causes ground vibrations which spread through the ground and diminish in strength with distance. Vibration which usually also has a negative impact on security and stability of the structures, facilities performance and peoples should be controlled by experimental analysis and results compared with relevant standards prescription values and criteria (Eurocodes, national codes, etc.). Sometimes it is necessary to predict or monitor vibration level of projected or constructed structures and buildings.

In the case study the results of the theoretical and experimental investigation of the M. R. Stefanik Bratislava Airport building structures vibrations caused by piling operations were analyzed mainly from the aspects of the safety of the building structures (Bencat et al. 2011). Also the influence of these vibrations on production process conditions and people being in production halls were analysis, too.

2 CONSTRUCTION VIBRATIONS

2.1 *Sources of vibrations*

Vibratory hammers for driving non-displacement piles usually have low to moderate force amplitudes and operating frequencies above 20 Hz. Displacement piles are driven by vibratory hammers with frequencies of around 10–40 Hz and commonly along with much higher force amplitudes (Warrington, 1992). The soil resistance to pile penetration and the seismic effect of vibratory driven piles depend substantially on soil conditions, pile type and vibratory hammer model. A coincidence of the operating frequency with the soil layer frequency may generate large ground vibrations of the soil surrounding the pile. The use of vibratory hammers with variable frequency and force amplitude may minimize damage due to accidental ground vibration amplification.

Ground vibrations. The main characteristic waves that are generated when a vibrating load is placed on the surface of a soil are the compression wave (P-wave), the shear wave (S-wave), and the surface wave (Rayleigh-wave). Each of these waves has a characteristic velocity calculated from the following equations:

$$CW \rightarrow C_P = (\lambda + 2\mu/\rho)^{1/2}, SW \rightarrow C_S = (\mu/\rho)^{1/2} \text{ and } RW \rightarrow C_R = (0.87 + 1.12\nu/1 + \nu)C_S,$$

where λ and μ are Lame coefficients of elastic medium, ν – Poisson ratio and ρ is soil density. The correspondence principle (Rizzo & Shippy 1971) can be applied to model material damping in the elastic medium by the use of a complex Lame coefficients $(\lambda + 2\mu)(1 + \mathrm{i}\delta)$, where $\delta \approx \delta_E \approx \delta_G$ represents the hysteretic material damping ratio for the compression and shear waves respectively. Natural ground conditions permits the ground to be modelled as a damped, viscoelastic half space. The viscoelastic model of soil simulation *using the complex modulus conception* $\mathrm{E}^* = E(1 + i\delta_E)$ and $G^* = G(1 + i\delta_G)$ respectively, offers a very good approach to the actual soil behavior (E, G and $\delta_E \approx \delta_G$ *are real and imaginary components of complex modulus*). The basic equations used to describe the viscoelastic half space analysis of wave propagation through ground with modulus in complex form cannot be fully described here, see Bencat (1992), Martinček (1975).

Sources of construction vibrations generate body and surface waves in soil medium. Body waves propagate through the soil deposits and rock. Compression

and shear waves are the main types of body waves that should be taken into consideration at relatively small distances from the construction sources. Surface waves, of which Rayleigh waves are the primary type, propagate along the upper ground surface. Rayleigh waves have the largest practical interest for structural engineers because building foundations are generally placed near the ground surface. In addition, surface waves contain more than 2/3 of the total vibration energy and their peak particle velocity are dominant on velocity records.

The proximity of the frequency of horizontal soil vibrations to one of the building's natural frequencies may generate the conditions of resonance in that building. Moreover, vertical ground vibrations can cause dangerous structural settlements. To prevent the unacceptable effect of construction vibrations, it is important to accurately predict expected ground and structure vibrations and also it is useful to perform the monitoring of the structure response due to construction vibrations. The construction vibration monitoring enables the vibratory pile drivers operating mode regulation to avoid undesirable vibrations level of the structures and also undesirable effects on facilities performance and peoples.

2.2 *Structure vibrations due to construction activities*

Harmful vibration effects of construction activities occur frequently. Vibrations may produce direct damage to structures when excitation frequencies of ground vibrations do not match natural frequencies of structures. Such damage usually occurs in nearby structures at distances about one pile length from driven piles. Intensity of structure vibrations depends on soil-structure interaction which determines structure response to the ground excitation. Building vibrations having low and high frequencies are usually generated by Rayleigh and compression waves, respectively. There are two frequency ranges of structure responses: 2–30 Hz and 30–450 Hz. Perhaps structure vibration damage obtained without the effect of resonant structure response can be considered mainly to be due to particle velocities (PPV) of ground vibrations higher than about 50 mm/s for frequencies of 2–30 Hz and all PPV obtained in the frequency range of 30–450 Hz (Svinkin 1999).

Resonant structure response. The proximity of the frequency ground vibrations to one of the building's natural frequencies may generate the condition of resonance. The PPV of structure vibrations can increases from two to seven times as high as vibrations measured at the ground. Under the condition of resonance, the maximum dynamic amplification even may be much higher (Quesne 2001). Dynamic settlements – ground and foundation settlements as a result of relatively small ground vibrations in loose soils may occur at various distances from the source. Densification and liquefaction of soils can occur under the vibration effects of construction activities. Additional causes of damage – soil excavation associated with pile driving and made in close proximity to existing building can produce structural damage, Dowding (1996) observed that permanent excavation deformations induced in adjacent structure generally exceeded those from pile driving equipment and suggested taking into account the accumulated effect of repeated dynamic loads, from production pile driving. This approach is especially important for historic and old buildings and also for building in those great number people are allocated (theatres, airports, schools, hospitals, etc.).

3 PREDICTION AND MONITORING OF THE BUILDING VIBRATION

3.1 *Assessment of building vibration due to construction activities*

Assessment of building vibration due toconstruction activities caused by pile driving is a problem that can be solved through the application of research. This research consists mainly of defining the relationship between intensity fluctuations in the soil, the pile driving energy quantity and the distance from the vibration source. Through intensity fluctuations can appear in different physical quantities, such as the *oscillation velocity, acceleration, frequency, ground motion intensity, displacement and energy*. There are accessible several standards in the field of measurement of vibration in the construction industry in the European Union and USA.

In Slovakia in the field of measuring and assessing of building vibrations due to ground motion the most commonly used standard is Slovak Standard STN EN 1998 – 1/NA/Z1 (2010) based on EC8.

The usual concern related to construction vibration is building damage. A considerable amount of research has been done to define acceptable levels of construction-induced vibration to limit damage to neighboring buildings. Pre- and post-construction inspections and real-time monitoring systems are used to avoid damage claims associated with the construction process. For sensitive equipment or historic and old building also in the case of buildings with allocation of many people, however, the vibration levels of concern are two to three orders of magnitude lower than those associated with even minor cosmetic damage. In such cases, more sophisticated monitoring systems are needed to measure and assess the potential adverse effects of construction-related vibration. This article describes also the evolution of remote monitoring systems being used for the special case related to vibration in sensitive facilities of airport near construction sites.

3.2 *The analytic – experimental prediction models*

The analytic – experimental approach suggests the test and the theory data combination to calculate the prediction level of ground vibration. In this process

as an input signal can be used accelerations (velocities) spectrum $\overline{S}_{\ddot{w}\ddot{w}}(\omega)$ measured at the nearest ground point to the different kind of piles and hammers and generate experimental spectra data bank for authorized driving equipment and the same procedure to use for individual case study. On the surface of a linear viscous–elastic half space, the displacement response spectrum $S_{ww}(\omega)$ can be expressed in terms (Bendat & Piersol 1993). to the input spectrum of ground vibration accelerations $\overline{S}_{\ddot{w}\ddot{w}}(\omega)$, by

$$S_{\ddot{w}\ddot{w}}(\omega) = |H(\omega)|^2 \overline{S}_{\ddot{w}\ddot{w}}(\omega), \quad (1)$$

where $|H(\omega)|$ is the frequency response function magnitude for the half space medium and $\ddot{w}(t)$ is vibration accelerations of the surface measured at a distance l from the measured point near the driving pile. In this approach it can be used as the input spectra $\overline{S}_{\ddot{w}\ddot{w}}(\omega)$ measured at nearest ground point to the pile. The frequency response function (transfer function) of the ground can be derived via experimental impulse seismic method (ISM) or cross–hole test data, from which elastic and attenuation parameters of the ground can be obtained, too. The measuring output response acceleration spectrum at the distance $S_{\ddot{w}\ddot{w}}(\omega)$ due to input accelerations spectrum $\overline{S}_{\ddot{w}\ddot{w}}(\omega)$ the FRF – $H(\omega)$ is possible derived by (1), too.

4 MEASUREMENTS ON SITE

4.1 *The building site description*

The new part of the M. R. Štefánik Bratislava Airport building development involved the relocation of the old technological collector under area of the operated airport buildings into the part of reinforced concrete collector along the new terminal and the terminal under reconstruction. Reinforced concrete tube collector cross section has internal dimensions of 2.5 m wide and 3.3 m high. The thickness of the walls, ceiling and base plate are consistently 300 mm tube is structurally designed as a reinforced concrete structure using a U-shaped, covered with prefabricated ceiling. Foundation of the collector and its technical chambers and it is about one meter below the ground water level and therefore it was necessary to make earth works using steel sheet pile (profiles Larsen 3n, length 10 m), which enabled to encircle the collector site very shortly after water pumps installation and the performing water pressure insulation. Sheet piles driving were performed by vibration ramming machines (MS 16HFV and 206H40). Trench shoring was insured by Larsen 3n steel sections for an average pit bottom depth of 5.3 m (Figure 1).

4.2 *The experimental tests at nearby construction site and airport building*

The ground vibrations and airport building response due to pile driving were measured by accelerometers

Figure 1. Vibratory pile driving in collector site. Location L2 Airport Bratislava.

BK – 8306 (Brüel–Kjaer). The output signals from the accelerometers were preamplified and recorded on portable PC equipped with A/D converters software packages *NI* and *DISYS*. The experimental analysis has been carried out in the Laboratory of the Department of Structural Mechanics, University of Žilina (Bencat et al. 2011). The ground and structure vibrations frequencies were obtained using spectral analysis of the recorded ground response dynamic components, which are considered as ergodic and stationary. Spectral analysis (spectra, PSD) was performed via National Instrument software package NI LabVIEW. The wave velocities have been investigated by means of the correlation and spectral analysis (Bendat & Piersol 1993) in order to obtain cross correlation functions $R_{xy}(t)$ and coherence function $\gamma^2_{xy}(f)$.

(i) Ground dynamic parameters.To calculate the predicted vibration level and projected dynamic response for a new airport terminal T2 building and adjacent operating T1 terminal building, it was needed to know the soil dynamic parameters and FRF for the building site. In situ impact tests in the T2 terminal building site (location L1 – 35.0 m distance from T1) were performed (Bencat et al. 2011), see also Figs. 2.3. The objective of experimental measurements of transient signal was to find:

- the Raleigh's and share wave velocities by using standard equipment of ISM,
- the same dynamic characteristics as mentioned in stationary signals investigation (at nearby pile region) via the spectral and correlation procedures. The impulse test results are as follows: $C_R = 155.10\,\mathrm{ms}^{-1}$; $\delta_G = 0.117$; $E_o = 149.20$ MPa; $G_0 = 55.95$ MPa,

The calculation includes data: $\lambda_R = 9.2$ m, $\rho = 1950\,\mathrm{kgm}^{-3}$, $\alpha = 0,0398(\mathrm{m}^{-1})$, $l = 16$ m, (B2–B3, ISM points distance) $F_{RE} = 1.061457$ and $\nu = 0.33$.

The attenuation coefficient α (m^{-1}), was obtained by Golicyn's formula via standard deviations $\sigma(0)$, $\sigma(y)$ of displacement amplitude

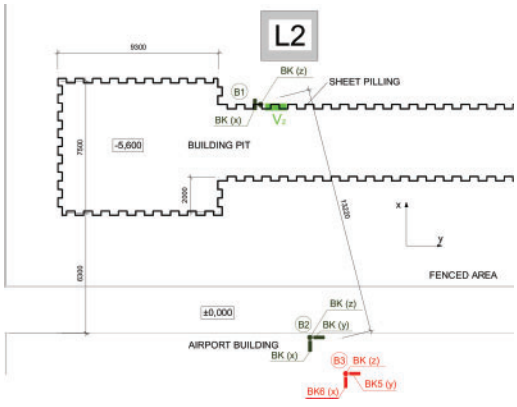

Figure 2. Measured points in L2 location (Position S2).

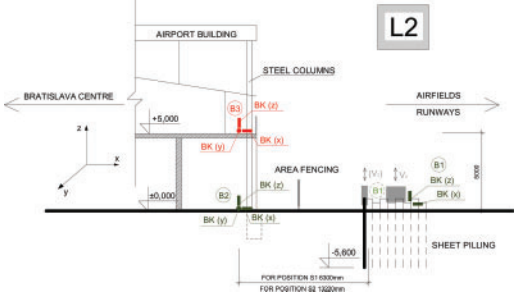

Figure 3. Measured points position in L2 location.

vibration at the distances l_0, l_y from source of excitation using the *displacement* PSD $G_{ii}^{(0)}$ and $G_{kk}^{(y)}$ (Bencat & Papan 2011).

(ii) Buildings structure dynamic response (BSDR). The main purpose of the pile driving tests at the site was to determine the distance where ground vibrations could be expected to be lower than the limiting value recommended e.g. by STN EN 1998-1/NA/Z1 (2010) or vibratory pile drivers (VPD) op-erating mode regulation. From Swedish Standard (1999) the maximum allowable calculated vibration velocity (vertical component) is $v_{\max} = 7.8$ mm/s. Before starting of tests and monitoring BSDR series, the operation mode rating of all pile drivers was set up to avoid unfavorable level of vibration on airport terminal structure (calibration). However, some concern was expressed with regard to environmental considerations (occupants). It was reason to carry out 9 measurements and 10 days continual monitoring of the dynamic response of the airport terminal buiding structure at selected representative points, (Figs. 2.3). Information about the measured objects, type of measurement and the distances to the source of vibration caused by the VPD are given in Table 1. The Airport Bratislava building site layout and accelerometers and DLP positions during the experimental tests are shown in Figures 2–3.

Figure 5 shows a schematic overview of used monitoring system. The sensors are connected to an analyzer that also provides power to the sensors. The analyzer is connected to a laptop computer that can either be an integral part of the analyzer (the analyzer software runs on the laptop) or it can serve only as a communication device to pull data off the analyzer (Newmark et al. 2011). The laptop is connected to the internet, which allows remote control, remote data download and a conduit for alarm notifications.

Results of experimental tests and monitoring via extreme values of all measurements are summarized in the accompanying Figure 6. As an example of the of the VPD induced vibrations velocities spectral analysis result (PSD) in the structure at point BK2 and the ground and structure velocities time depended functions $v(t)$ at points BK1 and BK2 at are plotted on Figure 4.

5 CONCLUSIONS

This paper presents an overview of some prediction model for the ground-borne vibrations and the buildings structure dynamic response due to pile driving process. The numerical an numeric-experimental based on spectral analysis approach for ground response at the distance and dynamic response of building structures calculation procedure were introduced and also in the experimental process was carried out using this approach.

The relevant calculated data values following from experimental spectral and amplitude analysis of the Airport Bratislava building dynamic response (spectral picks limit, vibration levels, etc.) were compared with relevant standards prescription values and criteria (Figure 6). From these comparisons it follows that the standards prescription values and criteria regarding building structure during vibratory driving of sheet piles in the adjanced construction site were fulfilled.

Data-driven model of random lateral pedestrian excitation

V. Racic, J.M.W. Brownjohn & A. Pavic
The University of Sheffield, UK

ABSTRACT: Randomness and narrow band nature are the two essential features of lateral walking loading not addressed adequately in the existing design guidelines for footbridges. One of the reasons for this is the lack of a comprehensive database of lateral walking forces in the form of continuously recorded time series that can be used for development of statistically reliable characterisation of these forces for application in the civil engineering context. This paper has addressed the issue by establishing a large database of measured lateral walking time series recorded by a state-of-the-art instrumented treadmill at the University of Sheffield. Another reason is the lack of an adequate modelling strategy which can simulate reliably the actual forcing records. Motivated by the existing models of wind and earthquake loading, speech recognition techniques and a method of replicating electrocardiogram (ECG) signals, a data-driven mathematical model has been developed to generate synthetic force signals with realistic temporal and spectral features. This multi-disciplinary modelling strategy offers a radical departure from traditional Fourier-based representations of lateral walking loads towards more reliable and more realistic vibration serviceability assessment of footbridges.

1 INTRODUCTION

More than a decade after the London Millennium Bridge debacle (Fitzpatrick et al. 2001), structural designers still have to manage significant uncertainties in lateral dynamic loads induced by pedestrian occupants due to crude guidance based on insufficient and fragmented science (Zivanovic et al. 2005, Ingólfsson et al. 2011). The present study takes a step forward by bringing together a comprehensive database of continuously measured lateral walking loads and their mathematical model which can simulate accurately the measurements. Since the measured loads were generated on a ground-mounted instrumented treadmill (Figure 1), the model simulates the forces induced by individuals walking on stiff surfaces, i.e. without the lateral bridge motion and hence discounting effects of human-structure dynamic interaction. Such a model is an essential prerequisite for future quality models of group and crowd lateral pedestrian loading under a wider range of conditions. From the structural engineer's point of view, guidance is still lacking on the proportion of pedestrians in a given situation who coordinate their body motion and the scale and character of the resulting net dynamic loads on the structure, with or without influence of the motion of the structure itself. In fact, motion of the structure is just one type of cue or stimulus among several others affecting group/crowd pedestrian loads (Racic et al. 2009), such as proximity of individuals and different audio, visual and tactile stimuli.

2 EXPERIMENTAL DATA ACQUISITION

All walking tests were carried out in the Light Structures Laboratory in the University of Sheffield (Figure 1). The acquisition of walking forces started at a speed of 2 km/h and continued in increments of 0.5 km/h up to the maximum walking speed, i.e. an ultimate self-selected speed at which jogging, rather than walking, is more comfortable for a test subject. Pacing rate was not prompted by any stimuli such as a metronome, and it was determined only from sub-sequent analysis of the generated force signals.

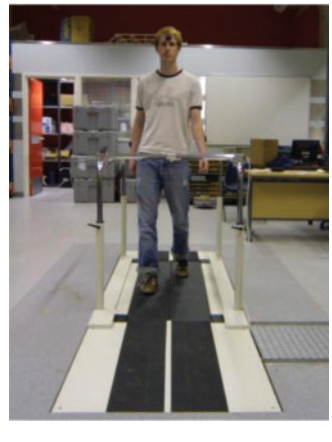

Figure 1. Experimental setup.

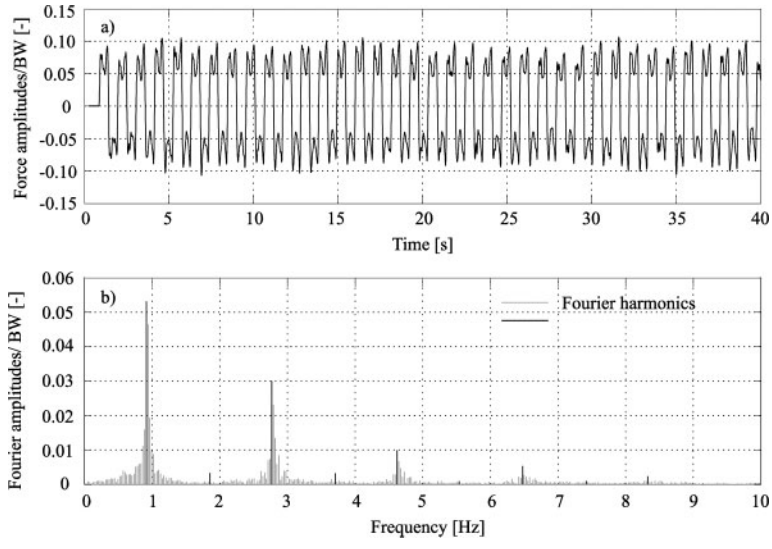

Figure 2. An example of measured (a) force-time history and the corresponding (b) Fourier amplitude spectrum. Dominant harmonics at integer multiples of lateral walking frequency $f_w = 0.92$ Hz are bold.

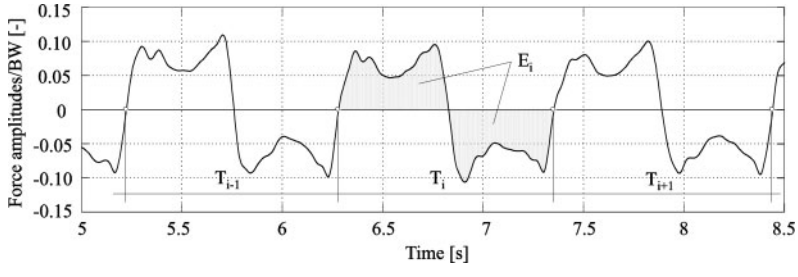

Figure 3. A portion of a force-time history after applying a fourth-order low-pass Butterworth digital filter with cut-off frequency 15 Hz. The force is recorded at fixed treadmill speed of 4.5 km/h, while the estimated average lateral frequency is 0.92 Hz.

Each test was completed when at least 64 successive footfalls were recorded. A typical measured force-time history and the corresponding Fourier amplitude spectrum is shown in Figure 2.

In total, 85 volunteers (57 males and 28 females, body mass 75.8 ± 15.2 kg, height 174.4 ± 8.2 cm, age 29.8 ± 9.1 years) were drawn from students, academics and technical staff of the University of Sheffield. All together they generated 850 lateral walking force time series of kind illustrated in Figure 2a. Each walking time series was sampled at 200 Hz.

The next section describes the concept of modelling individual lateral force records as a narrow band process. In Section 4 this model is fitted to all 850 force records, yielding a numerical generator of random walking time series.

3 MODELLING OF IMPERFECT REAL WALKING

As humans are not perfect robots, force measures fluctuate invariably with time from one walking cycle to the next (Figure 2). A walking cycle can be defined between any two nominally identical events of the total force-time history. In this study, the point of intersection between the force trace and time axis at which the first derivative of the force is positive was selected as starting (and completing) event (Figure 3).

From the 40 s long force signal given in Figure 2a and yielding about 40 cycles, a window comprising 34 successive cycles was extracted from the middle of the signal. Three cycles at the beginning and end of the force record were cast aside as their natural variability might be affected by the measuring process. In the next section, the selected 34 cycles will be used to curve fit morphology of the force, a so called "template cycle", which can be scaled (stretched and compressed) along the synthetic time and amplitude axes to reflect inter-cycle variability present in the actual force-time history. This modelling strategy is motivated by an existing numerical generator of electrocardiogram (ECG) signals (McSharry et al. 2003) which have similar near-periodic features as walking time series. Modelling variability of the cycle intervals and force amplitudes is presented respectively in

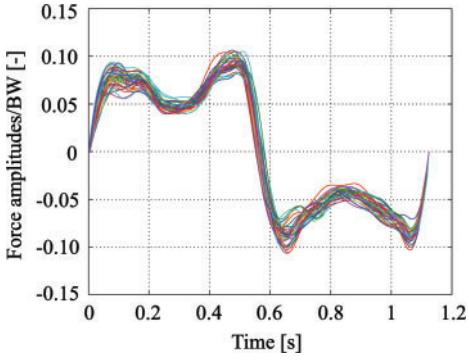

Figure 4. Resampled weight-normalised cycles.

Sections 3.2 and 3.3, while generation of synthetic force signals is outlined in Section 3.4.

3.1 *Template cycle*

The 34 weight-normalised walking cycles have been temporarily displaced and resampled to the length of the longest cycle, as shown in Figure 4.

Visual inspection does suggest that there is a common waveform of the force which distorts along time and amplitude axes on a cycle-by-cycle basis. Their average is considered an inadequate representative of the force morphology due to misalignments of the common events, such as positions of the local extreme values. To line up the force cycles, a technique called dynamic time warping (DTW) had been applied before their average was computed. More details can be found in Racic & Brownjohn (2012).

The underlying shape of the template cycle can be modelled mathematically as a sum of 29 equidistant Gaussian functions (Racic & Brownjohn (2012)):

$$Z(t)=\sum_{j=1}^{29} A_j e^{-\frac{(t-t_j)^2}{2\delta^2}} \tag{1}$$

where $Z(t)$ is the curve fit, the parameter A_j is the height (also called weight) of the j-th Gaussian peak, t_j is the position of the centre of the peak, and the common parameter δ controls the width of the Gaussian bell functions. Aiming for the minimum number of Gaussians in the sum necessary to describe accurately the template cycle, values of parameters δ, t_j, and A_j were optimised using non-linear least-square curve fit (Bates & Watts 1998). As a result, the positions of Gaussian centres are optimally located in every eight sample (29 of them), the optimal common width is $14/f_s$, while the optimal heights are illustrated in Figure 8a.

3.2 *Variability of cycle intervals*

Variations of cycle intervals T_i $(i=1,\ldots,34)$ can be represented by a dimensionless set of numbers τ_i:

$$\tau_i=\frac{T_i-\mu_T}{\mu_T} \tag{2}$$
$$\mu_T=mean(T_i)$$

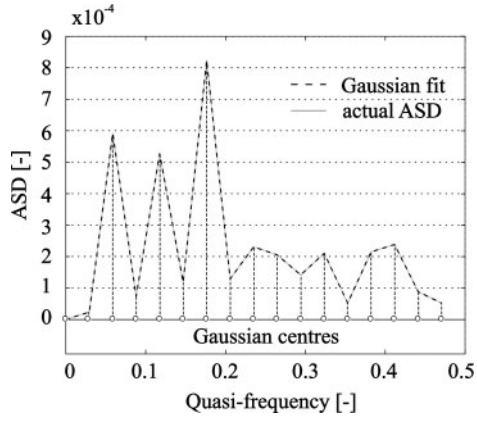

Figure 5. ASD of τ_i and its fit.

Taking τ_i as a series having zero mean value, variance of τ_i can be obtained as the integral of its auto spectral density (ASD) (Newland 1993). Assuming that the variation of τ_i does not change for the given test subject, pacing rate and duration of walking (e.g. due to fatigue and physical discomfort), the aim here is to use the ASD of the actual τ_i data to generate synthetic series τ'_k $(k=1,\ldots,N)$ of arbitrary length (e.g. $N \gg 34$) with the same statistical properties, such as standard deviation and "pattern" of variation between successive τ_i values.

The ASD of τ_i can be calculated as (Newland 1993):

$$S_\tau(f_m)=\frac{A_\tau^2(f_m)}{2\Delta f},\quad f_m=\frac{m}{34},\quad m=0,\ldots,16 \tag{3}$$

where $A_\tau(f_m)$ is a single-sided discrete Fourier amplitude spectra and $\Delta f=1/34$ is the spectral line spacing (Figure 5).

Similarly to the template cycle (Section 3.1), the ASD $S_\tau(f_m)$ can be analytically described by a sum of Gaussian functions (Figure 5):

$$S'_\tau(f)=\sum_{j=1}^{17} W_j e^{-\frac{(f-c_j)^2}{2b^2}} \tag{4}$$

Here, parameter W_j is the height of the j-th Gaussian peak, c_j is the position of the centre of the peak, and b is the common width of the Gaussian function. The Gaussian centres c_j, are placed in each sample on the quasi-frequency axis to fit exactly the actual ASD (Figure 5). For such fixed positions of c_j and predefined widths $b=\Delta f$, Gaussian heights W_j can be computed using the non-linear least-square method (Bates & Watts 1998).

Generation of synthetic series τ'_k $(k=0,\ldots,N)$ starts by calculating $S'_\tau(f_n)$ values using Equation (5) at discretely spaced frequency points $f_n=n\Delta f'$, where $n=0,\ldots,N/2-1$ and $\Delta f'=1/N$. The synthetic ASD amplitudes are then used in conjunction with Equation (4) to generate a set of Fourier amplitudes $A'_\tau(f_n)=\sqrt{2\Delta f' S'_\tau(f_n)}$. Finally, assuming random

distribution of phase angles in the range $[-\pi, \pi]$, $A'_\tau(f_n)$ are used in inverse FFT algorithm to generate a set of N synthetic variations τ'_k. Different realisations of the random phases may be specified by varying the seed of the random number generator, hence many different series τ'_k can be generated with the same spectral properties.

According to Equation (2), scaling τ'_k by μ_T and adding the offset value μ_T, results in a series of synthetic intervals T'_k. Moreover, assuming that the test subject does not vary significantly their gait in a narrow range of (lateral) walking rates, μ_T value can be slightly changed in the scaling process to generate cycle intervals at rates close to $1/\mu_T$. Empirical evidence for this is presented in Section 4.

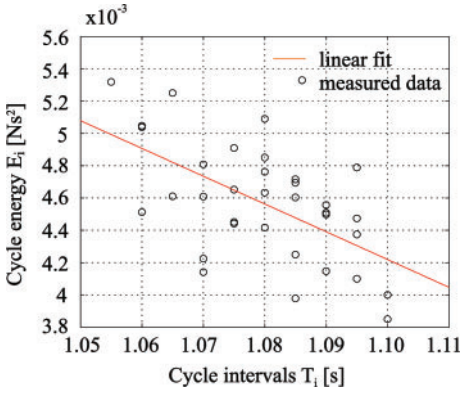

Figure 6. Cycle energy vs. cycle intervals.

3.3 *Variability of force amplitudes*

Energy of weight-normalised walking cycles E_i can be defined as the integral of squared weight-normalised force amplitudes over the corresponding cycle intervals T_i (Figure 3). The linear trend between these two parameters (Figure 6) makes it possible to describe energy transfer between successive cycles using the following linear regression model (Bishop 2006):

$$E_i = \rho_1 T_i + \rho_0 + \Delta E_i \tag{5}$$

Here, $\rho_1 = -0.017$ and $\rho_0 = 0.023$ are regression coefficients and ΔE_i is the subsequent error (also known as a disturbance term), which is a random variable and is usually modelled as a random Gaussian noise (Bishop 2006).

Given a set of synthetic cycle intervals T'_k $(k = 1, \ldots, N)$ generated as explained in Section 4.2, the corresponding synthetic series E'_k can be calculated using Equation (6). These energies can be assigned to template cycles by scaling their amplitudes by factors α_k:

$$\alpha_k = \sqrt{\frac{E'_k}{E_{tc}}} \tag{6}$$

where E_{tc} is the energy of the template cycle. Arranged in a sequence along the time axis, the scaled template cycles reflect the smooth variations of the force amplitudes on a cycle-by-cycle basis, as presented in the next section.

3.4 *Generation of synthetic forces*

Visual comparison of Figure 7a to 1a and Figure 7b to 1b shows apparent similarity between a measured

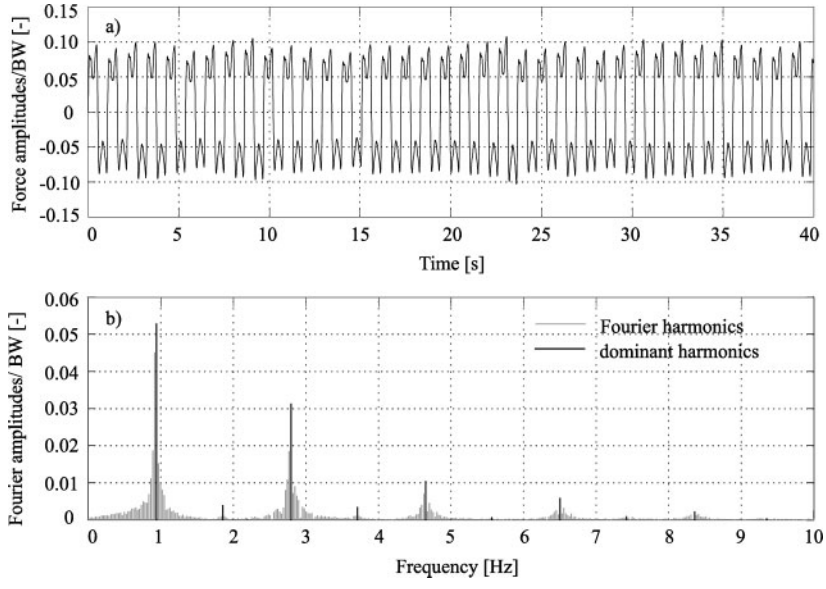

Figure 7. (a) An example of synthetic time series and (b) the corresponding discrete Fourier amplitude spectrum.

signal and an example artificial force signal in both time and frequency domain.

4 DEVELOPMENT OF RANDOM NUMERICAL GENERATOR OF FORCE SIGNALS

Each of the 850 force records in the database (Section 2) was processed using the concept described in Section 3. Multiple sets of information, such as parameters of the template cycle $Z_k(t)$, the ASD $S'_\tau(f)$, disturbance term $\Delta E_i(t)$ and the regression coefficients ρ_1 and ρ_0, were extracted and stored in MATLAB structure files (MathWorks 2011). These are called "mat files" in the remaining part of the paper.

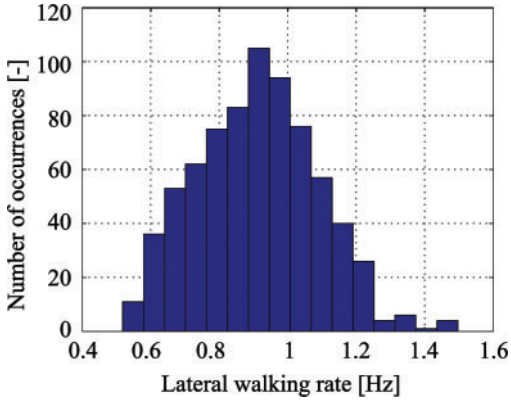

Figure 8. Histogram of lateral walking frequencies f_w.

The mat files were classified into 16 categories (clusters) with respect to the lateral walking frequency, as shown by the histogram in Figure 8. As each bar in the histogram is only 0.06 Hz wide, it can be assumed that any mat file in a cluster can be used to generate synthetic walking time series at any frequency within the cluster's narrow frequency range. As already mentioned in Section 3.2, this means that the modelling parameters extracted from real walking at a certain rate can be used to synthesise walking forces at close rates in the same cluster. The flow chart in Figure 9 outlines the algorithm of creating synthetic force signals.

For the same set of input parameters – lateral walking rate 1 Hz and walking period 40 s, Figure 10 illustrates examples of force signals generated after the model was run twice in succession. A visual comparison of the time series provides convincing evidence that the model does account for the inter-subject variability. On the other hand, the ability to generate different degrees of the intra-subject variability is more obvious from comparison between the corresponding

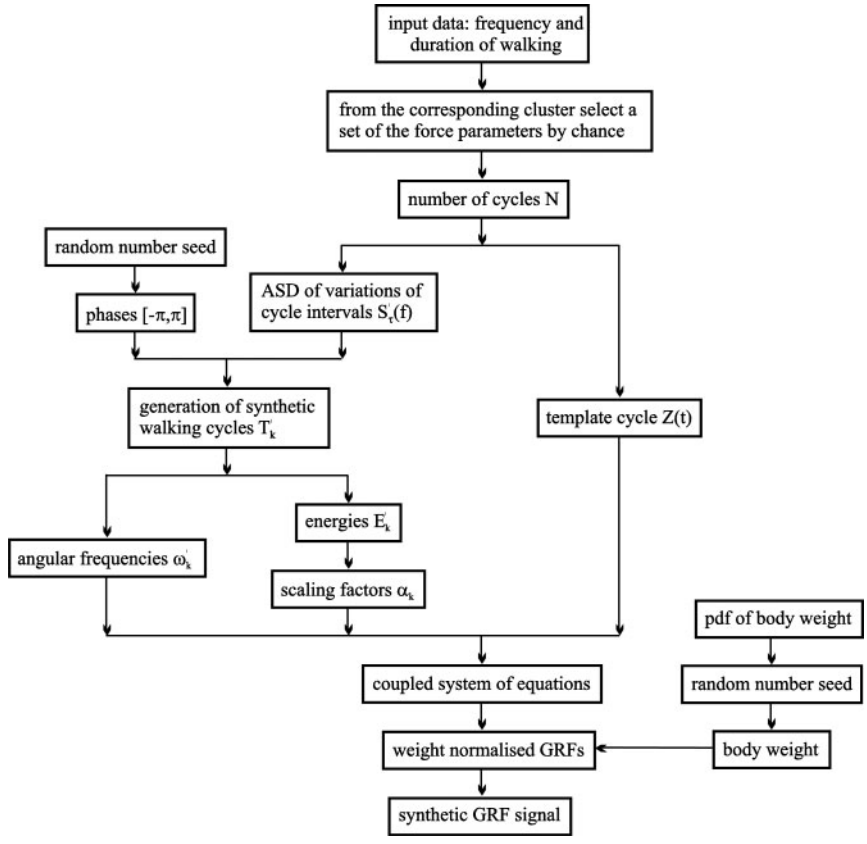

Figure 9. Flow chart.

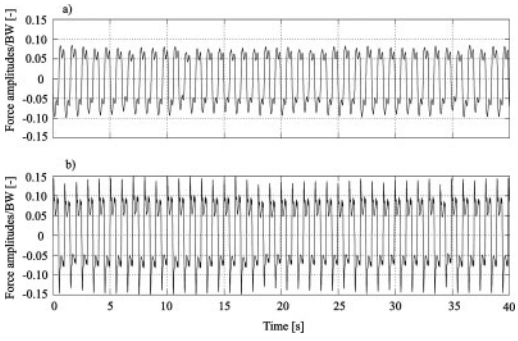

Figure 10. Examples of walking time series for specified $f_w = 1$ Hz and duration 40 s.

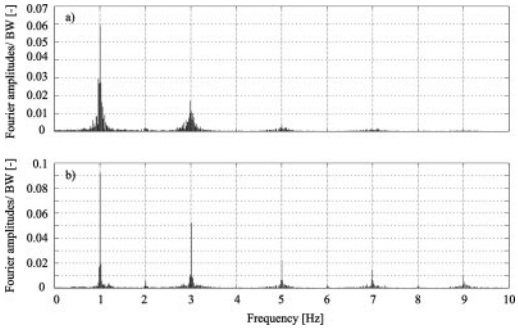

Figure 11. Fourier amplitude spectra of the signals given in Figure 10.

frequency spectra (Figure 11). The broader spread of energy around dominant harmonics in Figure 11a relative to 11b indicates that walking of the first "virtual" pedestrian is characterised by greater intra-cycle variability.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the financial support provided by the UK Engineering and Physical Sciences Research Council (EPSRC) for grant reference EP/E018734/1 ("Human Walking and Running Forces: Novel Experimental Characterisation and Application in Civil Engineering Dynamics") and to thank all test subjects for participating in the data collection.

ABSTRACT: The present contribution demonstrates the possibilities of a 3D motion tracking technique, originating from the movement science and entertainment industry, for the in situ analysis of the walking behaviour of pedestrians. Based on the registered movement, stride-to-stride variations are identified which enable to simulate the imperfect real walking forces. The technique is used in a unique experiment to simultaneously register the behaviour of (groups of) pedestrians and the structural response of a lightweight steel footbridge. The calibrated numerical model of the structure and the information gathered using the motion tracking system enable detailed step-by-step simulations. Accounting for the in situ identified imperfect walking behaviour of the test-subjects increases the agreement between the measured and the simulated response significantly. The remaining difference in magnitude between measurements and simulations, may be explained by an increase in damping due to the increase in amplitude of the structural response or the presence of pedestrians.

1 INTRODUCTION

Due to the trend towards greater slenderness, footbridges are very often lively structures, prone to human-induced vibrations (Brownjohn et al. 2004, Van den Broeck et al. 2011). Predicting the dynamic response of these structures due to crowd-induced loading has therefore become a critical aspect of the vibration serviceability design (Caetano et al. 2010, Živanović et al. 2005).

The human-induced forces and walking behaviour have been studied thoroughly in laboratory conditions (Racic et al. 2009). A remaining challenge is the analysis of the walking behaviour of pedestrians and crowds *in situ*. In view of this challenge, the authors see great potential in a 3D motion tracking technique originating from the movement science and entertainment industry.

A full-scale experiment is performed in which the structural response of a lively footbridge and the walking behaviour of the pedestrians are registered simultaneously. Numerical simulations are performed based on the calibrated numerical model of the structure and information gathered using the motion tracking system.

The outline of this paper is as follows. First, the 3D motion tracking technique is presented. Second, it is shown that the registered movement of the test-subject allows to identify the imperfect walking behaviour. In the final section, the in situ experiments are presented and the results of the numerical simulations are discussed.

2 3D MOTION TRACKING

The Xsens MTw Development Kit measurement system consists of multiple wireless inertial units (figure 1), incorporating 3D accelerometers, gyroscopes, magnetometers and a barometer. The accompanied Awinda radio protocol ensures time synchronisation between the MTw's across the wireless network. The sensors are securely fixed onto the test-subject with specially designed click-in full body straps.

3 APPLICATION IN LABORATORY CONDITIONS

The preliminary research by Van Nimmen et al. (2013) considered experiments in laboratory conditions and studied the relation between the accelerations of the body segments and the measured ground reaction forces. It is shown that the same main step frequency of the test-subject is identified from the frequency analysis of the measured ground reaction forces and the lower back accelerations. This step frequency along with the static weight of the test-subject, determine the vertical single foot force as defined by Li et al. (2010).

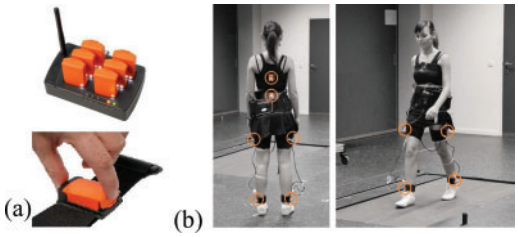

Figure 1. © Xsens – MTw Development Kit consisting of multiple wireless inertial units (MTw's) and specially designed click-in full body straps (a). Configuration setup of the wireless inertial units (MTw's) in laboratory conditions (b).

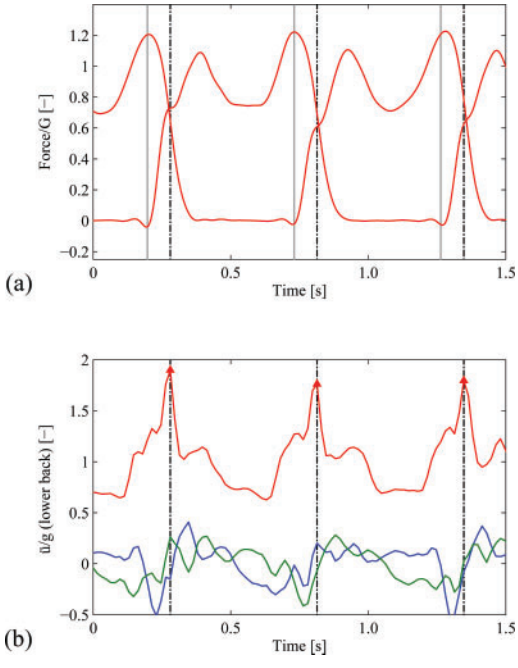

Figure 2. For a normal walking of speed of 5 km/h: (a) normalised ground reaction forces registered by the instrumented split-belt treadmill and (b) normalised measured accelerations at the lower back for the longitudinal (blue), lateral (green) and vertical (red) component.

Secondly, it is shown that both the acceleration levels measured at the lower back and at the ankles, enable to identify the time period in between two successive steps, and therefore, the pacing rate of the test-subject (figure 2). Figure 3 shows that the simulation of ground reaction forces based on a generalised single foot force model and the in situ identified pacing rate, allows for a good approximation of the imperfect real walking forces.

4 APPLICATION IN SITU

In this section, the 3D motion tracking technique is applied in a unique experiment to simultaneously

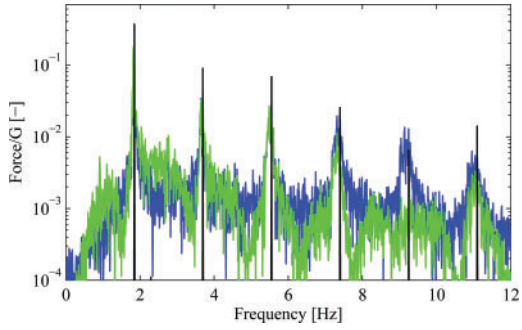

Figure 3. The Fourier series coefficients of the measured vertical ground reaction forces for a normal walking speed of 5 km/h (blue) and the corresponding simulated vertical walking forces according to Li *et al.* with main step frequency f_s and pacing rated identified based on the tracked motion of the body segments of the test-subject (green) and the perfectly periodic forces with the identified average step frequency and the time in between two successive steps equal to $1/f_s$ (black).

Figure 4. Eeklo footbridge.

register the behaviour of pedestrians and the structural response of a lightweight steel footbridge. The in situ identified modal characteristics of the structure are applied to calibrate its numerical model. Numerical simulations are performed applying step-by-step force models and the impact of the in situ identified imperfect walking behaviour of the test-subjects is assessed. This section consists of four parts: (1) the description of the footbridge and (2) the different experimental setups, (3) the analysis of the walking behaviour *in situ*, and (4) the numerical simulations and discussion of the results.

4.1 *Eeklo footbridge*

The footbridge considered in these experiments is located in Eeklo, at Aalstgod, and forms a safe passage across the N49 for pedestrians and cyclists. The bridge (2002) has three spans, a main middle span of 42 meters (across the N49) and two side spans of 27 meters (figure 4). The bridge is simply supported with land abutment at the sides and two pillars at the midspan. Both the abutments and the pillars are equipped with neoprene supports.

An extensive measurement campaign was carried out to obtain the operational modal characteristics of the footbridge. Output-only system identification is

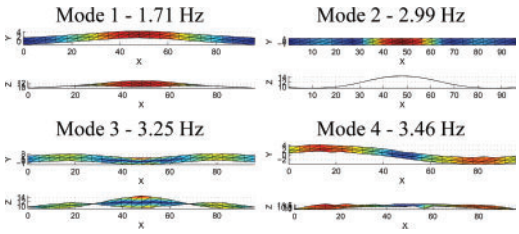

Figure 5. The first four identified modes of the Eeklo footbridge: respectively the top and side view.

performed based on ambient vibrations, mainly due to wind and nearby highway traffic (Peeters and De Roeck 1999, Reynders and De Roeck 2008). In total, 14 modes were identified with a frequency up to 12 Hz (table 1). Some of the lower operational eigenmodes and eigenfrequencies identified by this analysis, are presented in figure 5 which clearly illustrates that combined lateral-torsional modes alternate with vertical bending modes.

The FE model was constructed in great detail according to the as-built plans and is calibrated using the results of the operational modal analysis: model parameters are adopted such that an optimal correspondence is found between measured and calculated modal characteristics. This will result in a better representation of the dynamic behaviour of the structure and, therefore, increase the accuracy of the numerical predictions of the response to pedestrian loading. For the presently considered footbridge, the updating variables are limited to the stiffnesses of the neoprene supports, modelled with three translational springs (one in vertical, lateral and longitudinal direction) at each support.

Table 1 summarizes the results of the updating procedure. It lists the values of the measured natural frequencies $\tilde{f}$, calculated natural frequencies f, the relative error ε_j, and MAC values between measured and calculated mode shapes. This table shows that an excellent agreement is found between the numerical model and the measurements. The relative errors on the frequencies of all modes are limited to 1.76% and the MAC values are high.

4.2 *Experimental setups*

In this experimental study, different types of setups were considered including free walking and synchronised walking. In case of synchronised walking, the step frequency (or its second harmonic) of the test-subjects was chosen so as to match one of the natural frequencies of the structure. These resonant conditions were realized for both the first ($f_s = \tilde{f}_1 = 1.71$ Hz) and the second mode ($f_s = \tilde{f}_2/2 = 1.49$ Hz) of the structure. The step frequencies of the pedestrians were synchronised using a metronome signal, a process which was practiced by the test-subjects in laboratory conditions beforehand.

Different group sizes, ranging from one pedestrian up to six, are considered in various formations: two by two or all lined up one by one, and symmetrically (figure 6b) or asymmetrically (figure 6a) distributed with respect to the longitudinal axis of the structure. The response of the structure is registered with five triaxial sensors, for which the location was determined using an optimal sensor location algorithm (Papadimitriou and Lombaert 2011). The walking behaviour of the pedestrians is registered with the 3D motion tracking technique. Due to the limited number of MTw's, only one sensor is fastened to each test-subject (figure 6). For reasons of visibility and connectivity, the location of the sensor was set at the front of the torso instead of the back. Although good results were obtained using this sensor configuration, in future experiments preference will again be given to the lower back position because this limits the influence of skin motion artifacts resulting into an even clearer picture of the registered pedestrian motion.

Table 1. Identified modal characteristics (mode number $\tilde{N}$, natural frequencies $\tilde{f}$, damping ratios $\tilde{\xi}$) for all modes with a natural frequency blow 13 Hz and corresponding predicted natural frequencies of the calibrated numerical model (f), the calculated Modal Assurance Criterion (MAC) and the relative frequency deviation (ε).

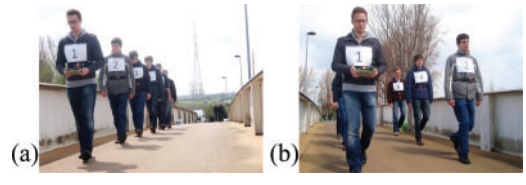

Figure 6. Synchronized walking of (a) 6 persons in a row and (b) two by two.

4.3 *Analysis of the walking behaviour in situ*

The identification of the pacing rate *in situ* is illustrated for a setup where the second harmonic of the walking load is set to match the frequency of the second mode of the structure ($f_s = \tilde{f}_2/2 = 1.49$ Hz). For this setup, it takes about 90 seconds to cross the

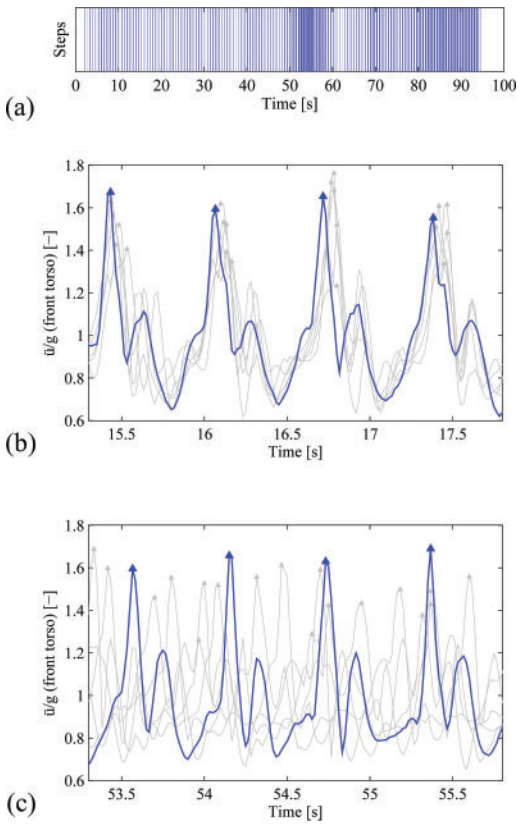

Figure 7. Identified pacing rate for a setup considering synchronised walking ($f_{metronome} = \tilde{f}_2/2 = 1.49$ Hz): visualisation of each step in time (a) and corresponding accelerations measured at the front of the torso for the 6 test-subjects (b–c) for times characterised by a high (b) and a low (c) synchronisation rate.

footbridge. Figures 7b and 7c present the accelerations measured at the front of the torso for the 6 test-subjects. For reasons of clarity, the signal of the first pedestrian is emphasized. These signals are clearly similar to the results obtained in laboratory conditions, as presented in figure 2b. Based on this registered movement, the beginning of each step and thus the pacing rate can be identified for each test-subject. As a result of the time synchronisation among the MTw's, the identified in situ walking behaviour also allows to study the synchronisation rate of the different test-subjects.

In figure 7a, all steps of all test-subjects are visualised in time with a single vertical line. If these lines coincide, it means that the different test-subjects are taking their steps at more or less the same time. A high rate of synchronisation has therefore been obtained. Times characterised by a high sychronisation rate, can be identified in figure 7a as equally spaced lines. The lack of white spacing will therefore indicate a lower synchronisation rate. As discussed in section 3, the induced forces can be simulated based on the in situ identified pacing rate and the generalised single foot force model that accounts for the identified mean step frequency and the weight of every test-subject. For this setup, the rate of synchronisation is relatively high during the first 40 seconds. The synchronisation is lost between 50 and 60 seconds and gets partially restored towards the end (figure 7c).

4.4 *Numerical simulations*

The essential features of the simulation model are the dynamic footfall load, the dynamic behaviour of the footbridge and the response calculation.

The vertical component of the walking force, as discussed in section 3, is modelled as a series of moving single footsteps for which the time history of the vertical component is described by Li et al. (2010). The lateral component is described by a rectangular force with an alternating sign for left and right foot and with a contact time equal to the vertical force. A dynamic loading factor of 0.04 is adopted as recommended by Butz et al. (2007).

The dynamic behaviour of the footbridge is characterized by the modal parameters (natural frequencies, mode shapes and damping factors). The natural frequencies and mode shapes of the calibrated finite element model of the structure (section 4.1) are applied together with the in situ identified modal damping factors. The response calculation is based on the time integration of the state-space equations formulated in terms of the modal coordinates. For the presented simulations, all modes with a natural frequency below 20 Hz are taken into account.

Figure 8 presents the measured and simulated acceleration response at midspan for the setup where the subjects were walking on one side of the bridge, with a pacing rate targeted at $\tilde{f}_1$. This figure presents the lateral response which is in accordance with the dominant component of the first mode. In total, 4 different responses are presented: the simulated acceleration response due to (1) the perfectly periodic forces based on the step frequency as set by the metronome signal, (2) perfectly periodic forces based on the identified mean step frequency of the test-subjects, (3) the imperfect walking forces as a result of the identified pacing rate and (4) the measured response. This figure illustrates that the response of the structure is clearly overestimated by the perfectly periodic forces. Although accounting for imperfect walking behaviour by applying the identified pacing rate still seems to overestimate the response, a good qualitative agreement is found with the measured response i.e. the two signals are almost equal up to a scaling factor. For both this simulated and measured response, a decrease in acceleration level can be observed after about 40 seconds, which is due to a reduced synchronisation of the test-subjects. A comparison of the responses in the frequency domain shows that again the simulation model that accounts for imperfect walking behaviour, gives the best approximation of the measured response. The underestimation at low frequencies is mainly due to ambient excitation of the bridge due to wind and nearby traffic, which is unaccounted for in this analysis. The errors on the predicted response for higher

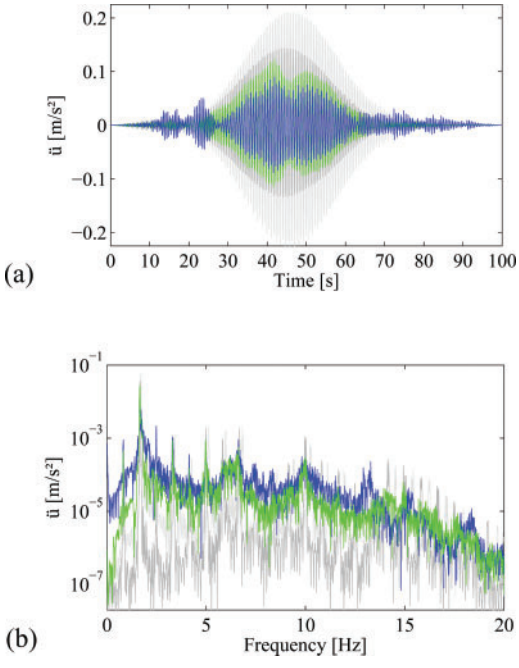

Figure 8. (a) Time series of the lateral acceleration levels in the center span of the bridge and (b) corresponding Fourier series coefficients: (blue) measured (green) simulated accounting for the identified pacing rate of each pedestrian (gray) simulated only applying the main step frequency.

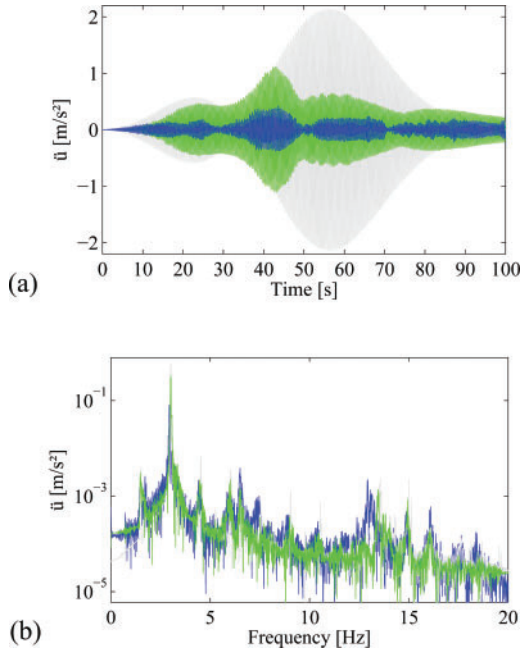

Figure 9. (a) Time series of the vertical acceleration levels in the center span of the bridge and (b) corresponding Fourier series coefficients: (blue) measured (green) simulated accounting for the identified pacing rate of each pedestrian (gray) simulated applying the average step frequency as set by the metronome signal.

frequencies, are for the greatest part attributed to modelling errors still present in the calibrated finite element model. The good qualitative agreement between the two responses but the difference in amplitude, may be explained by an increase in damping. This increase can be due to the presence of the pedestrians (Brownjohn et al. 2004) but structural damping has also been found to increase with amplitude (Kijewski-Correa and Pirnia 2007, Hudson and Reynolds 2012). Moreover, it has to be acknowledged that the in situ identified damping ratios are also subject to a significant degree of uncertainty (Reynders et al. 2008).

Figure 9 presents the measured and simulated vertical acceleration response at midspan for the setup where the subjects were walking two by two, with a targeted pacing rate equal to $1/2\tilde{f}_2$. Since the mean step frequency of all the test-subjects was equal to the rhythm guided by the metronome signal for this setup, this figure presents only three responses: the simulated acceleration response (1) due to the perfectly periodic forces based on the step frequency as set by the metronome signal, (2) due to the imperfect walking forces accounting for the identified pacing rate and (3) the measured response. This figure again illustrates that the response of the structure is clearly overestimated by the perfectly periodic forces. Accounting for imperfect walking behaviour by applying the identified pacing rate predicts in this case a response almost three times larger then the measured response but again, but again a good qualitative agreement is found between the two signals. The comparison of the responses in the frequency domain, shows again that the simulation model that accounts for imperfect walking behaviour leads to the best approximation of the measured response. The comparison in frequency domain shows that both simulated and measured responses are clearly dominated by the contribution of the second mode ($\tilde{f}_2$).

The results of the numerical simulations should be analysed critically. Although the modelling errors of the calibrated model of the structure are limited to the higher frequencies, all identified damping ratios are subject to a significant degree of uncertainty. The identification of the main step frequency and pacing rate from the registered walking behaviour of each test-subject, enables a good approximation of the imperfect real walking forces with small differences due to the application of the generalised force model. The difference in amplitude between the predicted and measured response presented in figure 9, is striking and cannot simply result from these remaining uncertainties. The difference may be explained by an increase in damping as a result of the larger vibration amplitudes or the presence of the pedestrians. Due to the fact that the dominant mode has a very small modal damping ratio ($\tilde{\xi}_2 = 0.19\%$) and a low modal mass (2217 kg), it can be expected that even six persons (together 477 kg) have a non-negligible impact on the dynamic behaviour of the structure.

The present analysis shows that the considered lightweight steel footbridge is highly sensitive to human induced vibrations and can be an interesting case to study human-structure interaction. In view of this objective, additional experiments will be performed including motion tracking for multiple test-subjects.

5 CONCLUSIONS

A 3D motion tracking technique is presented for the in situ analysis of the walking behaviour of pedestrians. The technique enables to identify the main step frequency and pacing rate of the test-subject. Applying a generalised model for the ground reaction forces available in literature, based on the weight of the test-subject and the identified pacing rate, provides a good approximation of the imperfect real walking forces.

The technique is applied in a unique experiment where simultaneously the behaviour of (groups of) pedestrians and the structural response of a lightweight steel footbridge is registered. From the registered motion of the pedestrians, the pacing rate and the rate of synchronisation among the pedestrians can be identified. Numerical simulations are performed applying series of moving single footsteps and a calibrated numerical model of the structure. The results show that the traditionally assumed perfectly periodic forces clearly overestimate the structural response. A good qualitative agreement is found between the simulations that account for imperfect real walking behaviour and the measured response. The remaining difference in amplitude of the predicted and measured response may be explained by an increased damping as the result of the increase in amplitude of the structural response and human-structure interaction.

Vibrations in a multi-storey lightweight building structure: Influence of connections and nonstructural mass

L.V. Andersen & P.H. Kirkegaard
Department of Civil Engineering, Aalborg University, Aalborg, Denmark

ABSTRACT: This paper provides a quantification of the changes in vibration level that can be expected in a lightweight multi-storey wooden building due to reduced connection stiffness or added nonstructural mass. Firstly, the impact of changes in the floor-to-wall connections is examined. Secondly, a study is performed regarding variations of the vibration level due to different placements of nonstructural mass inside the building. The analyses are carried out by means of a modular three-dimensional finite-element model. Each floor and wall panel is modelled in high detail, including door and window openings. By a substructure approach, the panels are assembled to construct a global building model that allows analysis within a reasonable computation time.

1 INTRODUCTION

Timber is an environmentally friendly building material and with the recent progress in construction methods and structural engineering it has become possible to construct large multi-storey wooden buildings. However, transmission of noise and vibrations between residential units in such lightweight structures is a potential risk. Assessment of the dynamic performance in the design stage is therefore necessary. In this context, a correct modelling of the connections between wall and floor panels and the main structure may be important. Further, since the building itself has limited mass, furniture and other nonstructural elements can have significant impact on the dynamic properties of the structure.

In the low and mid-frequency range, statistical energy analysis (Craik 1996) and the European standard EN12354-1 (European Committee for Standardization 2000) provide unreliable results for lightweight structures (Mahn 2007). Instead, analysis can be performed by utilization of a finite-element (FE) model as proposed by, for example, Brunskog and Davidsson (2004), Løvholt et al. (2011), Maluski and Gibbs (2000), or Fiala et al. (2007). However, a solid FE model including structural details such as individual joist and studs will contain millions of degrees of freedom if several wall and floor panels are to be included in a model of a multi-storey building.

Andersen et al. (2012) proposed the use of a modular FE model in which the walls and floors are treated as substructures, leading to a significant reduction of the number of degrees of freedom. This approach is employed in the present paper for dynamic analysis of a four-storey building. The analyses have been made in the frequency domain within the range 0–250 Hz.

In order to study the influence of nonstructural mass in terms of furniture or persons present in the rooms of the building, the model is constructed such that discrete masses can be added at a number of points on each floor. Ohayon and Soize (1998) suggested the application of fuzzy structures for these unknown secondary systems. However, for simplicity a mass of 100 kg is utilized to represent a nonstructural element in the present analyses. The impact of placing additional mass on a dynamically excited floor, or by placing the mass on other floors, has been examined. Further, the influence of having hinged, semihinged or rigidly coupled connections between walls and floors has been examined.

2 FINITE-ELEMENT BUILDING MODEL

A finite-element (FE) model of the building has been created in the commercial software code Abaqus 6.12-2 (Dassault Systèmes Simulia Corp. 2012), utilizing Python scripting and a substructure approach. Firstly, based on rigorous FE models and system reduction, substructures are extracted for each wall and floor panel. These substructures are then assembled to form a building model that is two rooms in length, four storeys high, and one room wide. The module sizes in the length (x), height (y) and width (z) directions are $L = 6.0$ m, $H = 3.0$ m, and $W = 4.2$ m, respectively. Figure 1 provides an illustration of the global FE model. In the following subsections, more details will be given about the panel substructure models as well as the assembly of the global model.

2.1 *Panel substructures*

Three different lightweight panels are modelled and analysed, i.e. wall panels to be used as vertical divisions in the global x and z-directions, and floor panels to form the horizontal divisions in the global

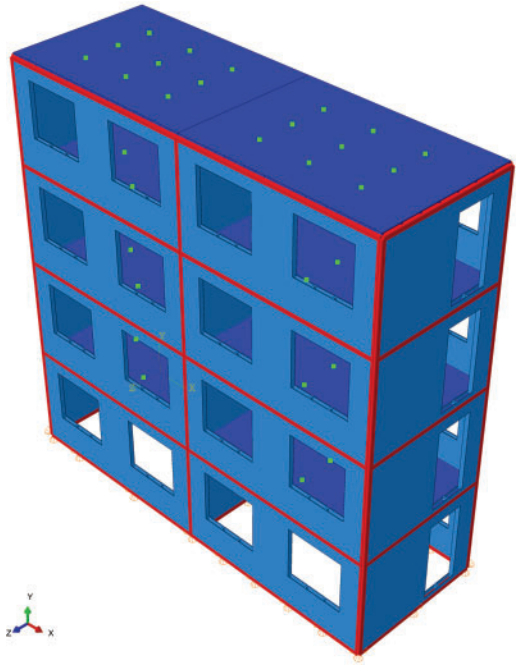

Figure 1. Building model. The green dots indicate positions at which loads or discrete nonstructural masses may be applied.

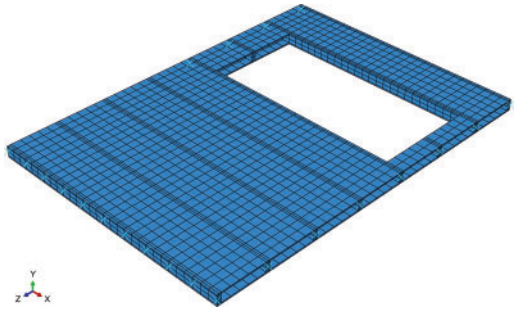

Figure 2. FE model of $4.2 \times 3.0\,\mathrm{m}^2$ (width × height) wall panel for vertical divisions in the global x-direction.

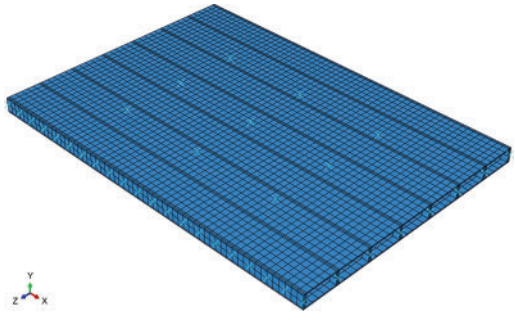

Figure 3. FE model of $6.0 \times 4.2\,\mathrm{m}^2$ (length × width) floor panel for horizontal divisions in the global y-direction.

y-direction. All panels are made of wood, simplified as an isotropic linear viscoelastic material with Young's modulus 9.5 GPa, Poisson's ratio 0.35, and mass density $455\,\mathrm{kg/m}^3$. Structural damping with a loss factor of 1% has been employed in all parts of the model.

The walls parallel to the (y,z)-plane have the overall dimensions $(W \times H) = 4.2 \times 3.0\,\mathrm{m}^2$ and a thickness of 130 mm. They are made as double-leaf panels with two 15 mm thick plates connected to a set of vertical studs. The studs have a cross-sectional area of $100 \times 50\,\mathrm{mm}^2$, and the centre-to-centre distance is 600 mm, leading to a total of eight studs in each panel including the two members placed along the sides of the panel. Glued connections are assumed between the plates and the studs, i.e. the structural members are fully tied on the interfaces, and a door opening has been cut in each wall panel as illustrated in Figure 2. The opening is 2.40 m high, 1.15 m wide, and it is placed 0.20 m from the bottom of the panel. The model is discretized into 20-node brick finite elements with quadratic spatial interpolation of the displacement field and full integration of the mass and stiffness. A maximum mesh size of 100 mm is allowed in the structured hexahedral mesh. The cross sections of the studs are subdivided into four elements, two in each of the width and thickness directions.

Similarly, the floors of the building are made as lightweight timber panels with the dimensions $(L \times W) = 6.0 \times 4.2\,\mathrm{m}^2$. They consist of two plates connected to joists placed along the length direction. The plates have a thickness of 20 mm, whereas the joists are 50 mm wide and 200 mm high, providing a total panel height of 240 mm. The distance between the joists, centre-to-centre, is 600 mm. An illustration is given in Figure 3. Again 20-node brick elements have been employed, using the same meshing rules as for the wall panel providing the horizontal divisions in the x-direction.

Finally, the walls parallel to the (x,y)-plane have the dimensions $(L \times H) = 4.2 \times 3.0\,\mathrm{m}^2$ and a thickness of 130 mm. The model contains two window openings as illustrated in Figure 4. Each window has a height of 1.6 m and it is placed 1.0 m from the bottom of panel. As in the case of the other two panel models, a discretization into 20-node brick elements with a maximum mesh size of 100 mm is carried out.

For each of the three panels, a system reduction is carried out in order to provide a substructure macro finite element. As proposed by Craig and Bambton (1968) and further explained by Craig (1981), the system matrices achieved by Guyan reduction (Guyan 1965) of the system matrices has been enriched by a set of internal modes of a model fixed at the retained degrees of freedom.

In the present analyses, original nodes have been retained on along the edges of the panels with a distance of 300 mm. Only the nodes at the middle plane of the panels are retained. For example, 11 nodes are retained along the sides of the wall panels, one per

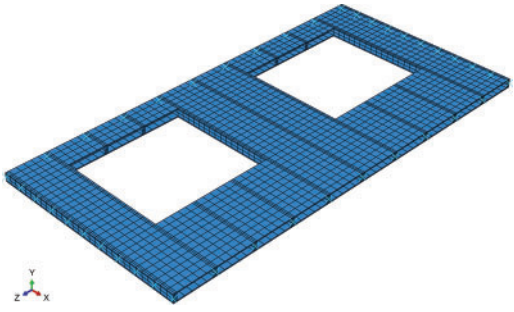

Figure 4. FE model of $6.0 \times 3.0\,m^2$ (length × height) wall panel for vertical divisions in the global z-direction.

three elements over the height direction, and one node is retained at the centre of the end cross sections of the studs. For the wall panel shown in Figure 2 this provides a total of 34 retained nodes. Additional retained nodes are included in the floor panel substructure to allow the application of loads as well as discrete nonstructural masses. The nodes are placed on the top of the floor in the one-half and one-quarter points, leading to a total of nine additional retained nodes per floor panel. The retained nodes are marked by crosses in Figures 2–4.

In the original panel FE models, nodes are only associated with translational degrees of freedom. To allow coupling of rotations between adjacent panels, artificial shell elements have been introduced in the cross sections of the beams at the positions of the retained nodes along the panel edges. These shells have a thickness of 10 mm, a mass density of $0.01\,kg/m^3$ and a Poisson's ratio of 0. The elements are only intended to provide rotational stiffness. In the reference model, Young's modulus is 10^7 GPa, ensuring full rotational rigidity. Two alternative models of each panel are analysed: A model with semi-hinged connections in which Young's modulus of the shells is 10^4 GPa, and a model with hinged connections, obtained by defining Young's modulus of the shells as 10 GPa.

2.2 *Global assembly and analysis*

The substructures created from the FE models of the wall and floor panels are assembled to form the building illustrated in Figure 1. Following the approach proposed by Andersen et al. (2012) and Kiel et al. (2012), the individual substructures are attached to an artificial skeleton made of beam elements with nearly no mass. The stiffness of the skeleton is made high enough to avoid spurious modes of vibrations and low enough to prevent significant impact on the overall static and dynamic properties of the building. In the present case, 3-node Timoshenko beam elements with a node distance of 300 mm and a cross-sectional area of $10 \times 10\,mm^2$ are adopted. A mass density of $1\,kg/m^3$ and a Young's modulus of 1 GPa are applied. The total mass of the building is 11,294 kg, and the global model has 35,000 degrees of freedom.

Two types of analysis are carried out. Firstly, the undamped eigenfrequencies are determined in the frequency range 0–250 Hz. Secondly, the steady state response of the building to time-harmonic excitation is determined at 2001 uniformly distributed discrete frequencies in the interval 0–250 Hz. The load is applied as a concentrated force with unit amplitude and acts vertically in the middle of the Floor 1-2-1 which is the floor belonging to room 1 in the x-direction, room 2 in the y-direction, and room 1 in the z direction. With reference to Figure 1, this is the leftmost room of the second storey. Likewise, Floor 1-3-1 is the floor right above Floor 1-2-1, and Floor 2-4-1 belongs to the rightmost room of the top storey. The eigenvalue problem is solved in 104 s on an Intel i7 CPU 860@ 2.80 GHz, using a single core. Computation time for the steady state analysis is about 3.0 s per frequency. The analyses are performed for buildings with different connection stiffness and added nonstructural mass. The following models are considered:

- A reference building model with rotationally rigid joints and no added mass,
- a model with 100 kg of nonstructural mass placed at each of the nine points on every floor in the left side of the building, i.e. the side where the force is applied,
- a model with 100 kg of nonstructural mass added to the similar points in the right side of the building, i.e. the unloaded side,
- a model with 100 kg of nonstructural mass added to all points in all rooms,
- a model with semi-hinged connections obtained by reducing the stiffness of the shell elements used for coupling of the rotational degrees of freedom,
- a model with hinged connections obtained by a further reduction of of the shell stiffness.

3 RESULTS AND DISCUSSION

3.1 *Eigenfrequencies*

Figure 5 shows a mode count for different floor panels. The first natural frequency of the reference floor, fixed at the retained edge nodes, is 42.5 Hz, while the corresponding values for the semi-hinged and hinged floors are 35.3 Hz and 30.1 Hz, respectively. For a pinned floor, all models provide a first natural frequency of 30.1 Hz. Hence, the hinged connections and the reference building model provide two limits. In the first case, the building will act as if only the translational degrees of freedom are tied at the connections between adjacent panels, whereas all degrees of freedom (including rotational degrees of freedom) are effectively tied in the reference building model.

Further, in Figure 5 it is observed that the modal density is not significantly influenced by the boundary conditions, i.e. the overall mode count is the same for all models. However, a pronounced increase of the modal density occurs beyond 300 Hz.

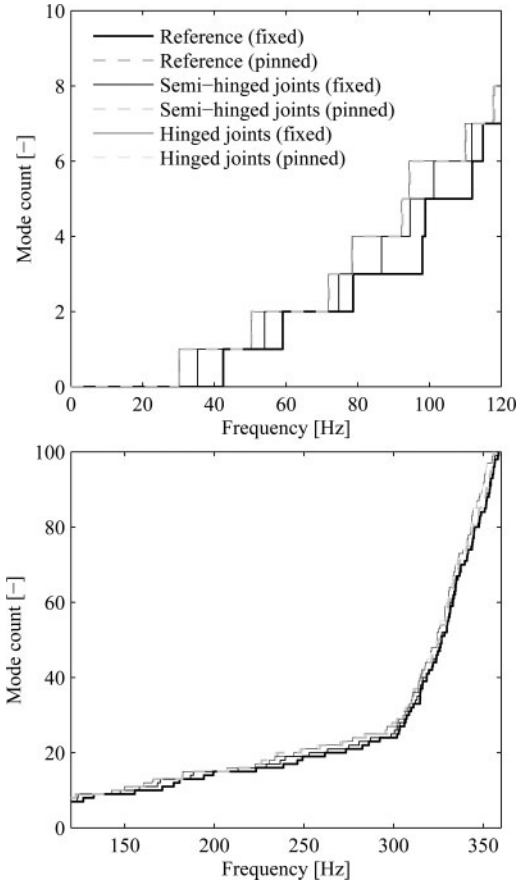

Figure 5. Mode count for floor panels with different connection stiffness and pinned or fixed along the edge. Top: Frequency range 0–120 Hz. Bottom: Frequency range 120–360 Hz.

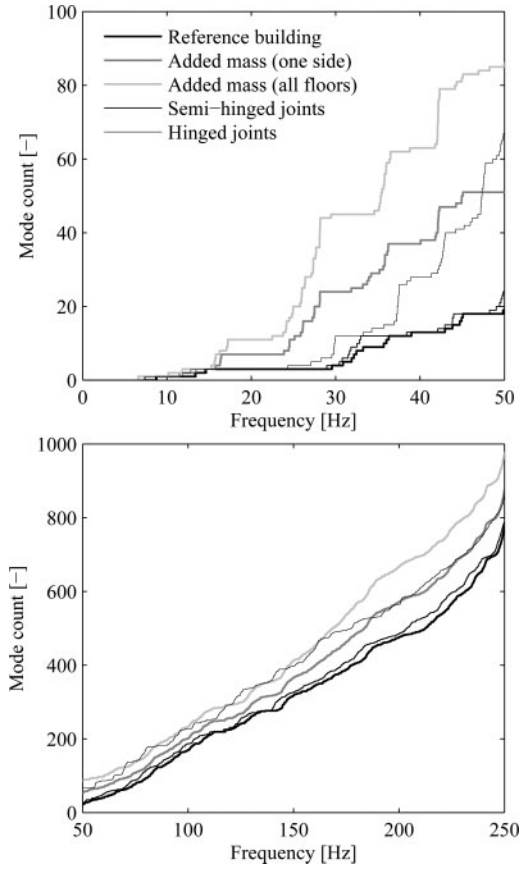

Figure 6. Mode count for global building models with different added mass and connection stiffness properties. Top: Frequency range 0–50 Hz. Bottom: Frequency range 50–250 Hz.

Mode counts for the building models listed above are provided in Figure 6. As expected, added nonstructural mass leads to a higher modal density in the low-frequency range. Especially, the first natural frequencies related to resonance of the floors with added mass are 15.6–17.2 Hz, and several additional floor vibration modes occur in the range 24.0–28.2 Hz. For the reference building with no added mass, the first floor vibration modes occur around 30 Hz, and the next modes occur near 50 Hz.

In the low-frequency range, only small differences are observed in the mode counts for the reference building and the model with semi-hinged connections—especially within the low-frequency range. As expected, the reduced stiffness leads to a small reduction of the natural frequencies related to floor vibrations, but it has only got a marginal impact on the global modes of the building. However, compared to the reference building model, the model with hinged connections has significantly more modes in the frequency range 25–50 Hz. At frequencies near 80 Hz and from 120–145 Hz, the mode count for the model with hinges is even higher than the model with nonstructural mass added to every floor.

3.2 *Steady state response to harmonic excitation*

For each floor panel in the building, the steady state response has been extracted at the nine nodes which are retained on the top of the floor. The complex amplitudes of velocity are considered, and a root-meansquare (RMS) value is obtained for each floor as:

$$\langle V \rangle_{\mathrm{RMS}} = \sqrt{\frac{1}{9} \sum_{n=1}^{9} \mathbf{V}_n^H \mathbf{V}_n}, \tag{1}$$

where $\mathbf{V}^n$ is the complex velocity amplitude vector at node n, and $\mathbf{V}_n^H$ denotes its conjugate transpose. Figures 7 to 12 show the RMS velocity response measured in decibel according to the definition

$$\langle V \rangle_{\mathrm{RMS}}^{\mathrm{dB}} = 20 \log_{10} \left(\frac{\langle V \rangle_{\mathrm{RMS}}}{V_0} \right), \quad V_0 = 1 \text{ nm/s}. \tag{2}$$

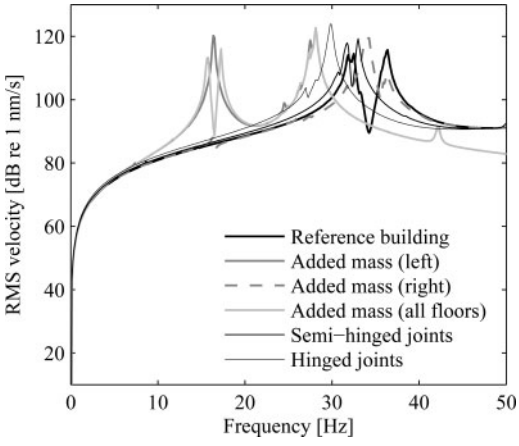

Figure 7. Steady state response to harmonic point force excitation in the middle of Floor 1-2-1; RMS velocities of Floor 1-2-1 in the low-frequency range 0–50 Hz.

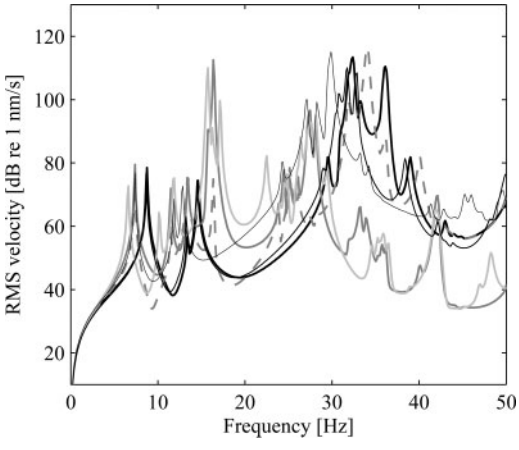

Figure 8. Steady state response to harmonic point force excitation in the middle of Floor 1-2-1; RMS velocities of Floor 1-3-1 in the low-frequency range 0–50 Hz.

In Figures 7 and 10 it is observed that the maximum response occurs near the natural frequencies of the loaded floor, i.e. Floor 1-2-1. When nonstructural mass has been added on the floor, the velocity response is overall decreasing with an increase of the frequency, whereas the trend is the opposite for a floor with no added mass. No influence of added mass in the other (right) side of the building is visible.

Figures 8 and 11 show results for Floor 1-3-1 which is placed in the room right above the room with the loaded floor. As expected, added nonstructural mass has led to a reduction of the frequencies related to the first global modes of resonance of the building. At higher frequencies, the response is again lower (about 40 dB lower) for the two cases with added mass on the loaded floor, but no significant impact of added mass in the other side of the building can be observed. Further, the hinged connections lead to a response

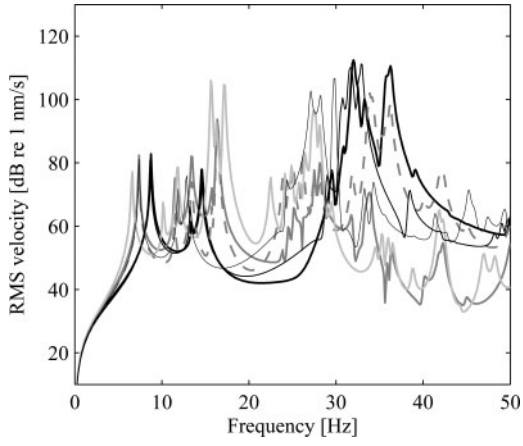

Figure 9. Steady state response to harmonic point force excitation in the middle of Floor 1-2-1; RMS velocities of Floor 2-4-1 in the low-frequency range 0–50 Hz.

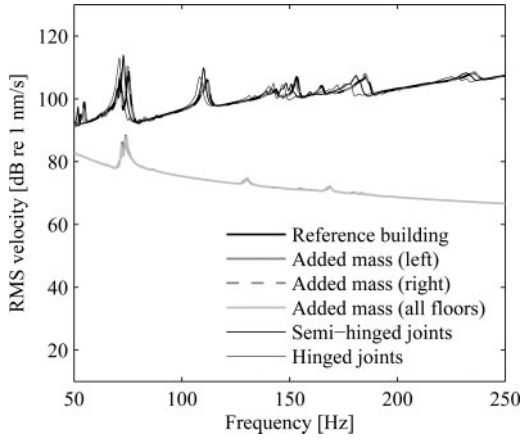

Figure 10. Steady state response to harmonic point force excitation in the middle of Floor 1-2-1; RMS velocities of Floor 1-2-1 in the mid-frequency range 50–250 Hz.

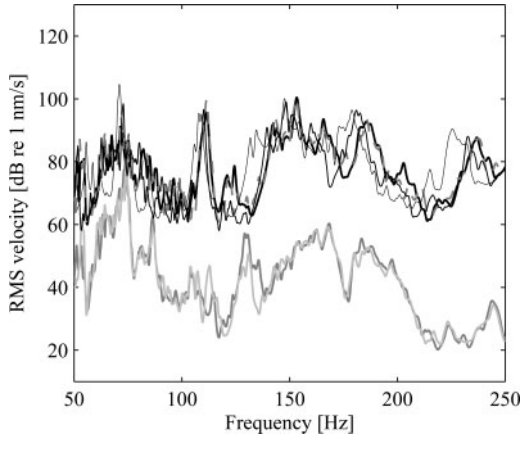

Figure 11. Steady state response to harmonic point force excitation in the middle of Floor 1-2-1; RMS velocities of Floor 1-3-1 in the mid-frequency range 50–250 Hz.

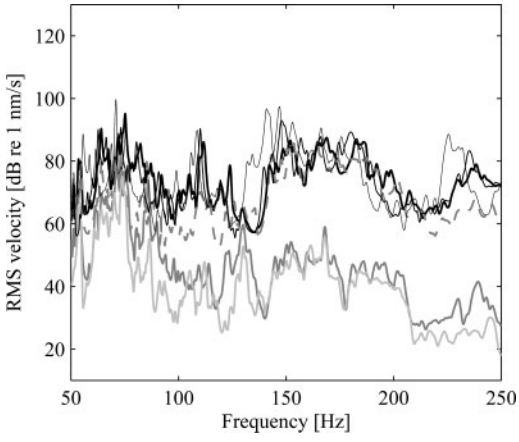

Figure 12. Steady state response to harmonic point force excitation in the middle of Floor 1-2-1; RMS velocities of Floor 2-4-1 in the mid-frequency range 50–250 Hz.

which is in some frequency intervals 10–20 dB higher or lower than the response in the reference case.

Finally, Figures 9 and 12 illustrate the response of Floor 2-4-1 in the room that is farthest away from the loaded floor. Interestingly, there is only a small influence of adding nonstructural mass on the floor itself, i.e. in the right side of the building. Again, the main influencing factor is nonstructural mass placed in the left side of the building, i.e. where the load is applied.

4 CONCLUSIONS

The influence of added nonstructural mass and reduced wall–floor connection stiffness in a lightweight multi-storey wooden building has been examined regarding the dynamic structural response.

It has been found that a significant change in the stiffness of the connections between walls and floors can occur without any substantial influence on the global dynamic response. In the considered case of a concentrated vertical harmonic force, vibrating in the middle of a single floor, differences less than about 10 dB are generally obtained in the RMS velocities related to floor vibration. Hence, variations of the connection stiffness due to, for example, craftsmanship are not likely to have an impact on the overall dynamic response of a building dramatically. However, the stiffness of the individual floors, and therefore the local modes of resonance, may be influenced.

When nonstructural mass is added to the loaded floor, the response of the entire building is generally change significantly. Differences of about 40 dB have been observed in the RMS floor vibration velocities. On the other hand, placing nonstructural mass on the floors in the other side of the building has minor impact on the response—even in rooms in the other side of the building far away from the load. This is an important result regarding performance and analysis of vibration measurements in real lightweight buildings.

Direct velocity feedback versus a geometric controller design of remotely located vibration control systems

D.S. Nyawako, U. Ubaid, P. Reynolds & M.J. Hudson
Departments of Civil and Structural Engineering and Automatic Control and Systems of Engineering, The University of Sheffield, Sheffield, UK

ABSTRACT: The mitigation of human induced vibrations in floors continues to be a key area of research particularly as a result of advancement in material and design technologies enabling the design of light, slender and more open plan structures. These floors are typically characterised by low and close natural frequencies as well as low modal damping ratios, and these combinations of factors contribute to their increased susceptibility to human induced vibrations. Amongst the remedial measures pursued to enhance their vibration serviceability performance, active vibration control (AVC) technologies are emerging as a viable technology and predominantly direct output feedback approaches have been pursued in past analytical studies and field trials.

It has often been assumed that actuators and sensors can be located where vibration attenuation is desired and this may not always be feasible. The research work presented in this paper compares the vibration mitigation performances of the direct velocity feedback scheme that has been extensively used in past floor vibration control researches against a geometric controller design approach that has been developed to provide a design freedom for reducing vibration in both local and remote locations. The geometric controller design approach assumes the inability to locate the actuators and sensors at the remote location but acknowledges that this measurement can be obtained during the commissioning stage and used during the design phase to enhance both local and remote locations. All the analytical and experimental studies are based on a laboratory structure. The work demonstrates comparable vibration mitigation performances of the dominant mode of vibration of the laboratory structure for both approaches but also demonstrates potential for additional enhancement to the second vibration mode of the laboratory structure with the geometric controller design approach. Approximately 20–25 dB attenuation in the first and second vibration modes of the laboratory structure were achieved.

Keywords: active control, human-induced vibrations, geometric controller design

1 INTRODUCTION

Vibration serviceability is now the dominant design criterion for many floor structures, mainly in the commercial sector due to two key factors. Firstly, modern floors are more slender and lightweight than in the past as a result of improved design methods, structural materials and constructiontechnologies. The drivers for improved construction technology include reduced economic cost, increased flexibility of usage, and lower carbon footprints due to reduced material usage. Secondly, there is a trend towards more open plan floor layouts that have fewer full height partition walls than in the past. This reduces the amount of inherent damping present in finished floor structures and hence increased levels of response to human induced excitation. These floors are also characterised by low and close natural frequencies which fall within the range of frequencies produced by human activities as well as their harmonics.

Amongst the remedial measures pursued to enhance the vibration serviceability performance of office floors, AVC technologies are emerging as a promising and viable technology. This has been seen in some past field trials. In those investigations, combinations of direct output feedback (DOFB) and model-based AVC control schemes were successfully used to augment damping for selected vibration modes in each of the floors studied and in the process suppress human-induced vibrations[1,2,3,4,5,6]. Predominantly single-input-single-output (SISO) and multi-SISO collocated sensor and actuator pairs were utilized in both the DOFB, for example, direct velocity feedback (DVF) and model-based controller schemes. In most of these past implementations of AVC in office floors, it was possible to site actuator and sensor pairs at required locations. There was one case in which it was not possible to site the actuators and sensor pairs at a desired location.

Recently, a geometric controller design approach for harmonic or broadband control of remotely located vibration has been developed for trials in the marine and aerospace sectors for large scale structures or those exposed to harsh environments[7,8,9]. The concept behind this controller design approach is that for large scale structures or where the system environment is harsh, it may not be feasible to locate sensors or even actuators where vibration attenuation is desired or this may be prohibitively expensive. The optimal control of local vibration may in turn result in an enhancement at remote locations. These researches therefore define a design freedom for reducing vibration both at local and remote points, and can be applied for either discrete frequency and/or broadband control and often involves an inversion of the local path plant dynamics. The geometric controller design approach assumes the inability to locate the actuators and sensors at the remote location but acknowledges that this measurement can be obtained during the commissioning stage and used during the design phase to enhance both local and remote locations. This approach may in turn be beneficial for floor vibration control in which, as the authors have found out, the presence of services or other facilities may often hinder the siting of actuators and sensors at desired locations.

The research work presented here compares vibration mitigation performances between the DVF control scheme and the geometric controller design approach. An overview of the design methodologies for each of the controller schemes and appropriate compensators designed to achieve desired closed-loop specifications with the plant model known are presented. Some stability studies are shown as well as a brief insight into the use of the geometric controller approach for controlling both local and remote vibration. The work in this paper is organized as follows: section 2 introduces the plant and actuator dynamics as well as an overview of the design methodologies with DVF and the geometric controller design approach. Also shown are results of stability studies for both controller design approaches. In section 3, the results of uncontrolled and controller frequency response functions (FRFs) in both the analytical studies and experimental implementation are presented and some conclusions are included in section 4.

2 PLANT MODEL AND CONTROLLER SCHEMES

The laboratory structure used for the AVC studies is a simply-supported in-situ cast post-tensioned slab strip with a span of 10.8 m, width of 2.0 m and depth of 275 mm. The dynamic properties for the AVC studies are evaluated from a point accelerance FRF test in figure 1c using a collocated sensor and actuator pair (S1, A1) as shown in figures 1a and 1b. Figure 1c also shows the transfer function between actuator A1 and remote sensor S2 which is an additional measurement used for the geometric controller design. An analytical

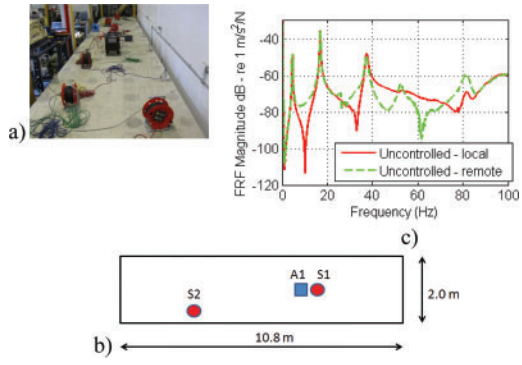

Figure 1. Plan view of laboratory structure showing test location for AVC studies and measured point mobility FRF for AVC design (A1 – actuator 1, S1 – local sensor 1, S2 – remote sensor 2).

Table 1. Estimated modal properties of laboratory structure.

Mode	f_i (Hz)	ζ_i (%)
1	4.45	1.0
2	16.80	0.4
3	37.30	1.0

model of the point accelerance FRF is obtained in the Laplace domain using the modal expansion approach as shown in Eq. 1. s is a complex variable, $\mu_i \geq 0$, ζ_i and ω_i are the inverse of the modal mass, damping ratio and natural frequency associated with the ith mode of vibration. A summary of the modal properties of the first three bending modes of vibration estimated from the EMA test are shown in Table 1.

$$G_s(s) = \sum_{i=1}^{3} \frac{\mu_i s^2}{s^2 + 2\zeta_i \omega_i s + \omega_i^2} \tag{1}$$

The actuators are APS Dynamics model 400 electrodynamic shakers. Their dynamic characteristics, expressed by the transfer function between the force applied to the structure, $f(t)$, and the input voltage command, $v(t)$, can be described by the linear second order system in Eq. 2 when they are driven in the current drive mode, which is the mode of operation used here. $K_c = 300$, $\zeta_{act} = 0.07$ and $\omega_{act} = 8.168$ rads/s are the force-voltage constant, damping ratio and natural frequency, respectively.

$$G_{act}(s) = \frac{K_c s^2}{s^2 + 2\zeta_{act}\omega_{act} s + \omega_{act}^2} \tag{2}$$

DVF with an inner loop compensation for the actuator is shown in figure 2. $C_0(s)$ is a lossy integrator that includes a feedback gain component, γ_{dc}, as shown in Eq. 3. This is designed to impart significant damping in the structure. The designed inner loop actuator

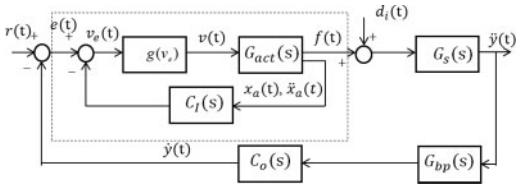

Figure 2. Direct velocity feedback with inner loop actuator compensation.

compensator, $C_I(s)$, is shown in Eq. 4. This achieves a closed-loop transfer function of the actuator inner loop with a frequency of 1.30 Hz and a damping ratio of 0.60. As noted before, DVF is implemented in a SISO set-up with the collocated actuator and sensor pairs A1, S1 shown in figure 1b. $\gamma_{dc} = 300$ and the DVF scheme is designed to achieve damping ratios of 0.16 and 0.075 in modes 1 and 2, and ensures a gain margin (GM) of 9.5 dB and phase margin (PM) greater than 30°. A second-order Butterworth filter with cut-off frequency 1.0–100 Hz is also implemented in both analytical and experimental studies. Stability studies are evaluated using both the root locus plot $G_s(s)G_{act}(s)G_{acomp}(s)C_o(s)$ as shown in figure 3.

$$C_0(s) = \frac{\gamma_{dc}}{s+\beta},\ C_I(s) = \frac{s^2+1.14s+66.72}{s^2+9.80s+66.72} \tag{3,4}$$

where:
$G_s(s)$ Floor model
$G_{act}(s)$ Actuator model
$G_{bp}(s)$ Band pass filter
$f(t)$ Actuator force
$d_i(t)$ Input disturbance
$e(t)$ Error signal
$r(t)$ Reference signal
$g(v_e)$ Saturation nonlinearity
$\ddot{y}(t)$ Structural acceleration response
$\dot{y}(t)$ Structural velocity response
$C_0(s)$ Transfer function of outer loop
$v(t)$ Final control voltage signal
$C_I(s)$ Transfer function of inner loop
$v_e(t)$ Initial control voltage signal
$x_a(t)$ Displacement of actuator moving mass
$\ddot{x}_a(t)$ Acceleration of actuator moving mass

The formulation of the geometric controller design approach is derived from the works of[8,9,10] assuming a two input two output system with the transfer function matrix relating the disturbance and control inputs to the remote (S2 in figure 1c) and local (S1 in figure 1c) vibration outputs as shown in Eq. 5. $y(s)$ and $z(s)$ are the locally measured and remote vibration whilst $u(s)$ and $d(s)$ are the local control force and remote disturbance force, respectively. Eq. 6 shows the control input as a function of the locally measured vibration. These past works have also been extended to deal with stable controller designs for non-minimum phase dynamics. Through the definition of a design variable, $\alpha(s)$ in Eq. 7, the location vibration output, $y(s)$ and remote vibration output, $z(s)$, in the presence of the feedback

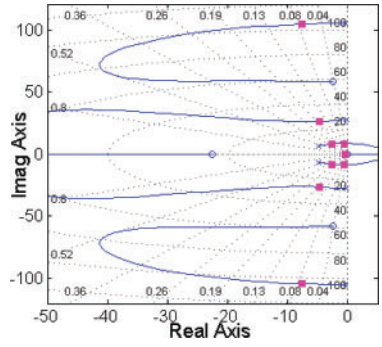

Figure 3. Root locus plot for DVF control scheme.

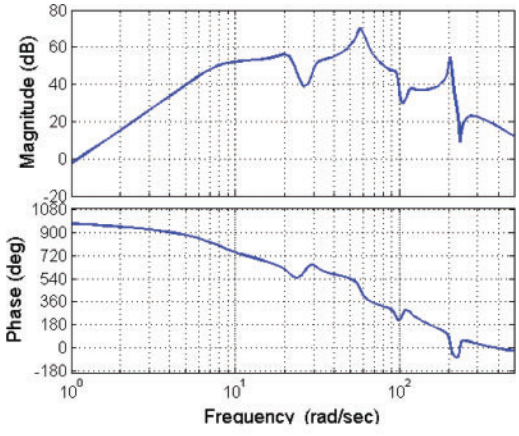
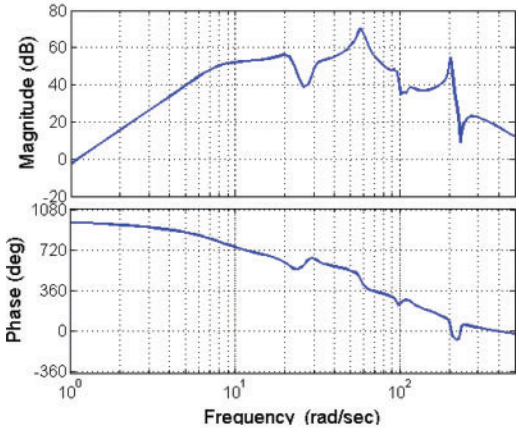
control signal in Eq. 6 can be expressed as shown in Eqs. 8 and 9. Various design objectives can be outlined through the selection of the design variable, $\alpha(s)$, for example, attenuation of remote vibration without increment in local vibration, or attenuation in vibration of both the remote and local vibration. Further details of specifying the design objectives for either harmonic or global controller can be seen in[8,9,10].

$$\begin{bmatrix} y(s) \\ z(s) \end{bmatrix} = \begin{bmatrix} g_{11}(s) & g_{12}(s) \\ g_{21}(s) & g_{22}(s) \end{bmatrix} \begin{bmatrix} u(s) \\ d(s) \end{bmatrix} \tag{5}$$



$$u(s) = -k(s)y(s) \tag{6}$$

$$\alpha(s) = -\frac{g_{11}(s)k(s)}{1+g_{11}(s)k(s)} \tag{7}$$



$$y(s) = [1+\alpha(s)]g_{12}(s)d(s) \tag{8}$$

$$z(s) = \left[1+\alpha(s)\frac{g_{12}(s)g_{21}(s)}{g_{11}(s)g_{22}(s)}\right]g_{22}(s)d(s) \tag{9}$$

In the work presented here, $k(s)$ is selected using a parametric design of $\alpha(s)$ to attenuate vibration at both the local point (S1) and remote point (S2) shown in figure 1b. The derived compensators for two different designs: geometric controllers 1 and 2 with this procedure are shown in figures 4a and 4b and figures 5a and 5b show the Nyquist contours for the stability studies. Controller 1 is tuned to offer similar vibration mitigation performance as DVF in both the first and second vibration modes of the laboratory structure whilst with controller 2, it is demonstrated that there is potential to achieve further attenuation in the second mode of vibration i.e. flexibility to isolate and enhance target modes of vibration. From figures 6a and 6b, since the centres of both design 'mobius' circles derived for both local and remote locations from Eqs. 5 to 9 almost overlap[7,8,9], this gives the design freedom to enhance damping at both locations simultaneously. The geometric controller design here includes a 3rd order band pass filter with cut-off frequency 1.75–26.5 Hz.

3 UNCONTROLLED AND CONTROLLED FREQUENCY RESPONSE FUNCTIONS

The results of uncontrolled and controlled frequency response functions (FRFs) predicted analytically and measured experimentally for both the local and remote locations are shown in figures 7 and 8 for DVF, and geometric controller schemes 1 and 2. They reflect approximately 20–25 dB attenuations of the first and second modes of vibration of the laboratory structure. With the geometric controller (GC) design scheme, since the compensator design incorporates approximate inversion in the plant dynamics, feedback gains have to be curtailed so that the influence of the anti-resonances in the open loop FRF do not degrade the vibration mitigation performances as seen in figures 7 and 8 or in the worst case become sources of instability.

4 CONCLUSIONS

The geometric controller scheme offers a new design freedom for controlling vibration at both a local and remote location by using design mobius circles. This can be tuned to guarantee that a controller designed does not degrade the vibration serviceability performance at both the local and remote location as outlined in the works of[7,8,9]. This approach to design can be beneficial to AVC of human induced office floor vibrations where the presence of services and other facilities would mean that there are restrictions on the potential locations of sensors and actuators. As a result of the approach making use of an inversion in plant dynamics, additional compensation or gain regulation can be used to ensure the anti-resonances of the open loop system do not degrade the vibration mitigation performance objective. In this work, vibration mitigation performances of DVF and the geometric controller schemes have been found to be quite comparable and there is potential for further attenuation of the second mode of vibration with the geometric controller formulation.

V. Racic
Department of Civil & Structural Engineering, University of Sheffield, UK

ABSTRACT: Increasing vibration serviceability problems of modern structures have drawn researchers' attention to the walking-induced vibration modelling and assessment of floors and footbridges. Changes of dynamic properties of structure due to presence of stationary people have been studied extensively in the literature. However, little is known about the similar effects of walking people, mainly due to the lack of experimental evidence and credible models capable of simulating human-structure dynamic interaction (HSI) in the vertical direction. This paper uses a single degree of freedom mass-spring-damper (MSD) model to simulate dynamics of walking crowd on structure and investigates the sensitivity of the coupled crowd-structure system frequency and damping to properties of crowd model. Results of this study show that when the natural frequency of the crowd model is less than the natural frequency of the structure, both natural frequency and damping ratio of occupied structure are more sensitive to crowd's model stiffness. Similarly, when the natural frequency of the crowd model is greater than the natural frequency of the structure, both natural frequency and damping ratio of occupied structure are more sensitive to crowd's model mass. It also can be seen that natural frequency of theoccupied structure has no sensitivity to damping of the crowd model while its damping ratio shows a limited sensitivity to the crowd's model damping with the maximum where both natural frequencies are equal.

1 INTRODUCTION

Recent increase in vibration serviceability problems of flexible structures under human dynamic loading have led to concerns about both safety and comfort of pedestrians using such structures. Hence, there is demand for more accurate and inclusive design methods (Shahabpoor & Pavic 2012, Zivanovic et al. 2010, Kasperski 1996, Reid et al. 1997, SCOSS 2001). As to the walking-induced dynamic loading, current design approaches, such as those in BS 5400 (2006) and Eurocode 5 (2004), use deterministic walking force models and simply ignore human-structure interaction effects and inherent stochasticity of the walking force (Shahabpoor & Pavic 2012, Zivanovic et al. 2010, Dougill 2006). Research (Shahabpoor & Pavic 2012, Zivanovic et al. 2010, Ellis & Ji 1997,Willford 2002, Brownjohn et al. 2004, Pavic 2011), mostly based on full-scale measurements, have indicated that interaction of the human body, as a bio-mechanical system, with the structure have significant effects on dynamic properties of the joint human-structure system and should be considered. It often leads to a considerable reduction in response and some change in the natural frequency of the structure (Shahabpoor & Pavic 2012, Zivanovic et al. 2010, Dougill 2006, Pavic 2011).

To address HSI, different types of mechanical or biomechanically-inspired models, such as single/ multiple degrees of freedom mass-spring dampers MSDs (Archbold 2004, 2008, 2011, Caprani et al. 2011) and single/bipedal inverted pendulum (Bocian 2011), are used to simulate kinematics of human motion for both vertical and horizontal directions and different postures and types of activities (Macdonald 2009, Matsumoto & Griffin 2003, Wei & Griffin 1998). This paper uses a classic single degree of freedom mass-spring-damper (S-MSD) model to simulate crowd-structure interaction during walking by using human body MSD properties. Although this S-MSD model may not be the best option for modeling human, the simplicity of its dynamics allows easy investigation of highly relevant coupled human-structure system dynamics under different loading conditions. The principal aim of this study is to improve understanding of the sensitivity of the occupied structure dynamic

[1] In this paper, 'crowd' is called to any group of people with more than a single person.

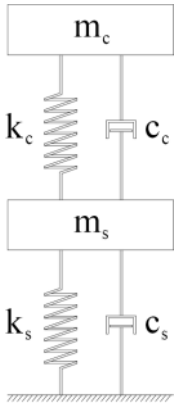

Figure 1. Conceptual 2DOF model of coupled crowd-structure system (stationary walking people).

properties to each of the currently uncertain *crowd* parameters. This is done for a range of common structures and crowd occupation scenarios and should help dealing with large uncertainty when modeling crowds on structures during design process.

Section 1 of the paper presents a very short introduction into the subject and rationale of this research. Section 2 describes the proposed coupled S-MSD model and its formulation for the considered crowd occupation scenarios. Section 3 presents the analysis specifications and Section 4 illustrates the parameters used in the models. Section 5 presents the results of the parametric study and sensitivity analysis and finally Section 6 closes the paper by highlighting the important findings and making conclusions.

2 S-MSD MODEL DESCRIPTION

To simulate the problem, only the first mode of structural vibration is considered and is conceptualized using a SDOF oscillator with the corresponding modal properties (m_s, k_s and c_s). Considering only one structural mode does not affect the generality of the results as mode superposition principle applies to linear structures which is an acceptable assumption for this kind of problem.

In all simulations, a S-MSD model (m_c, k_c and c_c) is used to simulate the effects of the crowd's MSD properties on the structure. This model represents 'stationary' walking pedestrian an imaginary case in which people are 'walking' on the 'anti-node' of the first mode of vibration but their location on the structure does not change[2]. Being stationary, such coupled crowd-structure system can be represented as a simple conventional two degrees of freedom system as illustrated in Figure 1, the behavior of which can be studied using closed form solutions of 2DOF equations of motion.

[2] e.g. assume walking on a series of treadmills distributed over the length of a beam-like structure

More detailed discussion about the selected 2DOFs crowd-structure model and its equations of motion are presented by Shahabpoor et al. (2013).

3 ANALYSIS SPECIFICATIONS

The natural frequency f_{os} and damping ratio ζ_{os} of the occupied structure are chosen to represent dynamics of the occupied structure. In the first step, crowd's properties (m_c, k_c and c_c) are changed one at a time and the effect of this single parameter on natural frequency f_{os} and damping ratio ζ_{os} of the occupied structure are calculated.

In the next step, the *rates of change* of f_{os} and ζ_{os} of the occupied structure with respect to change of crowd's model properties m_c, k_c and c_c is considered as the sensitivity criteria. The chosen rate of change provides a measure of '*how fast'* the occupied structure properties f_{os} and ζ_{os} change as uncertain crowd's parameters m_c, k_c and c_c change.

To allow for comparison, as units of MSD parameters are different, a typical set of initial values for structure and crowd's parameters (m_{ci}, c_{ci}, $k_{ci,}$ f_{si} and ζ_{si}), are selected and unit-less ratios m_c/m_{ci}, c_c/c_{ci}, $k_c/k_{ci,}$ f_{os}/f_{si} and ζ_{os}/ζ_{si} are used for presentation. To ensure generality of results, the same analysis is repeated for several initial values and results are compared. The effects on f_{os} and ζ_{os} are considered for the changes of m_c (Case 1), k_c (Case 2), and c_c (Case 3).

In all three cases, the selected crowd parameter is varying over a certain range and other two parameters of the crowd model are kept constant and equal to the initial set of values.

4 MODEL PARAMETERS

The exact parameters used in the crowd – structure 2DOF model are described in this section. These parameters are selected to be realistic and to cover a range of possible values (in the case of the varying parameter).

4.1 *Dynamic parameters of structure model*

The dynamic parameters of the crowd and structure models that are used in simulations are presented in for different analysis cases. An imaginary simply supported beam is selected as the structure and its first mode properties m_{si}, k_{si} and c_{si} are selected in a way to be both realistic and corresponding to a light weight structure. The latter is needed to highlight the crowd-structure interaction effects better. Three different natural frequencies (and therefore stiffnesses for the same mass m_{si} of 6500 kg) are selected for the structure to cover the scenarios in which the natural frequency of the structure is lower, close to and higher than the assumed natural frequency of the crowd model.

Table 1. Dynamic parameters of human and structure models used in different analysis cases.

Analysis case	Initial values	Case 1	Case 2	Case 3	Unit
Structure model parameters					
Mass			6500		kg
Damping ratio			0.005		–
Natural frequency			2–4		Hz
Crowd model parameters					
Mass	168	8.4–462	168	168	kg
Stiffness	61698	61698	3085–169669	61698	N/m
Damping	1803	1803	1803	90–4958	N · s/m
Damping ratio	0.28	1.25–0.169	0.984–0.133	0.014–0.770	–
Natural frequency	3.05	13.64–1.84	0.68–5.06	3.05	Hz

4.2 *Dynamic properties of crowd model*

The initial parameters of the crowd model m_{ci}, c_{ci} and k_{ci} are adopted from the results of studies done by the author to simulate crowd's dynamics on a real-life test structure. An extensive set of experiments were carried out on the Sheffield laboratory test structure (2 meters wide and 11 meters long pre-stressed concrete beam) with the groups of 2-15 pedestrians walking on it. An S-MSD crowd model was then fitted to each test scenario and the corresponding crowd's parameters were found. Properties corresponding to a group of 6 walking people are selected as the initial values for the crowd model. A six-people group represents a normal spatially-unconstrained crowd on the assumed test structure and is a very good starting point to study the effects of varying crowd parameters.

The ranges of possible crowd parameters m_c, c_c, k_c, are adopted from the values reported by researchers for individuals and groups of people (Archbold et al. 2011, Zhang et al. 2000, Rapoport et al. 2003, Bertos et al. 2005, Lee & Farley 1998, Geyer et al. 1998) and are presented in Table 1.

5 ANALYSIS RESULTS

Distinction should be made between the results that are presented in Sections 5.1 and 5.2. The former provide a measure of '*how effective*' crowd parameters m_c, k_c and c_c are on occupied structure dynamics (represented by f_{os} and ζ_{os}) while the latter gives a measure of the sensitivity of f_{os} and ζ_{os} to crowd's uncertain parameters.

5.1 *Parametric analysis*

Figure 2 and Figure 3 present a typical set of results for $f_{si} = 4$ Hz. Results of analysis Cases 1, 2 and 3

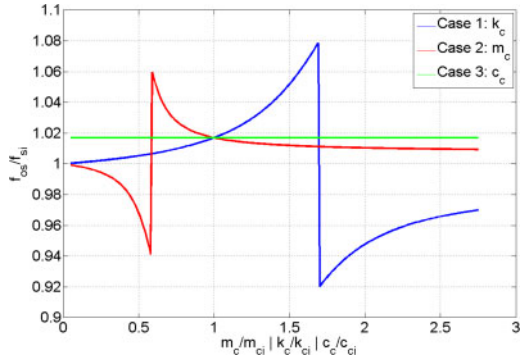

Figure 2. Effects of the m_c, k_c and c_c on f_{os} ($f_{si} = 4$ Hz).

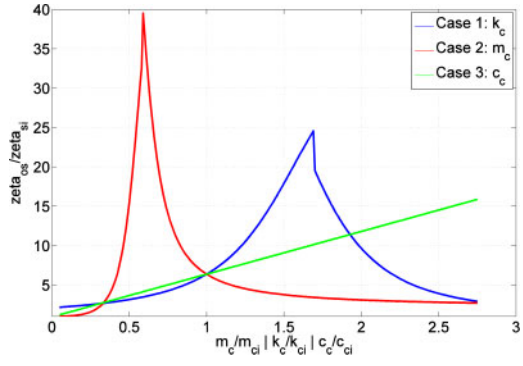

Figure 3. Effects of the m_c, k_c and c_c on ζ_{os} ($f_{si} = 4$ Hz).

corresponding to changing crowd's m_c, k_c and c_c are plotted on the same graph to be able to compare them. The horizontal axis presents the ratio of the crowd parameters to their initial values 'X', while the vertical axis presents the ratio of the changes in the occupied structure parameters 'Y'. These parameters are presented in equations 1 and 2, respectively.

$$X = {}^{x_c}/_{x_{ci}} \;\therefore\; (x_c = m_c, c_c, k_c) \tag{1}$$

$$Y = {}^{y_{os}}/_{y_{si}} \;\therefore\; (y_{os} = f_{os},\ \zeta_{os}) \tag{2}$$

As the natural frequency of a SDOF is proportional to k/m, increase of stiffness or decrease of mass leads to the increase of the natural frequency. Keeping this in mind and knowing that $f_{ci} = 3.05$ Hz and $f_{si} = 4$ Hz in Figure 2 and Figure 3, increasing stiffness of the crowd model k_c (blue trace) or

decreasing its mass m_c (red trace) leads into an increase of the crowd's natural frequency f_c and makes it closer to the structure's initial frequency f_{si}.

A closer look at Figure 2 and Figure 3 shows that the extreme values of m_c and k_c graphs (red and blue traces) represent the cases where natural frequencies of the crowd and initial structure model are equal ($f_{si} = f_c$). This means that m_c and k_c have maximum effects on f_{os} and ζ_{os} when $f_{si} = f_c$. It also can be

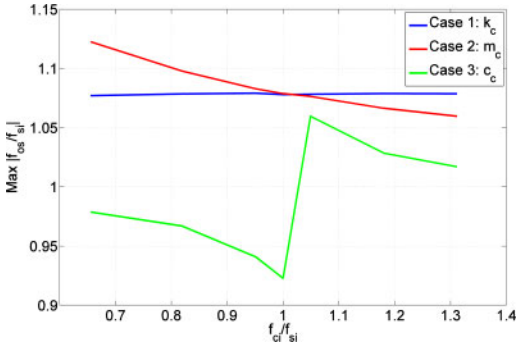

Figure 4. Maximum effects of the m_c, k_c and c_c on f_{os} for $f_{ci} = 3.05$ Hz and f_{si} varying from 2–4 Hz.

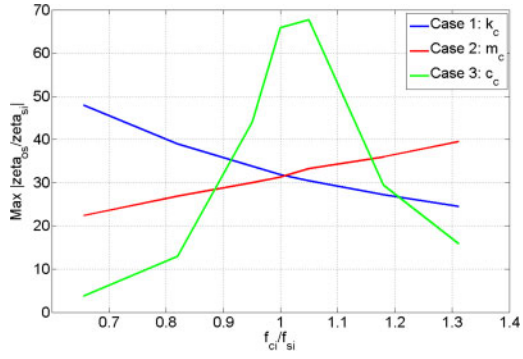

Figure 5. Maximum effects of the m_c, k_c and c_c on ζ_{os} for $f_{ci} = 3.05$ Hz and f_{si} varying from 2–4 Hz.

seen that increasing ζ_c has no significant effects[3] on f_{os} but increases ζ_{os}. An extensive discussion of the observed trends in Figure 2 and Figure 3 is presented by Shahabpoor et al. (2013).

To compare the effects of the crowd's parameters m_c, c_c, k_c, on the occupied structure's dynamics, a family of initial values is considered in which initial natural frequency of crowd model f_{ci} is 3.05 Hz and structure initial natural frequency f_{si} varies from 2 to 4 Hz. For each (f_{ci}, f_{si}) pairs, a set of XvsY curves similar to the ones presented in Figure 2 and Figure 3, are plotted. Maximum absolute value of each of XvsY graphs are then plotted against their corresponding f_{ci}/f_{si} (which is equal to $3.05/f_{si}$) and are presented for f_{os}/f_{si} and ζ_{os}/ζ_{si} in Figure 4 and Figure 5 accordingly.

As it can be seen in Figure 4 and Figure 5, as $3.05/f_{si}$ increases, maximum effects of m_c on f_{os} decrease and its effects on ζ_{os} increase. k_c has the opposite effects and as $3.05/f_{si}$ increases, its maximum effects on f_{os} increase and on ζ_{os} decrease. Maximum effects of crowd's damping c_c on both f_{os} and ζ_{os} is highest when $f_{ci} = f_{si}$.

5.2 *Sensitivity analysis*

Sensitivity here is defined as the rate of change of f_{os} and ζ_{os} to the changes in m_c, k_c and c_c. The sensitivity here is an indicator of '*how fast*' the effects of the crowd parameters on the occupied structure parameters change. Results of this section are presented in Figure 6, Figure 7, Figure 8 and Figure 9. In these figures, the horizontal axis presents the ratio of the crowd parameters X as is given in equation 1 and the vertical axis presents derivative of Y (given in equation 2) with regards to X.

Figure 6 displays the sensitivity of ζ_{os} and Figure 7 displays the sensitivity of f_{os} for two typical initial

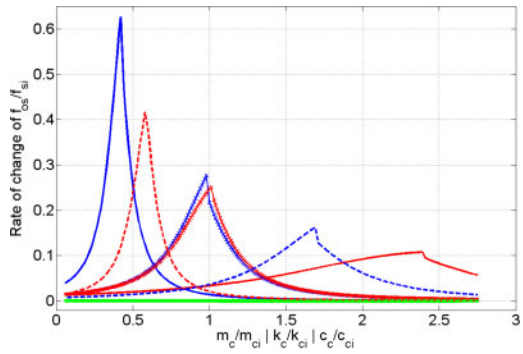

Figure 6. Sensitivity of f_{os} to m_c (red trace), k_c (blue trace) and c_c (green trace): Continues traces: $f_{si} = 2$ Hz; Crossed traces: $f_{si} = 3$ Hz; Dashed line: $f_{si} = 4$ Hz.

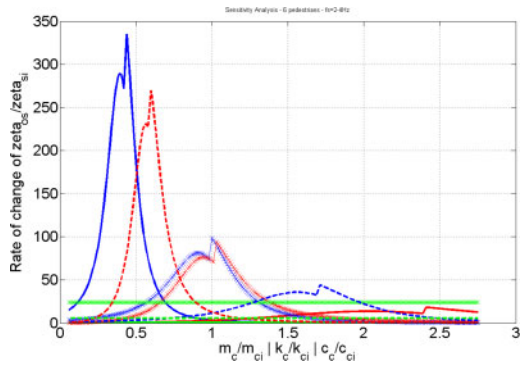

Figure 7. Sensitivity of ζ_{os} to m_c (red trace), k_c (blue trace) and c_c (green trace): Continues traces: $f_{si} = 2$ Hz; Crossed traces: $f_{si} = 3$ Hz; Dashed line: $f_{si} = 4$ Hz.

structural frequencies $f_{si} = 2$ and 4 Hz. Similar to the findings in Section 5.1, sensitivity of ζ_{os} and f_{os} to m_c and k_c increase significantly when frequency of the crowd and structure models are close in value.

For the case $f_{ci} < f_{si}$ (when $f_{si} = 4$ Hz), as both Figure 6 and Figure 7 show, when k_c (dashed blue trace) increase from k_{ci} and mass m_c (dashed red

[3] The case presented in Figure 2. Effects of the m^c, k^c and cc on fos ($fsi = 4$ Hz and Figure 3 is corresponding to the system with proportional damping matrix. In systems with non-proportional damping distribution, natural frequency is dependent on damping but its effects is not significant. Further discussion about details of this issue is beyond the scope of this paper.

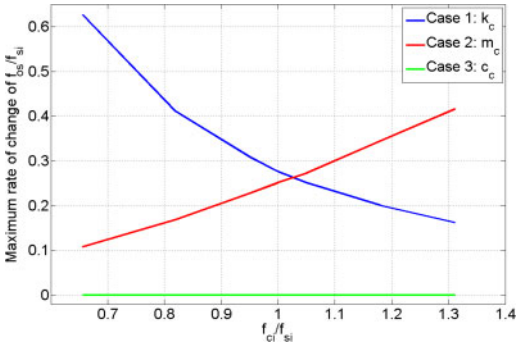

Figure 8. Maximum sensitivity of the f_{os} to m_c, k_c and c_c for $f_{ci} = 3.05$ Hz and f_{si} varying from 2–4 Hz.

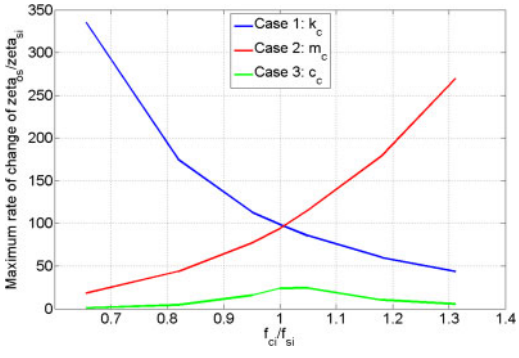

Figure 9. Maximum sensitivity of the ζ_{os} to m_c, k_c and c_c for $f_{ci} = 3.05$ Hz and f_{si} varying from 2–4 Hz.

trace) decrease from m_{ci}, their corresponding sensitivity curves show a peak. These peaks can be shown to correspond to $f_{si} = f_c$. The same applies when $f_{ci} > f_{si}$ (when $f_{si} = 2$ Hz) and the sensitivity curves show maximum when k_c (blue trace) decrease and m_c (red trace) increase. Also, as Figure 6 illustrates, rate of change of f_{os} is not sensitive to c_c while sensitivity of ζ_{os} is maximum when $f_{si} = f_{ci}$ (crossed green line in Figure 7).

To compare the sensitivity of f_{os} and ζ_{os} to m_c, k_c, and c_c, the same family of initial values that is described in the previous section is considered in which $f_{ci} = 3.05$ Hz and f_{si} varies from 2 to 4 Hz. For each (f_{ci}, f_{si}) pairs, then, a set of X vs Y′ curves similar to the ones presented in Figure 6 and Figure 7 are plotted. Maximum values of X vs Y′ graphs are then plotted against teir corresponding f_{ci}/f_{si} and are presented for f_{os} and ζ_{os} in Figure 8 and accordingly.

It can be seen in Figure 8 and Figure 9 that by increasing the f_{si}, maximum sensitivity of the f_{os} and ζ_{os} to k_c decrease (blue traces) and its maximum sensitivity to m_c increase (red traces). This means that when $f_{ci} < f_{si}$, both f_{os} and ζ_{os} are more sensitive to k_c, while when $f_{ci} > f_{si}$, both f_{os} and ζ_{os} are more sensitive to m_c. It also can be seen that f_{os} has no sensitivity to c_c while ζ_{os} shows a limited sensitivity to c_c with the maximum at $f_{ci} = f_{si}$.

6 CONCLUSION

Modelling crowd dynamics on structures have always been a challenge due to uncertainty of human parameters. This paper combines results of the parametric study and sensitivity analysis that are done on a 2DOF mass-spring-damper human-structure model to describe effects and sensitivity of the occupied structure to the crowd model parameters m_c, k_c and c_c. Results of this analysis provide valuable insight for engineers to choose more realistic crowd properties during design process and researchers to understand better the human-structure interaction mechanisms.

ABSTRACT: Human-structure interactions are not completely understood yet. This paper presents an experimental study focusing on the interaction between a human and a flexible support, with a major aim to better understand how the behavior of a human subject, bouncing on a flexible structure, adapts to the support motion. Exploratory experiments are undertaken with a 7 m-span timber footbridge tested in the Human Motion Analysis Laboratory of the University of Liege. The movements of the coupled system composed of the subject and the footbridge are recorded by Motion Capture technology; the subject's 3-D body motion is defined by three important angles: ankle, knee and hip. The interaction between the subject and the footbridge is also quantified by means of force platform measurements. The experiments indicate an influence of the support amplitude and natural frequency on the phase shift between the oscillatory floor motion and the three angles characterizing the motion.

1 INTRODUCTION

Vandalism is coined as a specific kind of footbridge loading characterized by the intentional and wellcoordinated action of one or several persons, moving their own body with the sole aim to increase the structural vibration level to a maximum value. The term *vandalism* actually covers several kinds of action (Zivanovic S. 2005), among which only bouncing—sometimes also referred to as bobbing or yogging—is considered in this paper. It consists in a near harmonic knee-extension motion at a frequency equal to, or as close as possible to, a structural natural frequency, which brings the structure into resonance. Of major importance is the reaction force under the vandal's feet, i.e. the basic information required for the structural design of the footbridge since it may be seen as an external loading from the designer's point of view. A proper estimation of this force and of the resulting structural response allows estimation of occurrence of possible harmful vibrations which could, for instance, result in negative vertical reaction forces at the abutments. Several models of reaction forces resulting from bouncing do exist, but are essentially limited to motionless rigid supports (Duarte E. 2009). Recently, Harrison et al. (Harrison R. E & Dougill 2006, Harrison R. E. 2008) have studied this humanstructure interaction on flexible supports as a function of a number of parameters including the structural mass and damping. A mass- and damping-dependent reduction of the reaction force was observed, while approaching resonance. In contrast with existing literature which mainly relies on the body motion description as a single degree-of-freedom system, experimental results reported in this paper include the measurement of three representative body motion angles as well as the floor reaction force and the structural response. The paper is divided into a short description of the experimental setup, a presentation of the main results, followed by the proposition of a simple loading model.

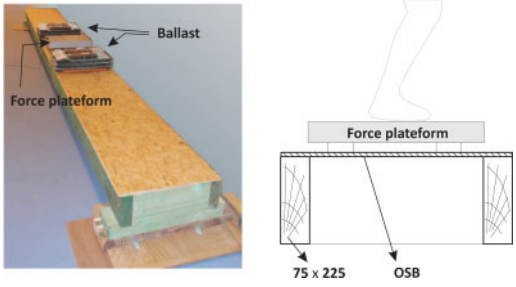

Figure 1. Picture of the toy footbridge, with a force platform at mid-span. Laboratoire d'Analyse du Mouvement Humain (LAMH).

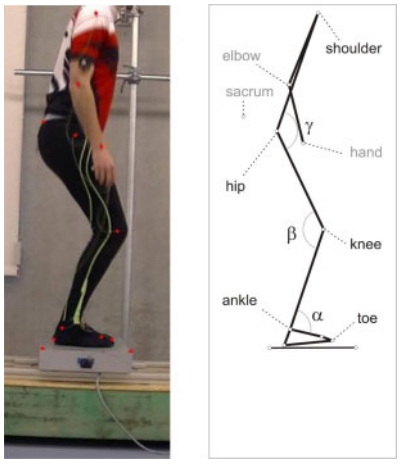

Figure 2. Markers location and reconstructed model with rigid body segments. (Red dots in the picture indicate the full set of measured anatomical references – only four of them are used to define the kinematic angles).

2 DESCRIPTION OF THE EXPERIMENTAL SETUP

2.1 *The footbridge*

A toy footbridge composed of two timber beams with a cross-section of 75 × 225 mm is designed to behave as a simply supported span of 6.7 m. The two main beams are covered by oriented strand board (OSB) screwed on top of them. This bare structure is ballasted with steel load in order to tune the natural frequency in the range [2.4; 4.2] Hz, see Fig. 1. These additional dead loads are securely fastened to the structure in order to hinder any relative vertical motion. During the experiment, the vandal stands at midspan, where a force platform is installed in order to record the reaction forces. The structure responds in its fundamental vibration mode.

2.2 *Instrumentation of the human-structure system*

The instrumentation is performed with a Motion Capture system composed of cameras, markers and the *CODAmotion* software. The system localizes in space the diodes (markers) placed in various strategical points of the investigated system. Figure 2 shows a snapshot of the planar model constructed with rigid body segments connecting the measured joints, as well as a picture of the vandal in a similar position. Essentially instrumentation of two corners of the force plate allow estimation of the structural motion at mid-span while five anatomical references, namely the great toe, the ankle, the knee, the hip and the shoulder, provide information about the posture during the excitation. Because the body motion is studied in a vertical plane, these four anatomical references define three *kinematic angles* α, β and γ, that describe the motion precisely enough.

The reaction force is acquired with a force platform *Kistler, 9281 EA* which is firmly fastened to the footbridge in order not to disturb the subject's motion. The recorded data are logged and properly synchronized between the markers and the force platform with the software *CODAmotion, V6.79.2*. The force platform data is sampled at 1000 Hz and immediately downsampled to match the 200 Hz sampling frequency of the markers for further postprocessing.

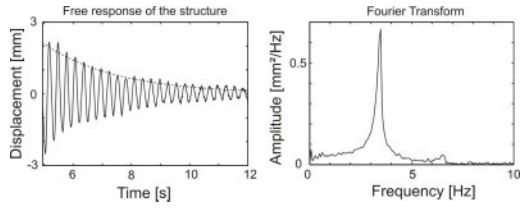

Figure 3. Free-response of the footbridge in the 3.4 Hz configuration: time series and Fourier transform. Estimated damping ratio is 2%.

Table 1. Modal masses m, natural frequencies f of the ballasted structure and natural frequencies f_{eff} of the human-structure system.

Configuration	1	2	3	4	5	
m	1154	811	615	412	275	kg
f	2,4	2,8	3,4	3,9	4,6	Hz
f_{eff}	2,3	2,8	3,2	3,7	4,2	Hz

2.3 *Considered configurations*

Five configurations are considered. Each of them corresponds to a different ballast and thus to a different natural frequency. The effective natural frequency involving the coupled human-structure system is slightly less than the natural frequency of the ballasted structure itself, see Tab. 1. Figure 3 represents the free response of the beam in configuration 3, with the corresponding frequency spectrum. Such free decay responses are used to identify a damping ratio of 2% in each configuration.

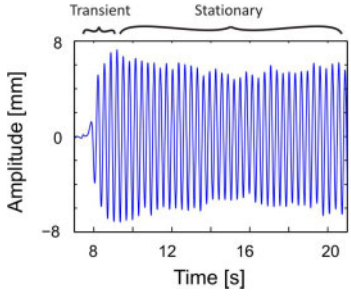

Figure 4. Vertical displacement of the flexible floor, measured with respect to the static deflection of the footbridge under the own weight of the experimenter.

2.4 *Test instructions and measurement protocol*

The results presented next are obtained with a unique subject weighting 87 kg, male, aged 23. The sole test instruction is to bring the structure into resonance as fast as possible, while keeping heels in contact with the support, and to hold a constant excitation level during at least 15 seconds. A typical response signal thus features two distinct parts: a short transient regime followed by a stationary response with a somewhat constant amplitude.

Tests are reproduced 20 times targeting various levels of amplitude in this stationary regime (slight, weak, medium, large, very large), which is feasible because the sole experimenter was trained and could judge how much energy should be imparted in the test, before it starts.

These two regimes are illustrated in Figure 4, with an example of the displacement of the flexible support, measured with the opto-electronic system, and expressed with respect to the static deflection under the own weight of the test subject.

3 RESULTS

3.1 *Overview of a typical result*

Figure 5 represents the displacement, velocity and acceleration of the footbridge in configuration 3. The transient phase is apparently as short as 1 second. This is by no means much shorter than the transient phase associated with a linear time-invariant system of natural frequency 3.2 Hz and damping ratio 2% ($t_r \simeq 1/(3.2 \cdot 0.02) = 15$ s), which evidences the existence of a strong human-structure interaction, *reductio ad absurdum*.

The corresponding time evolution of the reaction force is represented in Figure 6, together with the phase shift between the force and the structural displacement. The typical profile of the force further illustrates the shortness of the transient phase. It systematically starts with a decreasing magnitude, down to half of the body weight (BW), as the subject pumps down, lowering his center of mass—this corresponds to a decrease of the three angles α, β and γ—. The structural motion

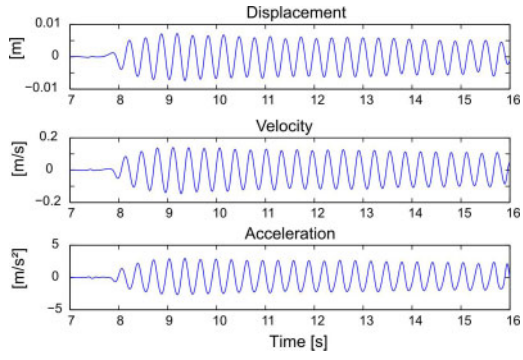

Figure 5. Typical response of the footbridge in configuration 3.

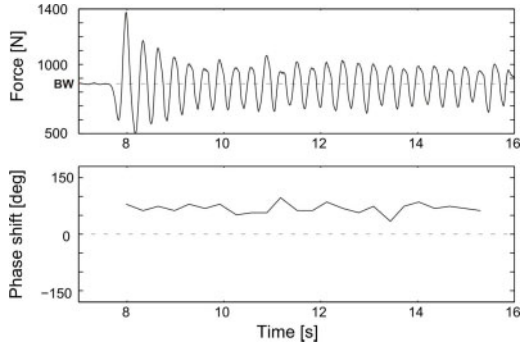

Figure 6. Force reaction and phase shift between force reaction and structural displacement.

is thus initiated upward. Then the subject sets forth, with a knee-bending motion, which results in a significantly increased reaction force, up to 1.6 times the body weight and triggers the structure oscillations. A couple of such pumping cycles is sufficient to reach the steady regime.

A key event in this human-structure interaction is the sensibility of the test subject to adequately identify the right instant when to set forth (around 7.85 s in this example). In this particular test setup, the pump-down phase results in a perceptible motion ($v \simeq 1$ mm/s) because the potential energy stored in the footbridge under the full body weight transforms into a significant kinetic energy as the reaction force drops to half of the body weight.

Once the stationary regime is achieved, the phase shift between the reaction force and the structural displacement oscillates with slight amplitudes around approximately 70°.

Figure 7 shows the time evolution of the kinematic angles α, β and γ, as well as their phase shift with respect to the structural displacement. Starting from a more or less vertical rest position, the subject bends his knees, identifies the structural natural frequency from the weak initial motion and performs a quasiperiodic motion. A couple of cycles only is enough for the subject to adapt his excitation frequency, amplitude and

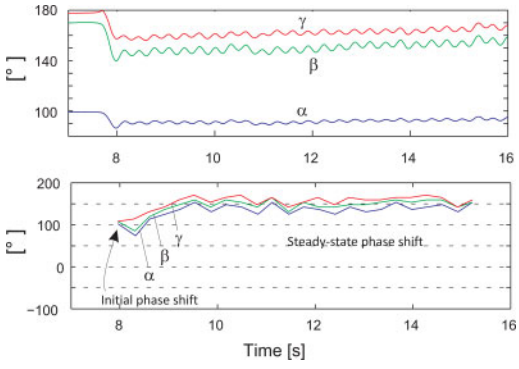

Figure 7. Kinematic angles and phase shift between them and the structural displacement.

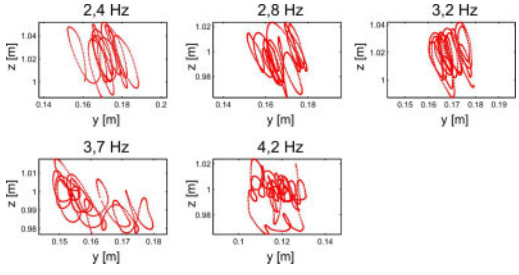

Figure 8. Trajectories of the centre of mass of the subject,for various natural frequencies of the support. While an quasiperiodic motion is observable for 2.4 Hz, 2.8 Hz and 3.2 Hz, the response for 3:7Hz and 4:2Hz is rather chaotic.

delay in order to maximize the structural response. The slight long-term drift in the kinematic angles indicates a slow change of the posture, which may be attributed to the weariness of the subject. Average phase shifts in the steady regime $\bar{\alpha} = 138°$, $\bar{\beta} = 150°$ and $\bar{\gamma} = 157°$ show that these angles are all a phase ahead of the structural displacement. Furthermore, the small advance of the chest-leg angle γ indicates that the human motion seems to be initiated from the chest to the knees, and then feet.

Actually, trajectories of the center of mass of the subject (estimated with a sensor located on the sacrum) indicate a kind of quasi-periodic elliptical motion, at least in cases where resonance is achieved 2.4 Hz, 2.8 Hz and 3.2 Hz, see Figure 8, while the motion is rather chaotic for larger natural frequencies.

Interestingly, the phase shifts between kinematic angles and the structural motion seem to witness a longer transient regime, as it takes from 8 s to 9 s before the phase shifts between kinematic angles and the structural displacement stabilize. For this reasons, results of the parametric study are analyzed next in the light of two different shifts, the *initial phase shift* which is measured as the force starts increasing and the *steady-state phase shift* which corresponds to the long term phase shift, see Figure 7.

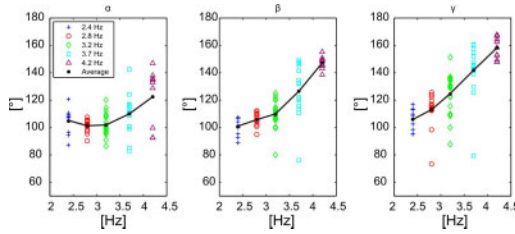

Figure 9. Initial phase shifts for various natural frequencies of the footbridge.

3.2 *Parametric study*

Figure 9 shows the initial phase shift for each measurement and for each angle. The black line connects average results. Despite a significant scatter in the data, this diagram shows a clear trend: initial phase shift of angles β and γ roughly exhibit an augmentation rate of about 30°/Hz, with a larger initial phase shift for γ. The ensemble average for angle α is approximately equal to 100° for frequencies equal to 2.4 Hz, 2.8 Hz and 3.2 Hz and increases up to 120° for higher natural frequencies. Also, the initial phase shift associated with α is smaller than the phase shifts associated with β and γ, which suggests that the motion is well initiated from top to bottom, which generalizes what was observed for configuration 3.

Steady-state phase shifts are reported in Figure 10 as a function of the maximum displacement of the footbridge on the left, and as a function of the natural frequency on the right. Again, despite a significant scatter in the data, there is a clear trend indicating that the higher the natural frequency, the larger the phase shift. More precisely the rates of increase of angles α, β and γ are approximately equal to 8°/Hz, 16°/Hz and 10°Hz, respectively.

Figure 11 represents the phase shift between the reaction force and the footbridge displacement, as a function of the maximum structural displacement (left) and of the natural frequency (right). While the optimum phase shift between a harmonic force and the response of a single-degree-of-freedom that maximizes the energy pumping into the system is, from a mechanical viewpoint, equal to 90°, the human brain-body controller is not able to adjust to this optimality of control. Figure 11 indicates that this optimum delay is only materialized when vibration amplitudes of the footbridge are small. Even for moderate structural displacements and accelerations, this optimum phase shift is hardly hold by the subject. Indeed, the time delay required for communication between the brain and the sensorimotor activities, the treatment of information generated by sensory organs, the identification of a natural frequency and finally the muscle activation make it impossible for a human being to adjust to this mechanical optimum.

For natural frequencies of 2.4 Hz, 2.8 Hz and 3.2 Hz, the phase shift seems to stabilize around 110° for displacements in the range 1.5–4.5 cm. For smaller amplitudes, large scatterness indicates that the subject

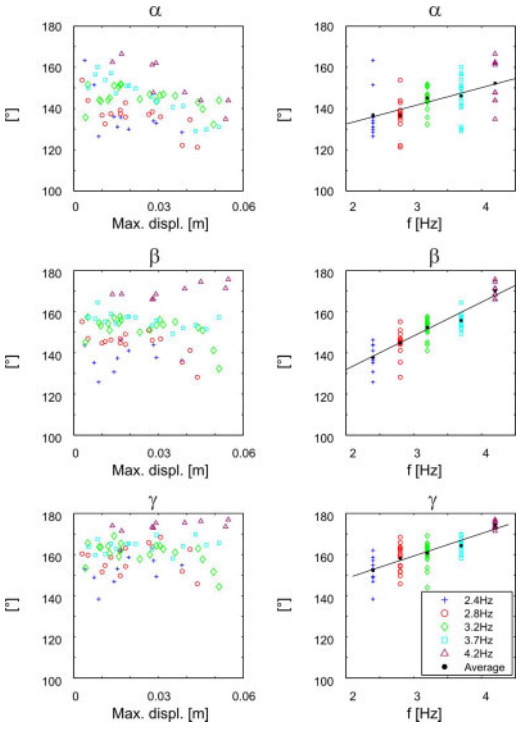

Figure 10. Steady-state phase shift between the kinematic angles and the structural displacement represented as a function of the maximum displacement (left) and of the structural natural frequency (right).

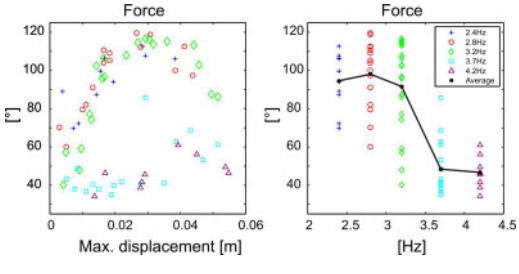

Figure 11. Steady-state phase shift between the force and the structural displacements represented as a function of the maximum displacement (left) and of the structural natural frequency (right).

has difficulties in feeling a sufficient level of vibration, and in adapting its motion to that frequency; he thus provides the impulse with a smaller delay (80°).

A similar explanation may justify the short delay (40°–60°) for frequencies of motion equal to 3.7 Hz and 4.2 Hz. In this case, the frequency of the motion is too high and the subject is not able to move that fast. The existence of this discontinuity in the response, when considered as a function of the natural frequency of the footbridge, is however not observable in the body posture, i.e. in angles α, β and γ, see Figure 10. This indicates that, despite an apparently similar body behaviour, the subject is not able to impose an optimum phase shift in the force.

4 CONCLUSIONS

This experimental study of the human-structure interaction in a bouncing motion has objectivized a series of facts. First, the human body motion—parametrized in this study with three kinematic angles, which is a major innovation of this experiment—seems to be initiated from chest to feet. Second, there are basically two conditions in which the subject is not able to tune his excitation frequency on the structural motion. On the one hand, for small amplitudes of vibration, the subject is not capable of identifying the natural frequency and the phase of the structural loading, which makes it impossible for him to properly synchronize. On the other hand, for large frequencies of support oscillations, the subject has not the physical reactivity to excite the footbridge fast enough, which finally translates into a chaotic uneffective motion. This is presumably due to the communication with the brain feedback, and the delay in the muscle activation. In both cases, this results in a reaction force, i.e. the force transmitted from the vandal to the structure, that is not optimally synchronized with the support motion, and consequently turns into small amplitudes of vibration. Actually in these cases, the phase shift between the support motion and the reaction force may even drop down to 40°–60° in the latter case.

The results obtained with a single subject indicate the existence of a critical natural frequency (in the range [3.2; 3.7] Hz for this particular subject) beyond which synchronization of the force and structural displacement is not achieved. As perplexing as it may appear, this discontinuity in the reaction force does not replicate in the steady-state phase shift between the kinematic angles and the support motion. Additional experimental work, involving EMG in order to survey muscle activity, will be carried out in a near future in order to clarify this point.

Dynamics of structural components subjected to large rotations using a flexible multibody approach

J. Ambrósio

ABSTRACT: Different finite element formulations handle the dynamics of deployable structures, being the co-rotational approaches popular. Flexible multibody dynamics formulations of complex structural and mechanical systems, including rigid and elastic components, use the finite element method to represent the flexibility of the components while describing the large rigid body motion using the fundaments of rigid body dynamics. Here, bodies of a multibody system deform while undergoing large rigid-body motions. A set of reference conditions is imposed to define a unique displacement field that includes the large rigid body motion and the system elastodynamics. The efficiency in the computer implementation is achieved by using a component synthesis approach involving vibration and static correction modes. The approach is demonstrated byanalyzing the deployment of a space satellite antenna in which the elastodynamic coupling with the large rotations plays a major role.

1 INTRODUCTION

Earlier work dealing with the elastodynamics of mechanical systems the deformations of the system components, assumed elastic and small, is superimposed to their large rigid body motion. Erdman and Sandor (1972) and Thompson and Sung (1986) discuss the inertial coupling between the small deformation of the elastic linkages of the system and their gross motion with some contradictory views.

Using reference frames fixed to planar flexible bodies, Song and Haug (1980) suggest a finite element based methodology, which yields coupled gross rigid body motion and small elastic deformations. Shabana and Wehage (1986) further developed and generalized the approach by using substructuring and the mode component synthesis to reduce the number of generalized coordinates required to represent the flexible components. Yoo and Haug (1986) account for the contribution of the truncated modes by introducing static correction modes. The selection of the modes to use, in order to improve accuracy and efficiency, has been addressed by Koutsovasilis (2013) while Heckmann (2010) discusses the suitability of boundary conditions for modes of vibration. Other type of system reductions are proposed by Fehr and Eberhard (2011).

The structure of the equations of motion for flexible multibody systems include the mass and stiffness matrices, commonly used for finite element models, the mass and inertia matrices and the gyroscopic and centrifugal force vectors, always present in multibody formulations, and the inertia coupling terms, which are only encountered in these formulations. The coupling terms involve matrices involving the finite element shape functions that are not available in the common finite elements. Using a lumped mass formulation for the inertia terms Ambrósio and Gonçalves (2001) showed not only that all the terms required in the flexible body equations of motion are readily available from any commercial finite element code but also that any type of linear finite element can be used in the model. The recovery of the stresses that develop in the flexible bodies of the system, generally necessary during design, can be achieved using procedures such as that proposed by Tobias and Eberhard (2011).

The space dynamics community was naturally involved with the dynamics of flexible bodies undergoing large rigid body motion. Kane, Ryan and Banerjee (1987) showed that though most of the flexible multibody methods, at the time, could capture the inertia coupling between the elastodynamics of the system components and their large motion but they would still produce incorrect results because they neglected the dynamic stiffening effects.

Geradin and Cardona (1991) show that the floating reference frame methods used in flexible multibody dynamics have the ability to lower the geometric nonlinearities of the flexible bodies, but not to eliminate them because the moderate rotation assumption about the floating reference frame is still required. The work of researchers in the finite element community, such as that by Belytschko and Hsieh (1973) or Simo and Vu-Quoc (1988), among others, addressed similar problems from different points of view.

Defining it as an absolute nodal coordinate formulation, Shabana (1997) used finite rotations nodal coordinates enabling the capture of the geometric nonlinear deformations. Further work on this approach is developed by Maqueda and Shabana (2007) to include nonlinear material constitutive models. Another approach taken by Ambrósio and Nikravesh (1992) to model geometrically nonlinear flexible bodies is to relax the need for the structures to exhibit small moderate rotations about the floating frame using an incremental finite element approach within the flexible body description. Approaches to flexible multibody modeling using meshless methods are proposed by Ibanez and Orden (2011).

The work presented here assumes linear deformations when measures in the body fixed coordinate frame of the moving bodies of the system. Methods dealing with nonlinear or material deformations are not discussed here.

2 FLEXIBLE MULTIBODY SYSTEMS: A FINITE ELEMENT APPROACH

Let the principle of the virtual works be used to express the equilibrium of the flexible body in the current configuration $t + \Delta t$ and an updated Lagrangean formulation be used to obtain the equations of motion of the flexible body (Ambrosio, 1996). Let the finite element method be used to represent the equations of motion of the flexible body. Referring to Fig. 1, the assembly of all finite elements used in the discretization of a single flexible body results in its equations of motion written as

$$\begin{bmatrix} \mathbf{M}_{rr} & \mathbf{M}_{r\phi} & \mathbf{M}_{rf} \\ \mathbf{M}_{\phi r} & \mathbf{M}_{\phi\phi} & \mathbf{M}_{\phi f} \\ \mathbf{M}_{fr} & \mathbf{M}_{f\phi} & \mathbf{M}_{ff} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{r}} \\ \dot{\boldsymbol{\omega}}' \\ \ddot{\mathbf{u}}' \end{bmatrix} = \begin{bmatrix} \mathbf{g}_r \\ \mathbf{g}'_\phi \\ \mathbf{g}'_f \end{bmatrix} + \begin{bmatrix} \mathbf{s}_r \\ \mathbf{s}'_\phi \\ \mathbf{s}'_f \end{bmatrix} - \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{f} \end{bmatrix} - \begin{bmatrix} \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{K}_L + \mathbf{K}_{NL} \end{bmatrix} \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \\ \mathbf{u}' \end{bmatrix} \tag{1}$$

where $\ddot{\mathbf{r}}$ and $\dot{\boldsymbol{\omega}}'$ are the translational and angular accelerations of the body fixed reference frame, respectively, and $\ddot{\mathbf{u}}'$ denotes the nodal accelerations measured in body fixed coordinates. The local coordinate frame $\xi\eta\zeta$, attached to the flexible body, is used to represent the gross motion of the body and its deformation.

In Eq. (1) it is not assumed any type of reference conditions that relate the displacement of the finite elements to the body local frame. Eq. (1) describes thoroughly the motion of the flexible body. Even if only small elastic deformations occur, this equation is highly nonlinear due to a variant mass matrix, nonlinear external applied forces, gyroscopic and centrifugal forces and non-constant stiffness matrices. The variant mass matrix for the flexible body results from the assembly of the individual contributions of each finite element. Submatrices $\mathbf{M}_{rr}$ and $\mathbf{M}_{ff}$ are constant and

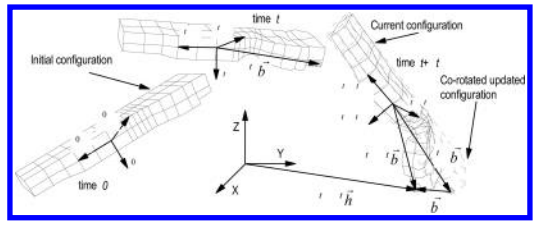

Figure 1. General motion of a flexible body.

represent respectively the mass of the entire body and the standard finite element mass matrix. $\mathbf{M}_{rf}$ and $\mathbf{M}_{\phi f}$ are the time variant matrices responsible for the inertia coupling between the gross motion of the body and its deformations.

The major differences between the equilibrium equations expressed by Eq. (1) and the standard nonlinear finite element equations consists in the fact that Eq. (1) is expressed with respect to a body fixed coordinate system $\xi\eta\zeta$ while in standard nonlinear finite elements only the global referential exists and, consequently, all quantities are measured directly in the *XYZ* coordinate system.

2.1 *Linear deformations in a flexible body*

If the deformations of the flexible body are linear elastic the nonlinear term $\mathbf{K}_{NL}\Delta\mathbf{u}'$ on Eq. (1) disappears, the nodal displacement increments $\Delta\mathbf{u}'$ are replaced by the nodal displacements $\mathbf{u}'$ and the equivalent nodal force vector $\mathbf{f}$ vanishes. The equations of motion for the linear elastic flexible body are finally given as

$$\begin{bmatrix} \mathbf{M}_{rr} & \mathbf{M}_{r\phi} & \mathbf{M}_{rf} \\ \mathbf{M}_{\phi r} & \mathbf{M}_{\phi\phi} & \mathbf{M}_{\phi f} \\ \mathbf{M}_{fr} & \mathbf{M}_{f\phi} & \mathbf{M}_{ff} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{r}} \\ \dot{\boldsymbol{\omega}}' \\ \ddot{\mathbf{u}}' \end{bmatrix} = \begin{bmatrix} \mathbf{g}_r + \mathbf{s}_r \\ \mathbf{g}'_\phi + \mathbf{s}'_\phi \\ \mathbf{g}'_f + \mathbf{s}'_f - \mathbf{K}_L\mathbf{u}' \end{bmatrix} \tag{2}$$

For a finite element model that involves elements with three nodal translations and three nodal rotations the nodal coordinates vector is

$$\mathbf{u}' = \left[\boldsymbol{\delta}_1'^T \; \boldsymbol{\theta}_1'^T \; \boldsymbol{\delta}_2'^T \; \boldsymbol{\theta}_2'^T \cdots \boldsymbol{\delta}_n'^T \; \boldsymbol{\theta}_n'^T \right]^T \tag{3}$$

Eqs. (1) and (2), cannot be solved without the reference conditions, which ensure that the displacement field of the flexible body is unique. Different types of reference conditions are discussed next.

2.1.1 *Body-fixed frames*

A straightforward type of reference conditions corresponds to that of the fixed body frame in which a given number of nodal degrees of freedom (dof), never less than 6, are constrained. The body-fixed reference conditions are written as:

$$\boldsymbol{\Phi}^{(bf)} \equiv \begin{Bmatrix} \boldsymbol{\delta}'_k \\ \boldsymbol{\theta}'_k \end{Bmatrix} = \mathbf{0} \qquad (k = 1,..,n_c) \tag{4}$$

where k refers to the fixed nodes that are not successively numbered in the finite element mesh and the

superscript *(bf)* denotes that the constraints are related to the body fixed conditions. Although Eq. (4) seems to imply that all dof of the fixed nodes are constrained, such is not necessary, provided that among all nodes at least 6 dof are constrained.

The constraints described by Eq. (4) are added to the equilibrium equations of the flexible body, given by Eq. (2), using Lagrange multipliers, as

$$\begin{bmatrix} \mathbf{M}_{rr} & \mathbf{M}_{r\phi} & \mathbf{M}_{rf} & \mathbf{0} \\ \mathbf{M}_{\phi r} & \mathbf{M}_{\phi\phi} & \mathbf{M}_{\phi f} & \mathbf{0} \\ \mathbf{M}_{fr} & \mathbf{M}_{f\phi} & \mathbf{M}_{ff} & \left(\Phi_{\mathbf{u}'}^{(bf)}\right)^T \\ \mathbf{0} & \mathbf{0} & \Phi_{\mathbf{u}'}^{(bf)} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{r}} \\ \dot{\boldsymbol{\omega}}' \\ \ddot{\mathbf{u}}' \\ \boldsymbol{\lambda}^{(bf)} \end{bmatrix} = \begin{bmatrix} \mathbf{g}_r + \mathbf{s}_r \\ \mathbf{g}'_\phi + \mathbf{s}'_\phi \\ \mathbf{g}'_f + \mathbf{s}'_f - \mathbf{K}_L \mathbf{u}' \\ \boldsymbol{\gamma}^{(bf)} \end{bmatrix} \quad (5)$$

in which the constraint Jacobian matrix $\boldsymbol{\Phi}_{u'}^{(bf)}$ is made of unit and null entries and the right-hand-side of the acceleration $\boldsymbol{\gamma}^{(bf)}$ is null.

Usually the body fixed reference conditions are implicitly included by removing the nodal coordinates in Eq. (4) and the corresponding lines and columns of the stiffness and mass matrices.

2.1.2 *Mean axis conditions*

These conditions are defined by 6 constraints that enforce the kinetic energy associated with the deformation, measured with respect to an observer stationed on the flexible body,to be minimum (Cavin and Dusto, 1977). Setting the partial derivatives of the kinetic energy with respect to the translational and rotational velocity vectors to zero leads to

$$\dot{\boldsymbol{\Phi}}^{(ma)} \equiv \begin{Bmatrix} \sum_{k=1}^{n} m_k \dot{\boldsymbol{\delta}}'_k \\ \sum_{k=1}^{n} m_k \tilde{\mathbf{b}}'_k \dot{\boldsymbol{\delta}}'_k + \sum_{k=1}^{n} \boldsymbol{\mu}_k \dot{\boldsymbol{\theta}}'_k \end{Bmatrix} = \mathbf{0} \quad (6)$$

Eq. (6) represents in the 6 equations that form the mean axis conditions. They imply that the linear and the angular momentum due to the elastic deformation are null.

To add Eq. (6) as a constraint to the equation of motion of the flexible body, described by Eq. (2), let

$$\dot{\boldsymbol{\Phi}}^{(ma)} \equiv \boldsymbol{\Phi}_{\mathbf{u}'}^{(ma)} \dot{\mathbf{u}}' = \mathbf{0} \quad (7)$$

in which the Jacobian matrix $\Phi_{u'}^{(ma)}$ is given by

$$\boldsymbol{\Phi}_{\mathbf{u}'}^{(ma)} = \begin{bmatrix} m_1\mathbf{I} & \mathbf{0} & \cdots & m_k\mathbf{I} & \mathbf{0} & \cdots & m_n\mathbf{I} & \mathbf{0} \\ m_1\tilde{\mathbf{b}}'_k & \boldsymbol{\mu}_1\mathbf{I} & \cdots & m_k\tilde{\mathbf{b}}'_k & \boldsymbol{\mu}_k\mathbf{I} & \cdots & m_n\tilde{\mathbf{b}}'_n & \boldsymbol{\mu}_n\mathbf{I} \end{bmatrix} \quad (8)$$

The time derivative of Eq. (7) yields the constraint acceleration equation

$$\ddot{\boldsymbol{\Phi}}^{(ma)} \equiv \boldsymbol{\Phi}_{\mathbf{u}'}^{(ma)} \ddot{\mathbf{u}}' = \mathbf{g}^{(ma)} \quad (9)$$

The Jacobian matrix given by Eq. (8) and vector $\boldsymbol{\gamma}^{(ma)}$ in Eq. (9) are now used in Eq. (5) instead of the equivalent quantities that refer to the body fixed conditions.

2.1.3 *Principal axis conditions*

The reference conditions that associate the origin of the reference frame to the instantaneous center of the referential and its directions to the principal inerta directions are designated by principal axis conditions (Nikravesh and Lin, 2003)

$$\boldsymbol{\Phi}^{(pa)} \equiv \sum_{k=1}^{n} \begin{Bmatrix} m_k \boldsymbol{\delta}'_k \\ \left(m\, b_\xi b_\eta + \mu_\eta \theta_\zeta\right)_k \\ \left(m\, b_\eta b_\zeta + \mu_\zeta \theta_\xi\right)_k \\ \left(m\, b_\xi b_\zeta + \mu_\xi \theta_\eta\right)_k \end{Bmatrix} = \mathbf{0} \quad (10)$$

in which the vector that locates node k with respect to the body reference frame is $\mathbf{b}'_k = \begin{bmatrix} b_\xi & b_\eta & b_\xi \end{bmatrix}^T$. The second time derivative of Eq. (10) and the corresponding Jacobian matrix $\boldsymbol{\Phi}_{\mathbf{u}'}^{(pa)}$ and the right-hand side vector $\boldsymbol{\gamma}^{(pa)}$ are now used in Eq. (5) instead of the quantities that refer to the body fixed conditions.

2.2 *Generalized elastic coordinates reduction*

The equations of motion for the linear flexible body, in the form described by Eq. (5), is computationally inefficient due to the large number of coordinates necessary to describe complex models. This problem is overcome using component mode synthesis technique, static condensation approaches or a combination of both, reducing considerably the size of the problem. For the sake of conciseness only the mode synthesis technique is explored here.

The modes used may be the natural modes of vibration, static correction modes or other deformation modes (Yoo and Haug, 1986). Let the nodal displacements of the flexible part of the body be described by a weighted sum of deformation modes

$$\mathbf{u}' = \mathbf{X}\,\mathbf{w} \quad (11)$$

where the vector of modal coordinate $\mathbf{w}$ represents the contributions of the vibration modes towards the nodal displacements and $\mathbf{X}$ is the modal matrix.

Let the set of modes used in the mode synthesis, in Eq. (11), include a set of modes of vibration $\mathbf{X}_v$ and a set of static condensation modes $\mathbf{X}_s$ as

$$\mathbf{X} = \begin{bmatrix} \mathbf{X}_v & \mathbf{X}_s \end{bmatrix} \quad (12)$$

The evaluation and selection of the modes to be used in mode component synthesis is of fundamental importance for numerical accuracy and efficiency.

2.2.1 *Modes of vibration*

The modal matrix includes a selected number of modes of vibration $\mathbf{x}_i$ that are obtained by solving the eigenproblem associated to the finite element description of the flexible body

$$\mathbf{K}_L \mathbf{x}_i = \varpi_i \mathbf{M}_{ff} \mathbf{x}_i \quad (13)$$

The modes of vibration obtained, defined as free modes, correspond to those of a structure that is free in space. The modes of vibration $\mathbf{x}_0$ associated to the 6 lowest frequencies ϖ_i of the eigenproblem, generally null, represent the rigid motion with respect to the body reference frame, and are included in the modal matrix $\mathbf{X}_v$.

2.2.2 *Static correction modes*

The use of a small number of modes of vibration is unable to represent local deformations of the flexible body. Even if no external loads are applied on the flexible body, the points at which the kinematic joints are attached have to transmit the joint reaction loads and, consequently, their neighbourhood experiences local deformations. The use of the static condensation modes $\mathbf{X}_s = \left[\, \boldsymbol{\varphi}_1 \cdots \boldsymbol{\varphi}_s \cdots \boldsymbol{\varphi}_S \,\right]$ describes local deformations (Yoo and Haug, 1986; Geradin and Cardona, 1991).

To calculate each static correction mode let a nodal load vector $\mathbf{f}_a$ be defined with all its entries are null, except for the degree of freedom of the node in which an unit concentrated force or moment is applied. The force cannot be applied to the flexible body because no reference conditions are implied when the vibration analysis is performed. Instead, a pseudo-static equilibrium force $\mathbf{f}_e$, in which the unit force $\mathbf{f}_a$ is balanced by the rigid body inertial forces, is used. The pseudo-static equilibrium force is

$$\mathbf{f}_e = \left(\mathbf{I} - \mathbf{M}_{ff}\mathbf{X}_0\mathbf{X}_0^T\right)\mathbf{f}_a \tag{14}$$

The deformation mode $\hat{\boldsymbol{\varphi}}_s$ associated to the pseudo-static equilibrium force is obtained by solving the static equilibrium equation for the flexible body

$$\mathbf{K}_{ff}\hat{\boldsymbol{\varphi}}_s = \mathbf{f}_e \tag{15}$$

Before the deformation mode can be used it has to be orthogonalized and normalized with respect to the vibration modes and to the other static condensation. Let vectors $\boldsymbol{\alpha}_0$ and $\boldsymbol{\alpha}_v$ be defined as

$$\begin{aligned} \boldsymbol{\alpha}_0 &= \mathbf{X}_0^T\mathbf{M}_{ff}\hat{\boldsymbol{\varphi}}_s \\ \boldsymbol{\alpha}_v &= \mathbf{X}_v^T\mathbf{M}_{ff}\hat{\boldsymbol{\varphi}}_s \end{aligned} \tag{16}$$

Then, the new deformation modes orthogonal to the rigid body and kept vibration modes are obtained as

$$\breve{\boldsymbol{\varphi}}_s = \hat{\boldsymbol{\varphi}}_s - \mathbf{X}_0\boldsymbol{\alpha}_0 - \mathbf{X}_v\boldsymbol{\alpha}_v \tag{17}$$

The new deformation modes have to be orthogonal to each other also. The procedure is implemented by using successively Eqs. (16) and (17) with the vibration modes substituted by the other deformation modes. The result is that all modes are orthogonal to each other. The final step in obtaining the static deformation modes is the normalization. For the purpose let the β_s be defined as

$$\beta_s = \breve{\boldsymbol{\varphi}}_s^T\mathbf{M}_{ff}\breve{\boldsymbol{\varphi}}_s \tag{18}$$

in which the deformation modes $\breve{\boldsymbol{\varphi}}_s$ are assumed to be orthogonal to each other. Then, each one of the static correction modes is finally obtained as

$$\boldsymbol{\varphi}_s = \frac{1}{\sqrt{\beta_s}}\breve{\boldsymbol{\varphi}}_s \tag{19}$$

The pseudo-natural frequencies associated to each of the static correction mode are evaluated as

$$\varpi_s^2 = \boldsymbol{\varphi}_s^T\mathbf{K}_L\boldsymbol{\varphi}_s \tag{20}$$

The balance between the number of vibration modes and static correction modes used in each flexible body model is problem dependent. It is not necessary that a static correction mode is associated to every degree of freedom to which a joint reaction or external force is applied. However, static correction modes must be associated to dof where the most significant forces are applied.

2.2.3 *Mode synthesis*

Due to the assumption of linear elastic deformations the modal matrix is invariant. A simpler system of equations is obtained by using the orthonormality of the modes with respect to the mass matrix, which implies that $\mathbf{X}^T\mathbf{M}_{ff}\mathbf{X} = \mathbf{I}$ and $\mathbf{X}^T\mathbf{K}_{ff}\mathbf{X} = \Lambda$, where Λ is a diagonal matrix containing the squares of the flexible body natural and pseudo-natural frequencies. This leads to

$$\begin{bmatrix} \mathbf{M}_{rr} & \mathbf{M}_{r\phi} & \mathbf{M}_{rf}\mathbf{X} & \mathbf{0} \\ \mathbf{M}_{\phi r} & \mathbf{M}_{\phi\phi} & \mathbf{M}_{\phi f}\mathbf{X} & \mathbf{0} \\ \mathbf{X}^T\mathbf{M}_{fr} & \mathbf{X}^T\mathbf{M}_{f\phi} & \mathbf{I} & \left(\boldsymbol{\Phi}_{\mathbf{u}}^{(bf)}\mathbf{X}\right)^T \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\Phi}_{\mathbf{u}}^{(bf)}\mathbf{X} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \ddot{\mathbf{r}} \\ \dot{\boldsymbol{\omega}}' \\ \ddot{\mathbf{w}} \\ \boldsymbol{\lambda}^{(bf)} \end{bmatrix} = \begin{bmatrix} \mathbf{g}_r + \mathbf{s}_r \\ \mathbf{g}'_\phi + \mathbf{s}'_\phi \\ \mathbf{X}^T\left(\mathbf{g}'_f + \mathbf{s}'_f\right) - \Lambda\mathbf{w} \\ \boldsymbol{\gamma}^{(bf)} \end{bmatrix} \tag{21}$$

where any reference condition previously described can be used instead of the body fixed condition implied by the superscript (bf).

Although Eq. (22) represents the dynamic equilibrium of a flexible body with the reference conditions included it is seldom found in the literature. When the body fixed condition is used, the nodal degrees of freedom of the flexible body to which the coordinate frame is attached are null. In this case, such degrees of freedom are removed from the nodal displacement vector $\mathbf{u}'$ and the corresponding lines and columns of $\mathbf{K}_L$ and $\mathbf{M}_{ff}$ are eliminated before the eigenproblem is solved. These are referred as fixed modes and are not discussed here.

3 APPLICATION TO THE DEPLOYMENT OF A SATELLITE

The antenna consists in two identical subsystems, each with three coupled planar 4-bar links that unfold two panels on each side. The central panel is attached to the main body of the satellite. Each system has 2 dof, driven individually by actuators. During launching the antenna and the solar array are folded, as shown in Fig. 2a. Upon unfolding the satellite achieves the configuration in Fig. 2b.

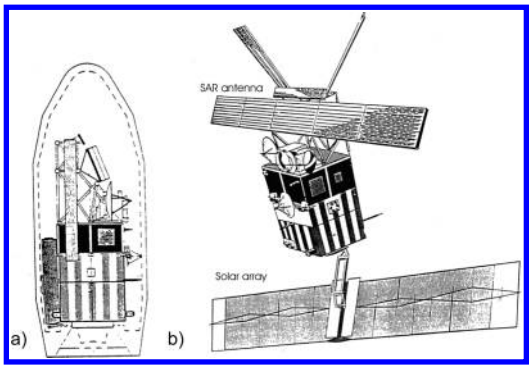

Figure 2. Satellite with the antenna a) folded and b) unfolded.

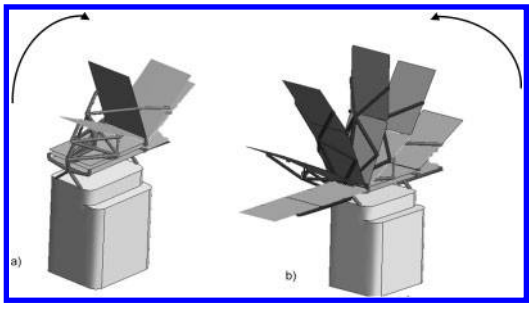

Figure 3. Unfolding process: a) 1st phase b) 2nd phase.

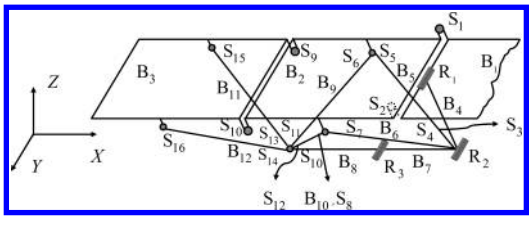

Figure 4. Multibody model of the antenna.

The unfolding process consists in two phases, schematically represented in Fig. 3. Functional requirements for the final configuration impose that the alignment between panels is obtained within a tolerance smaller than 0.5°.

The model used for one half of the folding antenna, schematically depicted Fig. 4, is composed by 12 bodies (B_1,…, B_{12}), 16 spherical joints (S_1,…, S_{16}) and 3 revolute joints (R_1, R_2, R_3). The geometry of each panel is $1.994 \times 1.300 \times 0.002$ m. All truss members have a circular cross-section (Anatharaman and Hiller, 1991). The material used in the model is a carbon reinforced plastic IM6/SC1081 with a matrix of Epoxy SC1081 and fibers in Carbon IM6. Note that the material model is not necessarily that of the real satellite antenna, as the characteristics of such material are not publicly available. Referring to Fig. 5, the properties of the composite material, for a single layer with an orientation of 0° relatively to the X axis are: $E_1 = 177$ GPa; $E_2 = 10.8$ GPa; $G_{12} = G_{13} = 7.6$ GPa; $G_{23} = 8.504$ GPa; $\nu_{12} = 0.27$; with a specific mass of 1600 kg/m^3.

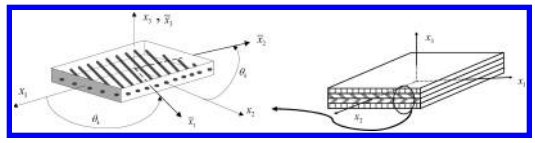

Figure 5. Coordinate system and layer numbering used for a typical laminated plate and orthotropic layer.

Table 1. Layer orientations of the satellite panels before and after optimization.

Panels	Design variable	Lower bound	Initial value	Optimal value	Upper bound
2 = 3	ϕ_1/ϕ_2	−90°/−90°	55°/−55°	+1°/−47°	+90°/+90°

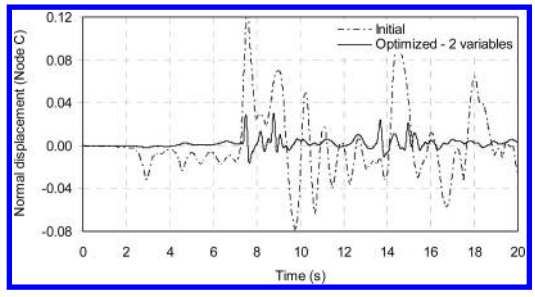

Figure 6. Normal displacements of node coincident with S_9 (see Fig. 4) for the initial and optimal laminates.

The actuator, applied in revolute joint R_3, is modeled as a nonlinear spring and damper actuator. The spring-damper-actuator has piecewise-linear characteristics with damping. The actuation law presented here is different from that reported by Anantharaman and Hiller (1991), which was used to model the antenna with panels made of isotropic material.

The flexibility of the multibody systems components made of composite materials is very sensitive to the layer orientation of the lay-ups that form the laminate. In order to get a stiffer antenna, an optimization problem is formulated as the minimization of the deformation energy of the panels (Ambrósio et al., 2007). In order to avoid that at a given instant the deformation of the panel exceeds predefined limits, the maximum value of the deformation energy, in each panel, is constrained to be below a given threshold. All material models considered for the optimal problem were symmetric laminates. The layer orientations of the panel material for the original and optimal configurations are depicted in Table 1.

The normal displacements of the panels, with respect to the body fixed frame, are greatly reduced in the optimized model with respect to the original one, as shown in Figs. 6 and 7. It is also observed that in the initial design the panel deformations involve mostly the bending mode while the optimal panel oscillations are mostly torsion deformation.

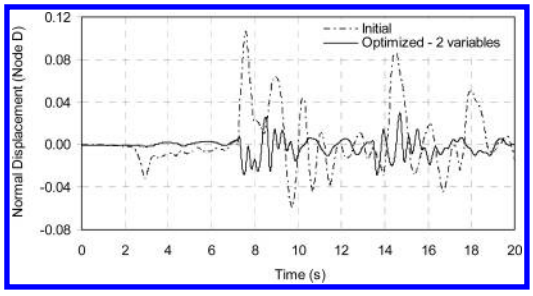

Figure 7. Normal displacements of node coincident with S_{10} (see Fig. 4) for the initial and optimal laminates.

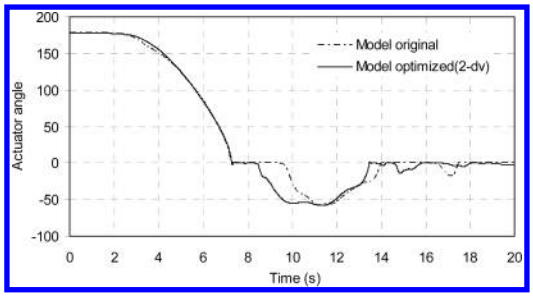

Figure 8. Actuator angle for the initial and optimal laminates during the first phase.

In Fig. 8, the actuator angle history during the first phase of the unfolding antenna is presented for the original and the optimum designs. It is clear that both designs lead to similar end alignments of the panels without any qualitative difference between the angle histories.

4 CONCLUSIONS

A computationally efficient methodology to handle the large displacements and rotations of flexible multibody systems involving linear elastic deformations is presented here. By using reference conditions as algebraic constraints it is possible to apply free-free vibration and static modes in a component mode synthesis approach to reduce the size of the problem. The application of the methodology to the deployment of a satellite demonstrates its virtues and exemplifies the modelling possibilities of structural mechanisms made of composite materials.

ABSTRACT: In this paper, we present a novel model which comprises a conventional pendulum and the presently proposed SD oscillator being of an oblique spring pinned to its rigid support. This model provides a cylindrical dynamical system with both smooth and discontinuous regimes depending on the value of a system parameter and also the dynamics transient relying on the coupling strength between the pendulum and the SD oscillator. The unperturbed system behaves both standard (smooth) and nonstandard (discontinuous) nonlinear dynamics of equilibrium bifurcations, periodic patterns and their separatrices of homoclinic and heteroclinic orbits of the first type, second-type and double heteroclinic orbits. Chaotic attractors are presented when the system is excited under the perturbation of viscous damping and external harmonic forcing within smooth regime. The results presented herein this paper show the dependency of the demonstrate attractors depending the coupling strength of the the pendulum and the SD oscillator exhibiting pendulum-type, SD-type and their mixture.

1 INTRODUCTION

Complex nonlinear phenomena always exhibited in a simple model, such as pendulum and SD oscillator. We will start from a smooth and discontinuous (SD) oscillator (Cao et al. 2006, Cao et al. 2008, Cao et al. 2008) and a mathematical pendulum (Nelson & Olsson 1986, Formalskii 2006) to introduce an archetype nonlinear model which is coupled with an SD oscillator and a pendulum to form the so called rotating SD oscillator. Both the SD oscillator and the pendulum are the reliable nonlinear system to reflect the nature behaviours of the nonlinear system without any truncation. The motivation of this paper is to present an archetype oscillator by combining the classical pendulum with the recently proposed SD oscillator to explorer the complex dynamics behaviour resulted by the coupling strength of the oscillators.

2 RELIABLE NONLINEAR OSCILLATORS

In this section we will give briefly introduction to the SD oscillator and the conventional pendulum, by using which an archetype rotating SD oscillator is proposed with both smooth and discontinuous dynamics.

2.1 *SD oscillator*

The SD oscillator was firstly proposed and investigated by Cao, Wiercigroch, Pavlovskaia, Grebogi, & T. Thompson (2006) which is an archetype nonlinear dynamical system with both smooth and discontinuous

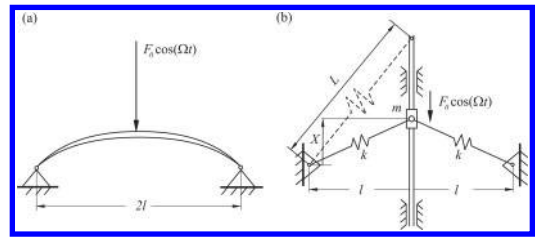

Figure 1. A shallow elastic arch and the simplified oscillator; (a) an elastic arch consisting of a beam and the rigid supports at each end; (b) vertically governed oscillator with a pair of springs pinned to rigid supports.

nonlinear dynamics due to the geometry configuration, see also Cao et al. (2008) and Cao et al. (2008) for details. This model is based upon a simple elastic beam, seen Thompson & Hunt (1973), as shown in Fig. 1a. This oscillator is similar to a snap through truss system composing of a mass m linked by a pair of inclined elastic springs which are capable of resisting both tension and compression. Each of the springs is of stiffness k pinned to a rigid support, as shown in Fig. 1b or Fig. 4a. Although the springs themselves provide linear restoring resistance, the resulting vertical response on the mass is a strong nonlinear force because of the geometric configuration.

The dimensionless equation of motion can be written in the following form by letting $w_0^2 = \frac{2k}{m}$, $x = \frac{X}{L}$ and $\alpha = \frac{l}{L} \geq 0$,

$$\ddot{x} + \omega_0^2 x(1 - \frac{1}{\sqrt{x^2 + \alpha^2}}) = 0, \qquad (1)$$

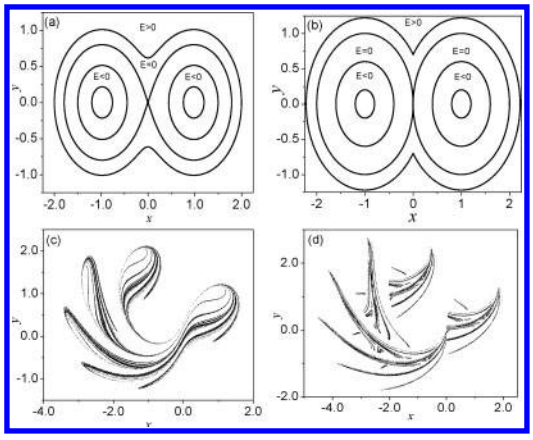

Figure 2. Phase portraits: (a) and (b) for $\alpha = 0.5$ and $\alpha = 0$, respectively, and the SD attractors: (c) and (d) for for $\alpha = 0.25$ and $\alpha = 0$, respectively, for $f_0 = 0.8$, $\xi = 0.015$ and $\omega = 1.015$ with the largest Lyapunov exponents 0.09432, 0.0473 and the Lyapunov dimension 1.5432, 1.4025.

in which, the smoothness parameter α defines the ge ometry of the oscillator (as shown in Fig. 1b) governing the property of the system. For $\alpha > 1$ the system epresents a pre-tensional discrete elastic string, while if $\alpha = 0$, the model corresponds to an oscillating mass supported by two parallel vertical springs.

When $\alpha = 0$ system (1) can be written in the following form,

$$\ddot{x} + \omega_0^2(x - \mathbf{Sign}(x)) = 0. \tag{2}$$

It is worth reiterating here that the discontinuous system (Filippov 1960, Filippov and Arscott 1992, Leine et al. 1998, Leine et al. 2000, Leine and Van Campen 2002) is obtained by decreasing of the smoothness parameter α to 0. Both system (1) and system (2) are call the SD oscillator.

Again the perturbed dimensionless system of (1) can also be obtained by letting $\tau = \omega_0 t$, $f_0 = \frac{F_0}{2kL}$, $\xi = \frac{\delta}{2mw_0}$ and $\omega = \frac{\Omega}{\omega_0}$,

$$x'' + 2\xi x' + x(1 - \frac{1}{\sqrt{x^2 + \alpha^2}}) = f_0 \cos\omega\tau, \tag{3}$$

where "′" denotes differentiation with respect to τ.

Attentions have been paid to the investigation of the nonlinear behaviours of the system in the past years. Tian, Cao, & Li (2010) and Lai & Xiang (2010) generalised the conventional averaging technique and the multiple scale method the this system to get the Hopf bifurcations and the semi-analytical solutions. Tian, Cao, & Yang (2010) investigate the detailed analysis about the co-dimension two bifurcation behaviour near the equilibrium bifurcation point at $\alpha = 1$. Cao, Wiercigroch, Pavlovskaia, Grebogi, & Thompson (2008) and Cao, Xiong, & Wiercigroch (2011) studied the limit case dynamics when parameter $\alpha = 0$ showing the complicated resonant behaviour and also the discontinuous chaotic sea with detailed formulation of the resonances which is no longer satisfying the law of $n\omega_0 = m\omega_1$, n, m are the relative prime integers. This formulation provides a better understanding of the complex resonant behaviours and a further application to describe chaos symbolically. Wang, Zhang, & Hong (2011) investigated the interior crisis of the SD Oscillator by using mapping cell method.

As for the irrational properties of the SD oscillator with both smooth and discontinuous phases, there occurs barrier for the conventional methodologies. An open problem was proposed by Cao, Wiercigroch, Pavlovskaia, Michael, Thompson, & Grebogi (2008) for the construction of the analytical solutions for the SD oscillator. Tian, Yang, Cao, & Wu (2012) tried a transformation to covert this irrational system to a new parametric space to get the further step to the problem. Cao, Wang, Chen, & Wiercigroch (2012) provides a series of irrational elliptic function to present the analytical solutions for the SD Oscillator, by using which the chaotic threshold can be derived by expanding the Melnikov method.

Applications and the experimental investigations are also made about the original SD oscillator. Leger, Pratt, & Cao (2012) considered the fully nonlinear dynamics with impact and friction by introducing Coulomb cone presented all the possible equilibrium bifurcations of the SD oscillator with impact and friction. Han, Cao, Chen, & Marian (2012) presented a rig-coupled SD oscillator showing the bifurcations of the multiple stability, dynamic bucklings and also the conditions of the bifurcations. Tian, Yang, Cao, & Han (2012) modelled the bridge-vehicle intersection to explorer the dynamic behaviour by using a variable stiffness SD oscillator, the results show the excellent agreement withe the experiment data. Chen, Cao, Feng, & Tian (2012) set up a experimental rig to investigate the nonlinear behaviour approaching the real system and the numerical studies.

2.2 *Pendulum*

None can ignore the influence of pendulum on the history of science, which is a frequent topics in a modern universities. Even the first application of pendulum can be dated back to AD 132, when it is used in Seismograph, see (Bielenstein 1980) for instance, until 1582, Galileo found the law of isochronism (Galileo 1592) through classical experiments, which marked the beginning of scientific research of pendulum. In 1674, Huygens discovered the periodicity of large swings (Michael, Matthews, & Gauld) which deviates from the law of isochronism. This is one of the earliest records of nonlinear phenomenon.

In modern times, several kinds of pendulum systems have been proposed and investigated, such as mathematical pendulum (Liang & Brian 2006) , double pendulum (Dullin 1994), spring pendulum (Lee & Park 1997) and spherical pendulum (Miles 1984) as well. Recent years, nonlinear behaviour of pendulum still attracts the study, such as Lobas, Kovalćhuk, & Bambura (2007) investigated the nonlinear behaviour

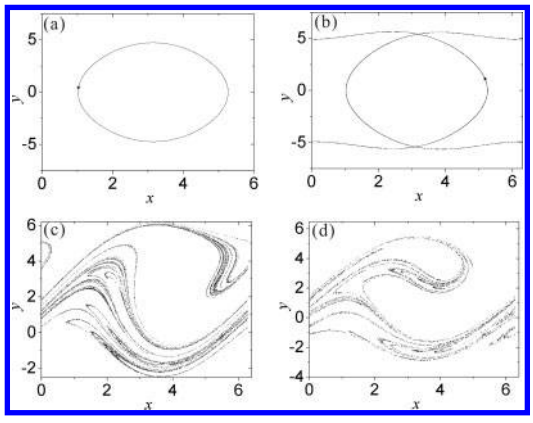

Figure 3. Pendulum trajectories for $\xi = 0.125$, $f_0 = 5.0$: (a) and (b) for the type I and type II periodic solution when $\omega = 1.05$ and $\omega = 2.1$, respectively; (c) and (d) are the classical pendulum ($h = 0$) for $f_0 = 5.0$, $\xi = 0.25$ with the largest Lyapunov exponents 0.3248 and 0.3342, the corresponding Lyapunov dimension 1.5651, 1.5717, respectively, for $\omega = 1.05$ and 1.7.

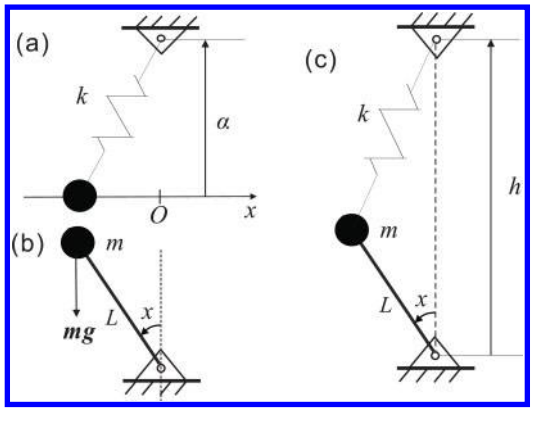

Figure 4. (a) SD Oscillator, (b) inverted pendulum and (c) the rotating SD oscillator comprising an SD oscillator and an inverted pendulum.

of the inverted pendulum systems subjected to a linear spring providing a follower force, and others demonstrated a rich behaviour for pendulum systems, see Nelson & Olsson (1986) and Formalskii (2006) for example.

Here we present some primary attractors for the classical inverted pendulum, as shown in Fig. 4b. The dimensionless equation of motion with damping and external excitation of frequency ω and amplitude f_0 can be obtained as the following by re-scalling transformations (omitted).

$$\ddot{x} + 2\xi\dot{x} - \omega_0^2 \sin x = f_0 \cos \omega t. \tag{4}$$

Fig. 3 shows the phase portraits for the periodic solutions (Fig. 3a and 3b) and the chaotic attractors in Fig. 3c and 3d, the detail explanation can be seen in the corresponding captions.

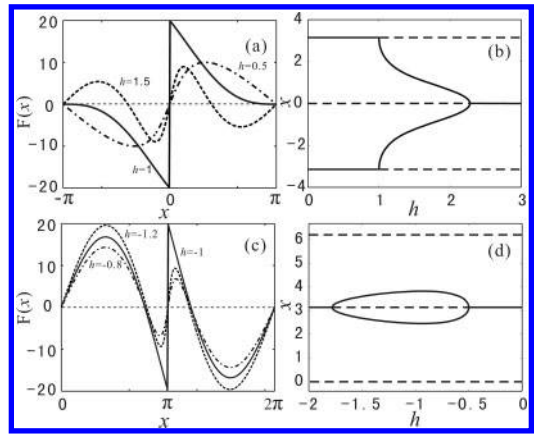

Figure 5. Restoring forces and the equilibrium bifurcations for $\omega_0 = \sqrt{20}$: (a) and (c) nonlinear restoring force $F(x)$ for $h > 0$ and $h < 0$ respectively, (b) and (d) bifurcation diagrams for x versus h, for $h \geq 0$ and $h \leq 0$, respectively.

3 ROTATING SD OSCILLATOR

3.1 *Equation of motion*

Let us consider a so called rotating SD oscillator, shown in Fig. 4a, which comprises the original SD oscillator, with a spring of stiffness k and relax length l linked by a mathematical pendulum of length L and a lump mass m. The governing equation of the dimensionless form can be written as the following by letting $L = 1$, $l = 1$, and $\omega_0^2 = \frac{k}{m}$.

$$\ddot{x} - F(x) = 0, \tag{5}$$

where $F(x) = g \sin x - \omega_0^2 h \sin x - \frac{\omega_0^2 h \sin x}{1+h^2-2h\cos x}$, and the graphs are plotted in Figs. 5a and 5c, respectively, for $\omega_0 = \sqrt{20}$ for the different values of parameter h.

It can be seen that this system is smooth for $|h| \neq 1$ and discontinuous at $x = 0$ for $h = 1$ and $x = \pi$ for $h = -1$. The equilibria of system (5) can be obtained, by letting $F(x) = 0$, written as

$$\begin{aligned} &x_1 = 0, x_{2,3} = \pm\pi, \\ &x_{4,5} = \pm \arccos\left(\tfrac{1+h^2}{2h} - \tfrac{\omega_0^4 h}{2(g-\omega_0^2 h)^2}\right), \end{aligned} \tag{6}$$

which exist only for $\left|\frac{1+h^2}{2h} - \frac{w_0^4 h}{2(g-\omega_0^2 h)^2}\right| < 1$.

Figs. 5b and 5d plot the branches of the equilibria for $\omega_0 = \sqrt{20}$ and show the pitchfork bifurcations of the equilibria, the solid curves denote the stable branches and the dashed indicate the unstable ones.

In the same way the perturbed equation of the dimensionless system can also be obtained by letting $f_0 = \frac{F_0}{mL}$ and $\xi = \frac{\delta}{2m}$.

$$\ddot{x} + 2\xi\dot{x} - F(x) = f_0 \cos \omega t. \tag{7}$$

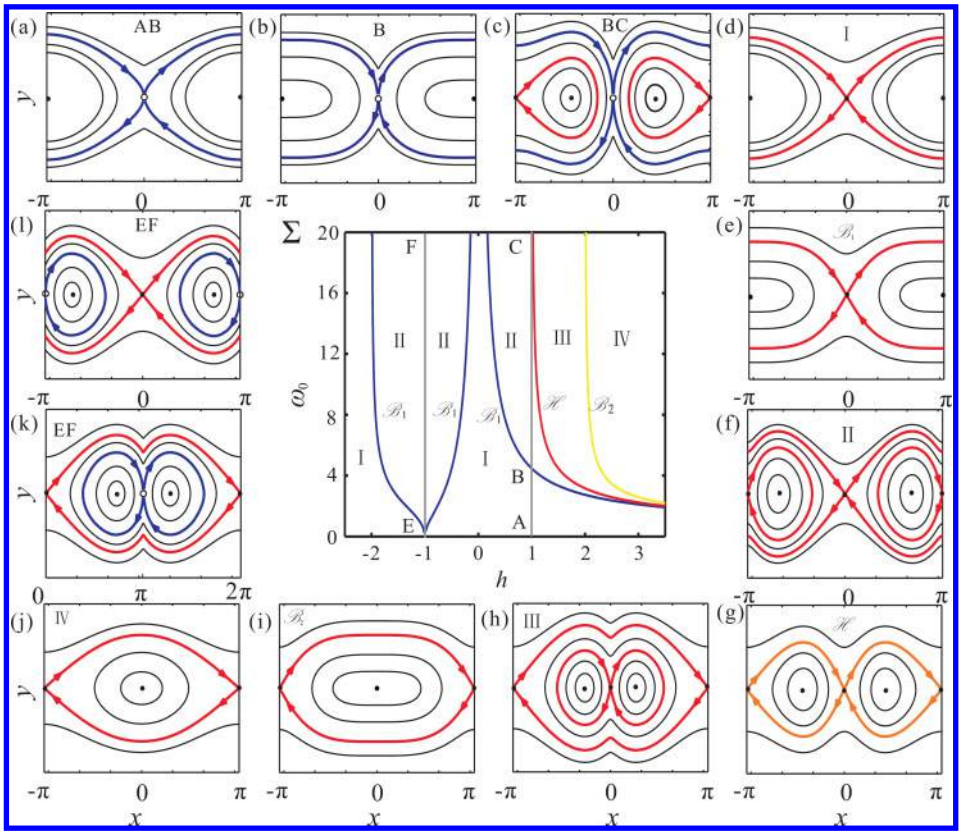

Figure 6. $\sum$. Bifurcation diagram, and (a)–(l) the corresponding phase portraits, the details seen in the context.

3.2 *Unperturbed dynamics*

Letting $\dot{x}x = y, \dot{y} = F(x)$ in system (5) yields the Hamiltonian of system as the following.

$$H(x,y) = \frac{y^2}{2} + (g - \omega_0^2 h)\cos x - \omega_0^2\sqrt{1+h^2-2h\cos x} - (g-\omega_0^2 h) + \omega_0^2|1-h|, \tag{8}$$

with the help of which, the trajectories of system (5) can be classified and analyzed. To do so, we calculate the transient sets on the surface of $F(x)$ in the parameter space (h, ω_0) plane as the following (Golubitsky, Stewart, & Schaeffer 1988).

$$\sum = \mathscr{B} \cup \mathscr{H} \cup \mathscr{D} = \mathscr{B}_1 \cup \mathscr{B}_2 \cup \mathscr{H}, \tag{9}$$

where $\mathscr{B}$ and $\mathscr{H}$ correspond to bifurcation set and hysteresis set, respectively, while $\mathscr{D}$ refers to the double limit set.

$$\begin{cases} \mathscr{B}_1 = \{\omega_0^2 h(1 - \frac{1}{|1+h|}) - g = 0\}, \\ \mathscr{B}_2 = \{g - \omega_0^2 h(1 - \frac{1}{|h-1|}) = 0\}, \\ \mathscr{H} = \{\omega_0^2(h-1) - g = 0\}, \\ \mathscr{D} = \emptyset. \end{cases} \tag{10}$$

which divides parameter space (h, ω_0) into four persistence regions, marked I, II, III and IV, as shown in Fig. 6$\sum$, $\mathscr{B}_1$, $\mathscr{B}_2$ and $\mathscr{H}$ are plotted with solid blue, yellow and red respectively, while the solid lines, marked grey, correspond to the discontinuous regimes for $|h| = 1$. All possible phase portraits of system (5) in parameter space, $(h, \omega_0 0)$, as shown in Fig. 6$\sum$, are plotted in Figs. 6a–6l, marked with the same symbols as in the corresponding parameter space in Fig. 6$\sum$.

The bold dots denote the centre and saddle points of the smooth equilibria connecting the corresponding heteroclinic, see Fig. 6g for example, homoclinic orbits, marked red, of the first, and the second kind in Fig. 6, respectively. While small cycles indicate nonstandard or saddle-like (Cao et al. 2006, Cao et al. 2008) for details, equilibria connecting the corresponding homoclinic-like orbits, marked blue, as shown in Figs. 6a–6c, 6k and 6l, respectively. Those dynamics present the global bifurcations for both smooth and discontinuous phenomena (Lamba and Budd 1994, Bressloff 1990) of pitchforks for equilibria and transitions for homoclinic and heteroclinic orbits. For example, smooth dynamics for $|h| \neq 1$ are displayed in Figs. 6d–6j, demonstrating two types of pitchfork bifurcations, seen Fig. 6, from Figs. 6d, 6e to Fig. 6f. Bifurcations of discontinuous for $|h| = 1$ are also given, for example Figs. 6a–6c, 6k and Fig. 6l,

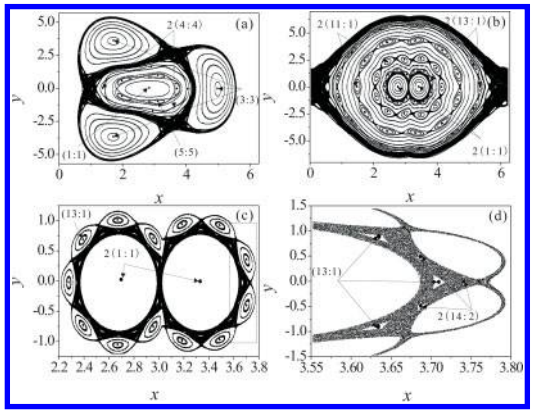

Figure 7. Chaotic sea and the quasi-periodic trajectories (islands) for $\xi = 0$: (a) Poincaré section for $f_0 = 10$, $\omega = 5.5$, $h = 1$, $\omega_0 = \sqrt{19.5}$, (b) Poincaré section for $f_0 = 20$, $\omega = 30$, $h = -1$, $\omega_0 = \sqrt{5}$, (c) the amplified area for the center part in (b), (d) locally amplified for the boxed area in (c).

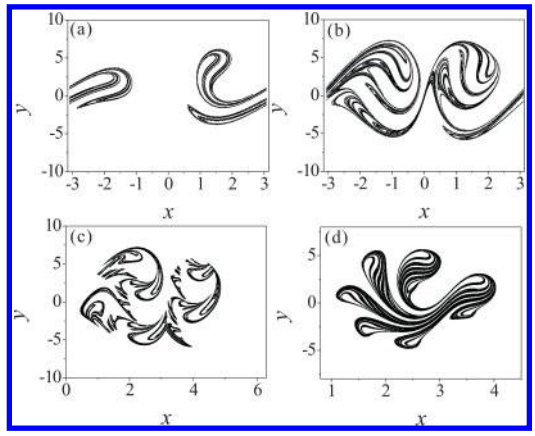

Figure 8. Rotating attractors:(a) and (b) for $h = 0.8$, 1.22 with the largest Lyapunov exponents 0.536155, 0.464603 and the corresponding Lyapunov dimension 1.52763, 1.49214, respectively, for $f_0 = 10$, $\xi = 0.24$, $\omega = 4.75$ and $\omega_0 = \sqrt{50}$; (c)–(d) for $h = -1$, -1.47 with the largest Lyapunov exponent 0.545585, 0.400991 and the Lyapunov dimension 1.73175, 1.67245, respectively, for $f_0 = 10$, $\xi = 0.1$, $\omega = 5.5$ and $\omega_0 = \sqrt{28}$.

which reveal a pitchfork bifurcation of the saddle-like equilibrium (0, 0) as well.

3.3 *Perturbed dynamics*

The time-dependent Hamiltonian can also be derived for the undamped system (7) for $\xi = 0$, written in the following form.

$$H(x,y,t) = \frac{y^2}{2} + (g - \omega_0^2 h)\cos x - (g - \omega_0^2 h) - \omega_0^2\sqrt{1 + h^2 - 2h\cos x} + \omega_0^2|1 - h| - f_0 x\cos\omega t, \quad (11)$$

in which time "t" is regarded the parameter, while system (7) acts as an one and half degree of freedom system with natural frequency ω_0 and the excitation frequency ω. The motions of this system are restricted within an torus with both action and angular variables (Chernikov, Sagdeev, Usikov, Zakbarov, & Zaslavsky 1987) for instance. The most interesting situation is the resonant behaviour (Lichtenberg & Lieberman 1992) occurred for $m\omega_0 - n\omega = 0$, m and n the related prime integers, which implies that the resonant motion can return to the starting point after m cycles of longitude and $n$cycles of latitude along the torus. Even the winding number of the resonance is defined $\alpha = \frac{n}{m}$, the period of the motion might be the integer times of the winding number (Guckenheimer & Holmes 1999). As examples, we show the Poincaré section, or a resonance web, for $f_0 = 10, \omega = 5.5, h = 1$, $\omega_0 = \sqrt{19.5}$ in Fig.7a with resonant solutions of (1:1), (3:3), (5:5), and a pair of (4:4). Fig.7b shows the Poincaré section for $f_0 = 20, \omega = 30, h = -1, \omega_0 = \sqrt{5}$ with resonant solutions of a pair of (1:1), a pair of (11:1), a pair of (13:1), a pair of (14:2) and (15:3) respectively.

In the following, numerical analysis are carried out to detect the complex behaviour for system (7) in the presence of both viscous-damping and external excitation of amplitude f_0 and frequency ω.

As the attractors we have presented for SD type in Fig. 5c and Fig. 5d and the conventional pendulum type in Fig. 3c and Fig. 3d when $h = 0$, Figs. 8a and 8b are the attractors for $h = 0.8$ and $h = 1.22$, respectively, and Figs. 8c and 8d are the attractors for $h = -1$ and $h = -1.47$, respectively, for the mixture of the SD and pendulum type. The attractors presented here show the chaotic transition among the pendulum and the SD oscillator and also the transition between the smooth and discontinuous ($h = -1$). It is interesting that the attractors of the system vary from the classical pendulum to the SD type depending on the strength of coupling.

4 CONCLUSIONS

In this paper, we have proposed and investigated an archetype oscillator exhibiting both smooth and discontinuous regimes. This system couples the conventional pendulum and the recently proposed SD oscillator. All the possible trajectory patterns of the unperturbed system have been demonstrated for the choosing of parameters h and ω_0 with various kinds homoclinic and heteroclinic orbits of the first and second type on the cylinder and the bifurcation transition. The system exhibits similar behaviour with the conventional pendulum and inverted pendulum and a bistable behaviour as parameter varying. For the perturbed system, numerical investigations show different type of attractors which are similar with that of pendulum or SD type or their mixture depending on the degree of coupling of the nonlinearities.

A hybrid time-frequency procedure for the solution of nonlinear dynamic problems

F.N. Correa & B.P. Jacob
LAMCSO – Laboratory of Computer Methods and Offshore Systems/COPPE/UFRJ – PostGraduate Institute of the Federal University of Rio de Janeiro, Civil Engineering Department, Rio de Janeiro, Brazil

ABSTRACT: This work presents extensions on the formulation of a Hybrid Time-Frequency domain Green Approach method (HTF-GA) for the solution of structural dynamic problems. The HTF-GA method is based on a step-by-step time domain solution procedure associated to the convolution between the Green functions of the problem and the vector of external loads. The hybrid approach is characterized by the fact that the Green functions are implicitly calculated in the frequency domain. Here the method is modified to uncouple the Green Function and represent complex problems with strongly non-linear behavior.

1 INTRODUCTION

The challenge of exploiting deep water offshore oil has been motivating studies on new alternatives for structural systems to support deepwater platforms, leading to the development of fixed compliant structures [1] and of moored floating platforms [2]. The behavior of such systems is characterized by large displacements leading to severe nonlinear dynamic effects, and also may have frequency-dependent mass, damping and stiffness properties.

This characteristic is associated not only to the intrinsic structural behavior of the system, but also to hydrodynamic effects due mainly to the fluid-structure interaction at the platform hull and sloshing effects that must be considered in the calculation of hull motions. In this context, this paper presents enhancements on the formulation of the hybrid time-frequency domain Green approach method (HTF-GA) for the solution of dynamic problems (see [3, 4] and the references thereof), modified here to solve strongly non-linear problems comprising an explicit method.

Classical numerical time-domain integration methods for the solution of equilibrium equations in dynamic analysis are based on the use of finite difference operators (or arbitrarily defined functions), that define the variation of the unknown values of displacements, velocities and accelerations within each time interval [5]. Solution procedures that combine time and frequency domain methods have been proposed to combine computational efficiency and the ability of dealing with frequency-dependent properties and time-dependent nonlinear effects [6, 7, 8, 9]. The HTF-GA method is based on the evaluation of the Green's function of the problem by Discrete Fourier Transform, adding advanced mathematical techniques to overcome numerical problems due to discontinuous functions and periodic effects.

The extension of the hybrid HTF-GA method presented in this work may be particularly suited for complex nonlinear applications, since it solves the equations of motion implicitly in the frequency domain, without explicitly calculating response spectra. The solution is presented directly in the time domain, without the need of transforming the domain of the external loadings acting on the structure. This way, to represent nonlinear effects without recalculating the Green Function and avoiding high CPU costs, the HTF-GA method is modified to solve the dynamic equation with the elastic forces placed at the right hand side. This means that the elastic forces are evaluated by the convolution integral of the method.

The resulting method may be classified as an explicit method, which will be particularly useful for instance on transient applications with severe nonlinear behavior. In comparison to current standard frequency-domain solution procedures, the main advantages of the hybrid method will be its ability to deal with highly nonlinear problems without compromising computational efficiency, and preserving all the advantages of a time-frequency method.

2 FORMULATION

It is well known [5, 10] that the spatial discretization via the Finite Element Method yields a set of second-order "semi-discrete" ODE – Ordinary Differential Equations, which in turn can be discretized and solved in time by an appropriate integration algorithm. For linear problems, this ODE corresponds to the equations of motion:

$$\mathbf{M}\,\ddot{\mathbf{u}}(t) + \mathbf{C}\,\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{F}(t) \tag{1}$$

where $\ddot{\mathbf{u}}(t)$, $\dot{\mathbf{u}}(t)$ and $\mathbf{u}(t)$ are vectors containing the unknown nodal values of, respectively, accelerations,

velocities and displacements; F(t) is the vector of external loads; **M, K** and **C** are the mass, stiffness and damping matrices.

2.1 *Green function*

The Green functions $\mathbf{G}(t)$ represent the transient response of a structural system due to the application of an impulsive load $\mathbf{F}_j(t) = I_j\delta(t-\tau)$ applied at the degree of freedom j at a given time $t = \tau$ (where δ is the Dirac delta function, and $\mathbf{I}_j$ is a vector with a unit non-zero entry only at dof j).

The Fourier transform of the Dirac delta function δ is simply $1/T$, one has the following expressions for the Green function matrices expressed in terms of harmonic components:

$$\mathbf{G}(t) = \frac{1}{T}\sum_{n=0}^{N-1}\mathbf{H}_n\, e^{jn\bar{\omega}t} \tag{2}$$

$$\dot{\mathbf{G}}(t) = \frac{1}{T}\sum_{n=0}^{N-1} jn\bar{\omega}\,\mathbf{H}_n\, e^{jn\bar{\omega}t} \tag{3}$$

where the transfer function matrix $\mathbf{H}_n$ is:

$$\mathbf{H}_n = (\mathbf{K}_n + \mathbf{C}_n.j.n.\varpi - \mathbf{M}_n.n^2.\varpi^2)^{-1} \tag{4}$$

Equations (2) and (3) include consequently periodicity effects associated to a Discrete Fourier Transform. This means that to solve transient responses without periodicity effects and without the need of extending the period of the Fourier transform the HTF-GA uses an advanced mathematical formulation [3] to express the matrix of Green functions $\mathbf{G}(t)$ and its time-derivative $\dot{\mathbf{G}}(t)$ as the sum of steady-state periodic components and "corrective" components, intended to represent the effects of unsatisfied initial conditions in the discrete Fourier transform procedure.

More details of the procedure to evaluate the Green Functions without periodicity effects may be found in [3].

2.2 *Basic formulation of the HTF-GA method*

Generalizing for MDOF systems such as those governed by Eq. (1), subjected to a general loading **F**(t) and with initial conditions $\mathbf{u}(0)$ and $\dot{\mathbf{u}}(0)$, an analytical solution for the displacement vector $\mathbf{u}(t)$ can then be expressed using Green Functions, as follows:

$$\mathbf{u}(t) = \left[\dot{\mathbf{G}}(t)\mathbf{M} + \mathbf{G}(t)\mathbf{C}\right]\mathbf{u}(0) + \mathbf{G}(t)\mathbf{M}\dot{\mathbf{u}}(0) + \int_0^t \mathbf{G}(t-\tau)\,\mathbf{F}(\tau)\,d\tau \tag{5}$$

A similar expression for the velocity response $\dot{\mathbf{u}}(t)$ can be derived:

$$\dot{\mathbf{u}}(t) = \left[\ddot{\mathbf{G}}(t)\mathbf{M} + \dot{\mathbf{G}}(t)\mathbf{C}\right]\mathbf{u}(0) + \dot{\mathbf{G}}(t)\mathbf{M}\dot{\mathbf{u}}(0) - \int_0^t \dot{\mathbf{G}}(t-\tau)\,\mathbf{F}(\tau)\,d\tau \tag{6}$$

Considering the equilibrium equation for $t \neq 0$ with $\mathbf{G}(t)$ as unknown, $\mathbf{M}\ddot{\mathbf{G}}(t) + \mathbf{C}\dot{\mathbf{G}}(t) + \mathbf{K}\mathbf{G}(t) = 0$, this last equation can be written in the following alternative form:

$$\dot{\mathbf{u}}(t) = -\mathbf{G}(t)\mathbf{K}\,\mathbf{u}(0) + \dot{\mathbf{G}}(t)\mathbf{M}\dot{\mathbf{u}}(0) + \int_0^t \dot{\mathbf{G}}(t-\tau)\,\mathbf{F}(\tau)\,d\tau \tag{7}$$

In establishing a recursive time-domain step-by-step solution, equations (5) and (7) are written taking $t = \Delta t$. Thus the response for the time step in the future is provided in terms of the convolution integral between the Green functions and the external force in this interval, added to terms that depend on the previous initial conditions $\mathbf{u}(t - \Delta t)$ and $\dot{\mathbf{u}}(t - t)$.

2.3 *Extension for mild non-linear problems*

Those last equations are oriented for linear transient analysis, but the HTF-GA method can be adapted for systems with nonlinear behavior.

For linear problems, the Green function matrices can be calculated only once. This will also be the case for problems where the degree of nonlinearity is such that allows the use of a pseudo-force technique, where the nonlinear component of the internal forces $\mathbf{R}(t)$ are included in the right-hand side of the equations.

The incorporation of the pseudo-force approach in the algorithm is simple. One needs only to add the nonlinear internal forces $\mathbf{R}(t)$ to the external loadings $\mathbf{F}(t)$ in the expressions that determine the numerical convolution integrals.

3 EXTENSION TO STRONGLY NON-LINEAR PROBLEMS

Up to this point, the HTF-GA method has been formulated to deal with linear and mildly nonlinear problems, with physical properties that may be frequency-dependent, focusing on inertial or structural dynamic problems. It is well known that implicit algorithms are in general more suited for the solution of inertial problems, since they allow the use of time steps larger than those required by explicit algorithms.

On the other hand, many dynamic problems are governed by intermediate or high-frequency components, such as in the case of slender offshore structures in transient and/or accidental situations. This is the case, for instance, of moored floating platforms during the rupture of one of its mooring lines; also, of the behavior of flexible jumpers (to convey fluids between floating plafforms) with bending restrictors presenting a multi-linear behavior. These cases are characterized by transient responses with severe nonlinear behavior, exciting higher components of the response. For these problems, conventional time-integration procedures would require the use of explicit algorithms with very small time steps. The advantage of explicit

schemes lies on the fact that the dynamic equations are reduced to a system of algebraic equations where the matrix of coefficient is diagonal, therefore not requiring expensive solvers for coupled systems. However, such schemes depend on using time steps smaller than a given critical value.

Following this line of reasoning, here the HTF-GA method is modified to uncouple the matrices of the Green functions and its derivative, and incorporate the elastic response on the vector of external loads. The goal is to solve, without high computational costs, such strongly nonlinear problems.

Recalling the equations of motion expressed by Eq. (1), this goal can be achieved by adding, on both sides of the equation, the fictitious elastic term $\eta\mathbf{I}\mathbf{u}(t)$, and transferring the actual elastic term to the right-hand side:

$$\mathbf{M}\ddot{\mathbf{u}}(t)+\mathbf{C}\dot{\mathbf{u}}(t)+\eta\mathbf{I}\mathbf{u}(t)=F(t)+\eta\mathbf{I}\mathbf{u}(t)-\mathbf{K}\mathbf{u}(t) \quad (8)$$

The fictitious elastic term is comprised by the identity matrix $\mathbf{I}$ affected by a real constant η, both multiplying the vector of unknown displacements $\mathbf{u}(t)$. The purpose of this elastic term is to stabilize the transfer function of the modified system, recalling that the transfer function becomes unstable if only mass and damping terms are incorporated.

In summary, the new transfer function can be assembled from Eq (8) following a procedure similar to the presented previously, now considering the fictitious elastic term along with the mass and damping matrices. This way, the new transfer function $\mathbf{H}_n^*$, the Green matrices and its derivative ($\mathbf{G}(t)^*$, $\dot{\mathbf{G}}(t)^*$) will be diagonal, thus uncoupling the system of equations:

$$\mathbf{H}_n^* = (\eta\mathbf{I}+\mathbf{C}i.n.\varpi-\mathbf{M}(n.\varpi)^2)^{-1} \quad (9)$$

$$\mathbf{G}(t)^* = \frac{1}{T}\sum_{n=0}^{N-1}\mathbf{H}_n^*.e^{i.n.\bar{\omega}.t} \quad (10)$$

$$\dot{\mathbf{G}}(t)^* = \frac{1}{T}\sum_{n=0}^{N-1}i.n.\bar{\omega}\,\mathbf{H}_n^*.e^{i.n.\bar{\omega}.t} \quad (11)$$

The displacements and velocities will then be expressed by the following equations:

$$\mathbf{u}(t) = \left[\dot{\mathbf{G}}(t)^*\mathbf{M}+\mathbf{G}(t)^*\mathbf{C}\right]\mathbf{u}(0) + \mathbf{G}(t)^*\mathbf{M}\dot{\mathbf{u}}(0) + \int_0^t \mathbf{G}(\tau)^*\left(\mathbf{F}(t-\tau)-\mathbf{F}_u(t-\tau)+\eta\mathbf{I}\mathbf{u}(t-\tau)\right)d\tau \quad (12)$$

$$\dot{\mathbf{u}}(t) = -\mathbf{G}(t)^*\eta\mathbf{I}\mathbf{u}(0) + \dot{\mathbf{G}}(t)^*\mathbf{M}\dot{\mathbf{u}}(0) + \int_0^t \dot{\mathbf{G}}(\tau)^*\left(\mathbf{F}(t-\tau)-\mathbf{R}(t-\tau)+\eta\mathbf{I}\mathbf{u}(t-\tau)\right)d\tau \quad (13)$$

As a consequence, both the actual and fictitious elastic terms ($\mathbf{F}_u(t)=\mathbf{K}\mathbf{u}(t)$) and $\eta\mathbf{I}\,\mathbf{u}(t)$ respectively, will be incorporated on the convolution integrals for the external forces.

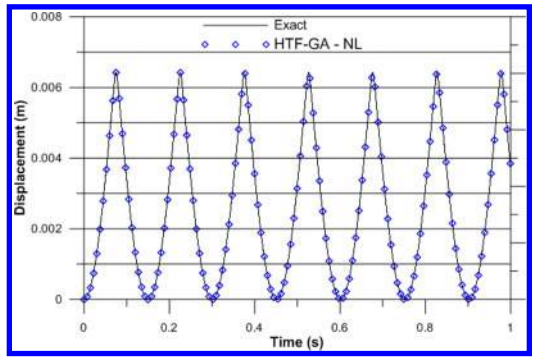

Figure 1. N-L SDOF Displacements.

It can be observed that, since $\mathbf{G}(0)^*=0$, the displacements $\mathbf{u}(t)$ are determined without the need of previously calculating the external loads, elastic forces and velocities on time t. Once $\mathbf{u}(t)$ is obtained, the elastic forces can be calculated, and then the velocity vector $\dot{\mathbf{u}}(t)$.

In general a value for the constant η can be attributed so as to make the natural periods of the modified system (with the added elastic term $\eta\mathbf{I}\mathbf{u}(t)$) greater than the natural periods of the original system.

4 CASE STUDY: SDOF SYSTEM

This section presents results for a SDOF spring-mass system, applying the new nonlinear formulation. This case represents a contact/impact condition restricting the motion of the spring. Consequently, the spring presents a nonlinear behavior, with stiffness varying with displacement, assuming an elastic bilinear spring, but with the second segment (for displacements larger than 0.006 m) presenting a much higher stiffness value, equal to 200 times the original value. The time step value is taken as $\Delta t = 0.0015$ s.

Figure 1 compares the displacements between the analytical (exact) and numerical responses. No visible difference can be observed. In the same figure, one can notice the small penetration of the system beyond the elastic contact condition, characterized by the higher stiffness value for displacements larger than 0.006 m.

5 CASE STUDY: OFFSHORE SYSTEM

This section presents results of the application of the proposed N-L HTF-GA method to solve the dynamic equations of an actual offshore engineering problem – a flexible riser that connects a floating platform to a subsea equipment to convey fluids that result from the oil exploitation procedures.

The riser, with nominal outer diameter equal to 581 mm, has a total length of 2000 m and connected to a platform installed at a water depth of 1000 m as illustrated on Figure 2. It is installed in a free-hanging catenary configuration, characterized by an angle of 7° at the top connection, between the axis of the riser and

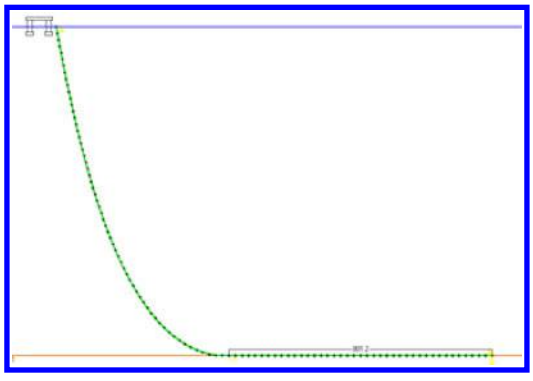

Figure 2. Flexible Catenary Riser.

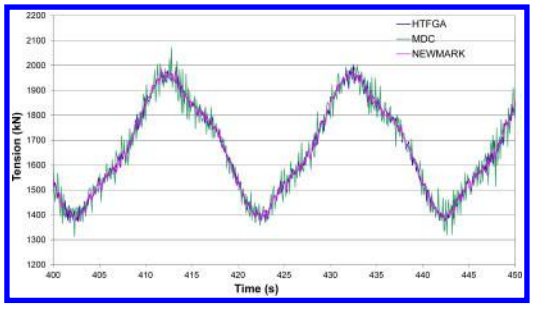

Figure 3. Riser Top Tension.

Table 1. Computational Performance (CPU times, s).

α-Newmark	Central Difference	HTF-GA
654.2	158.8	124.7

the vertical direction. The numerical model comprises a FE mesh of 500 frame elements with variable length (more refined at the top and touch-down regions).

The riser is submitted to its dead weight, marine currents, and a horizontal harmonic motion prescribed at its top. The results are expressed in terms of tensions at the top of the riser. Three algorithms are compared: the N-L HTF-GA method presented here, along with the classical Central Difference method [5], and a non-linear implementation of an implicit alpha-Newmark method with numerical damping [11, 12]. The total simulation time is 1000s, and all methods employ the time step value of 0.01 s.

Figure 3 compare the results obtained by all three methods, for a short time window of the complete response. It can be observed that the green curve, corresponding to the Central Difference method, presents considerable numerical noise, while the other two methods (alpha-Newmark and HTF-GA) presents smoother responses.

Table 1 presents the CPU times, in seconds, required for the execution of each method. It can be observed that the HTF-GA is about five times faster than the implicit alpha-Newmark method, and even faster than the explicit Central Difference method, with the additional advantage of presenting more accurate responses without spurious noise.

6 FINAL REMARKS

In this work, the HTF-GA method (originally presented in [3]) is enhanced to solve non-linear problems with the characteristics of an explicit algorithm. The main advantage of this new method is its ability to remove the stiffness matrix from the Green function, while keeping the transfer functions stable. The elastic behavior is solved by the convolution integrals of the method. Because the Green functions do not incorporate the non-linear stiffness matrix, this matrix may be calculated only once for the entire analysis, assuming the mass and damping matrix are constant; the explicit characteristic is retained (that is, the Green functions are completely decoupled) when diagonal, "lumped" mass matrices are considered.

The Green function matrices (which are characterized in the time-domain) are still implicitly determined in the frequency domain in terms of its steady-state harmonic components defined by a Fourier transform, therefore the method keeps its ability to deal with frequency-dependent mass and damping matrices.

The aspects related to causality and convergence of the Fourier series were presented in [3], where it was observed that the calculation of the Green function matrices $\mathbf{G}(\Delta t)$ and $\dot{\mathbf{G}}(\Delta t)$ also influences the accuracy of the method, depending not only on the selection of the time step Δt, but also on the adequate selection of the value N that define the number of terms in the truncated series. While the analysis of the properties of the original method was presented in [3], a detailed analysis of its new explicit form presented here will be presented in subsequent works.

The two case studies presented here were intended to illustrate the use of the N-L explicit formulation of the HTF-GA method for two different classes of dynamic problems: respectively impact and inertial (structural dynamic) problems. The results indicated that the method is able to deal with both classes of problem with good results. The method will be most suited to deal with transient problems associated to large F.E. models and strong non-linear behavior, which could not be evaluated efficiently by the standard form presented in [3].

Further studies on this line of research are being performed, and include other enhancements on the method such as adaptive time-step selection to assure the stability of the explicit N-L HTF-GA method.

ABSTRACT: The three-dimensional motions and instabilities of a clamped-free, inextensible cruciform column under axial loads are investigated in this paper. Special attention is given to the nonlinear oscillations of columns with low torsional stiffness and its influence on the bifurcations and instabilities of the structure, a problem not tackled in the previous literature on this subject. For this, the nonlinear integro-differential equations describing the flexural-flexural-torsional couplings of the column are used, together with the Galerkin method, to obtain a set of discretized equations of motion, which are in turn solved by numerical integration using the Runge-Kutta method. Both inertial and geometric nonlinearities are considered in the present analysis. Using several tools of nonlinear dynamics, a complex dynamic behavior of the column is observed near to the region where a 1:1:1 internal resonance occurs. In this region several bifurcations leading to multiple coexisting solutions, including planar and nonplanar motions are obtained. Finally, the paper shows how the tools of nonlinear dynamics can help in the understanding of the global safety and integrity of the model, thus leading to a safe structural design.

1 INTRODUCTION

The stability of slender cruciform columns under static loading has been a frequent research topic due to its low torsional stiffness and the dangerous flexural-torsional coupling in the post-buckling regime. One of the first studies on this topic was conducted by Hutchinson and Budiansky (1976). Later, Dabrowski (1988), Cimetire *et al*. (2004) and Schurig and Bertram (2011) also studied the torsional stability of cruciform columns under compressive loads and their design was discussed by Kim and Hirohata (2005) and Trahair (2012), among others. However, little is known on the nonlinear vibrations and dynamic stability of cruciform columns.These columns can, when excited, exhibit large displacements, as well as nonplanar motions, leading to various types of bifurcations, coexistence of different solutions and dynamic jumps, causing sudden changes in the stress and strain states of the structure.

When the first torsional frequency is well above the minimum flexural frequencies, a simplified two-degree-of-freedom model is used in the nonlinear nonplanar vibration analysis of slender columns (Crespo da Silva and Glynn, 1979; Nayfeh and Pai, 1989; Pai and Nayfeh, 1990; Arafat, Nayfeh and Chin, 1998). However, for a slender cruciform column the lowest torsional frequency may be of the same order as the flexural frequencies and a strong flexural-flexural-torsional coupling may occurs. In particular, for certain geometries,such as the cruciform one, a 1:1:1 internal resonance can be observed leading to a complex nonlinear dynamic behavior. Many others cross section geometries exhibit low torsional stiffness, such as cold formed steel sections (Davies, 2000), leading to similar phenomena.

To correctly describe the dynamic characteristics of slender columns with low torsional stiffness, it is necessary to consider in the equations of motion both geometric and inertial nonlinearities. Crespo da Silva and Glynn (1978a; 1978b) derived the equations of motion for a three-dimensional inextensible beam, including both types of nonlinearity. Due to its high accuracy, their formulation was the basis for several investigations (Lee *et al*, 2008; Aghababei *et al*, 2009), including the present work.

So, our aim here is, using the tools of nonlinear dynamics, to study three-dimensional motions and instabilities of a clamped-free, inextensible cruciform column under axial loads with emphasis on the influence of a static preload on the linear frequency spectrum, nonlinear frequency-amplitude relation, stability boundaries in the force control space, dynamic bifurcations and basins of attraction, thus giving a detailed description of this problem.

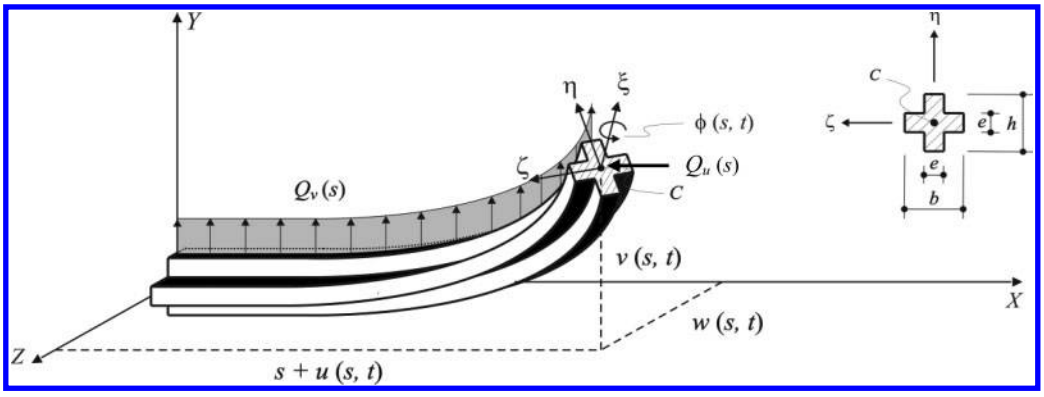

Figure 1. Coordinate systems, displacements, loads and column cross section.

2 DYNAMIC SYSTEM

A uniform, homogeneous, inextensible and initially straight column of isotropic linear elastic material, length L and mass m per unit length is considered in this analysis. A deformed column segment of length s is shown in Figure 1, where the axes X, Y and Z define the inertial rectangular coordinate system, while ξ, η and ζ denote a local orthogonal curvilinear coordinate system of the column at arc length s in the deformed configuration, which coincides with the principal axes of the column cross section.

The column has a cruciform cross section with height h, width b and wall thickness e, as shown in the Figure 1. The system is subjected to an axial load applied at the free end and given by $Q_u(t) = P_s + q_u\cos(\Omega_u t)$, where P_s is the static load and $q_u\cos(\Omega_u t)$ is a harmonic excitation with frequency Ω_u, magnitude q_u and t is the time. Additionally, in the Y direction a uniformly distributed lateral harmonic excitation defined by $Q_v(t) = q_v\cos(\Omega_v t)$ is also considered, where q_v is the excitation magnitude and Ω_v the excitation frequency.

3 EQUATIONS OF MOTION

Using only one mode approximation in the Galerkin procedure, the following third-order dimensionless PDEs equations of motion are obtained:

$$\left[\int_0^1 F_\gamma^2 ds\right]\ddot{\gamma} + \left[c_\gamma \int_0^1 F_\gamma^2 ds\right]\dot{\gamma} - \left[\beta_\gamma \int_0^1 F_\gamma'' F_\gamma \, ds\right]\gamma = \alpha_{\gamma 1}\,\gamma\, v^2 + \alpha_{\gamma 2}\,\gamma\, w^2 + \alpha_{\gamma 3}\, v\, w + \left[\alpha_{\gamma 4}\,(v\,w)^{\bullet} + \alpha_{\gamma 5}\, v\,\dot{w}\right]^{\bullet} + \alpha_{\gamma 6}\,\gamma\,\dot{v} + \alpha_{\gamma 7}\,\gamma\,\dot{w} + \alpha_{\gamma 8}\,\dot{v}\,\dot{w}\,, \tag{1}$$

$$\left[\int_0^1 F_v^2 ds - J_\zeta \int_0^1 F_v'' F_v ds\right]\ddot{v} + \left[c_v \int_0^1 F_v^2 ds\right]\dot{v} + \left[\beta_y \int_0^1 F_v^{IV} F_v \, ds + \int_0^1 [P_s + q_u \cos(\Omega_u t)]F_v F_v'' \, ds\right] v = \alpha_{v1}\,\gamma\, w + \alpha_{v2}\, v\,\gamma^2 + \alpha_{v3}\, v\, w^2 + \alpha_{v4}\, v^3 + \alpha_{v5}\left(v^2\right)^{\bullet\bullet} v + \alpha_{v6}\left(w^2\right)^{\bullet\bullet} v + \alpha_{v7}\, v^2\,\ddot{v} + \alpha_{v8}\, v\, w\,\ddot{w} + \alpha_{v9}\,\dot{w}\,\dot{\gamma} + \alpha_{v10}\, w\,\dot{v}\,\dot{w} + \alpha_{v11}\, v\left(\dot{w}\right)^2 + \alpha_{v12}\left(\dot{v}\,\gamma^2\right)^{\bullet} + \alpha_{v13}\,\gamma\,\ddot{w} + \alpha_{v14}\, v\left(\dot{v}\right)^2 + \alpha_{v15}\, w\,\dot{\gamma} + \int_0^1 F_v\, q_v \cos(\Omega_v t) ds\,, \tag{2}$$

$$\left[\int_0^1 F_w^2 ds - J_\eta \int_0^1 F_w'' F_w ds\right]\ddot{w} + \left[c_w \int_0^1 F_w^2 ds\right]\dot{w} + \left[\beta_y \int_0^1 F_w^{IV} F_w \, ds + \int_0^1 [P_s + q_u \cos(\Omega_u t)]F_w F_w'' \, ds\right] w = \alpha_{w1}\,\gamma\, v + \alpha_{w2}\, w\,\gamma^2 + \alpha_{w3}\, w\, v^2 + \alpha_{w4}\, w^3 + \alpha_{w5}\left(w^2\right)^{\bullet\bullet} w + \alpha_{w6}\left(v^2\right)^{\bullet\bullet} w + \alpha_{w7}\, w^2\,\ddot{w} + \alpha_{w8}\, w\, v\,\ddot{v} + \alpha_{w9}\,\dot{v}\,\dot{\gamma} + \alpha_{w10}\, v\,\dot{w}\,\dot{v} + \alpha_{w11}\, w\left(\dot{v}\right)^2 + \alpha_{w12}\left(\dot{w}\,\gamma^2\right)^{\bullet} + \alpha_{w13}\,\gamma\,\ddot{v} + \alpha_{w14}\, w\left(\dot{w}\right)^2\,. \tag{3}$$

Details of this formulation, not considering the axial loads, can be found in Crespo da Silva (1991), where $v = v(t)$ and $w = w(t)$ are the deflections of the column in the Y and Z directions, respectively, and $\gamma = \gamma(t)$ is the angle of torsion. The nondimensional parameters of stiffness β_y and β_γ are used and c_v, c_w and c_γ, are the linear viscous damping coefficients. The superscript ($'$) denotes partial differentiation with respect to s and the superscript ($''$) means differentiation with respect to time t. Finally, the eigenfunctions $F_v(s)$, $F_w(s)$ and $F_\gamma(s)$ are of the following form:

$$F_{v,w} = C_{v,w}\{\cosh(r_{1,3}\,s) - \cos(r_{2,4}\,s) - K_{v,w}[\sinh(r_{1,3}\,s) - (r_{1,3}/r_{2,4})\sin(r_{2,4}\,s)]\}, \quad (4)$$

$$F_\gamma = C_\gamma \sin[(\pi/2)s]. \quad (5)$$

The quantities r_1 to r_4 are obtained from the solution of the characteristic equation:

$$r_{1,3}^4 + r_{2,4}^4 + 2\,r_{1,3}^2\,r_{2,4}^2\cosh(r_{1,3})\cos(r_{2,4}) + r_{1,3}\,r_{2,4}(r_{2,4}^2 - r_{1,3}^2)\sinh(r_{1,3})\sin(r_{2,4}) = 0\,. \quad (6)$$

In the above equations α_{vi}, α_{wi} e $\alpha_{\gamma i}$ (for $i = 1, 2, 3, \ldots$) are the Galerkin coefficients (Carvalho, 2013).

4 NUMERICAL RESULTS

4.1 *Influence of the axial load on the frequency-amplitude relation*

For the numerical analysis, a column with $h/b = 1.0$, $e = 0.06b$ (see Figure 1), $L = 25b$, distributed moments of inertia $J_\eta = J_\xi = 6.8978 \cdot 10^{-5}$ and $J_\xi = 1.3796 \cdot 10^{-4}$, stiffness parameters $\beta_y = 1.0$ and $\beta_\gamma = 6.9123 \cdot 10^{-4}$, and normalized modal amplitudes $C_v = C_w = 1.0$ and $C_\gamma = 1.4142$, is adopted.

The lowest natural flexural frequencies of the unloaded column are $\omega_{0v} = \omega_{0w} = \omega_{0\gamma} = 3.5161$. Figure 2a shows that as the axial load increases the square natural frequency decreases linearly, becoming zero when the static axial load reaches its critical value, $P_{cr} = (\pi^2 EI/4L^2)$.

In addition, Figure 2b illustrates the influence of the static axial load on the nonlinear frequency-amplitude relation. The unloaded column exhibits a small degree of geometric nonlinearity with hardening behavior. As the axial load increases, the degree of geometric nonlinearity decreases, but the importance of inertial nonlinearities in the equations of motion increases. At a certain load level, the curve starts to bend to left. For high load levels, it exhibits a strong softening behavior.

The described behavior is typical of bar structures, where geometric nonlinearities lead to increasing effective stiffness, while inertial nonlinearities lead to a loss of stiffness.

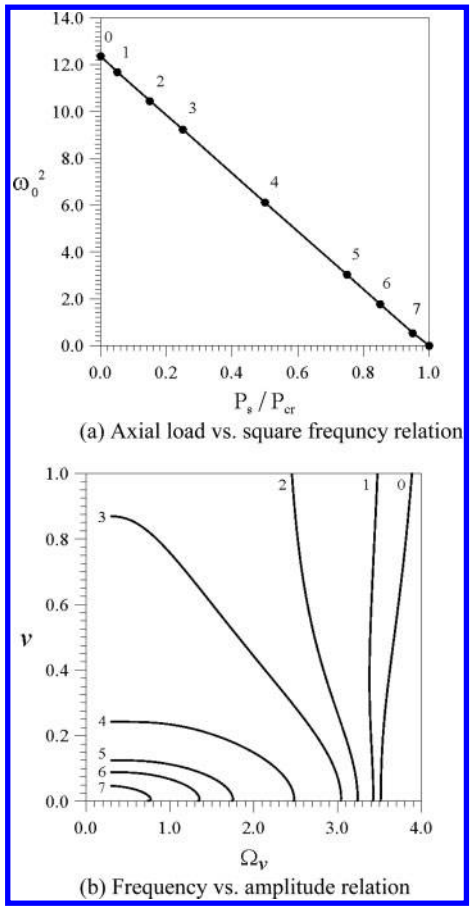

Figure 2. Influence of axial load on the lowest natural frequency and on the nonlinear frequency vs. amplitude relation.

4.2 *Parametric instability at principal and fundamental resonance regions*

Now, the nonlinear dynamic behavior of the clamped-free column subjected only to a harmonic axial load is studied.Here and in the following sections the linear viscous damping coefficients are $c_v = c_w = c_\gamma = 0.6\%$. Figure 3 shows the parametric instability boundary of the column in the excitation frequency Ω_u – excitation magnitude q_u control space.The first important parametric instability region is associated with the fundamental resonance, which occurs when the excitation frequency is equal to the lowest natural frequency ($\omega_0 = 3.5161$). The second V-shape region, on the right side, is associated with the principal parametric instability region, occurring when the excitation frequency is two times the lowest natural frequency of the column ($2\omega_0 = 7.0322$).

To understand the loss of stability and the bifurcations associated with the instability boundary, a study of the three-dimensional motions of the column in these two parametric instability regions ($\Omega_u = 2\omega_0$ and $\Omega_u = \omega_0$) is carried out.

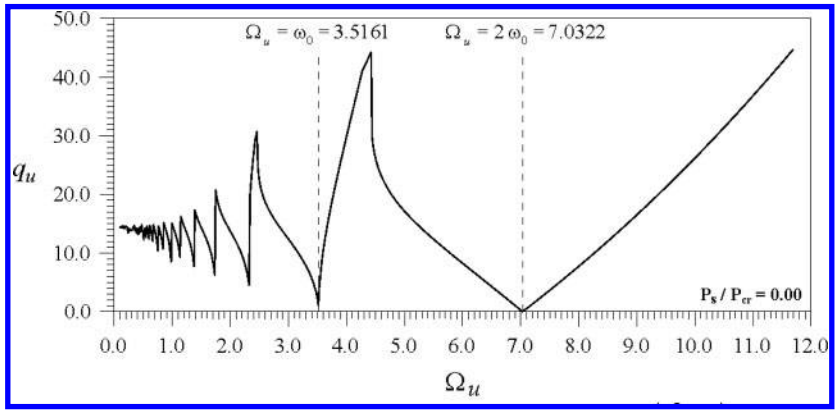

Figure 3. Parametric instability boundary in the force control space. Axial load: $q_u\cos(\Omega_u t)$.

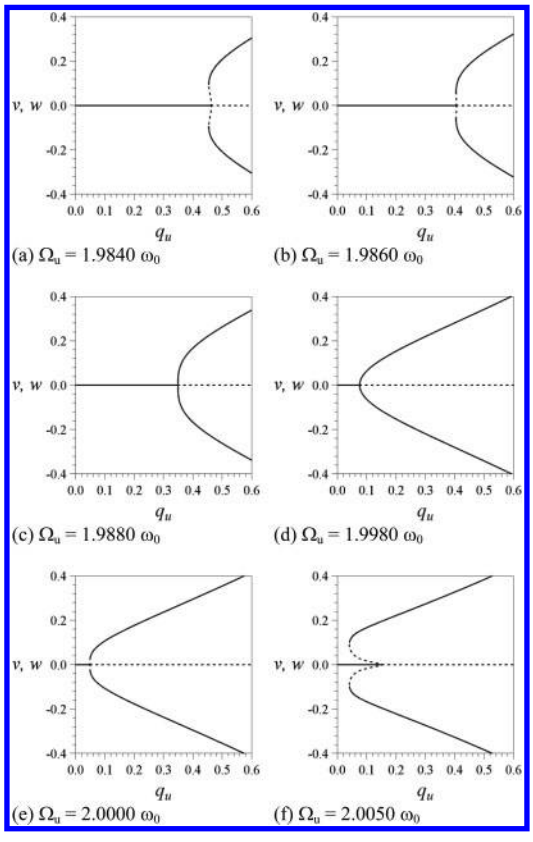

Figure 4. Bifurcation diagrams in the vicinity of the principal parametric instability region ($\Omega_u = 2\omega_0$).

As a starting point, Figure 4 displays the bifurcation diagrams for $\Omega_u \approx = 2\omega_0$. This bifurcation diagram is obtained by using the continuation algorithm and by taking the excitation magnitude q_u as control parameter.

In all cases the trivial solution (T) becomes unstable leading to a nontrivial solution (NT) with a period equal to twice of the forcing period. However, for $1.986_1\omega_0 < \Omega_u < 2.000_1\omega_0$ the trivial solution losses stability through a supercritical bifurcation, being subcritical out of this range. In addition, Figure 5 shows, at $\Omega_u = 2\omega_0$, the bifurcation diagram obtained by the use of the force brute algorithm. So, unstable solution branches are not identified in Figure 5. The transversal displacements v and w are analogous, as shown in Figure 5a. So, the angle of torsion is zero, as shown in Figure 5b.

A time history associated with the non-trivial solution (NT) is shown in Figure 6, considering $q_u = 0.70$. The period two of the non-trivial solution is confirmed by the existence of two fixed points of the Poincaré map (NT1 and NT2) shown in Figure 6b, which illustrates the three-dimensional motion of the column. Figure 7 show the bifurcation diagram for $\Omega_u = \omega_0$, which corresponds to the lowest critical load in the fundamental resonance region (see Figure 3).The trivial solution (T) becomes unstable at $q_u \approx 1.378$ where the column suffer a subcritical pitchfork bifurcation, leading to two non-trivial solutions with period equal to that of the forcing, denoted by NTA and NTBin Figure 8. Thus, between $q_u \approx 1.113$, where a saddle-node bifurcation along the nontrivial path occurs, and $q_u \approx 1.378$, threecoexistingperiodic solutions are observed (Figure 8) and the response of the structure is a function of the initialconditions.In this region the displacements v and w are no analogous due to the symmetry breaking effect of the pitchfork bifurcation. So, the angle of torsion, although small, is not zero (Figure 7b), leading to a flexural-torsional coupled motion of the structure.

4.3 *Influence of the static preload on the parametric instability boundary*

To illustrate the effect of the static preload (P_s) on the parametric instability of the system, Figure 9 shows four bifurcation diagrams for increasing values of the static preload, where, in each case, ω_0 is the lowest natural frequency of the loaded column, as shown in Figure 2a.

So, this corresponds to the lowest parametric instability load in the principal parametric resonance

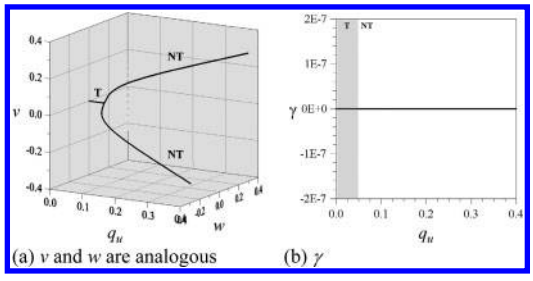

Figure 5. Bifurcation diagrams for $\Omega_u = 2\omega_0$ obtained by the force brute method.

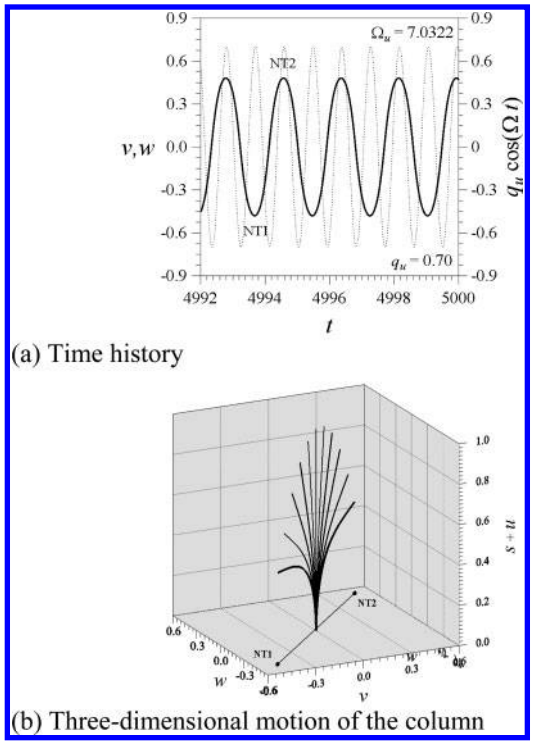

Figure 6. Time history v vs. t (analogous w vs. t) and nontrivial solution of the column (NT), considering $q_u = 0.70$ and $\Omega = 2\omega_0$.

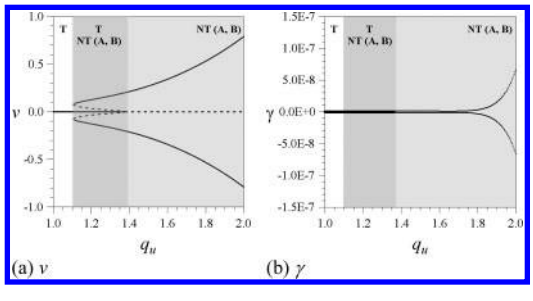

Figure 7. Bifurcation diagrams for $\Omega_u = \omega_0$.

region. These diagrams are obtained by increasing the axial load (q_u) and considering $\Omega_u = 2\omega_0$. Comparing the diagrams in Figure 9, one observes that, as P_s increases, the parametric critical load increases

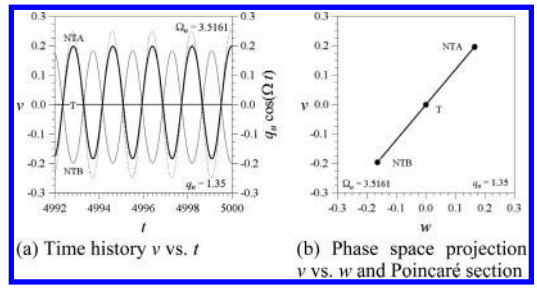

Figure 8. Stable solutions at $q_u = 1.35$ and $\Omega_u = \omega_0$.

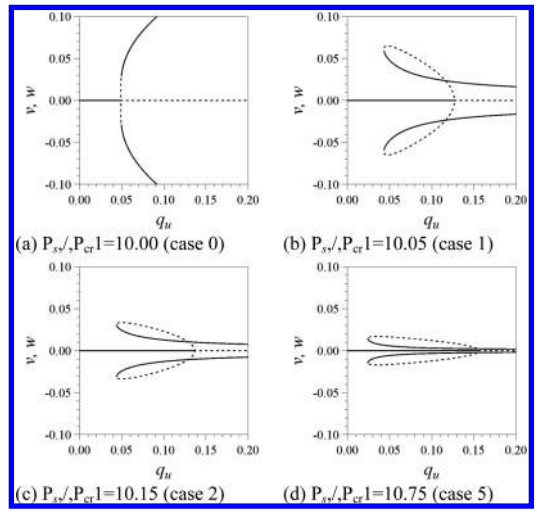

Figure 9. Bifurcation diagrams for the column under increasing static preload at $\Omega = 2\omega_0$. In each case, ω_0 is the lowest natural frequency of the loaded column.

while the load associated with the saddle-node bifurcation along the nontrivial path decreases, increasing the range of q_u where coexisting solutions can be observed.

4.4 *Influence of the static preload on the nonlinear response of the column under lateral excitation*

Next, we investigate the influence of static axial load on the dynamic nonlinear behavior of the beam under a distributed lateral harmonic excitation given by $Q_v(s) = q_v \cos(\Omega_v t) = 0.025 \cos(\Omega_v t)$ at the primary resonance region $\Omega_v = \omega_0$, applied in the Y direction (see Figure 1). Figure 10 showstwo projections of the resonance curves considering $P_s/P_{cr} = 0.00$ and $P_s/P_{cr} = 0.15$. The continuation *software* AUTO (Doedel*et al.*, 1998) is used in Figure 10a and brute force algorithm in Figure 10b.

As the static load increases, the natural frequency of the structure decreases (Figure 2) and the resonance region moves to the left, approaching zero, and most stable solution branches observed in the Figure 10a become unstable, as shown in Figure 10b for $P_s/P_{cr} = 0.15$. For this load level, a region without stable periodic solution appears. Figure 11 shows the time

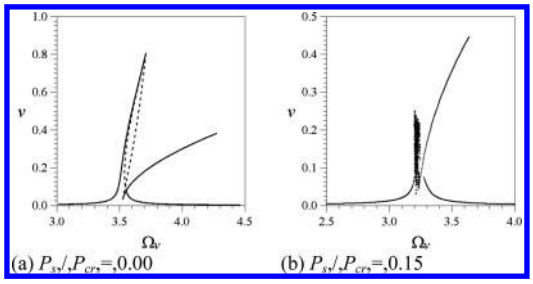

Figure 10. Influence of static preload on the resonance curvesof the column under lateral harmonic excitation ($q_v = 0.025$).

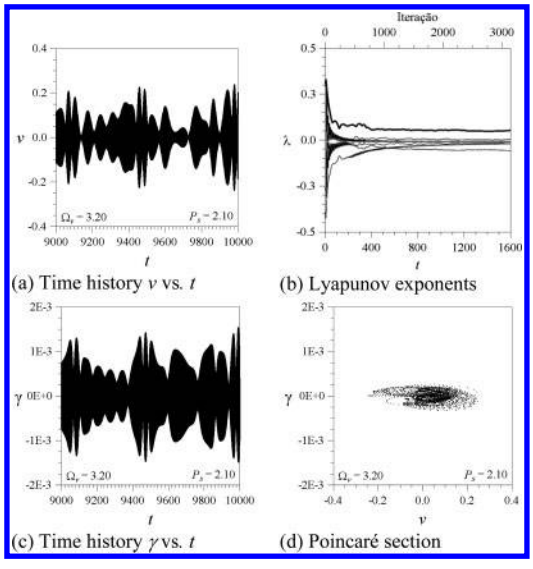

Figure 11. Characteristic chaotic response of the preloaded column. $P_s/P_{cr} = 0.15$, $q_v = 0.025$ and $\Omega_v = 3.20$.

history and the evolution of Lyapunov exponents (λ_i, for $i = 1, \ldots, , 6$) at $\Omega_v = 3.20$. At least one of the exponent is positive ($\lambda_i > 0$), characterizing the motion as chaotic.

5 CONCLUSIONS

The flexural-flexural-torsional response of a cruciform column with low torsional stiffness was investigated by taking into account geometric and inertial nonlinearities. The column geometry is such that all three lowest natural frequencies are of the same order. The column was subjected to a static preload plus a harmonic axial excitation. A bifurcation analysis shows that the static pre-load has a profound influence on the frequency-amplitude relation and on the resonance curves, which become more complex when the lateral harmonic excitation is considered. Multiplicity of solutions is observed as well as, regions without any stable periodic solution, where chaotic motions are detected.

ABSTRACT: We introduce a two-degrees-of-freedom, non-smooth model of a Jeffcott rotor with a bearing clearance. During operation, the rotor makes intermittent contact with a snubber ring with viscoelastic support. This configuration gives rise to a rich and complex dynamical behaviour, which is explored both theoretically and experimentally. This work extends the previous investigations undertaken by the CADR within University of Aberdeen to gain a deeper insight into the system response (Gonsalves et al. 1995, Karpenko et al. 2002, Karpenko et al. 2002). To this end, careful numerical simulations are carried out and then compared with experimental data obtained from a rig (see Fig. 2) previously constructed and designed at the CADR.

1 PHYSICAL AND MATHEMATICAL MODELLING

Consider a two-degrees-of-freedom rotor with a bearing clearance excited by an out-of-balance rotating mass as shown in Fig. 2. This physical setting allows the rotor to make intermittent contact with the outer snubber ring during operation. The mathematical description of the system is made under the following assumptions: the snubber ring is massless and with viscoelastic support; there is no dry friction between the rotor and the snubber ring; there are no gyroscopic forces acting on the system; and the gravity force is neglected. To derive the equations of motion, we choose the coordinate system shown in Fig. 3, centered at the static position of the snubber ring O_{s_0}. We denote by $(\varepsilon_x, \varepsilon_y)$ the eccentricity between the center of the equilibrium position of the rotor O_{r_0} and O_{s_0}. Due to the physical configuration of the system, we must have $D \leq \gamma$, where γ denotes the radial clearance between the rotor and the snubber ring. According to the physical and geometrical setting shown in Figs. 1 and 3, the equations of motion are

$$M\ddot{x}_r + c_r\dot{x}_r + k_r(x_r - \varepsilon_x) + N_{sx} = m\rho\omega^2\cos(\omega t + \theta_0), \quad (1)$$

$$M\ddot{y}_r + c_r\dot{y}_r + k_r(y_r - \varepsilon_y) + N_{sy} = m\rho\omega^2\sin(\omega t + \theta_0), \quad (2)$$

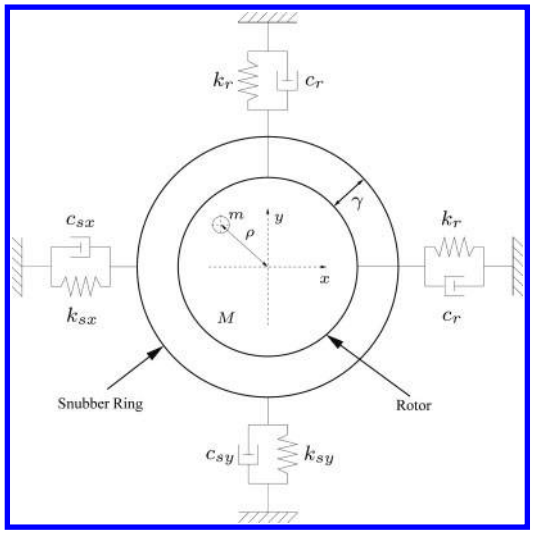

Figure 1. Physical model of a Jeffcott rotor with a snubber ring. The rotor of mass M is excited by an out-of-balance rotating mass producing a centrifugal force of magnitude $m\rho\omega^2$.

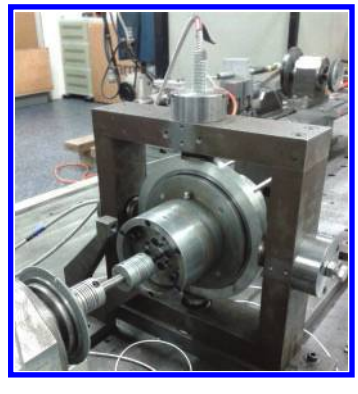

Figure 2. Photograph of the experimental setup.

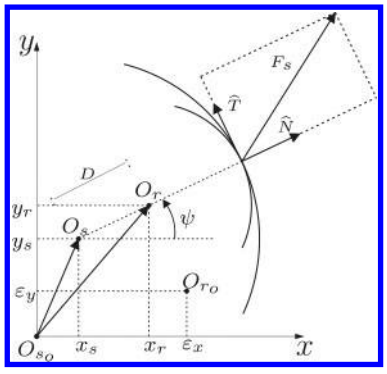

Figure 3. Geometrical representation of the force produced by the snubber ring when an impact occurs. $\widehat{T}$ and $\widehat{N}$ represent tangential and normal unit vectors, respectively, at the contact surface.

$$\dot{x}_s = \chi_t(x_r, y_r, \dot{x}_r, \dot{y}_r, x_s, y_s, k_{sx}, k_{sy}), \tag{3}$$

$$\dot{y}_s = \Upsilon_t(x_r, y_r, \dot{x}_r, \dot{y}_r, x_s, y_s, k_{sx}, k_{sy}). \tag{4}$$

Here, $(N_{sx}, N_{sy})^T = N_s$ stands for the normal force produced when the rotor hits the snubber ring. It is computed as the normal component of the snubber ring force F_s (see Fig. 3), which is given by

$$\begin{pmatrix} N_{sx} \\ N_{sy} \end{pmatrix} = \begin{cases} \begin{pmatrix} \langle F_s, \widehat{N} \rangle \cos(\psi) \\ \langle F_s, \widehat{N} \rangle \sin(\psi) \end{pmatrix}, & D \geq \gamma, \\ 0, & D < \gamma. \end{cases}$$

When there is no contact ($D < \gamma$), the equations 3 and 4 reduce to

$$k_{sx}x_s + c_{sx}\dot{x}_s = 0, \quad k_{sy}y_s + c_{sy}\dot{y}_s = 0$$

and when the snubber ring and the rotor are in contact ($D \geq \gamma$), the motion of the snubber ring is assumed to obey the Principle of Minimum Total Potential Energy and thereby χ_t and Υ_t are computed.

The mathematical model of the rotor given by the equations 1–4 defines a piecewise-smooth dynamical system, which is linear for $D < \gamma$ (i.e. no contact with the snubber ring) and nonlinear otherwise. Thus, an intermittent contact of the rotor with the snubber ring produces a complex dynamical behaviour which will be numerically and experimentally explored.

2 MAIN RESULTS

In order to validate the mathematical model experimentally, the parameters of the rig were carefully identified as follows: rotor mass $M = 10.2$ kg, vertical and horizontal eccentricities $(\varepsilon_x,\ \varepsilon_y) = (0.04,\ 0.32)$ mm, mass imbalance $m = 0.06$ kg, $\rho = 3.5$ mm, radial clearance $\gamma = 1$ mm, stiffness of the rotor $k_r = 79$ kN/m, damping of the rotor $c_r = 1.75$ kg/sec, vertical and horizontal stiffness of the Snubber ring $(k_{sx},\ k_{sy}) = (2.8,$ 4) kN/mm, vertical and horizontal damping of the snubber ring $(c_{sx},\ c_{sy}) = (55.79,\ 350.42)$ kg/sec.

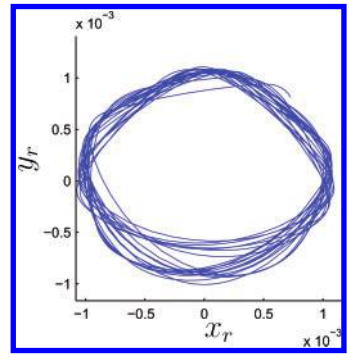

Figure 4. Numerical result: motion of the rotor center o_r showing quasi-periodic response, for the rotational frequency 16.23 Hz.

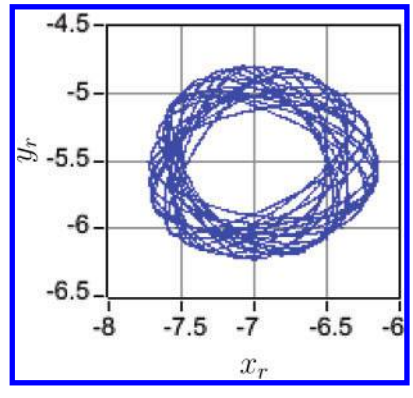

Figure 5. Experimental result: motion of the rotor center o_r (in Volts), for the rotational frequency 16 Hz.

Using the identified physical parameters, the mathematical model (1)–(4) was integrated and the phase response is shown in Fig. 4. In this picture, we can identify a quasi-periodic motion. Moreover Fig. 5 depicts the corresponding experimental results measured from the rig shown in Fig. 2, where a good agreement with the numerical simulation can be observed.

A computational study of the upper Lyapunov exponent and the uniform persistence for monotone skew-product semiflows

J.A. Calzada & R. Obaya
Departmento Matemática Aplicada, E. Ingenierías Industriales, Universidad de Valladolid, Valladolid, Spain

ABSTRACT: In this paper the authors study almost-periodic neural networks of Hopfield type given by variable delayed differential equations. They main result of the work states the stabilization role for the fast or instantaneous inhibitory self-connections. We describe a computational method based on the numerical calculus of a continuous separation that provides the upper Lyapunov exponent of the system. As an example we develope a numerical simulation of a neural network with variable delayed interconexions.

1 INTRODUCTION

The study of artificial neural networks, and in particular of its dynamics, is of great interest due to the application to different scientific and technical problems such as biological modeling, pattern recognition, cognitive simulation and engineering applications (Chua & Yang 1988a, Chua & Yang 1988b, Grossberg 1988, Wu 2001). One of the more outstanding models in artificial neural network was introduce by Hopfield (Hopfield 1982, Hopfield 1984) in terms of a system of ordinary differential equations (ODE), which describes the voltage on the input of each neuron.

A single constant delay $\tau > 0$ was introduced for the first time by Marcus and Westervelt (Marcus & Westervelt 2009) and Gopalsamy and He (Gopalsamy & He 1994) introduced the existence of several constant delays in the distinct communication channels between neurons. In the works of van den Driessche *et. al.* (van den Driessche & Zou 1998, van den Driessche, Wu, & Zou 2001) and Arratia *et al.* (Arratia, Obaya, & Sansaturio 2012) it is shown, for the case of several delays, how the specific values of τ_{ij} can change to a significant extent the dynamic of the system.

A new dynamical theory for deterministic monotone non-autonomous differential equations has recently been developed (Shen & Yi 1998, Novo, Obaya, & Sanz 2007, Novo, Obaya, & Villarragut 2009). Such equations are described using the skew-product formalism in the terms given by Sell (Sell 1967a, Sell 1967b) and Johnson *et. al* (Johnson & Moser 1982).

The objective of this work is to introduce computational methods based on the calculus of the upper Lyapunov exponent to study neural networks with variable delay.

2 PRELIMINARIES

Let us consider a non-autonomous system of delayed functional differential equations (FDE)

$$y_i' = -a_i(t)\, y_i(t) + \sum_{j=1}^{n} b_{ij}(t)\, f_j(y_j(t-\tau_{ij}(t))) + c_i(t), \quad (1)$$

which modelize a network of n neurons with decaying coefficients $a_i(t)$, delayed transmission signal coupled by a interconnection matrix $B(t) = [b_{ij}(t)]$ and external input $c_i(t)$. The matrix of delays $[\tau_{ij}(t)]$ is variable with $\tau_{ij}(t) \geq 0, i, j = 1, \cdots, n$. The coefficients $a_i(t) > \alpha > 0, \forall t$, $b_{ij}(t)$, $c_i(t)$ and delays $\tau_{ij}(t) > 0$ are almost-periodic.

We are going to apply methods of the dynamical theory of non-autonomous monotone differential equations to study the long time behaviour of the solutions of (1).

We assume the following conditions over the activation functions $f_i, i = 1, \cdots, n$

(A1) $f_i \in C^1(\mathbb{R}), f_i(0) = 0$.

(A2) $\lim_{s\to\infty} f_i(s)/s = 0$.

(A3) $0 < f_i'(s) \leq 1 = \sup_{t\in\mathbb{R}} f_i'(t)$.

We take $\tau = \max_{1\leq i,j\leq n}\{\tau_{ij}(t),\ t \in \mathbb{R}\}$ and introduce the state space $X = C([-\tau, 0], \mathbb{R}^n)$ endowed with the norm $\|x\|_\infty = \sup_{s\in[-\tau,0]} \|x(s)\|$ for every $x \in X$, which converts it into a Banach space. For each $k > 0$, $B_k = \{x \in X |\ \|x\|_\infty \leq k\}$ will represent the closed ball of center 0 and radius k. We denote by r he maximal size of external input which is physically admissible.

The standard theory of FDE (Hale 1977, Hartung & Turi 1997) provides, for every $t \in \mathbb{R}$, $t \geq 0$ and $x \in X$ a vectorial solution $y(t, x)$ of (1) with $y(s, x) = x(s)$ for all $s \in [-\tau, 0]$. From the vectorial solution we can

define the functional solution, which stores the vectorial solution during the last period of lenght τ, that is $u(t,x)(s)=y(t+s,x)$ for every $s\in[-\tau,0]$, $t\in\mathbb{R}$, $t\geq 0$. Obviously $u(0,x)=x$ for every $x\in X$.

We apply methods of the dynamical theory of monotone non-autonomous FDE (Novo, Obaya, & Villarragut 2009, Novo & Obaya 2013, Arratia, Obaya, & Sansaturio 2012) to deduce conditions which imply, for every external input, the existence of a unique almost-periodic solution which is globally exponentially stable.

For each almost-periodic function $d(t)$ we denote

$$d^+(t)=\max(d(t),0),\quad d^-(t)=\max(-d(t),0)\,.$$

and represent by $|d|_\infty=\sup\{\|d(s)\|,\ s\in\mathbb{R}\}$. We consider supplementary conditions for the FDE (1)

(A4) The diagonal delay corresponding to a non-positive coefficient b_{ii} vanish on $\mathbb{R}$; i.e. $\tau_{ii}(t)\equiv 0,\forall t\in\mathbb{R}$.

(A5) The diagonal delay corresponding to a non-positive coefficient b_{ii} is small enough, satisfying

$$0\leq\tau_{ii}(t)\leq\frac{1}{|a_i+e\,b_{ii}^-|_\infty},\quad i=1,\cdots,n$$

Let us consider the map $M:\mathbb{R}\to\mathcal{M}_{n\times 2(n+1)}$ with $M(s)=[a(s),b_{ij}(s),\tau_{ij}(s),c_i(s)]$. For every $t\in\mathbb{R}$ we take $M_t(s)=M(t+s)$. The hull of M is the set $\Omega(M)=\text{closure}\{M_t,\ t\in\mathbb{R}\}$ for the compact open topology. This is a compact set where is defined a continuous flow $\sigma:\mathbb{R}\times\Omega\to\Omega$, $\omega\mapsto\omega\cdot t$ by time translation (see Novo & Obaya 2013, Arratia, Obaya, & Sansaturio 2012).

We consider the family of FDE on the hull

$$y_i'=-a_i(\omega\cdot t)\,y_i(t)+\sum_{j=1}^{n}b_{ij}(\omega\cdot t)\,f_j(y_j(t-\tau_{ij}(\omega\cdot t)))+c_i(\omega\cdot t)\,, \tag{2}$$

Following the arguments of van den Driessche, Wu, & Zou 2001 and Arratia, Obaya, & Sansaturio 2012 we introduce a set of new variables given by $y_{n+i}=-y_i$, $i=1,\ldots,n$, and taking the new activation functions $g_i(x)=-f_i(-x)$, for every $x\in\mathbb{R}$, $i=1,\ldots,n$, we obtain the extended family of FDE ($i=1,\ldots,n$)

$$\begin{aligned}y_i'=&-a_i(\omega\cdot t)\,y_i(t)+b_{ii}(\omega\cdot t)\,f_i(y_i(t-\tau_{ii}(t)))\\&+\sum_{\substack{j=1\\j\neq i}}^{n}b_{ij}^+(\omega\cdot t)\,f_j(y_j(t-\tau_{ij}(t)))\\&+\sum_{\substack{j=1\\j\neq i}}b_{ij}^-(\omega\cdot t)\,g_j(y_{n+j}(t-\tau_{ij}(t)))+c_i(\omega\cdot t)\end{aligned}$$

$$\begin{aligned}y_{n+i}'=&-a_i(\omega\cdot t)\,y_{n+i}(t)+b_{ii}(\omega\cdot t)\,g_i(y_{n+i}(t-\tau_{ii}(t)))\\&+\sum_{\substack{j=1\\j\neq i}}^{n}b_{ij}^+(\omega\cdot t)\,g_j(y_{n+j}(t-\tau_{ij}(t)))\\&+\sum_{\substack{j=1\\j\neq i}}b_{ij}^-(\omega\cdot t)\,f_j(y_j(t-\tau_{ij}(t)))-c_i(\omega\cdot t)\,,\end{aligned}$$

which satisfies all the conditions (A1)–(A5) stated before. If we set $\tilde{y}_1=(y_1,\ldots,y_n)\in\mathbb{R}^n$, $\tilde{y}_2=(y_{n+1},\ldots,y_{2n})\in\mathbb{R}^n$ and $\tilde{y}=(\tilde{y}_1,\tilde{y}_2)\in\mathbb{R}^{2n}$, we can represent the family of FDE in short form by

$$\begin{cases}\tilde{y}_1'=\tilde{F}_1(\omega\cdot t,\tilde{y}_t)+C(\omega\cdot t)\\ \tilde{y}_2'=\tilde{F}_2(\omega\cdot t,\tilde{y}_t)-C(\omega\cdot t)\end{cases} \tag{3}$$

Let us introduce the extended phase space $\tilde{X}=C([-\tau,0],\mathbb{R}^{2n})=X\times X$. For each $\omega\in\Omega$ and $\tilde{x}\in X$, $\tilde{y}(t,\omega,\tilde{x})$ will denote the vectorial solution of (3) for $t\geq 0$ with $\tilde{y}(s,\omega,\tilde{x})=\tilde{x}(s)$ for all $s\in[-\tau,0]$. Likewise $\tilde{u}(t,\omega,\tilde{x})$ will represent the functional solution defined by $\tilde{u}(t,\omega,\tilde{x})(s)=y(t+s,\omega,\tilde{x})$, $s\in[-\tau,0]$.

If the FDF (1) satisfies (A1)–(A3) and (A4) then the solutions of (3) satisfies monotony properties for the standard ordering: that is if $\tilde{x}_1,\tilde{x}_2\in\tilde{X},\tilde{x}_1\leq\tilde{x}_2$ for the standard order then $\tilde{u}(t,\omega,\tilde{x}_1)\leq\tilde{u}(t,\omega,\tilde{x}_2)$ for every $t\geq 0$, $\omega\in\Omega$.

Next we describe a different order which is technically more complex but it is important in applications. Let $D=(d_{ij})$ a real matrix with $d_{ij}\geq 0$ for every $1\leq i,j\leq n$. We introduce the definition of the D-exponential ordering on X. If $x_1,x_2\in X$ $x_1\leq_D x_2\Leftrightarrow x_1\leq x_2$ and it is verified for $-\tau\leq s\leq t\leq 0$.

$$(x_2(t)-x_1(t))\geq e^{D(t-s)}(x_2(s)-x_1(s)),$$

If the FDE (1) satisfies (A1)–(A3) and (A5) then the solution of (3) satisfies monotony properties for the exponential ordering, that is if $\tilde{x}_1\leq_D\tilde{x}_2$ then $\tilde{u}(t,\omega,\tilde{x}_1)\leq_D\tilde{u}(t,\omega,\tilde{x}_2)$ for $t\geq 0$, $\omega\in\Omega$.

It is clear that $x(t)$ is an almost-periodic solution of (2) through $\omega\in\Omega$ if and only if $\tilde{x}(t)=(x(t),x(t))$ is an almost-periodic solution of (3) through $\omega\in\Omega$.

For each $k\in\mathbb{R}$ we denote by $\bar{k}_m=(k,\ldots,k)\in\mathbb{R}^m$ and by $\hat{k}_m\in C([-\tau,0],\mathbb{R}^m)$ the constant function $\hat{k}_m(s)=\bar{k}_m$ for every $s\in[-\tau,0]$.

We define $\rho(r)$ as the inferior of all the real positive numbers k_1 such that for every $k\geq k_1$

$$\begin{aligned}&\tilde{F}_1(\omega,\hat{k}_{2n})<<-\bar{r}_n,\qquad \tilde{F}_2(\omega,\hat{k}_{2n})<<-\bar{r}_n,\\&\bar{r}_n<<\tilde{F}_1(\omega,-\hat{k}_{2n}),\qquad \bar{r}_n<<\tilde{F}_2(\omega,-\hat{k}_{2n})\,,\end{aligned} \tag{4}$$

where $<<$ means that the strong inequality verifies for all the components of the vector.

Let us consider $r\geq 0$. We define for $i=1,\cdots,n$

$$\delta_i(r)=\inf\{f_i'(s)|\ |s|\leq\rho(r)\}>0\,. \tag{5}$$

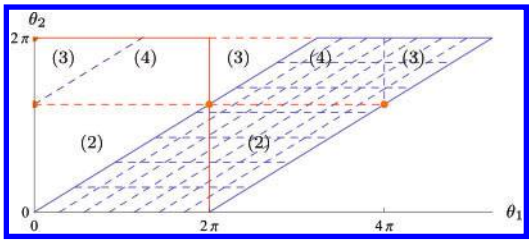

Figure 1. Equivalence of $\mathbb{T}^2$ and $\mathcal{R}$ as base space for flux construction.

It is proved (Arratia, Obaya, & Sansaturio 2012) that if $x(t)$ is an almost-periodic solution of (1) then $\|x\|_\infty \leq \rho(r)$.

We introduce the linear FDE (LFDE) that will be used to control the size of the solutions of the linearized equations of the FDE (1)

$$\begin{aligned} z_i' = & -a_i(\omega\cdot t)\, z_i(t) \\ & + [b_{ii}(\omega\cdot t) - \delta_i(r) b_{ii}(\omega\cdot t)]\, z_i(t-\tau_{ii}(\omega\cdot t)) \\ & + \sum_{j=1}^{n} |b_{ij}(\omega\cdot t)| z_j(t-\tau_{ij}(\omega\cdot t))\,. \end{aligned} \tag{6}$$

For each $\omega\in\Omega$ and $x\in X$, $z(t,\omega,x)$ will denote the vectorial solution of (6) with $z(s,\omega,x) = x(s)$, for all $s\in[-\tau,0]$ and $v(t,\omega,x)$, with $v(t,\omega,x)(s) = z(t+s,\omega,x)$, for all $s\in[-\tau,0]$ and $t\geq 0$, will represent the corresponding functional solution.

The solution of (6) satisfies the same conditions of monotony mentioned for (3).

We now state the main result of this section that is a version, for a neural network with variable delays, of theorem 5.1 of Arratia, Obaya, & Sansaturio 2012.

Theorem 1.
Let us assume that the FDE (1) verifies (A1)–(A3) and one of the conditions of (A4) or (A5). If the LFDE (6) is uniformly exponentially stable then for every arbitrary input $C(t) = (c_1(t),\ldots,c_n(t))$ with $\|C\|_\infty \leq r$ there is an unique almost-periodic solution of (1) $e:\mathbb{R}\to\mathbb{R}^n$ such that for all $k>0$ there are constants $\kappa,\alpha>0$ fulfilling

$$\| u(t,x) - e(t) \| \leq \kappa\, e^{-\alpha t} \| x \|, \tag{7}$$

for every $x\in B_k$, $t\in\mathbb{R}$ with $t\geq 0$.

This results confirms the stabilization role for the fast or instantaneous inhibitory self-connetions. The objetive of this work is to describe computational methods based on the numerical calculus of a continuous separation, that provides the upper Lyapunov exponent of (3). In particular if this exponent is negative (3) is uniformly exponentially stable and the conclusions of the previous statement applies.

3 NUMERICAL SIMULATION

In order to illustrate the results of the work we consider the non-autonomous system of FDE with variable delay given by

$$\begin{aligned} y_1'(t) = & [-1+0.3\cos(\alpha t)]\, y_1(t) \\ & + [-1.5+\sin(t)]\, \tanh(y_1(t)) \\ & + [1.4-\sin(t)]\, \tanh[y_2(t-(2-\cos(t)))] + c_1(t) \end{aligned} \tag{8}$$

$$\begin{aligned} y_2'(t) = & [-1+0.3\sin(\alpha t)]\, y_2(t) \\ & + [-1.3+0.3\cos(t)]\, \tanh[y_1(t-(2-\cos(t)))] \\ & + [-1+0.3\cos(t)]\, \tanh[y_2(t)] + c_2(t)\,, \end{aligned}$$

where $\alpha = (\sqrt{5}-1)/2$ and $c_i(t)$, $i=1,2$ are the external inputs with $c_i(t) = d_i + d_i^\star \sin(\alpha t)$, $i=1,2$ and $\|c_1\|_\infty$, $\|c_2\|_\infty \leq 0.3$. This equations verify conditions (A1)–(A3).

If we consider the map $M:\mathbb{R}\to\mathcal{M}_{2\times 4}(\mathbb{R})$

$$M(s) = \begin{pmatrix} a_1(s) & b_{11}(s) & b_{12}(s) & \tau(s) & c_1(s) \\ a_2(s) & b_{21}(s) & b_{22}(s) & \tau(s) & c_2(s) \end{pmatrix}$$

being a_i, b_{ij} and c_i the elements of formula (1) and $\tau(t)$ the variable delay present in the system. The hull of M is homeomorphic to the 2-torus $\mathbb{T}^2$ and a flow can be obtained by time translation (Cornfeld, Fomin, & Sinay 1982, Arratia, Obaya, & Sansaturio 2012)

$$\begin{aligned} \sigma : \mathbb{R}\times\mathbb{T}^2 &\longrightarrow \mathbb{T}^2 \\ (t,\theta_1,\theta_2) &\mapsto (\theta_1,\theta_2)\cdot t = (\theta_1+\alpha t, \theta_2+t)\,. \end{aligned}$$

Under this flux the orbits in $\mathbb{T}^2$ are dense and $(\mathbb{T}^2,\sigma)$ is uniquely ergodic: that is admits a unique invariant meausure. Let us consider, as a more suitable base space for the flux, the rhomboid

$$\mathcal{R} = \{(\theta_1,\theta_2) = (x_0+\alpha t, t), \quad x_0, t\in[0, 2\pi]\},$$

defined by translation of $\mathbb{T}^2$ and which is constituted by trajectories of the system. This change can be done by the 2π-periodicity of the system as can be seen in figure 1.

Finally the flux $(\mathcal{R},\sigma)$ and the flux $(\mathbb{T}^2,\sigma)$ are homeomorphic.

Let us consider the following family of FDE defined over the hull, $y' = F((\theta_1,\theta_2)\cdot t, y_t)$, given by

$$\begin{aligned} y_1'(t) = & [-1+0.3\cos(\theta_1+\alpha t)]\, y_1(t) \\ & + [-1.5+\sin(\theta_2+t)]\, \tanh(y_1(t)) \\ & + [1.4-\sin(\theta_2+t)]\, \tanh[y_2(t-(2-\cos(\theta_2+t)))] \\ & + c_1((\theta_1,\theta_2)\cdot t) \end{aligned} \tag{9}$$

$$\begin{aligned} y_2'(t) = & [-1+0.3\sin(\theta_1+\alpha t)]\, y_2(t) \\ & + [-1.3+0.3\cos(\theta_2+t)]\, \tanh[y_1(t-(2-\cos(\theta_2+t)))] \\ & + [-1+0.3\cos(\theta_2+t)]\, \tanh[y_2(t)] + c_2((\theta_1,\theta_2)\cdot t) \end{aligned}$$

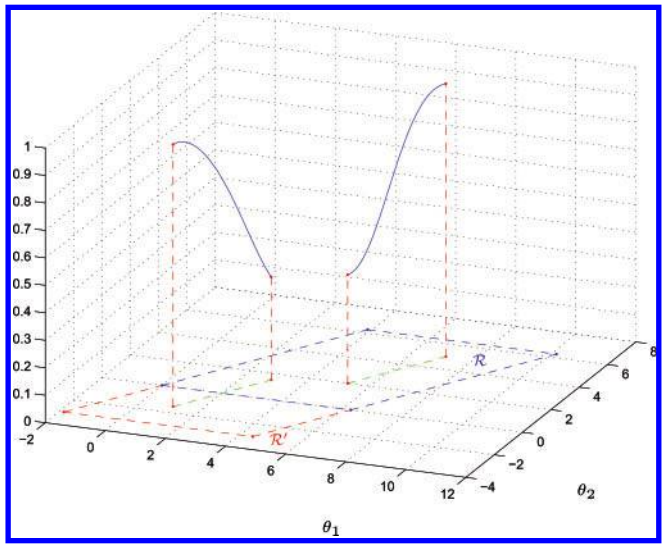

Figure 2. Vectorial solutions defined over the extended rhomboid $\mathcal{R}'$ (dashed blue and red line) and the corresponding functional solutions defined over the rhomboid $\mathcal{R}$ (dashed blue line).

whose solutions induce the skew-product semiflow

$$\varphi : \mathbb{R}_+ \times \mathcal{R} \times X \longrightarrow \mathcal{R} \times X$$
$$(t, \theta, x) \mapsto (\theta_1 + \alpha t, \theta_2 + t, u(t, \theta, x))$$

where $X = C([-\tau, 0], \mathbb{R}^2)$. Let $\tilde{y}(t, \omega, \tilde{x})$ denote the vectorial solution of (9). The functional solution $\tilde{u}(t, \omega, \tilde{x})$ is obtained by means of the vectorial solution $y(t, \theta, x)$ in the point ω and τ units of time backwards across the trayectory (see figure 2)

$$u(t, \theta, x)(s) = y(t + s, \theta, x), \quad s \in [-\tau, 0], t \geq 0.$$

In order to represent this solution we have introduced the extended rhomboid (full graph in the plane θ_1–θ_2 of figure 2)

$$\mathcal{R}' = \{(x_0 + \alpha t, t), \quad x_0 \in [0, 2\pi], t \in [-\tau, 2\pi]\}.$$

The system (8) is the element of this family corresponding to $(\theta_1, \theta_2) = (0, 0)$. We embed this family into a four dimensional group of FDE fullfiling conditions (A1)–(A5) defining new variables $y_3 = -y_1$ and $y_4 = -y_2$ and taking new activation functions $g_i(x) = -f_i(-x)$, $i = 1, 2$

$$\begin{aligned}
&g_i(x) = -f_i(-x),\ i = 1, 2\\
&y_1'(t) = [-1 + 0.3\cos(\theta_1 + \alpha t)]\, y_1(t)\\
&\quad + [-1.5 + \sin(\theta_2 + t)]\tanh(y_1(t))\\
&\quad + [1.4 - \sin(\theta_2 + t)]\tanh[y_2(t - (2 - \cos(\theta_2 + t)))]\\
&\quad + c_1((\theta_1, \theta_2) \cdot t)
\end{aligned}$$

$$\begin{aligned}
y_2'(t) &= [-1 + 0.3\sin(\theta_1 + \alpha t)]\, y_2(t)\\
&\quad + [1.3 - 0.3\cos(\theta_2 + t)]\tanh[y_3(t - (2 - \cos(\theta_2 + t)))]\\
&\quad + [-1 + 0.3\cos(\theta_2 + t)]\tanh[y_2(t)] + c_2((\theta_1, \theta_2) \cdot t)\\
y_3'(t) &= [-1 + 0.3\cos(\theta_1 + \alpha t)]\, y_3(t)\\
&\quad + [-1.5 + \sin(\theta_2 + t)]\tanh(y_3(t))\\
&\quad + [1.4 - \sin(\theta_2 + t)]\tanh[y_4(t - (2 - \cos(\theta_2 + t)))]\\
&\quad + c_1((\theta_1, \theta_2) \cdot t)\\
y_4'(t) &= [-1 + 0.3\sin(\theta_1 + \alpha t)]\, y_4(t)\\
&\quad + [-1 + 0.3\cos(\theta_2 + t)]\tanh[y_4(t - (2 - \cos(\theta_2 + t)))]\\
&\quad + [1.3 - 0.3\cos(\theta_2 + t)]\tanh[y_1(t)] + c_2((\theta_1, \theta_2) \cdot t)
\end{aligned} \tag{10}$$

which in a short form can be written as

$$\begin{cases} \tilde{y}_1' = \tilde{F}_1(\theta \cdot t, \tilde{y}_t) + C(\theta \cdot t) \\ \tilde{y}_2' = \tilde{F}_2(\theta \cdot t, \tilde{y}_t) - C(\theta \cdot t) \end{cases}$$

where $\tilde{y}_1 = (y_1, y_2)$ and $\tilde{y}_2 = (y_3, y_4)$ and $\tilde{F}_i : \mathbb{R} \times X \to \mathbb{R}$, $i = 1, \ldots, 4$ are the components of the field. The system (10) is monotone for the usual ordering.

We are going to determine the variation region for the almost-periodic solution. Let us consider $r = 0.3$. In order to find the value of $\rho(0.3)$ given by (4) we must find the inferior of $k > 0$ verifying simultaneously the following inequalities

$$\begin{cases} -0.7k - 0.1\tanh k \leq -0.3 \\ -0.7k + 0.3\tanh k \leq -0.3, \end{cases}$$

A direct calculus let us obtain $\rho(0.3) = 0.6828810924$. Taking in to account the definiton of δ_i, $i = 1, 2$ in (5) and the fact that, in this case, the values of $\delta_1 = \delta_2$, we get

$$\delta(0.3) = 1 - \tanh^2[\rho(0.3)] = 0.6478892387.$$

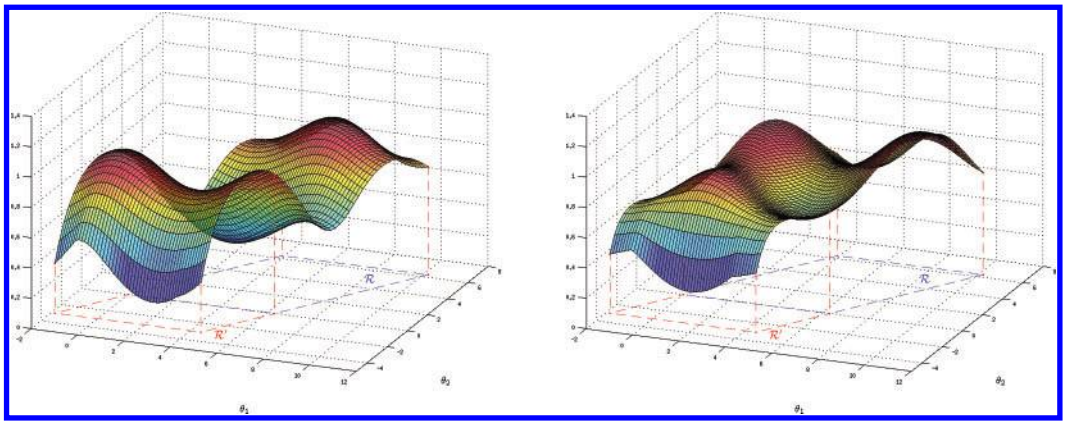

Figure 3. Vectorial and functional solutions for the first (right image) and second (left image) component of system (11). In both figures we represent the rhomboid $\mathcal{R}$ (dashed blue line) and the extended rhomboid $\mathcal{R}'$ (dashed blue and red line).

The family of LFDE given by (9) is

$$\begin{aligned} z_1' &= -[1-0.3\cos(\theta_1+\alpha t)+\delta(0.3)\,(1.5-\sin(\theta_2+t))]\,z_1(t) \\ &\quad +[1.4-\sin(\theta_2+t)]\,z_2[t-(2-\cos(\theta_2+t))] \qquad (11) \\ z_2' &= -[1-0.3\sin(\theta_1+\alpha t)+\delta(0.3)\,(1-.3\cos(\theta_2+t))]\,z_2(t) \\ &\quad +[1.3-0.3\cos(\theta_2+t)]\,z_1[t-(2-\cos(\theta_2+t))]\,. \end{aligned}$$

The solutions of the LFDE (11) define a linear skew-product semiflow $\eta{:}\mathbb{R}_+ \times \mathcal{R} \times X \to \mathcal{R} \times X$ that is monotone for the standard ordering and admits a continuous separation of type II in terms given by Novo *et al.* (Novo, Obaya, & Sanz 2013b). We remark that this concept introduce a slight modification of the classical concept given by Poláčik *et al.* (Poláčik & Tereščák 1993) that does not require the strong monotony of the semiflow and finds specific application in the case of finite delay FDE. This means that the existence of subspaces $\{X_1(\theta_1,\theta_2)\}_{(\theta_1,\theta_2)\in\mathcal{R}}$, $\{X_2(\theta_1,\theta_2)\}_{(\theta_1,\theta_2)\in\mathcal{R}}$ satisfies the following properties

(S1) $X_1 = X_1(\theta_1,\theta_2) \oplus X_2(\theta_1,\theta_2)$ and $X_1(\theta_1,\theta_2)$, $X_2(\theta_1,\theta_2)$ vary continously in K

(S2) $X_1(\theta_1,\theta_2) = \mathrm{span}\{x(\theta_1,\theta_2)\}$ with $x(\theta_1,\theta_2) \gg 0$ and $\|x(\theta_1,\theta_2)\| = 1$ for any $(\theta_1,\theta_2) \in K$.

(S3) there exits a $t_0 > 0$ such that if for some $(\theta_1,\theta_2) \in \mathcal{R}$ there is a $z \in X_2(\theta_1,\theta_2)$ with $z > 0$ then $v(t,\theta_1,\theta_2,z) = 0$ for any $t \geq t_0$

(S4) for any $t > 0$, $(\theta_1,\theta_2) \in \mathcal{R}$
$$v(t,\theta_1,\theta_2)\,X_1(\theta_1,\theta_2) = X_1(\eta(t,\theta_1,\theta_2))$$
$$v(t,\theta_1,\theta_2)\,X_2(\theta_2,\theta_2) \subset X_2(\eta(t,\theta_1,\theta_2))$$

(S5) there are $M > 0$, $\delta > 0$ such that for any $(\theta_1,\theta_2) \in \mathcal{R}$, $z \in X_2(\theta_1,\theta_2)$ with $\|z\| = 1$ and $t > 0$,
$$\| v(t,\theta_1,\theta_2,z) \| \leq M e^{-\delta t} \| v(t,\theta_1,\theta_2,x(\theta_1,\theta_2)) \|\,.$$

We are interested in the calculus of the upper Lyapunov exponent for this system. For this purpose first we calculate the main direction $X_1(\theta_1,\theta_2)$. The vectorial solution, $z((\theta_1,\theta_2)\cdot t)$ for all $(\theta_1,\theta_2) \in \mathcal{R}'$ and t in an adequate interval, is given by the integration of (11). For this numerical integration we use the Matlab *ddesd* solver for delay differential equations with general delays (Shampine 2005). This routine belongs to a family of Runge-Kutta based methods endowed with a interpolating scheme so not only the solution in final integration point is achive but also a continous extension along the integration interval. This methods estimate and bound not the local error on each integration step but the defect of the continuous extension (Enright 1989). In this way the achived accuracy is independent of the method itself.

Calculating this integration for the points of $\mathcal{R}'$ we obtain the surfaces of figure 3 (for the two components of the solution). The second type of solution is the functional one $v(\theta_1,\theta_2)(s) = z((\theta_1,\theta_2)\cdot s)$ for all $s \in [-\tau, 0]$. This solution is obtained integrating over the rhomboid $\mathcal{R}$.

Using general theoretical results of uniform persistence related to a minimal set of a monotone skew-product semiflow (Novo, Obaya, & Sanz 2013b, Novo, Obaya, & Sanz 2013a) and the numerical method of Calzada *et al.* (Calzada, Obaya, & Sanz 2013) we are going to calculate numericaly the upper Lyapunov exponent for this system.

The exponent is calculated by means of a double integration along the rhomboid $\mathcal{R}$. The first integration develops for lines crossing the rhomboid's base at a point $x_0 \in [0, 2\pi]$. For one of this lines we start the integration and let pass a enough quantity of time to assure we are in $X_1(\theta_1,\theta_2)$ when we arrive at the rhomboid's base point $(x_0, 0)$, $x_0 \in [0, 2\pi]$. Then we integrate along the 2π length time interval to reach the top of the rhomboid. The second integration is made in x_0 variable and gives us the final estimation of the Lyapunov exponent (Calzada, Obaya, & Sanz 2013).

For the external inputs $c_1 = 0.3$ and $c_2 = -0.3$ we have obtained a value for the upper Lyapunov exponent of $\lambda = -0.00437662$. So for every arbitrary input $c(\omega)$ such that $\|c(\omega)\| \leq 0.3$ there is a continuous invariant function $e{:}\Omega \to X$ such that for every $(\omega, x) \in \Omega \times X$ (see theorem 5.1 in Arratia, Obaya, & Sansaturio 2012)

$$\lim_{t\to\infty} \| u(t,\omega,x) - e(\omega\cdot t) \| = 0\,,$$

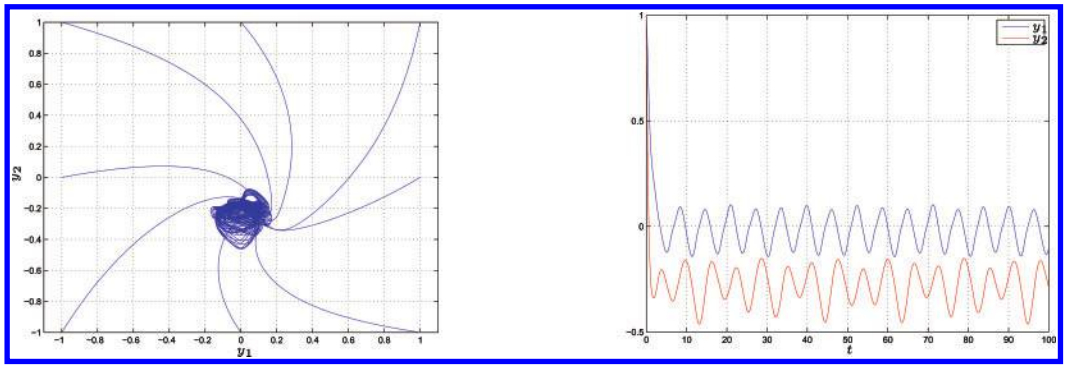

Figure 4. Numerical simulation for solutions of FDE (9). We show the trajectories proyected over the (y_1, y_2) plane (left image) for $0 \leq t \leq 100$ and on the plane (y_1, t) (right image).

The family of FDE (9) has only one minimal set of the phase space and the solutions of (1) are asymptotically almost-periodic. The exponential convergence in theorem 1 depends on the value of constant $-\alpha$ (which is equal to the Lyapunov exponent) given by (7). In our example the near to zero value for the exponent justifies the slow exponential convergence in the short term (see fig. 4).

Vibrations of cables with bending stiffness by an asymptotic approach

T. Canor

V. Denoël
ArGEnCo Department, Structural Engineering Division, University of Liege, Belgium

ABSTRACT: Vibrations of cables with a small bending stiffness concerns many engineering applications such as the fatigue assessment of stay cables. With the Finite Element (FE) method, the analysis can be performed with nonlinear truss elements, but bending effects are not taken into account. Otherwise, beam elements can be used, but the smallness of the bending stiffness may lead to numerical instability and mediocre results in boundary regions.

In this context, the paper presents an alternative method to calculate the time evolution of the profile of bending moments in boundary layers of cables, avoiding heavy FE analysis. The developments combine the theory of vibrations of extensible rods with asymptotic methods. The equations are decoupled between the slow dynamics of the boundary regions and the fast dynamics of the span. Then, a composite solution is constructed by means of a matched asymptotic procedure.

1 INTRODUCTION

The vibration analysis of cables with a small bending stiffness is a problem encountered in many engineering applications such as the fatigue assessment of stay cables (cable stayed bridges or prestressed concrete beams), the modeling of pipeline laying operation or the determination of bending stresses in drillpipe assemblies. The elastic theory of rods models the static and dynamic deflections of general elastic beams and cables (Antman 2005, Coleman et al. 1993). However, the smallness of the bending stiffness leads to consider a singularly perturbed equations and the existence of boundary layers near the anchors (Hinch 1991). In these small regions, the curvature and the bending moment change sharply compared with the rest of the cable especially. This phenomenon is magnified for clamped beams. Standard numerical techniques fail to solve these problems efficiently.

Static deflection of cables with a small bending stiffness is a widely covered topic. A matched asymptotic expansion has been used (Stump & van der Heijden 2000) to study the spatial deflection of a bent and twisted inextensible cable. Denoël & Detournay (2010) propose an application of multiple scales methods to study a beam with a small bending stiffness, offering a better accuracy for a larger range of bending stiffness than the matched asymptotic method. From another viewpoint, Denoël & Canor (2013) have developed a patching method allowing to quantify the size of the boundary layer of the cable using an Eulerian description of a catenary in the span and a nonlinear beam model in the boundary layers.

Concerning nonlinear vibration of cables, the finite element method widely used in structural dynamics presents some weaknesses. The use of nonlinear truss elements (Impollonia et al. 2011) neglects completely the bending effects, while nonlinear beam elements may lead to instability because of the smallness of the bending stiffness. Mediocre results can be obtained for indirect excitations in boundary layers. These zones in which the bending moment increases sharply, require an expensive mesh refinement with small elements which leads to increase the computational burden or to have ill-conditioned systems. In the range of analytical or semi-analytical methods, Stump & Fraser (2000) have used matched asymptotic expansion to study the boundary layer behaviour of moving strips in a steady state deflection (no inertial forces). Pellicano et al. (1998) study the dynamical behaviour of an axially moving beam with hinged extremities: a linear modal analysis associated with matched asymptotic expansion allows to decouple quite efficiently the equation of the beam, eventhough the potential nonlinear bending behaviour is not considered. The modal analysis for cable with small bending stiffness is also presented in the works of Ricciardi et al. (2008) and Lacarbonara et al. (2008). The modal approach may seem attractive, nevertheless the complex analytical shape of modes is a drawback just to take into account small

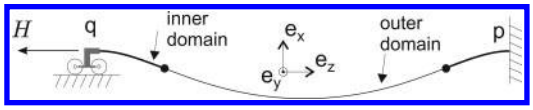

Figure 1. Sketch of problem.

perturbations in the boundary regions. Furthermore, modal analysis of slack cables is usually based on rough approximations.

As an alternative to numerical methods and modal analysis, provided the complexity of the analytical developments does not preclude their application, these problems may be tackled with appealing analytical procedures such as matched asymptotic or multiple scales methods (Hinch 1991). This work proposes to start with classical theory of rod vibration and to use the potentiality of asymptotic methods to derive an efficient and smart formulation to analyse the vibration of taut and clamped cable with bending stiffness as sketched in Figure 1.

2 FORMULATION OF THE PROBLEM

2.1 *Theory of extensible rods*

The classical theory of rods (Antman 2005) models the motion of elastic structures submitted to external forces in large displacements and large rotations. The rod deflection is described with a configuration vector $\mathbf{r}(s,t)$ which defines a curve $C(t)$. The variable s identifies the position of a material point of the rod in the stress-free reference configuration $\mathbf{r}^0(s)$, while t denotes the time. The function $\mathbf{r}(s,t) : [0, l] \times \mathbb{R}^+ \to \mathbb{R}^3$ is a continuous function with l the length of the rod in $\mathbf{r}_0(s)$. The tangent vector to $C(t)$, noted $\partial s\mathbf{r}$, is defined as the strain vector $\mathbf{v}$ such that $\partial s\mathbf{r} = \mathbf{v}$. The norm of $\mathbf{v}$ is usually called the *stretch*.

A local basis, different from the Frenet basis related to the curve $C(t)$ at a point s, is usually introduced. The cross section is determined by the orientation of two orthogonal vectors $\tilde{\mathbf{d}}_1(s,t)$ and $\tilde{\mathbf{d}}_2(s,t)$. The local basis is completed by the definition of a third vector $\tilde{\mathbf{d}}_3(s,t) = \tilde{\mathbf{d}}_1 \times \tilde{\mathbf{d}}_2$ which is normal to the surface of the cross section of the rod. If the rod in unshearable but extensible, the strain vector in the local basis has a single component defined such that $\mathbf{v} = [0, 0, 1 + v_3]^T$ with $v_3 \in [-1, +\infty]$ the strain in the axial direction of the rod.

The dynamics of rods is modelled by a set of partial differential equations in space and time. The conservation of linear and angular momenta yields

$$\partial_s \mathbf{N} + \mathbf{F} = \rho A \partial_t^2 \mathbf{r} \tag{1}$$

$$\partial_s \mathbf{M} + \partial_s \mathbf{r} \times \mathbf{N} = \rho I \left(\tilde{\mathbf{d}}_1 \times \partial_t^2 \tilde{\mathbf{d}}_1 + \tilde{\mathbf{d}}_2 \times \partial_t^2 \tilde{\mathbf{d}}_2 \right) \tag{2}$$

where $\mathbf{M}(s,t)$ and $\mathbf{N}(s,t)$ are the vectors of internal moments and forces for a material point s at a time t, respectively. Furthermore, ρ, A and I are the mass density of the beam material, the cross section area and the second moment of area per unit of reference length. The parameters of the cable are independent of t and s. The section is supposed to be circular, so the second moment of area is independent of $\tilde{\mathbf{d}}_1$ and $\tilde{\mathbf{d}}_2$ as principal axes.

The conservation of planar cross section, or the Euler-Bernoulli hypothesis (Bernoulli 1694), is commonly assumed in rods and cables when the shear forces do not induce significant strain energy. The constitutive equation for internal moments with this assumption yields

$$\mathbf{M} = EI \left(\kappa_1 \tilde{\mathbf{d}}_1 + \kappa_2 \tilde{\mathbf{d}}_2 \right) + GJ\kappa_3 \tilde{\mathbf{d}}_3 \tag{3}$$

with E the Young modulus, G the shear modulus, GJ torsional stiffness, $\kappa_{1,2}$ the curvature in the direction $\tilde{\mathbf{d}}_{1,2}$ and κ_3 the twist density. The constitutive equation for internal forces takes into account the extensibility and the unshearability of the rods, such that

$$N_3 = EAv_3. \tag{4}$$

At this stage, because of the assumption of unshearability, the complete set of 9 equations involves 9 unknowns, which leads to a well-posed problem.

2.2 *Euler angles*

Euler angles (Antman 2005, Coleman et al. 1993) can be interpreted as a generalization of the spherical coordinates. In the theory of elastic rods, they are often used because they provide an efficient description of the orientation of a cross section compared with a reference system, in spite of some drawbacks, as discontinuities. The method consists in mapping the fixed basis $\{\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z\}$ with the local basis of the cross section by a set of three successive rotations of angles $\psi(s,t)$ (precession), $\theta(s,t)$ (nutation) and $\varphi(s,t)$ (spin). In the reference configuration $\mathbf{r}^0(s)$, the axis of the rod lies on the $\mathbf{e}_z$-axis and the two principal axes of the cross section are parallel to $\mathbf{e}_x$- and $\mathbf{e}_y$-axes.

The first two rotations match the vector $\mathbf{e}_z$ with the unit vector $\tilde{\mathbf{d}}_3(s,t)$ normal to the cross section of the rod. In spherical coordinates, this normal vector reads

$$\tilde{\mathbf{d}}_3 = \cos\psi \sin\theta \mathbf{e}_x + \sin\psi \sin\theta \mathbf{e}_y + \cos\theta \mathbf{e}_z. \tag{5}$$

The two unit vectors $\tilde{\mathbf{d}}_1(s,t)$ and $\tilde{\mathbf{d}}_2(s,t)$ at abscissa s are contained in a plane perpendicular to $\tilde{\mathbf{d}}_3(s,t)$. The transformation between the fixed basis and the local basis is completed by a last rotation $\phi(s,t)$ around $\tilde{\mathbf{d}}_3(s,t)$ such that $\tilde{\mathbf{d}}_1(s,t)$ and $\tilde{\mathbf{d}}_2(s,t)$ are expressed in terms of $\psi(s,t)$, $\theta(s,t)$ and $\phi(s,t)$ (see (Antman 2005)). At this stage, the nine components of the local basis depend on three angles only. The curvature vector in terms of Euler angles reads

$$\begin{aligned} \boldsymbol{\kappa} = {} & (\sin\phi\partial_s\theta - \cos\phi\sin\theta\partial_s\psi)\tilde{\mathbf{d}}_1 + (\cos\phi\partial_s\theta \\ & + \sin\phi\sin\theta\partial_s\psi)\tilde{\mathbf{d}}_2 + (\cos\theta\partial_s\psi + \partial_s\phi)\tilde{\mathbf{d}}_3. \end{aligned} \tag{6}$$

However, because the cable is reasonably assumed to have a circular cross section, the orientation of $\tilde{\mathbf{d}}_1(s,t)$ and $\tilde{\mathbf{d}}_2(s,t)$ is independent of the rotation $\phi(s,t)$, because every couple of orthogonal unit vectors normal to $\tilde{\mathbf{d}}_3(s,t)$ are principal axes (Coleman et al. 1993). A new local basis may be defined by imposing a clockwise rotation $\phi(s,t)$ around $\tilde{\mathbf{d}}_3(s,t)$ to the couple $\tilde{\mathbf{d}}_1(s,t)$ and $\tilde{\mathbf{d}}_2(s,t)$, such that

$$\mathbf{d}_1 = \cos\psi\cos\theta\mathbf{e}_x + \sin\psi\cos\theta\mathbf{e}_y - \sin\theta\mathbf{e}_z \quad (7)$$

$$\mathbf{d}_2 = -\sin\psi\mathbf{e}_x + \cos\psi\mathbf{e}_y \quad (8)$$

and $\mathbf{d}_3 = \tilde{\mathbf{d}}_3$. The same clockwise rotation imposed to the curvature vector yields

$$\boldsymbol{\kappa} = (\cos\theta\partial_s\psi + \partial_s\phi)\mathbf{d}_3 + \partial_s\theta\mathbf{d}_2 - \sin\theta\partial_s\psi\mathbf{d}_1. \quad (9)$$

2.3 *Dimensionless formulation*

A dimensionless formulation is introduced. Dimensionless vectors, variables and parameters are mentioned with Greek letters and bar symbols. The material coordinate s is scaled with respect to the stressfree rod length l, such as $\xi = s/l$ with $\xi \in [0, 1]$. The internal and external forces $\mathbf{N}$ and $\mathbf{F}$ are scaled by the total weight of the rod wl and the bending moment $\mathbf{M}$ is scaled by wl^2; w is the weight per unit of length. This choice is motivated by the time-invariance of w and l. The dimensionless time τ is obtained by scaling the time t with a reference period $T_1 = \sqrt{l/g}$ with g the gravitational acceleration. The dimensionless bending stiffness is given by $\varepsilon^2 = EI/wl^3$ and the position vector $\mathbf{r}$ is scaled by l. A parameter $\varepsilon_b = wl/EA$ is introduced in the constitutive equation of extensibility and a parameter γ is defined as the ratio between the torsional stiffness GJ and the bending stiffness EI.

The kinematic condition of unshearability but extensibility implies $\partial_\xi\bar{\mathbf{r}} = (1+v_3)\mathbf{d}_3$ and the curvature vector becomes

$$\bar{\boldsymbol{\kappa}} = (\cos\theta\partial_\xi\psi + \partial_\xi\phi)\mathbf{d}_3 + \partial_\xi\theta\mathbf{d}_2 - \sin\theta\partial_\xi\psi\mathbf{d}_1 \quad (10)$$

with $\bar{\kappa} = l\kappa$. Then, the equations of motion become

$$\partial_\xi\bar{\mathbf{N}} + \bar{\mathbf{F}} = \partial_\tau^2\bar{\mathbf{r}} \quad (11)$$

$$\partial_\xi\bar{\mathbf{M}} + \partial_\xi\bar{\mathbf{r}}\times\bar{\mathbf{N}} = \varepsilon^2\varepsilon_b\left(\mathbf{d}_1\times\partial_\tau^2\mathbf{d}_1 + \mathbf{d}_2\times\partial_\tau^2\mathbf{d}_2\right) \quad (12)$$

and the constitutive equations read

$$v_3 = \varepsilon_b\bar{N}_3 \quad (13)$$

$$\bar{\mathbf{M}} = \varepsilon^2\left(\bar{\kappa}_1\mathbf{d}_1 + \bar{\kappa}_2\mathbf{d}_2\right) + \varepsilon^2\gamma\bar{\kappa}_3\mathbf{d}_3 \quad (14)$$

Dimensionless variables offer the opportunity to compare efficiently the parameters of the problem. A cable is a structural element between a rod and a string. A string is supposed to be perfectly flexible and extensible ($\varepsilon = 0$), contrarily to a rod, a more complex element which is flexible, shearable and extensible. A cable is supposed to be an extensible rod with a small bending stiffness, i.e. ε is a small parameter. For classical cable structures made up of steel cables, the Young modulus of the material is so high that the ratio ε_b between the axial stiffness and the weight of the cable is also a small parameter.

For the sake of simplicity, the bar over all the dimensionless variables is deliberately omitted in the following developments.

3 ASYMPTOTIC APPROACH

3.1 *Outer solution*

The equation of motion in the outer domain is obtained by supposing that the bending effects are small in this region. In this domain, a regular asymptotic expansion in terms of ε for all variables of the problem reads

$$\mathbf{w} = \mathbf{w}_c + \varepsilon\mathbf{w}_{c,1} + \varepsilon^2\mathbf{w}_{c,2} + \ldots \quad (15)$$

with $\mathbf{w}(\xi, \tau)$ a generic vector representing the vectors $\mathbf{N}$, $\mathbf{F}$, $\mathbf{r}$ or the Euler angles.

After injecting Eq. (15) into Eq. (11) and Eq. (12), the leading order equation reads

$$\partial_\xi(\mathbf{N}_c) + \mathbf{F}_c = \partial_\tau^2\mathbf{r}_c \quad (16)$$

with the subscript c referring to the leading order in the outer domain. Equation (16) is the classical form of the equation of motion of extensible strings. The unshearability assumption in the angular momentum equation leads to $N_{c,1} = N_{c,2} = 0$. Euler angles in the outer domain are $\theta_c(\xi,\tau)$ and $\psi_c(\xi,\tau)$. The methods to solve this equation are numerous, as finite element method (Impollonia et al. 2011) or modal analysis (Warnitchai et al. 1995). The modal approach is probably less accurate, because it usually neglects the axial displacements and is limited to nonlinear vibrations of taut cables. The modal analysis assumes also synchronous vibration of material points.

3.2 *Inner solution*

The assumption of clamped-clamped beams (Fig. 1) explains the existence of two boundary layers at both anchors. To analyse the behaviour of the cable in these two boundary layers, a stretched coordinate ζ is introduced $\xi = \varepsilon\zeta$, modelling the fast variation of the curvature close to the anchors. This stretched variable $\zeta \in [0, \varepsilon^{-1}]$ is introduced in the equations of motion.

For the equilibrium equation in rotation, the rotational inertial forces are three orders of magnitude less than the variation of the bending moment in the boundary layer and they are thus neglected. Equation (12) becomes

$$\varepsilon^{-1}\partial_\zeta\mathbf{M} + (1+v_3)\mathbf{d}_3\times\mathbf{N} = \mathbf{0} \quad (17)$$

because of the kinematic equation. The stretched variable ζ is also introduced in the constitutive equation of $\mathbf{M}$ through the curvature vector κ, Eq. (10) becomes

$$\varepsilon\boldsymbol{\kappa} = (\cos\theta\partial_\zeta\psi + \partial_\zeta\phi)\mathbf{d}_3 + \partial_\zeta\theta\mathbf{d}_2 - \sin\theta\partial_\zeta\psi\mathbf{d}_1. \quad (18)$$

With Eq. (18) and Eq. (14), Eq. (17) becomes

$$\begin{cases} \partial_\zeta(\sin\theta\partial_\zeta\psi) + (1+v_3)N_2 & = 0 \\ \partial_\zeta^2\theta + (1+v_3)N_1 & = 0 \end{cases} \quad (19)$$

and $\partial_\zeta\kappa_3 = 0$, this latter one meaning that the twist moment is constant along the cable in the boundary layer, $\kappa_3 = \kappa_3^\star$. Actually, the twist moment is constant all along the rod, because of the hypothesis of unshearability.

Introducing the stretched variable in Eq.(11) yields

$$\partial_\zeta\mathbf{N} = \varepsilon\left(\partial_\tau^2\mathbf{r} - \mathbf{F}\right). \quad (20)$$

The right-hand side must be analysed more precisely to evaluate the real order of the inertial forces and the external forces. If no concentrated load acts in the boundary layer and if the external forces are at most of the same order of magnitude as wl, the term $\varepsilon\overline{\mathbf{F}}$ is at least of order ε.

The magnitude of the inertial forces requires more attention. The use of the stretched variable leads actually to consider two different problems in the outer and in the inner domains. The matched asymptotic approach is just a method to compose a solution. Therefore, the equation of motion can be considered separately in the boundary layer and in the span. The characteristic time scale in the boundary layer is not the same as in the span. Indeed, the boundary layer may be considered as a cantilever beam with a dimensionless length of ε (Denoël & Canor 2013), a unit dead load per unit length and a bending stiffness of ε^2. The ratio of the characteristic time in the inner domain τ_b and the one in the outer domain is thus of order ε (Clough & Penzien 1993). Because of the smallness of ε, the period τ_b corresponds to the period of a very rigid structure. Using a multiple scales approach in time, the time τ can be split into two contributions $\tau_1 = \tau$ related to the span and τ_2 related to the boundary layer with $\tau_2 = \varepsilon\tau$. The inertial forces read now

$$\partial_\tau^2\mathbf{r} = \partial_{\tau_1}^2\mathbf{r} + 2\varepsilon\partial_{\tau_1\tau_2}^2\mathbf{r} + \varepsilon^2\partial_{\tau_2}^2\mathbf{r} \quad (21)$$

and the conservation of linear momentum becomes

$$\partial_\zeta\mathbf{N} = \varepsilon\partial_{\tau_1}^2\mathbf{r} + 2\varepsilon^2\partial_{\tau_1\tau_2}^2\mathbf{r} - \varepsilon\mathbf{F} + \mathcal{O}(\varepsilon^3). \quad (22)$$

with $\mathbf{N}$ now a function of τ_1, τ_2 and ζ.

A regular asymptotic expansions in term of ε for all variables of the problem reads

$$\mathbf{u} = \mathbf{u}_0 + \varepsilon\mathbf{u}_1 + \varepsilon^2\mathbf{u}_2 + \ldots \quad (23)$$

with $\mathbf{u}(\zeta, \tau)$ a generic vector representing the vectors $\mathbf{N}$, $\mathbf{F}$, $\mathbf{r}$ or the Euler angles. With Eq. (23) into Eq. (20), the leading order of $\mathbf{N}$ is given by

$$\partial_\zeta\mathbf{N}_0 = \mathbf{0} \quad (24)$$

which is equivalent to disregard the external forces and the inertial forces in the boundary layer at a lower order of magnitude. This result must be understood with regard to the presumed small dimension of the boundary layer and that the forces are distributed along the cable in a quite regular manner, as the dead load and the inertial forces. The smallness of τ_b compared with τ_1 means also a quasi-static response of the boundary layer to an excitation at period close to τ_1. This short comment aims to explain intuitively that the boundary layer responds in a quasi-static manner with regard to the fast dynamics of the outer domain.

The leading order of the internal forces $\mathbf{N}_0$ can be projected in the leading order basis $\{\mathbf{d}_{1,0}, \mathbf{d}_{2,0}, \mathbf{d}_{3,0}\}$, and especially

$$N_2 = \mathbf{N}_0 \cdot \mathbf{d}_{2,0} = -\sin\psi_0 N_x + \cos\psi_0 N_y \quad (25)$$

with N_x, N_y and N_z the projections of $\mathbf{N}_0$ in a fixed basis $\{\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z\}$. These components are constant in this basis because of Eq. (24). Therefore, $\partial_\zeta N_2 = 0$ is only satisfied if ψ_0 is also constant in the boundary layer. The curvature vector is $\varepsilon\kappa = \partial_\zeta\theta_0\mathbf{d}_{2,0} + \partial_\zeta\varphi_0\mathbf{d}_{3,0}$ and the angular momentum equation reads

$$\partial_\zeta^2\theta_0 + (1+v_3)N_1 = 0 \quad (26)$$

and $N_2 = 0$. So, the constant $\psi_0 \in [0, 2\pi]$ is determined as $N_y = N_x \tan\psi_0$. The use of reciprocal function leads to discontinuity in the calculation of ψ_0. From a computational viewpoint, it is more convenient to calculate $\psi_0 = \arctan\left(\frac{N_y}{N_x}\right)$ and to adapt ψ_0 according to the signs of N_x and N_y.

Therefore, the equilibrium equation for the bending moment and the extensibility constitutive equation become

$$\partial_\zeta^2\theta_0 + (1+v_3)(V\cos\theta_0 - H\sin\theta_0) = 0 \quad (27)$$

$$v_3 = \varepsilon_b(V\sin\theta_0 + H\cos\theta_0) \quad (28)$$

with $V = (\cos\psi_0 N_x + \sin\psi_0 N_y)$ and $H = N_z$. These developments highlight two interesting results which make our approach very elegant: (i) the quasi-static response of the boundary layer avoid the computation of spatial beam dynamics, (ii) the low frequency oscillations in the boundary layer are contained in a plane characterized by the angle ψ_0, (iii) the torsion is decoupled from the bending dynamics.

By multiplying Eq. (27) by $\partial_\zeta\theta_0$, a first integral is found, such as

$$\begin{aligned} A(\tau) &= \frac{1}{2}(\partial_\zeta\theta_0)^2 + (H\cos\theta_0 + V\sin\theta_0) \quad (29) \\ &+ \frac{\varepsilon_b}{2}\left(\frac{(H^2 - V^2)}{2}\cos 2\theta_0 + VH\sin 2\theta_0\right) \end{aligned}$$

with $A(\tau)$ a first integration constant, which is determined by using the van Dyke's rule (Hinch 1991). The matching condition is usually formulated as the inner limit of a given variable equals the outer limit of this variable, such that

$$\left(\lim_{\varepsilon\to 0} y_{in}(\tau,\zeta)\right)_{\xi \text{ fixed}} = \left(\lim_{\xi\to 0} y_{out}(\tau,\xi)\right)_{\varepsilon \text{ fixed}} \quad (30)$$

with y a variable of the system. This equality leads to identify the internal forces $\mathbf{N}_0$ in the boundary layer to the reactions at the anchors calculated with the string dynamics and the angle ψ_0 to the rotation angle of the string at the anchor, such as

$$\lim_{\varepsilon\to 0,\xi \text{ fixed}} \mathbf{N}_0(\zeta,\tau) = \lim_{\xi\to 0,\varepsilon \text{ fixed}} \mathbf{N}_c(\xi,\tau) = \mathbf{N}_{c,p}(\tau) \quad (31)$$

$$\lim_{\varepsilon\to 0,\xi \text{ fixed}} \psi_0(\zeta,\tau) = \lim_{\xi\to 0,\varepsilon \text{ fixed}} \Psi(\xi,\tau) = \Psi_p(\tau) \quad (32)$$

with the subscript p denoting the anchor at $\xi = 0$. Concerning the rotation angle θ_0 in the plane orthogonal to $\mathbf{d}_2$, we have

$$\lim_{\varepsilon\to 0,\xi \text{ fixed}} \theta_0(\zeta,\tau) = \lim_{\xi\to 0,\varepsilon \text{ fixed}} \vartheta(\xi,\tau) = \vartheta_p(\tau) \quad (33)$$

$$\lim_{\varepsilon\to 0,\xi \text{ fixed}} \partial_\zeta\theta_0(\zeta,\tau) = \lim_{\xi\to 0,\varepsilon \text{ fixed}} \partial_\zeta\vartheta(\xi,\tau) = 0. \quad (34)$$

The constant $A(\tau)$ is calculated with these two matching conditions. Furthermore, if we note that $V = H\tan\vartheta_p$ which comes from Euler angles in the string dynamics, the equation in θ_0 becomes

$$\frac{1}{2}\left(\partial_\zeta\theta_0\right)^2 = 2f_p\sin^2\left(\frac{\Delta\theta_0}{2}\right) + \varepsilon_b\frac{f_p^2}{2}\sin^2\left(\Delta\theta_0\right) \quad (35)$$

or, in a differential formalism,

$$\frac{d\theta_0}{\sin\left(\frac{\Delta\theta_0}{2}\right)\sqrt{1+\varepsilon_b f_p\cos^2\left(\frac{\Delta\theta_0}{2}\right)}} = \pm 2\sqrt{f_p}d\zeta \quad (36)$$

with $\Delta\theta_0 = \theta_0 - \vartheta_p$ and $f_p(\tau) = \frac{H}{\cos\vartheta_p}$. A direct integration leads to

$$-\frac{1}{\sqrt{1+\varepsilon_b f_p}}\operatorname{arctanh}\left(\frac{\sqrt{2(1+\varepsilon_b f_p)}\cos\left(\frac{\Delta\theta_0}{2}\right)}{\sqrt{2+\varepsilon_b f_p+\varepsilon_b f_p\cos\left(\Delta\theta_0\right)}}\right) = \pm\sqrt{f_p}\zeta + B(\tau) \quad (37)$$

with $B(\tau)$ a second integration constant. For usual cable, the term $\varepsilon_b f_p$ which expresses the ratio between the tension in the cable and the axial stiffness, is small. According to some classical hyperbolic function properties, an explicit expression for θ_0 can be approximated by

$$\theta_0(\zeta,\tau) = \vartheta_p(\tau) + 4\arctan\left(B(\tau)\exp\left(\pm\sqrt{f_p\left(1+\varepsilon_b f_p\right)}\zeta\right)\right) \quad (38)$$

Only the minus sign is kept for stability reasons. The constant $B(\tau)$ can be calculated by imposing the rotation angle at the anchor p, such that

$$B(\tau) = \tan\left(\frac{\theta_p - \vartheta_p(\tau)}{4}\right) \quad (39)$$

with $\theta_p = \theta_0(0,\tau)$ the imposed boundary condition.

A composed solution can be expressed all along the beam in term of the initial space variable ξ, such that

$$\theta_0(\xi,\tau) = \vartheta(\xi,\tau) + 4\arctan\left(B(\tau)\exp\left(-\frac{\xi}{\varepsilon}\sqrt{f_p\left(1+\varepsilon_b f_p\right)}\right)\right) + 4\arctan\left(B(\tau)\exp\left(-\frac{1-\xi}{\varepsilon}\sqrt{f_q\left(1+\varepsilon_b f_q\right)}\right)\right) \quad (40)$$

with the subscript q denoting the anchor at $\xi = 1$.

4 APPLICATIONS

4.1 *In-plane vibration*

The first application aims at validating the previous developments by studying the response of a horizontal cable submitted to harmonic horizontal displacement of the anchor q (see Figure 1). In this example, the vibrations are contained in the vertical plane to simplify the comparison at this first stage.

The dimensionless properties of the system are $\varepsilon = 0.02$ and $\varepsilon_b = 5.6\cdot 10^{-5}$. The static deflection is characterized by a sag-to-span ratio equal to 5‰. The excitation is the function $2\cdot 10^{-4}\sin(2\omega_1\tau)$ with ω_1 the dimensionless natural circular frequency of the cable equal to 3.3. In this example, a classic analysis with beam finite elements is compared to the proposed approach in which the string dynamic is computed with truss finite elements. The bending moment at the anchors is calculated according to Eq. (40) and $M(\xi) = \varepsilon^2\partial_\xi\theta_0$. In this application, 70 elements are considered for the beam model against 30 for the truss model. Nonlinear corrotational finite elements are used in the numerical simulations. For the beam model, the mesh is adapted to be denser in the boundary regions. Because the number of nodes and the number of DOF per node are reduced, the computational time is drastically reduced between the truss and the beam models.

Furthermore, the instabilities susceptible to appear in the boundary layers are avoided.

Figure 2 highlights the good correspondence between the two methods. The values of the bending moment are identical in both applications, in spite of a short shift between the two time series, explained by the important sensitivity of the transient phase to the natural frequency and the damping model.

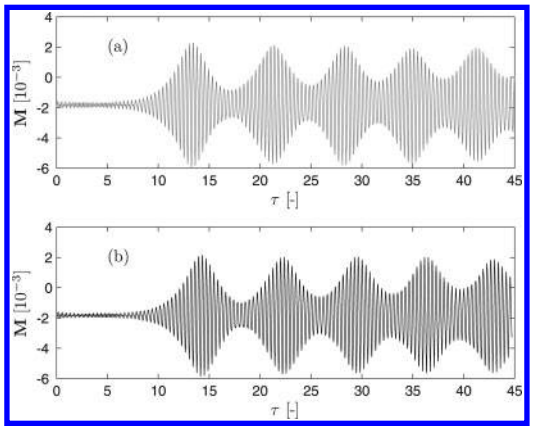

Figure 2. Bending moment $\mathbf{M}$ $[10^{-3}]$ at the fixed anchor p calculated with the proposed method (a) and a beam finite element model (b).

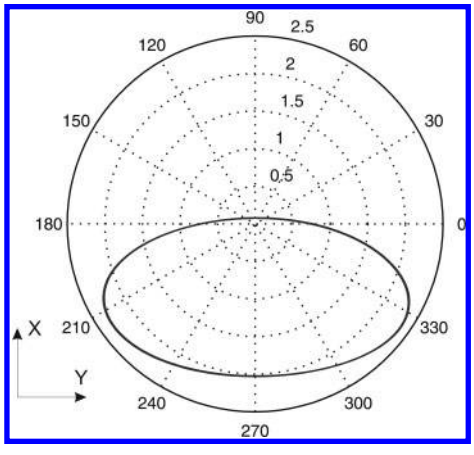

Figure 3. Polar plot of bending moment $\mathbf{M}[10^{-3}]$ in steady-state vibration at the fixed anchor p for different orientations ψ_0.

4.2 *Spatial vibration*

The second application illustrates the proposed developments for spatial vibrations. The characteristics of the cable are $\varepsilon = 0.01$, $\varepsilon_b = 10^{-4}$, the sag-to-span ratio is about 5‰. The cable is excited by an elliptic displacement of the anchor q, such as $x_q(\tau) = e_{0,x}\sin(\omega_2\tau)$ and $y_q(\tau) = e_{0,y}\sin(\omega 2\tau)$, with $e_{0,x} = 10^{-3}$ and $e_{0,y} = e_{0,x}/2$, with ω_2 the first in-plane natural frequency. The outer solution is calculated with only 20 truss finite elements.

In spatial steady-state vibration, the diagram of the bending moment is adequately shown in a polar graph with the value of the bending moment in the orientation $\psi_0(\tau)$ as in Figure 3. For spatial vibrations, the proposed method offers a real efficiency, because the mesh in the boundary layer must not be refined, the instability due to the twist and the smallness of the bending stiffness are discarded and the number of DOF is reduced (substantial in larger models).

5 CONCLUSION

In this paper, an analytical approach using matched asymptotic expansion has been developed. This method allows to calculate the bending moment in the boundary layers by decoupling the equation of motion between the span and the boundary layer. Because these regions respond in a *quasi*-static way, the proposed formula allows to build the curvature and the bending moment in the boundary layers only by the knowledge of the span vibration.

Singularities that induce a breakdown of determinism in mechanics

Mike R. Jeffrey
Department of Engineering Mathematics, University of Bristol, Bristol, UK

ABSTRACT: We will show that determinism can break down at certain singularities that arise in the mechanics of semi-rigid bodies. An example system consists of a wheel slipping and rolling along a surface, such that dry friction applies a torque to the wheel via a standard nonlinear tyre-like interaction. In a certain configuration the force on the wheel and its ensuing motion acquire many possible values. The subsequent motion is therefore infinitely sensitive to perturbation, constituting a point of non-determinism in an otherwise deterministic system. Moreover the device returns to the singularity repeatedly, so that it suffers repeated bursts of unpredictability, constituting an extreme non-deterministic form of chaos. A non-deterministic chaotic attractor was found for a range of parameters and tyre/friction models in (2013). Here, we explore the building blocks of this dynamics by stripping the model down to its key elements. We investigate the non-deterministic phenomenon when subjected to relaxations of the model that allow for smoothing, noise, and hysteresis. This is part of a wider theory currently emerging in the study of dynamical systems that undergo sharp switches in behaviour, whereby singularities can violate traditional rules of smooth dynamical systems.

1 INTRODUCTION

In dynamical systems modeling, discontinuities are widely used to model abrupt switches such as electronic relays, mechanical impact, and stick-slip motion; see e.g. (1999, 2008). Their application is increasingly reaching beyond traditional problems to include extreme nonlinearity and slow-fast timescale separation in electronics, mechanics, and the life sciences; e.g. (2011, 2010, 2003). Previous studies have progressed largely by extending established concepts from dynamical systems theory for smooth models, into a theory of *piecewise-smooth dynamics*. In recent years, however, certain discontinuity-induced phenomena have come to light that have no counterpart in smooth systems. They represent novel topological sources of unpredictable behaviour, and offer insight into the idealizations that are made in deriving empirical models of switching behaviour.

In (2010, 2011, 2013), certain physical models were shown to exhibit singularities at which determinism breaks down, meaning that, when the system is in one particular configuration, solutions of its differential equations become multi-valued.

The singularity occurs due to switching associated with stick-slip mechanics in (2013), and with a superconductivity threshold in (2011). A general classification of such singularities appears in (2011). Perhaps the most provocative outcome of these studies is an unconventional form of chaotic dynamics, driven by a loss of determinism at the so-called *Teixeira singularity* (2011). The singularity can occur in MIMO (multiple-input multiple-output) circuit models (2010), and was shown to create *non-deterministic chaos* in a mechanical friction model (2013).

The simplicity of the phenomenon itself is somewhat obscured in these preliminary studies, due to irrelevant nonlinearities in the practical models, and due to the rigours of normal form analysis in the general theory. Is the loss of determinism an artefact of modelling fundamentally smooth underlying physics using discontinuities, or does it provide insight into behaviour that is encountered daily, but dismissed as unmodelled error? To begin addressing these questions we focus here on the simple mechanism behind non-deterministic chaos, and the complex behaviour it creates; both appear for the first time in this paper.

In the mathematical sense, the configurations of interest are described by so-called two-fold singularities. They are *generic* in systems with at least two dimensions with one switch (2009), or two dimensions with more than one switch (2013). In the relatively young field of piecewise-smooth systems, however, it remains unclear whether 'genericity' implies a prevalence of such configurations in real systems. It also remains unclear exactly how one should recognize such behaviour in experimental data. Here we will present simulations of the typical dynamics in a stripped down model, which we then subject to smoothing, hysteresis, and noise.

We introduce the phenomenon of non-deterministic chaos by deriving a caricature encapsulating only the essential features of previous mechanical and electronic models. Our starting point is a mechanical system involving friction between a tyre and a dry revolving surface. In this conceptual model introduced

in (2013), a rolling wheel experiences a torque due to standard tyre-like contact forces, and this creates highly unpredictable rattling due to a singularity. The wheel system is introduced in sec. 2, and in sec. 3 the concept of non-deterministic chaos is introduced. A caricature model is derived in sec. 4, generalized to consider smoothing, noise, and hysteresis, and then these systems are simulated in sec. 5.

2 A MECHANICAL EXAMPLE

The mechanical device depicted in fig. 1 consists of a disc rotating with constant angular speed ω_0, on top of which sits a wheel, which is free to roll along a line placed a distance d from the disc axis. The wheel is fixed at an angle γ to this line. A tyre model for the contact force between the wheel and the disc then translates the frictional contact force into a torque on the wheel. The specifics of the tyre model (discussed in (2013)) are not vital to the dynamics observed.

The constraint by which the wheel moves along a line is also not crucial here, but is achieved by mounting it on a slider, embedded in a housing which is essentially another disc mounted coaxially above the lower disc; constants c_d, c_w, and k_w, give damping and spring coefficients between the housing and lower disc (subscript h) or wheel (subscript w).

For the time-varying displacement r and velocity v of the wheel, and the angular speed of the housing, ω, one obtains dynamical equations of the form

$$\begin{aligned} \dot{r} &= v \\ \dot{v} &= a_1(r,v,\omega) - b_1(r,v,\omega)\mathbf{sign}(h) \\ \dot{\omega} &= a_2(r,v,\omega) - b_2(r,v,\omega)\mathbf{sign}(h) \end{aligned} \qquad (1)$$

where a_i and b_i are nonlinear functions. The a_i capture the system geometry, while the b_i contain the contact model (for details we refer the reader to (2013)). More crucial is the function sign(h), which expresses the relative direction of the wheel's motion with respect to the disc, measured in the plane of the wheel. The function h is

$$h = (v - d(\omega - \omega_0))\sin\gamma + r(\omega - \omega_0)\cos\gamma\,. \qquad (2)$$

When this quantity vanishes for a period of time it means the wheel and the disc are in sticking contact. The equations governing sticking motion can be derived using Filippov's method (1988, 2003), which we describe briefly in the next section, and the resulting equations can be solved to simulate the device's dynamics (see (2013)). An alternative to Filippov's method, particularly suited to numerical simulation, is to smooth out the discontinuity in the sign function at $h=0$, so that it transitions smoothly between ± 1 in a small region $|h| < \varepsilon$ for small ε. The system is simulated by this method in fig. 2.

Although a smoothed-out model of the system is solvable using standard numerical tools, the system is then more stiff, as controlled by the parameter ε.

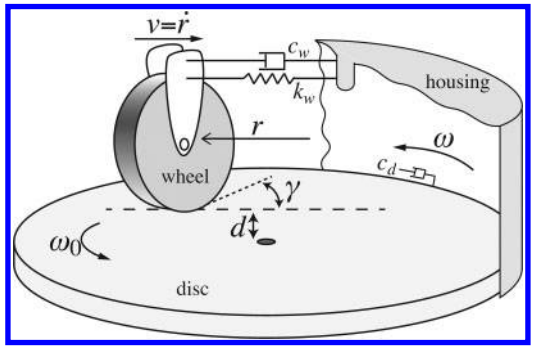

Figure 1. Sketch of the wheel assembly. Friction between the revolving disc, and a tyre on the wheel rim, apply linear and angular forces on the wheel as it rolls along the dashed line. The wheel-disc contact can stick or slip at different times.

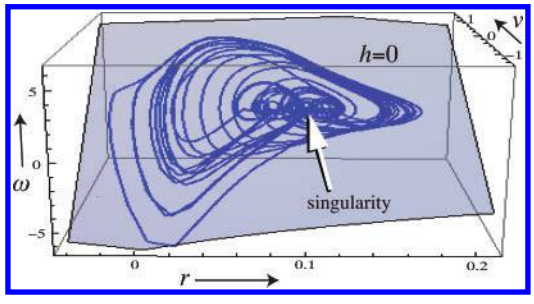

Figure 2. Simulation of the dynamics of the wheel assembly in fig. 1, indicating the sticking surface $h=0$, and the singularity. A solution of (1) is found by replacing the function sign(h) by tanh (h/ε), with stiffness parameter $\varepsilon = 10^{-3}$; [all simulations made in Mathematica™ using NDSolve].

Besides affecting computation time, smaller ε introduces instability to the simulation in ways that are poorly understood. As we describe below, the dynamics in fig. 2 involves the funnelling of solutions into and out of a singularity. In the discontinuous system this means that all trajectories at some time pass through the same point. That point represents a configuration of the physical device which can be reached from any initial conditions, and from which many different configurations of the system are possible at some later time. If the discontinuity is smoothed out, the system becomes extremely sensitive to initial conditions near the singularity. These problems are general properties, not specific to one system, but attributable to a specific class of singularities. Let us therefore isolate the features of the model that create these conditions.

3 A SCHEMATIC DEFINITION

At the heart of the mechanical system in fig. 2 lies a Teixeira singularity, a generic feature of discontinuous systems first studied in (1988, 1990). The discontinuity surface can be divided into regions where trajectories cross through it, are attracted to it, or

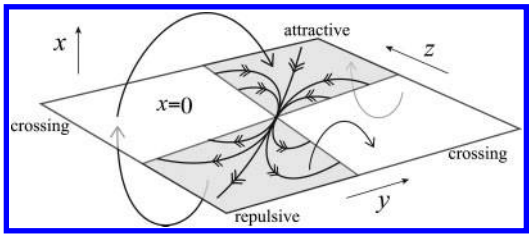

Figure 3. The Teixeira singularity – an isolated point in three dimensions, or an $n-3$ dimensional set in n dimensions. At a discontinuity surface ($x=0$) trajectories can cross (unshaded regions) or stick (double arrows, shaded regions). The sticking regions attract or repel the surrounding trajectories. The boundaries of the different regions intersect at the singularity.

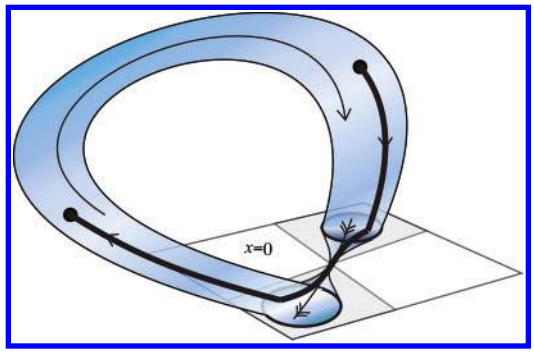

Figure 4. The mechanism of non-deterministic chaos: a Teixeira singularity on $x=0$, and a re-injection, that forces all trajectories to repeatedly visit the singularity. Any two points can be connected by a trajectory passing through the singularity, so which of these connections will persist under perturbation?

are repelled from it. All three types of behaviour are brought together at the singularity, as shown in fig. 3.

Consider a system

$$(\dot{x},\dot{y},\dot{z}) = \begin{cases} \mathbf{f}^+(x,y,z) & \text{if} \quad x>0 \\ \mathbf{f}^-(x,y,z) & \text{if} \quad x<0 \end{cases} \tag{3}$$

(we can increase the dimensionality, but three is the minimum required to understand the singularity), where $\mathbf{f}^{\pm}$ are smooth vector fields. The system switches between $\mathbf{f}^+$ and $\mathbf{f}^-$ at the discontinuity surface $x=0$ (which was $h=0$ in sec. 2). The standard way to define dynamics at $x=0$ (1988) is to take a linear combination of the two vector fields, say $\mathbf{g}^\lambda = \lambda\mathbf{f}^+ + (1-\lambda)\mathbf{f}^-$, and if there exists $\lambda\in[0,1]$ for which $\mathbf{g}^\lambda$ lies tangent to the surface, then $\mathbf{g}^\lambda$ defines a *sliding vector field* on $x=0$. This 'sliding' dynamics prescribes 'sticking' motion (double arrows in fig. 3), and the requirement $\lambda\in[0,1]$ (meaning $\mathbf{g}^\lambda$ lies somewhere between $\mathbf{f}^+$ and $\mathbf{f}^-$), confines sticking to the shaded regions in fig. 3, where $\mathbf{f}^+$ and $\mathbf{f}^-$ have opposing directions with respect to $x=0$. Elsewhere, the fields $\mathbf{f}^{\pm}$ cause trajectories to cross $x=0$ transversally. The boundaries between sticking and crossing are where $\mathbf{f}^+$ or $\mathbf{f}^-$ lie in the plane $x=0$, and a singularity forms where *both* $\mathbf{f}^+$ and $\mathbf{f}^-$ lie in the plane.

Various forms for this singularity are possible. Here we are interested in the case shown in fig. 3, when all sticking trajectories traverse the singularity, but moreover, they do so in the counterintuitive direction *from* the attractive region *to* the repulsive region. A local normal form for this scenario is known (1988, 1990, 2009), given by (3) with

$$\mathbf{f}_0^+(y) = (-y,1,v)\,, \qquad \mathbf{f}_0^-(z) = (z,w,1) \tag{4}$$

in terms of constants $v,w<0$ satisfying $vw>1$; from these equations one can easily sketch fig. 3. The point $(x,y,z)=(0,0,0)$ is the Teixeira singularity. Observe that a whole volume of trajectories will fall into the attractive sticking region, and then enter the singularity. Conversely, a whole volume of trajectories can be traced backwards in time to the repulsive sticking region, and thence to the singularity.

It is easy to show that passage through the singularity takes a finite amount of time (2009). This implies that when a trajectory traverses the singularity, its possible histories and possible futures are momentarily multi-valued — an instant of non-determinism.

The dynamics becomes more striking if we introduce a feedback to the system, as exists in the mechanical problem of sec. 2, so that every trajectory, once ejected from the repulsive side of the singularity, is eventually re-injected via the attractive side (see fig. 4). Although the system's immediate future becomes unpredictable when it arrives at the singularity, whichever exit path it follows will lead eventually back to the singularity, giving rise to repeating yet unpredictable dynamics, describable as *chaotic* (2009).

Without specifying the method of re-injection, we can understand very powerfully what this *non-deterministic chaos* represents. Taking *any* two points in the chaotic set, we can find a finite-time trajectory that connects them (see fig. 4). This means any configuration of the system can evolve into any other configuration (within the chaotic set). In a *deterministic* system, chaos arises when all trajectories pass exponentially close to one other given sufficient time. In a *discontinuous* system this is taken to an extreme, so that all trajectories intersect given sufficient time, when they pass through the singularity.

If we approximate the system by something deterministic, which of the possible trajectories through the singularity will persist? In the spirit of deterministic chaos, we expect the singularity to lead to an infinite sensitivity to initial conditions. To investigate its effect on the dynamics let us now give a specific form for the re-injection described above. To the local normal form (3), we must add a nonlinear term that dominates far from the singularity, steering trajectories from the repulsive sticking region, back towards the attractive region.

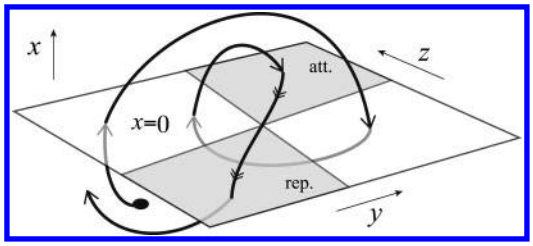

Figure 5. A typical trajectory of (5).

4 ANALYSIS OF A SIMPLIFIED MODEL

The required effect is easily achieved by adding a drift term in the $(0,1,1)$ direction, of strength α, and an attraction term $(0,-y,-z)$ of strength β, for some constants $\alpha,\beta>0$. Multiplying these by $|\mathbf{x}|^2=x^2+y^2+z^2$ ensures they only become significant far from the singularity, and we obtain a model

$$\begin{aligned}\mathbf{f}^+(x,y,z)&=(-y,1,v)+(0,\alpha-\beta y,\alpha-\beta z)|\mathbf{x}|^2\,,\\ \mathbf{f}^-(x,y,z)&=(\ z,w,1)+(0,\alpha-\beta y,\alpha-\beta z)|\mathbf{x}|^2\,.\end{aligned}\quad(5)$$

Any initial condition in a neighbourhood of the origin leads to a trajectory of the form shown in fig. 5.

By simulating this system, respecting crossing and sticking dynamics as described in the previous section, one finds that there exists a region around the origin where all trajectories intersect the origin in forward and backward time.

At the origin, the singularity dictates that no single path can be chosen uniquely from the continuum of possible trajectories. Nor is there any unique way to resolve this ambiguity. The discontinuous model is representative of a range of systems that become extremely sensitive to initial conditions near the singularity. To gain some insight we will smooth out the discontinuity, which restores determinism, and then add noise and hysteresis to the model. We define these models in the rest of this section, then we simulate each of them in sec. 5.

As a preparatory step, we relax the definition of (3) so that the switch takes place over a region $|x|<\varepsilon$, which collapses to a discontinuity at $x=0$ as ε tends to zero. We replace the system (3) with

$$(\dot{x},\dot{y},\dot{z})=\mathbf{f}^{\varepsilon}(x,y,z)\,,\quad(6)$$

for some small $\varepsilon\geq 0$, such that

$$\lim_{\varepsilon\to 0}\mathbf{f}^{\varepsilon}(x,y,z)=\begin{cases}\mathbf{f}^+(y) & \text{if}\quad x>0\,,\\ \mathbf{f}^-(z) & \text{if}\quad x<0\,.\end{cases}\quad(7)$$

This can be achieved by letting $\mathbf{f}^{\varepsilon}$ be a linear combination of $\mathbf{f}^{\pm}$, and considering

$$(\dot{x},\dot{y},\dot{z})=\mathbf{f}^{\varepsilon}=\mathbf{f}^-+(\mathbf{f}^+-\mathbf{f}^-)\phi\quad(8)$$

where (7) places a requirement on ϕ that

$$\phi=\{1\ \text{ for }\ x>+\varepsilon\ \ \&\ \ 0\ \text{ for }\ x<-\varepsilon\}+\mathsf{O}(\varepsilon)\ .\quad(9)$$

4.1 *Smoothing*

A smooth system is now found by letting ϕ be a smooth function $\phi=\phi(x/\varepsilon)$ (e.g. for the simulations to follow, we will mainly consider $\phi=\frac{1}{2}[1+\tanh(x/\varepsilon)]$). Substituting $x=\varepsilon u$ gives

$$(\varepsilon\dot{u},\dot{y},\dot{z})=\mathbf{f}^-(\varepsilon u,y,z)+[\mathbf{f}^+(\varepsilon u,y,z)-\mathbf{f}^-(\varepsilon u,y,z)]\phi(u)\,.$$

The result is a system where u varies on a fast timescale t/ε, while y and z vary on the slow timescale t. For such slow-fast systems, much is known about the correspondence between, for example, Fenichel's slow manifolds (1979), which occupy a region of space where the u component of $\mathbf{f}^-+(\mathbf{f}^+-\mathbf{f}^-)\phi$ vanishes, and the sticking regions which form as $\varepsilon\to 0$ (2007); these are recent but well established developments, so we do not explore them more deeply here.

4.2 *Noise*

A thorough study of how noise distributions propagate in the system is beyond the scope of the present paper. For brevity, we simulate noise in the system (8) by adding a random perturbation of size ε to the state $(x(t),y(t),z(t))$, after each time interval $\Delta t=0.3$. We let $\phi=\frac{1}{2}[1+\tanh(x/\varepsilon)]$.

4.3 *Hysteresis*

To introduce hysteresis to (1), let ϕ be a variable (which adds a dimension to the system), by adding to (8) the equation

$$\varepsilon'\dot{\phi}=\psi([x+\varepsilon(2\phi-1)]/\varepsilon')-\phi\quad(10)$$

where ψ is another function that satisfies

$$\psi=\{1\ \text{ for }\ w>+\varepsilon'\ \ \&\ \ 0\ \text{ for }\ w<-\varepsilon'\}+\mathsf{O}(\varepsilon)'$$

for some small ε'. Then ϕ is attracted (on the fast timescale t/ε') towards $+1$ if $x+\varepsilon(2\phi-1)>\varepsilon'$ and towards 0 if $x+\varepsilon(2\phi-1)<-\varepsilon'$. For the simulations to follow we let $\psi=\frac{1}{2}[1+\tanh(w/\varepsilon')]$ and $\varepsilon'=10\varepsilon$.

One further generalization that will not be considered here (due to space restrictions, and because the effect is in some ways similar to hysteresis), is to consider a delay in the switching function ϕ, for example $\mathbf{f}^{\varepsilon}=\mathbf{f}^-+(\mathbf{f}^+-\mathbf{f}^-)\phi(x(t-\delta)/\varepsilon)$ for some $\delta>0$.

5 SIMULATIONS

The purpose of the simulations below is to demonstrate the sensitivity of the model (5). For a standardized method we solve the ordinary differential equations using the default NDSolve function in Mathematica™. All simulations start from an initial point $(x,y,z)=(0.2,0,-1)$, with $\mathbf{f}^{\pm}$ fixed by parameters $v^+=-1.2$, $v^-=-1.4$, $\alpha=10^{-3}$, $\beta=10^{-5}$, and with stiffness parameter $\varepsilon=10^{-3}$.

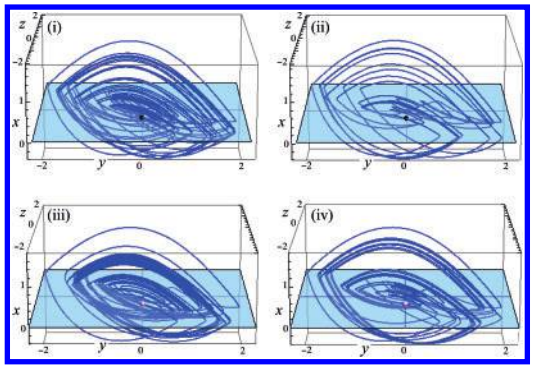

Figure 6. Simulation of: (i) the system in sec. 4.1 for $\phi = \frac{1}{2}[1 + \tanh(x/\varepsilon)]$; (ii) the hysteretic system (10), (iii–iv) the noisy system described in sec. 4.2, showing two separate simulations from the same initial conditions.

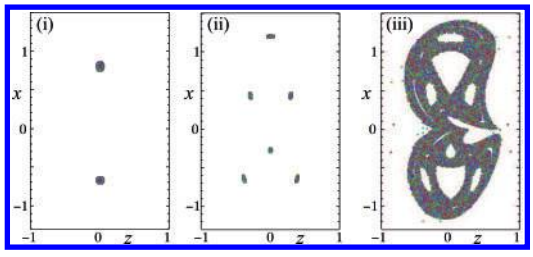

Figure 7. Poincaré sections for the system in sec. 4.1 with $\phi = \frac{1}{2}[1 + \tanh(x/\varepsilon)]$, for different iteration schemes: dividing the trajectory into time intervals (i) 20, (ii) 40, (iii) 100.

Each image in fig. 6 shows a single trajectory, winding around and revisiting the singularity repeatedly over a time $t = 150$. Despite some overall similarity, the detailed shape of the orbits differs markedly, exhibiting less organisation in the basic smoothed model (i) than when hysteresis is applied in (ii), and revealing changes in structure sensitive to random noise in (iii)–(iv).

Given the complexity of the phase space trajectories, more insight is gained by taking a Poincaré section, recording only coordinates where a trajectory passes through the plane $y = 0$. All of the sections below are simulated over a time $t = 2 \times 10^5$, but plotting only the latter half of the trajectory to omit transients.

We first highlight the sensitivity of the system to the method of simulation itself. One could use different numerical iteration schemes with different levels of precision to solve the dynamical system. We show one simple variant in fig. 7, dividing the total trajectory time into fixed intervals that force the adaptive NDSolve function to restart periodically. With this seemingly redundant change, the numerical simulation settles to different attractors (for the same time and initial conditions); we present examples of a periodic orbit, a period three orbit, and the seeming appearance of deterministic chaos.

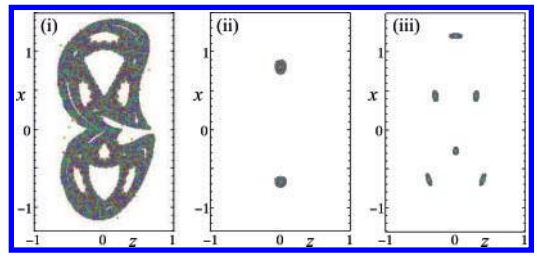

Figure 8. Poincaré sections for the system in sec. 4.1 with $\phi = \frac{1}{2}[1 + \tanh(x/\varepsilon)] + \sigma\sqrt{\varepsilon}e^{-x^2}$ and: (i) $\sigma = 0.01$, (ii) $\sigma = 0.1$, (iii) $\sigma = 0.13$.

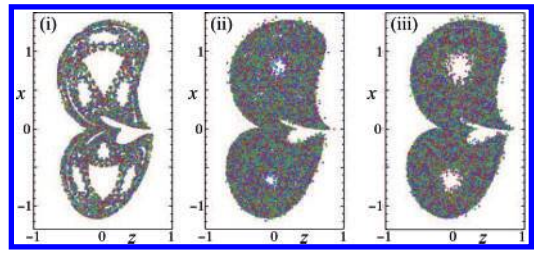

Figure 9. Poincaré sections for the system in sec. 4.1 with $\phi = \frac{1}{2}[1 + \tanh(x/\varepsilon)]$: (i) with hysteresis as described in sec.4.3; (ii) with noise as described in sec. 4.2 for two different runs.

One assumes that a more sophisticated simulation will reveal which result from fig. 7 is correct, but the ambiguity is compounded by other sensitivities in the system, such as the choice of how to smooth out the discontinuity. In fig. 8 we repeat the simulation in fig. 7(iii) using a perturbed smoothing function ϕ, which still tends to sign(x) as $\varepsilon \to 0$; this is no less valid, therefore, as an approximation of the discontinuous system (5). Small changes in the size of this perturbation give different attractors, as before.

Finally, in fig. 9, more physically realistic scenarios are simulated by repeating fig. 7(iii) with hysteresis added in (i) or noise added in (ii–iii).

These various simulations show for the first time the sensitive behaviour associated with non-deterministic chaos. We observe that many different deterministic systems lie close to the discontinuous system. The ambiguity of selecting between outcomes can be attributed to the existence of a non-deterministic singularity in the discontinuous limit, which amplifies even tiny changes in parameters. For some parameters the deterministic system exhibits stable periodic orbits (figs. 7(i–ii) and 8(ii–iii)), while for others the dynamics appears chaotic over some intricate attractor (figs. 7(iii), 8(i), 9(iii)), only some of which is washed out by noise (figs. 9(i–ii)). The important point is that all of these systems differ by only small changes in the defining model. Under these small changes the system jumps between regimes of periodicity or (deterministic) chaos.

6 CLOSING REMARKS

Renewed interest in recent years in a general theory of switching systems relevant to engineering applications, has inspired closer inspection of certain singularities where switching causes extreme sensitivity in a model, modeled dynamically by a breakdown of determinism. In this paper we described a mechanical model that exhibits such behaviour, constructed a toy model to study the phenomenon itself, and simulated its dynamics under relaxations of the model that take account of smoothing, hysteresis, and noise. This revealed unpredictability, partially organised by underlying structure, that survives from such a singularity when the idealization of discontinuity is relaxed.

On the dynamics of stacks of rigid blocks

F. Saitta, P. Clemente & D. Rinaldis
ENEA, Rome, Italy

ABSTRACT: The rocking motion of real bodies under external excitation can be often modeled by means of the theory of rigid body dynamics, neglecting the elastic deformations. Several studies paid attention to the dynamics of one block, under deterministic or stochastic excitation, whereas only few works focused on the case of two stacked blocks. In this paper the general problem of stacks with more than two rigid blocks is analyzed, typical of monumental ancient columns made of multiple stone blocks and also of stacks of drums filled with various material. Differing from previous papers, a vector based approach is adopted to write the equations of motion in a straightforward manner. Assuming non sliding rocking, the rotation angles are the Lagrangian parameters appearing in the equations of motion. Taking advantage of the Lagrange equations, the vector equation of motion is derived in a smart way. The impact has been accounted for by means of the conservation of angular momentum. Finally, the model is applied to the evaluation of seismic safety of the stack.

1 INTRODUCTION

Rocking motion of rigid blocks has been the subject of many research works. Indeed, many real structures under various kind of loads can be modeled in such way.

A first study on the subject was due to Housner (1963), which was inspired by the survival of some structure to the Chilean earthquake of May 1960. The work gave attention on the dynamics of the single rigid block and showed how the period of the structure varied with motion amplitude. The analysis of a tall slender block showed a major stability of such structures to earthquakes than expected. The equations of motion were obtained in direct way assuming the tilt angle as Lagrangian coordinate. The block could rotate with a rotation axis located at one base corner. Therefore, the inertia moment relative to that axis was considered in the equations.

A probabilistic approach to the study of the dynamics of a single block was proposed by Facchini et al. (1994). The tilt angle was the only Lagrangian coordinate and the friction coefficient was assumed sufficiently high to prevent the sliding of the block. The distribution of extreme values of the tilt angle of the block was used to investigate the stability of some monuments in Rome.

Zhang & Makris (2001) gave conditions for block overturning under cycloidal pulses, motivated by the similarities of such loads with fault-parallel and fault-normal component of motions recorded near the source of strong earthquakes. Makris & Konstantinidis (2003) gave a detailed comparison between the response of a single degree of freedom oscillator and the rocking response of a rigid block, introducing the concept of rocking spectrum.

Lenci and Rega (2006) introduced the recent developments in nonlinear dynamics to evaluate overturning conditions and charts, characterizing the response in the parameter space. The equations of motion were the same given by Housner. The excitation was periodic and, differing from previous works, the influence of the excitation phase in the block overturning was pointed out.

The slide-rocking behavior of a non-symmetric block was examined by Di Egidio and Contento (2009), with the aim of analyzing the dynamics of statues under seismic and impulsive ground motions. The exact nonlinear equations of motion were written in direct way for the different phases of motion and the rocking block was supposed isolated or not at the base.

A recent attempt to overcome the single block problem was proposed by Spanos et al. (2001), considering a system composed of two stacked blocks. Assuming the hypothesis of non-slide rocking response, the paper established the governing equations of motion for all the involved patterns, so as the impact and transition from a pattern to another. The model was applied for free vibrations or seismic induced motion. Another study on a two-block system was proposed by Kounadis et al. (2012), which discussed conditions for overturning under ground motion with different frequencies. They found that in some case the two-block system is more stable than the single one.

Other works focused their attention on the three-dimensional dynamics of the single block (Chatzis & Smyth 2012; Zulli et al. 2012).

In this paper the study of the dynamics of more than two stacked rigid blocks is shown. The motivation was given by the practice needs of evaluating the seismic stability of overpacks composed by several blocks. In addition, the extension of the analysis of two blocks to the case of several blocks is a complicate task due to the enormous number of patterns involved, which makes difficult the solution of the problem. Thus, a different vector way is chosen to write the equations of motion and the tilt angle with respect to the lower block was chosen as Lagrangian parameter. Assuming non sliding rocking, the angles are the only parameters in the equations of motion. The coordinates of the center of gravity of each block depend only on these tilt angles. Therefore, taking advantage of the Lagrange equations, the vector-form equation of motion is derived in a smart way.

2 ROCKING KINEMATIC OF STACKED RIGID BLOCKS

Consider first a single block as in Fig. 1 and suppose that the block can only rotate around the lower corners. The rotation angle θ is assumed to be positive for counterclockwise rotation. The following vector and matrices are introduced:

$$\boldsymbol{\Omega}_G(\theta)=\begin{bmatrix}\xi_G\\ \eta_G\end{bmatrix};\ \boldsymbol{\Gamma}(\theta)=\begin{bmatrix}sgn(\theta) & 0\\ 0 & 1\end{bmatrix};\ \boldsymbol{v}=-\begin{bmatrix}b\\ 0\end{bmatrix}$$

$$\mathbf{R}(\theta)=\begin{bmatrix}\cos(\theta) & -\sin|\theta|\\ \sin|\theta| & \cos(\theta)\end{bmatrix};\qquad (1a\text{-}g)$$

$$\boldsymbol{w}_G=\begin{bmatrix}b\\ h\end{bmatrix};\ \boldsymbol{w}_T=\begin{bmatrix}b\\ 2h\end{bmatrix};\ \boldsymbol{u}=\begin{bmatrix}0\\ h\end{bmatrix}$$

where $sgn(\bullet)$ is the sign function, $|\cdot|$ is the absolute value, b is the half base of the block, h the half height.

The coordinates in a planar reference system $O\xi\eta$ of the center of gravity are given by the following equation:

$$\boldsymbol{\Omega}_G(\theta)=\boldsymbol{\Gamma}(\theta)\left[\boldsymbol{v}+\mathbf{R}(\theta)\boldsymbol{w}_G\right] \qquad (2)$$

The coordinates of the middle point of the top base, are obtained as follows:

$$\boldsymbol{\Omega}_T(\theta)=\boldsymbol{\Gamma}(\theta)\left[\boldsymbol{v}+\mathbf{R}(\theta)\boldsymbol{w}_T\right] \qquad (3)$$

With some manipulation:

$$\boldsymbol{\Omega}_T(\theta)=\boldsymbol{\Gamma}(\theta)\left[\boldsymbol{v}+\mathbf{R}(\theta)(\boldsymbol{w}_G+\boldsymbol{u})\right]=\boldsymbol{\Omega}_G(\theta)+\mathbf{P}(\theta) \qquad (4)$$

where:

$$\mathbf{P}(\theta)=\boldsymbol{\Gamma}(\theta)\mathbf{R}(\theta)\boldsymbol{u} \qquad (5)$$

In the case of more than one block, Eq. (1) can be applied recursively to derive the coordinates of the centers of gravity of each block. As an example for two blocks (Fig. 2), the coordinates of the centre of gravity of the upper block, with reference to the $T_1\xi\eta$ system, are given by $\boldsymbol{\Omega}_G(\theta_2)$. In the global reference system Oxy, the coordinates are obtained adding the coordinates of T_1 (referred to O) with $\boldsymbol{\Omega}_G(\theta_2)$ multiplied by a rotation matrix $\boldsymbol{\Lambda}(\theta_1)$:

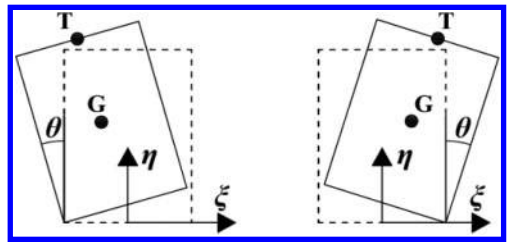

Figure 1. Rocking motion of a single block.

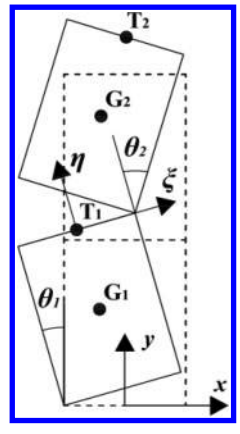

Figure 2. Rocking motion of two blocks.

$$\mathbf{x}_{G_1}(\theta_1)=\boldsymbol{\Omega}_G(\theta_1) \qquad (6)$$

$$\mathbf{x}_{G_2}(\theta_1,\theta_2)=\boldsymbol{\Omega}_T(\theta_1)+\boldsymbol{\Lambda}(\theta_1)\boldsymbol{\Omega}_G(\theta_2) \qquad (7)$$

Taking into account Eq. (4), the latter can be rewritten as follows:

$$\mathbf{x}_{G_2}(\theta_1,\theta_2)=\boldsymbol{\Omega}_G(\theta_1)+\mathbf{P}(\theta_1)+\boldsymbol{\Lambda}(\theta_1)\boldsymbol{\Omega}_G(\theta_2) \qquad (8)$$

In the general case of several blocks, the coordinates of the centre of gravity of the k-th block are given by:

$$\begin{aligned}&\mathbf{x}_{G_k}(\theta_1,\theta_2,..,\theta_k)=\\ &=\mathbf{x}_{T_{k-1}}(\theta_1,\theta_2,..,\theta_{i-1})+\boldsymbol{\Lambda}(\theta_1)..\boldsymbol{\Lambda}(\theta_{k-1})\boldsymbol{\Omega}_G(\theta_k)=\\ &=\sum_{i=1}^{k-1}\left\{\left[\prod_{j=0}^{i-1}\boldsymbol{\Lambda}(\theta_j)\right]\left[\boldsymbol{\Omega}_G(\theta_i)+\mathbf{P}(\theta_i)\right]\right\}+\\ &+\prod_{j=0}^{k}\boldsymbol{\Lambda}(\theta_j)\boldsymbol{\Omega}_G(\theta_k)\end{aligned} \qquad (9)$$

whereas the coordinates of the middle points of the top bases of each block are given by:

$$\mathbf{x}_{\mathrm{T}_k}(\theta_1,\theta_2,..,\theta_k)=\sum_{i=1}^{k}\left\{\left[\prod_{j=0}^{i-1}\mathbf{\Lambda}(\theta_j)\right]\left[\mathbf{\Omega}_{\mathbf{G}}(\theta_i)+\mathbf{P}(\theta_i)\right]\right\} \quad (10)$$

where the assumption $\theta_0 = 0$ has been done.

3 EQUATIONS OF MOTION

In order to derive the equations of motion, the following derivatives with respect to θ are useful:

$$\mathbf{\Omega}_{\mathbf{G}}'(\theta)=\mathbf{\Phi}(\theta)\boldsymbol{w}_G;\quad \mathbf{\Omega}_{\mathbf{T}}'(\theta)=\mathbf{\Phi}(\theta)(\boldsymbol{w}_G+\boldsymbol{u}) \quad (11)$$

$$\mathbf{\Omega}_{\mathbf{G}}''(\theta)=\mathbf{\Psi}(\theta)\boldsymbol{w}_G;\quad \mathbf{\Omega}_{\mathbf{T}}''(\theta)=\mathbf{\Psi}(\theta)(\boldsymbol{w}_G+\boldsymbol{u}) \quad (12)$$

where the following matrices have been introduced:

$$\mathbf{\Phi}(\theta)=\begin{bmatrix}-sgn(\theta)\sin(\theta) & -\cos(\theta)\\ sgn(\theta)\cos(\theta) & -\sin(\theta)\end{bmatrix} \quad (13)$$

$$\mathbf{\Psi}(\theta)=\begin{bmatrix}-sgn(\theta)\cos(\theta) & \sin(\theta)\\ -sgn(\theta)\sin(\theta) & -\cos(\theta)\end{bmatrix} \quad (14)$$

The coordinates of the N blocks can be put into a vector $\mathbf{x}_{\mathbf{G}}$:

$$\mathbf{x}_{\mathbf{G}}=\begin{bmatrix}\mathbf{x}_{\mathbf{G}_1} & \mathbf{x}_{\mathbf{G}_2} & \cdots & \mathbf{x}_{\mathbf{G}_N}\end{bmatrix}^{\mathrm{T}} \quad (15)$$

In order to evaluate the equations of motion the following derivative is necessary:

$$\frac{\partial\mathbf{x}_{\mathbf{G}}}{\partial\boldsymbol{\theta}}=\nabla_{\boldsymbol{\theta}}^{\mathrm{T}}\otimes\mathbf{x}_{\mathbf{G}}=\begin{bmatrix}\frac{\partial\mathbf{x}_{\mathbf{G}_1}}{\partial\theta_1} & \cdots & \frac{\partial\mathbf{x}_{\mathbf{G}_1}}{\partial\theta_N}\\ \vdots & \ddots & \vdots\\ \frac{\partial\mathbf{x}_{\mathbf{G}_N}}{\partial\theta_1} & \cdots & \frac{\partial\mathbf{x}_{\mathbf{G}_N}}{\partial\theta_N}\end{bmatrix} \quad (16)$$

In the previous equation:

$$\nabla_{\boldsymbol{\theta}}^{\mathrm{T}}=\begin{bmatrix}\frac{\partial}{\partial\theta_1} & \cdots & \frac{\partial}{\partial\theta_N}\end{bmatrix} \quad (17)$$

and $\otimes$ is the Kronecker product. The matrix in Eq. (16) is lower triangular, of order $2N \times N$, and can be rewritten as follows:

$$\begin{bmatrix}\mathbf{\Omega}_{\mathbf{G}}'(\theta_1) & 0 & \cdots & 0\\ \mathbf{\Omega}_{\mathbf{G}}'(\theta_1)+\mathbf{P}'(\theta_1)+\mathbf{\Lambda}'(\theta_1)\mathbf{\Omega}_{\mathbf{G}}(\theta_2) & \mathbf{\Lambda}(\theta_1)\mathbf{\Omega}_{\mathbf{G}}'(\theta_2) & & \vdots\\ \vdots & & \ddots & \vdots\\ \mathbf{\Lambda}(\theta_{N-1})\mathbf{\Omega}_{\mathbf{G}}'(\theta_N) & \mathbf{\Lambda}(\theta_1)\left[\mathbf{\Omega}_{\mathbf{G}}'(\theta_2)+\mathbf{P}'(\theta_2)\right] & \cdots & \mathbf{\Lambda}(\theta_{N-1})\mathbf{\Omega}_{\mathbf{G}}'(\theta_N)\end{bmatrix} \quad (18)$$

The second derivative is:

$$\frac{\partial^2\mathbf{x}_{\mathbf{G}}}{\partial\boldsymbol{\theta}^2}=\nabla_{\boldsymbol{\theta}}^{\mathrm{T}}\otimes\left(\nabla_{\boldsymbol{\theta}}^{\mathrm{T}}\otimes\mathbf{x}_{\mathbf{G}}\right)=\nabla_{\boldsymbol{\theta}}^{\mathrm{T}[2]}\otimes\mathbf{x}_{\mathbf{G}}=$$
$$=\begin{bmatrix}\frac{\partial^2}{\partial\theta_1^2} & \cdots & \frac{\partial^2}{\partial\theta_1\partial\theta_N} & \cdots & \frac{\partial^2}{\partial\theta_N\partial\theta_1} & \cdots & \frac{\partial^2}{\partial\theta_N^2}\end{bmatrix}\otimes\mathbf{x}_{\mathbf{G}} \quad (19)$$

In the previous matrix, the first row contains nil values except for the term $\partial^2\mathbf{x}_{\mathbf{G}_i}/\partial\theta_1^2=\Omega_{\mathbf{G}}''(\theta_1)$. The second row contains non nil values for derivatives involving the variables θ_1 and θ_2:

$$\frac{\partial^2\mathbf{x}_{\mathbf{G}_2}}{\partial\theta_1^2}=\mathbf{\Omega}_{\mathbf{G}}''(\theta_1)+\mathbf{P}''(\theta_1)+\mathbf{\Lambda}''(\theta_1)\mathbf{\Omega}_{\mathbf{G}}(\theta_2) \quad (20)$$

$$\frac{\partial^2\mathbf{x}_{\mathbf{G}_2}}{\partial\theta_2^2}=\mathbf{\Lambda}(\theta_1)\mathbf{\Omega}_{\mathbf{G}}''(\theta_2) \quad (21)$$

$$\frac{\partial^2\mathbf{x}_{\mathbf{G}_2}}{\partial\theta_1\partial\theta_2}=\mathbf{\Lambda}'(\theta_1)\mathbf{\Omega}_{\mathbf{G}}'(\theta_2) \quad (22)$$

Other rows can be constructed in the same way. Therefore, most of the elements are nil. The matrix is of order $2N \times N^2$.

The equation of motion can be easily derived applying the Lagrange equations, using the rotations θ_i $(i=1,..,N)$ as coordinates. Therefore, the i-th equations is:

$$\frac{d}{dt}\left(\frac{\partial T}{\partial\dot{\theta}_i}\right)-\frac{\partial T}{\partial\theta_i}+\frac{\partial V}{\partial\theta_i}=0 \quad (23)$$

or in vector form:

$$\frac{d}{dt}\left(\frac{\partial T}{\partial\dot{\boldsymbol{\theta}}}\right)-\frac{\partial T}{\partial\boldsymbol{\theta}}+\frac{\partial V}{\partial\boldsymbol{\theta}}=0 \quad (24)$$

where the kinetic and potential energy are given by:

$$T=\frac{1}{2}\left[\dot{\mathbf{x}}_{\mathbf{G}}^{\mathrm{T}}(\boldsymbol{\theta})\mathbf{M}\dot{\mathbf{x}}_{\mathbf{G}}(\boldsymbol{\theta})+\dot{\boldsymbol{\theta}}^{\mathrm{T}}\mathbf{I}_{\mathbf{G}}\dot{\boldsymbol{\theta}}\right] \quad (25)$$

$$V=g\boldsymbol{\delta}^{T}\mathbf{M}\mathbf{x}_{\mathbf{G}}(\boldsymbol{\theta}) \quad (26)$$

where $\boldsymbol{\delta}$ is a vector composed by N couples $[0,1]^T$.

The derivatives in Eq. (24) are expanded as follows:

$$\frac{\partial T}{\partial\dot{\boldsymbol{\theta}}}=\frac{\partial\dot{\mathbf{x}}_{\mathbf{G}}}{\partial\dot{\boldsymbol{\theta}}}^{\mathrm{T}}\mathbf{M}\dot{\mathbf{x}}_{\mathbf{G}}+\mathbf{I}_{\mathbf{G}}\dot{\boldsymbol{\theta}} \quad (27)$$

$$\frac{\partial V}{\partial\boldsymbol{\theta}}=\mathrm{g}\frac{\partial\mathbf{x}_{\mathbf{G}}}{\partial\boldsymbol{\theta}}^{\mathrm{T}}\mathbf{M}\boldsymbol{\delta} \quad (28)$$

$$\frac{\partial T}{\partial \boldsymbol{\theta}} = \frac{\partial T}{\partial \dot{\mathbf{x}}_G}\frac{\partial \dot{\mathbf{x}}_G}{\partial \boldsymbol{\theta}} = \frac{\partial \dot{\mathbf{x}}_G}{\partial \boldsymbol{\theta}}^{\mathrm{T}} \mathbf{M}\dot{\mathbf{x}}_G \tag{29}$$

By substituting Eqs. (27)–(29) into Eq. (24), and taking into account the chain rule of derivation:

$$\dot{\mathbf{x}}_G = \frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}\dot{\boldsymbol{\theta}} \tag{30}$$

with some manipulation the equation of motion in vector form is obtained:

$$\begin{aligned}\left(\mathbf{I}\otimes\dot{\boldsymbol{\theta}}\right)^{\mathrm{T}}\left(\nabla_{\boldsymbol{\theta}}^{\mathrm{T}[2]}\otimes\mathbf{x}_G\right)^{\mathrm{T}}\mathbf{M}\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}\dot{\boldsymbol{\theta}} + \frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}^{\mathrm{T}}\mathbf{M}\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}\ddot{\boldsymbol{\theta}} + \\ + \mathbf{I}_G\ddot{\boldsymbol{\theta}} + \mathrm{g}\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}^{\mathrm{T}}\mathbf{M}\boldsymbol{\delta} = 0\end{aligned} \tag{31}$$

where the following equality has been considered:

$$\nabla_{\boldsymbol{\theta}}^{\mathrm{T}}\otimes\left(\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}\dot{\boldsymbol{\theta}}\right) = \left(\nabla_{\boldsymbol{\theta}}^{\mathrm{T}[2]}\otimes\mathbf{x}_G\right)\left(\mathbf{I}\otimes\dot{\boldsymbol{\theta}}\right) \tag{32}$$

and $\mathbf{I}$ is the identity matrix of order N

The following $N \times N$ matrices are introduced:

$$\boldsymbol{\mu}(\boldsymbol{\theta}) = \frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}^{\mathrm{T}}\mathbf{M}\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}} + \mathbf{I}_G \tag{33}$$

$$\boldsymbol{\gamma}(\boldsymbol{\theta},\dot{\boldsymbol{\theta}}) = \left(\mathbf{I}\otimes\dot{\boldsymbol{\theta}}\right)^{\mathrm{T}}\left(\nabla_{\boldsymbol{\theta}}^{\mathrm{T}[2]}\otimes\mathbf{x}_G\right)^{\mathrm{T}}\mathbf{M}\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}\dot{\boldsymbol{\theta}} \tag{34}$$

The moment due to the weight of the blocks gives the following vector:

$$\boldsymbol{\rho}(\boldsymbol{\theta}) = \mathrm{g}\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}^{\mathrm{T}}\mathbf{M}\boldsymbol{\delta} \tag{35}$$

Finally, the equation of motion is rewritten in a more concise form:

$$\boldsymbol{\mu}(\boldsymbol{\theta})\ddot{\boldsymbol{\theta}} + \boldsymbol{\gamma}(\boldsymbol{\theta},\dot{\boldsymbol{\theta}}) + \boldsymbol{\rho}(\boldsymbol{\theta}) = \mathbf{0} \tag{36}$$

In first order form:

$$\dot{\boldsymbol{\Theta}} = \mathbf{A}(\boldsymbol{\Theta}) + \mathbf{v}(\boldsymbol{\Theta}) \tag{37}$$

where the following quantities are introduced:

$$\boldsymbol{\Theta} = \begin{bmatrix}\boldsymbol{\theta}\\ \dot{\boldsymbol{\theta}}\end{bmatrix};\ \mathbf{A}(\boldsymbol{\Theta}) = \begin{bmatrix}\dot{\boldsymbol{\theta}}\\ -\boldsymbol{\mu}^{-1}(\boldsymbol{\theta})\boldsymbol{\gamma}(\boldsymbol{\theta},\dot{\boldsymbol{\theta}})\end{bmatrix} \tag{38}$$

$$\mathbf{v}(\boldsymbol{\Theta}) = \begin{bmatrix}\mathbf{0}\\ -\boldsymbol{\mu}^{-1}(\boldsymbol{\theta})\boldsymbol{\rho}(\boldsymbol{\theta})\end{bmatrix} \tag{39}$$

This equation is solved numerically by means of the Runge-Kutta method, accounting for the conservation of the angular momentum during impact between blocks as will be shown in section 5.

4 GENERALIZED FORCES

In the framework of the Lagrange method, forces acting on the system allow to derive generalized forces β_h related with Lagrangian coordinates θ_h:

$$\beta_h = \sum_{i=1}^{N}\mathbf{F}_i^T\frac{\partial \mathbf{x}_{G_i}}{\partial \theta_h} \tag{40}$$

Assuming that the only forces are inertial due to ground motion, with some manipulation, the vector of N generalized forces can be written as follows:

$$\boldsymbol{\beta}(\boldsymbol{\theta},t) = -\left(\frac{\partial \mathbf{x}_G}{\partial \boldsymbol{\theta}}\right)^T\mathbf{M}\boldsymbol{\tau}\ddot{u}_g(t) \tag{41}$$

where $\boldsymbol{\tau}$ is a vector composed by N couples $[1, 0]^{\mathrm{T}}$.

In first order form, the vector to be added to the second member of Eq. (37) to derive the forced equation of motion is:

$$\mathbf{Q}(\boldsymbol{\Theta},t) = \begin{bmatrix}\mathbf{0}\\ \boldsymbol{\mu}^{-1}(\boldsymbol{\theta})\boldsymbol{\beta}(\boldsymbol{\theta},t)\end{bmatrix} \tag{42}$$

5 IMPACT BETWEEN BLOCKS

The variation of angular velocity of each block is accounted for by the conservation of the angular momentum, which can be written as the sum of two contributes, one due to the motion of the center of mass and a second contribute due to the instantaneous rotation with respect to the center of mass.

Given n blocks, the involved patterns are $3^n - 1$. Therefore, at each time step, the vector $sign(\boldsymbol{\theta})$ establishes the current pattern. When an impact occurs the system can switch to another pattern, characterized by a vector $\boldsymbol{\theta}$ with: *i*) a sign variation at the component related with the impact point; *ii)* the same sign as before impact; *iii)* the blocks remain in contact after impact.

The total angular momentum of the system with respect to a generic pole O is written as follows:

$$K_O = \sum_{i=1}^{N}\mathrm{K}_O^{(i)} = \sum_{i=1}^{N}I_{Gi}\dot{\psi}_i + \left[OG_i\times m_i\dot{\mathbf{X}}_{G_i}\right]_3 \tag{43}$$

In the previous equation $\mathbf{X}_{G_i} = [\mathbf{x}_{G_i}, 0]^T$ is the three-component vector of the coordinates of the center of mass, the pedix 3 indicates the third component, ψ_i is the tilt angle of the i-th block with respect to the vertical, related with θ_i as follows:

$$\psi_1 = \theta_1;\quad \psi_2 = \theta_1 + \theta_2;\quad \psi_3 = \theta_1 + \theta_2 + \theta_3\ \ldots\ldots \tag{44}$$

Obviously, N equations are necessary to obtain the N velocities. They can be derived by the imposition of the conservation of the angular momentum, before and after the impact, for the whole system with respect

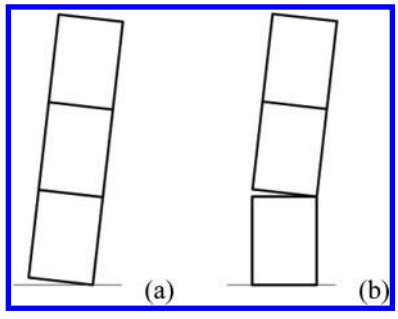

Figure 3. Initial conditions for the free rocking examples.

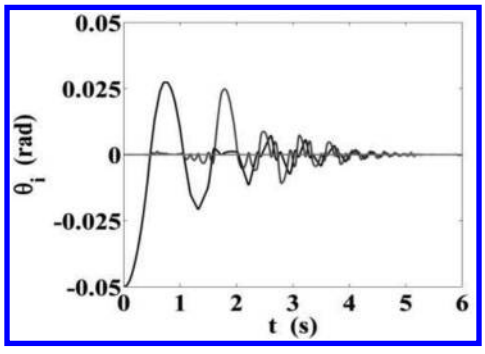

Figure 4. Tilt angle versus time for the three blocks: (Gray-level: Block 1 = Black; Block 2 = Dark gray; Block 3 = Light gray).

to the base vertex which is the center of rotation of the base block, if the block is rocking. Another equation can be written for the $N-1$ top blocks with respect to the vertex of the base of second block, if the block is rocking, and so on. At the level of impact, the pole of the momentum could switch to the other vertex or eventually the two blocks could remain in contact and behave as a single block. In this latter case the equations necessary become $N-1$ The assumed hypotheses are equivalent to those given in Spanos et al. (2001).

6 APPLICATIONS

A three-block pile is considered in the first application. The blocks have the following characteristics: $b_i = 0.440$ m and $h_i = 0.545$ m ($i = 1, \ldots, 3$). The mass of each block is $m_i = 1000$ kg and the inertia moment is $I_{Gi} = 292.61$ kgm^2.

The free oscillations with the initial conditions $\theta_{1,0} = -0.05$ rad (Fig. 3a), all the other rotations and velocities being zero, have been studied, using a time step of 0.001 sec in the numerical integration. In Fig. 4 the response is plotted, using decaying gray levels from the lower to top block. Fig. 5 reports the response in the phase plane. Shifts in velocity after impacts ($\theta = 0$) can be observed. In this case, after the first impact, the two top blocks start rocking approximately together.

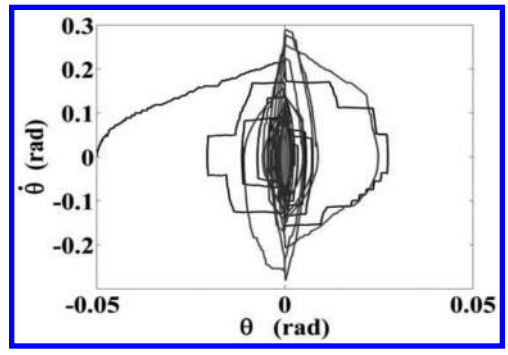

Figure 5. Response in the phase plane for free rocking with $\theta_{1,0} = -0.05$ rad.

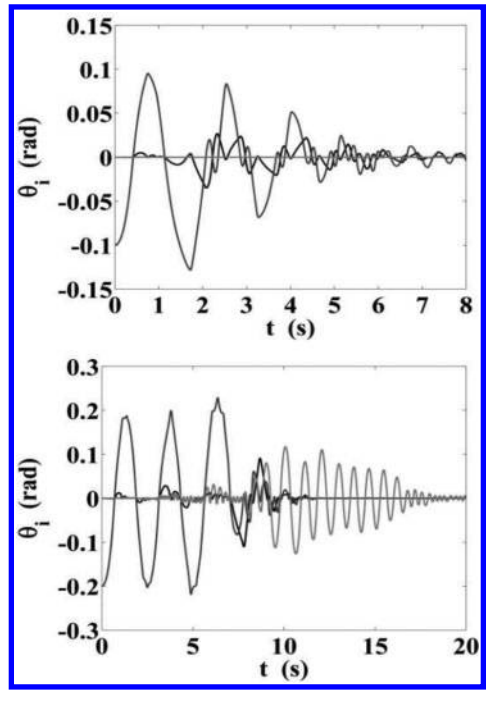

Figure 6. Tilt angle versus time for the three blocks: a) $\theta_{2,0} = -0.1$ rad; b) $\theta_{2,0} = -0.2$ rad.

In another example (Fig. 3b) the two cases of initial conditions $\theta_{2,0} = -0.1$ rad or $\theta_{2,0} = -0.2$ rad all the other rotations and velocities being zero, have been considered. The results are plotted in Figs. 6a and 7a and in Figs. 6b and 7b, respectively.

In this second example, jumps in velocity during impacts are more evident. Fig. 6a shows clearly changes in velocity of the top blocks due to impacts of the lower block with ground.

Finally, the analysis of a five-blocks system under seismic action has been considered. The base excitation, horizontally directed, is given by the N-S component of the 1940 El Centro earthquake (Fig. 8). The geometrical and mechanical characteristics of the blocks are the same used in the previous examples.

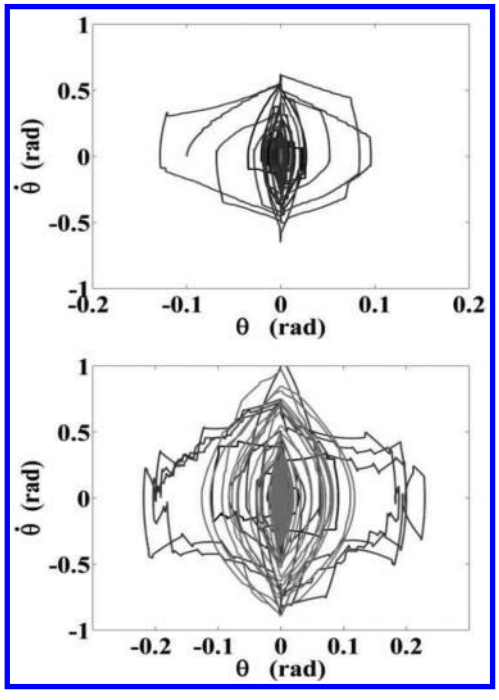

Figure 7. Response in the phase plane: a) $\theta_{2,0} = -0.1$ rad; b) $\theta_{2,0} = -0.2$ rad.

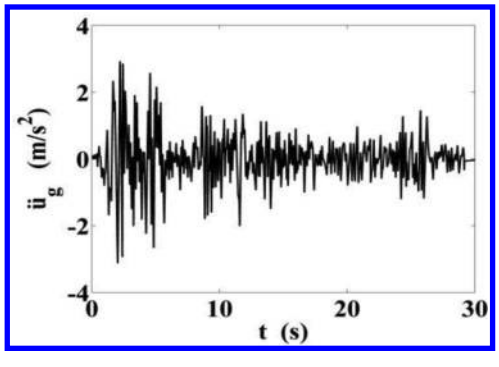

Figure 8. N-S component of El Centro earthquake.

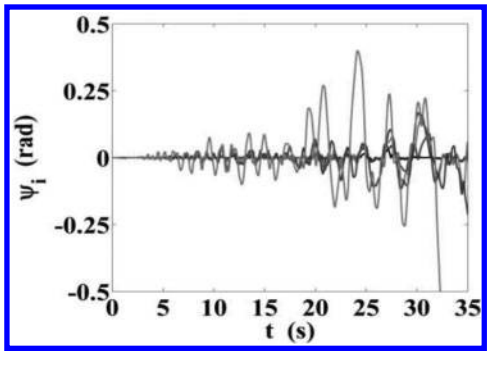

Figure 9. Time histories of tilt angles, with respect to the vertical, for the five blocks under seismic excitation.

Fig. 9 shows the time history of the tilt angles ψ_i. The system rocks with increasing amplitude for the whole event. Only at about 32 s, when the forcing action stops, the top block overturns.

7 CONCLUSIONS

A vector method for the rocking analysis of multiple block systems has been proposed in the paper. The method allows writing the equations of motion easily. Indeed, methods present in the literature, dealing with one or two blocks, becomes burdensome in these cases from a computational point of view. In order to show the suitability of the method in solving practical problems, some applications have been presented, with reference to free rocking response under imposed initial rotation or under seismic-induced motion. The first results are promising. Further verification would be necessary in order to check the accuracy and reliability of the procedure in practical applications. Besides, based on real materials behavior, more dissipative models for impact could be implemented and verified on the basis of experimental analysis. Furthermore, the method can be extended to three-dimensional cases.

ABSTRACT: Mechanical systems with impacting components have received considerable attention in the past due to their wide engineering applications. In this work, we study numerically a physical model that accounts for viscoelastic impacts and is able to reproduce the effect of the vertical progression (drift) observed e.g. in drilling applications (Pavlovskaia et al. 2001). The model is comprised of a harmonically excited mass simulating the penetrating part of the system and a viscoelastic slider, which represents the soil resistance. During operation, the system can move downwards in stick-slip phases, resulting in complex dynamical behaviour, which includes fold, period-doubling and grazing bifurcation of periodic orbits, as well as chaotic motion. The present work extends the previous investigations undertaken by the CADR within Aberdeen University (Pavlovskaia et al. 2001, Pavlovskaia and Wiercigroch 2007) to gain an insight into the bifurcation structure of the underlying system. Specifically, the system is analyzed numerically by means of the software TC-HAT, a toolbox of AUTO 97 allowing numerical continuation and bifurcation detection of periodic orbits in non-smooth dynamical systems.

1 PHYSICAL MODEL

In Fig. 1, we present a physical model describing the interaction between a harmonically forced impactor of mass m which collides with a medium modelled as a viscoelastic slider (Pavlovskaia et al. 2001).

Systems of this type are often described by piecewise smooth ODEs, due to the presence of non-smooth or discontinuous phenomena in the physical model. This results in fascinating and complex dynamical behaviour, ranging from various periodic responses to chaotic motion (Pavlovskaia et al. 2001). The equations of motion of the system can be given in compact form as follows (cf. (Pavlovskaia and Wiercigroch 2007)):

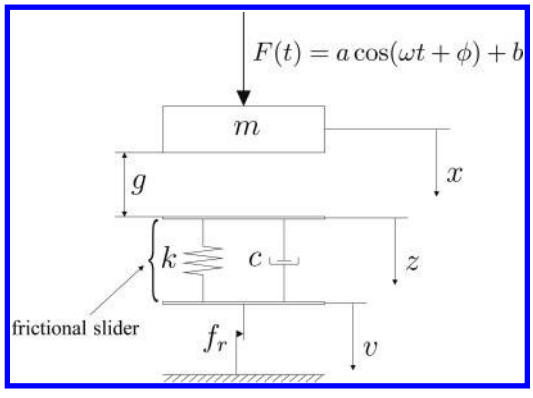

Figure 1. Physical model of a viscoelastic impact oscillator, with the dimensionless parameters $m = 1$, $c = 2\xi$, $k = 1$ and $f_r = 1$.

$$p' = y - P_1 P_3 \left(y + \frac{1}{2\xi}(q-1) \right), \tag{1}$$

$$\begin{aligned}
y' &= a\cos(s+\phi) + b - P_1 P_2 (1-P_3)(2\xi y + q) - P_1 P_3, \\
q' &= -\frac{1}{2\xi} q + P_1 P_2 (1-P_3) \left(y + \frac{1}{2\xi} q \right) + \frac{P_1 P_3}{2\xi}, \\
v' &= \left(y + \frac{1}{2\xi}(q-1) \right) P_1 P_3, \\
s' &= \omega,
\end{aligned}$$

with $P_1 := H(p-q-g)$, $P_2 := H(2\xi y + q)$ and $P_3 := H(2\xi y + q - 1)$, where $H(\cdot)$ stands for the Heaviside step function. In (1), the linear transformation $p = x - v$, $q = z - v$ has been introduced in order to decouple the periodic component of the system response captured by the variables (p, y, q) from the vertical progression v.

In our numerical study, we will consider a periodic solution $(p(t), y(t), q(t))$ of (1) of period $T > 0$ and we introduce the average rate of vertical progression (ROP) as solution measure, which is defined as

$$\text{ROP} := \frac{1}{T} \int_0^T \left(y(t) + \frac{1}{2\xi}(q(t)-1) \right) P_1 P_3 \, dt.$$

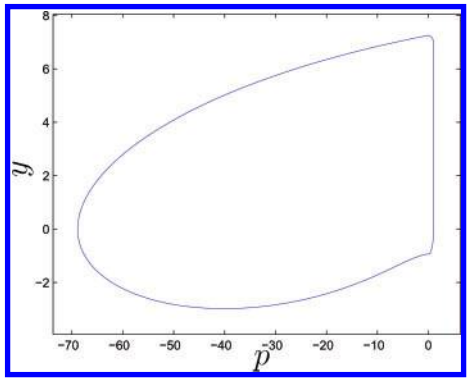

Figure 2. Initial periodic orbit of (1) for the parameter values $a = 0.3$, $\omega = 0.1$, $\xi = 0.05$, $b = 0.15$, $g = 0.02$ and $\phi = 0$.

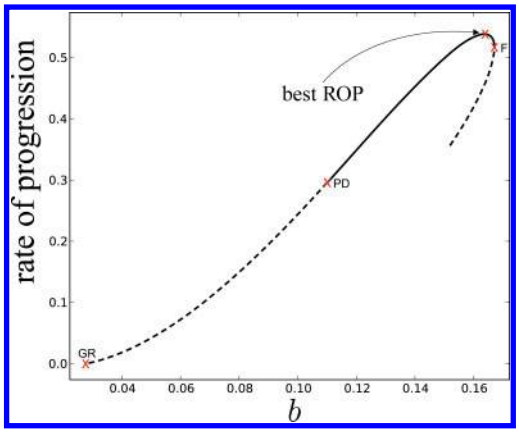

Figure 3. Numerical continuation of the periodic orbit shown in Fig. 2 with respect to the static force b. Dashed and solid segments denote unstable and stable periodic solutions, respectively.

This measure will allow us to monitor the efficiency of the periodic solution under the change of the external loading parameters, i.e. dynamic amplitude a, static force b and excitation frequency ω.

2 MAIN RESULTS

The previous analysis (Pavlovskaia et al. 2001) has shown that the best ROP is obtained when the system response is periodic and the frequency of the response is the same as the frequency of external excitation. Therefore we will concentrate on studying numerically this type of periodic response and its typical trajectory is depicted in Fig. 2. The results presented in this section are obtained by performing the numerical continuation of the period-1 orbit via TC-HAT (Thota & Dankowicz 2008), taking the ROP as solution measure and a, b and ω as the main bifurcation parameters.

In Figs. 3, 4 and 5, we can observe the dependance of the ROP on the control parameters b, a and ω, respectively. Here, the main role played by the parameters in the system can be identified, i.e., stability control of

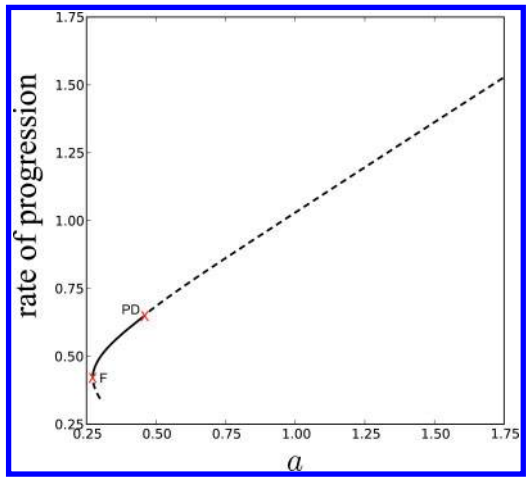

Figure 4. Continuation of the period-1 motion shown in Fig. 2 with respect to a.

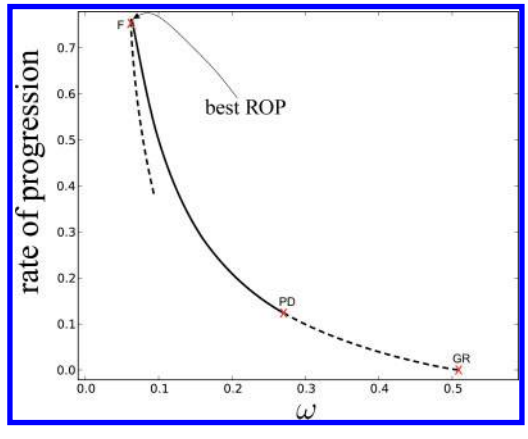

Figure 5. 1-parameter continuation of the periodic orbit shown in Fig. 2 with respect to the frequency of external excitation ω.

the period-1 motion and ROP adjustment. The stability windows are limited by fold and period-doubling bifurcations, while the ROP becomes zero at a grazing bifurcation. The present study thus provides accurate calculations for determining the stability windows as well as choosing the optimal penetration rates. This analysis may provide fundamental insight for designing and tuning control systems in various engineering applications.

Seismic behaviour and earthquake resistant design of long period structures

A. Astaneh-Asl
University of California, Berkeley, California, USA

ABSTRACT: The studies summarized in this paper focus on the effects of *far-field* ground motions on the response of long period structures such as long span bridges and tall buildings. In the studies two long span suspension bridges and two tall office buildings, with their fundamental period ranging from 5.9 to 17.5 seconds were subjected to a strong near field and a relatively weak far field ground motions and their response were studied. All structures were steel structures. The research indicated that the force and displacement response of these long period structures to far field, but weak ground motion were far greater than the response of the same structures to much stronger ground motion recorded close to the epicenter. The main parameter affecting the response was the long dominant period of vibration for far field motions being close to or longer than the fundamental period of vibration of the structures.

1 INTRODUCTION

Long period structures, such as long span bridges and tall buildings, are sensitive to long period content of the ground motion. Two characteristics of ground motion affect the response of long period structures the most. These are: (1) the *near field* velocity pulse, and (2) the long period component of *far-field* strong motions.

The first phenomenon, the *near field* velocity pulse, results in permanent displacement at the site of structures located near the ruptured fault. Ground motions with such permanent displacements cause larger force and displacement response in the structure than the ground motions that are base corrected and have a zero permanent displacement after the motion stops (McCallen et al, 2009).

The subject of the remainder of this paper is the second phenomenon, the *far-field* long period ground motions, arriving at the site of a long period bridge or building.

Long span bridges and tall buildings have relatively long fundamental period of vibration in the range of 3–20 seconds and sensitivity to ground motions with dominant long periods. The objective of this study was to investigate dynamic response of actual tall buildings and long span bridges with relatively long fundamental period of vibration to ground motions with dominant long period.

In the main study, a total of 12 steel buildings and bridge structures with their fundamental period ranging from three to 17.5 were subjected to two different ground motions, one a strong ground motion recorded relatively close to epicenter and the other a relatively weak motion recorded at a far-field distance from the epicenter. Later, Section 4 provides more details on the ground motions.

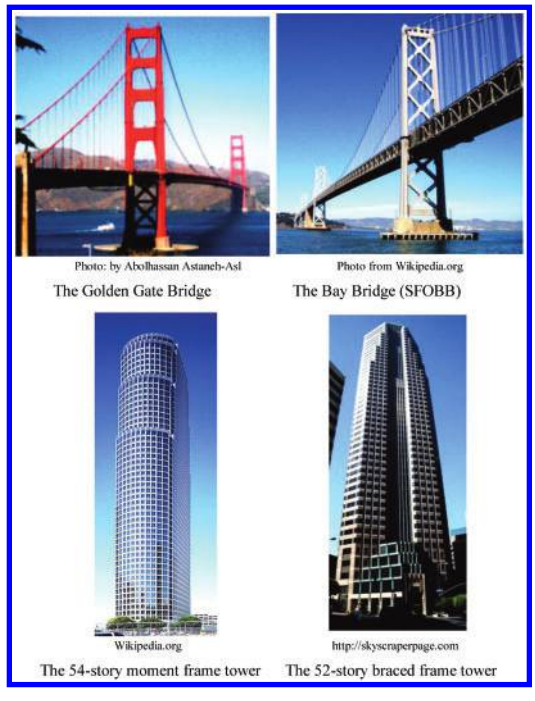

Figure 1. The four structures studied.

Figure 1 shows four of the 12 study structures summarized in this paper. They are the Golden Gate Bridge and the San Francisco Oakland Bay Bridge in the San Francisco Bay, and the 54-story moment frame and the 52-story braced frame towers in Los Angeles. For full report of studies of these four structures see Over,

Astaneh-Asl and Dreger (2010), Naeem and Astaneh-Asl (2012), Fan and Astaneh-Asl (2013), Zajac and Astaneh-Asl (2013), Leung and Astaneh-Asl, (2013) and Chen and Astaneh-Asl (2013.)

2 OBSERVATIONS DURING ACTUAL EARTHQUAKES

Far field long period ground motions and their effects on the structures have been recognized and studied since the 1960's. According to Koketsu and Miyake (2008), the far field long period, ground motions were first found in the seismograms of the 1968 Tokachi-oki and the 1966 Parkfield earthquakes.

Adnani, Marto and Hendriyawan, (2004) studied seismological effects of the far field ground motions obtained from the 2002 Sumatra, Mw = 7.4, earthquake on the peninsular Malaysia. According to the results, acceleration at the bedrock had been amplified about 2 to 7 times at the surface of Penang and Kuala Lumpur.

Observations on actual seismic performance of long span bridges and tall buildings located relatively far from the epicenter also points to the effects of far field long period ground motions. As an example, on August 23, 2011 a magnitude $M_w = 5.8$ earthquake with a focal depth of 6 km occurred in the US State of Virginia (USGS, 2013) and (Horton Jr. 2012). Although not very large quake, it resulted in damage to the Washington Monument, which is a 170 m tall structure located about 130 km from the epicenter. The reported damage was primarily in the form of cracks in the stones near the top of the monument. The monument has been closed since the quake, expected to open after three years of repair and retrofit efforts.

3 FAR FIELD GROUND MOTIONS

When a fault ruptures, the shock waves emanating from the ruptured fault particularly the surface waves while travelling through the ground loose their short period components and become a long period motion. During the travel, while the period of vibration is elongating the maximum peak ground accelerations decrease and the duration increase.

When long period surface waves arrive at the site of a structure, with fundamental period of vibration close to the dominant period of vibration of the ground motion, there will be resonance and the response of the structure to such ground motions can be quite significant even when the maximum peak ground acceleration can be quite small.

4 GROUND MOTIONS USED IN THE STUDY

Two ground motions recorded during past earthquakes were used in the studies. One ground motion representing the strong near field and relatively short period

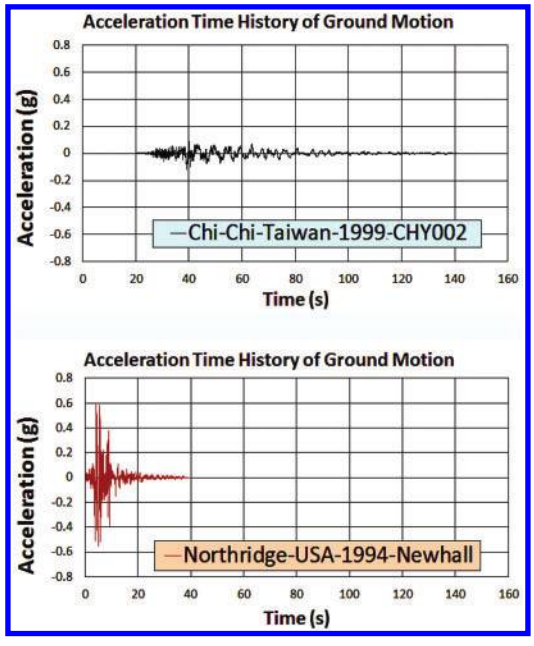

Figure 2. Time history of acceleration for N-S component of the ground motions used in the study.

motions, was the Newhall record obtained during the 1994 Northridge, California earthquake. The other was the CHY002 record of the 1999 Chi-Chi Taiwan earthquake representing relatively weak (small MPGA), far field and long period earthquakes. Figure 2 shows time history of acceleration for the N-S component of these two earthquakes. The other two components had similar features (Taing and Astaneh-Asl, 2013).

These two ground motions have profound differences. The Chi-Chi CHY002 ground motion (Figure 2, top) has relatively long duration of about 140 seconds while the Northridge Newhall ground motion has only 40 seconds durations. The maximum peak ground acceleration for the Northridge Newhall ground motion is about 0.60 g, while for the Chi-Chi CHY002 motions it is very small and only 0.08 g. The dominant period for the Northridge Newhall ground motion is about 2.5 seconds and for the Chi-Chi CHY002 ground motions it is about 6 seconds.

5 ANALYTICAL MODELS

In these studies the structural analysis software SAP2000 (CSI, 2013) was used to subject a 3-D elastic model of each long span bridge or tall building to three components of ground motions of the 1994 Northridge-Newhall and the 1999 Chi-Chi-CHY002 earthquakes. In the previous section, we discussed the ground motions. Since in all structures the response remained elastic, there was no need to introduce nonlinear member or connection elements in the models.

The main objective was to investigate the response of two existing long span bridges and two tall buildings

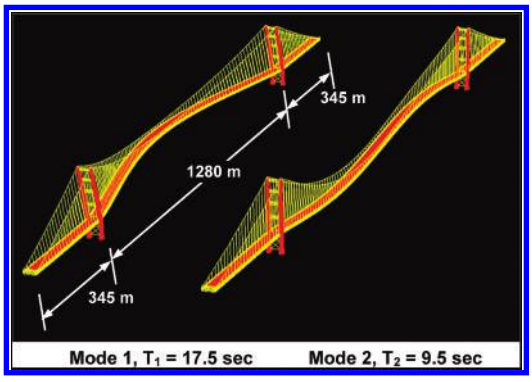

Figure 3. Two higher modes of the Golden Gate Bridge.

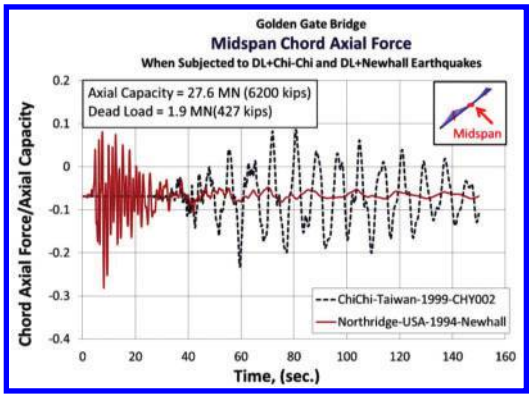

Figure 4. Time history of axial load in the midspan truss chords (Leung and Astaneh-Asl, 2013).

designed according to the governing design codes, to two different earthquake ground motions, one strong and near field and the other relatively weak but emanating from far field sources.

6 THE RESULTS

6.1 *The Golden Gate Bridge results*

The Golden Gate Bridge opened to traffic in 1937. Figure 3 shows the span lengths along with two highest mode shapes and periods of vibration. The seismic design of original bridge was based on 10%g horizontal acceleration acting on the mass. Since the 1989 Loma Prieta earthquake during which this bridge had only minor damage to its expansion joints, the entire bridge has been undergoing major seismic retrofit.

The Chi-Chi CHY002 ground motions with maximum peak acceleration of 0.08 g created almost the same axial forces in the stiffening truss chords for almost the same number of cycles that the Northridge Newhall ground motions with MPGA of 0.60 g produced, Figure 4.

Figure 5 shows midspan transverse displacements. For the strong near field Northridge Newhall motions, transverse displacements were relatively small and

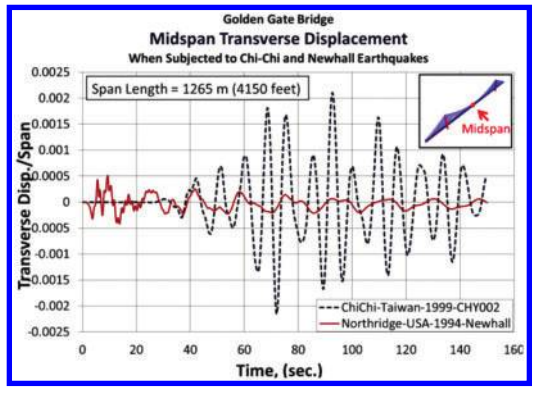

Figure 5. Time history of transverse displacement of the deck.

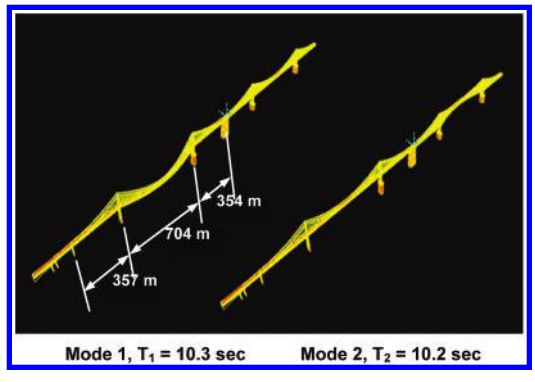

Figure 6. Two higher modes of the San Francisco Oakland Bay Bridge.

only for four cycles, Figure 5. For Chi-Chi CHY002 ground motions, transverse displacements were more than five times larger than the ones for Newhall ground motions and the number of cycles was quite large for Chi-Chi CHY002 motion.

6.2 *The San Francisco-Oakland Bay Bridge results*

The San Francisco-Oakland Bay Bridge opened to traffic in 1936. It was designed for a horizontal seismic force of 10% of its weight. Figure 6 shows the structural model used in the studies and higher modes of vibrations for the bridge as well as span length. The bridge is a double deck structure.

The longitudinal displacement response to the Northridge Newhall ground motion generated a maximum peak displacement of 0.0075 times the span length, while the maximum displacement for Chi-Chi CHY002 ground motion was 0.0063 times the span length, Figure 7. However, the number of large cycles generated by the Northridge Newhall case was only 3 while the Chi-Chi ground motion generated more than 20 displacement cycles. The large number of cycles in longitudinal direction is significant since the dampers placed between the stiffening trusses and the towers to control longitudinal motions are more effective for

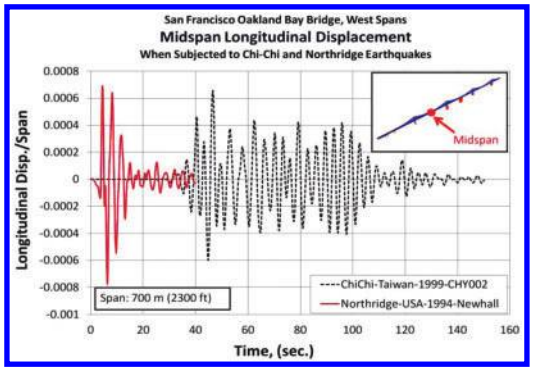

Figure 7. Time history of longitudinal displacement of the deck of the San Francisco Oakland Bay Bridge at midspan.

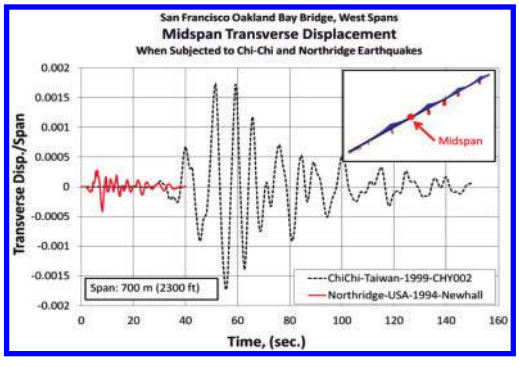

Figure 8. Time history of transverse displacement of the of the San Francisco Oakland Bay Bridge at midspan.

Chi-Chi ground motion with large number of displacement reversal cycles than for the Northridge motion with relatively small number of load reversal.

Figures 8 shows transverse displacement of the deck at midspan of the west main span. The transverse response to the much weaker ground motion of Chi-Chi was considerably greater than the response to much stronger ground motion of the Northridge earthquake.

More importantly, the maximum transverse displacement at midspan for Chi-Chi earthquake being 0.0017 times the span length, would most likely cause damage in the expansion joint while the almost negligible transverse displacements due to the Northridge ground motions would not cause any consequential damage.

6.3 *The 54-story steel moment frame tower results*

The 54-story moment frame structure is in Los Angeles built in 1990 as an office building. The tower height is about 214 m. The lateral force resisting system consists of perimeter tubular Special Moment Frames. Figure 9 shows a view of the tower and mode shapes one and three.

The building is instrumented by the California Strong Motion Instrumentation Program (SMIP, 2013). Using the data collected by the instrumentation during the 1994 Northridge earthquake, we verified the elastic 3-D model (Over, Astaneh-Asl, Dreger, 2010).

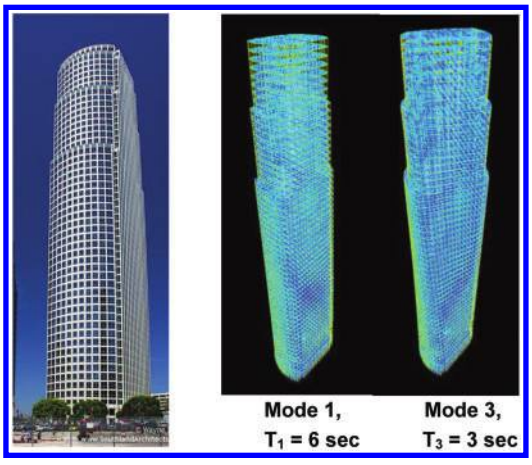

Figure 9. Modes 1 and 3 of the 54-story moment frame tower.

Table 1. Inter-story Drift Values and Non-structural Damage.

Type of Non-Structural Element	No Visible Damage	Visible but easily repairable damage	Severe Damage
Pre-cast concrete claddings	0.004	0.008	0.015
Glass windows, aluminum sash, hardened mastic	0.002	0.003	0.004
Glass windows, wood sash, soft (new) mastic	0.010	0.020	0.030
In-fill partitions	0.0025	0.004	0.008

Table 1 shows the relationship between drift and level of damage to non-structural elements of steel structures (Astaneh-Asl, 2003). The orbit roof drift response shown in Figure 10 indicates that the maximum roof drift for the Northridge ground motion is about 0.005, causing minor non-structural damage according to limits given in Table 1.

The maximum roof drift for Chi-Chi ground motion was 0.01, Figure 10, which could cause serious non-structural damage and some structural damage.

6.4 *The 52-story concentrically braced frame tower*

The 52-story concentrically braced frame structure was built in 1990, with a height of 219 m. The main lateral force resisting system in this office building is Special Concentrically Braced Frames within moment frames (Dual System). The braced bays have Chevron and V braces in both directions located around the

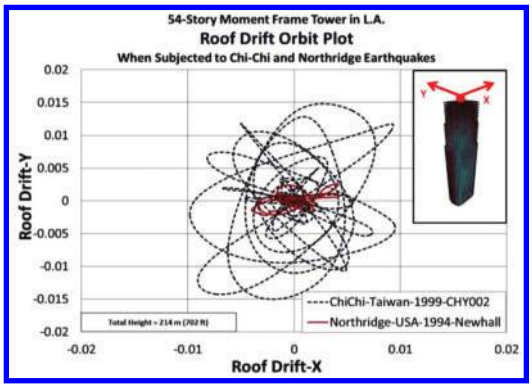

Figure 10. Orbit plot of roof drift for 54-story moment-frame tower.

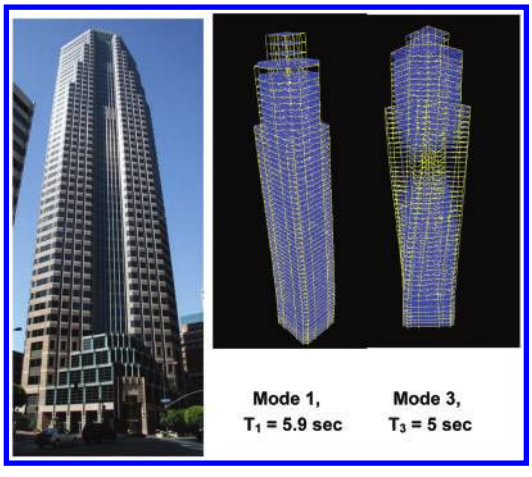

Figure 11. Modes 1 and 2 of the 52-story braced frame tower.

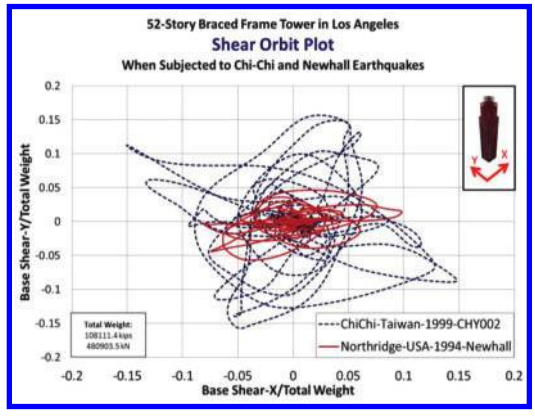

Figure 12. Orbit plot of base shear for 52story tower.

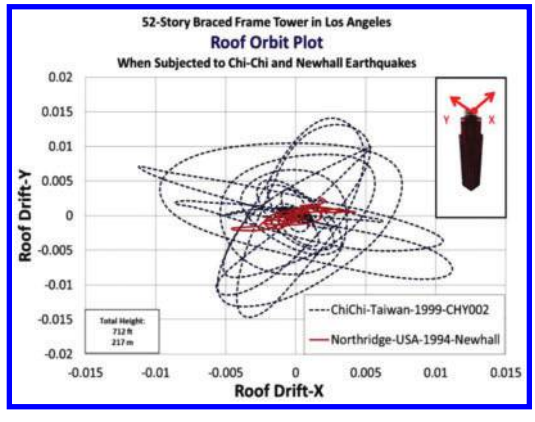

Figure 13. Orbit plot of time history of roof drift for 52-story concentrically braced frame.

core. The building is instrumented by the California Strong Motion Program (SMIP, 2013). Using the data collected by the instrumentation during the 1994 Northridge earthquake, we verified the elastic 3-D model (Naeem and Astaneh-Asl, 2012).

Figure 11 shows first two modes of the structure as well as its primary dimensions. Maximum base shear for the 52-story braced tower along the principle axes was 0.15 W (along x-x axis, Figure 12). Maximum drift along principle axes was 0.015 along the y-y axis, Figure 13, strong enough to cause serious non-structural and some structural damage such as buckling of the bracing members.

7 CONCLUSIONS AND RECOMMENDATIONS

In the studies summarized here, we subjected elastic 3-D models of the Golden Gate Bridge, the San Francisco Oakland Bay Bridge, a 54-story moment frame tower and a 52-story braced frame tower to ground motions recorded during the 1994 Northridge and the 1999 Chi-Chi, Taiwan earthquakes. The elastic time history analysis was done using SAP2000 structural analysis software.

The 1994 Northridge Newhall ground motion represents a *near field* motion with relatively short period (2.5 seconds), large maximum peak acceleration (0.6 g) and short duration (40 sec). The 1999 Chi-Chi CHY002 was selected to represent a *far field*, distant earthquake that has relatively low peak ground acceleration (0.08 g), relatively long dominant period (6 seconds) and long duration (140 sec). These two different ground motions allowed us to examine how the long span bridges and tall buildings, which have relatively long fundamental period of 6 seconds or longer, respond to near field and far field ground motions.

Based on the studies summarized herein we concluded that:

1. The study structures, which had a fundamental period of 5.9 to 17.5 seconds, had quite large response, in some cases sustaining serious non-structural damage and in a few case some structural damage to long period and weak, far field Chi-Chi CHY002 ground motion.

2. The same structures had equal or much smaller response to the much stronger near field Northridge Newhall ground motions.
3. The main parameter affecting the response was the dominant period of ground motion being close or greater than the period of vibration of the higher modes of the structure.
4. The maximum peak ground acceleration did not appear, at least in these four cases, to result in large responses.
5. The conclusions reached here were limited to the case study steel structures and should not be generalized for all long span bridges and tall buildings. More studies of long period structures subjected to far field long period, long durations, but low amplitude ground motions, are needed to develop generalized recommendations on how the effects of far field earthquakes should be considered in actual seismic design of long period structures.

Thinking outside the box: Integrated seismic system evolution in high rises

M. Sarkisian, N. Mathias & E. Long
Skidmore, Owings & Merrill LLP, San Francisco, CA, USA

ABSTRACT: International building codes typically tend to offer limited prescriptive design options for the seismic load resisting systems of high-rise structures. This, inevitably and unfortunately, has tended to restrict the creativity of designers, leading to a preponderance of "boxy" tall buildings, particularly in seismic regions. Codes do, however, offer opportunities for designers to use more strenuous but rewarding non-prescriptive design methodologies to develop and substantiate unique lateral system solutions. These methodologies, typically involving performance based design, rely on engineering first principles, non-linear analysis, and sometimes testing to accomplish desired ends.This paper will illustrate, using examples in regions of moderate and high seismicity, the integrated evolution of unique non-prescriptive high-rise structural systems and innovations in response to the specific architectural program, environmental control system, and aesthetic challenges in each case.

1 INTRODUCTION

When designing high-rise building structures, in regions of high seismicity, engineers find they have to contend with stringent prescriptive requirements that typically limit them to the use of only a few lateral systems: moment frames, shear walls, and various types of braced frames; alone or in combination. Codes furthermore impose strict requirements on building regularity. The result is that if strictly followed, prescriptive code requirements leave structural engineers with little room for innovation limiting the opportunities for architects and building services engineers to in turn be creative. Today's cities are replete with such buildings; relatively anonymous rectangular boxes with conventional structural systems.

It is possible, fortunately, to overcome this limitation by using non-prescriptive design methodologies permitted by most building codes. These typically involve the use of advanced analytical techniques and sometimes testing to validate designs and provide at least the same level of robustness as prescriptive designs. While the engineering effort is usually significantly greater than that involved in prescriptive design, the rewards in terms of being able to participate in innovative design coming up with creative solutions make it more than worthwhile.

In the following pages, examples of design solutions that were born of the interaction between programmatic, aesthetic and building system needs are presented. Examples are selected from recent work in areas of moderate and high seismicity in China, where the codes and review procedures for non-prescriptive design are well developed.Given their uniqueness, all the project examples presented were reviewed by panels of seismic experts in accordance with Chinese regulations.

2 CASE STUDIES

2.1 *Gemdale Plaza, Beijing*

The Gemdale Plaza project in Beijing consists of two high-rise reinforced concrete office towers, one 100 m tall and the other 150 m tall, and a retail podium along Chang-an boulevard, Beijing's principal thoroughfare (Fig. 1).

The architectural design envisioned the use of sun screens for shading purposes on the south and west facades of the towers. The sun screen expression was inspired by traditional oriental screens. Initially, the

Figure 1. Gemdale Plaza, Beijing.

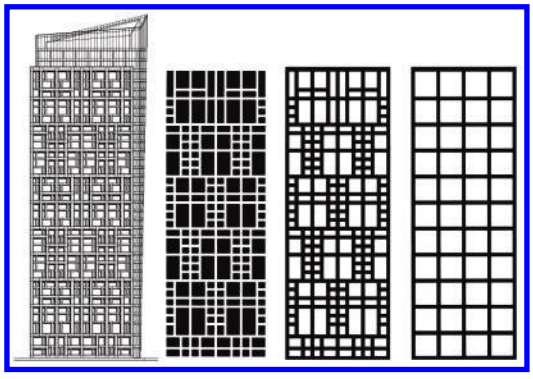

Figure 2. Screen Frame Mega Frame and Infill.

structural lateral system of the towers was conceived of as a core-perimeter moment frame system, with columns spaced at 6 m on center and girders at every floor. The sun screens, however, yielded an interesting possibility; to serve dual functions as the architectural aesthetic and shading devices as well as structure; thereby eliminating redundancy and adding rentable space to the plans. The concept of "screen frames" was thus born.

2.1.1 *Challenges and solutions*

The first challenge was to rationalize seemingly random screen members into a pattern that could serve as moment frames. Figure 2 shows an example of how this can be achieved; by creating a regular, multi-story mega-frame of primary members that carry the gravity loads of the tower as well as provide lateral resistance, and then using secondary "infill" members within the mega-grid to provide lateral stiffness only. For the Gemdale Plaza project, this resulted in screen frame mega columns at 9 m on center and mega girders every three stories. Gravity loads from the floor framing were directed only to the mega columns of the screen frames, allowing the frames to be pulled away from the edge of the floors creating a vertical gap between themselves and the exterior glazing (Fig. 3). The frames on the north and east facades, subject to less direct sunlight, had conventional moment frames with columns at 6 m on center and girders at every floor (Fig. 4).

Once the screen frames were rationalized, the next step was to "tune" their lateral stiffneses to match those of the conventional frames on the opposite faces each tower to minimize torsional irregularity. In order to keep gravity loads from straying into the secondary lateral stiffening infill members of the screen frames, delayed pour techniques were employed, where the infill member connections to the mega-frame members were only finalized after the towers were topped out and dead loads were in the primary mega-frame members. Extensive study of diaphragm demands where the floor framing connected to the screen frames across the gaps was needed to assure adequate capacity even in rare earthquakes and appropriate steel reinforced concrete details developed.

2.2 *Poly International Plaza, Guangzhou*

Located along the Pearl River in Guangzhou, the design of Poly International Plaza's two mixed-use

Figure 5. Poly International Plaza, Guangzhou.

towers blended familiar structural systems with architectural form to shape an innovative slender high-rise design solution with an aspect ratio of 8:1, framing riverfront views in a hot climate. Although Poly International Plaza used conventional seismic systems, such as a dual system composed of moment frames, braced frames, and outrigger trusses, the elements and materials of these systems were creatively integrated to define a distinctive solution that addressed the issues related to the slender proportions of the building (Fig. 5).

2.2.1 *Challenges and solutions*

To create the slender plan of each tower, a combination of reinforced concrete and steel elements were used in its lateral system (Figs 6, 7). Consequently, composite columns (in the north) were tied to reinforced concrete piers (south) with three-story high interior outrigger truss frames located in the mid-height and top sections of the building, and end frames composed of steel braced frames (east and west). Adjacent to this structure, the conventional reinforced concrete framed core was placed to the south, outside the moment resisting and braced frame perimeter, and tied back to the structure through slab diaphragms. The offset location of the core moved the bulk of service facilities and elevators out of the building to open the interior space to natural light and enhance the slender appearance of the towers.

The overall effect from the compilation of these lateral force resisting elements was a premium of open views in the north, sun-shading in the south, and a column-free interior office space. Moment frames maximized the amount of desirable natural indirect light in the building, while the core and braced frames

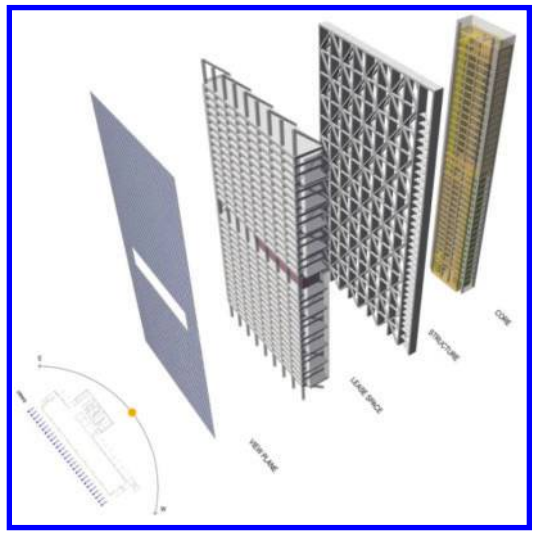

Figure 6. Structural System Components.

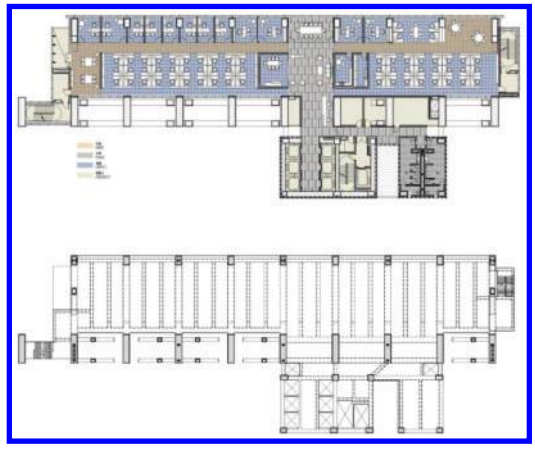

Figure 7. Typical Floor Plans, Architectural and Structural.

blocked direct light from overheating the building in the south, minimizing the demands on the HVAC system. Further, the double line of diagonal elements in the braced frames filtered light into dynamic patterns in the interior space.

In addition to its sun shading effects, the structural system yielded an unusually efficient design. The spine comprising the reinforced concrete piers and the double line of braced frames was very stiff, and served to resist in-plane seismic forces through brace action as well as out-of plane seismic forces acting as a stressed skin flange. This effectively achieved the strict drift requirements of the building codes in China. Three-story high openings penetrating both towers at the location of the mid-height outrigger truss frames also served dual roles by reducing wind loads and becoming social spaces that could double as refuge floors during an emergency.

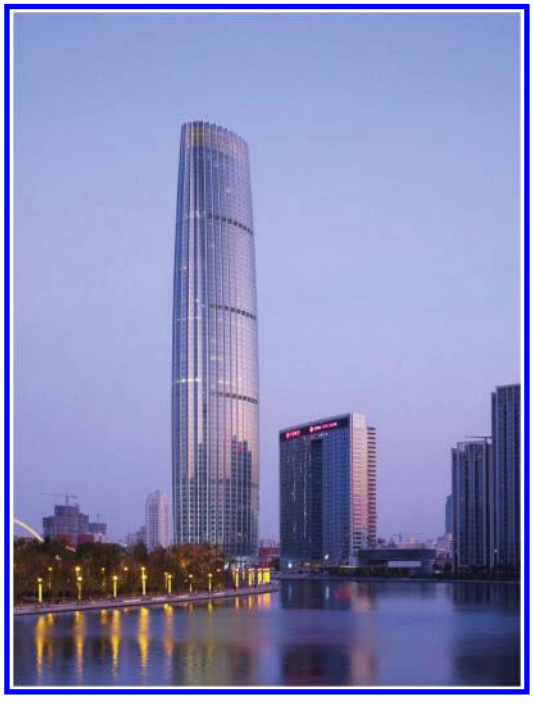

Figure 8. Jinta Tower, Tianjin.

Figure 9. Chinese Paper Art Inspiration.

2.3 *Tianjin Global Financial Tower, Tianjin*

At less than one kilometer from the main railroad station in the heart of downtown Tianjin, the Tianjin Global Financial Tower site is bounded on three sides by prominent urban thoroughfares and on the fourth by the Haihe River (Fig. 8).

Clad in a pleated glass exterior wall that recalls the structure and lightness of Chinese paper arts (Fig. 9), the 336.9 m tall office tower's uniquely folded surface catches light and maximizes views for occupants; its architectural expression combining the strength of a minimal form with an elegance of material and detail.

2.3.1 *Challenges and solutions*

Because of the tower's slender form—it has an overall aspect ratio close to 1:8—a key design challenge was to develop an efficient lateral system capable of resisting significant wind and seismic lateral loads while simultaneously keeping wind-induced lateral drifts and oscillations under acceptable limits.

Several structural system options were considered in the concept and early schematic design phases including an all concrete dual system with perimeter moment resisting frames and core shear walls;

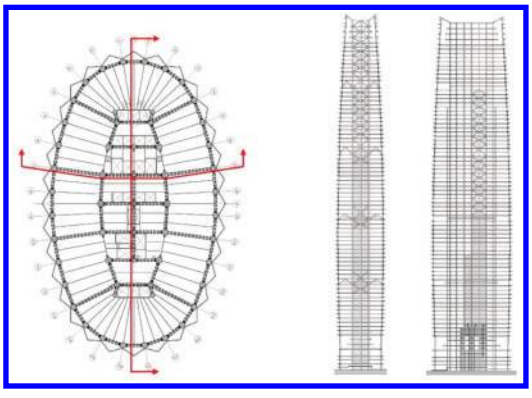

Figure 10. Typical Framing Plan and Sections.

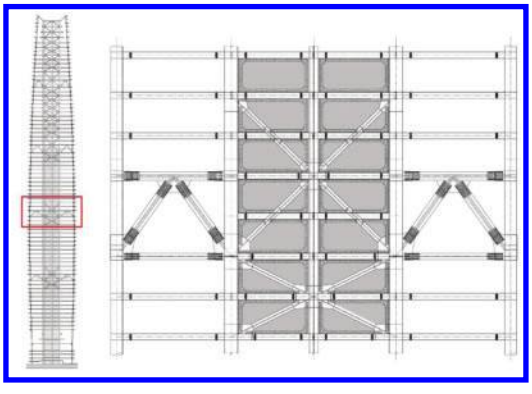

Figure 11. Outrigger Truss Elevation.

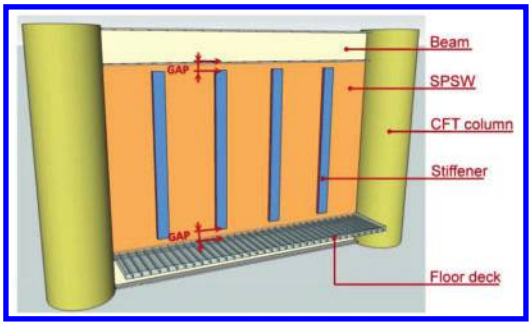

Figure 12. Steel Plate Shear Wall System Components.

composite systems with perimeter steel moment resisting frames, steel floor framing and composite metal deck slabs, and composite concrete and steel plate shear walls; and all steel systems with perimeter moment resisting frames and braced or steel plate shear wall (SPSW) cores; all in combination with outriggers in the slender direction. After relative evaluation of technical and financial merits, an all steel dual system utilizing slender stiffened SPSWs and core and perimeter frames was selected (Figs 11, 12, 13). The core and perimeter structures were connected to each other in the slender direction using steel outriggers. Columns were composite concrete filled tubes

Figure 13. Steel Plate Shear Wall.

Figure 14. Jinao Tower, Nanjing.

(CFT) to reduce dimensions and increase ductility.The minimal dimensional needs of SPSWs, the availability of substantial code provisions and design guides, research and testing data that highlighted the superior ductility of SPSWs, excellent predicted structural performance and a highly developed local steel industry, all contributed to a decision to use SPSWs in the tower core and an all steel structure.

2.4 *The Jinao Tower, Nanjing*

The 232 m tall Jinao Tower's (Fig. 14) structural system arose out of the demands of its mixed use program and unique environmental control system. The program consisted of office space in approximately the lower two thirds of its height and a hotel in the upper one third.

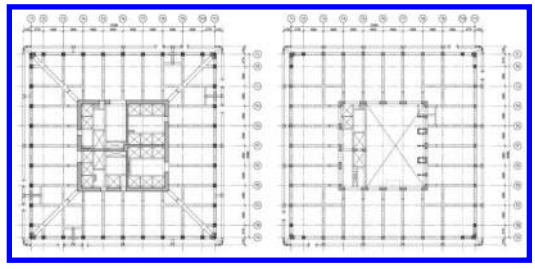

Figure 15. Typical Office and Hotel Framing Plans.

2.4.1 *Challenges and solutions*

In order to satisfy the stringent requirements of the Chinese codes, a concrete dual system consisting of a core and perimeter frame was selected. The hotel program, however, required a central atrium in the core necessitating that the core walls be extensively perforated to act as a central light well (Fig. 15). This resulted in a softening of the lateral system. Although strength requirements could be met, it was not possible to satisfy drift requirements without additional measures.

A unique solution was hit upon, noting that the project was shaped like a Chinese lantern with external folds in its double skin façade. The double skin facade system, which included slots in the outer facade to allow the entry of air, was part of the projects environmental control system, creating a temperature buffer between the inner and outer exterior wall systems. A tertiary structural system—an exterior steel mega-braced frame that only served to stiffened the building laterally to meet drift requirements without participating in gravity load support—was introduced, aligning itself with the folds of the double façade (Figs 16, 17, 18).

The steel braces, only 500 mm in diameter with a typical wall thickness of 25 mm, are designed to resist only lateral loads and superimposed live loads by stipulating a delayed construction sequence and appropriate joint details in order to keep proportions slender. The brace connections were finalized approximately a year after topping out the structure, allowing creep and shrinkage vertical building shortening to take place without impacting the braces.

The braces efficiently direct lateral wind and seismic loads from the superstructure to the foundation. Loads are managed, optimally shared between the core, perimeter moment frame and external steel braces through the "tuned" stiffness of the individual systems.Introducing the wrapping diagonal steel brace system on each side of the concrete tubular structure resulted in additional stiffening, a 40% design reduction in concrete and rebar in the lateral load resisting system, and a 20% design reduction in concrete and rebar for the overall building structure.

Several special studies were conducted to explicitly ensure the redundancy, ductility, and overstrength of the structural system. First, 3D non-linear pushover and time-history analyses were conducted to verify "life-safety" performance during rare earthquake

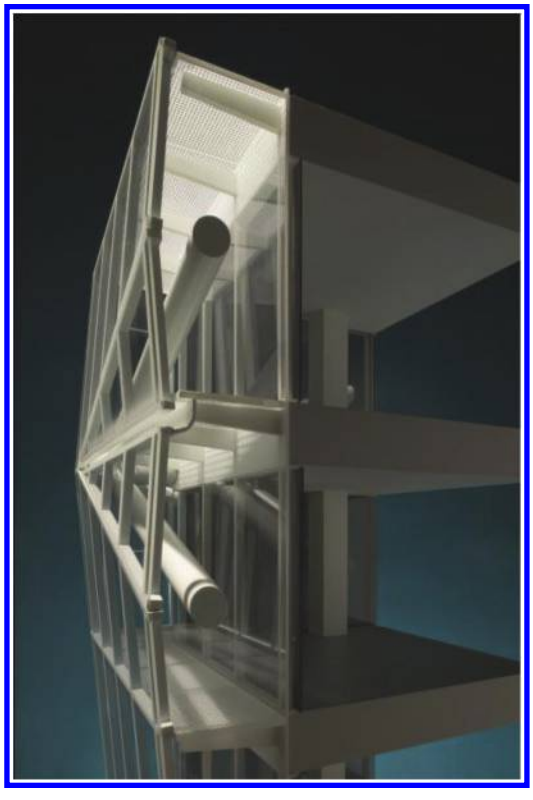

Figure 16. Perimeter System Model.

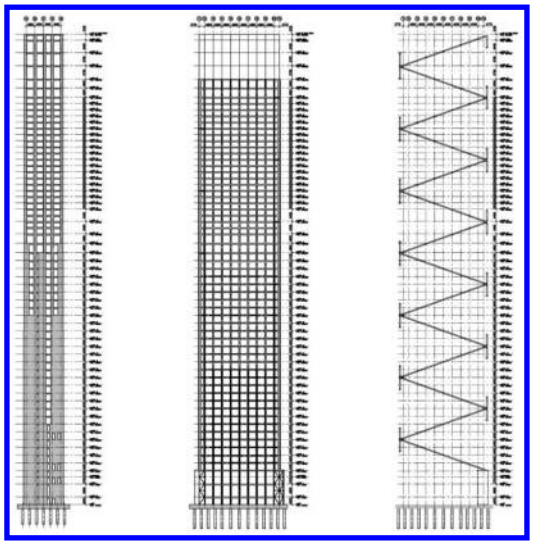

Figure 17. Inner Shear Wall Core, Perimeter Moment Frame, and Exterior Steel Brace Elevations.

demands (2000 year return) exceeding "collapse prevention" goals typically associated with such events. Second, key members and components including the steel pipe braces were designed to enhanced criteria to

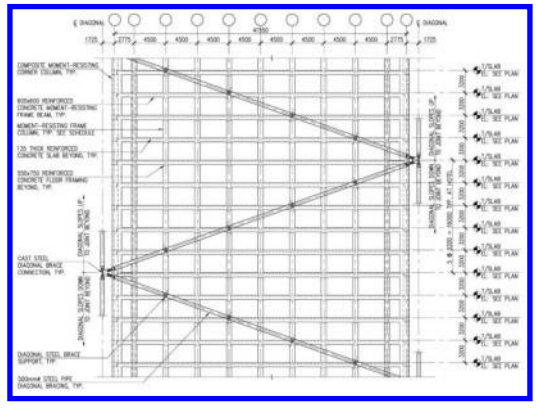

Figure 18. Enlarged Composite Elevation.

Figure 19. Full Scale Joint Testing.

ensure that they would remain elastic well beyond the baseline frequent earthquake (50 year return). Third, the force levels in the perimeter steel pipe braces were rechecked after the removal of any one brace to verify the redundancy of the structural system. Lastly, reduced scale shake table testing of the entire building and full scale testing of the typical exterior brace corner connection (Fig. 19) were conducted to validate expected performance.

3 CONCLUSIONS

It is hoped that the provided examples of structures in seismic regions will serve to show that the constraints and challenges of a real project, whether they be aesthetic, programmatic, related to site or any other reason can serve as design opportunities for structural engineers; giving them opportunities to arrive at appropriate and innovative structural solutions. With innovation, however, comes the responsibility for due diligence, and engineers who choose this course should be prepared to go the extra distance in terms of additional analysis and computation as well as peer reviews to ensure safety and efficiency of their designs.

Yokohama-Bay cable-stayed bridge seismic response analysis during the 2011 Great East Japan Earthquake

Y. Fujino & D.M. Siringoringo
Bridge & Structure Lab., Department of Civil Engineering, University of Tokyo, Japan

ABSTRACT: Yokohama Bay Bridge with the total span length of 860 m is the second longest span cable-stayed bridge in east of Japan and one of the most densely instrumented bridges in Japan. On March 11, 2011, northeastern Japan was shaken by the Great East Japan earthquake and at the bridge location JMA seismic intensity 5. This paper describes response analysis of the bridge, system identification, observation of the changes in dynamic characteristics, performance evaluation of link-bearing connection and post-earthquake field observation.

1 INTRODUCTION

1.1 *Bridge description*

Yokohama-Bay Bridge is a part of the Tokyo-Yokohama Bay Shore expressway link that connects Tokyo and Yokohama harbor area. The bridge is a continuous three-span double-deck cable-stayed with the total span length of 860 m (200 m–460 m–200 m). Bridge towers are of H-shaped, welded as monolithic section with the height of 172 m and width of 29.25 m. The girder is suspended from towers and piers by means of link bearings in such a way that the inertia force of superstructure on substructure is reduced during an earthquake by maintaining a longitudinal fundamental period about 7.7 seconds. By lengthening natural period, the structure is expected to have lower acceleration but larger displacement during an earthquake. Short links with the length of 2 m in a shape of inverted pendulum were utilized to connect the girder to the towers.

The bridge has eighty-five sensors measuring acceleration and displacement installed at 36 locations. Along the girder, sensors are installed at 12 locations with spacing of 115 m (Figure 1). At 14:46 on March 11, 2011, northeastern Japan was struck by the Great East Japan earthquake (moment magnitude of 9.0), the largest ever recorded in Japan. Epicenter of the earthquake was about 398 km away from the bridge, with the focal depth of 24 Yokohama-Bay Bridge dimension and sensor layout km. Even though the epicenter is very far away from the bridge, the fault rupture consists of about 500 km long from north to south and 220 km wide area of northeast Japan, which means that the closest distance from the bridge to the rupture fault area is about 180 km. JMA seismic intensity 5+ (equivalent to scale VII in MMI), out of the maximum scale of 7 was recorded on the bridge location.

This paper describes response analysis of Yokohama Bay Bridge under 2011 Great East Japan earthquake. The paper focuses on the response of superstructure, system identification, observation of the changes in dynamic characteristics, performance evaluation of link-bearing connection and post-earthquake field observation.

T8	71.38 [L], 67.27 [T]	17.50 [L] , 18.00 [T]

Note: L = Longitudinal, T = Transverse, V = Vertical, O = out-of-plane, I = in-plane

2 CHARACTERISTICS OF SEISMIC RESPONSE

2.1 *Characteristics of girder responses*

The girder responses were characterized by large transverse vibration as can be seen in Table 1. For girder, the maximum acceleration was in transverse direction, with the maximum girder displacement of more than 62 cm recorded in the middle of center-span. The girder large vibration is mainly due to one mode that is the first girder transverse mode at 0.28–0.32 Hz. Meanwhile, the girder vertical vibration is dominated by the first five vertical bending modes between 0.32 Hz and 1.2 Hz. The maximum girder vertical displacement is about 20 cm measured at the middle of the center span.

The frequency characteristics during main shock indicate that the predominant girder frequencies are closely-spaced around 0.32 Hz in both vertical and transverse direction. The results are different from previous investigation using seismic records of several smaller earthquakes (Siringoringo and Fujino 2006), where the first vertical and transverse mode was identified at 0.34 Hz and 0.28 Hz, respectively. Time-frequency wavelet analysis of girder transverse acceleration shows frequency peak at the initial response appears at 0.29 Hz. The frequency increases and reaches up to 0.32 Hz during the largest excitation (i.e.100–200 sec) before later decreases to 0.27 Hz near the end of response. On contrary for the vertical acceleration, the frequency peak at the initial response appears at 0.34 Hz. The frequency decreases slightly to 0.32 Hz during the largest excitation before increases to 0.34 Hz near the end of the response. The similar result was also observed during aftershock 1 (March 11, 2011 15:16). Changes in transverse and vertical frequency indicate non-linearity of the response.

2.2 *Characteristics of tower responses*

Maximum acceleration larger than 600 cm/s^2 was recorded on the top of both towers, which result in the maximum tower in-plane displacement of more than 50 cm. The large tower transverse vibrations were mainly dominated by the modes that correspond to the tower local frequency at 0.42 Hz. In out-of-plane direction the maximum accelerations were 252 cm/s^2 and 418 cm/s^2 for P2 and P3, respectively. The tower out-of-plane vibrations were mainly due to the bridge global modes associated with girder vertical modes such as the first vertical bending (0.32 Hz–0.34 Hz) and the first torsional mode (0.83 Hz), with the largest component is due to the second vertical bending modes at 0.48 Hz–0.52 Hz.

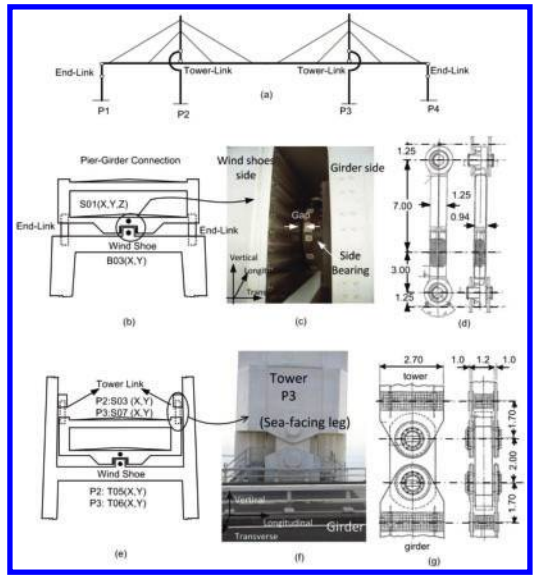

Figure 2. (a) Characteristics of pier-to-girder and tower-to-girder connections, (b) Schematic figure of tower-to-girder connection (c) snapshot photo of wind shoe transverse gap between tower/pier and girder, (d) detail figure of end-link, (e) Schematic figure of pier-to-girder connection, (f) photo of tower link, and (g) detail figure of tower-link.

2.3 *Characteristics of vibration on pier-girder and tower-girder connections*

Girder motion in longitudinal direction is accommodated by link-bearing connections (LBC) namely end-link at the end of girder (P1 and P4) and tower-link at the towers (P2 and P3) (Figure 2). In transverse direction the girder movement is restricted by wind shoes at all piers and towers. Note that there is small transverse gap between wind shoes and girder to accommodate tower-girder relative motion. The surface of wind shoes are made of stainless steel, while the girder's connection that faces the wind shoes have the form of side bearing with concave surface made of Teflon PTEE. The side bearing at end-piers and towers were designed to resist transverse load of 2,820 ton and 4,930 ton, respectively.

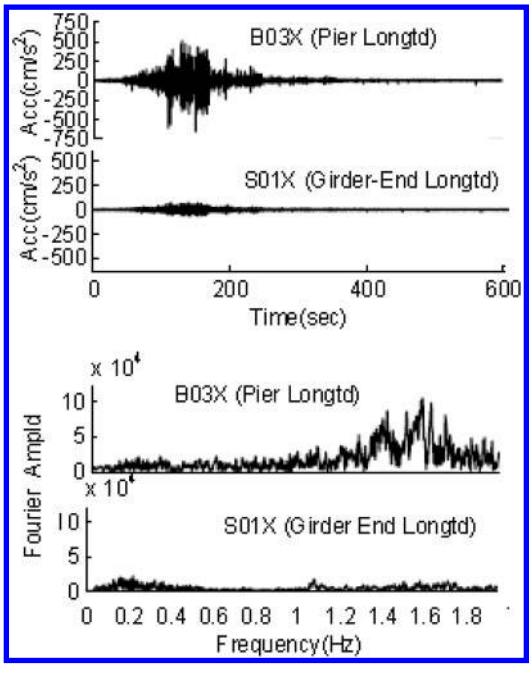

Figure 3. Longitudinal acceleration recorded on pier P1 (B3X) and on the girder above P1 pier (S1X), along with their Fourier spectra.

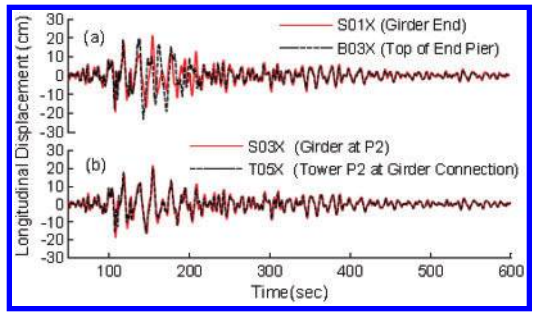

Figure 4. Comparison of longitudinal displacement (a) at end-pier P1 (B3X-S1X), (b) at tower P2 (S3X-T5X).

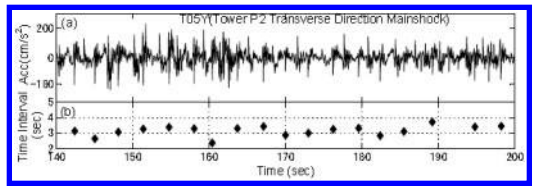

Figure 5. Accelerations of tower at deck level showing spike indicating impulses.

In design, the link bearing that connects pier and girder in longitudinal direction is expected to form a high type of connection so that large vibration energy from the pier or tower would not be transferred to the girder (Maeda et al. 1991). In such condition, relative displacement between pier and girder; and between tower and girder will be large and the high frequency components of pier and tower vibration will not be transferred to girder.

Figure 3 shows that pier longitudinal acceleration (B3X) was characterized by frequency peaks around 1.5 Hz and 2 Hz, while the girder longitudinal acceleration (S1X) located on the top of B3X, and was dominated by frequency peaks around 0.13 Hz. The maximum acceleration on the pier is about 500 cm/s^2 while the maximum acceleration at the girder is only about 50 cm/s^2. Moreover spectra plots of accelerations at the end of girder show that vibration energy is significantly smaller compared to that of the pier. The facts that girder longitudinal acceleration is dominated by low frequency component, significant reduction in amplitude of high frequency components of girder longitudinal acceleration and the large difference of vibration amplitude between pier and girder suggest that vibration energy from the pier was not transferred to the end-girder. Similar results were also observed on longitudinal responses of tower at the deck level (T5X and T6X).

Girder longitudinal displacement is one of the main concerns since excessive longitudinal displacement during a large earthquake may cause pounding to the approach spans and result in damage to the pier-to-girder connections. The results show, however, that the girder maximum longitudinal displacement (processed from acceleration) was relatively small in the order of 20 cm, which is still far below the maximum displacement 1.5 m as expected in the seismic retrofit program.

Relative displacement between girder and tower or between girder and piers at connections can be used as indicators of pier-to-girder and tower-to-girder performance during earthquakes. The results show that relative displacement between pier and girder in longitudinal direction are relative large (in order of 5–10 cm) (Figure 4). In fact at P1, pier-cap displacement (B3X) was lagged behind the girder (S1X) displacement during the largest excitation (time: 150–200sec) suggesting that girder movement was completely decoupled from pier movement for that short period of time. Meanwhile relative longitudinal displacements between girder and tower at connection are smaller than that of pier (1–5 cm).

In transverse direction, wind shoes limit girder transverse movement over the pier and tower. Small gap exists between girder and pier at wind shoes to allow for small relative displacement. This gap, however, most likely be exceeded during large excitation. Tower transverse accelerations are characterized by many periodic spikes similar to a periodic impulse response especially during the largest excitation between 100 s and 300 s. Figure 5 shows a close-up look of the acceleration response where periodic impulse exists between tower and girder indicating the occurrence of transverse pounding. In addition to the main shock, only the aftershock 1 (March 11,15:16) shows the same periodic impulse in the transverse

response of tower-to-girder connection. By observing time intervals between successive impulses during the largest excitation, we can estimate structural mode that triggers the pounding. The average time interval between consecutive impulses is about 3.2 second, which is equivalent to periodic motion at frequency range of 0.31–0.32 Hz. This result indicates that the transverse impulse at the tower-to-girder during the largest excitation period of the main shock was mainly caused by the girder first transverse mode.

3 SYSTEM IDENTIFICATION

Multiple-input multiple output (MIMO) system identification was employed to identify modal parameters of the bridge under seismic excitation. The methodology used in this study utilizes correlations between input-output data for realization of a state-space model and estimation of modal parameters. Detail information on the system identification algorithm and its application to Yokohama-Bay Bridge is given in reference (Siringoringo and Fujino 2008). In order to effectively implement the system identification, a set of input-output data was selected. As inputs, responses from triaxial accelerometers located at the bottom of the towers (P2 and P3) and the end-pier (P1) were selected (see sensor location in Figure 1). These responses were utilized, instead of the free-field responses as to minimize the effect of soil-structure interaction. As outputs 41 channels of acceleration from super structures were selected. These channels consist of accelerations from girder (23 channels), pier P1 (2 channels), tower P2 (8 channels) and tower P3 (8 channels). Since the input and output data are derived from multiaxial accelerations, the identified mode shapes have three-dimensional shape.

The system identification is based on assumption that modal parameters remain constant during a specific time-window in which the input-output data was analyzed. However, since the input excitation is large and the bridge may enter non-linear region during large excitation this assumption may not always be satisfied for the whole responses. Therefore, the analysis was conducted using a moving window scheme of a shorter time frame, during which the modal parameters were assumed to remain constant. For this reason, the total time history responses were divided into several shifted time windows consisting of 50 seconds of input and output data. Each time window generates a set of modal parameters, from which the change of parameters with respect to time can be evaluated.

3.1 *Results of system identification*

System identification generated fourteen modes between 0.1 Hz and 2.5 Hz where the girder modal displacement dominates the mode shapes. Their identified natural frequencies were in good agreement with the results from the previous earthquakes and the finite element model. In the following sections we shall focus discussion on the characteristics of three most dominant modes in respective motion direction that is the girder first longitudinal, first transverse and first vertical mode. The three modes dominate the girder vibration in three respective directions and they are most sensitive to the input amplitude.

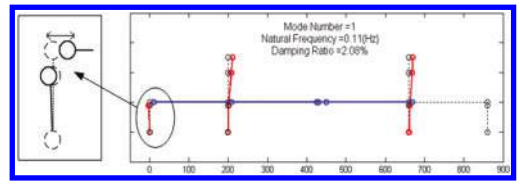

Figure 6. Longitudinal Mode shape with slip characteristic at the end-pier and girder connection.

The first mode identified by SI is the longitudinal sway mode. The mode is characterized by dominant girder longitudinal modal displacement with minimum coupling in vertical and lateral direction. Mode shape and natural frequency characteristic of this mode depend on the behavior of link-bearing connection (LBC) during the vibration. In design, the LBC is expected to function – thus modeled in FEM, as a longitudinal hinge connection. This means that relative modal displacement between girder and end piers are expected to be significantly large. Longitudinal mode shape with such condition is denoted as *slip mode*. Previous observations from seismic response reveal that this is not necessary true for all cases. For small earthquakes, system identification gives small relative modal displacements between end-piers and girder and higher frequency of longitudinal mode. Longitudinal mode shape with such condition is denoted as *stick mode*. The *stick mode* suggests that LBCs have not functioned as full-hinged connections and as a result force distribution on the end-piers and tower may be different than intended in design. A significant amount of additional force will be distributed to pier and tower if the LBCs remain stuck during large earthquake. Therefore it is important to investigate performance of LBC during large earthquake.

Figure 6 shows the mode shape of longitudinal mode identified from main shock, frame 4 (during the largest excitation) and the mode was identified at 0.13 Hz. Results of identification for the entire main shock response show that the mode was identified at around 0.12 Hz–0.13 Hz with large relative modal displacement between pier and girder indicating the *slip mode*. This is in agreement with the result of displacement of girder and pier at the pier-to-girder connection that shows a large relative displacement. It is also supported by the frequency characteristics of girder and pier accelerations at the pier-to-girder connection.

The second and the third identified global mode were the first transverse bending and first vertical bending, respectively. The two modes have distinct characteristics in that their natural frequencies and modal displacements depend on the amplitude of input excitation. During a large excitation, such as the 100–200 seconds of the main shock, frequency of the first transverse mode increases from 0.27 Hz to

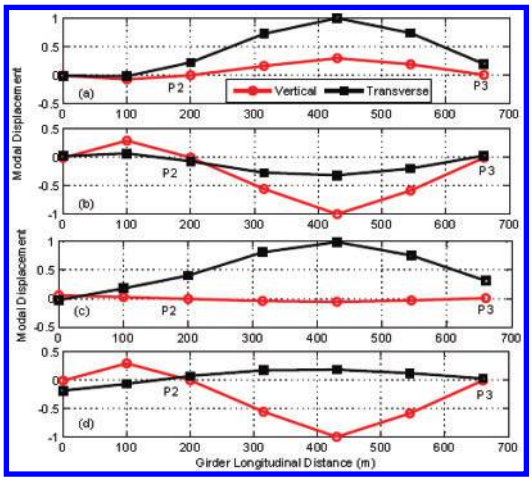

Figure 7. Characteristics of mode shapes with strong transverse-vertical coupling during the largest excitation of main shock 14:47 (Frame 4, t = 150–200 s): (a) girder first transverse mode and (b) girder first vertical mode. Characteristics of mode shapes with weak transverse-vertical coupling during the end of main shock 14:47 (Frame 11, t = 500–550 s): (c) girder first transverse mode and (d) girder first vertical mode.

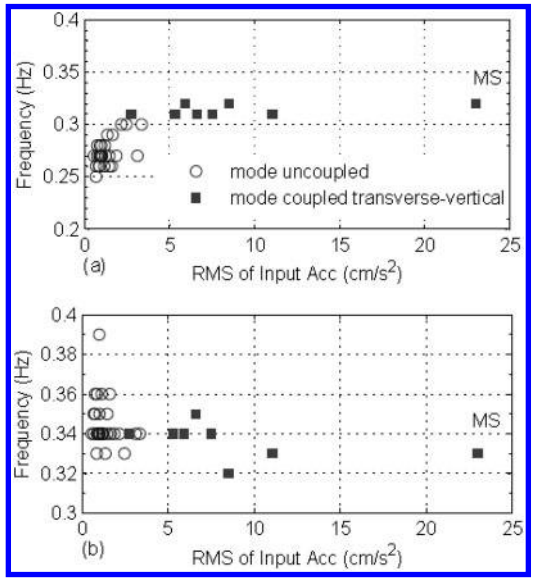

Figure 8. Variation of natural frequencies with respect to input acceleration for all analyzed seismic records: (a) 1st Transverse bending mode and (b) 1st Vertical bending mode (MS:main shock).

0.32 Hz, while frequency of the first vertical mode decreases from 0.35 Hz to 0.33 Hz.

The change in frequency is followed by the change in mode shape characteristics especially the girder transverse-vertical coupling pattern. During large excitation, strong transverse-vertical coupling of girder modal displacement was observed in both transverse and vertical modes. In this condition, the vertical mode has significant modal displacement in transverse direction and the transverse mode has significant modal displacement in vertical direction (Figure 7). At smaller excitation, as in the beginning and near the end of response, the transverse-vertical coupling becomes weaker, in that the vertical mode has very small transverse modal displacement and vice versa (Figure 7). Variations of natural frequency and coupling behavior of the first lateral and first vertical bending modes with respect to input amplitude for all records analyzed are shown in Figure 8.

The change in natural frequencies and transverse-vertical coupling behavior with respect to input amplitude indicate that the bridge response has entered the non-linear region during the main shock. Non linearity in cable-stayed bridge seismic response is known to be caused by several factors such as material nonlinearity, geometric nonlinearity due to large displacement in cable and behavior of pier-to-girder and tower-to-girder connections. However, considering the displacement resulted from seismic response is not so large as to cause significant geometric or material nonlinear, behavior of tower-girder and pier-girder connections are thought as a possible source of nonlinearity.

4 POST-EARTHQUAKE VISUAL INSPECTION

The main objective of inspection was to investigate condition of pier-girder and tower- girder connections after the earthquake. The bridge did not show any signs of serious damage and was in full operation following the earthquake. Visual inspection findings are as follows.

1. Circular marks left on the surface of wind shoes on the pier P1 and tower P2 suggesting that the girder had experience large relative longitudinal movement. The marks show that relative displacement between girder and tower (and pier) in the order of 8–10 cm had occurred (Figure 9(b)). For this relative displacement to occur, the link-bearing connection between girder and tower (and pier) must have slipped. Therefore the scratch mark on the surface of wind shoes supports the results of response analysis and the type of longitudinal mode generated by system identification.
2. In transverse direction, several marks of scraped paint were observed on the link head of tower P2. Nuts of several bolts on the upper disc of the lower head of P2 tower link were crushed and signs of scraped paint were clearly seen on the surface of the disc (Figure 9(c) and (d)). The scraped paint and broken nuts could be caused by transverse pounding between tower and girder at tower link and by combination of transverse and excessive vertical motion of girder at tower-to-girder connection.

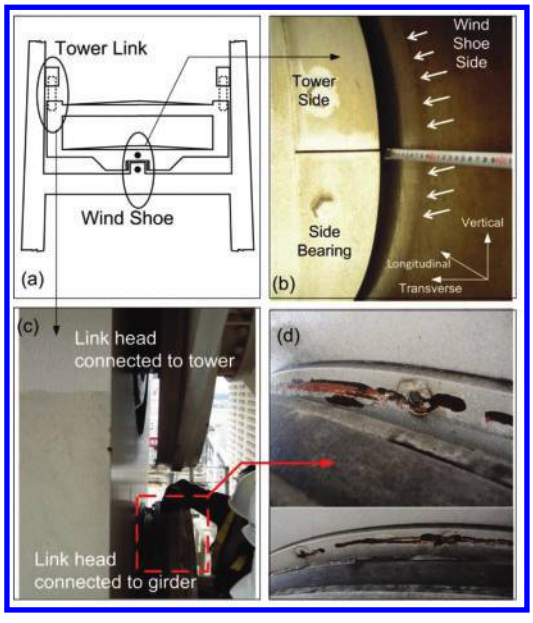

Figure 9. (a) Schematic figure of wind shoe and tower link. (b) Circular scratch marks on the surface of wind shoe as a result of side bearing movement indicate girder longitudinal movement. Distance between the marks and side bearing stationary is about 8 cm. (c) Location of head of tower link (P2) bottom head is connected to girder, top head is connected to tower. (d) Scratch marks on the surface of the bottom link head caused by combination of vertical and transverse movement of the girder. The arrows point to locations of three broken bolts caused by the movement.

5 CONCLUSIONS

Response analysis of Yokohama Bay Bridge under the 2011 Great East Japan earthquake has been discussed in this paper. During the main shock the bridge experienced intense shaking for about 10 minutes, but no structural damage was reported. Based on response analysis and system identification, the following conclusions can be drawn. (1) The input excitations recorded on the bridge foundation are still below the design and seismic-retrofit ground motions. The bridge experienced intense shaking for about 10 minutes, but no structural damage reported. (2) The bridge response during main shock was dominated by transverse movement of girder and tower. (3) During the main shock and aftershock March 15:16, girder accelerations show indication of response nonlinearity as denoted by the time variation of natural frequencies and the change in transverse-vertical coupling of the first transverse and vertical mode shapes. (4) Relative displacement response, characteristics of acceleration spectra and type of longitudinal mode at the pier-to-girder and tower-to-girder connections suggest that the link bearing have slipped as intended in design. (5) Recorded accelerations, results of system identification and visual inspection indicate that transverse pounding between girder and tower have occurred. Despite its occurrence, transverse pounding does not cause any structural damage at the present earthquake. In the future, however, effect of transverse pounding between girder and tower on bridge should be investigated in more detail and countermeasure if necessary must be taken, especially in anticipation for larger earthquake excitation.

Large natural draft cooling towers under earthquake excitation

M. Andres & R. Woermann
Krätzig & Partner Engineering Consultants, Bochum, Germany

D. Casucci
Institute of concrete structures and structural engineering, University of Kaiserslautern, Kaiserslautern, Germany

ABSTRACT: The paper deals with the behavior of large hyperbolic cooling towers under dynamic excitation of earthquakes. The column support is that component of a cooling tower which leads the entire loading from the shell into the foundation. Therefore a comparison between the traditional "V"- and "A"-columns and the most recent radial support was carried out. A parametric calculation has been performed, under consideration of three different sites and three different soil classes. Moreover, some analyses are performed to considerate the influence of wind in combination with earthquake loading as required by the previous version of the German VGB-guideline. Finally, the pushover approach of EN 1998-1 (2004) has been applied in order to perform a simplified non-linear verification in terms of displacements.

1 INTRODUCTION

Up to now the most common column support systems for a cooling tower are diagonal frameworks with different inclination and a circular or square cross section of the columns. Their efficiency is well known and proved by use in many cooling towers all over the world.

Since 20 years also radial support columns are increasingly used for different reasons, especially in countries like Germany and France. However, a few doubts remain about their applicability in areas prone to earthquakes. Due to higher internal forces and resulting higher ratios of reinforcement they are more expansive in terms of material. One advantage of this kind of support system is the simplification of construction. The installation does not require complex spatial scaffolding, which can be highly cost intensive. Another positive aspect is the larger air inlet area, due to smaller number of columns and bigger spacing between them. Furthermore, when flue gas is directly discharged into the centre of cooling towers, there is the need to transport huge gas tubes into the cooling tower. This may become difficult with inclined columns. It can be solved by skipping one column at construction phase and replacing it after pipe transportation. Another advantage of radial columns is the wide access opening to the tower for maintenance.

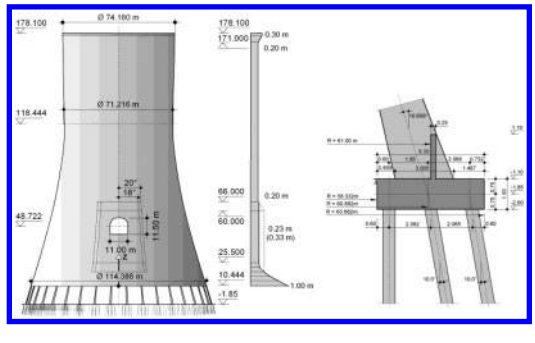
The behavior under earthquake loading of these different support systems are investigated in the following to evaluate the structural advantages of these different systems.

2 CASE STUDY

2.1 *Cooling tower for case study*

As case study the cooling tower of the E.ON hard coal power plant in Datteln has been chosen. This hard coal power plant is situated close to the city of Dortmund in Germany. Its net power capacity is 1055 MW, which is one of the most powerful single block plants of Europe. The cooling tower shell has a hyperbolic shape and rests on 36 radial supports, which are situated on a ring foundation (Fig. 1).

The tower has a height of 178.10 m with a diameter of 114.40 m at the base and 71.20 m at the throat. The thickness of the shell decreases from 1.00 m at the lower edge down to 0.20 m for the main part of the shell area. The cross section of the 36 radial columns varies



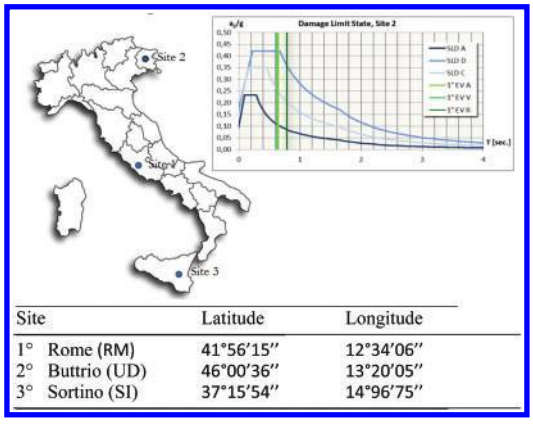


Figure 1. Dimensions of Natural Draft Cooling Tower Datteln.

Site	Latitude	Longitude
1° Rome (RM)	41°56′15″	12°34′06″
2° Buttrio (UD)	46°00′36″	13°20′05″
3° Sortino (SI)	37°15′54″	14°96′75″

Figure 2. Sites of study in Italy and seismic design spectra.

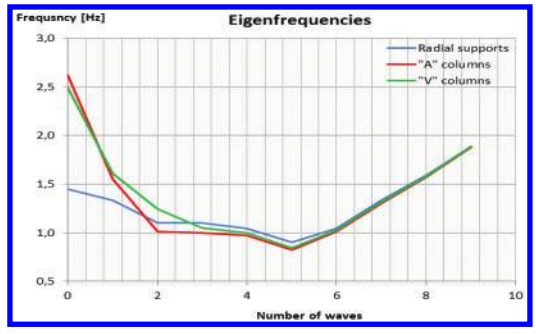

Figure 3. Eigenfreq. and wave no. of different column systems.

from 3.00 × 1.10 m at the bottom to 1.00 × 1.10 m at the top. The ring foundation has a thickness of 1.50 m and a width of 5.35 m (Andres & Woermann 2007). At Datteln power plant the cleaned flue gases, after having passed the electrostatic precipitator, are exposed directly through the cooling tower. For this reason a hole in the cooling tower shell as well as a thickening of the surrounding area for supporting the pipe is required. The main loadings which are decisive for the design of this cooling tower are wind and temperature, which both are defined by the German VGB-guideline (VGB 2010).

2.2 *Performed analyses*

In addition to the original radial support system, two alternative column arrangements are taken into account, the so-called "A"- and "V"-columns. These notations refer to the spacing between the columns heads at the lower shell edge. "V" denotes a diagonal arrangement that divides the lintel in equal divisions to reduce the bending stress at the shell base. "A" refers to the arrangement forming a true triangulated support framework at the shell base. For both of these two alternatives the diameters of the columns are chosen to 0.80 m with a pedestal at the foot of the columns.

To achieve a higher seismic load the tower is hypothetically located in three different regions in Italy (Fig. 2). To investigate the behavior of the different columns under earthquakes, three sites with different characteristics have been taken into account. The first location with low to medium base accelerations, the second with medium to high acceleration and the third with very high accelerations. Furthermore, to extend the carried out research, three subsoil classes of Eurocode A, C and D are considered.

The flue gas hole and the thickening are not considered in this parametric analysis. At first the seismic analysis is carried out with dynamic modal analysis for all 27 alternatives. Because the time-domaining non-linear analysis is computationally too burdensome in engineering practice, a non-linear static pushover analysis, as described in EN 1998-1 (2004), will be performed.

The significant construction costs and the immense consequences of a shutdown time due to possible structural failure prefer normally the elastic design, because reserves for the material ductility enhance the overall safety of the structure. EN 1998-4 (2006) clause 2.4 indeed prescribes a behavior factor 1.0 for the damage limitation state, and not greater than 1.5 in ultimate limit state verification. The seismic action is evaluated in dependence on a reference period of service life. For cooling towers normally a lifetime V_n of 100 years and an importance class of IV should be chosen for the seismic design.

All following analyses are performed with the finite elements program SOFiSTiK (2012).

3 LINEAR ANALYSIS

3.1 *Mode shapes*

All investigated cooling towers with the alternative support systems fulfill the requirements of the VGB (2010) regarding buckling safety, which impose a factor of buckling safety of 5.0 for wind and dead load.

Figure 3 shows the natural vibration eigenfrequencies correlated with the wave number of hyperbolic shell. The eigenfrequency is strictly related to the stiffness of the structure. The tower on radial supports is always stiffer for vibration wave numbers greater than 3 and generally more flexible for lowest wave numbers 0 and 1. It means that they are much less rigid for torsional motion of the shell, and quite less for translational motions. Moreover, it can be noticed that for higher wave numbers the difference between the alternative column support systems becomes smaller because of the decreasing amplitudes.

As Figure 4 shows, the larger deformations are located at column head level, while the shell is subject to a rotational/translational movement close to a rigid body. This behavior is more evident for those supports which are more flexible at lower wave number vibrations, such as radial ones and "V"-columns.

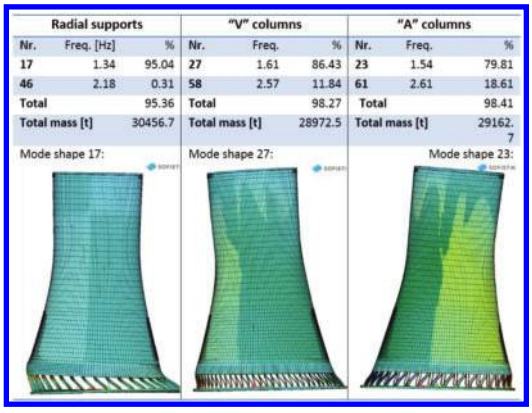

Figure 4. Mode shapes of different column systems.

It is worth to notice that the tower with radial supports has about 20% lower frequencies compared to the other solutions. This means that it has higher vibration periods, which lead to lower accelerations for most seismic design spectra.

Without taking earthquakes into account, results of the linear analysis show that towers on diagonal columns have a better behavior, especially with respect to the shells. Radial supports lead to higher thermal stresses and bending moments at the lower lintel of the shell.

3.2 *Serviceability limit state*

The VGB (2010) does not impose restriction on the serviceability limit state and therefore verification is formally not necessary. On the other hand in areas of high seismic risk, it seems to be appropriate to investigate this aspect also. Hence, in this section, it is shown how to impose a limitation for such structures.

For importance classes I and II it has to be verified that seismically action does not produce damage to construction elements without structural function, in order not to render the structure temporarily unusable. For example the limitation for a common frame building of these classes is the difference of the displacement between each floor level. The limit depends on the kind of structure and especially on the non-load-bearing walls.

The natural draft of a cooling tower will function until the structure hypothetically collapses. Normally a gap between the shell and the internal fill structures exists, so an uncoupled system can be assumed.

Since these proofs are not required in detail in EN 1998-1 (2004), the Italian design code is additionally observed (NTC 2008). For structures of importance class III and IV two verifications are necessary. The first one, regarding the Operational Limit State (O.L.S.), requires the avoidance of cracking under weak earthquake. To impose a limitation on the displacements, a couple of columns has been analyzed: Also under the strongest earthquake the calculated displacements are far below the limitation of the serviceability limit state.

The second requirement is concerned with the Immediate occupancy Limit State (I.L.S.), verifying the resistance as indicated below. At the I.L.S., in order to limit the suffered damage, the code requires a resistance verification for exceptional situations. In this case the ordinates of the spectra can be reduced by a factor $\eta = 2/3$. Furthermore, since it is an exceptional situation, all partial safety factor of the material can be set to 1.0. Because of the fact that in the Ultimate Limit States with behavior factor 1.0 all partial safety factors are the same this verification can be neglected.

3.3 *Capacity design on a cooling tower*

Capacity design is based on the fact that energy released by an earthquake is absorbed by the structure through damage of structural and nonstructural components. Seismic damages should occur in a controlled way and at precise points to avoid collapse of the whole structure. This behavior is normally achieved through cracking of reinforced concrete members or yielding of diagonal steel braces. The structure has to sustain significant deformation without failure. To achieve the desired failure mechanism, the members not participating in the failure are provided by additional strength or overcapacity. This method has a considerable advantage: with minimum increase of cost it is able to satisfy the requirements in terms of earthquake resistance. However, it must be considered that this method has been developed for frame structures, for which the behavior described above is relatively easy to obtain. The capacity design would necessarily have to provide overcapacity to the columns, as the weakest link of the structural integrity of the system. However in diagonal arrangement, one finds slender columns under high compression, hence there is no chance of a plastic hinge. Instead, it seems possible that this method may be successfully applied, although with modest benefit, on cooling towers with radial supports.

3.4 *Effects on the shell*

The effects of earthquakes on cooling tower shells are small in comparison with those ones of wind and temperature. Indeed wind bends the shell acting with different pressure coefficient over height and circumference. Earthquakes instead give horizontal impulses nearly constant along the ring foundation which firstly affect the columns. Radial support columns, which bend the lower shell edge at area with minor stiffness, lead to high internal forces at the first two shell meters. In this area the shell thickness and the reinforcement ratio are high. So forces can be distributed to adjacent areas without additional strengthening. The situation improves for diagonal arrangements, where the largest part of the seismic action is carried by the columns which are located under the stiff area of the shell with respect to the direction of the seismic action.

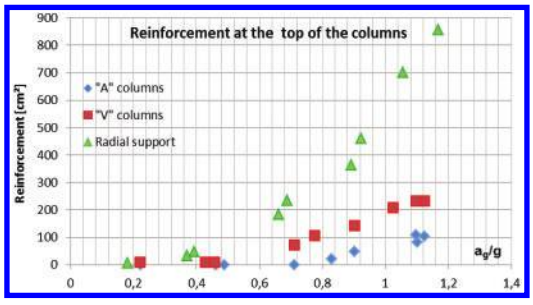

Figure 5. Reinforcement at columns head acc. to acceleration.

Above this edge-near shell area, effects of earthquake are negligible because of the rigid behavior of the shell.

3.5 *Effects on the columns*

Linear analysis shows that diagonal column arrangements resist well to horizontal acceleration. The columns are almost only affected by axial forces. That holds especially true for "A"-columns which lead horizontal forces effectively to the foundation. For "V"-columns instead bending moments become more important and axial forces are higher, because of minor inclination between the two columns. Thus the study shows that "A"-columns can resist to all investigated earthquakes without additional reinforcement with respect to the basic design for wind load, but "V"-columns require some additional longitudinal reinforcement for middle to strong earthquakes, as shown in Figure 5.

This situation gets significantly more worse for radial supports, which resist to horizontal acceleration only by bending. The behavior is less efficient than for the other cases and the reinforcement which results from the basic design is sufficient only for weak and medium earthquakes. Usually the dimensions of the columns have upper limits, because this affects the flow of incoming air. Also the reinforcement ratio is limited by the regulations of the design codes. Because of both limits, radial support columns should not be chosen in case of high earthquake excitation.

3.6 *Effect of wind on earthquake combination*

Regarding seismic actions, VGB-guideline requires to refer to the design code of the respective country where the tower will be built. In modern design codes often wind loading must not to be taken into account in combination with earthquakes. This is because the very low probability that both actions occur simultaneously. However, for tall structures such as cooling towers or shafts of wind turbines, it is far more probable that wind action is present than not. For this reason, the VGB-guideline, up to the previous edition, required to include a percentage of wind on the earthquake combination. In this case, the exceptional design situation for earthquake was assumed.

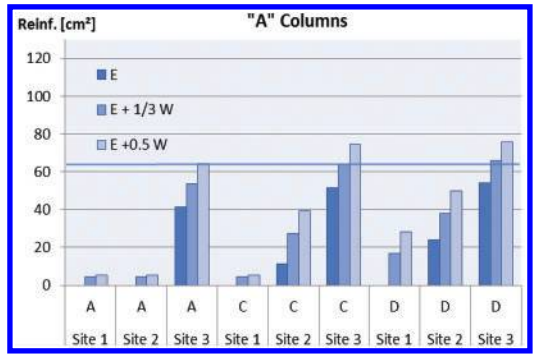

Figure 6. Reinforcement for wind-earthquake combination.

The effects of this combination on the columns are now evaluated. The following combinations will be considered in order to get certain information about the influence of the wind:

$$\sum G_{k,i} + A_R + 0.333W + \sum \psi_{2,i} \cdot Q_{k,i}$$

$$\sum G_{k,i} + A_R + 0.5W + \sum \psi_{2,i} \cdot Q_{k,i}$$

The main effects, if wind is involved, are bending and traction in the shell and additional compressive or tensile strengths in the columns. Since the shell continues to have no considerable problems with such low wind actions, we check again the effects on the columns, starting with the stiffer ones.

By observing the computed results the following remarks can be made:

1) "V"-columns require more reinforcement by rise of the base acceleration,
2) on "A"-columns the effect of wind load is more incisive, but generally they require less reinforcement than all the other cases,
3) in combination with wind load, the earthquake may become decisive also for "A"-columns (Fig. 6).

Furthermore also the influence of the wind direction with respect to earthquake excitations has been investigated. It can be shown that the influence is not very high, always less than 5%.

4 PUSHOVER ANALYSIS

In recent years this method has asserted itself increasingly, for the following reasons. Elastic analysis is not capable of providing reasonable estimates of inelastic deformation or damage. On the other hand nonlinear dynamic time history analysis is capable of providing this information, but is very time-consuming for larger structures.

The pushover analysis of a structure is a static nonlinear analysis under permanent vertical loads and gradually increasing lateral loading. The equivalent

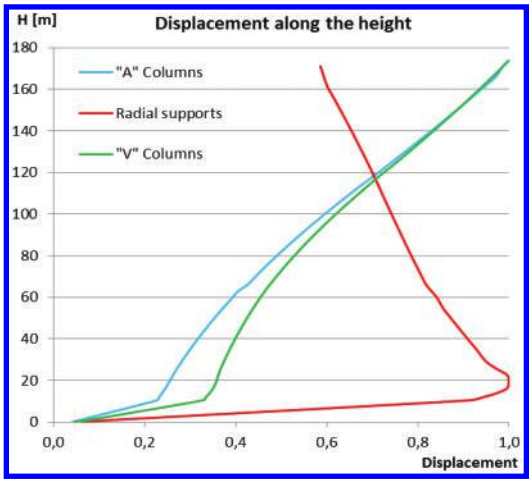

Figure 7. Normalized displacement of first mode shape.

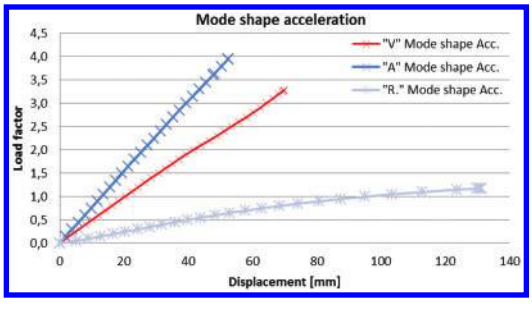

Figure 8. Pushover analysis with mode shape acceleration.

static lateral loading approximately represents earthquake induced forces. The analysis is carried out up to failure, thus it enables determination of collapse load and ductility capacity. For the pushover analysis two load distributions are generally applied. One distribution is constant over height, and the second is proportional to the first mode shape which activates the highest possible percentage of mass.

The second distribution varies over height. The average displacement of the nodes of each parallel circle has been calculated, generating a curve along the whole height. This curve was normalized to the maximum displacement and used to scale the acceleration. In Figure 7 the normalized displacement of the first mode shape is shown.

Figure 8 shows for example one of the results of this analysis. It can be seen that the radial column support is the only one which shows a ductile behavior. In this case the system is able to distribute the forces after reaching yield stresses into the neighbored areas.

The N2-method of EN 1998-1 (2004) is a nonlinear method for performance-based seismic design where the displacement demand must be compared with the displacement capacity of the structure. Such analysis methods are typically recommended for the performance assessment of existing structures. We use this method to evaluate the impact of earthquakes on the

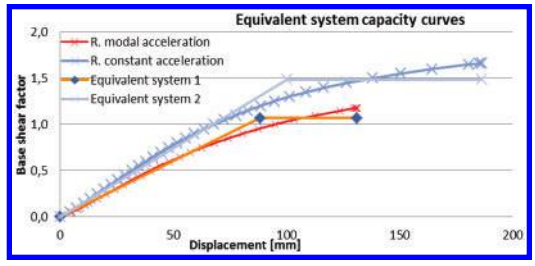

Figure 9. Equivalent capacity curve for radial support system.

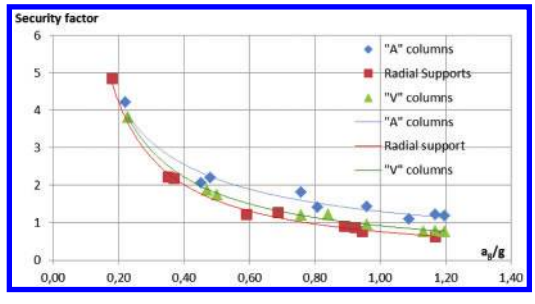

Figure 10. Security factors depending on the base acceleration.

cooling towers previously designed. Once the capacity curve of the whole structure is calculated, an equivalent system with only one degree of freedom is defined with a bilinear equivalent capacity curve (Fig. 9).

The theory of this method is simple and can be directly taken from EN 1998-1 (2004). In the case of a cooling tower, things are simplified because the shell can be considered as a rigid body.

Figure 10 shows the security factor, which is the quotient between the maximum displacement of the capacity curve and the demand for the specific acceleration. It can be seen that the results are nearly the same as from a linear analysis. “A”-columns still resist all investigated earthquakes, whereas radial and “V”-columns loose their capacity for stronger earthquakes.

5 COOLING TOWER AT KORADI POW. PLANT

This actual project comprises the design of three similar cooling towers with a height of 185.00 m in the state of Maharashtra, India for the TPS Expansion Project 3 × 660 MW, unit 8, 9 & 10 at Koradi near the city of Nagpur in central India. These cooling towers, being under construction now, are situated on extremely weak ground. Further information can be taken from Andres et al. (2012).

The above described studies concerning earthquake and the low soil bearing capacity lead to the stiff deep foundation system which is shown in Figure 11.

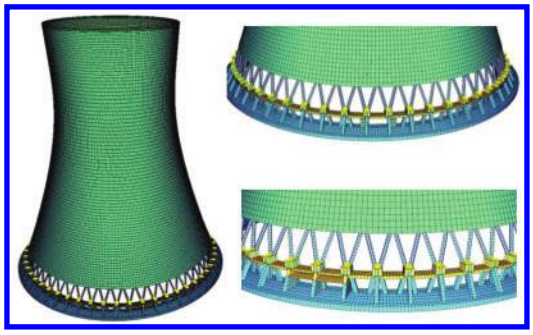

Figure 11. FE-Model of Koradi Tower.

6 CONCLUSIONS

Finally we affirm that radial columns are the less statically efficient ones, because of the temperature loads and the higher spacing at the lower lintel, which confer higher stresses to the shell. Since the cross section can not be enhanced, in order not to obstruct the air entrance surface, the reinforcement ratio rises quickly with the horizontal load exceeding the maximum allowable limit.

For "A"- and "V"-column systems the need of additional reinforcements for seismic actions results for higher horizontal loadings. However they are able to resist at most of the sites and soil conditions which were investigated. Furthermore they are the best choice for the shell because the lower lintel is divided in equal spaced pieces allowing to reduce internal forces and required materials.

Summarizing the results, radial columns, although more expensive and not extremely efficient, became recently most popular for many different not properly structural reasons. "V"-columns appear to be the best compromise until the seismic action does not reach too high values. Indeed, "V"-columns seem to be suitable for almost all sites where steam power stations will be built (Casucci 2012).

Future development of the European seismic code, Eurocode 8

E.D. Booth
Edmund Booth Consulting Engineer, Tring, UK

ABSTRACT: Publication of the ten structural Eurocodes during the first decade of the 21st century represented one of the most ambitious projects of European collaboration in structural engineering. Eurocode 8 – design of structures for earthquake resistance – was published in 2004, and its six parts gave it a scope which exceeded any other seismic code anywhere in the world; thus, it covered not just buildings, but also bridges and a range of other civil and industrial structures. Moreover, it applied to a very wide range of seismic hazard conditions, from the low seismicity of Northern Europe to the highly active regions of the South. Many of the provisions of the code were among the most advanced available at the time of publication, and represented a distinctly different tradition and approach from that found in US seismic codes such as ASCE 7 and ACI 318. However, earthquake engineering is a rapidly advancing discipline, and since the code was originally drafted there have been many important developments, including those in seismic hazard assessment, foundation and structural design, seismic performance specification and seismic analysis. Moreover, societal expectations for structural and non-structural performance in an earthquake are becoming much more demanding. Work on revising all the Eurocodes, including Eurocode 8 (EC8), is due to start in 2014, with the intention of publishing revised standards for use in around 2020. The paper reports on the current proposals for upgrading EC8. In the opinion of the author, who has been involved in EC8's development for over twenty years, a broad ranging review of objectives for EC8 should also be undertaken, to set out a framework for its development after the current revision process is complete.

1 INTRODUCTION

1.1 *Evolution of the structural Eurocodes*

The ten structural Eurocodes were published as finally approved standards during the period 2002 to 2005, and since 2010 they have superseded the national codes of many of the 33 European countries which are members of the European Committee for Standardisation (Comité Européen de Normalisation or CEN). This major change in practice represented a great challenge to European engineers; therefore, CEN decided that a period of stability was needed after the initial introduction of the Eurocodes. No changes to the Eurocodes were to be allowed for at least ten years after first publication, apart from essential corrections and clarifications. However, that period of stability is now complete and a formal review of all the Eurocodes will start in 2014. It is hoped that the revised standards emerging from the review will be approved for use from around 2020.

At the time of writing (March 2013), CEN/TC250, which is the Technical Committee of CEN overseeing all the Eurocodes, was about to submit a proposal to the European Commission identifying the work needed to update all the Eurocodes, including the seismic standard Eurocode 8 (EC8). This proposal requests funding from the European Commission for certain parts of the work, with the remainder intended to be carried out by voluntary activity. The Commission's response is due at the end of 2013. Funding from the Commission is expected to be very limited.

One primary aspiration for the next generation of Eurocodes will be to bring national practices more into line, by reducing the number of parameters and procedures for which national choice is permitted, as expressed in each nation's National Application Document. Another major aspiration is to simplify the codes. While those aspirations may be sufficient for many of the Eurocodes, the recent rapid and radical developments in earthquake engineering demand suggest more extensive changes will be needed to EC8.

1.2 *Eurocode 8 (EC8) – design of structures for earthquake resistance*

Creating a comprehensive and coordinated set of design rules to cover a very wide range of seismic engineering situations was a major task. The scope of the six parts of EC8 (see Table 1) exceeded that of any of the pre-existing European seismic codes, or indeed that of any seismic code anywhere in the world. It had to cover the very wide range of seismic hazard and construction types that exists over the various parts of Europe, and it also covered not only building structures but also bridges and a wide range of industrial and civil structures. Some innovative features made aspects of

Table 1. The six parts of EN1998 (EC8): Design of structures for earthquake resistance.

Number	Title
EN 1998-1	General rules, seismic actions and rules for buildings Section 1: General Section 2: Performance requirements and acceptance criteria Section 3: Ground conditions and seismic action Section 4: Design of buildings Sections 5–9: Specific rules for buildings in concrete, steel, composite steel-concrete, timber and masonry Section 10: Base isolation
EN 1998-2	Bridges
EN 1998-3	Assessment and retrofitting of buildings
EN 1998-4	Tanks, silos and pipelines
EN 1998-5	Foundations, retaining structures and geotechnical aspects
EN 1998-6	Towers, masts and chimneys

EC8 more advanced than any other code available in 2004; for example, the treatment of geotechnical issues was particularly ambitious. Therefore, the successful publication of EC8 nine years ago was a considerable achievement, and it has subsequently been used as a model for codes in countries outside Europe, such as Egypt and Vietnam.

However, earthquake engineering is a rapidly developing field, perhaps changing more rapidly than applies to the topic of any other Eurocode. The long period of drafting, which took over 15 years, means that many of the procedures and approaches in the code are considerably older than nine years. The feedback from users during the next revision process will of course provide much useful information on what needs changing and simplifying, and the process of harmonizing national choices will also be useful. However, more wide ranging changes are also needed.

2 THE EVOLUTION OF EC8

2.1 *Areas identified for redrafting by CEN*

As explained above, CEN Technical Committee TC250, which is responsible for the Eurocodes, is submitting proposals to the European Commission for the work required to revise and update the Eurocodes. The proposals relating to EC8 were prepared by the CEN sub-committee on EC8; the work items identified were as follows.

2.1.1 *European seismic zonation*

At present, EC8 specifies the seismic ground motions to be used in design in terms of a response spectrum. This is defined by means of the peak ground acceleration (PGA) on rock, which is used to scale standard spectral shapes depending on both the ground conditions at a particular site, and the magnitude of the earthquake controlling the seismic hazard. The return period of the PGA to be used for design is recommended as 475 years, although this is a 'nationally determined parameter (NDP)' which countries may vary. Similarly, spectral shapes are recommended but are also subject to national choice. However, EC8 gives no guidance on the seismic zonation itself – i.e. the values of design PGA to be used at a particular location. That is left for the national standard authority in the country concerned to define in its 'National Annex' (NA) to EC8 Part 1.

Each country has used somewhat different models and methods to define its seismic zonation and this has led to a lack of harmonization between CEN member countries. For example, the seismic hazard defined in the NA of one country on one side of a national border may be very different from that on the other side, as defined in the adjacent country's NA.

To address this, a major European collaborative project now nearing completion called SHARE (www.share-eu.org/), funded by the European Commission, has attempted to define a standard approach and common models to produce a harmonized European approach to seismic zonation, and has also proposed changes to EC8 procedures. In particular, the use of a single parameterfor defining hazard has been questioned. Currently EC8 specifies PGA at 475 year return period as the single defining parameter, but SHARE recommends use of multiple parameters based on spectral response at different periods. Allowing for the dependence of site amplification on the intensity of motion, not currently included in EC8, is also recommended. Both these changes were adopted some time ago in US seismic codes.

The results and recommendations of SHARE will be a major source for the proposed task of harmonizing European seismic zoning and more generally of improving the specification of design ground motions in EC8.

2.1.2 *Displacement based design*

Currently, the standard analysis method for buildingsin most seismic codes, including EC8, is based on an equivalent static or response spectrum method, with reduction factors (q in EC8 and R in the US seismic codes) modifying response to allow for the availableductility. These essentially linear elastic methods give no information on the distribution of plastic strains in the building, and the reduction factors are a crude measure of the ductile response available. In the last 20 years, efforts have been made to develop analysis methods which give a better indication of seismic performance without resulting in an unacceptable increase in complexity. These 'displacement based' methods involve idealizing the structure as an elasto-plastic single degree of freedom (SDOF) system, and setting the maximum displacement demand, rather than force demand as in more traditional methods, as the principle parameter determining design. The

distribution of displacements throughout the building structure, and the corresponding distribution of plastic strains, is then found by imposing the maximum displacement found from the SDOF model onto a non-linear model of the building structure in a process known as 'static pushover' or 'equivalent static' analysis.

It is claimed that these procedures result in more efficient and reliable structures, and facilitate better control of performance under serviceability as well as ultimate limit states. They form the basis of 'performance based design'.

Displacement based analysis methods in fact already appear in EC8, particularly for bridges in Part 2, and also for buildings in Part 1, although the latter are not fully described. During the current redrafting of EC8, the intention is to ensure that they are fully usable in practical terms, particularly for the design and retrofit of buildings. This would be relatively easy to do by building on the current procedures given in Annex B of EC8 Part 1, which are based on the N2 method of Fajfar (2000).

Revisions to the standard after 2020 might consider more radical departures. One possibility is that the direct displacement based design method of Priestley et al. (2007) could be adopted by EC8 as one of a number of options available to the designer. Sullivan et al. (2012) have described the procedure in code format suitable for inclusion in EC8.

2.1.3 *Steel, timber, masonry and aluminium building structures*

The current provisions in EC8 Part 1 for steel, timber and masonry building are recognized as needing significant updating. For steel buildings, the European Convention for Constructional Steel Works (ECCS) has prepared proposals for clarifying a number of issues in EC8. The ECCS proposals need to be reviewed and refined as necessary, taking into account recent research into the seismic design of steel structures. In particular, EC8 needs to reflect the results of work in the USA intended to address the issues which caused numerous failures of welded steel buildings in the Northridge, California and Kobe, Japan earthquakes of 1994 and 1995 respectively (AISC, 2010).

There have been many recent innovations in factory prefabricated timber panels for house construction, and these have included the development of new timber systems with earthquake resistance. Draft revisions to EC8 Part 1 reflecting these innovations have been prepared by Follesa et al. (2011) and these need to be reviewed and refined as necessary.

Masonry buildings form a large proportion of the domestic housing stock in Europe, but the current rules in EC8 Part 1 have been found to be onerous to apply in the low seismicity regions of Northern Europe. Moreover, the simple rules for masonry buildings given in EC8 are in need of overhaul, and are probably excessively conservative. These rules enable low rise masonry buildings to be designed without recourse to a seismic analysis by specifying minimum values of parameters such as the ratio of the total cross sectional area of walls to floor plan area. Updating is also needed to the rules for preventing walls failing out of their plane (as distinct from in-plane shear failures).

Eurocode 9 presents rules for the (non-seismic) design of aluminium structures, but none are given in EC8 and it is intended to redress this during its current revision.

2.1.4 *Infill frames and cladding*

Steel, and more especially concrete, frames infilled with brick masonry to form the external building envelope represent a common form of construction in Southern Europe. There is a complex interaction during an earthquake between the masonry infill and the frame which encloses it; in well-designed cases, the interaction can be favourable, but often it is highly deleterious. The rules in EC8 Part 1 are considered adequate to prevent the unfavourable interactions but need updating to allow designers to take more benefit from the favourable ones. There is also a need to improve the rules on providing restraint to prevent out-of-plane failures of the infill.

More generally, cladding has suffered damage in recent European earthquakes, particularly in portal-frame industrial buildings where the structure itself has performed well but the cladding has failed, giving rise to costly consequences. Improved design guidance is needed.

2.1.5 *Retrofit of buildings and bridges*

Part 3 of EC8 provides rules for the seismic assessment and retrofitting of existing buildings. Since most deaths and much of the loss due to earthquake shaking are caused by the collapse of inadequately designed existing buildings, this part is clearly of great importance, but in the author's view is the least satisfactory part of EC8. The procedures presented are rather general and theoretical, and more practical methods of assessing buildings are found in US documents, particularly ASCE 41 (ASCE, 2013).

It is hoped that the revisions to Part 3 will be able to improve this situation. It also intended to extend Part 3 to cover the retrofitting of not only buildings, but also bridges.

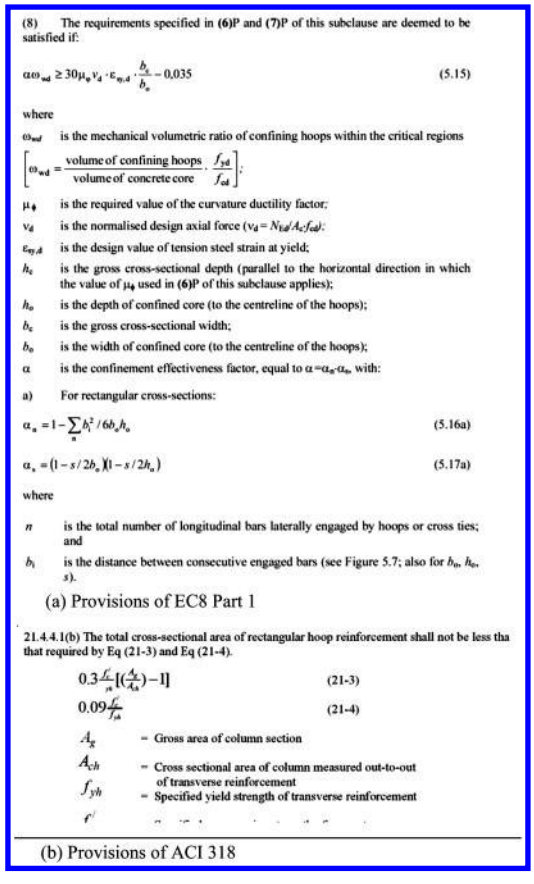
2.1.6 *Flat slab systems*

Flat slabs (floors which are supported by columns without an intermediate framework of beams) are currently not permitted by EC8 as a primary seismic resisting system, although they are permitted as a secondary system supporting gravity loads if the seismic loads can be taken by another system, such as a perimeter frame or series of shear walls. As a secondary system, it must be demonstrated that the flat slabs and their supporting columns can continue to carry the imposed gravity loads without yield occurring, under the deflections experienced during the design earthquake. However, some engineers in Northern Europe have found the EC8 rules for flat slabs difficult to

implement in practice, and improvements will be prepared. The rules for secondary systems more generally need review.

2.1.7 *Design of deep and shallow foundations*

It is considered that Part 5 of EC8 needs updating to include specific seismic design provisions for modelling, analysis, dimensioning and detailing of piles and shallow foundations, and some issues relating to the design of retaining walls and assessing slope stability also need review. One particular concern is to identify levels of seismicity below which particular issues, such as liquefaction or soil-pile interaction, can be safely neglected.



2.1.8 *Ductility classes*

EC8 specifies three ductility classes for buildings, called Ductility Class Low, Medium and High (DCL, DCM and DCH). DCL has no additional design and detailing requirements to those in the non-seismic Eurocodes, and is only recommended for areas of low seismicity. However, for medium or high seismicity areas, DCM or DCH must be chosen; DCM has higher lateral strength requirements than DCH but the design and detailing requirements are less complex. The distinction between DCM and DCH is particularly significant for reinforced concrete buildings, with relatively minor differences for steel and steel-concrete composite buildings and no practical distinctions for timber and masonry.

Similar distinctions between levels of ductility are found in US codes, and they serve an essential purpose in balancing the complexity of design and detailing requirements against the anticipated extreme seismic demand. In low seismicity areas, DCL structures can be detailed to non-seismic standards, with sufficient lateral strength for seismic resistance being provided in just the same way as for wind; this simplifies design while providing adequate safety. However, where seismic loading is the dominant consideration, more complex measures become necessary; these are currently provided by EC8 in ductility classes DCM and DCH.

The original intention was that the simpler rules for DCM would mean that safe but perhaps conservative designs could be achieved by small design offices, while larger more sophisticated practices could use the DCH rules to achieve more economy, and/or more complex structures.

In practice, this laudable aim has not in the author's opinion been achieved. As noted above, the DCH/DCM distinction is almost irrelevant to masonry and timber buildings, and there are few advantages in adopting DCH over DCM for steel or composite structures. The main differences are in the provisions for concrete, where the much more complex rules for DCH have been found in some cases to be impossible to apply. However, although the DCM rules are less extensive, in some cases they are still excessively complex whereas in other cases they are insufficiently rigorous.

(8) The requirements specified in **(6)P** and **(7)P** of this subclause are deemed to be satisfied if:

$$\alpha\omega_{wd} \geq 30\mu_\phi \nu_d \cdot \varepsilon_{sy,d} \cdot \frac{b_c}{b_o} - 0{,}035 \qquad (5.15)$$

where

ω_{wd} is the mechanical volumetric ratio of confining hoops within the critical regions $\left[\omega_{wd} = \frac{\text{volume of confining hoops}}{\text{volume of concrete core}} \cdot \frac{f_{yd}}{f_{cd}}\right]$;

μ_ϕ is the required value of the curvature ductility factor;

ν_d is the normalised design axial force ($\nu_d = N_{Ed}/A_c f_{cd}$);

$\varepsilon_{sy,d}$ is the design value of tension steel strain at yield;

h_c is the gross cross-sectional depth (parallel to the horizontal direction in which the value of μ_ϕ used in **(6)P** of this subclause applies);

h_o is the depth of confined core (to the centreline of the hoops);

b_c is the gross cross-sectional width;

b_o is the width of confined core (to the centreline of the hoops);

α is the confinement effectiveness factor, equal to $\alpha = \alpha_n \cdot \alpha_s$, with:

a) For rectangular cross-sections:

$$\alpha_n = 1 - \sum_n b_i^2 / 6 b_o h_o \qquad (5.16a)$$

$$\alpha_s = (1 - s/2b_o)(1 - s/2h_o) \qquad (5.17a)$$

where

n is the total number of longitudinal bars laterally engaged by hoops or cross ties; and

b_i is the distance between consecutive engaged bars (see Figure 5.7; also for b_o, h_o, s).

(a) Provisions of EC8 Part 1

21.4.4.1(b) The total cross-sectional area of rectangular hoop reinforcement shall not be less tha that required by Eq (21-3) and Eq (21-4).

$$0.3\frac{f'_c}{f_{yt}}\left[\left(\frac{A_g}{A_{ch}}\right) - 1\right] \qquad (21\text{-}3)$$

$$0.09\frac{f'_c}{f_{yt}} \qquad (21\text{-}4)$$

A_g = Gross area of column section

A_{ch} = Cross sectional area of column measured out-to-out of transverse reinforcement

f_{yh} = Specified yield strength of transverse reinforcement

f'

(b) Provisions of ACI 318

Figure 1. Comparison between EC8 and ACI 318 requirements for transverse steel at the ends of columns.

For example, the rules for confinement steel in the columns of moment resisting frames are based on a complex theoretical formula which is not easy to apply in practice (Figure 1(a)). They require a detailed calculation of the effectiveness of the confinement steel and are based on the 'mechanical volumetric ratio' of the steel, not a concept with which most structural engineers are familiar. The equivalent rules in the US standard ACI 318 are not only much simpler (Figure 1(b)), but also relate to a much simpler measure than volumetric ratio of steel, namely the ratio between the hoop steel's area and the concrete. There is no doubt that the EC8 formula is theoretically sounder. However, for DCM it only needs to be applied at the base of the columns, with steel at other locations governed by much simpler and less onerous rules, which in the author's opinion are likely to be insufficient in some cases.

By contrast, the rules for checking columns which are not part of the lateral load resisting structure (called 'secondary' elements by EC8) are less rigorous than their equivalents in ACI 318 and recent experience from earthquakes in New Zealand (Canterbury Earthquakes Royal Commission, 2012) and elsewhere suggest they are inadequate.

Simple rules to allow small practices to achieve safe designs are certainly very valuable, but the mean of achieving this in concrete buildings needs a radical overhaul, and also needs careful review for steel, timber and masonry buildings.

2.1.9 *New technologies for earthquake resistance*

Great advances have been made in developing a range of systems which result in better seismic performance than conventional structures. One such system, base isolation, is covered in section 10 of EC8 Part 1, but these rules do not provide the comprehensive guidance now found in US standards. Other technologies have been developed which are become widely used, such as provision of supplemental damping. These are not currently covered in EC8, though they are in US codes, and EC8 will have to be extended to provide rules for these new technologies if it is to maintain its position as a leading international standard.

2.1.10 *Part 4 (Silos, tanks and pipelines) and Part 6 (Towers, masts and chimneys)*

A review will be carried out of these parts, which will be updated as necessary.

3 LONGER TERM OBJECTIVES FOR EC8

The areas of EC8 identified as needing revision in CEN's proposals to the European Commission were described in Section 2. All the topics that they address need attention, and they will significantly improve the code. They will be supplemented by a clause by clause 'systematic review' of the standard, to identify further issues of detail that need revision.

Both this systematic review and the more fundamental review described in Section 2 will be constrained by a general desire to limit changes as far as possible to those intended to improve ease of use and to reduce the topics for which national choice is allowed. The intention is to maintain a large measure of stability in the form of the standard, so that design engineers using it do not have to face yet another taxing new learning period.

However, in the opinion of the author, over a longer period more radical changes are essential. To provide a framework for these changes, an overview of the future direction in which EC8 should be carried out. The Americans have produced overviews of this sort very successfully in the past, for example in SEAOC's vision 2000 report (SEAOC 1995).

Some suggestions of the form such a roadmap could take are provided by Booth and Lubkowski (2012), who propose the following ten characteristics of the ideal EC8.

1) Incorporates state-of-the-art technology, yet remains user friendly.
2) Allows state-of-the-art buildings to be designed without undue restrictions on creativity, yet provides clear and practical guidance for standard buildings implementable without unnecessary or impracticable demands on designers' expertise and time.
3) Provides the appropriate level of earthquake performance for a variety of limit states without excessive conservatism, allowing designers and their clients to define and control with confidence structural response to an earthquake.
4) Provides guidance on the use of emerging technologies, at least to some extent, and where such technologies are not explicitly referred to, does not prevent their use.
5) Applicable across a wide range of seismic hazard conditions, from very low to very high.
6) Provides procedures for specifying design ground motions adequate for standard cases, but also provides comprehensive guidance on more sophisticated procedures for non-standard cases.
7) Provides straightforward analysis methods for superstructure and foundations which are adequate for standard cases, but also provides comprehensive guidance on more sophisticated methods.
8) Applicable across the entire range of structural types covered by the Eurocode suite, including different construction materials (steel, concrete, masonry, timber etc.), and different end uses (commercial, residential, industrial, infrastructure, etc.).
9) Within its coverage of building design, applicable to a wide range of types, from high rise, high tech to simple low rise unreinforced masonry.
10) Gives guidance on the seismic assessment and retrofit of existing structures, as well as on design of new buildings.

Booth and Lubkowski (2012) discuss these ten objectives in more detail. They recognise that some of them may be hard to reconcile with each other – for example, the goal of providing user friendly provisions with that of keeping pace with state-of-the-art technology. Nevertheless, many of the objectives are already achieved, at least to some extent, in the Eurocode as it stands, and these include a number of objectives which US and other international codes do not address to nearly the same extent. Moreover, some others are addressed in CEN's current proposals, outlined in section 2. However, the author believes that defining a clear set of overall objectives would greatly enhance the rather piecemeal approach represented by the proposals described in Section 2 of this paper.

Defining overall objectives and setting a roadmap for EC8 is unlikely to influence the objectives of the current revision process, which have already been fixed. Moreover, radical changes to EC8 are not being encouraged at this stage, because of the desire to maintain stability in the standard. However, in the longer term, EC8 will have to develop in ways which are likely to be quite fundamental, given the rapid change in analysis techniques, technical solutions and societal requirements that are likely to continue to affect the discipline of earthquake engineering. An overarching review of the type proposed would help

ensure EC8's future position as a leading and distinct international seismic code, when its next major evolution is undertaken in the 2020's.

4 CONCLUSIONS

- The seismic Eurocode, EC8, is currently undergoing a major review, as part of a process expected to lead to publication of revised versions of all the Eurocodes for use in about 2020.
- Proposals by CEN (the body responsible for European Standards) for the topics to be included in this review are being submitted for approval to the European Commission. The proposals will greatly strengthen EC8, helping it to maintain its position as a leading and distinct international seismic standard.
- Major objectives for the current review are to simplify the Eurocodes, and to reduce the possibility for variation among CEN member nations in the ways they are implemented.
- The current revision process is constrained to some extent by the desire to limit the number of major changes to the Eurocodes, in order to maintain their stability.Moreover, CEN's proposals for the evolution of EC8 are somewhat piecemeal and lack a guiding vision.
- In the longer term, more radical changes to EC8 are needed, to reflect the rapid improvements in analytical techniques and technical solutions available to seismic engineers, as well as the changing demands of society for structural and non-structural performance in an earthquake.
- In order to guide changes to EC8 after the current review is complete, it is recommended that a 'road map' should be prepared. This would define the objectives that EC8 should aim for in future, and provide an overall framework for how to achieve those objectives, which may be less constrained by the need to limit radical changes.

ACKNOWLEDGEMENTS

The help by Professor Peter Fajfar (University of Ljubljana) and Zygmunt Lubkowksi (Ove Arup Partnership) in preparing this paper is gratefully acknowledged.

Dynamic shakedown design of structures under repeated seismic loads

S. Benfratello, L. Palizzolo & P. Tabbuso
Department of Civil, Environmental, Aerospace, Materials Engineering, University of Palermo, Italy

ABSTRACT: The paper is devoted to the formulation of an optimal design (minimum volume) problem of elastic perfectly plastic structures subjected to suitable combinations of static (fixed) and dynamic (seismic) loads. The structure is constrained to simultaneously respect two different safety criteria; actually, it must exhibit an elastic shakedown behaviour for the combination of loads characterizing the serviceability conditions and it must prevent the instantaneous collapse for the highest expected load condition (combination of loads characterized by the presence of fixed loads and maximum expected intensity of seismic action). The shakedown limit behaviour for the optimal structure will be imposed according with the unrestricted dynamic shakedown approach. The numerical application is devoted to the optimal design of a simple six floor plane steel frame and the solution is reached by utilizing a suitable harmony search algorithm.

1 INTRODUCTION

As it is well known, in the last decades several researchers devoted their studies to the optimal design problem of structures subjected to quasi-static loads and the main results are reported in several interesting books (see, e.g., Rozvany 1976, Save et al. 1985, Rozvany 1989, Haftka et al. 1990). These works contain original formulations characterized by different chosen objective functions, different special admissibility conditions as well as different computational approaches.

Other formulations have been proposed for the elastic optimal design (see, e.g., Cinquini et al. 1980), for the shakedown optimal design (see, e.g., Cohn et al. 1973, König 1975, Giambanco et al 1994a,b) and for the standard limit design (see, e.g., Maier et al. 1972).

Unfortunately, imposing just one of the cited criteria it is possible to make safe the structure just with reference to the selected corresponding structural limit state; on the contrary, the observance of suitable safety factors for the other limit states is disregarded. In order to extend the study to a more general case, some new formulations, in which suitably chosen different admissibility criteria (constraints) are simultaneously considered, have been proposed (see, e.g., Palizzolo 2004a).

Furthermore, for load conditions above the elastic shakedown limit, an alternating plasticity behaviour (plastic shakedown) is certainly preferable with respect to an incremental collapse one. A first formulation of the so-called plastic shakedown (no ratchet) optimal design of structures subjected to a combination of fixed and cyclic loads has been proposed, (see, e.g., Giambanco et al. 2002); in this formulation the restrictive hypothesis that the cyclic part of the load be a perfect one has been adopted, namely for each cyclic basic load condition an opposite one exists in the load space. Improved formulations and further applications (see, e.g., Giambanco et al. 2004, Palizzolo 2004b) have been also proposed.

Recently, further design formulations have been proposed for elastic plastic structures subjected to appropriate combinations of fixed and seismic loadings simultaneously preventing the overcoming of the elastic shakedown for serviceability conditions and the instantaneous collapse for full seismic conditions (see, e.g., Benfratello et al. 2009, Giambanco et al. 2011). In the referenced formulations the dynamic elastic response, to be utilized both for the shakedown limit and for the instantaneous collapse one, is evaluated by making recourse to a classical modal technique appropriately combining the single frequency responses; in other words, the response takes into account the dynamic features of the structures, and of the seismic action, but the shakedown yield condition is satisfied as in the case of quasi static cyclic loads.

Therefore, the present paper is devoted to the formulation of a special optimal design problem of elastic perfectly plastic frame structures subjected to different combinations of static (fixed) and dynamic (seismic) loads. In particular, the structure must be designed so as to be able to behave elastically when subjected to the action of the solely fixed load, to remain in the elastic shakedown domain in presence of serviceability conditions and to prevent the instantaneous collapse for suitably chosen combinations of fixed and high seismic loading. In the previous statement the serviceability conditions are conventionally defined as the superposition of suitably amplified fixed loads and seismic loads of appropriate low intensity.

In the present context the elastodynamic structural response is obtained by using a standard step-by-step method based on the mode superposition. Moreover, according to the unrestricted dynamic shakedown theory (see e.g., Borino et al. 1995), suitable domains are deduced by the cited responses, utilized in the elastic shakedown analysis as well as in the instantaneous collapse one.

Anyway, whatever the special formulation is utilized, substantially depending on the special limiting criterion imposed on the structure behaviour, it is very useful to know if the optimal structure, at the prescribed limit state, fulfils special limits on its functionality . In the present context these dangerous limit conditions will be disregarded, namely it is accepted the simplifying hypothesis that no secondary collapse modes can occur.

As known, the optimal design problem is a strongly non linear one, so in the scientific literature several different efforts have been devoted to the proposition of suitable computational approaches aimed to solve the relevant optimal design problem. In the present paper, the numerical application is devoted to the search for the minimum volume design of a flexural elastic perfectly plastic plane steel frame constituted by six floor. A suitable harmony search technique (see, e.g., Lee et al. 2005, Degertekin 2012) has been utilized.

The behavioural features of the obtained optimal structure for different load conditions are emphasized through the determination and interpretation of the related Bree diagram.

2 FUNDAMENTALS

In order to appropriately describe the proposed optimal design formulation, some fundamentals must be introduced mainly regarding the definition of some appropriate model both for the frame structure and for the acting loads.

2.1 *The structural model*

As known, the classical formulation of the static linear elastic analysis problem for plane frames constituted by n_b beam type elements, described by the Navier kinematical model, and n_N standard nodes (each characterized by three degrees of freedom) is given as follows:

$$\boldsymbol{d} = \boldsymbol{C}\boldsymbol{u} \tag{1a}$$
$$\boldsymbol{Q} = \boldsymbol{D}\boldsymbol{d} + \boldsymbol{Q}^* \tag{1b}$$
$$\tilde{\boldsymbol{C}}\boldsymbol{Q} = \boldsymbol{F} \tag{1c}$$

where $\boldsymbol{d}$ is the element nodal displacement vector of dimension $6 \cdot n_b$, $\boldsymbol{C}$ is the compatibility matrix with order $6 \cdot n_b \times 3 \cdot n_N$, $\boldsymbol{u}$ is the frame nodal displacement vector of dimension $3 \cdot n_N$, $\boldsymbol{Q}$ is the generalized stress vector evaluated at the extremes of the elements with order $6 \cdot n_b$, $\boldsymbol{D}$ is the frame internal (square block diagonal) stiffness matrix with order $6 \cdot n_b \times 6 \cdot n_b$, $\boldsymbol{Q}^*$ is the perfectly clamped element generalized stress vector with the same dimension of $\boldsymbol{Q}$, and $\boldsymbol{F}$ is the frame nodal force vector with the same dimension of $\boldsymbol{u}$. The solution to problem (1) is given by:

$$\boldsymbol{u} = \boldsymbol{K}^{-1}\boldsymbol{F}^* \tag{2a}$$
$$\boldsymbol{Q} = \boldsymbol{D}\boldsymbol{C}\boldsymbol{u} + \boldsymbol{Q}^* = \boldsymbol{D}\boldsymbol{C}\boldsymbol{K}^{-1}\boldsymbol{F}^* + \boldsymbol{Q}^* \tag{2b}$$

in terms of displacements and generalized stresses, respectively, with $\boldsymbol{K} = \tilde{\boldsymbol{C}}\boldsymbol{D}\boldsymbol{C}$ frame external square stiffness matrix of order $3 \cdot n_N \times 3 \cdot n_N$, and $\boldsymbol{F}^* = \boldsymbol{F} - \tilde{\boldsymbol{C}}\boldsymbol{Q}^*$ is the equivalent (in terms of structure node displacements) nodal force vector, where the over tilde means the transpose of the relevant quantity. Making reference to the seismic actions, let us consider the relevant frame as a flexural plane frame just subjected to an horizontal ground acceleration $a_g(t)$, where the masses are concentrated at each node, modeled as a Multi-Degree-Of-Freedom (MDOF) structure in which the dynamic equilibrium equations can be written in the following form:

$$\boldsymbol{M}\,\ddot{\boldsymbol{u}}(t) + \boldsymbol{B}\,\dot{\boldsymbol{u}}(t) + \boldsymbol{K}\,\boldsymbol{u}(t) = \boldsymbol{f}(t) \tag{3}$$

being $\mathbf{f}(t) = -\boldsymbol{M}\tau a_g(t)$, where $\boldsymbol{M}$ and $\boldsymbol{B}$ are the mass and damping matrices and τ is the influence vector. As known only the node horizontal displacements are dynamically significant and then the following static condensation procedure can be adopted. Let us operate a suitable partition and reordering of the above described matrices and vectors in such a way that in the case of free vibrations the equations of motion can be written:

$$\begin{pmatrix} \boldsymbol{M}_{tt} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} \end{pmatrix} \begin{pmatrix} \ddot{\boldsymbol{u}}_t(t) \\ \ddot{\boldsymbol{u}}_r(t) \end{pmatrix} + \begin{pmatrix} \boldsymbol{K}_{tt} & \boldsymbol{K}_{tr} \\ \boldsymbol{K}_{rt} & \boldsymbol{K}_{rr} \end{pmatrix} \begin{pmatrix} \boldsymbol{u}_t(t) \\ \boldsymbol{u}_r(t) \end{pmatrix} = \begin{pmatrix} \boldsymbol{f}(t) \\ \boldsymbol{0} \end{pmatrix} \tag{3a}$$

where $\mathbf{u}_t$ is the vector that collects the structure node horizontal displacements while $\mathbf{u}_r$ collects the vertical displacements and the rotations of the nodes. Equation (3a) can be usefully rewritten in the following form:

$$\boldsymbol{M}_{tt}\,\ddot{\boldsymbol{u}}_t(t) + \boldsymbol{K}_{tt}\,\boldsymbol{u}_t(t) + \boldsymbol{K}_{tr}\,\boldsymbol{u}_r(t) = \boldsymbol{f}(t) \tag{3b}$$
$$\boldsymbol{K}_{rt}\,\boldsymbol{u}_t(t) + \boldsymbol{K}_{rr}\,\boldsymbol{u}_r(t) = \boldsymbol{0} \tag{3c}$$

the first of which represents a system of differential equations while the second one is a system of algebraic equations. The solution of the equation (3c) assumes the form:

$$\boldsymbol{u}_r(t) = -\boldsymbol{K}_{rr}^{-1}\boldsymbol{K}_{rt}\,\boldsymbol{u}_t(t) \tag{3d}$$

Substituting equation (3d) into equation (3b) one obtains:

$$\boldsymbol{M}_{tt}\,\ddot{\boldsymbol{u}}_t(t) + \boldsymbol{K}_c\,\boldsymbol{u}_t(t) = \boldsymbol{f}(t) \tag{3e}$$

that represents the condensed equation of motion for free vibration and where $\boldsymbol{K}_c = \boldsymbol{K}_{tt} - \boldsymbol{K}_{tr}\boldsymbol{K}_{rr}^{-1}\boldsymbol{K}_{rt}$ is the

condensed stiffness matrix. By performing analogous steps it is possible to define a matrix $\boldsymbol{C}_d$ obtained by condensation of matrix $\boldsymbol{B}$.

As usual the equation (3e) can be solved with a classical modal technique according to the initial conditions that hereinafter are assumed to be $\boldsymbol{u}_t(0)=\boldsymbol{0}$, $\dot{\boldsymbol{u}}_t(0)=\boldsymbol{0}$. The dynamic characteristics of the structural behaviour are identified in terms of natural frequencies as well as damping coefficients. In this framework, as usual, the following coordinate transformation is adopted:

$$\boldsymbol{u}_t(t)=\boldsymbol{\Phi}\boldsymbol{z}(t) \tag{4}$$

being $\boldsymbol{z}(t)$ the modal displacement vector and $\boldsymbol{\Phi}$ the so-called modal matrix, normalized with respect to the mass matrix and whose columns are the eigenvectors of the undamped structure, given by the solution to the following eigenproblem:

$$\boldsymbol{K}_c^{-1}\boldsymbol{M}_{tt}\,\boldsymbol{\Phi}=\boldsymbol{\Phi}\,\boldsymbol{\Omega}^{-2} \tag{5a}$$

$$\tilde{\boldsymbol{\Phi}}\,\boldsymbol{M}_{tt}\,\boldsymbol{\Phi}=\boldsymbol{I} \tag{5b}$$

$$\tilde{\boldsymbol{\Phi}}\,\boldsymbol{K}_c\,\boldsymbol{\Phi}=\boldsymbol{\Omega}^2 \tag{5c}$$

In equations (5a,c), besides the already known symbols, $\boldsymbol{I}$ represents the identity matrix while $\boldsymbol{\Omega}^2$ is a diagonal matrix listing the square of the natural frequencies of the structure.

Once the modal matrix $\boldsymbol{\Phi}$ has been determined, the structure can be defined as a classically-damped one if $\tilde{\Phi}\,\boldsymbol{C}_d\,\boldsymbol{\Phi}=\boldsymbol{\Xi}$ is a diagonal matrix whose typical non zero element Ξ_{jj} is equal to $2\,\zeta_j\,\omega_j$, being ω_j and ζ_j the jth natural frequency and the jth damping coefficient, respectively. The equation of motion in the modal space can be written as:

$$\ddot{\boldsymbol{z}}(t)+\boldsymbol{\Xi}\,\dot{\boldsymbol{z}}(t)+\boldsymbol{\Omega}^2\boldsymbol{z}(t)=\boldsymbol{g}(t) \tag{5d}$$

where $\boldsymbol{g}(t)=\tilde{\Phi}M_{tt}\boldsymbol{f}(t)$.

The solution of the decoupled system of equations (5d) together with the corresponding initial conditions provides the complete structural response in terms of horizontal displacements. Once the horizontal displacements are known the remaining ones can be determined by means of equation (3d).

2.2 *The seismic loading model*

In order to formulate the relevant design problem a suitable loading model must be defined. For the purposes of the present paper reference will be made to civil and/or industrial constructions usually subjected to combinations of fixed (gravitational) loads and dynamically variable actions (earthquake). Furthermore, the cited load combinations must be able to describe the real significant state that the structure can suffer during its lifetime. So, three different load combinations will be considered: the first is constituted by the action of the solely fixed loads (basic condition); the second one is defined by the contemporary action of a suitably amplified fixed load and a low intensity seismic action (serviceability condition); the third one takes into account the simultaneous presence of amplified fixed loads and high seismic loads (ultimate load condition). It is clear that different behaviours will characterize the structure response for the different load combinations: purely elastic behaviour for the basic loads, shakedown for serviceability conditions, preventing of the instantaneous collapse for ultimate load conditions.

For the purposes of the present paper it is necessary to conveniently model the dynamic (seismic) action on the structure, especially with reference to the shakedown condition. Actually, as known, the real load history is unknown and, as a consequence, reference must be made to a suitably defined admissible load domain. The definition of such a domain is quite easy in the case of static and/or quasi-static load, while in the case of dynamic (seismic) actions reference will be made to the unrestricted dynamic shakedown theory (Borino et al. 1995). Following this theory the seismic acceleration $\ddot{u}_g(\tau)$ is expressed as the superposition of a discrete set of single-frequency wave components $\overline{\Psi}_{ij}(\tau)$, that is

$$\ddot{u}_g(\tau)=\sum_{i=1}^{n}\sum_{j=1}^{4}\xi_{ij}\,\overline{\psi}_{ij}(\tau)\quad 0\le\tau\le T \tag{6}$$

being T the duration of the seismic action and ξ_{ij} some coefficients required to satisfy the following admissibility conditions:

$$\xi_{ij}\ge 0\quad \sum_{i=1}^{n}\sum_{j=1}^{4}\xi_{ij}=1 \tag{7}$$

in order to fulfill the convex hull theorem (De Martino et al. 2000).

In equation (6) the intensity of the ith single-frequency wave component is related to the power spectral density of the considered earthquake corresponding to ith structural natural mode (Borino et al. 1995). The latter is here modeled by the well-known Kanai-Tajimi filter model as follows:

$$S_g(\omega_i)=\frac{\left[1+4\zeta_g^2\left(\omega_i/\omega_g\right)^2\right]S_0}{\left[1-\left(\omega_i/\omega_g\right)^2\right]^2+4\zeta_g^2\left(\omega_i/\omega_g\right)^2} \tag{8}$$

where ω_g, ζ_g are ground parameters and S_0 is the seismic intensity.

3 OPTIMAL DESIGN FORMULATION

The optimal design problem formulation for a given structure strongly depends on two elements: the selected objective function and the imposed limit states characterizing the optimal structural limit behavior.

It is important to emphasize that usually the optimal structure is regarded as the lowest weight one, the latter often being also the lowest cost one.

Therefore, let us consider an elastic perfectly plastic frame structure as above described and, according to the assumed loading model, let it be subjected to fixed mechanical loads and dynamic (seismic) loads. The minimum volume design problem formulation, where suitable constraints are imposed on the purely elastic behavior, on the elastic shakedown behavior, and on the instantaneous collapse, can be written as follows:

$$\min_{(\boldsymbol{t},\boldsymbol{u}_0,\boldsymbol{u}_d,\boldsymbol{\rho}_0,\boldsymbol{\rho}_1,\boldsymbol{\rho}_2)} V \tag{9a}$$

$$\boldsymbol{t}_{min} \le \boldsymbol{t} \le \boldsymbol{t}_{max} \tag{9b}$$

$$\boldsymbol{H}\boldsymbol{t} - \bar{\boldsymbol{h}} \ge \boldsymbol{0} \tag{9c}$$

$$\boldsymbol{K}\boldsymbol{u}_0 = \boldsymbol{F}_0^* \tag{9d}$$

$$\boldsymbol{Q}_0 = \boldsymbol{D}\boldsymbol{C}\boldsymbol{u}_0 + \boldsymbol{Q}_0^* \tag{9e}$$

$$\boldsymbol{M}_{tt}\,\ddot{\boldsymbol{u}}_t^S(t) + \boldsymbol{C}_d\dot{\boldsymbol{u}}_t^S(t) + \boldsymbol{K}_c\,\boldsymbol{u}_t^S(t) = -\boldsymbol{M}_{tt}\boldsymbol{\tau}\ddot{u}_g^S(t) \tag{9f}$$

$$\boldsymbol{u}_r{}^S(t) = -\boldsymbol{K}_{rr}{}^{-1}\boldsymbol{K}_{rt}\,\boldsymbol{u}_t{}^S(t) \tag{9g}$$

$$\boldsymbol{Q}^S(t) = \boldsymbol{D}\boldsymbol{C}\boldsymbol{E}\begin{pmatrix}\boldsymbol{u}_t{}^S(t)\\ \boldsymbol{u}_r{}^S(t)\end{pmatrix} \tag{9h}$$

$$\boldsymbol{Q}_+^S = \max_{0\le\tau\le t}\boldsymbol{Q}^S(t) \tag{9i}$$

$$\boldsymbol{Q}_-^S = \min_{0\le\tau\le t}\boldsymbol{Q}^S(t) \tag{9j}$$

$$\boldsymbol{M}_{tt}\,\ddot{\boldsymbol{u}}_t{}^I(t) + \boldsymbol{C}_d\dot{\boldsymbol{u}}_t{}^I(t) + \boldsymbol{K}_c\,\boldsymbol{u}_t{}^I(t) = -\boldsymbol{M}_{tt}\boldsymbol{\tau}\ddot{u}_g{}^I(t) \tag{9k}$$

$$\boldsymbol{u}_r{}^I(t) = -\boldsymbol{K}_{rr}{}^{-1}\boldsymbol{K}_{rt}\,\boldsymbol{u}_t{}^I(t) \tag{9l}$$

$$\boldsymbol{Q}^I(t) = \boldsymbol{D}\boldsymbol{C}\boldsymbol{E}\begin{pmatrix}\boldsymbol{u}_t{}^I(t)\\ \boldsymbol{u}_r{}^I(t)\end{pmatrix} \tag{9m}$$

$$\boldsymbol{Q}_+^I = \max_{0\le\tau\le t}\boldsymbol{Q}^I(t) \tag{9n}$$

$$\boldsymbol{Q}_-^I = \min_{0\le\tau\le t}\boldsymbol{Q}^I(t) \tag{9o}$$

$$\boldsymbol{\varphi}_+^E = \xi_0\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 - \boldsymbol{R} \le \boldsymbol{0} \tag{9p}$$

$$\boldsymbol{\varphi}_-^E = -\xi_0\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 - \boldsymbol{R} \le \boldsymbol{0} \tag{9q}$$

$$\boldsymbol{\varphi}_+^S = \xi_0^S\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 + \xi^S\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_+^S + \boldsymbol{\rho}_0 - \boldsymbol{R} \le \boldsymbol{0} \tag{9r}$$

$$\boldsymbol{\varphi}_-^S = -\xi_0^S\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 - \xi^S\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_-^S - \boldsymbol{\rho}_0 - \boldsymbol{R} \le \boldsymbol{0} \tag{9s}$$

$$\boldsymbol{\varphi}_+^{I1} = \xi_0^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 + \xi^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_+^I + \boldsymbol{\rho}_1 - \boldsymbol{R} \le \boldsymbol{0} \tag{9t}$$

$$\boldsymbol{\varphi}_-^{I1} = -\xi_0^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 - \xi^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_-^I - \boldsymbol{\rho}_1 - \boldsymbol{R} \le \boldsymbol{0} \tag{9u}$$

$$\boldsymbol{\varphi}_+^{I2} = \xi_0^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 + \xi^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_+^I + \boldsymbol{\rho}_2 - \boldsymbol{R} \le \boldsymbol{0} \tag{9v}$$

$$\boldsymbol{\varphi}_-^{I2} = -\xi_0^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_0 - \xi^I\tilde{\boldsymbol{G}}_p\boldsymbol{Q}_-^I - \boldsymbol{\rho}_2 - \boldsymbol{R} \le \boldsymbol{0} \tag{9w}$$

$$\tilde{\boldsymbol{A}}\boldsymbol{\rho}_0 = \boldsymbol{0} \quad \tilde{\boldsymbol{A}}\boldsymbol{\rho}_1 = \boldsymbol{0} \quad \tilde{\boldsymbol{A}}\boldsymbol{\rho}_2 = \boldsymbol{0} \tag{9x}$$

In equation (9b,c) $\boldsymbol{t}$ is the design variable vector, $\boldsymbol{H}$ is the technological constraint matrix, $\bar{\boldsymbol{h}}$ represents a suitably chosen technological vector. In equations (9c-o): $\boldsymbol{u}_0$ and $\boldsymbol{Q}_0$ are the purely elastic response to the assigned full fixed loads; $\boldsymbol{u}_t^S$, $\boldsymbol{u}_r^S$, $\boldsymbol{Q}_+^S$, $\boldsymbol{Q}_-^S$ are the elastic response to low seismic actions; $\mathbf{u}_t^I$, $\boldsymbol{u}_r^I$, $\boldsymbol{Q}_+^I$, $\boldsymbol{Q}_-^I$ are the elastic response to high seismic actions; $\mathbf{E}$ is a matrix necessary to reordering the structural displacements. In equations (9p-w): $\boldsymbol{\phi}_+^E$, $\boldsymbol{\phi}_-^E$, $\boldsymbol{\phi}_+^S$, $\boldsymbol{\phi}_-^S$, $\boldsymbol{\phi}_+^{I1}$, $\boldsymbol{\phi}_-^{I1}$, $\boldsymbol{\phi}_+^{I2}$, $\boldsymbol{\phi}_-^{I2}$ are the plastic potential vectors related to the purely elastic limit (apex E), to the elastic shakedown limit (apex S) and to the instantaneous collapse limit (apex I), respectively; $\boldsymbol{\rho}_0$, $\boldsymbol{\rho}_1$, $\boldsymbol{\rho}_2$ are the self-equilibrated stress vectors satisfying the equilibrium conditions expressed by equation (9x). In addition: $\tilde{\boldsymbol{G}}_p$ is an appropriate equilibrium matrix which applied to element nodal generalized stresses provides the generalized stresses acting upon the plastic nodes of the elements; A is a compatibility matrix which applied to element node displacements provides the plastic strains evaluated at the strain points; $\boldsymbol{R}$ is the relevant plastic resistance vector. Finally, ξ_0, ξ_0^S, ξ^S, ξ_0^I, ξ^I are scalar load multipliers suitable to define the load combinations.

4 APPLICATION

The optimal design of a steel frame has been obtained referring to the previously proposed formulation. The minimum volume design problem (9) has been solved, utilizing a suitable harmony search algorithm (Degertekin 2012), for the frame plotted in Fig. 1. The frame is constituted by square box cross section elements (Fig. 2) with $\ell = 250$ mm. The constant thickness t has been assumed as design variable.

Furthermore, the following geometrical and material characteristics have been assumed: $L_1 = 7.00$ m, $L_2 = 5.00$ m, $H = 4.00$ m, Young modulus $E = 210$ GPa, yield stress $\sigma_y = 235$ MPa. Two rigid perfectly plastic hinges are located at the extremes of all elements, considered to be purely elastic (Fig. 3); an additional hinge is located in the middle point of the longer beams.

The structure is subjected to a fixed uniformly distributed vertical load on the beams, $q_0 = 60$ kN/m and to seismic actions. Seismic masses are equal at each floor: $m_1 = 21.40$ kNs^2/m, $m_2 = 36.69$ kNs^2/m, $m_3 = 15.29$ kNs^2/m, and located at each structural nodes.

In the case of serviceability conditions the ground acceleration $\ddot{u}_g^S$ has been characterized by the following Kanai-Tajimi parameters: $\zeta_g = 0.65$, $\omega_g = 18$ rad/s and $S_0 = 0.0012$. In the case of ultimate limit load conditions, the ground acceleration $\ddot{u}_g^I$ has been characterized by the same parameters except for $S_0 = 0.0032$. The adopted load combinations are defined by the following load multipliers $\xi_0 = 1$, $\xi_0^S = 1.25$, $\xi^S = 1$, $\xi_0^I = 1.25$, $\xi^I = 1$. The results in terms of optimal volume and optimal thicknesses are reported in Table 1.

The obtained design features have been investigated through the determination of the relevant Bree diagrams related to the combinations of suitably amplified fixed loads and seismic actions. In Fig. 4 the cited diagrams are plotted where ξ_0 represents the fixed load multiplier and ξ_c the dynamic load one. It is easy to

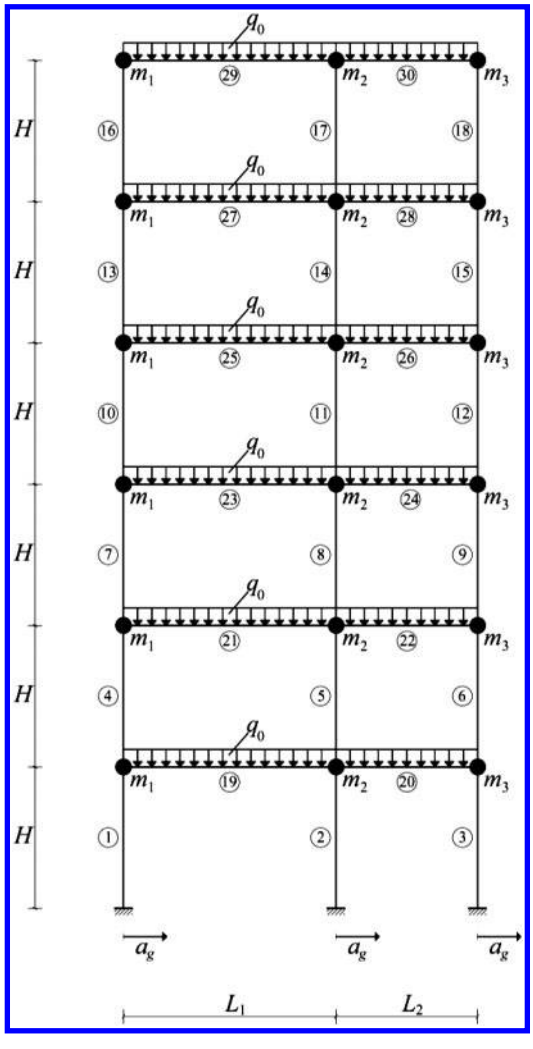

Figure 1. Six floor steel frame: geometry and load conditions.

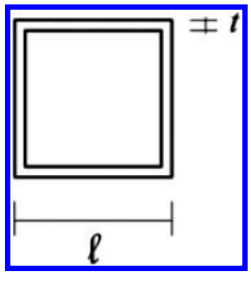

Figure 2. Typical square box cross section.

observe that, as expected, all the imposed behavioural constraints are satisfied. In particular, the structure shows to especially suffer the load combination involving high seismic loads: actually, it exhibits a certain safety margin in serviceability seismic conditions with to the shakedown limit, and it finds itself in a condition of impending collapse for fixed and high seismic loads.

5 CONCLUSIONS

The present paper has been devoted to the optimal design of elastic perfectly plastic frames subjected to fixed and dynamic actions. The optimal design problem has been formulated as the search for the minimum

volume structure and three different resistance limits have been simultaneously considered: the purely elastic limit, the elastic shakedown limit and the instantaneous collapse limit. In the proposed formulation, in order to take into account the seismic load, reference has been made to the unrestricted dynamic shakedown theory. In particular, a basic load condition has been defined as constituted by the solely assigned fixed loads; the serviceability conditions have been defined as the combination of amplified fixed loads and low seismic actions; the ultimate limit conditions have been defined as the combination of amplified fixed loads and high seismic actions. A computational application has been developed related to a six floor plane. The features of the obtained optimal structure have been deduced by the interpretation of the related Bree diagrams. It has been found that the structure obtained by the solution of the proposed optimal design problem guarantees a safe behaviour with respect to all the imposed limit states. The obtained results are encouraging and further numerical applications applied to practical engineering problems are expected as well as more restrictive descriptions of the basic loads utilized for the dynamic shakedown formulation.

Performance of buildings and other structures during the Tohoku Tsunami

I.N. Robertson
University of Hawaii at Manoa, Honolulu, Hawaii, USA

G. Chock
Martin & Chock, Inc., Honolulu, Hawaii, USA

ABSTRACT: In April, 2011, the American Society of Civil Engineers, ASCE, sponsored a team of engineers to survey tsunami effects on structures along the Tohoku coastline of Japan. The team was lead by Gary Chock, S.E., and consisted of 7 members of the recently formed ASCE 7 subcommittee on Tsunami Loads and Effects. The survey objectives were to investigate structural successes, failures and near failures in order to evaluate design provisions being considered for a new chapter on Tsunami Loads and Effects in the ASCE 7 design load standard for the USA. The survey results are extensively documented in a 350 page ASCE report (ASCE, 2013).

This paper gives an overview of the tsunami survey, and introduces the analysis methodology used to evaluate tsunami design provisions using full-scale field tsunami damage observations. Examples of building failure analysis will be used to demonstrate the potential for field validation of actual loading conditions most significant to structural response. The authors discuss how these findings influence the direction of the forthcoming ASCE 7 chapter on Tsunami Loads and Effects.

1 INTRODUCTION

On March 11, 2011 2:46 pm, the Great East Japan Earthquake of Moment Magnitude 9.0 generated a tsunami of unprecedented height and spatial extent along the northeast coast of the main island of Honshu. The ASCE SEI Tohoku Tsunami Reconnaissance Team conducted an investigation into the performance of buildings and other structures along the Tohoku coast region of Japan. In the course of two weeks the team was able to examine nearly all the towns and cities with significant damage due to the tsunami. The Japanese government estimated that over 250,000 buildings either collapsed or partially collapsed predominately from the tsunami. Topics covered in the scope of this investigation included: tsunami warning and evacuations, tsunami flow velocities, debris loading, building structural performance, bridge performance, seawalls and tsunami barriers, breakwaters, piers, quays, and wharves, scour effects, other structures, failure mode analyses, and economic impacts and initial recovery efforts. Detailed results of the survey are available in a 350 page report (ASCE, 2013).

2 TSUNAMI DETAILS

The primary affected coastline was on the main island of Honshu along the Tohoku region Figure 1. This area can be geographically subdivided further into the Sanriku coast of the three prefectures of Miyagi (north portion), Iwate, and Aomori, which has a 600 km saw-tooth coastline with numerous estuaries and coastal valleys, and the middle coastline from the city of Sendai in southern Miyagi leading southward towards Fukushima prefecture, where the coastline has broader low-lying plains. Along the Sanriku coast, in most instances the tsunami occurred as a long period high amplitude surge. Along the coastal plain south of Sendai southward to Natori City and Soma City, the offshore bathymetry caused the tsunami to break into a series of bores, which were seen on worldwide television networks as videos taken from Japanese news helicopters.

Approximately 20,000 people lost their lives as a consequence of the tsunami. The vast majority of these were located in the numerous coastal communities along the Tohoku coastline.

3 TSUNAMI WARNING AND EVACUATION

Japan's tsunami response plan did not rely on physical countermeasures alone. Japan, having a history of damaging historical tsunamis, has a variety of tsunami awareness signage established throughout the coastal regions by local government. There are signs clearly entreating evacuation immediately after an earthquake in the expected tsunami inundation zones.

In addition, in areas were high ground is too far removed from the coastline, selected buildings have been designated as vertical refuges from tsunamis.

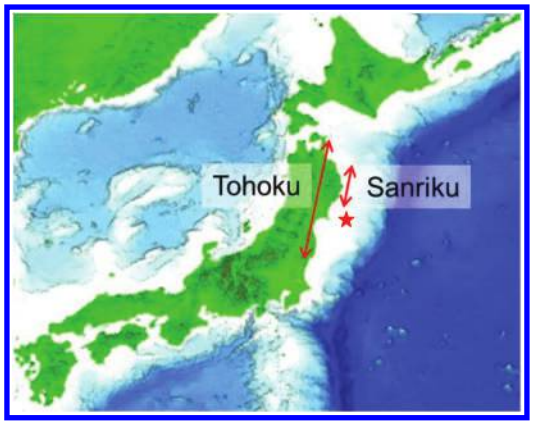

Figure 1. Earthquake epicenter and impacted coastline (ASCE).

Figure 2. Minamisanriku apartment building designed as vertical evacuation building (Robertson/ASCE).

Figure 3. Vertical refuge on roof of Minamisanriku coastal apartment building (Google Earth and ASCE).

Most of these are existing buildings that were evaluated for their suitability as vertical evacuation structures, while some are recently built specifically to serve a vertical evacuation function. Figure 2 shows an apartment building built on the coastline in Minamisanriku with the roof specifically designated as a vertical refuge from tsunamis (Figure 3).

Figure 4. Rikuzentakata City Hall Community Center and Gym designated as official tsunami evacuation center.

Access to the evacuation area was provided by external elevator and staircase accessible without entering the rest of the building. The roof level evacuation area measured a total of 660 square meters and was surrounded by a well braced 2 meter high guard fence. Even though this building was overtopped by 0.7 meters, the 44 people who sought refuge on the roof survived the tsunami.

Unfortunately, due to underestimation of the potential tsunami height, many of the designated vertical evacuation centers were not high enough to provide safe refuge during the tsunami (Figure 4) Japanese guidelines for selection, evaluation and design of vertical evacuation structures have been revised subsequent to the Tohoku Tsunami.

4 TSUNAMI FLOW CHARACTERISTICS

In order to evaluate tsunami loading on structures, it is important to obtain estimates for the flow depth and velocity at the site of interest. The Tohoku tsunami provided an unprecedented opportunity to analyze tsunami flow conditions based on video and field evidence. Much of this analysis can be performed remotely using only the captured videos and satellite imagery tools such as Google Earth. However, field verification of dimensions provides valuable confirmation of the assumptions made during video analysis. Field investigation is also necessary to determine flow depth which may be difficult to estimate from the video evidence alone.

Because this tsunami took place during daylight hours it was captured on video by numerous sources. After the Mw 9.0 earthquake, a number of news media helicopters and light planes were in the air to survey earthquake damage and fires initiated by the shaking. They were still in the air when the tsunami came onshore, so captured numerous videos of the incoming flow and its destructive path. In addition, numerous citizens witnessing the tsunami inundation and drawdown videoed the event. Many of these videos are now available online for analysis of the flow characteristics.

Figure 5 shows a typical analysis of aerial video footage of the tsunami surge passing over farmland

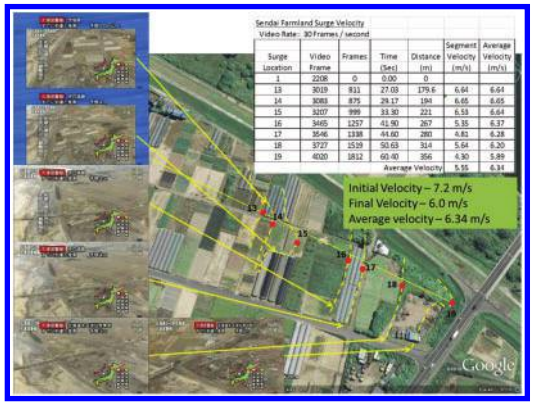

Figure 5. Aerial video analysis to determine flow velocity (Robertson/ASCE).

Figure 6. Light standard adjacent to coastal Takada Matsubara building in Rikuzentakata (Robertson/ASCE).

in the Sendai coastal plane. Maximum flow velocities captured by video analysis range from 5 to 8.5 m/s (18 to 30 kph).

Video evidence of tsunami flow characteristics is only available at certain locations depending on where helicopters or observers were located at the time of the inundation. Because of the variability in tsunami flow characteristics from location to location due to changes in bathymetry, topography and physical obstructions it is not always possible to base flow characteristics at one location on those determined for another location. If video evidence is not available at a location of interest, it is possible to estimate the flow characteristics by reverse analysis of a "flow surrogate".

Figure 6 shows a light standard that served as "flow surrogate" for analysis of a major shearwall blow-out inside the adjacent Takada Matsubara building. Based on structural analysis, the pushover of the light standards during the 10 meter deep inflow had the following sequence: under flexural bending, initial buckling of the thin walls occurred above the stiffeners of the base plate, resulting in rotation of the pipe until the initially dry light fixture frame at the top of the pole was lowered into the flow and captured debris. This debris load at the top of the pole greatly increased the moment at the base and initiated much more rotation until it generated tensile rupture of the anchor bolts (Figure 6). A depth-averaged flow velocity of at least 7.25 m/s was determined from structural analysis of the pole in order to create the initial buckling.

Similar analysis of other "flow surrogates" generated maximum flow velocities are various locations along the Tohoku coastline ranging from 4 to 10 m/s (14 to 36 kph).

5 DEBRIS IMPACT DAMAGE

As a tsunami flows over land it accumulates an enormous amount of debris consisting of vegetation, building materials, automobiles, boats and ships, and in some cases entire buildings. The resulting debris flow will impact structures in the path of the tsunami, often leading to localized damage due to debris impact strikes or overloading of structural elements or of the entire structure through the effects of debris damming.

Figure 7. Ship impact damage to steel framed building in Kamaishi harbor (Robertson/ASCE).

A particularly dramatic impact occurred when a large cargo ship in Kamaishi harbor broke free from its moorings and rammed into a steel framed warehouse building supported on concrete piled foundations (Figure 7). Analysis of a survivor video from a nearby building shows that the ship was traveling at 7.13 m/s (25.6 kph) immediately prior to impact. The impact destroyed two of the concrete piled foundations and collapsed half of one side of the steel warehouse framing. The ship subsequently grounded on an adjacent pier (Figure 7).

Accumulation of debris against structures leads to increased hydrodynamic loading due to damming effects. Even though a structure is designed with relatively open structural framing at the lower levels, accumulation of debris from collapsed surrounding buildings can result in dramatically increased drag loading on the "open" structure (Figure 8).

Figure 8. Debris accumulation on surviving building (Robertson/ASCE).

Figure 9. Surviving and damaged reinforced concrete buildings in Minamisanriku (Robertson/ASCE).

6 BUILDING STRUCTURAL PERFORMANCE

Along the Tohoku coast, tsunami inundation height was in the range of 5 to 30+ meters. In general, light-frame residential construction subject to about a story height or more of inundation will collapse. Therefore, complete collapse of residential light-frame construction occurred in nearly 100% of all affected areas extending to the edge of the inundation limit. In commercial and industrial areas, low-rise building collapses occurred in the approximate range of 75% towards 95%, with the higher collapse rate occurring as tsunami height reached the upper range (Figure 9). In these inundated coastal zones, buildings taller than 5 stories were uncommon. Despite this devastation, there were a number of these multi-story buildings that survived the tsunami without loss of structural integrity of their vertical load carrying system or foundation. In fact, a significant proportion of the surviving buildings did not appear to have significant structural damage. This provides some encouragement regarding the potential resilience of larger buildings having robust seismic designs and scour and uplift-resistant foundations.

Figure 10. Overturned structural steel building on mat foundation in Onagawa (Robertson/ASCE).

Figure 11. Buoyancy of the sealed cold storage room on the ground floor of this reinforced concrete building in Onagawa was sufficient to lift the building off its compression piles (Chock/ASCE).

In the town of Onagawa, a number of multi-story structural steel and reinforced concrete buildings overturned due to the combination of buoyancy and lateral hydrodynamic loading (Figure 10). A common feature of these buildings was the lack of a deep foundation system designed for uplift. Buildings on mat foundations or compression-only piles may not have sufficient resistance to overturning, sliding or buoyancy during inundation. Based on field measurements the two-story cold storage fishery building in Figure 11 was estimated to have a deadweight of 9000 kN. The refrigerated space on the ground floor was effectively sealed, leading to a neutrally buoyant condition as soon as the water inundation depth reached 7 meters. Video evidence confirms field measurements that the flow exceeded 10 meters at this location, resulting in this building floating off its foundations and flipping over.

7 BRIDGE STRUCTURAL PERFORMANCE

Numerous road and railway bridges in the inundation zone suffered severe damage or even total failure.

Figure 12. Road bridge failure in Rikuzentakata (Robertson/ASCE).

Figure 13. Surviving road bridge in Minamisanriku (Robertson/ASCE).

A relatively new three span road bridge in Rikuzentakata suffered collapse of all three deck spans and severe scour behind the abutments (Figure 12). The failure is attributed to a combination of buoyancy, enhanced by air pockets trapped between the bridge girders, and lateral hydrodynamic loading. Measurements of the bridge deck sections showed that when fully submerged, the deck had only 11% residual dead load to resist uplift. A number of road bridges survived even though they were fully submerged and subjected to flow velocities exceeding 7 m/s. In the case of a road bridge in Minamisanriku, survival is attributed to steel brackets which appear to have been installed as a seismic retrofit of the concrete bridge (Figure 13).

A coastal railway line along the Tohoku coastline suffered numerous bridge failures (Figure 14). In some cases the bridge girders were washed off the support piers, but in other cases the piers themselves failed in bending due to the lateral hydrodynamic loads. Road bridges can be replaced with temporary structures, however railway bridges are much more difficult to replace, hampering cargo and passenger transport for many months and even years.

Figure 14. Damage to railway bridge in Otsuchi (Robertson/ASCE).

8 FAILURE MODE ANALYSIS

A number of partial or near-collapse structures were surveyed in detail to serve as full-scale candidates for hydrodynamic loading evaluation. Failure analysis of these structures has provided valuable confirmation of loading expressions derived based on small scale laboratory experiments.

The Takada Matsubara Road Station in Rikuzentakata (Figure 6) endured a 10.5 meter tsunami inundation depth with flow of about 7–1/2 m/s, but suffered a failure of its principal transverse shear wall due to unbalanced hydrostatic and hydrodynamic forces of the incoming tsunami (Figure 15). Reinforcing steel was sampled and tested at 510 MPa average yield strength, consistent with JIS G3112 SD 490. A nonlinear finite element analysis of the wall identified the following sequence leading to the observed damage state:

1. Flexural yielding of the base of the wall as soon as the flow level reached 1.6 meters above grade.
2. Bottom half of side edge supports of the wall and the two ends of the mid-height horizontal beam yield when the flow level reached 2.2 meters.
3. The top and upper portions of the side supports of the wall yield and concrete shear cracks occur at the bottom when the flow reaches 2.7 meters.
4. Side supports and horizontal beam supports reach concrete shear failure cracking when the flow reaches 7.2 meters.
5. The top and upper portions of the side supports reach concrete shear failure cracking when the flow reaches 9.5 meters.
6. At 10.5 meters, the upper portion of the concrete wall hanging in tension drops down and relieves further loading increase; the unbalanced hydrostatic forces are relieved.

9 TSUNAMI DESIGN CODE DEVELOPMENT

Similar failure analyses were performed on numerous reinforced concrete and structural steel buildings,

Figure 15. Partial collapse of shear wall due to combined hydrostatic and hydrodynamic loading (Takagi/ASCE).

helping to verify loading expressions for use in a new chapter of ASCE 7, Minimum Design Loads for Buildings and other Structures (Chock *et al*, 2011). ASCE 7 is the basis for all loading conditions used in the International Building Code, the building code used in all 50 States in the USA. It does not currently provide guidance on tsunami design. An ASCE sub-committee was established in January 2011 to develop a chapter on Tsunami Loads and Effects. The sub-committee is currently working on a draft of the code provisions, with the hope that this chapter will be added to the 2016 edition of ASCE 7.

Lessons from the Tohoku Tsunami have also been incorporated into the second edition of FEMA P-646, Guidelines for Design of Structures for Vertical Evacuation from Tsunamis (FEMA, 2012). This document provides non-mandatory guidance to coastal communities considering construction of a tsunami refuge, either as a multi-story structure or a mound simulating high ground. Because it was developed specifically for vertical evacuation refuges, P-646 has greater conservatism than would be economically justified for non-refuge buildings. The Tsunami Loads and Effects chapter in ASCE 7 will provide more economical design requirements for all buildings exceeding 20 m in height.

10 CONCLUSIONS

The Tohoku Tsunami was a truly devastating natural disaster that caused considerable loss of life and tremendous economic hardship for the affected coastline of Japan. Recovery and reconstruction following this event will be expensive and protracted. In order to avoid similar consequences in other tsunami-prone communities, it is essential that greater resilience be incorporated during community development. Part of this resilience can be provided by designing mid- to high-rise coastal buildings for the anticipated tsunami loading. Lessons from the Tohoku Tsunami, and failure analyses performed on full-scale building failures, have provided valuable validation for tsunami loading expressions derived from laboratory experiments. These findings are being incorporated in a new chapter on Tsunami Loads and Effects being developed for ASCE 7. When adopted by coastal communities these code requirements will enhance the structural performance of multi-story steel and concrete buildings during future tsunamis.

Numerical investigation of the cyclic response of CHS braces

T. Sheehan & T. M. Chan
School of Engineering, University of Warwick, UK

J.H. Xing & L. Gardner
Department of Civil and Environmental Engineering, Imperial College London, UK

ABSTRACT: The behaviour of seismic-resistant buildings relies heavily upon the inclusion of energy dissipating elements. For concentrically-braced frames, the function of energy dissipation is accomplished by diagonal bracing members, whose performance depends upon both cross-sectional properties and global slenderness. Rectangular hollow sections are traditionally preferred in such applications. However these sections are susceptible to local buckling and, particularly in the case of cold formed tubes, have high residual stresses and reduced corner ductility. Hence as an alternative, this paper focuses on the hysteresis response of hollow circular tubes under cyclic axial loading. The uniformity of the circular cross-section may provide improved performance under cyclic loading over rectangular sections. In this paper, finite element analysis and a damage assessment method are first validated against experimental data on both hot-rolled and cold formed hollow CHS members. A series of parametric investigations is then carried out to access the influence of the local slenderness, global slenderness and steel material type on the hysteresis behaviour. Predictive expressions for displacement ductility and energy dissipation, incorporating both local and global slenderness, are proposed.

1 INTRODUCTION

The inclusion of dissipative devices is crucial in earthquake-resisting structures in order to absorb the energy from seismic loading, reduce element forces and moments around the frame and prevent catastrophic failure. This function is achieved by diagonal bracing members in concentrically-braced frames, but the performance is often compromised by buckling of the slender braces under compression, leading to an asymmetric response of the system between tension and compression. Tubular sections are becoming increasingly popular for this application owing to their inherent buckling resistance in compression, together with their visual appeal, ductility and torsional resistance. A considerable degree of attention has been paid to rectangular tubular sections owing to the ease of connection design, with experiments conducted by Nip et al. (2010a) comparing the response of hot-rolled carbon steel, cold formed carbon steel and cold formed stainless steel RHS braces. In recent years, research has also been conducted on curved tubular sections, which offer several advantages both aesthetically and structurally, owing to superior geometrical continuity around the section perimeter. Tests have been performed on circular hollow sections under monotonic loading, e.g. Packer et al. (2010), and elliptical hollow sections by Chan & Gardner (2008). Research has also been carried out on braces under cyclic axial loading, e.g. Elchalakani et al. (2003) tested twenty cold formed CHS braces to failure. However, there is scope to conduct further research to enhance current design recommendations in BS EN 1998-1 (2004) and to predict the ability of members to meet the displacement demands under seismic actions.

Numerical modelling is becoming increasingly popular since it requires less time and expense than that associated with laboratory experiments. Takeuchi & Matsui (2011) and Nip et al. (2010a) developed numerical models of tubular steel braces in ABAQUS, using the inbuilt nonlinear isotropic/kinematic hardening model to capture the material behaviour. Modelling has also been conducted on concrete-filled tubular columns in ABAQUS, such as by Goto et al. (2010), with a user subroutine to define the steel material behaviour. Following the success of these, ABAQUS was utilized in this study to examine the response of hollow hot-finished and cold formed circular braces. Results from recent experiments on CHS braces (Sheehan & Chan (2013)) were used to validate the simulation technique, enabling further parametric studies to be conducted, covering a wider range of cross-section and global slenderness values. Full 3-dimensional models, including geometric imperfections were created in order to capture both the overall load-displacement hysteresis response and the local behaviour. A strain-based fatigue model and suitable counting techniques were implemented to predict the number of cycles to fracture. The main results of interest were the total number of cycles endured and the

HF-H-3000	1.72	Hot-finished	Hollow

energy dissipation capability, as well as the influence of specimen dimensions on these parameters.

2 MODELLING OF HOLLOW STEEL BRACES

2.1 *Specimens*

Initially, models were generated to simulate the results from a series of experiments involving CHS braces under cyclic axial loading (Sheehan & Chan (2013)). A summary of the test specimens is provided in Table 1.

The tested sections were manufactured in two ways – hot-finished and cold formed – both with a nominal yield stress of 355 N/mm^2. All sections had the same nominal diameter of 48.3 mm and two wall thicknesses were utilised: 3.0 mm for the cold formed tubes and 3.2 mm for the hot-finished sections.The type of steel section is indicated by the first part of the specimen ID in Table 1, with 'CF' denoting cold formed steel and 'HF' signifying hot-finished specimens. The middle part of the specimen name refers to the fact that the member is hollow, since concrete-filled braces were also tested by Sheehan & Chan (2013) and numerical simulations of these are planned at a later stage. The brace length is also included in the specimen identification by the last four digits. Two lengths were employed: 1500 mm and 3000 mm. $\bar{\lambda}$ is evaluated in accordance with BS EN 1993-1-1 (2005).

2.2 *Element type and mesh size*

The steel tube was modelled using S4R general purpose shell elements. These are three-dimensional, double-curved elements consisting of 4 nodes with 6 degrees of freedom per node. A more refined mesh was employed at the end and mid-lengths over a distance equal to 3.0 times the section radius, since large local deformations were expected in these locations.

2.3 *Boundary conditions and loading*

Fixed-ended conditions were employed at the end of the tested brace and this was achieved in the models by constraining the ends of the tubes to a rigid plate. The models were subjected to the ECCS axial cyclic loading protocol (ECCS, 1986), as used for the experiments, and this was implemented by applying an axial displacement to one end of the tube. This loading protocol entailed symmetric cycles of compression and tension and was defined by means of axial displacements. The displacement amplitudes comprised one cycle at each of the first four values and three cycles at each of the higher displacements, following the sequence: $0.25\delta_y$, $0.5\delta_y$, $0.75\delta_y$, $1.0\delta_y$, $2.0\delta_y$, $2.0\delta_y$, $2.0\delta_y$, $4.0\delta_y$, $4.0\delta_y$, $4.0\delta_y$, $6.0\delta_y$, $6.0\delta_y$, $6.0\delta_y$, etc. up to failure. The yield displacement parameter δ_y, which was used to define the loading protocol was determined using the material yield stress, f_y, and the specimen length, L.

2.4 *Material modelling*

In order to accurately simulate the behaviour of steel under cyclic loading, a material model was required that would take into account phenomena such as the expansion of the yield surface during repeated cycles and the Bauschinger effect. The nonlinear isotropic/kinematic hardening model in ABAQUS was adopted for this study, which is based on the two-surface plasticity model of Chaboche (1986). This model consists of two surfaces in 3D stress-space, a yielding surface, within which the behaviour is elastic and the bounding surface, which defines the maximum stress. The main disadvantage of the ABAQUS inbuilt model is that the material parameters cannot be updated as the analysis progresses but the ease of implementation renders it favourable – only five input variables are required. The success of using this model has been previously demonstrated by Nip et al. (2010a) and Takeuchi & Matsui (2011). In the absence of experimental data, the ABAQUS material input parameters were adopted from the material tests of Nip et al. (2010b) and scaled suitably according to the yield stress.

2.5 *Fracture prediction*

A strain-based fracture model was employed for predicting fracture of the tube, using a relationship proposed by Coffin (1954) and Manson (1954) to calculate the number of cycles to failure for a specimen under repeated cycles of the same strain. This was given as

$$\frac{\Delta\varepsilon_p}{2} = \varepsilon'_f \left(2N_f\right)^c \tag{1}$$

where $\Delta\varepsilon_p/2$ is the plastic strain amplitude, $2N_f$ is the number of reversals to failure, ε'_f is the fatigue ductility coefficient and c is the fatigue ductility exponent. In the adopted approach, values of ε'_f and c were taken from material tests, previously conducted by Nip et al. (2010b) and using these, N_f was computed for each plastic strain amplitude, $\Delta\varepsilon_p/2$. Since the strain range varied significantly throughout the tests, the total accumulated damage was determined using Miner's rule (Miner (1945)). This consisted of a damage index, D, given by:

$$D = \sum_{i=1}^{n} \frac{n_i}{N_{fi}} \tag{2}$$

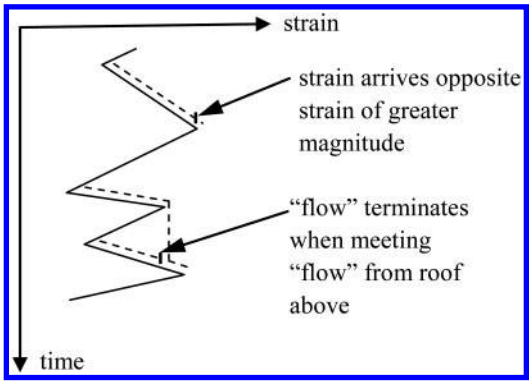

Figure 1. Illustration of 'rainflow' counting technique.

where N_{fi} is the number of cycles to failure for a particular strain amplitude and n is the number of cycles undergone by the test specimen at that strain. According to this damage model, failure occurred when D reached a value of 1. Two approaches were considered for evaluating the strain amplitudes in each cycle. The first was a "rainflow" counting algorithm proposed by Matsuishi & Endo (1968) to define strain amplitudes for a specimen undergoing irregular loading patterns. In this approach, the strain in successive cycles was envisaged as water flowing between levels of a pagoda roof, as depicted in Figure 1.

Strain was counted in half cycles, and under cycles of increasing amplitude, the 'flow' continued from one cycle to the next and the increase in strain amplitude was added onto the previous cycle. The half cycle terminated when interrupted by 'flow' from a previous cycle or when it arrived opposite a peak/trough of greater magnitude than that from which it originated. Compression and tension half cycles were initially counted separately. Half cycles of the same amplitude and opposite sense were then added together to form complete cycles. The second approach involved counting the differences between individual peaks and troughs in the strain progression as they occurred, accumulating the damage continuously.

The buckled shape at the mid-length is shown in Figure 2. This comprised a relatively flat portion in the centre of the compression face, with a region of higher curvature towards the edges. The most favourable predictions were attained by computing the average strain across the entire compression face, including both of these regions, and using the strains on the outside face.

Both the 'rainflow' counting technique and counting the individual ramps in the strain sequence provided reasonable estimations of the number of cycles to failure, with the 'rainflow' technique tending to slightly overestimate the number of cycles and counting the individual half cycles generally underestimating the performance. Hence these provided suitable upper and lower bounds to the anticipated number of cycles to fracture.

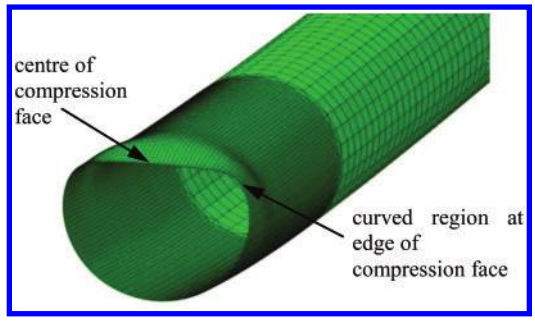

Figure 2. Deformed shape at brace mid-length.

Table 2. Number of cycles to failure for hollow steel brace models.

	No. of cycles to					
	global buckling		local buckling		fracture

CF-H-3000	3	3	8	9	11	17
HF-H-3000	3	4	9	8	17	24

2.6 *Geometric imperfections*

Global imperfection amplitudes were determined following a sensitivity study. The most satisfactory results were found using imperfection amplitudes equal to $L/1000$ and $L/750$ for the 1500 mm and 3000 mm specimens respectively. The global imperfection was implemented in the model by applying a lateral load at the mid-length. A study was also conducted to establish the most suitable local imperfection amplitude. The best agreement between test and FE results was achieved by using an imperfection of $t/100$, where t was the tube wall thickness, with models being less sensitive to changes in local imperfection at amplitudes lower than this. This was incorporated into the model by directly altering the nodal positions prior to commencing the analysis. The shape of the local imperfection was a sinusoidal wave along the length.

2.7 *Verification of FE model*

The accuracy of the models was assessed by comparing the numbers of cycles to local buckling, global buckling and fracture with the laboratory test results of Sheehan & Chan (2013). Results for the hollow steel tubes are presented in Tables 2 and 3 in addition to the maximum tensile and compressive forces. The numbers of cycles to local and global buckling showed close agreement in most cases except for the local buckling of specimen HF-H-1500. The number of cycles to fracture was underestimated by the numerical model in all cases. In spite of this, the models

provided a reliable prediction of the maximum tensile and compressive resistances.

Figures 3 and 4 compare the load-displacement hysteresis curves for two typical specimens.

Despite undergoing an earlier failure than their experimental counterparts, the numerical models produced similarly-shaped hysteresis curves, indicating an accurate simulation of the energy dissipation capability and general specimen behaviour.

2.8 *Parametric studies*

Once a suitable approach to numerical modelling was established, parametric studies were conducted for both the cold-formed and hot-finished sections. The specimens are summarised in Table 4.

Table 4. Specimens for parametric studies.

Specimen ID.		$D/t\varepsilon^2$			
Cold formed	Hot-finished	Cold formed	Hot-finished	Class	$\bar{\lambda}$
CF1	HF1	36.11	26.7	1	0.5
CF2	HF2	36.1	26.7	1	1.0

CF12	HF12	78.9	77.5	3	2.0
CF13	HF13	102.6	100.3	4	0.5
CF14	HF14	102.6	100.3	4	1.0
CF15	HF15	102.6	100.3	4	1.5
CF16	HF16	102.6	100.3	4	2.0

where:
D = cross-section outer diameter
t = tube thickness
A = cross-section area
L = specimen length
$\varepsilon = \sqrt{235/f_y}$, where f_y is the material yield stress
$\bar{\lambda}$ = global slenderness calculated in accordance with BS EN 1993-1-1 (2005).

Four specimen lengths were utilised for each section type to give values of $\bar{\lambda} = 0.5$, 1.0, 1.5 and 2.0 in accordance with BS EN 1993-1-1 (2005). Therefore all braces were within the recommended limit of $\bar{\lambda} \leq 2.0$ given in BS EN 1998-1 (2004). The tube diameter was kept constant and four different wall thicknesses were employed to provide a cross-section in each of the classifications 1, 2, 3, and 4 defined in BS EN 1993-1-1 (2005). The same material properties were used as those for simulating the experiments. It is evident from the experimental and numerical results that the number of cycles to failure and maximum displacement amplitude are influenced by both the local and global slenderness values. Figure 5 shows the variation in number of cycles to failure with global slenderness for each cross-section class and Figure 6 presents the relationship between the number of cycles to failure and cross-section slenderness for members of each global slenderness value. Similar trends were observed for each section type and hence the results are only displayed for cold formed sections in Figure 5 and for hot-finished sections in Figure 6.

For both hot-finished and cold formed tubes, the number of cycles to failure generally increased with global slenderness. Conversely, the total number of cycles generally decreased with increasing cross-sectional slenderness, $D/t\varepsilon^2$. However, these observations only reflect the predominant trends across the results and did not occur in all cases. Hence, relating

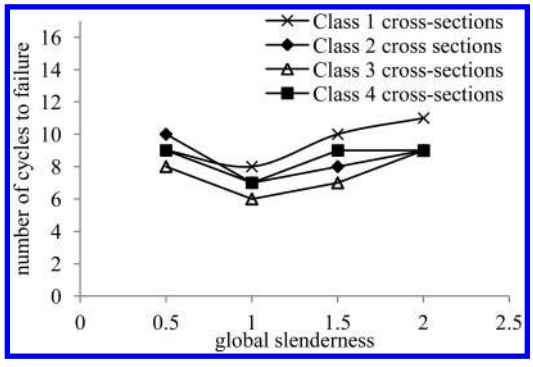

Figure 5. Relationship between number of cycles to failure and global slenderness for cold formed specimens.

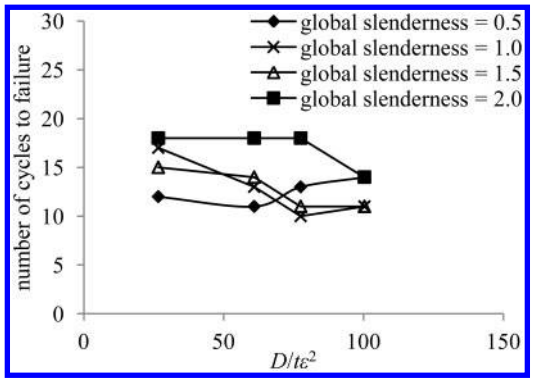

Figure 6. Relationship between number of cycles to failure and cross-section slenderness for hot-finished specimens.

the number of cycles to failure to a single slenderness parameter did not appear to be sufficient.

Relationships have been proposed previously to predict the maximum displacement amplitude as a multiple of the yield displacement of RHS braces, μ_Δ, by relating it to the local and global slenderness parameters separately, such as Goggins et al. (2006) but a combination of the two has also been proposed by Nip et al. (2010a). Using the parametric results, the following expressions were developed to predict the number of cycles to fracture for CHS braces.

For hot-finished specimens:

$$\mu_\Delta = 6.17 + 3.36\,\bar{\lambda} - 0.052 D/t\varepsilon^2 + 0.00045(D/t\varepsilon^2)^2 - 0.022\,\bar{\lambda}\, D/t\varepsilon^2 \quad (3)$$

For cold-formed specimens

$$\mu_\Delta = 6.08 + 1.39\,\bar{\lambda} - 0.1 D/t\varepsilon^2 + 0.00073(D/t\varepsilon^2)^2 - 0.013\,\bar{\lambda}\, D/t\varepsilon^2 \quad (4)$$

These were formulated based on the parametric results that employed counting of the individual strain half-cycles as they occurred, since this provided a more conservative estimation than the 'rainflow' counting algorithm, and also showed a closer agreement with the failure observed from the load-displacement hysteresis relationship and deformed shape. Figure 7 compares the predicted displacement ductility μ_Δ, from Equations (3) and (4) with the results from the parametric studies. The numerical simulations show a reasonable correlation to the predictions.

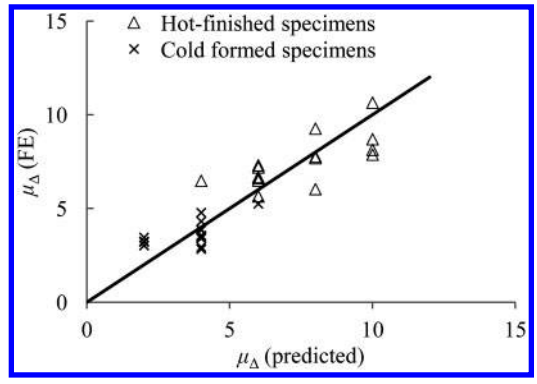

Figure 7. Load-displacement hysteresis for CF-H-3000.

Since a key function of the diagonal braces is to absorb the energy of seismic forces acting on the structure, expressions were also proposed for the anticipated energy dissipation of the brace. Two equations were proposed for each section type: one to predict the energy dissipated in the 8th loading cycle and the second to compute the total energy dissipation. The 8th cycle was selected following Goggins et al. (2006), who examined the energy dissipation at this particular displacement amplitude. The relationships are given by Equations (5) to (8).

For hot-finished specimens:

$$W_8 = 9.2 - 0.036\, D/t\varepsilon^2 - 4.46\bar{\lambda} + 0.016\bar{\lambda}\, D/t\varepsilon^2 + 0.77\bar{\lambda}^2 \quad (5)$$

$$W_T = 66.39 - 5.86\, D/t\varepsilon^2 - 345.3\bar{\lambda} + 0.092\left(D/t\varepsilon^2\right)^2 + 0.65\bar{\lambda}\, D/t\varepsilon^2 - 278.2\bar{\lambda}^2 - 0.0004\left(D/t\varepsilon^2\right)^3 - 0.0076\bar{\lambda}\left(D/t\varepsilon^2\right)^2 + 0.68\bar{\lambda}^2\left(D/t\varepsilon^2\right) + 58.62\bar{\lambda}^3 \quad (6)$$

For cold formed specimens:

$$W_8 = 7.98 - 0.029\, D/t\varepsilon^2 - 2.38\bar{\lambda} + 0.011\bar{\lambda}\, D/t\varepsilon^2 + 0.075\bar{\lambda}^2 \quad (7)$$

$$W_T = 155.5 - 2.75\, D/t\varepsilon^2 - 91.6\bar{\lambda} + 0.0057\left(D/t\varepsilon^2\right)^2 + 2.26\bar{\lambda}\, D/t\varepsilon^2 + 0.00011\left(D/t\varepsilon^2\right)^3 - 0.015\bar{\lambda}\left(D/t\varepsilon^2\right)^2 \quad (8)$$

where W_8 refers to the energy dissipated in the 8th loading cycle and W_T is the total energy dissipated. In both cases the energy is normalized with respect to $Af_y\delta_y$, where A is the cross-sectional area, f_y is the steel yield stress and δ_y is the yield displacement.

3 CONCLUSIONS

The behaviour of cold formed and hot-finished CHS braces under cyclic axial loading has been successfully

simulated using finite element modelling. Satisfactory analysis of the fatigue behaviour has been achieved by employing a strain-based approach in conjunction with Miner's rule (Miner (1945)) and the Coffin-Manson relationship (Coffin (1954), Manson (1954)). Expressions have been developed to predict the displacement ductility and energy dissipation capability in terms of both local and global slenderness parameters. The following conclusions can be drawn:

The nonlinear isotropic/kinematic hardening material model in ABAQUS provides a reliable prediction of the maximum compressive and tensile forces in the member and of the load-displacement hysteresis response.

The number of cycles to failure were generally underestimated by the ABAQUS models.

For estimating the number of cycles to failure, counting individual successive half cycles provides a suitable lower bound, whereas the rainflow algorithm gives an upper bound.

The displacement ductility, μ_{Δ}, was found to increase with increasing global slenderness, $\bar{\lambda}$, and decrease with increasing cross-sectional slenderness, $D/t\varepsilon^2$.

ACKNOWLEDGEMENT

The authors wish to thank Dr. Alan K. H. Nip from the Hong Kong Polytechnic University and Dr. Jihui Xing from Beijing Jiaotong University for their advice in conducting the analysis.

Parametric identification of building structures with seismic recordings

Ruichong Zhang
Colorado School of Mines, Golden, Colorado, USA

Lotfi O. Gargab
Tripoli, Libya

ABSTRACT: This study presents system identification of ten-story Millikan Library in Pasadena, California with a pair of the Yorba Linda earthquake of September 3, 2002. The proposed identification approach is based on wave features of generalized impulse and frequency response function (GIRF or GFRF), i.e., wave response at one structural response location to an impulsive motion at another reference location in time and frequency domains respectively. With a pair of seismic recordings at the two locations, GIRF/GFRF is obtainable. With a continuous-discrete model for the structure, a closed-form solution of GFRF, and subsequent GIRF with Fourier transformation of GFRF, can also be found in terms of structural physical properties above the impulse location. Matching the two sets of GIRF/GFRF from recordings and the model helps identify system parameters such as wave velocity or shear modulus.

1 INTRODUCTION

For seismic design, vibration control, and damage diagnosis of multi-story buildings, such as ten-story Millikan Library building located in Pasadena California, response characterization and system identification are fundamental and typically carried out with a discrete, multi-degree-of-freedom (MDOF) model. As far as one-dimensional (1D) horizontal motion is concerned, the Millikan Library building as shown in Fig. 1a can be modeled as a 10-DOF system with each floor mass and inter-story stiffness (i.e., physical parameters) calculable based on design configuration and materials. These physical parameters can also be calibrated in terms of identified vibratory features (i.e., modal frequencies, damping, and shapes—a function of physical parameters), through Fourier spectral analysis of 11-set acceleration recordings of the Yorba Linda earthquake of September 3, 2002.

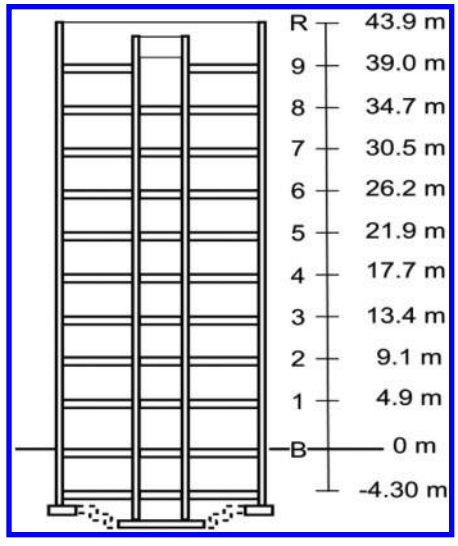

Figure 1a. Vertical cross-section of 10-story Millikan Library, Pasadena, California.

While the aforementioned discrete modeling is overwhelmingly used in structural engineering (e.g. Chopra, 1995), it has limitation in characterizing comprehensive seismic motion in structures with a finite number DOF modeling in general, and distorting time-space or wave features of seismic motion in buildings in particular. Misrepresenting the seismic responses in structures would falsely predict, likely underestimate, the maximum inter-story drift, a key index of seismic demand for structural design. This is due to the fact that time-delay peak waves at two neighboring floors would have the drift calculated as difference between one peak amplitude and one non-peak value, which is typically larger than the difference between two peak values without time-delay effect. This time-delay feature would also affect the efficacy of vibration control, if actuators installed in different floors are operated with a central feedback-control device.

More importantly, understanding and utilization of the wave features could create an alternative wave-based approach for system identification of multi-story buildings, which can be used to improve greatly

the efficiency of post-earthquake structural condition assessment. As well known, effectiveness of discrete-modeling-based system identification in general, and recognition of local physical parameters in particular, relies on a large number of recordings exemplified as 11-set recordings for the Millikan Library, which is neither common nor practical for most structures currently or in the near future. In contrast, a wave-based approach requires only a few of recordings. For example, the peak-to-peak wave traveling time between two different heights is measurable and directly related to wave velocity of the building segment. Similarly, the corresponding peak-amplitude reduction is associated with the segment damping. Both identified velocity and damping can then be related to local physical parameters such as shear modulus and hysteretic damping ratio if the building segment is modeled as a uniform shear-beam.

In fact, seismic responses are the result of wave propagation in large-scale structures such as high-rise buildings, pipelines, and towers, in which some wave-propagation features, such as time delay of traveling waves from one location to the other, play an important role in in-depth understanding of seismic recordings and effective identification of local structural features. Recent studies indeed show advantages of continuous-modeling over traditional discrete-modeling in some seismic response analyses and damage diagnosis of building structures. For example, Iwan (1996) proposed to use 1D uniform shear-beam model for buildings and obtained seismic drift spectrum for design. Safak (1999) introduced 1D continuous/discrete modeling for structure-soil system with impulsive seismic excitation in bedrock. Todorovska et al. (2001) modeled 2D anisotropic wave propagation for a real seven-story building. Snieder and Safak. (2006) employed seismic interferometry (SI) to extract structural responses from seismic recordings. Kohler et al. (2007) studied seismic propagating waves in a 3D steel moment-frame building and verified with ETABS finite-element modeling, among others. Building upon the aforementioned advances and others in relevant literature, this study uses recently-proposed 1D continuous-discrete modeling for wave propagation in building structures and examines response characterization and system identification.

2 MODELING OF WAVE PROPAGATION

In this study, a multi-story building is modeled as a series of continuous shear-beam layers for inter-story columns/walls and discrete lumped-masses for floors, as shown in Fig. 1b. Each inter-story is characterized with shear wave speed $v = \sqrt{G/\rho}$ where G and ρ are respectively equivalent shear modulus and mass density, hysteretic damping ratio γ_c, story height h, and cross-sectional area A, while each floor with lumped mass m_f, which excludes the mass overlapped with

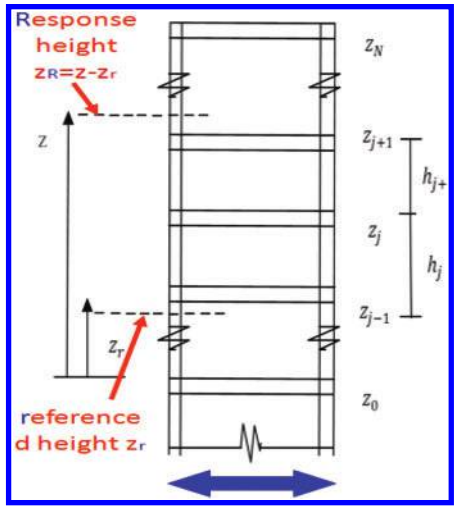

Figure 1b. A model for an N-story building subjected to seismic excitation.

columns and walls, and damping γ_f ($=c_f/m_f$) where c_f is the hysteretic damping coefficient.

The displacements $u(z,t)$ and $u(z_r,t)$ at two locations, referred to as response location z (or $z_R = z - z_r$) and referenced location z_r, can be found

$$u(z,t) = \int_{-\infty}^{\infty} D_{Rr}(\omega) U_{z_r}(\omega) e^{i\omega t} d\omega = \int_{-\infty}^{\infty} d_{Rr}(t-\tau) u(z_r,\tau) d\tau \qquad (1)$$

where D_{Rr} and d_{Rr} are respectively displacement responses at z (z_R) to displacement impulse at z_r in frequency and time domains, and U_{Z_r} is the frequency counterpart of $u(z_r,t)$. Equation (1) can also be interpreted as displacement response at z to a displacement input at z_r, which has the same mathematical form as traditional, vibration representation of displacement response to an external force (e.g., convolution integral), except the difference between force and motion inputs. Because of that, D_{Rr} and d_{Rr} are referred here to as wave-based or generalized frequency response function (GFRF) and generalized impulse response function (GIRF) respectively.

By definition, GFRF is the ratio of frequency displacements at the two locations, obtainable from FFT of the two recordings. With the continuous-discrete model (Zhang et al., 2011)], a closed-form solution of GFRF, and subsequent GIRF with Fourier transformation of GFRF, can be found as

$$D_{Rr}(\omega) = \frac{U_{z_R}}{U_{z_r}} = \frac{(1+R_{NR})T_{Rr}}{(1-R_{rR}R_{NR})(1+R_{Nr})}, \qquad d_{Rr}(t) = \int_{-\infty}^{\infty} D_{Rr} e^{i\omega t} d\omega \qquad (2a,b)$$

where wave transmission coefficient T_{Rr} is the up-going wave at z (z_R) which is propagated upward from an impulsive up-going wave input at z_r (i.e., $\delta(t)$ in time domain and unit in frequency domain), reflection

coefficient R_{Nr} (similar to other Rs) is down-going wave at z_r resulted from an impulsive up-going wave input at z_r which travels upward first, reflects at the free-top Nth story, and then propagates downward to z_r. Expressions of Ts and Rs can be found as function of building physical parameters above z_r. In particular, for the jth inter-story bounded with (z_{j-1}, z_j^-),

$$T_{j^-(j-1)} = T_{z_j^- z_{j-1}} = e^{-\gamma_{ij}|\omega|h_j/v_j} e^{-i\omega h_j/v_j} = T_{(j-1)j^-}$$
$$R_{j^-(j-1)} = R_{(j-1)j^-} = 0 \tag{3}$$

For the jth floor bounded with (z_j^-, z_j)

$$T_{jj^-} = \frac{2}{1 + r_{I_j} - r_{D_j} + ir_{M_j}} = B_{f_j} e^{-i\omega h_{ej}/v_j}$$
$$R_{jj^-} = T_{jj^-} - 1 \quad , \quad T_{j^-j} = T_{jj^-} r_{I_j} \quad , \quad R_{j^-j} = T_{j^-j} - 1 \tag{4}$$

where coefficients r_{Ij}, r_{Dj} and r_{Mj}, amplitude B_{fj} and equivalent floor-height h_{ej} can be found in terms of inter-story impedance (ρv) ratio, cross-sectional area (A) ratio, mass ratio (r_m), wave travelling time through inter-story length (h/v), i.e.,

$$r_{I_j} = \frac{\rho_{j+1} v_{j+1}}{\rho_j v_j} \frac{A_{j+1}}{A_j}, \quad r_{D_j} = \gamma_{f_j} r_{M_j}$$
$$r_{M_j} = r_{m_j} \frac{h_j}{v_j} \omega, \quad r_{m_j} = \frac{m_{f_j}}{m_j}$$
$$B_{f_j} = \frac{2}{\sqrt{(1 + r_{I_j} - r_{D_j})^2 + r_{M_j}^2}} \tag{5}$$
$$h_{ej} = \frac{v_j}{\omega} \tan^{-1} \frac{r_{M_j}}{1 + r_{I_j} - r_{D_j}}$$

For a composite building segment bounded with (z_l, z_n), or simply (l, n), with intermediate location z_m ($z_l < z_m < z_n$ or $z_l > z_m > z_n$) such as (z_{j-1}, z_j) with z_j^-, T and R in (l, n) can be found in terms of those in two sub-segments in (l, m) and (m, n) as

$$T_{ln} = \frac{T_{lm} T_{mn}}{1 - R_{mn} R_{lm}}, \qquad R_{ln} = R_{mn} + \frac{T_{mn} R_{lm} T_{mn}}{1 - R_{mn} R_{lm}} \tag{6}$$

3 SYSTEM IDENTIFICATION

With the aforementioned model for wave propagation at hand, this section shows system identification of the Millikan Library with the use of the general and degenerated models with a limited number of seismic recordings after the Yorba Linda earthquake of September 3, 2002.

In general, with a pair of seismic recordings at two locations, GFRF is obtainable as Fourier spectral ratio of the two recordings. One can first calculate the recording-based GFRF as

$$\tilde{D}_{j0} = \frac{\tilde{U}_j \tilde{U}_0^*}{|\tilde{U}_0|^2 + \varepsilon} \xrightarrow{\varepsilon \to 0} \frac{\tilde{U}_j}{\tilde{U}_0} \tag{7}$$

where $\tilde{U}$ is the seismic recordings in the frequency domain, superscript asterisk indicates the complex conjugate, and ε is a positive small number, implying the added white noise. The white noise is used primarily to avoid unstable calculation of GFRF at some frequencies near the notches in the spectrum $|\tilde{U}_0|^2$. As ε approaches zero, $\tilde{D}_{j0}(\omega) \Rightarrow \tilde{U}_j / \tilde{U}_0$, which is the Fourier spectral ratio or the definition of GFRF in Eq. 2a. Note that the tilde over quantities D and U is used to distinguish the recording-based quantities from those based on modeling or Eq. 2a.

With the continuous-discrete model for the structure, model-based GFRF can also be found in terms of wave transmission and reflection coefficients, which are related to structural physical properties above the impulse location. Matching the two sets of GFRF from recordings and the model helps identify structural parameters such as wave velocity or shear modulus.

3.1 *One-layer model*

One can examine a special case of the general model, i.e., uniform shear-beam or one-layer model without lumped floor mass. The GFRF of Eq. 2a becomes

$$D_{Rr} = \frac{\left(1 + e^{-i\omega(2H_r - 2z_R)/v_c} e^{-\gamma_c|\omega|(2H_r - 2z_R)/v_c}\right) e^{-i\omega z_R/v_c} e^{-\gamma_c|\omega|z_R/v_c}}{1 + e^{-i\omega 2H_r/v_c} e^{-\gamma_c|\omega|2H_r/v_c}} \tag{8}$$

where $H_r = z_N - z_r$ denotes the height of the building portion bounded by (z_r, z_N). The GIRF can then be found by substituting GFRF of Eq. 8 into Eq. 2b, where the integration can be evaluated with the method of residues. In particular, the integrand for d_{Rr}, a function of the real variable ω, is treated as a function of variable y, which has an infinite number of poles y_j ($j = 1,2,\ldots,\infty$) in the upper half complex plane, namely

$$\omega_j = (2j-1)\omega_0 \ , \ \omega_0 = \frac{\pi v_c}{2H_r}, \quad j = 1,2\ldots,\infty \tag{9a,b}$$

The integration of Eq. 2b can then be found as

$$d_{Rr} = 8\omega_0 \sum_{j=1}^{\infty} (-1)^{j+1} e^{-\gamma_c \omega_j t} \cos\left(\frac{\omega_j (H_r - z_R)}{v_c}\right) \sin(\omega_j t) \tag{10}$$

Equation 10 indicates that GIRF consists of an infinite number of motion modes, each of which has exponentially decaying damping factor, modal shape with cosine factor, and sinusoidal motion with modal frequency ω_j. This is essentially the traditional vibration perspective for seismic motion in buildings, in which the 1st modal frequency ω_1 (similar to higher-order modal frequencies) is interpreted as fundamental vibration feature of building's periodic, horizontal motion. Since ω_1 corresponds to $T_1 = 4H_r/v_c$ obtainable from Eqs. 9a,b, the fundamental period can also be viewed as four times of wave traveling time through the building height, i.e., wave interpretation.

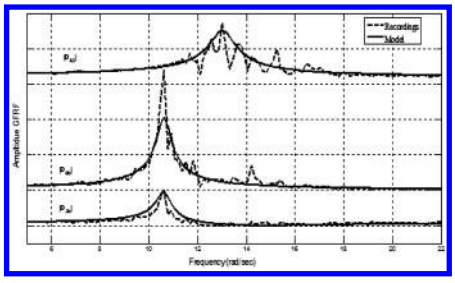

Figure 2. GFRFs at the 3rd and 8th floors with respect to basement and 3rd floors' motion.

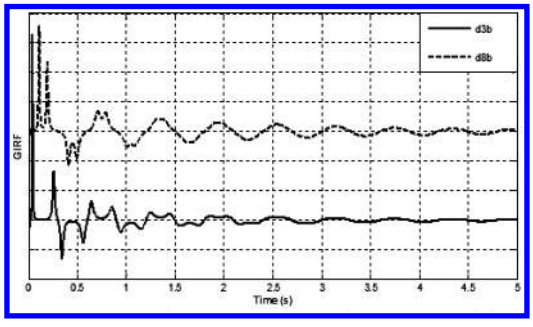

Figure 3. GIRFs at the 3rd and 8th floors with uniform shearbeam model ($v_c = 322$ m/s, $H_r = 48.2$ m, and $\gamma = 0.044$).

Figure 2 shows the match of recording- and uniform-model-based GFRFs of acceleration at the 3rd and 8th floors with respect to referenced motion at the basement and 3rd floors, in which ε is selected as 5% of total power spectrum of basement motion. The identified shear wave speeds for the whole building and the 3rd-floor-up building portion are 326 and 289 m/s, respectively; indicating that shear modulus (G) of the 3rd-floor-up building portion is less than that of the whole building if mass density (ρ) is assumed the same. Alternatively, the lower portion of the building (i.e., from the basement to the 3rd floor) is more rigid in shear resistance than the upper portion (from the 3rd floor to the top). The corresponding damping ratios are 0.028 and 0.040 respectively for the whole and the 3rd-floor-up building portion. The identified parameters indicating that the uniform shear-beam model is good enough to characterize the fundamentals of wave and vibration motion in multi-story buildings.

To validate the wave response features of the uniform shear-beam model, this study examines GIRF at the 3rd and 8th floors with respect to the basement motion shown in Fig. 3 where $v_c = 322$ m/s and $\gamma = 0.044$ are used based on Snider and Safak (2006). In particular, the first peak at the 3rd floor is rooted from the impulse propagation from the basement, which propagates further to the first peak at the 8th floor with damping-related reduced amplitude. That first peak at the 8th floor is then propagated to the top and then reflected to travel downward to the 8th and 3rd floors to generate the second peaks with sequential reduced amplitudes. The second peak at the 3rd floor continues propagating downward to the basement. Since the motion will disappear at the basement due to the fixed boundary, a negative, same-amplitude peak, balancing the positive one at the basement, is generated and propagated upward. That negative peak propagates to the 3rd and 8th floors with further reduced amplitudes, and continues following previous wave propagation cycle. As time goes on, the vibration features at those floors are then dominated by the character of the resonance of the whole building, while high-order motion modes are also involved. All these fundamental features are literally consistent with wave-propagation theory as well as pertinent others (e.g., Snieder, 2006).

3.2 *Two-layer model*

While the uniform shear-beam model captures fundamental features of a multi-story building, piecewise shear beams would be natural in characterizing the changing-properties of the structure along the height. For simplicity, one can examine a two-layer model without floor masses, which leads Eq. 2a to

$$D_{R0} = \frac{\left(1+\alpha\left(e^{-2i\omega(\tau_1-\tau_z)}+e^{-2i\omega\tau_2}\right)e^{-2i\omega(\tau-\tau_z)}\right)e^{-i\omega\tau_z}}{1+\alpha\left(e^{-2i\omega\tau_1}+e^{-2i\omega\tau_2}\right)+e^{-2i\omega\tau}} \quad (11a)$$

$$0 \le z \le h_1, \quad \tau_z = \frac{z}{v_1}$$

$$D_{R0} = \frac{2\left(1+e^{-2i\omega(\tau-\tau_z)}\right)e^{-i\omega\tau_z}/\left(1+r_{I_1}\right)}{1+\alpha\left(e^{-2i\omega\tau_1}+e^{-2i\omega\tau_2}\right)+e^{-2i\omega\tau}} \quad (11b)$$

$$h_1 \le z \le h_1+h_2, \ \tau_z = \frac{h_1}{v_1}+\frac{z-h_1}{v_2}$$

where τ_z is the flight time for waves traveling from referenced level z_0 to response location z_R, and

$$\alpha = \frac{1-r_{I_1}}{1+r_{I_1}}, \ \tau_1 = \frac{h_1}{v_1}, \ \tau_2 = \frac{h_2}{v_2}, \ \tau = \tau_1+\tau_2 \quad (12a,b,c,d)$$

The GIRF can be found by substituting GFRF of Eqs. 11a,b into Eq. 2b, where the integration can be obtained in a closed form with the method of residue for some special cases and numerically for general cases. Below are presented some special cases, which could help understand the characteristics of wave propagation in piecewise-uniform buildings and subsequently aid in system identification.

For $\gamma_1 = \gamma_2$ and $\tau_1 = \tau_2$, one can find

$$\omega_{2j-1} = \frac{(2j-1)\pi-\beta}{\tau}, \ \omega_{2j} = \frac{(2j-1)\pi+\beta}{\tau} \quad (13)$$

$$\gamma_{eq} = \gamma_1 = \gamma_2, \ \alpha = \pm\cos\beta$$

The closed-form solution of GIRF with Eq. 2b for $r_{I_1} = 1$, which could be, but not necessarily, the uniform or one-layer model, can be found with the same

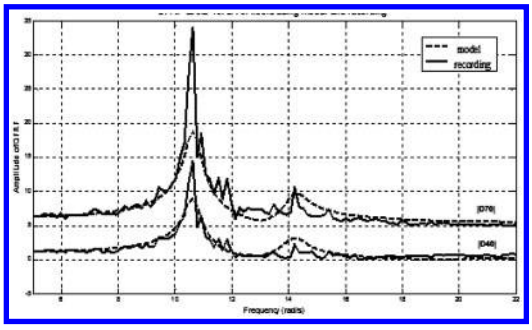

Figure 4. Comparison of GFRF amplitudes at the 4th and 7th floors with respect to impulsive basement acceleration obtained from seismic recordings and model.

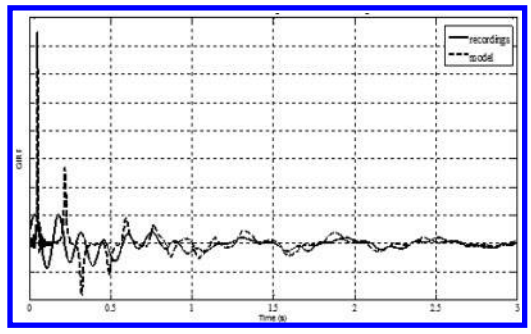

Figure 5. Comparison of GIRF at the 4th floor with respect to basement acceleration motion obtained from seismic recordings and model.

as Eq. 10. Accordingly, wave-propagation features of the two-layer model will be similar to those observed in the uniform shear-beam model.

For a pair of recordings available at the basement and floor 4 or floor 7, for example, the GFRF of $\tilde{D}_{40}$ or $\tilde{D}_{70}$, with $\varepsilon = 5\%$ of the total power spectrum of basement motion can be found in Fig. 4. In principal, all the frequencies corresponding to the spectral peaks in Fig. 4 can be regarded as modal frequencies and then used for system identification. For simplicity in practice and also for illustration with the use of a two-layer model without floor masses, parametric identification is carried out here based on two modal frequencies identified from Fig. 4 as $\omega_1 = 10.62$ rad/s and $\omega_2 = 14.21$ rad/s.

With the use of Eqs. 12a$\sim$d, the following are found: $\tau = 2\pi/(\omega_1 + \omega_2)$, $\beta = \pi(\omega_1 + \omega_2)/(\omega_1 + \omega_2)$, which yields $\tau = 0.253$ s and $\beta = 0.454$ rad, and subsequently $r_{I1} = 0.053$, $v_1 = 361.85$ m/s, $v_2 = 19.18$ m/s, $h_1 = 45.77$ m, $h_2 = 2.43$ m with Eqs. 13a$\sim$d & 14a$\sim$d. The identified slower velocity in the very-thinner layer 2 than those in layer one below makes sense, for the real building has one portion that consists of large floor masses and rigid columns and walls, which is below the very thin roof top, the other portion. It should be noted that the aforementioned identification is under special condition of $\gamma_1 = \gamma_2$ and $\tau_1 = \tau_2$. In general, parameters r_{I1}, v_1, v_2, h_1 and h_2, together with γ_1 and γ_2, can be found by minimizing the mean-square error of the model-based GFRF from recording-based GFRF in certain frequency range (say 5$\sim$22 rad/s), among many other identification algorithms.

While it is doable, this study instead presents the comparison of model-based GFRFs with the aforementioned, pre-selected parameters with recording-based ones, aiming to show the influences of some parameters in GFRF and GIRF. Figures 4 and 5 show, respectively, the comparison of recording-based GFRF at the 4th and 7th floors and GIRF at 4th floor with respect to band-limited ($\varepsilon = 5\%$) impulsive motion at the basement against model-based counterparts with respect to pure ($\varepsilon = 0\,\%$) impulsive motion at basement. These two figures indicate that the two-layer model is able to capture the fundamental wave and vibration features shown in the recordings, exemplified as the first and second modal frequencies in Fig. 4, and proximity of first couples of wave arrival times and well-matched resonant vibration features in Fig. 5. The major difference in spectral amplitudes at the first modal frequency in Fig. 4 and in wave amplitude and arrival time in the 0$\sim$0.5 s time window in Fig. 5 can be minimized with appropriate system-identification algorithm.

3.3 *General continuous-discrete model*

In general, the more the number of DOF used for the building system, the more robust the system identification is. This sub-section shows some results of the system identification using the continuous-discrete model with seismic recordings provided at the basement and 8th floor. The identification algorithm is carried out by numerically minimizing the mean squared difference of recording- and model-based GFRF with match at two pairs of identified modal frequencies, i.e., (10.62, 11.67) rad/s for one case and (10.62, 14.21) rad/s for the other.

Figures 6a,b shows the match between recording- and model-based GFRF with modal frequencies (10.62, 11.67) and (10.62,14.21) rad/s respectively. These results show that continuous-discrete model could flexibly capture dominant dynamic features of the system, exemplified as any two (or more in principle) modal frequencies identified from seismic recordings. They also indicate that the floor-to-column mass ratio, one of model parameters, plays a major role in determining the other parameters.

Figure 7 shows the GIRFs at selected locations with the building modeled as 11 continuous layers for inter-stories and 10 discrete masses for floors. In general, the wave features shown in Fig. 7 bear the similarity with those with uniform shear-beam model in Fig. 3. Besides the aforementioned fundamental wave features, multiple higher-frequency waves are also observed at those presented floors after the first motion peaks in Fig. 7. That is primarily caused by wave scattering at each and every of 10 floor-to-column boundaries, characterized with transmission

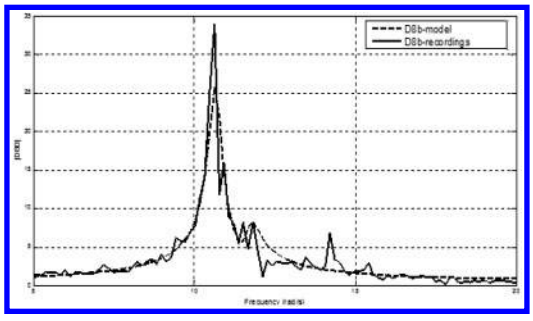

Figure 6a. System identification using seismic recordings at the basement and 8th floors with continuous-discrete model matching two modal frequencies (10.62,11.67) rad/s.

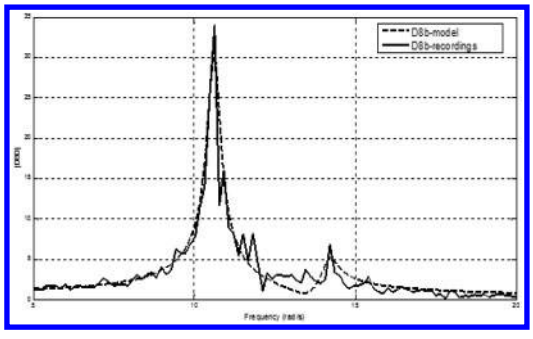

Figure 6b. System identification using seismic recordings at the basement and 8th floors with continuous-discrete model matching two modal frequencies (10.62,14.21) rad/s.

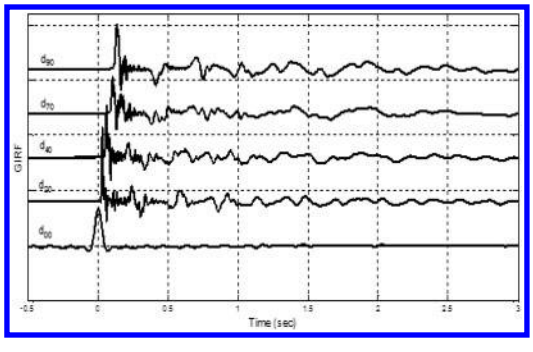

Figure 7. GIRFs at selected floors with continuous-discrete model.

and reflection coefficients in Eqs. 4 and 5. In other words, besides the dominant motion peaks at one floor (say the 1st and 2nd dominant peaks at around 0.1 and 0.25s for the GIRF at the 4th floor), other multiple peaks after the 1st peak are attributed to the arrival waves reflected and transmitted from other floors. All these make the wave responses complicated after initial arrival of impulse waves.

4 CONCLUSIONS

This study first presents continuous-discrete modeling of seismic wave propagation in multi-story building structures. It then derives the generalized impulse and frequency response functions (GIRF and GFRF) which are fundamentally important in constructing response to the motion input to a system, not the traditional force input. The features of GIRF and GFRF as well as seismic responses are also examined in detail, revealing not only well-observed vibration features of building structures, but also some perspective of seismic wave behaviors of structures which traditional vibration-based approach does not show clearly. The model is then used for system identification of Millikan Library building with recordings of Yorba Linda earthquake of September 3, 2002. Results show the proposed approach is efficient. While this study shows some applications of the modeling in system identification, it can be easily extended for damage diagnosis in post-earthquake conditional assessment for a pair of available recordings of an earthquake, which is the subject of future study.

Generation of spectrum compatible site-dependent earthquake load histories by evolutionary approach

F. Carli & C. Carino
Dipartmento di Ingegneria Civile e Architettura, Univ. di Pavia, Pavia, Italy

ABSTRACT: In this work a generation procedure for sets of simulated accelerograms is formulated on the basis of an assigned target design spectrum. The proposed approach accounts for both energy release and frequency content variability in time. The discussed evolutionary model is based on the assumption of decoupling the distribution in time of the energy release from the changing of the frequency content that is obtained by means of an amplitude modulation function and a frequency modulating function. The decoupling of the two main sources of the non-stationary behavior of natural time-histories allows the recognition of strict relations between recorded accelerograms at a site and the underlying evolutionary model here proposed. The numerical example is based on a specific record at a reference Italian seismic site and on the corresponding design spectrum from the national design code.

1 INTRODUCTION

In modern performance based design codes the specification of design forces for earthquake resistant design is often obtained via design spectra consistent at the specific site with the performance requirements. In many cases this underlying equivalent linear static/dynamic approach by modal combination rules can't be considered sufficient especially when studying the dynamics of large nonlinear systems. In that case the seismic load must be represented by a suitable set of earthquake time histories. Records of natural seismic events rarely comply with the design code requirement to be 'response spectrum compatible' at the specific site. This lack produces the need of suitable methods for the digital generation of synthetic accelerograms from the knowledge of a target response spectrum given by the code. Different methods are present in literature at this purpose (Cacciola & Zentner 2012): models bases on filtering and windowing Gaussian noise, others based on filtering white-noise of Kanai-Tajimi type, auto regressive approaches, autoregressive with moving average and recently also wavelet based models (Giaralis & Spanos 2009). More recently significant efforts were made to include both the amplitude variation and the changing in time of the frequency content (Sgobba et al. 2011). The present work is concerned with the formulation of a generation procedure for sets of simulated accelerograms on the basis of an assigned target design spectrum. The proposed approach is able to take into account for both the energy release in time and the contemporary variability of the frequency content on the basis of a possible decoupling of the two main sources of non-stationarity (Carli 1997). In particular the evolutionary approach is obtained by means of an amplitude modulation function and a frequency modulation function in time. That allows the recognition of strict relations between recorded accelerograms at a site and the underlying evolutionary model here proposed for the generation of spectrum compatible time histories. The work is completed by a numerical example in which a specific recorded sample at a reference site and the corresponding site dependent design spectrum prescribed by the Italian design code (Ministero delle Infrastrutture 2008) give all the information used for the complete definition of the simulation procedure.

2 FUNDAMENTAL RELATIONS

A complete and detailed description of a generic natural time signal $r(t)$ can be obtained by means of a suitable one-to-one mapping of $r(t)$ in the time t and frequency f domain by means of its complex spectral representation $R(f,t)$ (Newland 1993). Moreover in presence of a quasi-stationary stochastic process $r(t)$ of limited duration, an estimate of its power spectral density function $G_r(f,t)$ can be obtained as:

$$G_r(f,t) = R(f,t)^2 / d_0 \tag{1}$$

where $R(f,t)$ is defined as a smooth version of the amplitude spectrum of the underlying stochastic process $r(t)$, while d_0 represents the equivalent stationary duration of the signal. Previous works (Carli 1997) show the possibility and effectiveness of the separation

of the amplitude variability in time from the changing of the frequency content by the following basic relation:

$$R(f,t) = i(t)\, A_s(f,t) \tag{2}$$

with $i(t)$ the intensity function of the process $r(t)$ and $A_s(f,t)$ the amplitude stationary and frequency non-stationary amplitude spectrum. Therefore $A_s(f,t)$ represents a function with constant release in time of the power while allowing the variation of the frequency content, that is:

$$\int G_s(f,t_i)df = \text{constant}, \qquad \forall t_i \tag{3}$$

with $G_s(f,t) = A_s(f,t)^2/d_0$.

In this approach the intensity function $i(t)$ is therefore the only responsible of the power release of the process. That can be considered a suitable approximate description of the signal behavior only when smooth fluctuation in time of the energy release are involved.

In that context for the analytical formulation of $A_s(f,t)$ different approaches can be followed like seismological models based on multi-filtering techniques from source to site including attenuation law, or more empirical relations with less hints from the physical description of the natural event, till pure analytical models using suitable approximating functions. The main objective of this work is the formulation of a model suitable for the generation of load histories having spectral compatibility with a target response spectrum at the site prescribed by a building design code. Moreover the existence of a strict relation between the amplitude spectrum of an accelerogram and its zero damping pseudo-velocity response spectrum is also considered. The previous considerations suggested to test a formulation based on the following description of the $A_s(f,t)$ spectrum:

$$A_s(f,t) = A_s(f, f_0(t)) \tag{4}$$

whose analytical shape at time t changes on the basis of a single frequency parameter $f_0(t)$ that can change in time accordingly to a suitable function. In this model the $f_0(t)$ function is the only responsible of the changing of the spectral shape in time, assuming from that the term of frequency modulation function. In particular the following relation is here tested:

$$f_0(t) = \begin{cases} f_0(t_r), & 0 \le t \le t_r \\ e^{c_0 + c_1 t + c_2 t^2}, & t_r \le t \le t_{end} \end{cases} \tag{5}$$

Few time parameters are highlighting: t_{end} total duration of the accelerogram and t_r rise-time or ramp up time, that can be related to the starting point of the decay portion t_d simply by $d_0 = t_d - t_r$ that is the strong-ground-motion part of the load history, also known in literature as equivalent stationary duration. The proposed piece-wise function derives from the observation of the natural behavior of seismic records in which the frequency content is changing in time with regularity from high frequency content during the initial ramp up, to lower frequency content in time with important changing during the strong motion part and then slowly decreasing along the last part of the signal. From this model comes out the importance of the time characterization of the energy release in time to be expected at the considered site.

To play the role of single-parameter characterization of the variation in the frequency content $f_0(t)$ is here assumed to be the central frequency of the spectral representation in time. By this approach the decoupling of the two main sources responsible for the non-stationary behavior of strong ground motions is almost complete. The only connection between time and frequency formulations remains the frequency modulating function with the job of driving the variation of the frequency content in time.

3 TIME PARAMETERS

In the estimation process of the time parameters needed for the characterization of the accelerograms an important role is played by the intensity function $i(t)$ and the derived estimate of the equivalent stationary duration d_0 with its time location t_r and t_d. In particular $i(t)$ gives the distribution in time of the energy while d_0 gives the basis for the estimate of the frequency modulating function.

In literature different methods were proposed for the estimate of the equivalent stationary duration of a recorded time history but all the proposals show pro and cons. Here is used a method introduced by (Carli, 1997) where the equivalent stationary duration is estimated on the basis of the intensity function of the record as:

$$d_0 = \int_0^{t_{end}} i(t)dt \tag{6}$$

where $i(t)$ comes from the convolution of the strong ground motion by a suitable 'bell-shaped' window function $w(t)$ accordingly the followings:

$$e(t) = w(t) * r(t) \quad \text{with: } i(t) = e(t)/\max[e(t)] \tag{7}$$

The placement of d_0 in time is then obtained looking for the maximum energy release step of the record during a d_0 time portion. In particular, defining the cumulate function of $r(t)$ as:

$$C_r(t) = \int_0^t r^2(\tau)d\tau \tag{8}$$

d_0 can be easily located by the following maximizing condition (Carli 1997) solved for t:

$$\max\left[C_r(t+d_0) - C_r(t)\right], \quad 0 \le t \le (t_{end} + d_0) \tag{9}$$

t_r is therefore obtained leading to $t_d = t_r + d_0$.

It can be observed that the presented procedure for the evaluation of the envelope function $i(t)$ and

the time parameters allowing the definition of the strong motion part of a seismic record are somehow dependent on the selection of the smooth convolution window $w(t)$. Favorably the level of subjectivity of any reasonable choice is limited to the window function only and moreover it can be shown that the time characterization remains stable to that.

4 FREQUENCY SHAPES

As previously stated the observation of the evolution of the frequency content in time of natural seismic records suggested the adoption of the piece-wise function $f_0(t)$ in Eq. (5) with constants c_0 , c_1 and c_2 obtained by least squares fitting. To define the analytical form for $A_s(f,t)$, the amplitude stationary and frequency non-stationary amplitude spectrum to be used for the simulation of the spectrum compatible accelerograms, some hints can be obtained by the following general observations. It is known that the zero damping elastic (absolute) velocity response spectrum $S_{av}(f)$ of a generic seismic record $r(t)$ can be considered a reasonable approximation of its Fourier amplitude spectrum $R(f)$. It can be also taken into account that the spectral response $S_{av}(f)$ can be superposed with the elastic pseudo-velocity response spectrum $S_v(f)$ of $r(t)$ in a wide range of significant frequencies. Therefore a commonly used piecewise function, normalized to unit, $A_{su}(f)$ is here adopted for the analytical description of the spectral representation of a stationary simulated accelerogram $s(t)$:

$$A_{su}(f)=\begin{cases}\left(f/f_1\right)^2 & , \quad 0\le f\le f_1\\ 1 & , \quad f_1\le f\le f_2\\ \exp\left[\dfrac{(f_2-f)}{f_1}\right] & , \quad f_2\le f\end{cases} \tag{10}$$

with f_1 and f_2 the characteristic corner frequency of the spectral representation. The shape of the $A_{su}(f)$ resembles the one of the elastic design spectrum given by the Italian design code for seismic structure. For given values f_1 and f_2 a central frequency value f_0 of $A_{su}(f)$ can be easily calculated. Therefore assuming $f_0(t|f_1,f_2)$ to be the suitable modulating function $f_0(t)$ as previously defined in Eq. (5), the following time-frequency spectral representation $A_s(f,t)$ of a random process $a_s(t)$, stationary in time but non-stationary in frequency, can be obtained:

$$A_s(f,t) = c_s(t)\ A_{su}(f\,|\,f_1(t),f_2(t)) \tag{11}$$

being $f_1(t)$ and $f_2(t)$ in one-to-one relation with $f_0(t|f_1(t),f_2(t))$ estimated at time t, and $c_s(t)$ a normalizing factor to guarantee a constant energy release in time.

5 SPECTRUM COMPATIBILITY PROCEDURE

On the basis of the previously defined relations, the logical scheme used in the present work for the generation of evolutionary and spectrum compatible site-dependent earthquake load histories $a(t)$ can be summarized in the following steps.

5.1 *Time characterization*

a) selection from a public database of recorded seismic signal of a suitable record $r(t)$ to be used as a reference descriptor of the local seismicity
b) evaluation of the intensity function $i(t)$, equivalent stationary duration d_0, rise-time t_r, decay time t_d and signal duration t_{end} employing the approach described in Eqs. (7–9)
c) estimation of the continuous function $f_0(t)$ by approximation of the time varying values of the central frequency $f_0(t_i|\Delta t)$, with Δt a suitable moving time interval, using Eq. (5). A usual selection for seismic signals is $\Delta t = 1$ sec. The values $f_0(t_i|\Delta t)$ can be easily obtained by common methods usually employed for the estimation of the time-frequency amplitude spectra $R(f,t_i)$ of a non-stationary natural record $r(t)$ by time-segmented approach (Geckinli & Yavuz 1983).

5.2 *Frequency characterization*

d) definition of the two corner frequency functions $f_1(t)$ and $f_2(t)$ on the basis of the just estimated central frequency $f_0(t)$, e.g. assuming $f_2(t) = f_1(t) + 1$
e) construction of one sided real valued amplitude spectrum $A_s(f,t)$ from Eq. (6) having constant power per unit time, that is:

$$\int A_s^2(f,t)df\,dt = \left(\int r^2(t)dt\right)_{end} / d_0 \tag{12}$$

5.3 *Simulation procedure*

f) generation of the an initial amplitude stationary simulated accelerogram $a_s(t)$ by the classic approach:

$$a_s(t) = \sum_i A_s(f_i,t)\cos(2\pi f_i\, t+\varphi_i) \tag{13}$$

g) amplitude modulation of $a_s(t)$ to obtain the initial simulated accelerogram $a(t)$:

$$a(t) = i(t)\ a_s(t) \tag{14}$$

h) evaluation of the pseudo-velocity elastic response spectrum $S_v(f)$ of $a(t)$
i) estimation of the unit difference factor $\Delta S_v(f)$ calculated as:

$$\Delta S_v(f) = \left[S_{vd}(f)-S_v(f)\right]/S_{vd}(f) \tag{15}$$

with $S_{vd}(f)$ the elastic design response spectrum given by the building code at the considered site

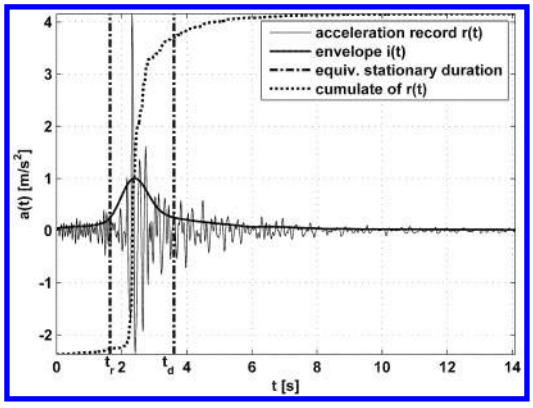

Figure 1. The reference record $r(t)$, its cumulate $C_r(t)$. The calculated envelope function $i(t)$ and the position of the equivalent stationary duration $d_0 = 1.96$s, $t_r = 1.65$s, $t_d = 3.61$s.

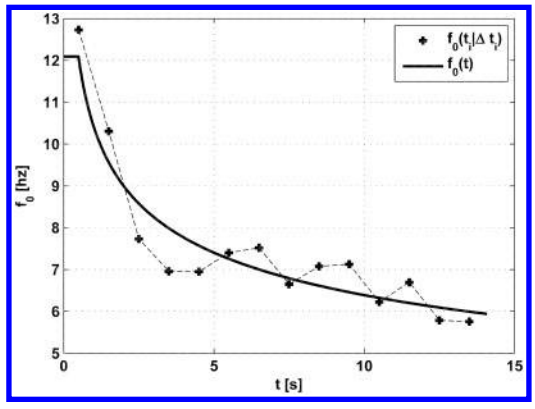

Figure 2. The data points corresponding to the central frequency values of the segmented record at time intervals Δt_i, and the corresponding approximation function $f_0(t)$.

j) correction of $A_s(f,t)$ by the $\Delta S_v(f)$ factor
k) iterate steps from f) to j) till some convergence criterion is fulfilled

6 NUMERICAL EXAMPLE

The main objective of the numerical application here reported is to show the behavior and effectiveness of the proposed procedure for the generation of synthetic time histories. In particular the level of compatibility with the target elastic spectrum prescribed at the selected site by a building design code is verified while employing as site dependent input data a single significant seismic record used as the reference indicator for the time characterization of the simulation procedure. In particular the site here selected is Ancona (Italy). It was selected considering the following features: it is located in a seismic active zone of medium level (classified as seismic Zone 2 with peak ground acceleration $0.15g < a_g < 0.25g$), public seismic records are available (Ambraseys et al. 2002), the records from the main 1972 seismic event show a significant variation of the frequency content in time.

The recorded signal $r(t)$ here used as reference for the time-frequency characterization of the proposed model is the NS component of the acceleration recorded at Ancona-Palombina station in date 21.06.1972, h.15.06.44 starting time, sampling period: 0.01 s, record length: 14.080 s. The record is here characterized in time and frequency following the approach described in Eqs. (6–9). At first the intensity function $i(t)$ is estimated by the convolution with a window function $w(t)$ of Gaussian type with standard deviation set equal to 1 s. The equivalent stationary duration is estimated, $d_0 = 1.96$ s, and then located in time, $t_r = 1.65$ s and $t_d = 3.61$ s, with the aid of $C_r(t)$ the cumulate of $r^2(t)$.

The original record $r(t)$ and the obtained results are summarized in Figure 1.

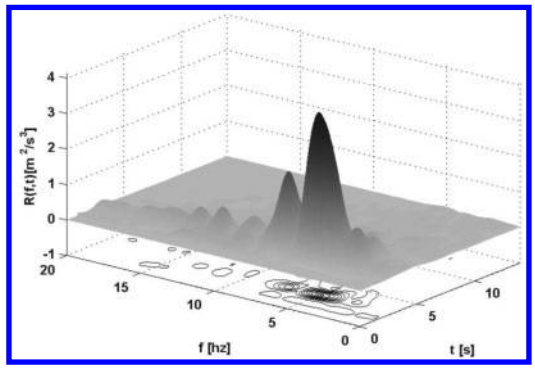

Figure 3. One sided time-frequency spectral representation $R(f,t)$ of the reference record $r(t)$.

A short time spectral representation of the frequency content of the record is then performed adopting for the segmentation of the signal a time-tapering window function of Tukey type and time-width $\Delta t = 1$ s (Geckinli & Yavuz 1983).

Naming $R_i(f)$ the one-sided amplitude spectrum of the corresponding time segment $r_i(t)$ the central frequency $f_0(t_i|\Delta t)$ of $R_i(f)$ can be promptly calculated allowing the evaluation of the approximating function $f_0(t)$ given in Eq. (5). The estimated values $f_0(t_i|\Delta t)$ for the selected record and the corresponding central frequency function obtained by least-square fitting procedure are shown in Figure 2 while Figure 3 gives a smoothed version of the one-sided spectral representation of the reference accelerogram in time and frequency $R(f,t)$ (Eq. 1). The obtained central frequency function allow the numerical evaluation of both $f_1(t)$ and $f_2(t)$ in Eq. (10) with the assumption of a constant width of the flat part: $f_2(t) - f_1(t) = 1$. From that the stationary one-sided spectrum $A_s(f,t)$ is evaluated (Fig. 4).

The iteration procedure is then performed using as global convergence criterion that the norm of the unit difference factor have to be less than 20% of the

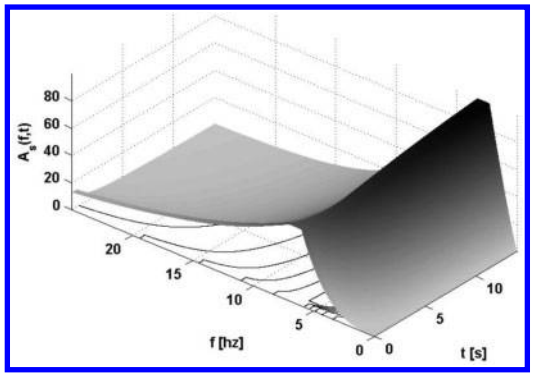

Figure 4. The normalized frequency evolutionary spectrum $A_s(f,t)$ with constant energy release in time of the proposed model.

this example $A08(t)$ and $B08(t)$. The pseudo-velocity response spectra calculated for $A01(t)$ and $B01(t)$ are plotted vs. the reference design spectrum at the site in Figure 9. The same comparison is presented in Figure 10 for the signals $A08(t)$ and $B08(t)$ at convergence.

7 CONCLUSIONS

In this paper a first proposal for the generation of synthetic acceleration time histories is presented. The main distinctive feature of the proposed approach is the generation of evolutionary signals in which both amplitude and frequency content change during the time resembling the natural behavior of recorded seismic signals. The complete non-stationary behavior is obtained in simplified way introducing a decoupled description of the frequency content from the amplitude non-stationarity. The numerical example is set up to show the step by step characterization of the model. It can be recognized the need of a small amount of data for its site localization. The obtained accelerograms show a natural appearance and the corresponding spectra significantly approach the target design spectrum. Nevertheless more work is needed to obtain a more strict convergence to the desired target.

ABSTRACT: The traditional approach for seismic analysis is based on a uniform excitation assumption, which works well for normal buildings, but is not quite accurate for long span structures, such as bridges, dams, and pipe network systems. For long span bridges, different supports might be subjected to significantly different seismic excitations, foundation types, soil conditions, seismic inputs, with different incidence angles. In general, four main factors may contribute to the spatial variation of earthquake excitations: a) incoherence effect, b) attenuation effect, c) site effect and d) propagation effect. During the last 30 years, many researchers have been working on the numerical analysis of seismic behavior of long span bridges under uniform or non-uniform ground motion; however, few experimental studies of large scale bridge models subjected to earthquake loading have been carried out. Although there are many shake tables in universities and research institutes all over the world, few have a multiple shake table system which can provide non-uniform excitations to different parts of the structural model. A dual shake table testing system has been developed at the Hong Kong University of Science and Technology and a 1:120 reduced scale model of a cable-stayed bridge with a main span of 430 m is designed and constructed for the purpose of this study. This paper describes the factors involved in the scale factor selection and the detailed design processes of different components of the model, including towers, girders, stayed-cables as well as artificial masses. The earthquake records from the SMART-1, as well as the PEER Strong Motion Database, are used in the shake table test. The results of the modal tests, the identical-input excitation tests and the varying-input excitation tests are presented, for the purpose of a) evaluating the design of the reduced scale model and the experimental method, b) studying the dynamic performance of long span bridges, and c) improving understanding of the response of long span bridges subjected to spatially varying earthquake ground motion.

1 INTRODUCTION

The traditional approach for seismic analysis is based on a uniform excitation assumption, which postulates that earthquake excitations at all the points along the base are identical. The assumption works well for normal buildings but is not quite accurate for long span structures, such as bridges, dams, and pipe network systems, etc. For long span bridges, which are long with respect to the wavelengths of the input earthquake ground motions, different supports might be subjected to significantly different seismic excitations (Nazmy & Abdel-Ghaffar 1992). This complicated correlation phenomenon is attributed to the fact that different piers may have different foundation types, soil conditions, seismic inputs, with different incidence angles as well as different travel paths due to reflections/refractions. In general, four main factors may contribute to the spatial variation of earthquake excitations (Kiureghian et al. 1992, Kramer 1996, Mylonakis et al. 2001, Lupoi et al. 2005): a) Incoherence effect. The seismic source is not a single point but a finite-sized region and the ground material is not homogeneous, but consists of different types of materials. Reflection and refraction of waves in the strata cause losses of coherency of the seismic wave. b) Attenuation effect. The energy of the wave may also decrease along with propagation, and this causes a reduction in excitation amplitude. c) Site effect. Different site conditions may lead to different influences on the seismic excitation. Different soils have different wave characteristics. When a wave travels through various strata, some strata may amplify the response, however some may do just the opposite. d) Propagation

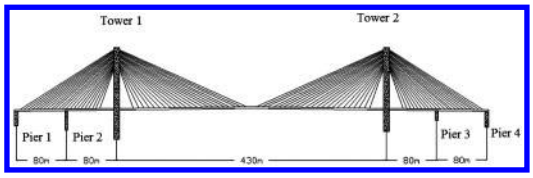

Figure 1. Elevation of the cable-stayed bridge.

effect. The wave travel speed isn't infinite, which will result in different arrival times of the ground motion at the piers.

During the last 30 years, many researchers have been working on the numerical analysis of seismic behavior of long span bridges under uniform or non-uniform ground motion; however, few experimental studies of full bridge models subjected to earthquake loading have been carried out in the past few decades. Three reasons can be given as follows: a) Full scale field testing is almost impossible for this research area. b) It is a very difficult and complex task to perform reduced scale model testing for earthquake loading. c) One prerequisite for dynamic model testing of non-uniform excitation is the multiple shake table system. Although there are many shake tables in universities and research institutes all over the world, few have a multiple shake table system which can provide non-uniform excitations to different parts of the structural model.

Based on the above reviews and considerations, a dual shake table testing system is developed and a 1:120 reduced scale model of a cable-stayed bridge with a main span of 430 m is designed and constructed for the purpose of this study. This paper describes the factors involved in the scale factor selection and the detailed design processes of different components of the model, including towers, girders, stayed-cables as well as artificial masses. The earthquake records from the SMART-1, as well as the PEER Strong Motion Database, are used in the shake table test. The results of the modal tests, the identical-input excitation tests and the varying-input excitation tests are presented, for the purpose of a) evaluating the design of the reduced scale model and the experimental method, b) studying the dynamic performance of long span bridges, and c) improving understanding of the response of long span bridges subjected to spatially varying earthquake ground motion.

2 MODEL DESIGN

2.1 *Characteristics of the prototype*

The prototype is a double-deck cable-stayed bridge with a main span of 430 m and side spans of 160 m on either side, as shown in Figure 1. Most of the main span, 387 m, is of steel/concrete composite construction, consisting of steel frames, steel webs and concrete slabs. The rest of the main span and both side spans are constructed using prestressed concrete box girders. The bridge girder is vertically supported by 4 piers and 2 towers. The two H-shape concrete towers are founded on bedrock, with a height of 150 m above the water level. Each tower consists of 2 shafts and 3 cross beams. The bridge consists of 176 stay cables, arranged in two vertical planes.

Table 1. Summary of scale factors used in physical model.

Frequency	1:0.0913	Model weight	1:161022
Modulus		1:11.182	

2.2 *Design of the reduced scale model*

In model testing, it is the "similitude requirements" that relates the reduced scale model to the prototype structure. The similitude requirements are based on the theory of modeling, and can be derived from dimensional analysis (Harris 1979; Liam Finn & Gohl 1987, Blaney & Mallow 1987). The Pi theorem was proposed by Buckingham in 1914. The theorem states that "*any dimensionally homogeneous equation involving certain physical quantities can be reduced to an equivalent equation involving a complete set of dimensionless products*".

In order to derive the scale factors for all the quantities, two parameters should be determined: the geometric scale S_L and the scale factor for Young's Modulus S_E. The geometric scale S_L is determined by the dimensions of the dual shake table and the length of the prototype. An innovative dual shake table testing system has been designed and constructed for the purpose of this study (Yang 2007). Each table is 1.5 m * 1.5 m, with a maximum payload of 2 ton and an operation frequency of 0–50 Hz. Another parameter which should be determined in advance is S_E, which relates to the selection of material for the model construction. Based on the results of material testing and comparison, acrylic is finally selected for the fabrication of the reduced scale model. After determining S_L and S_E, all the scale factors for different quantities can be derived accordingly. A summary of scale factors adopted in the proposed physical model can be found in Table 1.

Considering that the AMS (Artificial Mass Simulation) model can adequately simulate the dynamic behavior of the prototype and provide a practical modeling method for shake table testing, a reduced scale model of the prototype bridge is designed based on the scaling law of AMS model in this study. Figure 2 shows the finished 3-D spatial model.

3 SHAKE TABLE TESTING

An instrumentation scheme, including 10 channels of accelerometers, 8 channels of displacement

Figure 2. Finished model of the cable-stayed bridge.

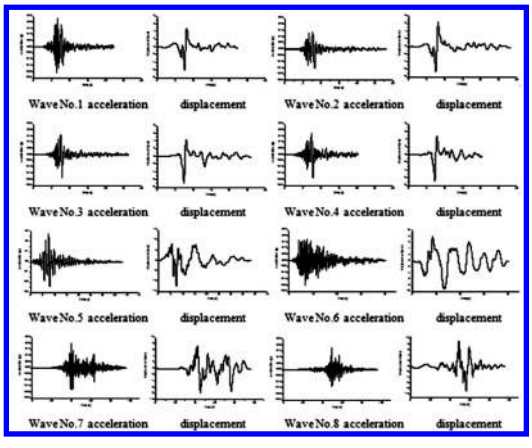

Figure 3. Acceleration and corresponding displacement inputs used in this study.

transducers and 15 channels of strain gauges, is designed for the shake table testing. The data are recorded at a rate of 256 Hz. These channels are fixed on either the dual shake table or bridge model, to measure the response of the overall bridge.

3.1 *Input ground motion and test protocol*

The ground acceleration records from the SMART-1 as well as the PEER Strong Motion Database are adopted in this test. The SMART-1 are used as the non-uniform ground motion input, while the PEER records is used to study the wave propagation effects on long span bridges under different soil conditions.

The numerical processing scheme suggested by the USGS (United States Geological Survey) is adopted here to transform the collected acceleration records to the displacement records, since it is very important that an appropriate data processing scheme should be adopted to minimize the effects of noise, as well as produce reliable and reasonable signals. The acceleration time-histories and the corresponding displacement time-histories of all the inputs in this study are shown in Figure 3.

The test protocol for the shake table testing is divided into three stages. Firstly, in test stage I, a modal test is performed by using 0.1 g white noise input excitation. Secondly, in test stage II, two groups of

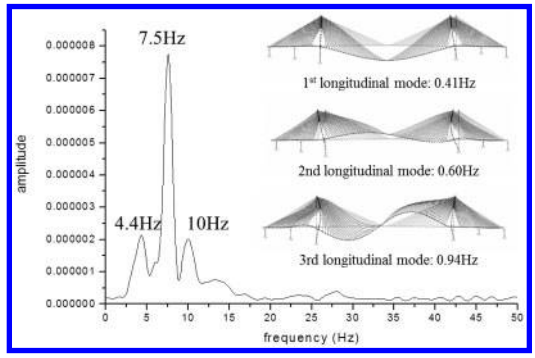

Figure 4. Comparison of modal test results with numerical modal analysis results.

earthquake records from SMART-1 (waves No. 1 & No. 2; waves No. 3 & No. 4) are used for performing the uniform and non-uniform excitation tests. In the "identical input" test, both tables have the same input wave; while in the "varying input" test, different input waves are applied to different tables. The wave propagation effect is studied by changing the wave passage velocity, including five cases, 400 m/s, 600 m/s, 1000 m/s, 2000 m/s and infinite. The distance between the two main towers (430 m) is used to calculate the difference of the arrival time for the two tables. Finally, in test stage III, four input waves (waves No. 5–No. 8), representing different site classifications, are used for the test, and the effect of wave propagation is taken into consideration.

3.2 *Test results and discussions*

3.2.1 *Test stage I: Modal testing*

The modal test is carried out before the earthquake ground motion excitation tests. The vibration of the reduced scale model is induced by 0.1 g white noise input excitation. A refined finite element model of the prototype bridge is developed in this study and the modal test result is compared with the result from the FEM analysis for evaluating the design of the reduced scale model. As shown in Figure 4, from the spectral response of the signals recorded by the strain gauge near the bottom of Tower 2, the frequencies of the first three longitudinal vibration modes of the physical model can be easily identified, i.e., 4.4 Hz, 7.5 Hz and 10 Hz. Since the scale factor for the frequency is 0.0913 (see Table 1), the natural frequencies of the corresponding prototype bridge can be calculated accordingly, i.e., 0.40 Hz, 0.68 Hz and 0.91 Hz. Compared with the results from the finite element analysis, which are 0.41 Hz, 0.60 Hz and 0.94 Hz, the reduced scale model represents the dynamic nature of the prototype quite well, which thereby verifies the design of the reduced scale model.

3.2.2 *Test stage II: Identical input & varying input excitation test*

Typical results of test stage II-Group A (Input waves No. 1 & No. 2) are presented in Figs.9–11. From

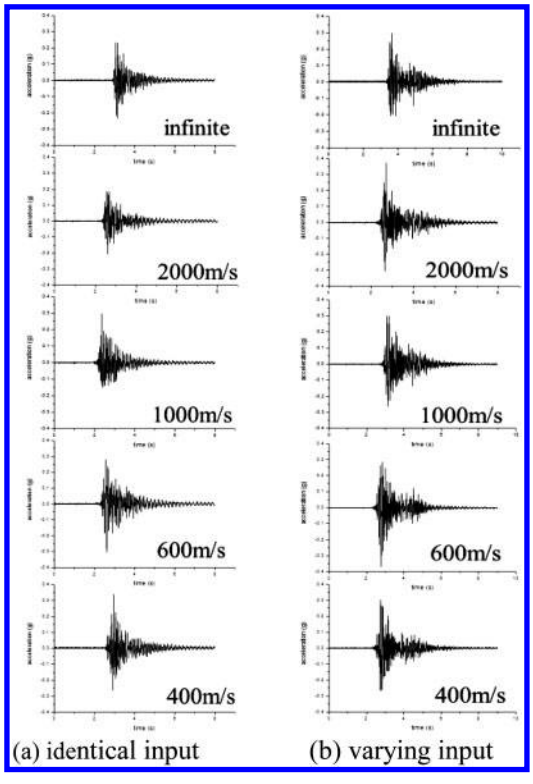

Figure 5. Vertical acceleration time-histories at quarter location of the girder under test stage II-Group A.

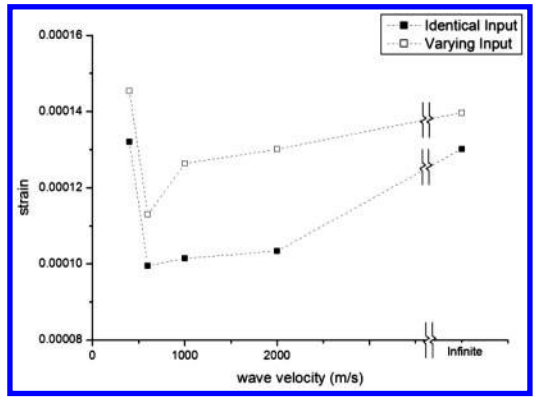

Figure 6. Strain gauge records near the top of Tower 2 under test stage II-Group A.

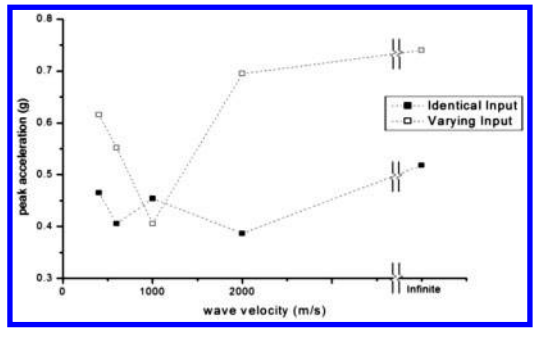

Figure 7. Peak longitudinal accelerations at the top of Tower 1 under test stage II-Group B.

these figures, one can find that non-uniform excitation strongly influences the dynamic response of the bridge model. Comparing the results at the same wave velocity, in most cases, the "varying input" excitation results in a much larger response than the "identical input", and an amplification of the response to an extent of 20–50% can be observed. The wave propagation effect also has a significant influence on the results. As shown in Figure 5, in most cases, the wave propagation effect observably increases the vertical acceleration at the quarter location of the girder (except in the case where the wave velocity is equal to 2000 m/s, in Figure 5a). Compared with the recorded time-history under uniform excitation (infinite wave velocity), an amplification of about 50% can be observed in some cases. However, from Figure 6, it can be seen that except for the case of a wave velocity equal to 400 m/s, the wave propagation effect slightly reduces the strain at the top of the tower. Since the strain gauges attached along the tower shaft are installed for measuring the longitudinal bending response of the tower, the above results imply that, in general, the wave propagation effect may increase the vertical response while slightly reducing the longitudinal response of the cable-stayed bridge. The exceptions found in above results also indicate that the value of the wave propagation velocity may play an important role in studying the bridge response subjected to non-uniform excitation.

Typical results of test stage II-Group B (Input waves No. 3 & No. 4) show that the spatial variation effect of the input ground motion has significant influences on the dynamic response of the bridge model. In most cases, the responses under the "varying input" mode are larger than the ones under the "identical input" mode. The response amplification from the effect of "varying input" excitation can be easily observed from these figures. The wave propagation effect also affects the results. When comparing the vertical acceleration time-histories at the quarter location of the girder under the "identical input" condition, with different wave velocities, one finds that the wave propagation effect increases the vertical response of the girder by a maximum extent of 50% (in the case of a wave velocity of 1000 m/s). Figure 7 presents the non-uniform excitation effect on the longitudinal response of the bridge. It can be seen that the wave propagation effect may slightly weaken the longitudinal response of the model. A maximum reduction of 40% can be observed in terms of the longitudinal peak acceleration.

3.2.3 *Test stage III: Identical input excitation test (Different site classifications)*

Typical results of test stage III-Input wave No.5 are presented in Figure 8. It can be seen that the wave propagation effect has a high visible influence on the

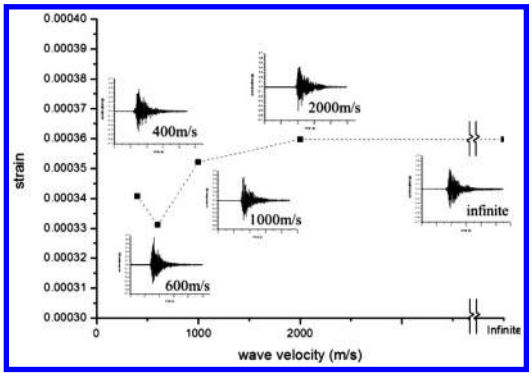

Figure 8. Vertical acceleration time-histories at the quarter location of the girder and strain gauge records near the bottom of Tower 2 under test stage III-Wave No. 5.

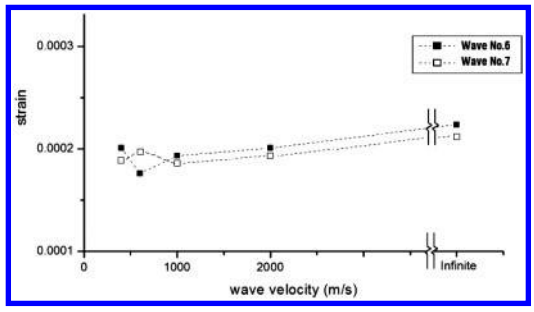

Figure 9. Strain gauge records near the bottom of Tower 2 under test stage III-Wave No. 6 & No. 7.

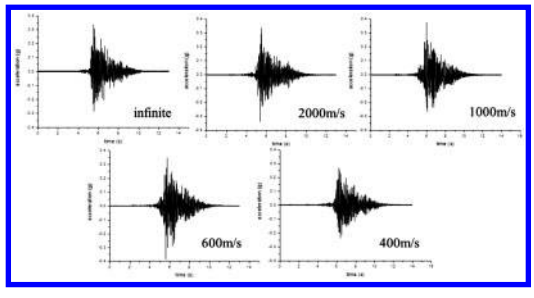

Figure 10. Vertical acceleration time-histories at the quarter location of the girder under test stage III-Wave No. 8.

bridge response when subjected to earthquake excitation in the site of soft soil. Comparing the case of uniform excitation with the cases of wave velocities of 1000 m/s or 600 m/s, the peak vertical acceleration at the quarter location of the girder increases more than 30%. However, when studying the longitudinal vibration of the tower, a reduction of approximately 10% and 25% can be observed in the recorded strain near the bottom of Tower 2. Therefore, the conclusion that can be drawn from the test results of stage III-Input wave No. 5 is that, in general, under the site classification of soft soil, the vertical response of the girder is amplified while the longitudinal response of the tower is reduced, when considering the wave propagation effect. This conclusion tallies with the previous findings of test stage II.

Similar results are observed from test stage III-Input wave No. 6 and No. 7 that the wave propagation effect significantly increases the vertical response of the bridge significantly. A maximum increase of 40% can be observed from the two tests when comparing the peak acceleration value of the uniform excitation with the one for the case of wave velocity set equal to 1000 m/s. Figure 9 shows the strain gauge records near the bottom of Tower 2 under test stage III-Wave No. 6 and No. 7. In test No. 6, it can be seen that the longitudinal response of the bridge is slightly reduced when considering the effect of the wave passage. However, in test No. 7, comparing the results from non-uniform excitation cases with those from the uniform input, the longitudinal vibration response of Tower 2 decreases.

Figure 10 shows the time-histories of the vertical acceleration at the quarter location of the girder under test stage III-Input wave No. 8 at different wave velocities. It can be seen that no significant changes, in terms of peak value and wave form, can be observed, when comparing the results from uniform excitation with the ones considering wave propagation effects. Investigating the results from Input wave No. 8 with the ones from Input wave No. 5–7, one can see that the wave propagation effect has the least influence on the dynamic response of the bridge model under Input wave No. 8, which is a recorded earthquake ground motion from a site classified as rock.

4 CONCLUSIONS

To study the dynamic response of long span bridges subjected to non-uniform excitation, 1:120 reduced scale model of a cable-stayed bridge with main span of 430 m is designed and tested on a dual shake table system. Based on this experimental test, the general comments can be made.

A reduced scale model of a cable-stayed bridge is designed and constructed in this research, based on the scaling law for an AMS (Artificial Mass Simulation) model. By choosing a "more flexible" material for model construction (with a smaller Young's Modulus compared with the prototype material), the self-weight of the reduced scale model can be significantly decreased. The design of the artificial mass is a key point in developing an AMS model, which has a significant influence on whether or not the reduced scale model can represent the structural nature of the prototype.

Seismic records from SMART-1 array and PEER Strong Motion Database are used in this study. The records from digital arrays of strong-motion seismographs can represent the nature of the spatial vibration, and are more applicable and reliable than artificial earthquake records in the study of non-uniform excitation. During the transformation of the acceleration

time history to a displacement time history, the numerical processing scheme suggested by USGS provides a comparatively effective and dependable solution and can produce rational and stable results.

In Test Stage I, the modal test is performed by using 0.1 g white noise input excitation. The modal test results tally with the numerical modal analysis results of the prototype bridge fairly well, and thereby verifies the design of the reduced scale model. In Test Stage II, two groups of earthquake records from SMART-1 are used for performing varying input and identical input excitation tests. The results of varying-input excitation show that non-uniform excitation strongly influences the dynamic response of the bridge model. In most cases, the "varying input" excitation results in a much larger response than the "identical input". The value of the wave propagation velocity plays an important role in studying the bridge response subjected to non-uniform excitation. The wave propagation effect increases the vertical responses of the bridge, while reducing the longitudinal responses. In Test Stage III, four input waves, representing different soil conditions, are used to study the effect of wave propagation for different site classifications. For the site classified as having soft and medium soil, the effect of wave propagation tallies with the previous findings from test stage II. However, for harder sites like rock, less obvious changes can be noticed and less consistent rules are obtained, implying that the wave propagation effect has less influence on the dynamic response of the bridge model for a site classified as having harder soil.

Seismic design of the self anchored suspension bridge: San Francisco Oakland Bay Bridge

M. Nader
T.Y. Lin International

B. Maroney
Caltrans

ABSTRACT: The seismically vulnerable East Span of the San Francisco-Oakland Bay Bridge is being replaced with a dual east bound and west bound 3.6 km long parallel structure. The iconic single tower asymmetric self-anchored suspension bridge was selected by an international panel of experts from a total of four design alternatives that were developed for the signature main span. Analytically, geometrically, and in the design of practical details for fabrication and durability, the Self Anchored Suspension Bridge is a unique structure requiring innovative solutions and departures from conventional design. Whether a similar bridge of this scale will ever again be proposed is unknown. However, the set of methods and technologies developed to meet these challenges offer an illustrative study of designing a world class structure, an architectural icon, and a seismic innovation all at one time in one of the most seismically challenging areas in the world. The bridge will be open to traffic by the summer of 2013.

1 INTRODUCTION

The seismically vulnerable East Span of the San Francisco-Oakland Bay Bridge is being replaced with a dual east bound and west bound 3.6 km long parallel structure. The Bay Bridge lies between the Hayward and the San Andreas faults which can generate magnitude 7.5 M and 8.1 M earthquakes, respectively. Performance criteria require that the bridge must be operational immediately following a 1500-year return period earthquake from either of these two faults.

Four distinct structures will make up the new bridge crossing: a low-rise post-tensioned concrete box girder near the Oakland shore; a 2.4 km long segmental concrete box girder; a self-anchored suspension signature span; and a post-tensioned concrete box girder that connects to the east portal of the Yerba Buena Island tunnel (Figure 1).

Comparable to the levels specified in the 1930 Uniform Building Code for buildings, the Bay Bridge was designed for only 10 percent gravity (0.1g) earthquake accelerations. In 1989, the Loma Prieta earthquake measuring 7.1 on the Ritcher scale with an epicenter 70 miles to the south of San Francisco caused a 15 m section of the upper deck of the East Span of the San Francisco-Oakland Bay Bridge to collapse. A more severe earthquake is expected to occur in the next 30 years and will cause significant damage and possibly the collapse of the existing East Span's truss structures. Retrofitting the structure was not only determined to be expensive and unreliable but also very difficult to implement while the bridge is under heavy use.

2 GEOTECHNICAL CONDITIONS

The site geology varies dramatically along the length of the bridge. Figure 2 is a geological profile at the bridge alignment. At the western end of the bridge (YBI), the piers are founded on rock. As the bridge alignment progresses east towards Oakland, the bedrock Franciscan Formation drops abruptly and the remaining piers overlie deep Bay muds, followed by the inter-layered clays and sands of the Alameda Formation. The main span tower structure is sited on relatively shallow, sloping bedrock. The remainder of the skyway is founded on a significant thickness of sediment.

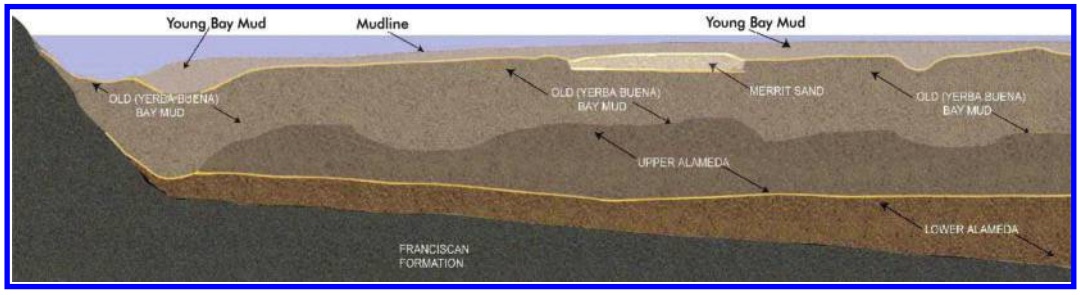

Figure 2. Soil Profile.

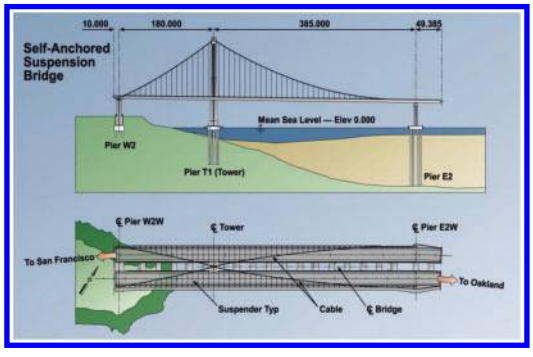

Figure 3. Elevation of the Self Anchored Suspension Bridge.

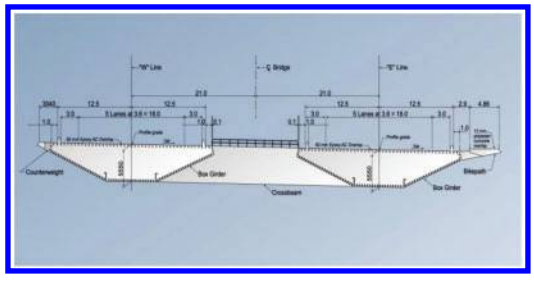

Figure 4. Typical Cross Sections of Bridge – Dual Box Girders.

3 SEISMIC PERFORMANCE CRITERIA

The bridge is designed to provide a high level of seismic performance. It is designed to resist two levels of earthquake, a functional evaluation earthquake (FEE) and a safety evaluation earthquake (SEE). After a functional evaluation earthquake, the bridge will provide full service almost immediately and there will be minimal damage to the structure. Minimal damage implies essentially elastic performance and is characterized by minor inelastic response, narrow cracking in concrete, no apparent permanent deformations, and damage to expansion joints. After a safety evaluation earthquake, the bridge will provide full service within days and will sustain repairable damage to the structure. Repairable damage is damage that can be repaired with minimum risk of losing functionality; it is characterized by yielding of reinforcement, spalling of concrete cover and limited yielding of structural steel.

4 SELF ANCHORED SUSPENSION BRIDGE

The Self-Anchored Suspension (SAS) portion of the new East Span of the San Francisco-Oakland Bay Bridge consists of dual box girders suspended from cables which are supported on the 160 m tower located off of the eastern shore of the Yerba Buena Island. The SAS spans 565 m between the piers E2 and W2, with a 385 m main span, over the navigational channel, and a 180 m back span (Figure 3).

The asymmetry of the bridge subjects pier W2 to a vertical uplift while the bridge is lightly supported on pier E2. The main tower therefore carries most of the bridge dead load. The uplift at pier W2 is fully counterbalanced by the pre-stressed concrete cap beam at pier W2. This ensures that the bridge is always balanced without relying on the pier to carry any tension. In order to balance the moments in the box girder caused by the 49 m cantilever at the east anchorage, suspenders do not support a 35 m segment of eastern end of the main span.

The box girders are not supported by the tower and are therefore "floating" at the tower with the suspenders providing the only connection between the box girders and the tower. This implies that while the tower carries most of the bridge dead load, the tower is not the primary element that carries the bridge seismic loads. The tower seismic response is mainly governed by its own mass and stiffness (the tower acts as a propped cantilever with a spring support at the tower saddle). The gap between the tower and the deck is designed to be large enough to prevent any impact during a Safety Evaluation Earthquake. Piers E2 and W2 are designed to provide the main lateral seismic support of the bridge.

The 0.78 m diameter cable is anchored to the east anchorage and is looped around the west bent through deviation saddles. The suspenders are splayed to the exterior sides of the box girders and are spaced at 10 m.

The superstructure consists of dual hollow orthotropic steel box girders (Figure 4). These girders are in longitudinal compression (reacting against the cable tension force) and are a part of the gravity load system. Transverse diaphragms spaced at 5 m

support the orthotropic deck and distribute the suspender loads to the entire box. The box girders are connected together by 10 m wide by 5.5 m deep cross-beams spaced at 30 m on center. These cross beams carry the transverse loads between the suspenders (span of 72 m) and ensure that the dual boxes act compositely during wind and seismic loads (Vierendeel truss action).

The bridge carries a pedestrian path on the south side of the eastbound deck. The pedestrian path eccentric load is balanced by a counter-weight on the north side. At the west bent, the steel box girders frame into the prestressed cap beam. The connection between the orthotropic steel box girders and concrete cap beam is subjected to the compressive reaction forces to the cables. Additional prestress is added through post-tension strands connected at each steel orthotropic rib.

The 160 m main tower is composed of four shafts interconnected with shear links along its height. The tower shafts are stiffened pentagonal steel box sections which taper along the height. The tower shafts are provided with diaphragms spaced at 4 m. The tower shafts are rigidly connected at the top and bottom by tower saddle grillage and tower base grillage, respectively (Figure 5).

The tower is fixed to a 6.5 m deep pile cap with anchor rods and dowels. The pile cap consists of a steel moment resisting frame encased with concrete and is supported on thirteen (13) 70 m long 2.5 m diameter steel shell pipe piles filled with concrete and embedded into rock. The rock slope is benched to give the piles equal lateral stiffness and to reduce torsional response (approximate clear length is 20 m).

The hinges in the transition spans between the SAS and Skyway as well as the SAS and YBI structures are designed to allow the structures to move relative to each other in the longitudinal direction and to rotate about the longitudinal axis of the bridge. The hinges are comprised of compact steel beam pipe section capable of transferring live loads and seismic loads. These hinge pipes are designed to fuse before any other bridge components in case of an overload (Figure 6).

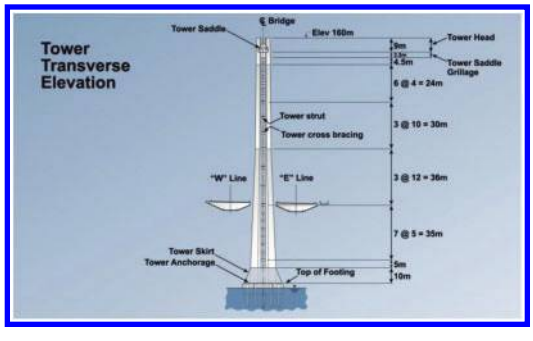

Figure 5. Single Tower with Four Shafts Interconnected with Shear Links.

5 SINGLE TOWER DESIGN

The tower shear links play a significant role in resisting the seismic loads as well as to supply the tower with the proper stiffness during service load conditions. The tower shear links are designed to satisfy the following criteria:

- Supply the tower with the required stiffness for service load conditions.
- Remain almost elastic during a functional evaluation earthquake (FEE)
- Plastify during a safety evaluation earthquake (SEE); thus dissipating energy
- Limiting the damage in the tower shafts (shafts are designed to remain almost elastic).
- To be replaceable after an SEE, if necessary

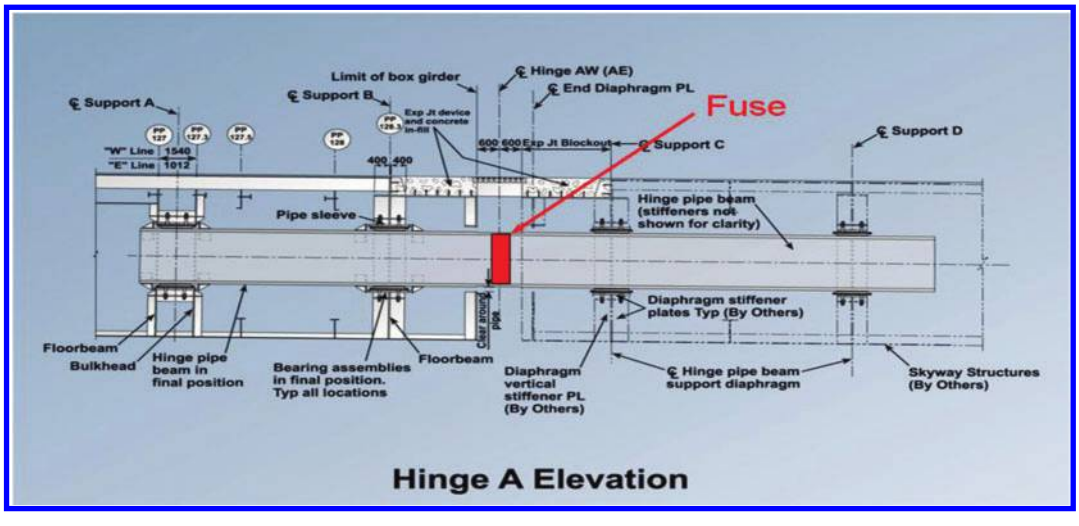

Figure 6. SAS to Skyway Hinge.

In order to satisfy the above requirements, various configurations of the tower were evaluated where the strength and stiffness of the shear links as well as their location along the height of the tower were varied. These studies were primarily done in the form of static pushovers to determine the response of the tower during service loads, wind loads, FEE and SEE loads. An optimal layout of these links was then established as well as the stiffness and yield strength of the shear links.

Although the tower shafts are designed to remain elastic during SEE, the shafts were designed as stiffened box section per ATC-32. This insured that the shafts could undergo large inelastic compressive strains without locally buckling.

A pushover analysis of tower is shown in Figure 7. This analysis was performed to evaluate the base shear versus top of tower displacement relationship; to optimize the design of the tower shear link and shaft; to evaluate the lateral ductility of the tower before collapse; and to evaluate the ductility demands on the shear links and tower shafts at various levels of displacement demand. Figure 14 shows the effects of using shear links on the lateral behavior of the tower. As noted the tower has stable behavior for displacements much larger than the SEE displacement demands (1 m). Figure 8 shows a full-scale test specimen tested at the University of California at San Diego at a rotation of 0.07 radians.

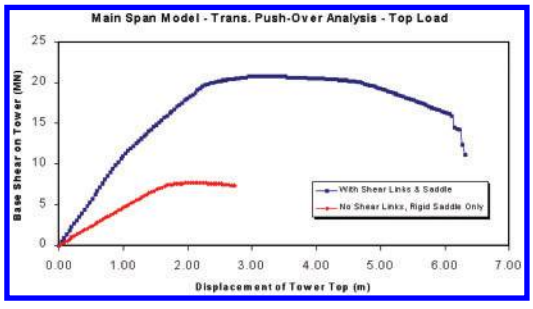

Figure 7. Pushover Analysis of the Single Tower.

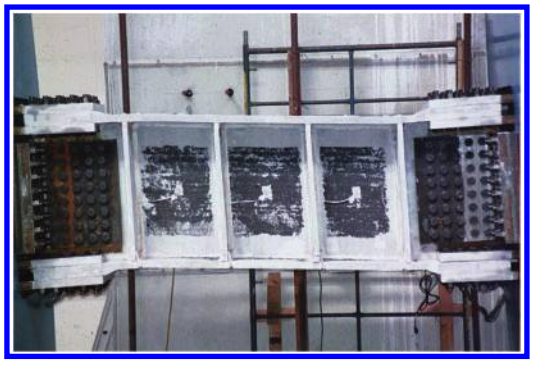

Figure 8. Full Scale Test of Shear Link Type 1 at UCSD.

6 SEISMIC PERFORMANCE

Seismic analysis was performed using the ADINA general-purpose finite element program. Three forms of analysis were employed: time history analysis (global model), pushover analysis and local detailed analysis. Time history analysis was used as the primary means of analysis for several reasons. Foremost among these is that the bridge foundations are subjected to different excitations. The tower and west pier of the bridge are founded on rock while the east pier is supported in deep soil. The ground motions at these supports are completely different in character and intensity. This was reflected in the analysis by applying different time histories of ground displacement at the supports.

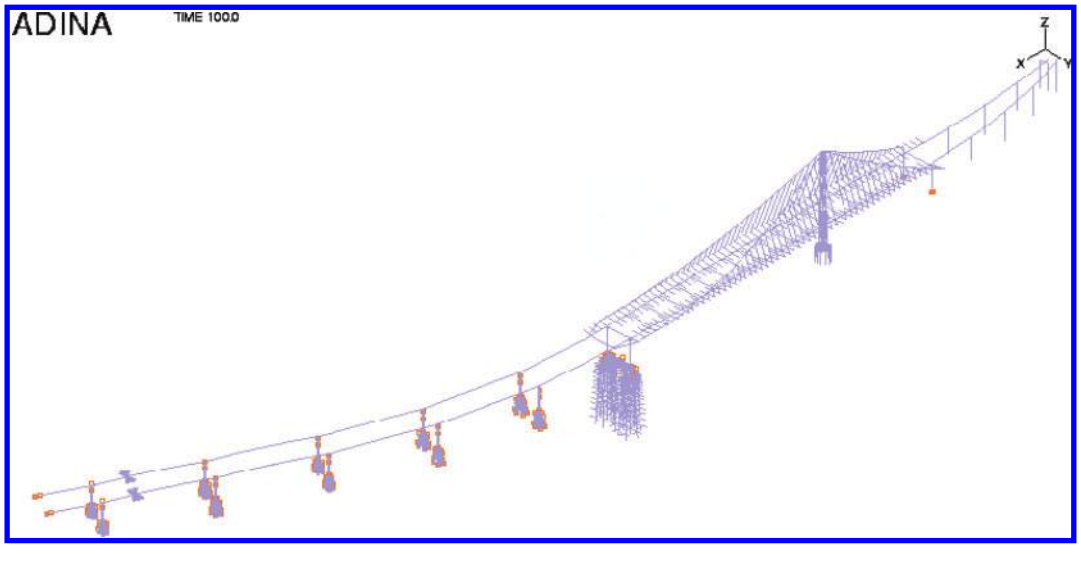

Figure 9. Adina Model of the Suspension Bridge.

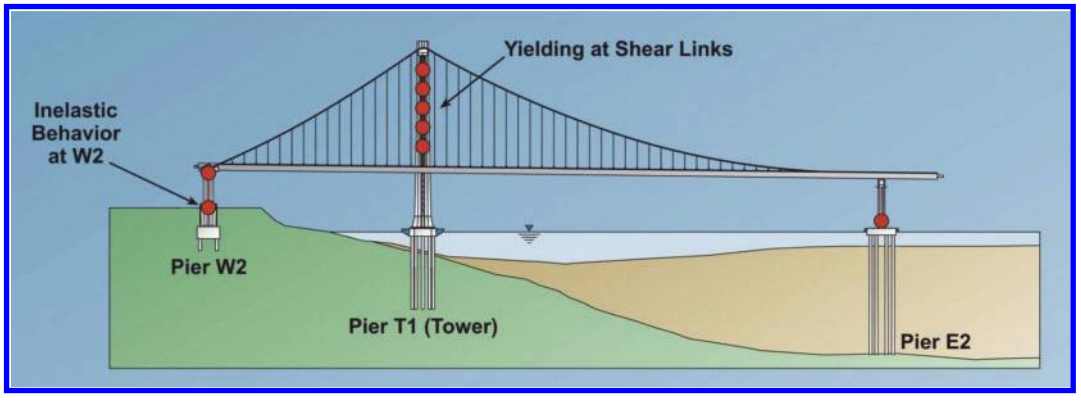

Figure 10. Seismic Response of the Bridge.

A large-displacement analysis and the use of non-linear material where necessary to allow the designers to capture the true behavior of the bridge (geometric stiffness of bridge, P-delta effects, slacking of suspenders, plastic hinging of piers, tower shear links, etc.). The model was "built" in a single step, in the dead load state. Initial strains in the deck, cables and suspenders were applied in this single step rather than simulating the construction sequence of the bridge. Time history analyses were done as restart analyses from the dead load state. Push Over analysis was primarily used to evaluate ductility of critical elements and to establish failure mode sequence. Local detailed analysis was used to establish local strain/stress demands and to evaluate the modeling used for the global model. The ADINA global model of the Self-Anchored Suspension Bridge is shown in Figure 9.

As discussed earlier the bridge is designed based on a limited ductility design in which plastic deformations are clearly defined and predetermined. Figure 10 summarizes the seismic response of the bridge. As noted the bridge is designed to remain largely elastic with the exception of the east and west piers which are designed to form plastic hinges. The plastic strain in these piers is limited to 2/3 the ultimate strains based on Manders equation for confined concrete columns. The shear links between the tower shafts are also designed to yield in shear during the SEE earthquake. The maximum rotation demand on these links is 0.04 radians compared with an ultimate rotation of 0.09 radians. The piles were designed to sustain minimal damage (strains less than 0.01 for concrete and 0.02 for steel) when subjected to the SEE displacement demands. The tie down at the west pier was designed with a factor of safety of two.

Seismic performance of an asymmetric base-isolated building in the 2011 Great East Japan Earthquake

Y. Fujino & D.M. Siringoringo
Bridge & Structure Lab., Department of Civil Engineering, University of Tokyo, Japan

ABSTRACT: Analysis of strong motion recordings during the March 11, 2011 Great East-Japan Earthquake of an asymmetric base-isolated building located in Tokyo-Bay area is reported in this paper. The building, whose structural configuration is of braced steel frames, consists of two parts: seven-story and fourteen-story building with vertical void. Seismic responses were recorded including the strongest shaking (PGA 0.80–1.40 m/s^2) experienced during the Great East-Japan Earthquake. The building survived the earthquake without structural damage. Response analysis shows that despite the considerable shift in effective frequency of the building due to the increase in flexibility of isolation system during the main shock, large acceleration was recorded on the superstructure with the peak floor accelerations of nearly 3 m/s^2. Contrary to common symmetric base-isolated buildings where vibration is dominated by translational mode, the seismic responses of superstructure were dominated by torsional modes that caused large peak floor acceleration.

1 INTRODUCTION

Base isolation as a seismic mitigation technique for buildings and bridges has gained popularity in Japan especially after the 1995 Hyogo-ken Earthquake. The favorable responses during an earthquake, ability to limit structural damage to a low and repairable level and ability to maintain functionality of structure even after a large earthquake are some advantages that have increased the acceptance of base isolation technology among engineers and building owners.

There are two main concerns regarding the torsional response of asymmetric base-isolated buildings: the asymmetricity of isolation system and the asymmetricity of superstructure system. In both cases the asymmetricity could be caused by the eccentricity either in superstructure or in isolation system. When eccentricity exists in superstructure system, the coupled lateral-torsional motions occur as they do in the non-isolated buildings. Effect of torsional motion can be significant when the building has large eccentricity. The outer isolators will experience larger force than the inner isolators when torsional motion is dominant. Large rotation of the building contributes significantly to the corner deformation in that the outer columns of the structure will experience larger shear force as a result of combined shear and moment from floor eccentricity.

This paper describes a study from strong motion recordings of an instrumented building. The study described in the paper includes: 1) seismic response evaluation of instrumented asymmetric base-isolated building during main shock of March 11, 2011 Great East Japan earthquake using system identification, 2) investigation on the seismic response characteristics considering the building asymmetricity and 3) evaluation of the long-term seismic response characteristics of the building for over a year that includes the foreshock, main shock and aftershocks and various amplitude earthquakes in 2011-2012. The high-quality seismic responses recorded on the building is significant considering the earthquake magnitude and seismic intensity recorded on site and the number of vibration sensors used in the building is larger than those usually used in other buildings.

1.1 *Description of building and monitoring system*

The monitored structure is the SIT Building located in Tokyo Bay area. The building consists of two parts: building B seven stories tall and building C fourteen stories tall (Figure 1). Building B is 81 m long, 21.6 m wide and 31.2 m high with 16 bays in longitudinal direction and 3 bays in transverse direction. Building C is 97.2 m long, 43.2 m wide and 67.5 m high with 19 bays in longitudinal direction and 6 bays in transverse direction. Both buildings are of braced steel frames and connected at the corner by elevator shaft to form an L-shaped asymmetric structure. The fourteen-story research building has vertical opening in the middle starting from the second to the seventh floor, which divides the building into the northwest section and northeast section, named hereafter as Section C-NW and Section C-NE, respectively. Meanwhile, the seven-story classroom building has some voids on its floors to provide access for escalator. Both buildings are connected by concrete slab on the basement level, on top of which the isolation systems are located.

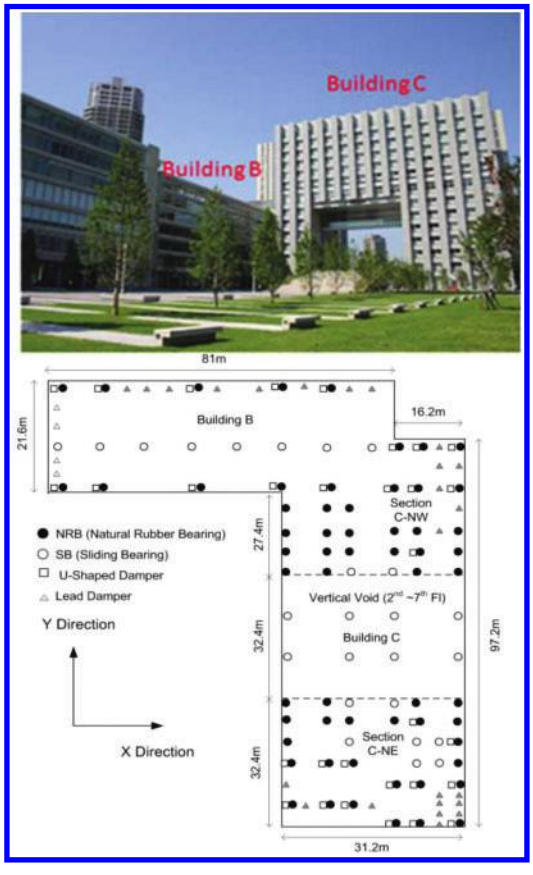

Figure 1. SIT Building and isolation layout.

The isolation system consists of 37 natural rubber bearing (NRB) and 34 sliding bearing (SB). In order to limit the horizontal motion, dampers are added to the isolation system. Two type of dampers are used namely the lead damper (28 units) and of U-shaped steel dampers (33 units). Layout of isolators and dampers is given in Figure 2. Owing to its L-shaped and vertical void, eccentricity ratios of some floors are larger than 10%, indicating significant asymmetricity of the building.

2 CHARACTERISTICS OF SEISMIC RESPONSE

2.1 *Characteristics of ground motions*

Figure 3. shows time histories of ground acceleration obtained from free-field Acc-112 during the main shock. The excitation lasted for about 10minutes, in which the significant duration (i.e. 95% energy of the excitation) remained for about 6 minutes since the arrival of the primary wave. The maximum ground acceleration in X, Y and vertical direction were 0.16 g, 0.17 g and 0.08 g, respectively. The ground accelerations have dominant frequency content between 0.7 Hz and 1.2 Hz in both X and Y directions.

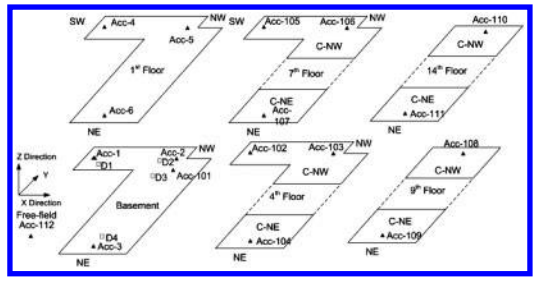

Figure 2. Layout of seismic monitoring system.

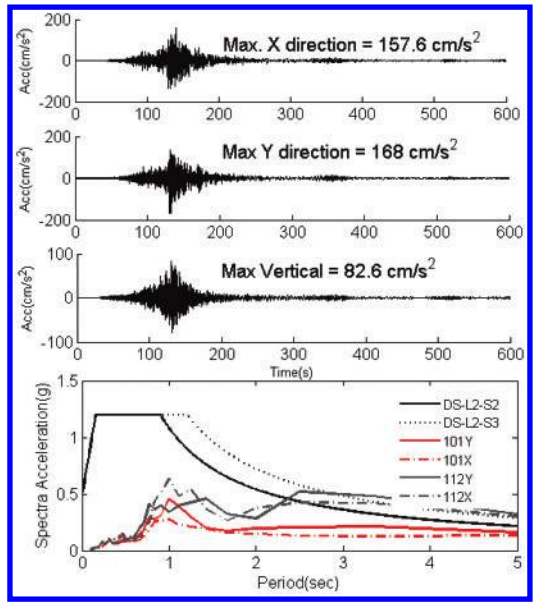

Figure 3. Ground motions accelerations and their response spectra.

In Figure 3, response spectra of two ground accelerations, namely Acc-101 (basement level) and Acc-112 (free-field sensor) are plotted together with the design response spectra for Level-2 earthquake with soil condition class 2 and 3, as specified in the Japan's Building Code. As can be seen, spectra of the main shock are still smaller than the original design spectra, especially for the period range below 3 sec, which is the range of the building's natural periods. Considering this fact, ground motions of the present earthquake are not potentially damaging to the bridge. Moreover, spectra of the main shock have large amplitude in the period range of 0.8–1.2 s (0.83 Hz–1.25 Hz), which will be shown later is the range for certain natural frequencies of the building.

2.2 *Characteristics of building response*

The building responses are characterized by large horizontal vibration of the superstructure. In the building B, the largest horizontal vibration is recorded in Y direction, with the peak acceleration on the 7th floor

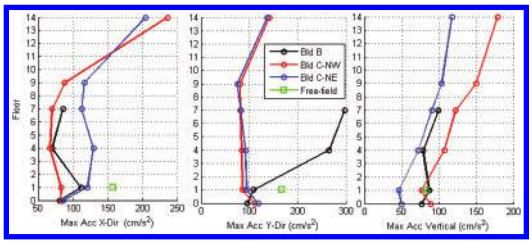

Figure 4. Recorded maximum acceleration amplitude for each floor in each direction (Note: 0 = basement level, free-field sensor: Acc-112).

nearly 300 cm/s^2 (Figure 4), or about three times of the basement acceleration. Large acceleration on the southeast section of building B was also recorded on the 5th floor, with peak acceleration of 265 cm/s^2. This large acceleration can be considered exceptional considering that the peak acceleration on the basement level of southeast section of building B is only 96 cm/s^2. Response amplification of the superstructure was also observed on building C in X direction. Peak accelerations on the 14th floor of the NE and NW sections were about 204 cm/s^2 and 236 cm/s^2, respectively, or about 2.5 times of the ground acceleration (Figure 4).

The transfer functions of accelerations on top floors of Building B and C in Y and X directions respectively are shown in Figure 5. We can see that the response of Building B is dominated by frequency peak at 0.86 Hz, while for the Building C is mainly due to frequency component at 0.58 Hz. The significant acceleration amplification of superstructure is rather unexpected in a base-isolated building. One of assumptions in design of seismically isolated structure is that lateral deformation is concentrated on the isolator level and the superstructure behaves rigidly without significant dynamic amplification. In Japan, the common design practice is to limit the horizontal floor acceleration to the maximum 300 cm/s^2 in design for Level 2 ground motion (Peng et al. 2005). Limiting large floor acceleration is necessary to protect nonstructural components, highly sensitive equipments, and computer facilities that can be found in the building. In the following sections we shall discuss the reason behind significant dynamic amplification of the superstructure.

3 SYSTEM IDENTIFICATION

Seismic behavior of the building is examined thoroughly by evaluating the vibration modes pertinent to the seismic responses using system identification procedures. A multiple-input multiple output (MIMO) system identification is utilized in this study. The methodology is based on the System Realization using Information Matrix (SRIM) (Juang 1997), which utilizes correlations between input-output data for realization of a state-space model and estimation of modal parameters. Detail information on the algorithm and

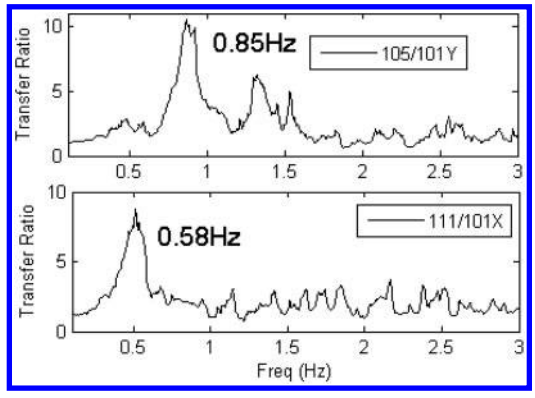

Figure 5. Transfer Functions of recorded accelerations on top floors of Building B and C in Y and X direction, respectively.

its application seismic-induced excitation is given in reference (Siringoringo and Fujino 2008).

To effectively implement the system identification, a set of input-output data was selected. Responses from triaxial accelerometers located at the basement, the same level as the isolators (i.e. Acc-1, Acc-2, Acc-3 and Acc-101), were selected as inputs. Meanwhile accelerations from the superstructure (i.e. Acc-4, Acc-102 until Acc-111) were selected as outputs. Note that the input and output data are derived from multiaxial accelerations, so that the identified mode shapes have three-dimensional shape.

It should be mentioned that in the time-invariant assumption, modal parameters remain constant during a specific time-window in which the input-output data was analyzed. However, considering that the response of base-isolated building may enter nonlinear region during large excitation this assumption may not be satisfied throughout the whole responses. Therefore, a piece-wise linear analysis was conducted using moving time window. Shorter time window was selected for analysis, during which the modal parameters were assumed to remain constant. For this reason, the total time history responses were divided into several shifted time windows consisting of 50 seconds of input and output data. Each time window generates a set of modal parameters, from which the change of parameters with respect to time can be evaluated. By applying this procedure, the 600 s main shock response was divided into twelve time windows of input-output data.

3.1 *Results of system identification*

The multi-input multi-output time-invariant SRIM system identification results in three dominant modes: the first translation mode identified at 0.44 Hz–0.55 Hz, the first torsional modes identified at 0.58 Hz–0.68 Hz and the second torsional mode at 0.85 Hz–0.95 Hz. As illustrated in Figure 6, the first mode has characteristic of large modal displacement at the isolator layer and small modal displacement of

the upper-stories resembling the rigid body motion of the superstructure, which is typical characteristics of the fundamental base-isolation mode. The second is the torsional mode with large modal displacement concentrated on the corner of Building C. On the hand, the third mode is the torsional mode with large modal displacement concentrated on the corner of Building B and small modal displacements on the superstructure of Building C.

In design, two scenarios of isolator behaviors and the effect to modal parameters were considered, one is the case for small and medium earthquake in which the initial stiffness of isolators were considered, the other one is during exceptionally large earthquake, where the isolators enter the secondary stiffness. In the first scenario, isolators are expected to enter the initial stiffness and the estimates of building's natural frequencies are 0.5 Hz, 0.64 Hz and 1.05 Hz for the first, second and third modes, respectively. For the second scenario, large deformation of isolation 40 cm is assumed and as the result the building's motion will be dominated by the first translation mode. In such condition, the first natural frequency of the building could reach as low as 0.16 Hz and the superstructure moves as rigid body. When large deformation occurs on the isolators during significantly large earthquake, it is expected in design that the torsional modes of superstructure become insignificant and the translation mode due to the flexibility of isolation will govern vibration of the building. Comparing the identified natural frequencies with the estimates from two scenarios, one can see that the identified frequencies are closer to the estimates for small and moderate earthquake. The identified frequencies of the first the modes, however, are lower the analytical estimation.

3.2 *Variation of modal parameters during main shock*

The general trend (Figure 7) shows that the strong shaking causes significant reduction in effective frequency. The natural frequency of the first mode decreases from about 0.6 Hz in the beginning of the response to about 0.44 Hz during the largest excitation (t = 150−−250 sec). The similar reduction in natural frequencies was also evident from the second and the third modes. Reduction of natural frequencies identified during the largest excitation. The second and the third mode also show the reduction from 0.68 Hz and 0.95 Hz in the beginning of the response to 0.58 Hz and 0.85 Hz, respectively, during the largest excitation. The frequencies increase slightly near the end of excitation when excitation amplitude become smaller but do not recover to their conditions before the arrival of seismic.

Damping ratios of the all modes increase from about 3–4% in the beginning of the response to nearly 15% during the largest excitation. At the end of the responses, the damping ratios are generally decreasing nearly to their original values. The increase in damping is related to the performance of isolators and dampers that become fully engaged during largest excitation, as shown by the largest isolator deformation occurring during t = 130–170 second. Large damping in the present earthquake is in agreement with common practice in Japan that is to design number of dampers so that the equivalent damping is about 15 to 20% (Peng et al. 2005).

4 RELATIONSHIP BETWEEN MODE SHAPES, ISOLATION DEFORMATION AND INTENSITY OF GROUND MOTION

The influences of excitation intensity on the isolator's relative displacement for the first three dominant modes are described in Figure 8. In this figure, abscissa represents the ground motion amplitude in term of response spectra of acceleration Acc-101 for 5% damping. The response spectra of horizontal ground acceleration were calculated at the frequencies that correspond to the first three modes (i.e. 0.44 Hz for the first mode, 0.58 Hz for the second mode and 0.85 Hz for the third). In such a way, we can quantify the frequency components of the ground motion that are relevant to the natural frequencies of the structure.

To quantify the influence of excitation intensity on isolator displacement, an index called Relative Isolator Modal Displacement (RID) index is used for the ordinate. For each mode shape, the RID measures relative modal displacement at isolator level with respect to the modal displacement at the roof level, which is normalized to unity. When isolator displacement is large, the RID value will become closer to unity, and for

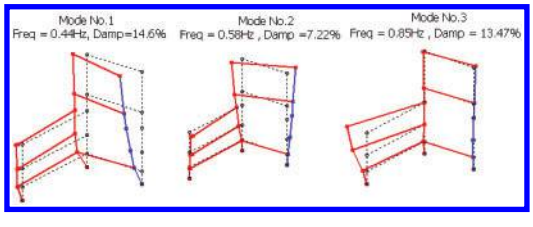

Figure 6. Mode shapes of the Building identified during the largest excitation of the main shock.

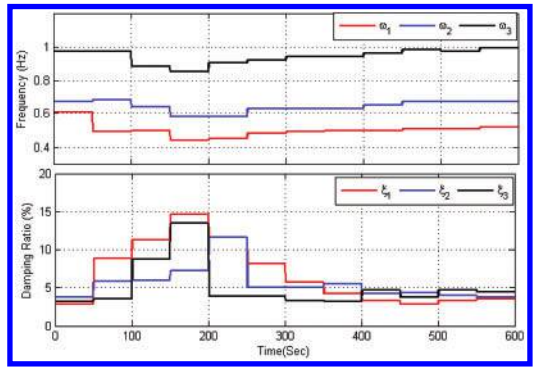

Figure 7. Time variation of identified frequencies and damping ratios during the main shock.

an ideal rigid superstructure; the RID value is equal to one. The RID index also describes the influence of isolator displacement on the global modal displacement for each mode. As can be seen on the figure, only the first mode shows a strong relationship between the RID and spectra acceleration, in that the RID values increase significantly as the spectra acceleration increases.

The foregoing results provide an explanation on the large amplification experienced by the superstructure during the main shock. As mentioned previously, responses of the top floors are dominated by vibration modes that correspond to the torsional modes. These torsional modes lie within the dominant frequency range of excitation as demonstrated by the response spectra of Acc-101, indicating the occurrence of resonance between input excitation and structural torsional modes. Furthermore, from the RID plot we know that isolator displacements do not have significant influence on the torsional modes as illustrated by Figure 8. This suggests that even though the base-isolation system had worked during the main shock, its function was inadequate to prevent torsional effect on the superstructure response due to characteristics of the building. It should be mentioned, however, that this condition depends upon the excitation intensity and the amplitude of isolator displacement.

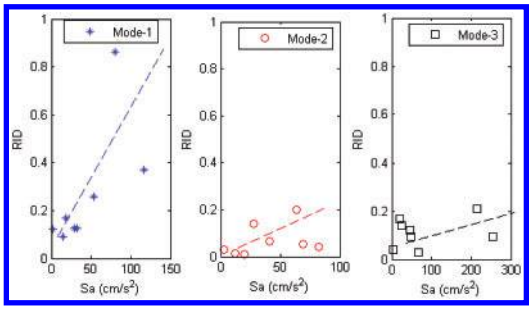

Figure 8. Influence of the excitation intensity on isolator's relative displacement.

In the design process, it is described that when larger excitation occurs (i.e. level 2 earthquake in Japan's seismic design code), isolator displacement will be significantly larger and natural frequency of the building will drop to 0.16 Hz, in which case the effect of torsional motion on the total response of the building will be minimized. Nevertheless, significant response amplification in the moderate excitation (i.e. earthquakes smaller than level 2) is still possible, and this

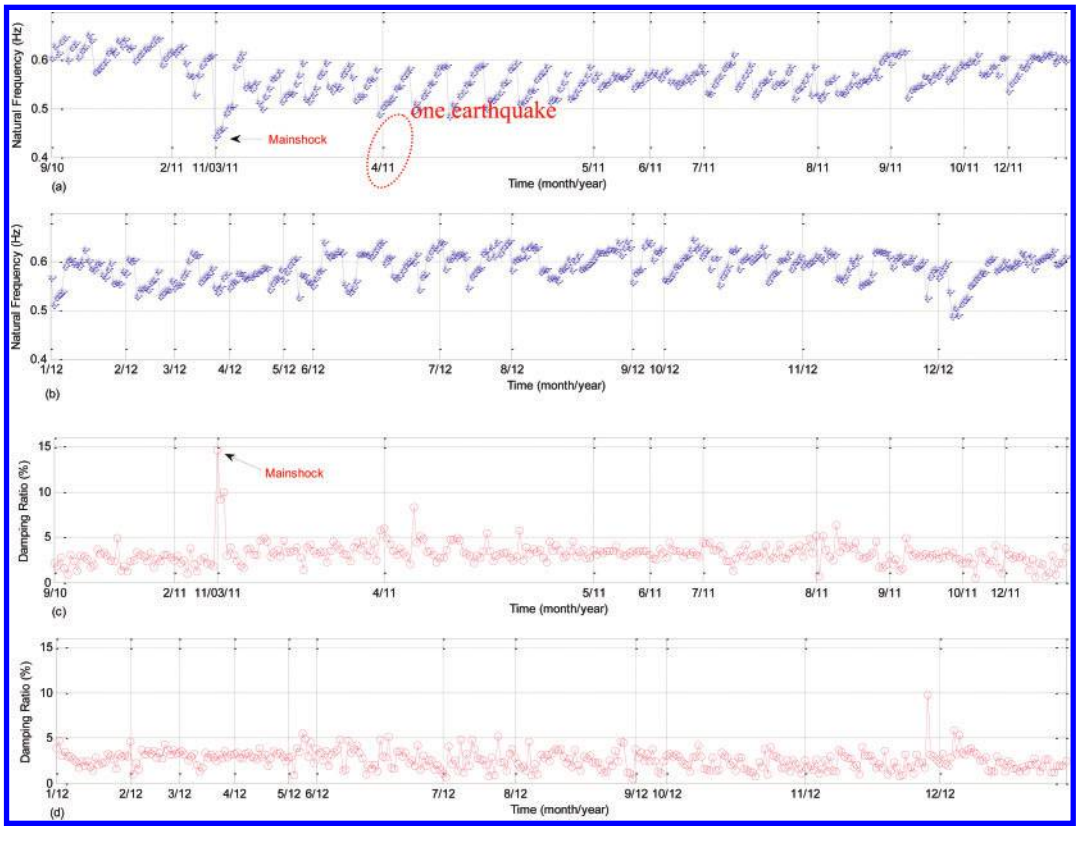

Figure 9. Long-term time sequential variation of the first mode: (a) Natural frequency Sept 2010–Dec 2011, (b) Natural frequency Jan 2012–Dec 2012, (c) Damping ratio Sept 2010–Dec 2011 and (d) Damping ratio Jan 2012–Dec 2012. Note the circle in (a) showing the variation of frequency in one earthquake event.

could be critical to nonstructural elements or sensitive equipments in the building.

5 LONGTERM VARIATION OF NATURAL FREQUENCY AND DAMPING RATIO

Since installed in September 2010, about 140 seismic events have been recorded by the monitoring system until December 2012. Most of the earthquakes were of small and moderate scale (JMA seismic intensity 3 or less) and only ten events including the March 11,2011 main shock have seismic intensity larger than 4. With relatively large earthquake database, we can investigate behavior of the building and observe the trend in modal parameters with respect to the level of seismic excitation and their long-term variations.

Figure 9 shows the sequential long-term variation of the first mode. Note that we focus discussion on the first mode, since it is the mode that is significantly affected by isolator behavior. As shown on the figure, for one seismic event, the natural frequency reaches the minimum value in the beginning of the record that is during the largest excitation and increases gradually towards the end of the record. Similar behavior is repeated in the next earthquake event. These repetitions result in the sharp turns in alternating directions as time progresses. The minimum frequency of the first mode for the entire monitoring records is 0.44 Hz observed during the main shock of the March 11, 2011 earthquake. Prior to that event, the lowest observed frequency was slightly higher 0.55 Hz, recorded during the foreshock event on February 9, 2011. Note that natural frequency of the first mode was higher before the foreshock event with an average of 0.6 Hz. The main shock of the March 11, 2011 earthquake was followed by several aftershocks with moderate level of excitations, and in the course of two months the building experienced frequent earthquakes with JMA seismic intensity 3–4. One can note from the figure that it takes about two months (May 2011) for the natural frequency to return to its pre-main shock value.

The prolonged effect of reduction in natural frequency is thought to be caused by the stiffness reduction of isolator system as results of the property known as the Mullins' effect (Clark et al. 1997), which is a temporary and recoverable reduction in modulus due to cyclic straining history on a rubber. The reduction in effective modulus with cycling of elastomeric isolator system depends on the material properties of elastomer and the strain history. Large excitation, long duration experienced during the main shock, and the occurrences of many moderate level aftershocks that follow immediately within a short period of time are thought to contribute significantly to the prolonged effect on the strain history of isolator system and delay the recovery of isolator's effective modulus.

6 CONCLUSIONS

Based on response analysis and system identification during the 2011 Great East-Japan Earthquake, the following conclusions are drawn:

1. The building experienced frequency reduction and increase of damping during the main shock. Frequency reduction indicates the increase in flexibility due to base-isolation system, as demonstrated by reduction of the first mode from about 0.6 Hz in the beginning of the response to about 0.44 Hz during the largest excitation. Meanwhile, the increase in damping is a consequence of shear deformation in isolation system and functioning of the damper system during the large excitation.
2. Despite the functioning of base-isolation system, strong response amplifications on the upper-stories were during the main shock. Unlike typical base-isolated building where the first sliding mode dominates the response, the torsional modes dominate the horizontal accelerations of the superstructure, and amplification of superstructure is caused by the torsional modes. Torsional modes were not significantly influenced by performance of the isolation system. Moreover, natural frequencies of the torsional modes coincided with the frequencies of ground motions that have the largest energy. These combined factors are thought to be the reason behind strong amplification of the superstructure.
3. Large excitation, long duration experienced during the main shock, and the occurrence of many moderate level aftershocks that follow immediately within a short period of time contribute significantly to the prolonged effect on the strain history of isolator system and delay the recovery of isolator effective modulus.

Assessment of evaluation methods of dynamic response of multi-span bridge to mining tremor

J.M. Dulinska & M. Fabijanska-Kopacz
Institute of Structural Mechanics, Cracow University of Technology, Krakow, Poland

ABSTRACT: In this paper assessment of evaluation methods of dynamic response of a 4-span bridge to a mining tremor in Legnica-Glogow Copperfield, Poland (LGC) was presented. The time history analysis including spatial variability of ground motion was performed. It occurred that non-uniform excitation may cause the increase of stresses in comparison with uniform excitation. The time history analysis with simplifying assumption of uniform excitation does not always lead to conservative assessment of dynamic response. The response spectrum method was also performed. The elastic spectrum recommended in Eurocode-8 and the local spectrum established for the LGC were used. The results indicated that the Eurocode 8 spectrum strongly overestimated the dynamic response of the long bridge with low natural frequencies. Better results were obtained for the local spectrum. For comparison dynamic response of a shorter bridge with higher natural frequencies was evaluated. For that bridge the results obtained for both spectra were almost identical.

1 INTRODUCTION

Numerous studies involve research on analyzing and designing of engineering structures located in seismic areas. In Poland natural seismic incidents occur very rarely, but there are mining activity regions where mining tremors frequently happen. The evaluation of dynamic responses of engineering structures subjected to mining tremors became a task of intensive studies in recent years. However, the vast majority of these studies focuses on the influence of mining tremors on residential buildings (Kuzinar 2005; Tatara 2002; Tatara, 2006). The recognition of effects of mining shocks on other structures, like bridges are still insufficient (Dulinska 2011; Dulinska & Fabijanska-Kopacz 2012).

Since energy and amplitudes of vibrations caused by highly energetic mining tremors are comparable with those resulting from small earthquakes, methods used for evaluation of dynamic responses of structures to mining tremors are identical with methods applied in seismic engineering. Two main evaluation methods of dynamic response of a structure to kinematic excitation are commonly used: the time history analysis (*THA*) based on numerical integration of equation of motion, and the response spectrum analysis (*RSA*) based on spectral curves provided for a variety of soils by Eurocode 8 (2004).

In this paper both methods were introduced in the dynamic analysis of a 4-span bridge subjected to a mining tremor registered in the LGC (Legnica-Glogow Copperfield), which is the major mining activity region in Poland.

The *THA* method was implemented considering non-uniformity of kinematic excitation resulting from spatial variability of ground motion. This effect is typical for long structures, such as bridges, pipelines and dams (Crewe & Norman 2006; Dulinska 2006; Dulinska 2011; Sextos & Kappos 2009; Zerva 2009). For comparison uniform excitation was also introduced. The results of the dynamic response of the bridge obtained with the *THA* method for both uniform and non-uniform kinematic excitation were assessed. The *RSA* method was also used to evaluate the dynamic response of the bridge to the mining tremor. Two response spectra were applied in the analysis: the horizontal elastic response spectrum recommended in Eurocode 8 and the local elastic response spectrum established for LGC (Tatara 2002). The assessment of applications of both spectra in case of mining tremor was conducted according to the accuracy of the obtained of results.

2 THE MAIN DATA OF THE BRIDGE

The evaluation of the dynamic response to a strong mining shock was conducted for the existing 4-span cable concrete bridge with elastomeric bearings located in Poland (Fig. 1). The bridge is 157.5 m long. The length of the longest span is 56 m. The height of the piers varies from 7 to 21 m. The abutments are situated 32 and 34 m away from the extreme piers. The height of the cross section of the concrete deck changes along the length of the bridge form 1.9 m at the abutments to 3.3 m at the central pier.

The geometry of the superstructure cross section and the view of the central pier are presented along with the main dimensions in Figure 2. The bridge

Figure 1. View of the existing 4-span bridge (157,5 m long).

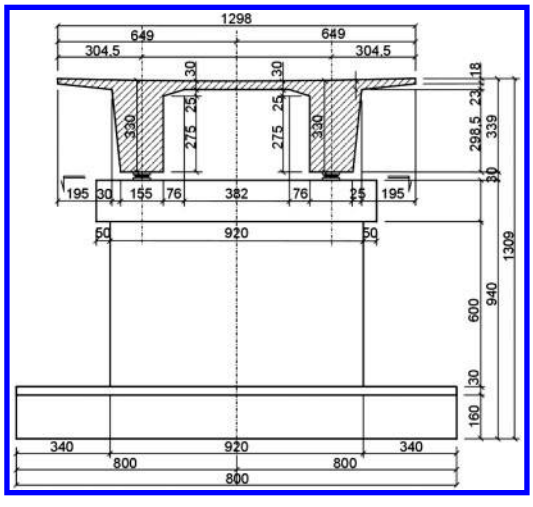

Figure 2. Main dimensions of the cross-section of the superstructure and the view of the central pier.

is equipped with elastomeric bearings as linking elements between the superstructure and the piers. The elasticity modules are taken as 4.4 and 3.8 GPa for the superstructure and the piers, respectively. The fixed boundary conditions reflected the high rigidity of the foundation rock.

Numerical analyses of the bridge were performed with the Abaqus software – a general-purpose system for static and dynamic calculations in engineering (Abaqus 2010). A mesh of 8-node linear brick and 10-node quadratic tetrahedron finite elements was used. The numerical model of the bridge with cross sections selected for the dynamic analyses is shown in Figure 3.

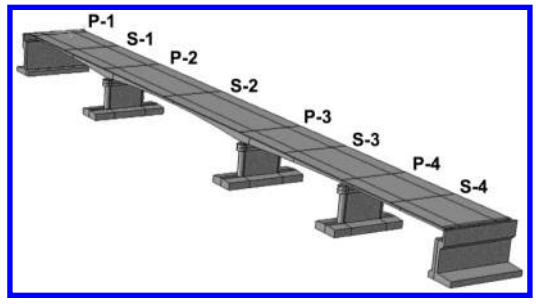

Figure 3. Numerical model of the bridge with cross sections selected for dynamic analyses.

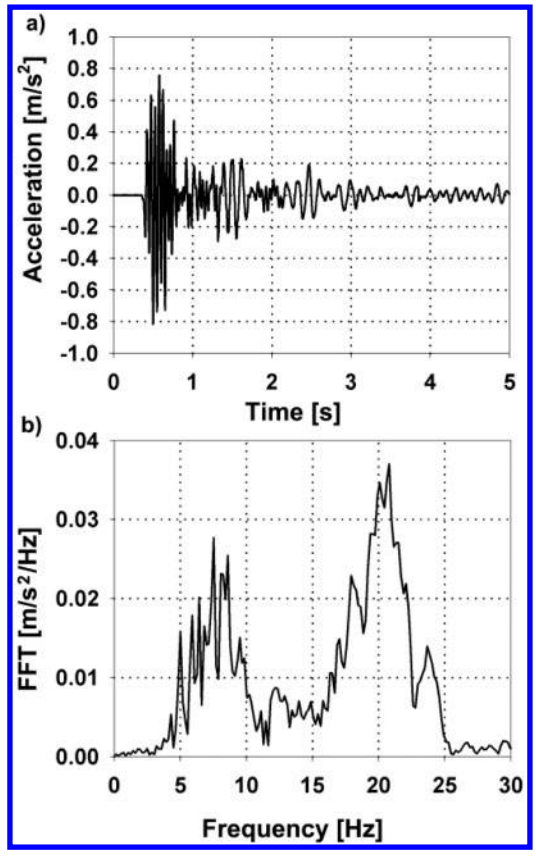

Figure 4. Ground vibration resulting from mining tremor in horizontal NS direction: (a) time history of accelerations, (b) amplitude-frequency spectrum of the signal.

3 MINING TREMOR DATA

For the analysis of the dynamic response of the bridge a real mining tremor registered in the Legnica-Glogow Copperfield was selected (Tatara 2002). The time history of accelerations in horizontal direction NS, parallel to the longitudinal axis of the bridge, as well as the frequency spectrum of the signal are shown in Figure 4.

The maximum acceleration of 0.8 m/s^2 occurred during the shock in horizontal direction NE (see Fig. 4a). The frequency-amplitude spectrum of this high-frequency shock shows maxima at the dominant frequencies of about 7 and 20 Hz (see Fig. 4b). The maximum acceleration of 0.38 and 0.45 m/s^2 occurred in horizontal direction WE and in vertical direction Z, respectively. A similar range of dominant frequencies in these directions was be observed.

4 ASSESSMENT OF DYNAMIC RESPONSE UNDER UNIFORM AND NON-UNIFORM KINEMATIC EXCITATION (*THA* METHOD)

The objective of this study was to assess the effect of non-uniformity of kinematic excitation on the dynamic response of the long bridge which is commonly neglected in the time history analysis. A model of non-uniform kinematic excitation, which takes into consideration the wave passage effect only, was applied for the dynamic analysis (Dulinska 2006; Dulinska 2011). In this model it is assumed that subsequent points of the ground in the direction of wave propagation undergo the same motions with a certain time delay dependent on the wave passage velocity. Neither loss of coherence of the signal nor possible changes of the vibration amplitudes with regard to different local ground conditions are taken into consideration (Zerva 2009).

The time history analysis was carried out with the Hilber-Hughes-Taylor time integration algorithm provided in the ABAQUS software for a direct step-by-step solution. In order to evaluate the relation between the dynamic response of the bridge and the wave passage velocity, the investigation of the response to non-uniform excitation propagating with velocities ranging from 500 to 4000 m/s was performed. For the purpose of comparison the dynamic response to uniform kinematic excitation was also evaluated (this corresponds to the infinite wave passage velocity).

Figure 5 presents the time histories of maximal principal stresses at cross-section F1 (see Fig. 3) computed for uniform and non-uniform kinematic excitation (with wave passage velocities 1500 and 500 m/s). It could be observed in Figure 5 that the maximal principal stresses obtained with the assumption of uniform kinematic excitation were larger then maximal principal stresses obtained for the non-uniform kinematic excitation with the wave passage velocity of 1500 m/s. At the wave passage velocity of 500 m/s maximal principal stresses increased again.

The relation between the maximal principal stresses and the wave passage velocity for selected cross sections is presented in Figure 6. Generally, the plots show the reduction of maximal principal stresses to a certain wave velocity. The initial decrease results from the reduction of the average values of excitation amplitudes.

Further reduction of the wave velocity causes the increase in maximal principal stresses. At low velocities the wave passage produces significant quasi-static effects which can be attributed to the changes of the subsoil geometry during the passage of the wave. It happened that the stresses obtained for non-uniform kinematic excitation with low wave passage velocity occurred greater than stresses obtained for uniform excitation (see Fig. 6, cross section P2).

The *THA* method, based on direct integration of equations of motion, in case of the investigated long bridge correctly evaluates the dynamic response only when non-uniformity of kinematic excitation is considered. The presented analysis highlights that the simplifying assumption of uniform kinematic excitation is not recommended for long structures. No doubts, including the correct wave passage velocity in the model is also essential for the accurate assessment of the dynamic response of the bridge to non-uniform kinematic excitation.

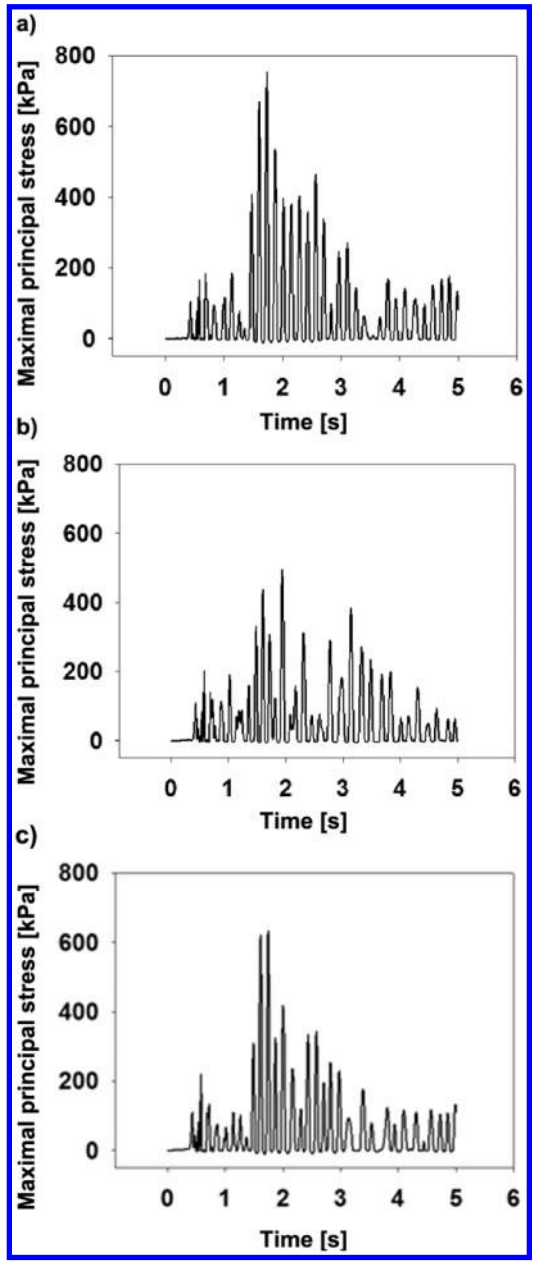

Figure 5. Time histories of maximal principal stresses at cross-section P1: (a) uniform kinematic excitation, (b) non-uniform kinematic excitation, v = 1500 m/s, (c) non-uniform kinematic excitation, v = 500 m/s.

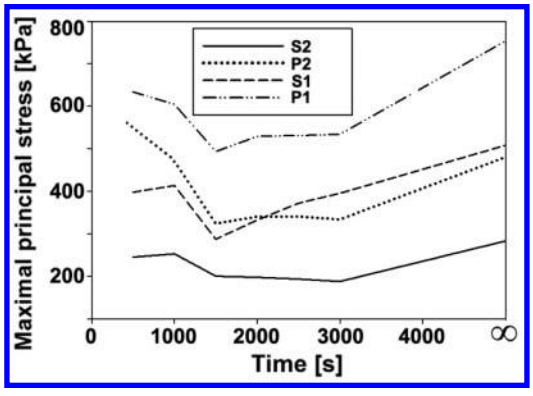

Figure 6. Relation of maximal principal stresses and wave passage velocity for selected cross-sections of the bridge.

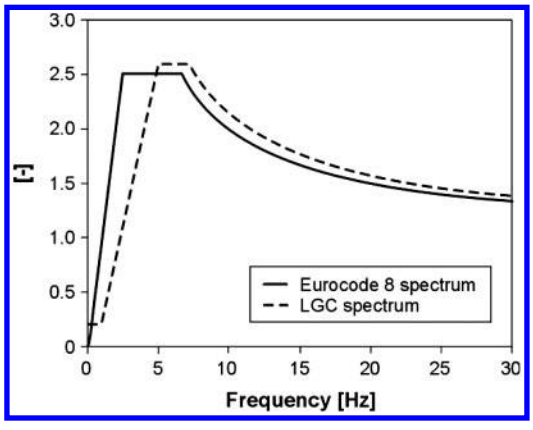

Figure 7. The shapes of the horizontal response spectrum recommended in Eurocode 8 and established for LGC region.

5 ASSESSMENT OF DYNAMIC RESPONSE OBTAINED WITH DIFFERENT ELASTIC RESPONSE SPECTRA (*RSA* METHOD)

The evaluation of the dynamic response of the bridge with the *RSA* method was also carried out. The method is only approximate, but it estimates the peak response of a structure to a particular base motion. Two spectra were applied in the analysis, using the *SRSS* method for modal summation (Abaqus 2010). Firstly, the elastic response spectrum recommended by Eurocode 8 (ground type A, damping 5%) was implemented. Then, the elastic response spectrum established for the LGC region was used. The proposed local spectrum is based on studies of a selected set of ground motion data resulting from mining tremors in the LGC region (Tatara 2002).

In Figure 7 the horizontal elastic response spectrum from Eurocode 8 is compared with the local spectrum established for the LGC region.

The presented horizontal elastic response spectra were applied in both horizontal directions with the maximum ground acceleration of 0.8 and 0.38 m/s^2 in the direction parallel and perpendicular to the bridge longitudinal axis, respectively. Since three direction of the ground motion during the mining tremor were taken into account in *THA* method, the vertical response spectra were also taken into consideration with the maximum ground acceleration of 0.45 m/s^2.

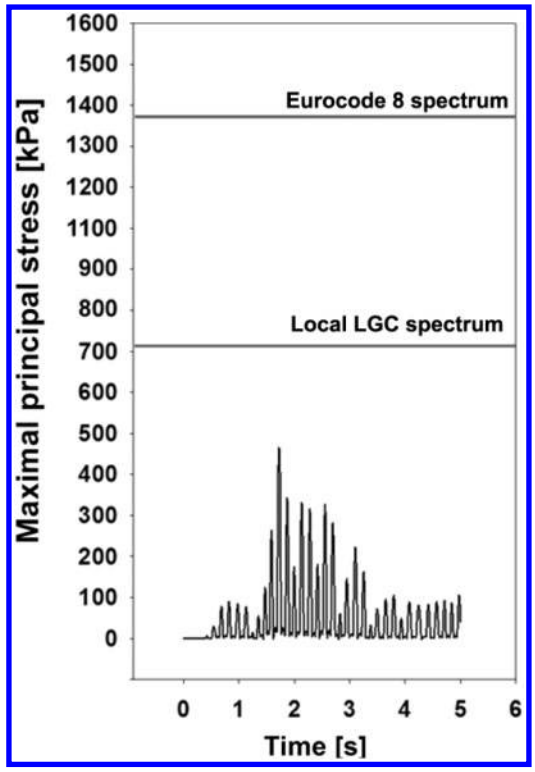

Figure 8. Relation between maximal principal stresses at cross section S3 obtained from *THA* and *RSA* method with the Eurocode 8 and the local LGC elastic response spectrum.

The relation between maximal principal stresses at cross section S3 (see Fig. 3) obtained from the time history analysis and from the response spectrum analysis with both abovementioned elastic response spectra is presented in Figure 8. Similar relation for cross section P3 is shown in Figure 9.

In Table 1 the differences between maximal principal stresses obtained from *THA* and *RSA* method with the elastic response spectrum recommended in Eurocode 8 are presented for all selected cross sections (see Fig. 3). The differences between stresses obtained from *THA* and *RSA* method with the local elastic response spectrum established for the LGC region are summarized in Table 2.

On the basis of the results presented in Figures 8 and 9 as well as in Table 1 it could be noticed that the differences between maximal principal stresses obtained from the exact *THA* and the approximate *RSA* methods reached up to 270%. The results obtained from both methods differed less significantly when the local LGC elastic response spectrum was used in the analysis. They reached up to 80% (see Table 2).

In summary, the dynamic response of the bridge to the mining tremor was significantly overestimated

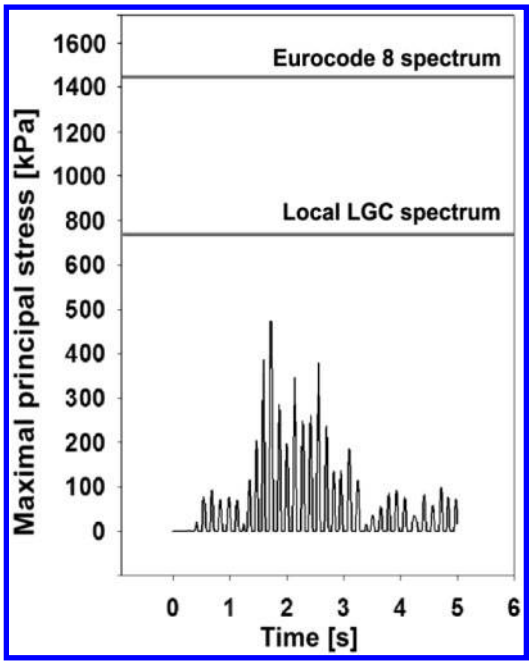

Figure 9. Relation between maximal principal stresses at cross section P3 obtained from *THA* and *RSA* method with the Eurocode 8 and the local LGC spectrum.

Table 1. Differences between maximal principal stresses at all selected cross sections (see Fig. 3) obtained from *THA* and *RSA* method with the elastic response spectrum recommended in Eurocode 8.

Cross section	Maximal principal stress [kPa]		Difference [%]
	THA	*RSA* (EC8 spectrum)

S3	439	1377	213
P4	352	705	101
S4	322	725	125

if the elastic response spectrum recommended by Eurocode 8 was introduced. More accurate results were obtained if the local elastic response spectrum established for the Legnica-Glogow Copperfield region was applied.

For the purpose of comparison exactly the same dynamic analysis was performed for a bridge with different dimensions. This bridge was four times shorter than the previous one, its total length was 40 m (Dulinska & Szczerba 2013). The main dimensions and points selected for the dynamic analysis are presented in Figure 10.

The relation between maximal principal stresses at point BS1 (see Fig. 10) obtained from the time history

Table 2. Differences between maximal principal stresses at all selected cross sections (see Fig. 3) obtained from *THA* and *RSA* method with the local elastic response spectrum established for LGC region.

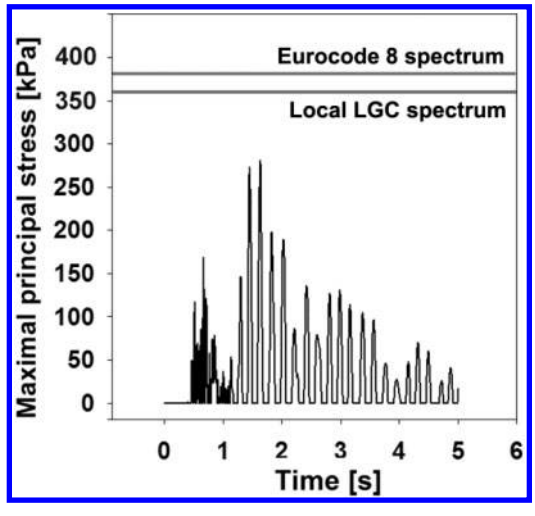

Figure 11. Relation between maximal principal stresses at point BS1 of the short bridge (see Fig. 10) obtained from *THA* and *RSA* method with the Eurocode 8 and the local LGC spectrum.

analysis and from the response spectrum analysis with both the Eurocode 8 and the local LGC elastic response spectra is presented in Figure 11.

It may be observed from Figure 11 that for the shorter bridge the results obtained for both response spectra were almost identical.

The main reason of the dissimilarity of results obtained for the investigated bridges lies in the differences in the length and stiffness of the structures.

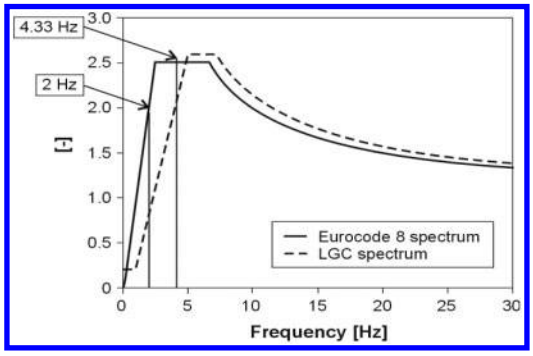

Figure 12. Location of first natural frequencies of the bridges on the investigated spectral curves.

These differences resulted in different values of natural frequencies of the bridges.

The first natural frequency of the longer bridge was 2 Hz, whereas the first natural frequency of the shorter bridge was 4.33 Hz. These frequencies were associated with vibrations in transverse direction.

The second natural frequencies which correspond to the vertical mode of vibrations of both bridges also differed distinctly. The value of 2.40 Hz was evaluated for the longer bridge, whereas the value of 7.09 Hz was obtained for the shorter bridge.

Figure 12 localizes the first natural frequencies of both bridges on the investigated spectral curves.

The local spectrum established for the LGC region is shifted towards higher frequencies. The maximum values of accelerations in the spectrum recommended in Eurocode 8 start from 2.5 Hz, whereas in the local spectrum – from 5.0 Hz. Therefore, for the longer bridge with the first natural frequency of 2.0 Hz, the value of the spectrum recommended in Eurocode 8 is 2.5 times greater than the value of the local LGC spectrum. Such a discrepancy does not occur for the shorter bridge with the first natural frequency of 4.33 Hz. The value of the spectrum recommended in Eurocode 8 is only 20% greater than the value of the local LGC spectrum.

6 CONCLUSIONS

In this paper the dynamic response of the 4-span prestressed bridge to the mining tremor was studied. The performed dynamic analysis allowed to assess the *THA* and the *RSA* methods of evaluation of the dynamic response of bridges to mining tremors.

The following conclusions as well as some general remarks for engineering practice may be drawn from the three-dimensional FE dynamic analysis:

In the case of the long bridge the *THA* method correctly evaluated the dynamic response only when the non-uniform kinematic excitation was taken into account. It occurs that the simplifying assumption of uniform excitation does not always lead to conservative assessment of the dynamic response of bridges to mining tremors. Proper recognition of the wave passage velocity is necessary for accurate assessment of the dynamic response of bridges to non-uniform kinematic excitation.

The approximate *RSA* method estimated the peak response of the long bridge to the mining tremor with accepted accuracy, provided that local elastic response spectrum established for the LGC region was introduced. The proposed response spectrum was based on the local ground motion data resulting from mining tremors in this particular mining activity area. The application of the elastic response spectrum recommended in Eurocode 8 (ground type A, damping 5%) significantly overestimated the dynamic response of the long bridge (with relatively low natural frequencies) subjected to the mining tremor.

The problem pertain only to long bridges with low natural frequencies. The analysis of the dynamic response of the shorter bridge with higher natural frequencies showed that the results obtained for both elastic response spectra were almost identical.

Characterization of the seismic behavior of steel pallet racks in cross-aisle direction

C. Braham & H. Degée
Structural Engineering Division, University of Liege, Belgium

ABSTRACT: Stability of steel storage racks in the cross-aisle direction is typically ensured by cold-formed steel bolted upright frames with diagonal bracing. Accurately determining the shear behaviour of these frames is essential for a proper seismic design and stability of the rack. In this paper, an experimental study of cross-frame designed to resist earthquake action is summarized. Structures are tested under transverse loading representative of the earthquake action, in static and cyclic conditions, with the objective of assessing the actual shear stiffness, shear resistance and deformation capacity of a set of earthquake-resistant cross-frames with different bracing configurations. The work is part of a larger research project called Seisracks2 (Storage Racks in Seismic Areas) carried out at European level.

1 INTRODUCTION

Racking systems are not regular buildings but a very particular form of steel construction. They differ from buildings in terms of their use, the loads that are supported, the geometrical dimensions and the components used in their construction. These components are normally thin-gauge cold-formed profiles and, in the case of uprights, are typically continuously perforated. This gives the required functionality, adaptability and flexibility needed to cope with the great variation in the different types of goods that are stored.

Prediction of the structural behavior of pallet racks is difficult because affected by the particular geometry of their structural components, i.e. members made by high slenderness thin-walled elements hence prone to global, local and, for the uprights, distortional buckling problems. Moreover specific modeling and design rules are required for these non-traditional steel structures, especially for the beam-to-upright and base-plate joints in the down-aisle direction (Fig. 1) that exhibit a strongly non linear behavior. In the cross-aisle direction, stability is ensured by frames consisting of two uprights connected by bracing members as shown in Fig. 1.

Rack design is even more complicated for storage racks installed in seismic zones, where they must be able to withstand horizontal and vertical dynamic forces and where, besides the usual global and local collapse mechanisms, additional limit states such as for instance the fall of the pallets with subsequent damage to goods, people and to the structure itself must be considered.

Whilst the basic technical description of an earthquake is obviously the same for all types of structures, it is of great importance to define whether or not it is possible to apply the "general design rules" (applicable to ordinary steel structures) to a rack. Furthermore it is necessary to consider how to modify correctly the general principles and technical requirements, in order to take into account the peculiarities of racking and to achieve the requested safety level. For instance, many specific physical phenomena strongly affect the structural behaviour of a racking system during an earthquake, such as the energy dissipated in the deformation of stored goods or when pallets slide on their supports.

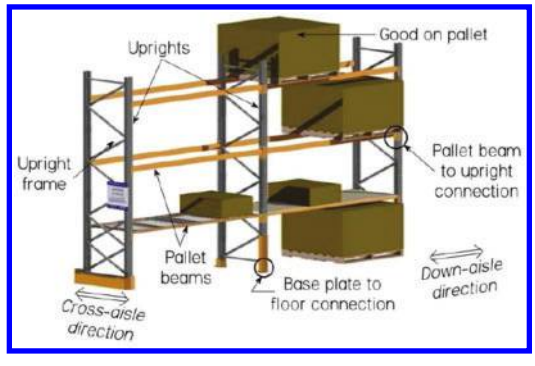

Figure 1. Typical storage rack configuration.

To this purpose, a working group had been initiated by the European Racking Federation. The main outcome of this working group is a new Code of Practice issued in September 2010 [8] and relying on a number of pre-existing standards. It includes also outcomes of the most recent researches carried out in Europe and the USA (see Ref. [9] for a comprehensive state of art and critical comment on FEM 10.2.08). In January 2011, the ERF working group has been converted into

a CEN working group (within TC 344) with the aim of transposing the Code of Practice into a European standard EN. Alternatively, reference can be made to the Rack Manufacturers Institute (R.M.I.) specifications which include few pages proposing a way to account for seismic actions.

However, only a limited number of experimental results are available to cover these issues, which questions the reliability of the rules implemented in the various reference design procedures.

Results presented in this paper are part of a wide research project "Seisracks2 – Storage Racks in Seismic Areas" (which is an extension of Seisracks1 project) funded by the European Union (RFCS research program). This research program aims at constituting a scientific background document for the conversion of the Code of practice FEM 10.2.08 to a European Standard and is intended to cover various items such as:

- The out-of-plane behavior of the beams and of the beam-to-upright connections;
- The actual structural behavior in cross-aisle direction depending on the geometrical configuration and on the type of connections of bracings between the uprights;
- The actual behavior in the down-aisle direction in presence of eccentric vertical bracings;
- The influence of the rate occupancy and of the location of the palletized goods;
- The reactions transferred to the concrete slab.

Within this project, these issues are planned to be investigated by means of component testing, full scale (push-over) testing and in-situ testing of racking systems in operating warehouses, all of these testing complements by numerical simulations.

More specifically, the present paper intends to summarize the current situation of one of the main aspects of this research, namely the investigations carried out on the cross-aisle behavior, with the objective of covering a wide range of configurations (D/Z/X type of cross bracing including different types of connection) and to investigate their consequences on the transverse stiffness, resistance and deformation capacity of the frame.

It must be emphasized however that, at the time of concluding the present paper, experimental activities are still under way and that the paper must then be considered as a milestone and not as definitively conclusive.

2 TEST SETUP AND TEST SPECIMENS

The European Standard EN 15512 [1] requires testing to evaluate the transverse stiffness per unit length of an upright frame. In the recommended test setup, shown in Fig. 2, an upright frame composed of at least two bracing panels is restrained in the transverse direction at two corners. One upright is pinned in the longitudinal direction at one end and a longitudinal load F is applied at the opposite end of the other upright through its centroidal axis. The exploitation of the experimental measurements consists then in determining the upright frame longitudinal shear stiffness and deriving then the transverse shear stiffness using Timoshenko and Gere's [2] shear formulae. It is generally considered that, upright frames braced with diagonal bracing members only, considering the full cross-section of the diagonals may lead to an overstimation of the shear stiffness by a factor up to 20. The purpose of the test is thus to estimate the reduction of the diagonal cross-section to be used in further analysis. Finite element models developed in some studies available in the literature [3,4,5] were also not really able to accurately reproduce the experimental test results and produced stiffness values that are 2 to 5 times greater than the observed results. The authors attribute the difference between FE results and experimental test results to the joint flexibility and the distortion of the upright, caused by the eccentricity between the uprights and the bracing members at the joints, which was not considered in the FE analysis.

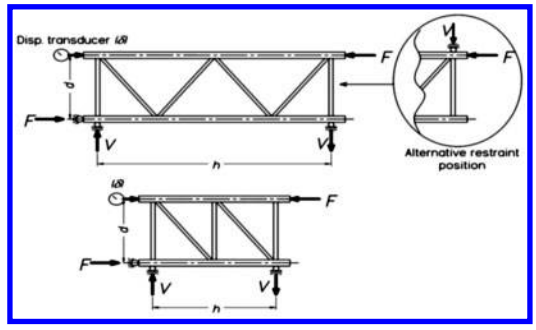

Figure 2. Upright frame shear stiffness setup in EN 15512 [1].

The EN 15512 test is however characterizing the behavior under pure shear, while the reality of the earthquake situation implies the combination of a shear loading varying over the height of the frame and combined with a significant overall bending contribution.

The purpose of the alternative test setup proposed in the present study is thus to aim at a more realistic loading procedure with the perspective of assessing the transverse stiffness, resistance and deformation capacity of cross-frames under seismic conditions; the cross-frame tests are carried out on specimens similar to those classically used for the characterization of the pure shear behavior (although longer) but with an adapted loading. Tests are carried out statically ("pushed over") and cyclically under transverse loading representative of the earthquake action.

Eurocode 8 [10] recommends that, when the fundamental mode shape is dominant, it can reasonably be approximated by horizontal modal displacements increasing linearly along the height. The associated horizontal forces F_i should be taken as being given by:

$$F_i = F_b \frac{z_i m_i}{\Sigma z_j m_j} \quad (1)$$

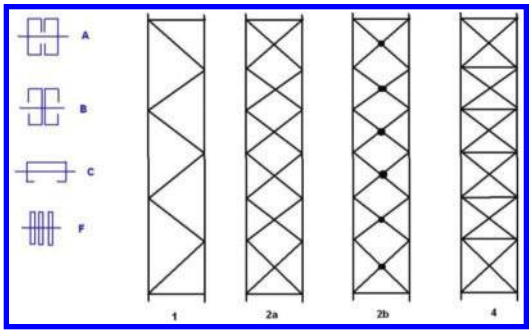

Figure 3. Typologies of upright frames.

where:

- z_i, z_j are the heights of the masses m_i, m_j above the level of application of the seismic action (foundation or top of a rigid basement);
- F_i is the horizontal force acting on storey i;
- F_b is the seismic base shear in accordance with expression (4.5) of Eurocode 8;
- m_i, m_j are the storey masses computed in accordance with 3.2.4(2) of Eurocode 8.

Industrial partners involved in the project (4 European companies) were invited to provide at least one configuration out of the types suggested in Fig. 3 with the objective of getting a wide range of situations (design for high/moderate seismicity, D/Z/X type of cross bracing). For confidentiality reasons the names of the Industrial partners are not given here nor the details of the profile sections, diagonal-to-upright connection or upright to base-plate connection. 4 basic typologies have been selected regarding the geometrical pattern of the diagonals, as well as 4 types of diagonal-to-upright connections, shown in Figure 3.

In the standard shear test, a frame assembly with a minimum number of two bracing panels shall be connected to a rigid vertical column by pin-connecting the upright ends and tested horizontally for the ease of the execution, as reminded in Fig. 2. In the present study, a more realistic configuration has been chosen (although complicating the setup) consisting in 8 meter high frames tested transversally with 4 load levels equally distributed over the height of the frame with a constant spacing of 2 m. These load levels correspond to the beam levels of the case-studies configurations, i.e. to levels where the masses are actually present. Vertical side guides are placed at each of these levels to prevent out-of-plane instabilities. The objective is clearly to test the frame in a real loading configuration in terms of shear and overall bending moment distribution.

In practice, the loads are indirectly applied on the structure by mean of one single jack F acting on a distribution beam that is acting then on two other beams, in such a way that the support reactions of this two-levels loading system satisfy Eq. (1). Loads acting directly on the upper side, transfer hoops are foreseen to distribute the load between the two uprights. No

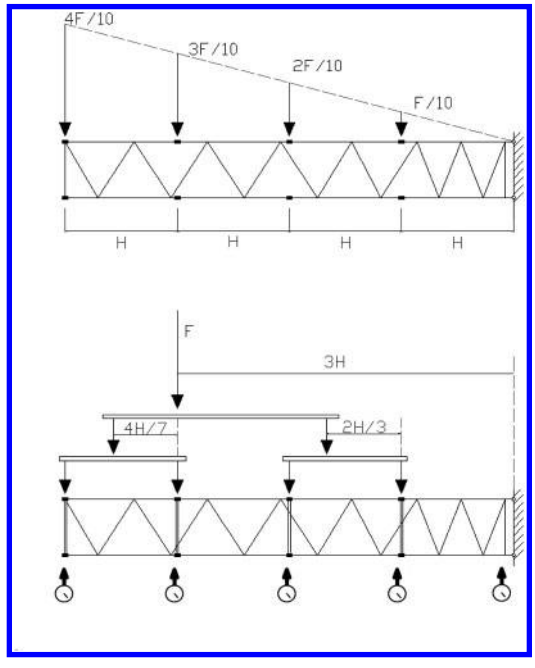

Figure 4. Test setup.

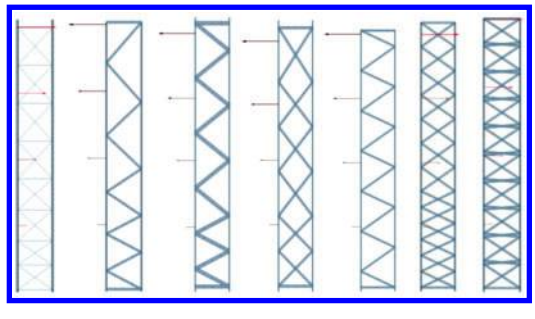

Figure 5. Tested configurations.

direct axial force is applied on the uprights, implying the base connection to be design, and if necessary reinforced appropriately, to resist the tension induced by the overall bending of the system, in order to focus on a collapse in the main part of the frame and not in its connections to the floor. Displacement transducers are located next to the bottom horizontal bracing member and at each beam level. Two extra transducers measure the relative displacement between uprights at the first two beam levels.

Figure 5 depicts the 7 different configurations of cross-frames to be tested. For confidentiality reasons no dimensions are revealed, nor of the bracing panels neither of the element cross-sections. For symmetric configurations (configs. 1, 4, 6 and 7), 1 pushover and 1 cyclic test are planned, whereas for asymmetric configurations, (configs. 2, 3 and 5), 2 pushover (one in each direction) and 1 cyclic test will be carried out.

Figure 6. Artificial hinge.

Figure 7. Original connection.

3 PRELIMINARY OBSERVATIONS

At the time of issuing the paper, experimental tests have been realized on one configuration so far (config. 1 of Fig. 5, with X bracings and horizontal members, designed with account taken for both the compression and tension diagonals as part of the resisting system), considering different ways of executing the base connection. The behavior of the upright-to-base-plate connection is intended to be covered by the research project Seisracks2 but with tests that are not discussed here. The aim of the study presented in this paper is specifically to emphasize on structural failure modes of the cross-frame either in the upright or in the bracing members but not in the upright-to-base-plate connection which is tested separately.

According to the traditional design assumptions, the upright-to-base-plate as well as the base-plat-to-floor connections are supposed to be simple pinned connections. Therefore, in order to stick as close as possible to his assumption, a first approach was to add an artificial hinge under the base-plate as seen in Figure 6. The rotation is thus supposed to occur in this artificial hinge instead of in the base-plate, resulting in an offset of the point of zero moment and to a slight change of the distribution of internal forces in the very bottom part of the structural system.

As a matter of comparison, a second configuration consisted in reproducing the same test but with connecting the frame to the vertical support according to the real way of doing. This connection is represented in Figure 7 where the base-plate is fixed with its original bolts.

3.1 *Cross-frame partially loaded – Test 1*

These first two tests were realized by applying only the two bottom loads (corresponding to F/10 and 2F/10 on Fig. 4). In this case, the loading is mainly in shear

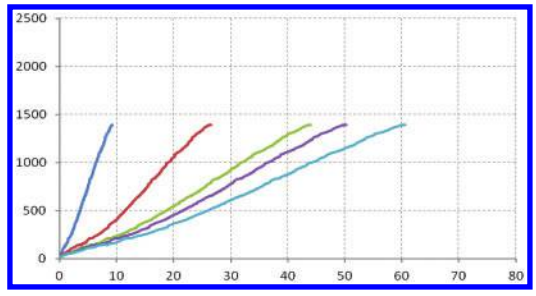

Figure 8. Total force F_b [daN] vs. displacement of the different beam-levels [mm] for the hinged connection (2 levels loaded).

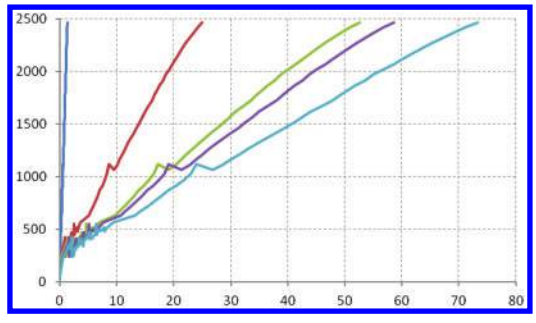

Figure 9. Total force F_b [daN] vs. displacement of different beam-levels [mm] for the original connection (2 levels loaded).

with a limited contribution of the overall bending. Displacements measured during the tests are represented in Figure 8 for the hinged connection and in Figure 9 for the normal connection:

The hinged configuration results in large displacements of the bottom horizontal diagonal situated at around 70 mm from the base-plate because of the rotation induced at the hinge level. The displacement reached 10 mm at failure for a total load of 1390 daN where the system fails by buckling of the lower compressive diagonal, followed by a load transfer to the tension diagonal finally resulting in the shearing of the bolts of the lower diagonal in tension of the bottom panel.

The original configuration collapses for a much larger applied load (up to 2400 daN) with the same failure mode: buckling of diagonals in compression followed by shearing of bolts of diagonals in tension. But the transverse displacement of the bottom horizontal member close to the base-plate is much lower than in previous case, only 1 mm.

The additional hinge induces actually a significant drift of the frame since its lower part behaves like a quasi-articulated parallelogram delimited by the additional real hinge on one side and the upright-to-base-plate connection behaving quasi like an hinge (as assumed in design) on the other hand.

This first case with additional hinges is thus finally found as not really representative of what is observed

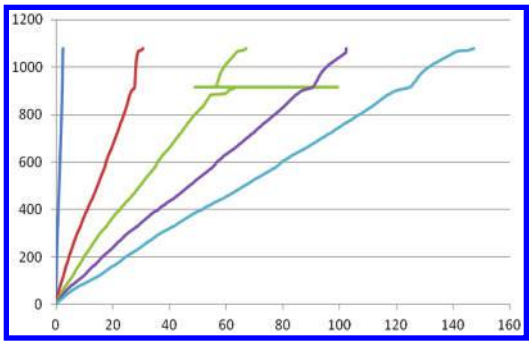

Figure 10. Total force F_b [daN] vs. displacement of different beam-levels [mm] with 4 load levels – rigid connection.

in reality and is therefore abandoned. All following tests will be realized without the additional hinges.

3.2 *Cross-frame fully loaded – Test 2*

An additional test has been realized on the same frame without the additional hinge and with the loads applied as illustrated in Figure 4. The total applied force vs. displacements of the different beam-levels is shown in Figure 10.

Failure of the cross-frame occurs now for a much lower total transverse load (1000 daN) compared to the previous test with 2 load application points and with the same base conditions. The failure mode is completely different as well, i.e. failure in shear of all bolts connecting the upright to the base-plate of the upright on the tension side due to the higher overall bending. However, in normal conditions, the uprights of the cross-frames are not subjected to such high tension forces: pallets stored on the rack provide a pre-compression of these uprights, and thus of their base connections, and overturning due to the earthquake would only decompress these connections. The case of uprights in tension should not be met in practice and base connections are therefore not meant to withstand uplift forces. New tests will thus be carried out on a system with over-designed base connection in order to focus on failure modes of interest for the present study.

4 FINITE ELEMENT ANALYSIS

The frames have been modelled with the non linear finite element software FinelG developed in University of Liège. They consist of 8 meter long uprights pinned at their bottom and linked up with diagonals which are simply hinged at their ends.

4.1 *Cross-frame partially loaded – Test 1*

A numerical analysis has been realized on the cross-frame partially loaded with F_b equal to 2066 daN (cf §3.1), applying 1/3rd on the first beam-level and 2/3rd on the second, leading to the results shown in the last line of Table 1, where the reduced area of the diagonals A_{red} calibrated to match the measured displacements is equal to $A_{real}/10$. These results have to be compared with those obtained with the test with the standard base-plates.

Table 1. Displacements of beam-levels.

	$\delta_{H\sim70\,mm}$ mm	$\delta_{H=2\,m}$ mm	$\delta_{H=4\,m}$ mm	$\delta_{H=6\,m}$ mm	$\delta_{H=8\,m}$ mm
Test	1.1	17.6	33.2	46.5	58.5
FinelG	1.1	20.1	36.4	41.3	44.4

Table 2. Displacements of beam-levels.

	$\delta_{H\sim70\,mm}$ mm	$\delta_{H=2\,m}$ mm	$\delta_{H=4\,m}$ mm	$\delta_{H=6\,m}$ mm	$\delta_{H=8\,m}$ mm
Test	2.4	27.9	58.1	95.9	132
A/28	1.2	28.4	56.1	81	98.1
A/40	1.6	39.9	78	111.5	134.1

Displacements resulting from the numerical analysis match relatively well as far as the bottom beam-levels are concerned. Beam-levels 3 and 4 reveal lower displacements with the numerical analysis which might result of the fact that this part of the cross-frame is unloaded.

4.2 *Cross-frame fully loaded – Test 2*

The same numerical model has been used applying the load at failure resulting from the test described in §3.2 (F_b equal to 1000 daN) and distributed as illustrated on Fig. 4. The area of the diagonals has now to be reduced by dividing the gross area by 28 in order to fit the bottom measured displacements and by 40 to fit the top measured displacements; these displacements are shown in Table 2.

It appears actually quite difficult to make the experimental and numerical displacement match at the same time for the two lower and the two upper levels. Different reduced areas have to be chosen. This may be due to the variation of the diagonal's inclination from bottom to top of the frame. Additional investigations are in progress to investigate this issue.

4.3 *Fully loaded additional cross-frames*

All cross-frames to be tested during this project have been modeled in FinelG using a reduced area for the diagonals. This reduced area is the one obtained with the standard shear test in accordance with the European Standard EN 15512 [1]. These shear tests have been realized on portions of cross-frames with the same profiles; the portions are generally composed of two bracing panels. Test results on 8 meter long cross-frames tested transversally will probably

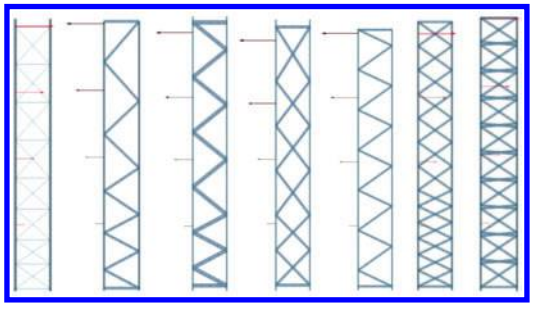

Figure 11. Cross-frames to be tested during this project.

Table 3. Maximum expected base shear F_b [kN] and corresponding displacement [cm] with a linear elastic analysis for the frames of figure 11.

18	21	8.5	21	6	28	24
7.5	5.3	22	12.4	3.8	8	6.8

require to adapt these reduced areas in order to calibrate the results which may be different than the ones obtained by calibrating results comming from longitudinal shear tests, in accordance with the preliminary observations and conclusions of section 4.2.

However the values obtained numerically can be considered as a preliminary assessment, in terms of maximum displacements of the top of each cross-frame ans of the corresponding total shear force are represented in Figure 11.

The first line in table 3 gives the maximum expected total base shear F_b in kN applied on the frame in an elastic linear analysis until failure of either the diagonals or the upright. The second line gives the corresponding top displacement in cm.

5 CONCLUSIONS

This paper has presented the general context of a study currently in progress to investigate the behavior of cross frames of pallet racks under earthquake loading. More specifically, the paper presents the motivations of the study, the set of planned test specimens, the test set-up and some preliminary results on one of the configuration.

Although the results are still very partial, some tentative conclusions can already be drawn:

- The common assumption of a purely pinned behavior of the base connections in the plane of the cross-frame seems adequate. This implies that no additional hinge need to be used in the test set-up to avoid the development of local mechanisms;
- The design of cross-frames considering compression and tension diagonals as part of the resisting system results in a brittle behavior with no plastic deformation capacity;
- The reduction of the cross-sectional area of the diagonals calibrated on standard shear tests should be modulated according to the paneling of the structural system.

These conclusions are of course to be confirmed and quantified (specifically regarding the cross-section reduction) for the remaining test configurations.

Passive energy dissipation characteristics of yielding shear panel device produced from steel and stainless steel

M. Ashraf
School of Engineering and IT, The University of New South Wales, Canberra, Australia

M.R. Hossain
School of Civil Engineering, The University of Queensland, Australia

ABSTRACT: Yielding Shear Panel Device (YSPD) is a newly developed passive energy dissipation device that exploits the stable hysteretic shear energy dissipation characteristics of a metal plate. YSPD is a simple device, which is composed of a thin metal diaphragm plate welded within a small segment of a square hollow section (SHS). The device is designed to be fitted on to a structure in such a way that it automatically gets activated to absorb excessive energy during the horizontal excitation as a result of any seismic activity. Performance of YSPDs produced from ordinary carbon steel has recently been evaluated both experimentally and numerically. Stainless steel offers significantly higher ductility, which makes stainless steel favourable for use in energy absorption. The current research exploits already validated numerical models for steel YSPDs to examine the characteristics of YSPDs produced from stainless steel. Two stainless steel alloys austenitic 1.4301 and lean duplex 1.4162 grades are used in the developed finite element models using ANSYS. Obtained results show that stainless steel could be considered as a viable option for manufacturing passive energy dissipation devices to mitigate damages due to seismic excitations.

1 INTRODUCTION

Recent catastrophic earthquakes demonstrate the possible severity of seismic activity that could cause significant damages to structures resulting in complete demolition of buildings. Damaged structures need to go through complex and expensive retrofitting techniques to be used for the purpose. Minimization of structural damages due to earthquake is a major area of research which contributed to the development of a number of active, semi-active and passive control mechanisms during the last few decades. Added damping and stiffness ADAS (Whittaker et al. 1991), Triangular added damping and stiffness TADAS (Tsai & Hong 1992) and steel plate shear wall SPSW (Timler and Kulak 1992) are commonly used metal yielding devices in design. ADAS and TADAS use out-of-plane bending deformation of steel plates to dissipate energy, whilst SPSW exploit the in-plane shear deformation of metal plates. Yielding shear panel device (YSPD) is a newly proposed passive energy dissipation device that is designed to utilise the diagonal tension field that develops in the post-buckling regime of a thin steel plate under shear. Williams and Albermani (2003) initially proposed the concept and performed experimental investigation followed by further experimental, theoretical and numerical evaluation of YSPD by Chan et al. (2009), Hossain et al (2011) and Hossain and Ashraf (2012).

The current research investigates the relative performance of different constituent metals i.e. three grades of ordinary steel and two stainless steel alloys, when used to produce YSPD. Hossain et al. (2011) developed finite element models for steel YSPD using ANSYS and verified their performance against available monotonic and cyclic test results. These models will be used in the current paper to investigate changes in energy dissipation characteristics of YSPD as a result of using different constituent material.

2 YIELDING SHEAR PANEL DEVICE (YSPD)

YSPD is a simple passive energy dissipation device, which relies on the in-plane shear deformation of a thin metal diaphragm plate welded inside a square hollow section (SHS). YSPD is designed to be placed beneath a structural beam using a V-brace so that it automatically comes into play in the event of any horizontal excitation. Figure 1 shows the basic geometry and the proposed assembly for installing YSPD within a building frame.

Chan et al. (2009) conducted a series of monotonic and cyclic tests using various plate thickness and device configurations for YSPD. The tested specimens were fabricated using a short segment of a square hollow section (SHS) with a steel diaphragm plate welded inside the SHS. Four bolt holes were drilled on each

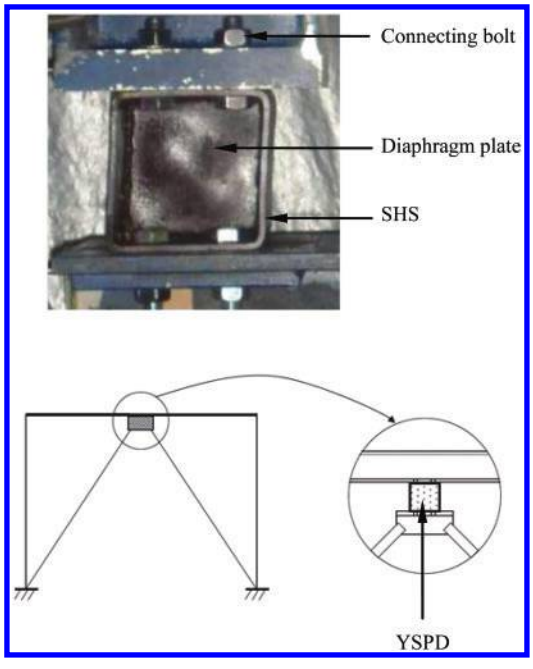

Figure 1. Basic geometry and the proposed assembly for YSPD.

of the two opposite SHS flanges for connecting the device to the test setup; this connection is analogous to the practical assembly where YSPDs are proposed to be connected using bolts to ensure easy installation and replacement. The SHS provides a boundary to the diaphragm plate so that shear forces can be applied to the plate, in addition to providing necessary detail for connections to the parent structural frame. Most importantly, the SHS serves as a boundary element allowing the tensile strips to be formed and the tension field to be developed following the post-buckling of the thin diaphragm plate. As a result of sufficiently large displacements occurring in the diaphragm plate, the input energy originating from an earthquake could be dissipated through plastic deformation.

3 ANALYTICAL FORMULATION OF YSPD

Chan et al. (2009) classified YSPDs into two different categories based on the slenderness ratio of the diaphragm plate for theoretical evaluation. Material stress-strain response was considered elastic, perfectly-plastic with a von Mises yield criterion. Diaphragm plates were assumed to be simply supported by the SHS and were classified as either compact or slender depending on whether or not the critical shear buckling stress τ_{cr} exceeds the material yielding stress. The critical shear stress for a simply supported plate is given by Equation 1 (Timoshenko 1961),

$$\tau_{cr} = k_e \frac{\pi^2 E}{12(1-\nu^2)} \left(\frac{t}{d}\right)^2 \quad (1)$$

where k_e is a coefficient which depends on the aspect ratio and end restraints of the plate e.g. k_e is equal to 9.34 for square pates, whilst E and ν are Young's modulus and Poisson's ratio respectively. Assuming an insignificant contribution from the SHS, Chan et al. (2009) proposed Equation (2) to estimate the theoretical elastic in-plane lateral stiffness of YSPD

$$k_{YSPD} = Gt \quad (2)$$

where G is the shear modulus of steel and t is the thickness of the diaphragm plate. The proposed Equation 2 is too simplistic and does not consider effects of boundary conditions in predicting initial stiffness. Hossain et al. (2011) carried out further investigation and proposed Equation 3 to obtain an appropriate expression for k_{YSPD} including the contribution from both diaphragm and SHS in addition to incorporating the effects of support rotation using a reduction factor ϕ.

$$\frac{1}{k_{YSPD}} = \frac{1}{k_{diaphragm}} + \frac{1}{\emptyset k_{SHS}} \quad (3)$$

All necessary details on theoretical formulation for YSPD are available elsewhere (Hossain & Ashraf 2012).

4 FINITE ELEMENT MODELLING OF YSPD

Finite element (FE) models for steel YSPDs were developed using ANSYS and the obtained results were verified using available test results. The basic assumptions and formulations adopted in the FE modelling process are briefly discussed herein, whilst the detailed description is available in Hossain et al. (2011).

Bilinear kinematic hardening model available in ANSYS was used as the constitutive model for both the diaphragm plate and the SHS. General purpose shell element 'SHELL181' was used for its suitability in large rotation, and/or large strain nonlinear applications. SHELL181 is a four-noded full integration quadrilateral shell element with six degrees of freedom at each node. An appropriate mesh size was achieved through convergence analysis. Developed FE models were analysed elastically to obtain suitable Eigenmodes to model initial geometric imperfections for use in the subsequent nonlinear analysis. Obtained results, however, showed insignificant effect of initial geometric imperfections on the force-displacement response of YSPD. Diagonal tension in the diaphragm plate makes the incorporated initial imperfections less effective when compared to its significance in other types of loading e.g. members subjected to longitudinal compression. The 1st Eigenmode was, therefore, used to define the distribution of initial imperfections as this normally represents the lowest buckling capacity. Amplitude of 0.2t, where t is the thickness of the diaphragm plate, was used to obtain a reasonable imperfection distribution.

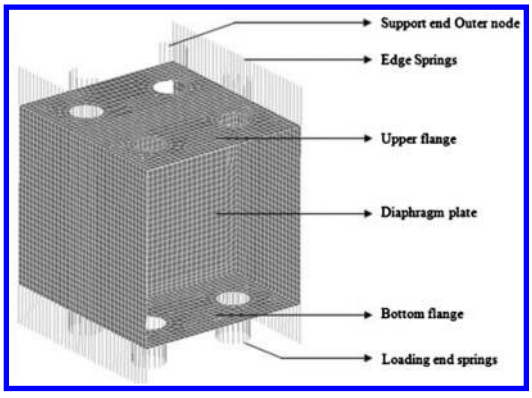

Figure 2. FE model in ANSYS for a typical YSPD.

Modelling appropriate support conditions for YSPD was one of the challenging tasks in FE modelling as it showed significant effects on the overall load-deformation response. Deformations and movements observed in the bolts and the edges of YSPD were modelled using a combination of hinge and spring supports as shown in Figure 2. All nodes along four edge lines are supported by 'COMBIN39' spring elements, which act as a tension-compression element. Stiffness of the spring elements in tension and compression are defined separately to allow the elements exhibit appropriate force-displacement response in tension as well as in compression.

It is worth noting that residual stresses were also incorporated within the FE models and a marginal reduction on the initial slope of the load-deformation behaviour was observed; the overall effect of assumed typical residual stresses on YSPD was negligible.

5 LOAD-DEFORMATION CHARACTERISTICS OF STAINLESS STEEL YSPD

The effect of material properties on the energy dissipation characteristics of YSPD is examined by using stainless steel as the constituent material. Stainless steel shows significantly higher ductility than mild steel. Austenitic stainless steel EN 1.4301 and lean duplex stainless steel EN 1.4162 have been used as constituent materials for YSPD in developed FE models. Chaboche Model (Chaboche 1989, Chaboche 1991) is used to accurately simulate the nonlinear stress strain behaviour exhibited by stainless steel alloys. Material properties and model parameters for the considered stainless steel alloys are summarized in the Table 1. Figure 3 compares the Chaboche model prediction for the austenitic stainless steel stress-strain response against those obtained from test results.

Three YSPDs with size $100 \times 4 \times 2$, $110 \times 5 \times 3$ and $120 \times 6 \times 4$ are considered to evaluate the performance of stainless steel in energy dissipation. Three grades of ordinary steel HA250, HA300 and HA350 as specified in AS/NZS 1594:2002 with nominal yield strength of 250, 300 and 350 MPa respectively are also

Table 1. Chaboche model parameters for the considered stainless steel alloys.

Stainless Steel Grade	Material properties		Model parameters					
	E GPa	$\sigma_{0.2}$ MPa	α_1	γ_1	α_2	γ_2	α_3	γ_3
1.4301	187	398	28246	758	2441	8.66	50	0
1.4162	198	635	28260	310	2631	29.62	10	0

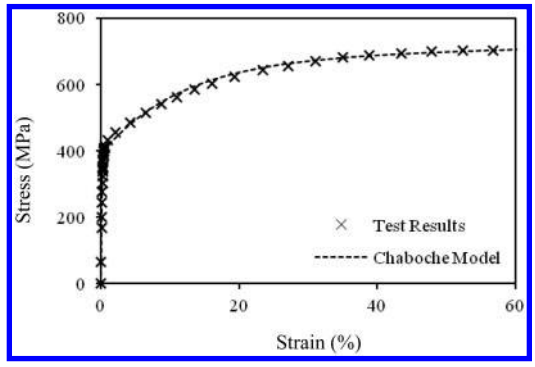

Figure 3. Chaboche model prediction for austenitic Grade 1.4301.

considered for comparison. Figure 4 shows the monotonic force displacement response of YSPDs for the considered constituent materials. Austenitic and lean duplex stainless steel shows similar initial stiffness and yielding deformation but demonstrates potential for higher energy absorption.

Three considered YSPDs were subjected to cyclic loading – a four cycle loading history of amplitudes 1, 5, 10 and 20 mm was applied for the cyclic loading as shown in Figure 5. Figure 6 shows the load-deformation response of YSPDs when subjected to the cyclic loading. Austenitic and lean duplex stainless steel showed considerably larger force-deformation loops when compared against those obtained for the considered steel grades. Higher yield strengths of the considered stainless steel grades obviously contributed to larger loops. Additional displacement would have been useful to investigate the effects of significant strain hardening observed in stainless steel. Further analysis is currently underway to examine the energy absorption of stainless steel YSPDs subjected to rather extreme loading conditions.

The amount of energy dissipated in one cycle is measured by calculating the area bounded by the cyclic response. Total amount of dissipated energy for the developed finite element models were calculated and the comparison for energy dissipation with the cumulative number of cycles are plotted in Figure 7. Lean duplex YSPDs absorbed energy at a higher rate and eventually dissipated approximately 1.8 times more energy than that of a similar 250 MPa steel

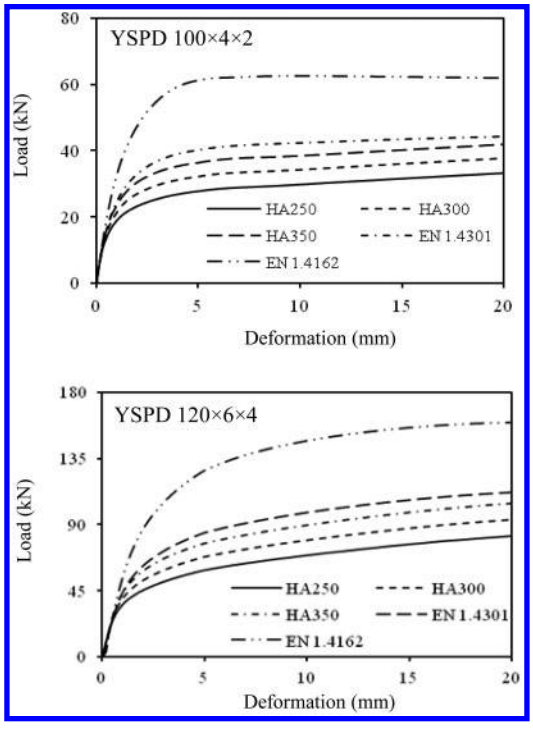

Figure 4. Force displacement response of steel and stainless steel YSPDs under monotonic loading.

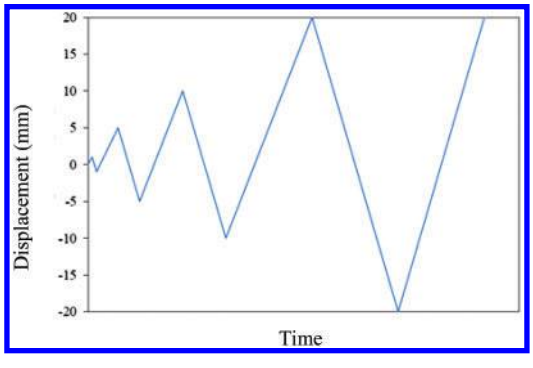

Figure 5. Displacement history applied for cyclic loading.

YSPD. Austenitic stainless steel, however, demonstrated slightly improved performance when compared against HA350 grade steel.

The performed study provides some understanding of the behavior of stainless steel YSPD and presents a preliminary comparison against its steel counterpart. The main barrier in promoting stainless steel in construction is its high material cost. In the case of small devices like YSPD, the material cost is insignificant. The higher strength of lean duplex grade should provide means for absorbing more energy in the event of seismic excitation. In the event of a prolonged or a severe earthquake, significantly high ductility offered by stainless steel alloys should allow the YSPDs to act as "structural fuse" and should be able to

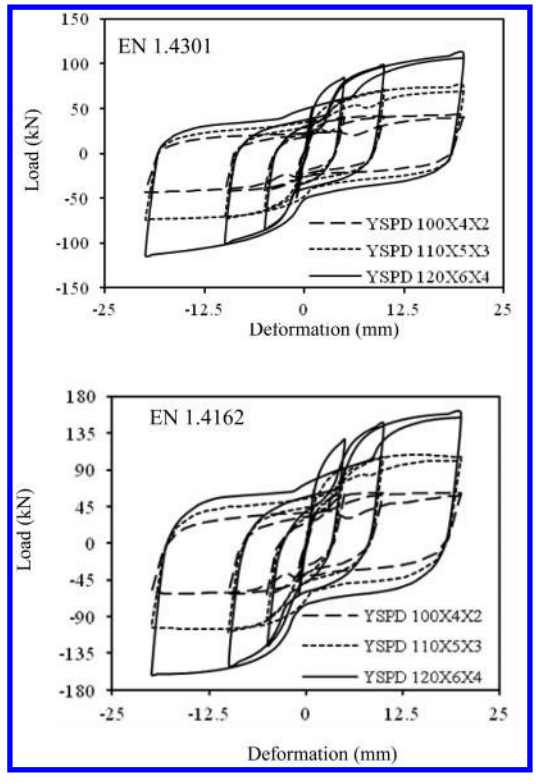

Figure 6. Response of stainless steel YSPDs subjected to cyclic loading.

absorb significant amount of excessive energy exerted on to the structures; this could play significant role in maintaining the integrity of the main structural components.

6 CONCLUSION

The structural performance of a newly developed passive energy dissipation device YSPD has been evaluated using finite element modelling techniques. FE models developed for steel YSPDs were verified using available test results and are used in the current paper to investigate the characteristics of YSPD produced from stainless steel. Two grades of stainless steel – austenitic 1.4301 and lean duplex 1.4162 are used in the current study in addition to three AS/NZS steel grades –HA250, HA300 and HA350. Results obtained both for monotonic and cyclic loading using the developed FE models show that stainless steel YSPDs could absorb more energy than their steel counterparts, with lean duplex exhibiting significantly better performance. Higher 0.2% proof strength and significant strain hardening of lean duplex 1.4162 allowed more energy absorption. Higher ductility of stainless steel should facilitate YSPDs to dissipate more energy in extreme loading conditions and hence could provide better resistance to main structural components.

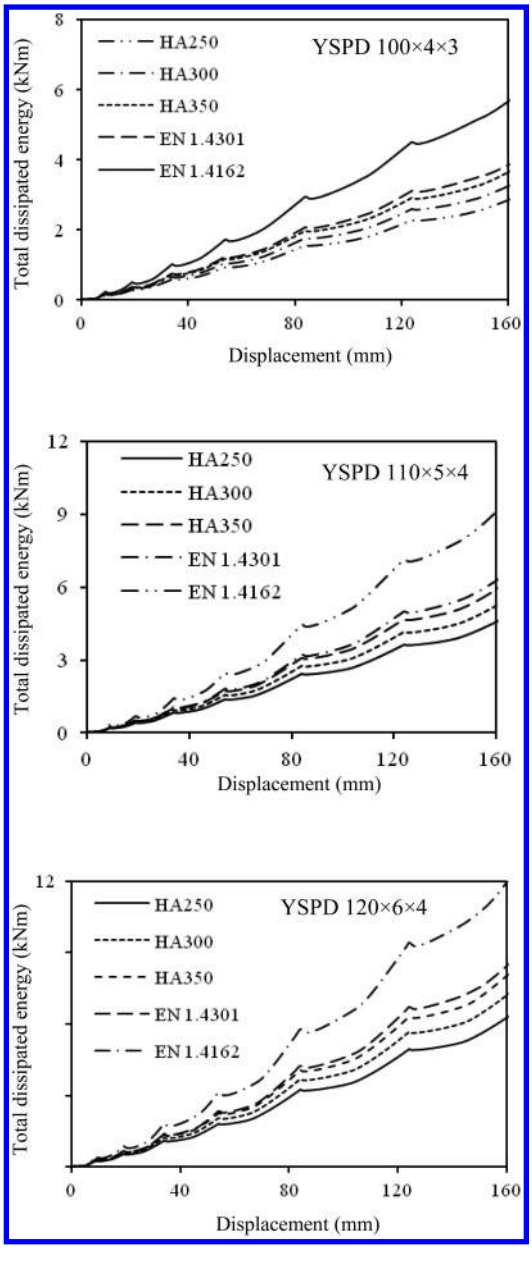

Figure 7. Cumulative energy absorption of stainless steel YSPDs subjected to cyclic loading.

The current research paves the way for further investigation in this area to explore the full potential of using stainless steel in passive energy dissipation devices.

Seismic behavior of exposed column bases in buckling restrained braced frames

Yao Cui

Satoshi Yamada
Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT: In Buckling Restrained Braced (BRB) frames, the axial and shear force on the column base is more critical compared with conventional moment resisting frames. Quasi-static tests of exposed column bases with BRB were conducted. It was found that the column base was uplifted when the BRB force increased to maximum tension strength. The friction force between base plate and mortar lay will be absent and then slip of base plate will occur. In this paper, a numerical study was conducted to investigate the effect of the slip of base plate on the BRB behavior. The effects of the number and size of anchor rods on the slip were briefly discussed.

1 INTRODUCTION

Buckling restrained braces (BRBs) are commonly used as primary energy dissipation elements in new construction and seismic retrofit project. It was commonly used in high-rise building and showed good ability in energy dissipation. However, there are around 80% buildings were low-to-rise structures. However, the use of BRB in low-to-medium rise building is rare. Considering the benefit of BRB, it is necessary to promote the use of BRB in low-to-medium rise building.

Exposed column base are commonly used in low-to-medium rise Moment Resisting Frames (MRFs) because of easy construction and promising seismic behavior. In Japan, it is recommended to design the column base failed at the anchor bolts rather than at the column bottom. Previous experimental studies on the seismic behavior of exposed column base in conventional braced frames (Hatanaka et al. 2002, Fukuhara et al. 2010) indicated that the anchor rods of exposed column base would experience severe shear deformation. The study on the exposed column base with BRB is not extensively studied. In this study, both experimental and numerical studies were conducted to investigate the effect of BRB on the exposed column base.

2 EXPERIMENTAL STUDY

2.1 *Test program*

The details of the test could be found in Cui et al. (2012). The test program is briefly introduced here.

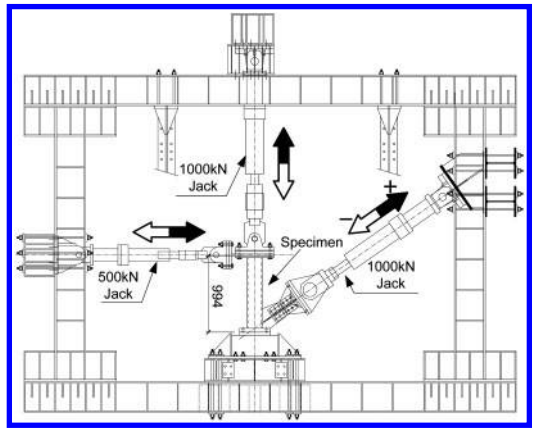

Figure 1. Test setup (unit:mm).

Three specimens were fabricated at approximately 2/3 scale. Each of specimens comprised a cold-formed square-tube cross sections column having the width of 200 mm and the thickness of 12 mm, a shop-welded hot-rolled square base plate (300 and 50 mm in the width and thickness, respectively), four or six machined anchor rods with the nominal diameter of 30 mm and a concrete foundation beam confined in a steel box.

The test specimen was placed in the loading frame shown in Figure 1. The foundation steel box was clamped to the reaction floor. The column top was clamped to two hydraulic jacks, one is the horizontal direction and the other is the vertical direction. The

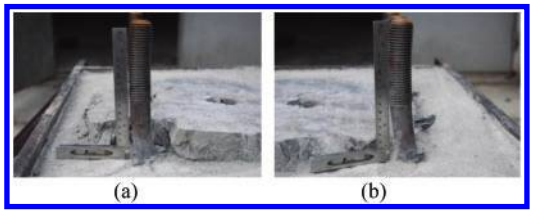

Figure 2. Deformed anchor rod: (a) in gusset plate side; (b) in the opposite side of gusset plate side.

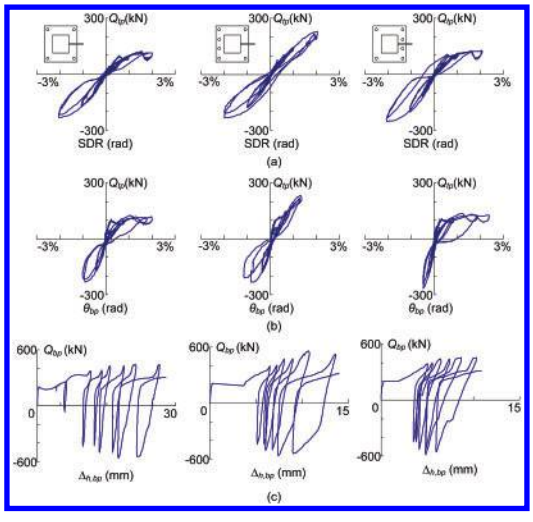

Figure 3. Test results: (a) Q_{tp}–SDR relationship; (b) Q_{tp}–θ_{bp} relationship; (c) Q_{bp}–Δ_{slip} relationship.

gusset plate was clamped to one hydraulic jack, which was used to reproduce the BRB behavior. The positive loading was defined when the BRB was in tension. The positive loading directions of each jack are illustrated in Figure 1.

2.2 *Test results*

No damage was observed in the concrete foundation during the test. All the anchor rods experienced sever lateral deformation as shown in Fig. 2. It is notable that the anchor rods in the opposite side of gusset plate (Fig. 2(b)) deformed more serious than that in the gusset plate side (Fig. 2(a)). Anchor rods in the opposite side of gusset plate is elongated and shear.

The test results till the story drift of 2% are shown in Figure 3. Figure 3(a) shows the relationship of the shear force on the top of column (Q_{tp}) and the relative story drift angle. Figure 3(b) shows the relationship of the shear force on the top of column (Q_{tp}) and the rotation of base plate (θ_{bp}). Compared these two figures, it is notable that the base plate rotation contribute mostly to the story drift angle in the positive loading (when BRB in tension). On the contrary, the column deformed mainly in the negative loading (when BRB in tension) due to the increased compressive axial force from BRB vertical component. Therefore, the anchor

Table 1. Test results.

(a) Moment resistance, M_{bp}(kNm)

	Positive loading		Negative loading	
Spec.	Measured	Calculated	Measured	Calculated
BRCB1	132	138	246	260
BRCB2	248	270	246	260
BRCB3	138	138	278	341

(b) Shear resistance in positive loading, Q_{bp}^{+} (kN)

Spec.	Measured	Calculated	
		Q_f	Q_{ab}
BRCB1	455.5	191	318
BRCB2	573.6	419	318
BRCB3	462.2	191	636

rods in the opposite side of gusset plate showed severe deformation compared with the other side as observed in Figure 2.

The measured moment and designed moment is compared in Table 1. The moment resistance was evaluated as suggested by AIJ (2006). It should be noted that the moment could be evaluated well at the peak loading with the current design guide. As shown in Table 1(b), the calculated friction forces between base pate and mortar are smaller than the measured shear resistance in positive loading, Q_{bp}^{+}. It indicated the slip of base plate could be noted in the design. Different from the moment resisting frame, the shear resistance should not be considered by the minimum of the friction force and the anchor rods resistance in design.

2.2.1 *Shear behavior*

The friction capacity depends on the normal force (compression) between the base plate and the mortar and the friction coefficient. The slip of base plate was suddenly increased when the shear force at the base plate is around 200 kN for all specimens. It is primary because the friction force lost as the vertical force on the base plate was reduced by the vertical component of BRB tensile force. The amount of BRB force when the friction force is absent could be calculated using Equation 1:

$$F_{\mathrm{br}} \cdot \cos 35^\circ + M_{bp}/L = \mu \cdot (N_0 - 2.5F_{br} \cdot \sin 35^\circ) \quad (1)$$

where F_{br} = brace axial force; M_{bp} = moment at base plate; L = specimen height; N_0 = axial force contributed by moment-resisting frame (500 kN); and μ = friction coefficient between base plate and mortar layer (0.5).

Since M_{bp} is relatively small when the friction force is broken, it is omitted in the calculation. According the equation 1, friction force is broken when the

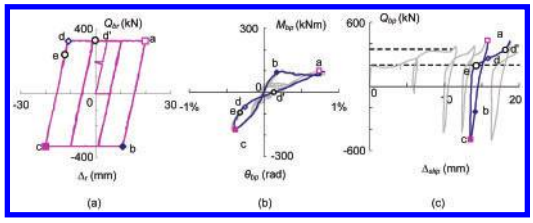

Figure 4. (a) Braced behavior; (b) column base slip behavior; (c) column base rotation behavior.

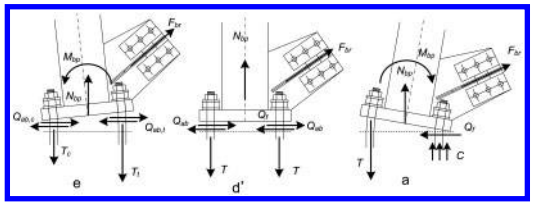

Figure 5. Resisting mechanism of column base with BRB.

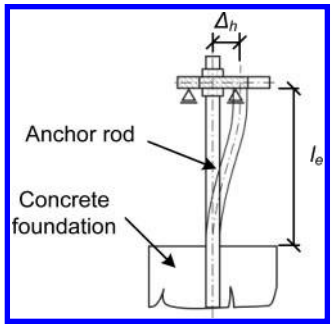

Figure 6. Horizontal deformation of anchor rods.

brace force is 163 kN, which is coincident with the experimental results.

As discussed in Cui et al. (2012), the slip of base plate occurred when the friction force between base plate and mortar layer is broken, point e in Fig. 4, and recovered when the base plate touched with the mortar ($\theta_{bp} > 0$), point d′ in Fig. 4. In this region, the resisting mechanism of column base is described in Fig. 5.

At increasing horizontal displacement the shear force increases till it reaches the friction capacity. Before the friction force was recovered, the column base experienced the direction change of the moment resistance. Because the mortar does not have sufficient strength to resist the bearing stresses between the anchor rods and the mortar, considerable bending of the anchor rods may occur, as shown in Figure 2. Tension, shear and bending will occur in the anchor rods due to the horizontal displacement. The deformation of anchor rods could be described as shown in Figure 6. Such horizontal deformation was cumulated, since such deformation developed in one loading direction (load from negative loading to positive loading). Equation 2 was used to evaluate the horizontal displacement in the very beginning.

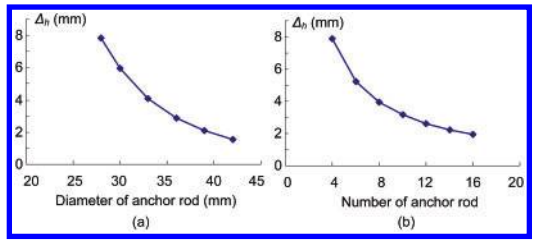

Figure 7. Effect of parameters on the horizontal displacement of anchor rod: (a) diameter of anchor rod; (b) number of anchor rod.

$$\Delta_h = \frac{F_{br,y}/n \cdot \cos 35° \cdot l^3}{12EI} \tag{2}$$

$$I = \frac{\pi d^4}{64} \tag{3}$$

where, n = the number of anchor rods; $F_{br,y}$ = the yield strength of BRB force, 400 kN; E = the young modulus of anchor rod; d = the diameter of anchor rod; l = the effective length of anchor rod (the sum of base plate thickness and the mortar layer thickness). Should be noted that the lateral load on the top of column was ignored, since it is far less than the lateral components of BRB yield force.

Using Equation 2, it is calculated that the horizontal displacement of the three specimens are 8 mm and 5 mm, which are close to the measured slip at the 1st loading cycle. However, Equation 2 is a simple way to roughly evaluate the slip at the very beginning. The effect of anchor rods arrangement is not able to be traced. But it still could give the designers the general image of the horizontal deformation of anchor rods.

Figure 7 shows the effect of diameter and number of anchor rods on the horizontal displacement. The horizontal displacement is reduced as the diameter or number of anchor rod increased. But it is notable that the horizontal displacement could not be completely overcome by simply increase the size or number of anchor rods.

3 NUMERICAL STUDY

3.1 *Numerical model*

The general-purpose finite element program ABAQUS version 6.9 (2010) was used to the effect of column base slip on the BRB frames behavior. The prototype frame of the experiment discussed above was modeled as shown in Figure 8 (a). Half of the specimen was modeled.

Beam elements (B31) were used for the column in the frame part. Truss elements (T3D2) were used for the BRB. The column base part was modeled in details, as shown in Figure 8 (b). A four-node linear reduced integration with an hourglass control shell

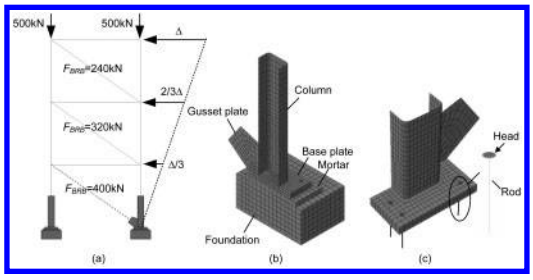

Figure 8. Numerical model: (a) loading condition; (b) modeling of column base model; (c) modeling of anchor rod.

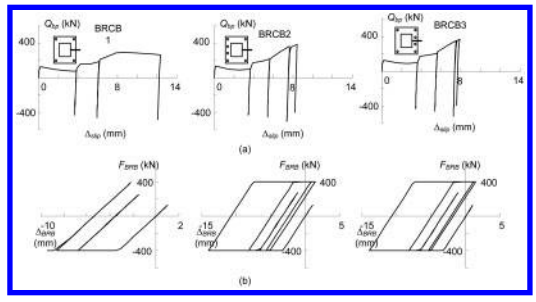

Figure 9. Analysis results: (a) Q_{bp}-Δ_{slip} relationship; (b) BRB behavior.

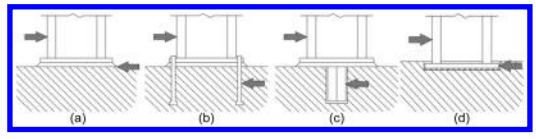

Figure 10. Shear transfer mechanisms: (a) surface friction; (b) anchor rod bearing; (c) shear key; (d) foundation bearing.

element (S4R) was used for the column. Two layers of eight-node hexahedral incompatible mode elements (C3D8I) were adopted to model the base plate to accurately trace the bending behavior. The foundation beam and mortar were considered as an elastic component to reduce the calculation time. Interaction between the bottom of base plate and the upper surface of the mortar was modeled to allow for contact behavior with friction. As shown in Figure 8 (c), the bolts were modeled as beam elements, having a diameter equal to the nominal bolt diameter of 28 mm and restrained at the lower node. The heads of the bolts were modeled as shell disks, S4R, having a constant thickness equal to the average thickness of the actual bolt head. The sections were modeled as rigid by giving them a linear elastic material response.

The multilinear kinematic hardening option was adopted to simulate the material behavior of steel, with the parameter value provided by the associated material tests. For the column and base plate, the stress-strain curve was assumed to be bilinear with a strain hardening ratio of E_s/100, where E_s is Young's modulus of steel. For the anchor bolts, a fracture strain was assigned to consider the rupture of anchor bolts. Bilinear hysteresis curve of BRB is applied to the truss element.

Lateral displacement on the 3rd story was controlled. Story drift angle of 1/300 rad, 1/150 rad, and 1/100 rad of each two cycles were controlled. However, due to the serious lateral deformation of anchor rods, the analysis was stopped in the very early loading age.

3.2 *Numerical results*

The analysis results are shown in Fig. 9 (a) and (b). It is noted that the slip was reduced nearly half by using extra two anchor rods, which is similar as observed in the experimental study. Because of the slip of the base plate, the axial deformation of BRB was reduced. As shown in Fig. 9(b), the BRB behaved different from the expected one, which is shown in Fig. 4(a). Although the frame with 'BRB3' showed the smallest slip, the BRB behavior is nearly the same as the one with 'BRB2'.

Based on the analytical results, it concludes that the BRB contribution was significant reduced due to the slip of base plate. It would limit the develop of the BRB application in low-to-medium rise building. As discussed above (Fig. 7), the slip of base plate could not be completely overcome by using larger or more anchor rods. Other method should be developed to avoid the slip and to ensure the BRB behavior in the low-to-medium rise building.

4 FURTHER DISCUSSION

There are four mechanisms for shear forces to be transferred from the column base into the supporting concrete foundation. They are friction between the base plate and mortar layer (Fig. 10 (a)), shear and bending of the anchor rods (Fig. 10 (b)), shear key bearing on the foundation (Fig. 10(c)) and bearing of the column embedded in a slab or foundation beam (Fig. 10 (d)).

It was observed that the first two mechanisms were not promising and sufficient for heave shear loads. The other two mechanisms, shear key and embedded column, showed great shear resistance in other studies. Further study should be continued to investigate the effect of these two mechanisms in the column base of BRB frames.

5 CONCLUSIONS

In moment frames, the shear is often transferred through friction developed in the bearing potion of the base plate. However, when such a bearing zone is not present (e.g., in braced frames or in moment frames where the columns have tensile axial loads), shear transfer mechanisms must be carefully considered and designed. The main findings of this paper are summarized as follows:

1) The exposed column base in BRB frames showed unsymmetrical hysteresis behavior in positive and negative loading.

2) The shear behavior is critical for the exposed column base in BRB frames. The friction force between the base plate and foundation beam was broken when the BRB force was in tension. Significant slip occurred then.
3) The slip of base plate was cumulated in cyclic loadings. And such slip would reduce the effect of BRB behavior.
4) The slip was reduced by increasing the number of anchor rods. However, the arrangement of the anchor rods had slightly contribution to increase the seismic behavior of exposed column base.
5) Other methods to reduce the slip of base plate should be studied, such as stopper in front of base plate or shear key under base plate.
6) In the design, not only the shear resistance should be checked, but also the deformations at serviceability.

Multi-storey steel structures: Seismic energy modal distribution

O. Prodan, I. Ladar & N. Chira
Technical University of Cluj-Napoca, Romania

ABSTRACT: The Present contribution reviews the already classical transformations of seismic input energy into multi-storey structures and emphasizes the less developed distribution of this energy to the natural modes of vibration. The computation is conducted on two scaled down steel multi-storey frames dynamically modeled as mdof systems. The main objective of the intended contribution is to introduce a modal approach to energy based analysis and design. While the structural engineer enjoys a good command of transformation of seismic input energy into kinetic, strain, damping (inherent viscous and hysteretic) energy components, the modal distribution of seismic input energy is less exhibited and practiced. A short theoretical part dealing with modal energy based analysis is developed. It is followed by several numerical results carried out on steel multi-storey structures seismically acted on via a laboratory shaking table. Associated relevant results in terms of input energy and its structural modal components are presented. Inferred conclusions and an avaricious bibliography are presented.

1 INTRODUCTION

Why is the energy approach to seismic analysis and design of structures a new and, eventually, a more general technique to the analysis and design of structures located in seismic areas? First, the answer to the question may start with the direct evidence that what the earthquake introduces, primarily, into a structure is energy. Not stresses and not displacements/ deformations. They come later as the result of energy input. Then, the energy is a synthetic parameter comprising both, vector quantities (stresses, displacements, velocities, accelerations) and scalar quantities (masses, damping associated parameters, elastic and plastic properties of the structures). It has to be emphasized that a synthetic quantity, as the seismic induced energy, will allow a synthetic approach to structural analysis and, most important, design. Energy approach [1], [2], [3] will not lead to (numerical) values of stresses and displacements that may be compared to some allowable limits. Energy approach, as it is formulated [4], [5], [6] will not lead to any mechanical (static and kinematic) state of a seismically acted upon structure that is specified in seismic design codes. If this is a shortcoming, it is not a shortcoming of the energy approach. The shortcoming could be of the analysis and design techniques. This shortcoming is not going to last, the energy based analysis and design are, already, firmly formulated [7], [8], and are rapidly and successfully catching up [9], [10]. The mass distribution and, mainly, the proposed modal distribution of seismic input energy into multi-story structures may constitute useful tools in the hands of structural engineer to an optimal structural conceiving. It may be helpful in assigning an optimal location of dampers into the design structure aiming at fulfilling the fundamental requirement of energy based design criterion:

Energy dissipating capacity ≥ Energy demand

where, energy demand is the input energy of the design (code provided) earthquake.

The study refers to the energy formulations of seismic analysis of multi-story structures in its relative form. A short emphasize on the relevance of the two forms is added and commented. Mass and proposed modal decompositions of seismic input energy are developed and followed by numerical analysis results obtained from energy based analysis of steel multi-story structures seismically acted upon.

2 MASS AND MODAL APPROACH TO THE SEISMIC INPUT ENERGY

Following (nxn) matrices and (nx1) vectors are associated to a classical dynamic n dof viscously damped model (Fig. 1) seismically acted in elastic domain: inertia matrix $\mathbf{M}$, stiffness matrix $\mathbf{K}$, classical [11] viscous damping matrix $\mathbf{C}$, modal matrix $\mathbf{\Phi}$, kinematic relative vectors $\mathbf{u}$ (displacements), $\dot{\mathbf{u}}$ (velocities) and $\ddot{\mathbf{u}}$ (accelerations), unit vector $\mathbf{1}$, inertia vector $\mathbf{m} = \mathbf{M} \cdot \mathbf{1}$ and recorded ground acceleration vector $\ddot{\mathbf{u}}_g$. The modal orthogonal eigen vectors $\mathbf{\Phi}_j$ and eigen values ω_j $(j = 1 \div n)$ associated to natural mode of vibration j are, also, considered. An elastic elementary displacement set $d\mathbf{u}$ compatible with structural constraints is considered. The elementary work equation – associated to linear elastic behavior – reads:

$$\ddot{\mathbf{u}}^T \cdot \mathbf{M} \cdot d\mathbf{u} + \dot{\mathbf{u}}^T \cdot \mathbf{C} \cdot d\mathbf{u} + \mathbf{u}^T \cdot \mathbf{K} \cdot d\mathbf{u} = - \mathbf{m}^T \cdot \ddot{u}_g \cdot d\mathbf{u} \quad (1)$$

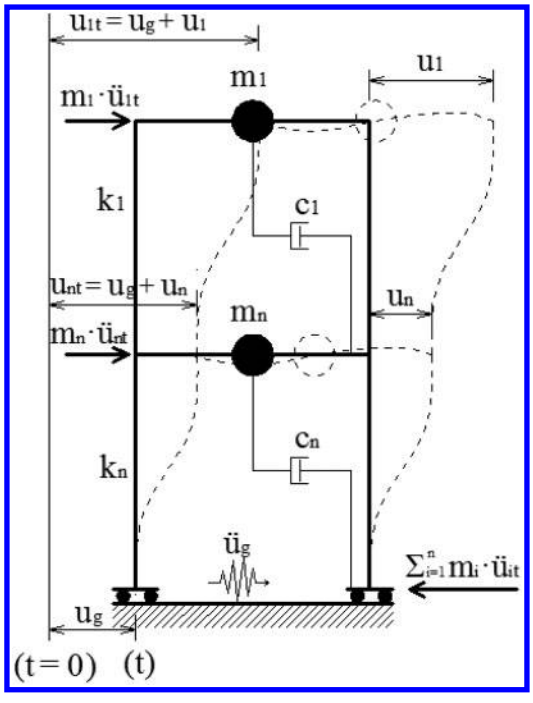

Figure 1a. Seismically induced displacements to mdof structure.

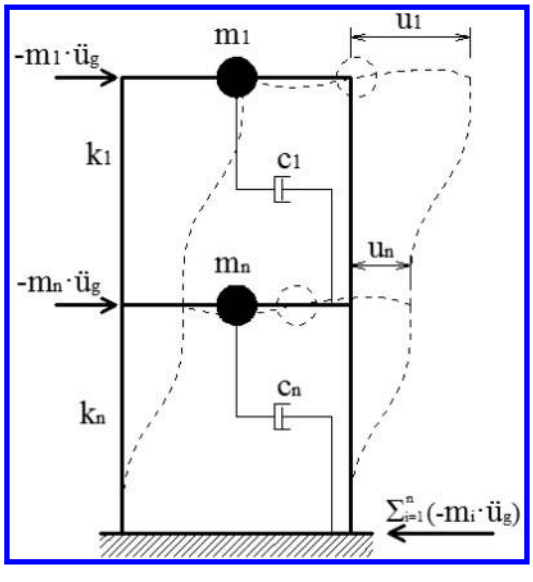

Figure 1b. Relative displacements **u**.

where^T denotes matrix transposition and δ is the virtual differential operator. Modal coordinates **u** are transformed into a new set **x** of coordinates through:

$$\mathbf{u} = \mathbf{\Phi}\cdot\mathbf{x} \qquad (2a)$$

The elastic elementary displacement in **x** reads:

$$d\mathbf{u} = \mathbf{\Phi}\cdot d\mathbf{x} \qquad (2b)$$

Substituting coordinates **u** by the new modal set **x** leads to the work equation:

$$\ddot{\mathbf{x}}^T\cdot\mathbf{\Phi}^T\cdot\mathbf{M}\cdot\mathbf{\Phi}\cdot d\mathbf{x}+\dot{\mathbf{x}}^T\cdot\mathbf{\Phi}^T\cdot\mathbf{C}\cdot\mathbf{\Phi}\cdot d\mathbf{x}+\mathbf{x}^T\cdot\mathbf{\Phi}^T\cdot\mathbf{K}\cdot\mathbf{\Phi}\cdot d\mathbf{x}=-\mathbf{m}\cdot\ddot{u}_g\cdot\mathbf{\Phi}\cdot d\mathbf{x} \quad (3)$$

Taking into account the orthogonality property of **M**, **C** and **K** matrices, a simple mathematical processing of virtual work equation (3) leads to the differential equation in x_j:

$$\mathcal{M}_j\cdot\ddot{x}_j + \mathcal{C}_j\cdot\dot{x}_j + k_j\cdot x_j = -(\mathbf{\Phi}_j)^T\cdot\mathbf{M}\cdot\mathbf{1}\cdot\ddot{u}_g(t) \qquad (4)$$

Subscript j denotes the natural mode of vibration and scalar L_j is given by:

$$L_j = (\mathbf{\Phi}_j)^T\cdot\mathbf{M}\cdot\mathbf{1} = (\mathbf{\Phi}_j)^T\cdot\mathbf{m} \qquad (5)$$

Integration of differential equation (4) leads to the classical solution $x_j(t)$ $(j = 1 \div n)$ of the traditional convolution integral associated to natural mode of vibration j in the form:

$$x_j(t) = -(\Gamma_j/\omega_j)\cdot\int_0^\tau \ddot{u}_g(\tau)\cdot e^{-\zeta_j\omega_j(t-\tau)}\cdot\sin[\omega_j(t-\tau)]\cdot d\tau \qquad (6)$$

where time variable $\tau \in [0, t_c]$, ω_j is j^{th} mode circular frequency and ζ_j is the modal critical viscous damping ratio. Modal participation factor $\Gamma_j = L_j/\mathcal{M}_j$ is, also, traditional. If the nxn diagonal matrices $\mathcal{M} = \mathbf{\Phi}^T\cdot\mathbf{M}\cdot\mathbf{\Phi}, \mathcal{C} = \mathbf{\Phi}^T\cdot\mathbf{C}\cdot\mathbf{\Phi}$ and $\mathcal{K} = \mathbf{\Phi}^T\cdot\mathbf{K}\cdot\mathbf{\Phi}$ are introduced in (3), the set of n simultaneously uncoupled differential equations reads:

$$\ddot{\mathbf{x}}^T\cdot\mathcal{M}\cdot d\mathbf{x} + \dot{\mathbf{x}}^T\cdot\mathcal{C}\cdot d\mathbf{x} + \mathbf{x}^T\cdot\mathcal{K}\cdot d\mathbf{x} = -\mathbf{m}^T\cdot\mathbf{\Phi}\cdot\ddot{u}_g\cdot d\mathbf{x} \qquad (7)$$

where the non-zero entries $\mathcal{M}_j$, $\mathcal{C}_j$ and $\mathcal{K}_j$ of diagonal matrices $\mathcal{M}, \mathcal{C}$ and $\mathcal{K}$ are given by:

$$\mathcal{M}_j = (\mathbf{\Phi}_j)^T\cdot\mathbf{M}\cdot\mathbf{\Phi}_j,\ \mathcal{C}_j = (\mathbf{\Phi}_j)^T\cdot\mathbf{C}\cdot\mathbf{\Phi}_j \text{ and } \mathcal{K}_j = (\mathbf{\Phi}_j)^T\cdot\mathbf{K}\cdot\mathbf{\Phi}_j \quad (8)$$

By substituting (8) into equation (7), the work equation takes the scalar form:

$$\sum_{j=1}^n \mathcal{M}_j\ddot{x}_j dx_j dt + \sum_{j=1}^n \mathcal{C}_j\dot{x}_j dx_j dt + \sum_{j=1}^n \mathcal{K}_j x_j dx_j dt = -\mathbf{m}^T\cdot\mathbf{\Phi}\cdot\ddot{\mathbf{x}}\cdot d\mathbf{x}\cdot dt \quad (9)$$

where $d\mathbf{x}$ is the usual differential: $d\mathbf{x} = \dot{\mathbf{x}}\cdot dt$.

Integration of (9) from $t = 0$ to $t = t_c$ (earthquake duration) leads to the (relative) modal energy balance equation:

$$E_{kj} + E_{dj} + E_{sj} = E_{ij} \qquad (10)$$

where energy modal j^{th} components read:

$$\text{Relative kinetic energy } E_{kj} = \int_0^t \mathcal{M}_j\cdot\ddot{x}_j\cdot\dot{x}_j dt \qquad (11a)$$

Dissipated energy by (inherent) viscous damping

$$E_{dj} = \int_0^t \mathcal{C}_j\cdot\dot{x}_j\cdot\dot{x}_j dt \qquad (11b)$$

Elastic strain energy $E_{sj} = \int_0^t K_j \cdot x_j \cdot \dot{x}_j dt$ (11c)

Seismic relative energy input $E_{ij} = -\int_0^t \mathbf{m}^T \cdot \mathbf{\Phi}_j \cdot \dot{x}_j \cdot \ddot{u}_g dt$ (12)

Similar mathematical incursion associated to total displacement $\mathbf{u}_t = \mathbf{u} + \mathbf{1} \cdot u_g$ (Fig. 1) leads to the absolute modal kinetic and absolute modal seismic input energy formulation (not dealt with here). The dissipated energy by viscous damping and strain energy preserve their form in both (relative and absolute) formulations [5]. All above integrating computation corresponds to [0, t_c] time interval. Energy balance at every instant $t \in [0,t_c]$ requires the emphasize of instant values of energy components. Energy balance at $t = t_c$ would "eliminate" stored (kinetic + strain) energy components as they vanish at the end of earthquake action.

3 NUMERICAL RESULTS

A set of two steel multistory scaled frames (Fig. 2) have been numerically analyzed. The frames have been experimentally tested aiming at a comparative study of added damping effect on energy input and distribution (not included here). Traditional n dof ($n = 2$ and $n = 3$) dynamic model is adopted. Applied seismic inputs are several scaled down accelerograms associated to the shaking table. Presented results have been selected form applying Kobe 1995 recorded and scaled down accelerogram (Fig. 3). The results are part of an entire set of laboratory results and are focused at energy decomposition into its modal components. No reference is made here to the laboratory calibration, selection of appropriate structures, lumped masses and digital recordings.

Experimentally analyzed structures (Figs 2a–2b) exhibit an accentuated flexibility (mainly lateral) that allows (by the large values of modal vibration periods T_j) a relevant emphasize of modal contributions to total seismic response. Processing relations 8) with computed modal analysis associated parameters (T_j, ω_j, $\mathbf{\Phi}_j$, ζ_j) the following numerical results (Table 1 and Table 2, respectively) have been obtained in the case of a critical damping ratio $\zeta_j = 2\%$ for all natural vibration modes:

Induced kinematic parameters $\mathbf{u}$ (displacements), $\dot{\mathbf{u}}$ (velocities) and $\ddot{\mathbf{u}}$ (accelerations) have been digitally recorded for each floor (lumped masses) via installed digital transducers. Numerical integrations of relations (6), (11) and (12) have been carried out numerically, following a recurrence numerical integration procedure [11] for a constant time interval step $\Delta t = 0.001$ sec.

Eloquent images of the obtained numerical results (modal energy components) are presented (Figs 4–5).

The classical mechanical energy (the stored energy) is presented as the sum of its kinetic and strain energy components. Also, it is computed in its cumulated form during the earthquake duration t_c. The surface by the mechanical energy curve (Fig. 4a) is the energy that

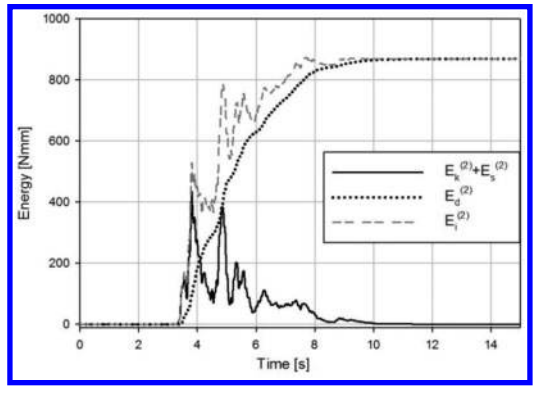

Figure 5b. Modal energy components $E^{(2)}$ n = 3 dof structure.

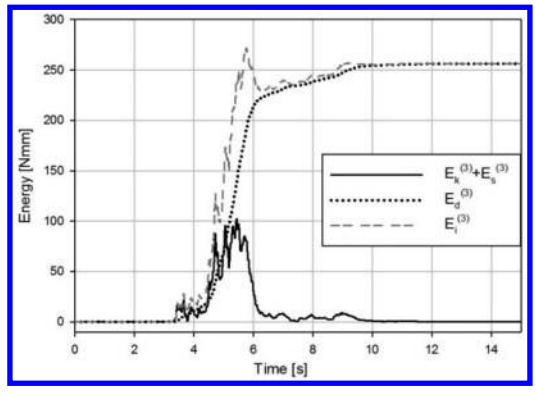

Figure 5c. Modal energy components $E^{(3)}$ n = 3 dof structure.

has to be "taken care" by the structural engineer by appropriate added damping equipment.

A clear difference (of about 1 to 10) between the 1st and 2nd modal values (of input energy and dissipated energy (by viscous damping) components may by ascertained (Figs 4–5) in in the case of both (n = 2 dof and n = 3 dof) structures. The ratio of modal value of energy component and the value of input energy may constitute a modal participation factor in terms of energy.

Indeed, in the case of n = 2 dof structure the assessment of modal energy participation would lead to a 95% participation of the first mode and of about 5% participation of the 2nd mode (Figs 4a, 4b and 6a). In the case of n = 3 dof structure, the energy share of the 1st mode would be about 83% (Fig.6b).

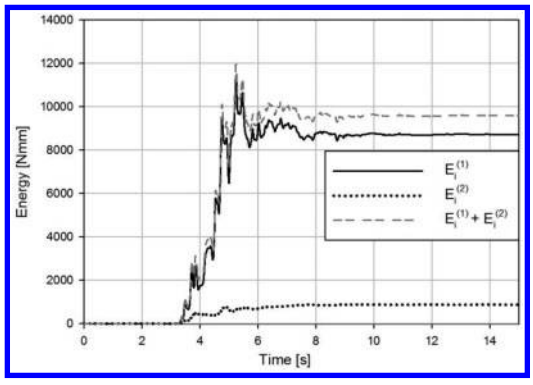

Figure 6a. Total energy $\sum E_i$ n = 2 dof structure.

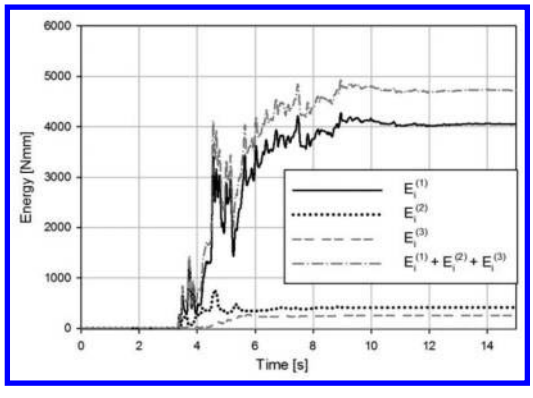

Figure 6b. Total energy $\sum E_i$ n = 3 dof structure.

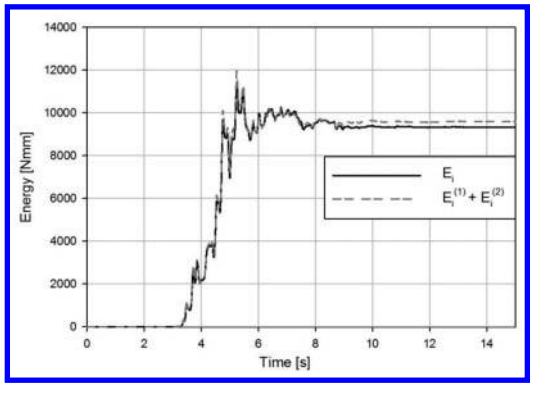

Figure 7a. Total input energy $\sum E_i$ n = 2 dof.

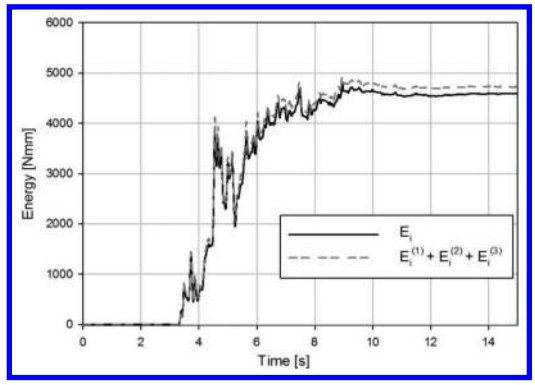

Figure 7b. Total input energy E_i n = 3 dof.

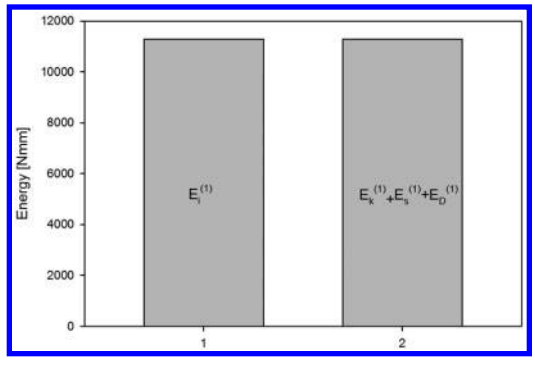

Figure 8a. Modal (j = 1) energy balance at t = 5.253 sec. n = 2 dof structure.

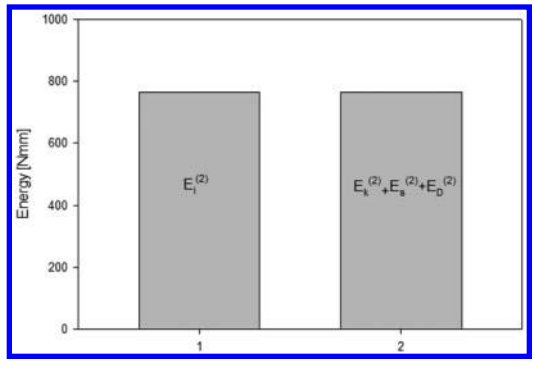

Figure 8b. Modal (j = 2) energy balance at t = 4.607 sec. n = 3 dof structure.

An energy balance may be ascertained at "modal level" associated to every instant t (Figs 8a, 8b) as well as the global (structural) level. Such an instant balance may express the required dissipation capacity (design provided) according to the (code) earthquake type (shock, long duration, etc.).

Computed modal coordinates x_j allow for the computation of (total) seismic response by applying the coordinate transformation (2a). Developing (2a) for the case of total (seismically induced) displacement u_i of mass m_i it takes the classical form of modal summing up:

$$u_i = \Sigma_j \Phi_{ij} \cdot x_j \tag{13}$$

Total seismic response in energy terms (Fig. 6) is, simply, the summing up of corresponding energy modal responses:

$$E = \Sigma_j E_j \tag{14}$$

Table 3. Energy modal participation – input energy.

	nmv	Classical modal participation factor Γ_j	Energy modal participation factor
n = 2 dof	j = 1	1.201	0.952
	j = 2	−0.201	0.048
n = 3 dof	j = 1	1.249	0.776
	j = 2	−0.328	0.17
	j = 3	0.079	0.054

Table 4. Modal participation – dissipated and stored energy.

	nmv	Dissipated energy modal participation E_d/E_i	Stored energy $(E_k + E_s)/E_i$
n = 2 dof	j = 1	0.4	0.6
	j = 2	0.39	0.61
n = 3 dof	j = 1	0.575	0.425
	j = 2	0.69	0.31
	j = 3	0.59	0.41

It is customarily to compare obtained numerical results to homologous values computed via a traditional approach. Consequently, a set of results computed in SAP2000 computer program versus the results computed by proposed technique are, also, provided (Fig. 7).

4 CONCLUSIONS

A modal approach to seismic response in energy terms and energy based elastic analysis of seismically acted upon multi-story steel structures is presented. Energy components are associated to the relative motion only. The values of left-hand-side of equation (10) is very close to the value of right-hand-side of this equation as it may be ascertained in Fig. 6. Also, an acceptable accuracy may be seen (Fig. 7) in the values of both sides of equation (14), exhibiting – numerically – the validity of proposed modal decomposition.

Closeness inside cca. 3% difference may be noted between the results of proposed modal approach and those computed via SAP2000 computer program (Fig. 8).

Modal contribution to the total seismic response may be more profoundly exhibited and assessed. It may be extended over post-elastic behavior and over seismically protected structures via added damping and added mass.

Regarding the proposed modal energy decomposition, one may note the easiness of expressing modal participation in terms of energy. It is customarily [11] to express modal participation in terms of displacements (mainly lateral), base shear, stress resultants. Similar participation may be straightforward express in energy quantities. It may be expressed in total input energy and, also, in its (kinematic, strain, dissipated) components. The modal participation to (total) input energy is presented in Table 3. Such modal participation assessment may open the possibility of expressing the effectiveness of added damping to seismic mitigation.

Modal participation of dissipated energy may be the most useful tool in the hands of structural engineer. For the analyzed cases, such results are presented in Table 4 at t = 5.5 sec.

An energy expressed modal participation avoids the negative values of modal participation factors. Also, energy approach to modal participation allows for a time variation of modal participation that, in its turn, expresses instant state in modal participation at important instants of seismic action.

ABSTRACT: A building which has rigid basement and has dominant first mode, is separated into two parts as rigid basement and upper stories in determining of seismic loads. It is clear that separating the building which has rigid basement into two parts is reasonable. However, separating the building into two parts does not hold true if the building has semi-rigid basement. In this study, we used RC frame buildings which have different rigidity level in basement to investigate the effect of the basement rigidity on seismic response of RC buildings. The level of the ratio of the column width and total frame span length which makes the floor as rigid was investigated. Also we investigated the difference between equivalent seismic load method and mode superposition method which are used to determine seismic base shear for sample buildings while shear walls ratio increases.

1 INTRODUCTION

Many buildings have basement and most of them are surrounded by continuous perimeter walls. The basement stories with RC peripheral walls and rigid diaphragms is called as *rigid basement.* In buildings with RC peripheral walls in their basement and basement floor behaving as rigid diaphragm in their horizontal direction, seismic loads are determined based on the mass of upper stories from the top of basement floor according to Turkish Seismic Code 2007 (TSC 2007) and Eurocode 8 (EC 8). There are two common analysis techniques for seismic design such as linear and nonlinear analysis. Both techniques have two procedure as static and dynamic. In this study, linear static analysis was performed for the seismic analysis of buildings. If participation of first mode is dominant on response than higher modes, most of codes allow us to assume the building as single degree of freedom (SDOF) system. If participation of first mode is higher than 70% it is assumed that first mode is dominant according to TEC 2007. First mode of building can be considered in determining the seismic load and it is called as *equivalent seismic load method.* Taking into account the higher modes of the building additional to first mode in seismic analysis is named as *mode superposition method.* Both methods are linear static seismic analysis. A building which has rigid basement and has dominant first mode, is separated into two parts as rigid basement and upper stories in determining of seismic loads. It is clear that separating the building which has rigid basement into two parts is reasonable. However, does that hold true for the buildings which has *semi-rigid* basement?

In this study, rigidity of the first floor of frames was increased gradual. Effect of shear wall ratio on response of vibration modes and the ratio of base shear of equivalent seismic load and base shear of mode superposition method were investigated. Also, the limit of shear walls are ratio that makes the basement rigid was investigated. Sample frames were modeled by using SAP2000 as 2D frame.

2 SAMPLE FRAMES

5-storey, 3 bays 2D RC frame building have been considered within the scope of this study. 11 sample buildings were generated based on the ratio of column width and total frame span length. Sample buildings were named based on rigidity ratio. Columns width were increased gradually to achieve the rigidity ratio and rigidity ratio was increased with the interval of 10% from 0% to 100%. First frame was named as 0% and dimension of outer columns is 40 × 30 cm × cm, dimension of inner columns is 60 × 30 cm × cm. First floor represents basement in the buildings. Column and beam dimensions are same for all sample buildings except first floor. Schematic view of frames were given in Figure 1. In Figure 1b horizontal dimensions of columns of first floor were increased to determine the 70% rigidity ratio. In Figure 1c, the frame has continuous shear wall.

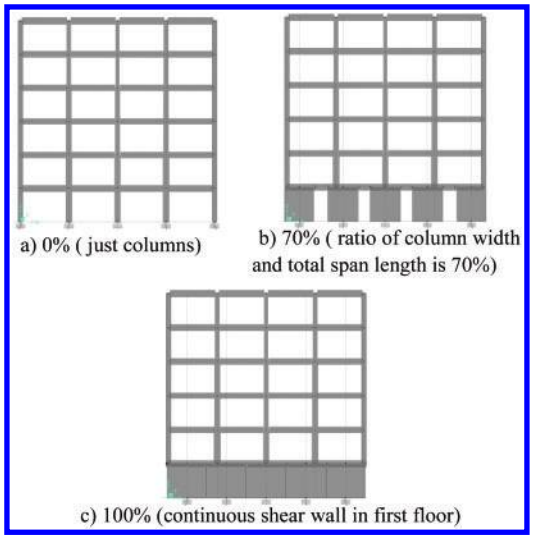

Figure 1. 2D frame used in the study.

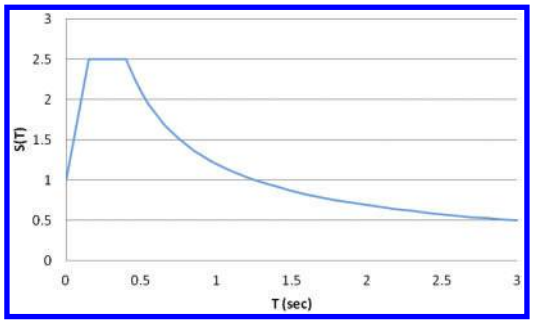

Figure 2. Standard acceleration spectrum (TSC 2007).

3 LINEAR STATIC SEISMIC ANALYSIS METHODS

3.1 *Equivalent seismic load method*

If the response of a structure is controlled by fundamental mode, the structure can be assumed as SDOF and seismic base shear is determined based on fundamental mode T_1.

$$V_t = \frac{W \times S(T) \times A_0 \times I}{R} \quad (1)$$

W is weight of building, A_0 effective ground acceleration coefficient, I is building importance factor, S(T) spectrum coefficient and R strength reduction factor. An example of standard acceleration spectrum was given in Figure 2.

Additional equivalent seismic load (ΔF_N), acting at the top storey of the building is determined by Equation 2.

$$\Delta F_N = 0.0075\ N\ V_t \quad (2)$$

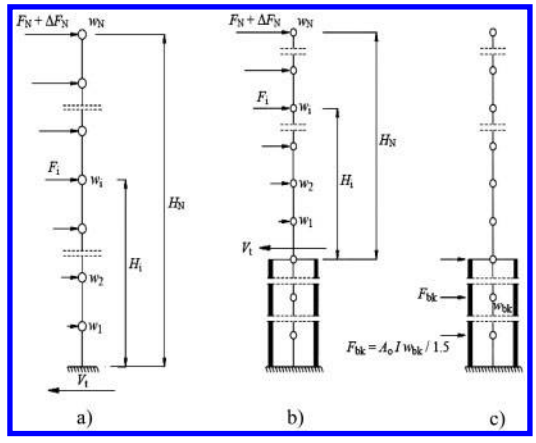

Figure 3. Seismic load distribution to stories of the building (TSC 2007).

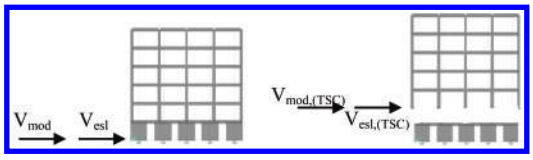
Total equivalent seismic load (V_t) is distributed to stories of the building in accordance with Equation 3. This distribution is applied excluding the ΔF_N.

$$F_i = (V_t - \Delta F_N)\frac{w_i h_i}{\sum_{j=1}^{N} w_j h_j} \quad (3)$$

Total equivalent seismic load distribution was given in Figure 3a. w_i is weight of i'th storey of building, F_i is design seismic load acting at i'th storey of building, F_{bk} is equivalent seismic load acting at rigid basement and H_i is the height of i'th storey of building measured from the top foundation level. In buildings with rigid peripheral basement walls, height of i'th storey is measured from the top of ground floor level.

In buildings with RC peripheral walls at their basements being very rigid relative to upper stories and basement floors behaving as rigid diaphragms in horizontal planes, equivalent seismic loads acting on the basement stories and on the upper stories are calculated independently. Calculation and distribution of total equivalent seismic load for upper stories and rigid basement stories were given in Figure 3b and Figure 3c, respectively.

In calculating equivalent seismic loads acting on rigid basement stories, seismic weights of basements only are taken into account and Spectrum Coefficient is taken as S(T) = 1. In determining equivalent seismic loads acting on basement storey, R is equal to 1.5.



3.2 *Mode superposition method*

In this method, base shear is determined by the statistical combination of maximum contributions obtained from each of the sufficient number of vibration modes considered. The criterion of sufficient number of vibration mode to be considered in determining the seismic load is sum of effective participating masses calculated for each mode shall in no case be less than 90% of the total building mass (Chopra 2001, TSC 2007).

4 RESULTS

Periods of sample buildings were given in Table 1. Seismic base shears of sample buildings based on equivalent seismic load method and mode superposition method and their ratio were given in Table 2. Effect of basement rigidity on base shear ratios (the ratio of the base shear which was determined according to mode superposition method and the base shear which was determined according to equivalent seismic loading method) was given in Figure 4.

In Table 2, V_{mod} is the base shear which was determined according to mode superposition method, V_{els} is the base shear which was determined according to equivalent seismic loading method and $V_{esl,(TSC)}$ is the base shear which was determined according to equivalent seismic loading method with separating rigid first floor and upper stories. According to Table 1, it can be seen that periods nearly constant after 50% rigidity. Thus, seismic base shear is determined separating rigid basement and upper stories (TSC 2007; EC 8) for the buildings which have a rigidity ratio higher than 50%.

It can be seen from Table 2, the ratio between V_{mod} and V_{esl} changes according to rigidity ratio. V_{mod}/V_{esl} is 0.97 for 0% value of rigidity ratio and 0.83 for 40% value of rigidity ratio while it is 0.75 for 100% value of rigidity ratio. According to the results, ratio of V_{mod}/V_{esl} decreases while rigidity of basement increases. If the building does not have shear walls in its basement, there is no important difference between the methods of determining of base shear. However, it is important that which method is used for determining base shear while shear walls ratio increases. If the building has rigid basement V_{mod} and $V_{mod,(TSC)}$ are nearly same.

Modal amplitudes of three modes were given in Figure 5. Changing of top storey amplitude was given in Figure 6. It is clear from the figures of amplitude, amplitudes are nearly same for all the sample buildings after 30% rigidity ratio. However, the amplitude is constant after 50% rigidity ratio.

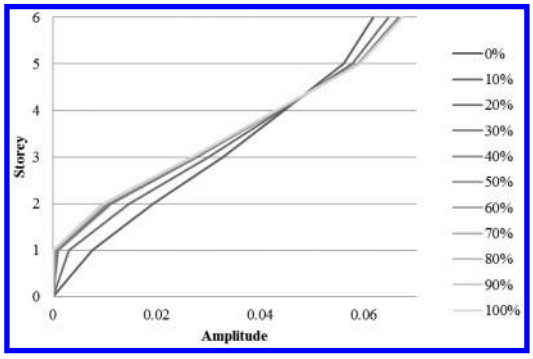

Figure 5. First mode amplitude of sample buildings.

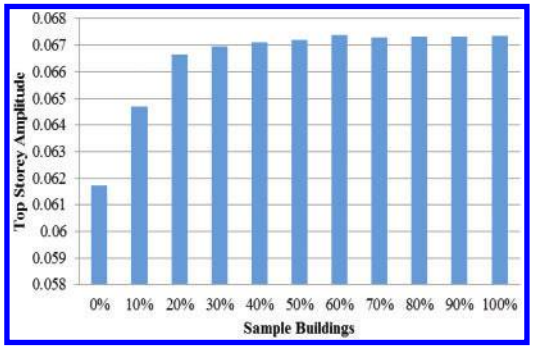

Figure 6. Top storey amplitude of sample buildings.

5 CONCLUSIONS

Following conclusions can be drawn from the results of the current study:

- Periods of the sample buildings are nearly constant after level of the 50% basement rigidity ratio. That means, modal behavior are nearly same after 50% ratio level. Basement behaviors as semi-rigid less than that rigidity ratio.
- According to the results, difference between base shear determining methods increases. In fact, codes allow us to neglect basement if it is rigid. However, there is no information about neglecting semi-rigid basement. If a building has semi-rigid basement, nearly 20% difference between base shears of equivalent seismic load and mode superposition methods.
- If a building does not have rigid basement, the base shears of mode superposition method and equivalent seismic loading method are nearly same. If the building have rigid basement equivalent seismic loads acting on the basement stories and on the upper stories are calculated independently. Thus, there will be no difference between the methods of determining base shear. However, it is important that which method is used to determine the base shear if the building has semi-rigid basement.
- Further studies are needed to determine the rigidity ratio level which provides rigid basement behavior.

ABSTRACT: The Nonlinear Static Pushover analysis is extensively used for the seismic assessment of structures for every type of building. The paper proposes the Bidirectional Pushover Analysis (BPA) to overcome the torsional problems in plan and elevation of asymmetric buildings, when bidirectional ground motion is considered. Different reinforced concrete frame structures are selected and modeled in 3D. The N2 method is then applied bidirectional to estimate the actual non linear response. Results in term of floor interstory drifts and floor rotations from the bidirectional pushover analysis, are compared with the nonlinear dynamic time history analysis. A suite of twenty European bidirectional seismic ground motions were selected. It was found that BPA matches with the bidirectional non linear time history analysis when the ratio Y/X is around 0.6, which is different from the ratio of 0.3 provided by the European seismic code when bidirectional linear analysis is performed.

1 INTRODUCTION

Among the nonlinear static methods (Pushover) implemented in codes, one relatively simple that incorporates performance-based engineering concepts is the *N2 method* formulated by Fajfar and Gaspersic (1996) as a variant of the *capacity spectrum method* (CSM) (Fajfar, 1999).

The *N2 method* combines the pushover analysis of a multi-degree-of-freedom (MDOF) system model with the response spectrum analysis of an equivalent single-degree-of-freedom (SDOF) system. The applicability of the method is restricted to 2D planar analysis, and it is based on three main assumptions: (i) the structure vibrates predominantly in the first mode; (ii) the deformation shape is time independent; (iii) the inelastic response spectra used in the analysis is obtained by applying a reduction factor R_μ to the elastic response spectra. The limitation of the *N2 method* is that it is not suitable in the case of high-rise buildings and/or torsionally flexible plan-asymmetric buildings (Kilar and Fajfar, 1997). In the first case for example, higher mode effects are important, and some demand quantities determined by the *N2 method* may be underestimated (De Stefano and Pintucchi, 2008, 2010).

Nowadays the research efforts are directed toward extending the applicability of pushover methods considering: (i) the contribution of highest modes of vibration (Gupta and Kunnath, 2000; Chopra et al., 2004a–b, Kalcan and Kunnath, 2006; Kim and Kurama, 2008), (ii) the effect of stiffness degradation (Kim and Kurama, 2008)), (iii) the changes in dynamic properties after the formation of first plastic mechanism as a function of the level of inelasticity and the torsional effects of irregular buildings (Fajfar et al., 2005) and (iv) and the effect of bi-directional seismic ground motion (Lin and Tsai, 2008). Chopra and Goel (2002, 2004a–b) proposed an appropriate modal combination rule assuming several displacement shapes, representing the predominant vibrating modes determined by one pushover analysis.

The main goal of this paper is to verify the accuracy of the extended N2 pushover method on 3D vertically irregular structural models under bidirectional seismic ground motions. A bidirectional use of the N2 method for asymmetric structures that allows the assessment of the maximum floors displacements and rotations on both X and Y directions at the same time, is proposed. The procedure consists on imposing different ratios of lateral load patterns applied simultaneously on orthogonal directions to an irregular structure and evaluate the maximum displacements through the N2 method (Fajfar, 1999). Finally the results of a parametric study are presented in term of displacements and storey drifts, obtained by the bidirectional pushover analysis and compared with the results of a more accurate approach (NRHA).

2 BIDIRECTIONAL PUSHOVER ANALYSIS

Standard practice consists in determining separately the two peak responses of the structure due to each ground motion component (NS and EW) and combine these peak responses according to one of the multi-component combination rules: the simplified square root of sum of squares (SRSS) rule (Lopez, 2001), the CQC3 rule (Menun, 1998) etc.

The SRSS rule have been adopted to combine the simultaneous effect of bidirectional ground motions used during the analysis. The maximal floor displacements and maximal floor rotations of *bidirectional pushover analysis* (BPA) along the X and Y directions have been compared with the median results of the *non linear response history analysis* (NRHA). The procedure can be summarized in the following steps:

Step 1: The Seismic demand is obtained by using the inelastic acceleration displacement response spectra (ADRS) format (Fajfar, 1999). The acceleration spectrum can be determined by applying a reduction factor R_μ such that $S_a = S_{ae}/R_\mu$; where R_μ is the reduction factor which is defined as follows:

$$R_\mu = \begin{cases} (\mu - 1)\dfrac{T}{T_C} + 1 & T < T_c \\ R_\mu = \mu & T \geq T_C \end{cases} \quad (1)$$

Step 2: the first vibration mode is evaluated by eigenvalues analysis and normalized to the roof top displacement.

Step 3: The modal participation factor Γ is evaluated as follow

$$\Gamma = \frac{\Phi^T M 1}{\Phi^T M \Phi} = \frac{\sum m_i \Phi_i}{\sum m_i \Phi_i^2} = \frac{m^*}{\sum m_i \Phi^2_i} \quad (2)$$

where is $m_i^* = \Sigma m_i \cdot \Phi_i$. is the modal mass.

Step 4: first mode shape lateral load profile is applied both in X and Y direction in order to perform pushover analysis. Lateral load is maintained constant in the X direction, while it is amplified in the Y direction as shown in Table 1 for example and with the direction represented in Figure 1. It assumed that the ratio g of the lateral load pattern for bidirectional simultaneous pushover analysis is given by:

$$\gamma = Y/X \quad (3)$$

where $X = m_i \Phi_i$ and $Y = \gamma m_i \Phi_i$.

Table 1. Bidirectional pushover lateral load ratios.

20%: R = X + 0.2Y	30%: R = X + 0.3Y	40%: R = X + 0.4Y
50%: R = X + 0.5Y	60%: R = X + 0.6Y	70%: R = X + 0.7Y
80%: R = X + 0.8Y	90%: R = X + 0.9Y	100%: R = X + Y

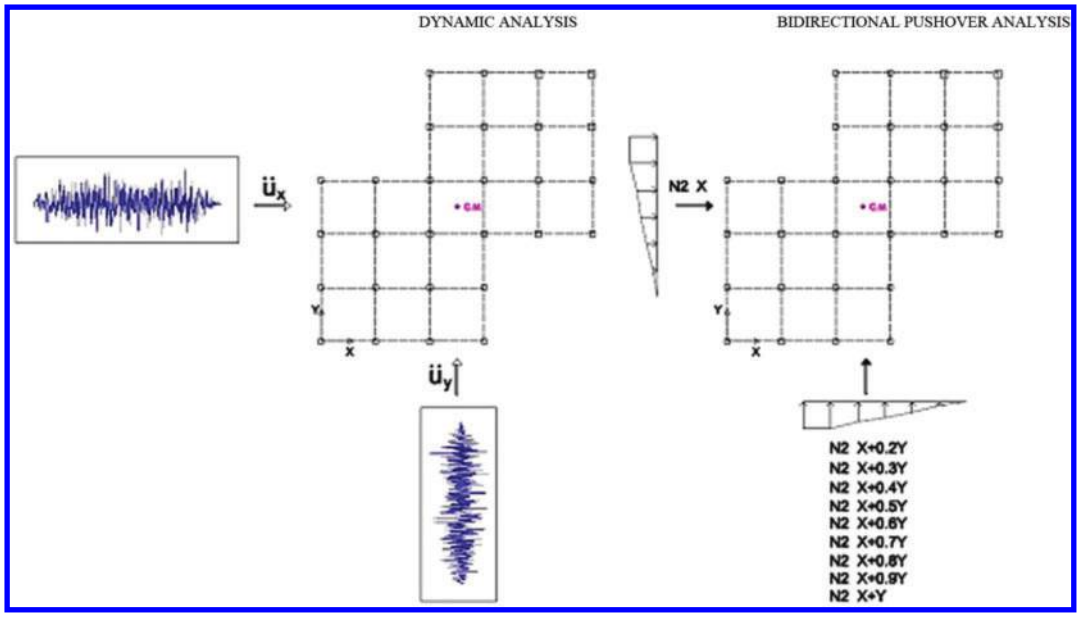

Figure 1. Bidirectional excitation adopted for dynamic non linear analysis and bidirectional pushover analysis.

Step 5: Transform the MDOF system capacity curve into an equivalent SDOF system using the following formulas

$$D^* = D_t/\Gamma ; F^* = V/\Gamma \quad (4)$$

where D_t is the target displacement of the MDOF system in the x direction, usually at the top of the building.

- Evaluate the displacement seismic demand of the SDOF system using the graphical procedure proposed in the N2 method;
- Transform SDOF displacement demand to maximum top displacement D_t of the MDOF system (target displacement);
- Determination of the associated displacement in the transversal direction Y.
- The torsional effects are evaluated numerically as ratio between corners and mass centre displacements (u_c/u_{cm}) on each floor (Fajfar *et al*., 2005). In other words, the floor rotations are evaluated numerically to calculate the torsional correction factors.

3 DESCRIPTION OF THE SIX STOREY BUILDINGS USED IN THE ANALYSIS

The proposed BPA is applied to an ensemble of six irregular six-story RC frames structures (Figure 2) that have been designed according to the requirements of EC8 (CEN, 1994). All the buildings are plan asymmetric in both X and Y directions, and irregular in elevation. The frames are equally spaced at a distance of 4 m with a storey high of 3.5 m. Each model is designed using a tapered square shape columns system. The reinforced concrete floors slabs are 20 cm thick.

3.1 *Numerical modeling*

The buildings are designed and selected using a parametric approach considering two parameters γ and α which quantify the torsional effects. The parameter α is defined as the ratio between the lower rotational frequency and the lower translational frequency. The parameter γ is defined as ratio between the moment of inertia evaluated around the global center of stiffness ($M_l \cdot d_l^2$) and the polar moment of inertia evaluated around the center of mass I_q. Analytically they are defined as follow:

$$\alpha = \min_{n \le N}\left(\frac{\omega_{\theta,n}}{\min\left(\omega_{x,n};\omega_{y,n}\right)}\right); \quad \gamma = \frac{M_l \cdot d_l^2}{I_{\theta,l}}; \text{ with: } l = n \quad (5)$$

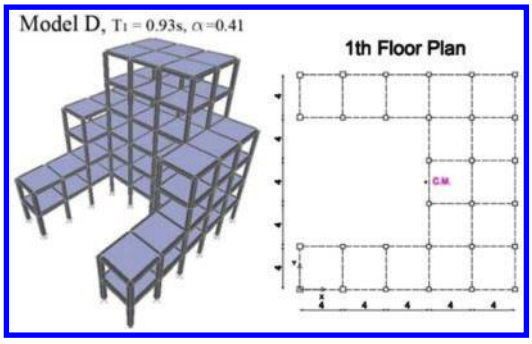

Figure 2. One of the six 3D reinforced concrete structural models adopted in the analysis.

The 3D building structures have been modelled in SAP2000 (CSI, 2011) using the rigid diaphragm constrains in the horizontal plane. The column-beam end connections were modelled with rigid offsets. The number of degree of freedom is three times the number of stories ($N = 6$). Five percent damping is used in all the analyses. The P-Δ effect is not taken in account in the analysis. The first mode is translational in the X-direction, the second is translational in the Y-direction, whereas the third mode is mainly torsional in all the structural models considered. The inelastic member model used is the beam element with concentrated plasticity at both end parts of each element. A bilinear is usually used. A simplified elasto-plastic (Isotropic) model for RC material has been adopted.

3.2 *Ground motion selection*

Two ensembles of 20 earthquake bi-directional records are selected from the Italian earthquake ITACA database (Working Group ITACA, 2010) website. All the selected records have local Magnitude M_L between 4.0 and 7.0, and source distance R between 2 and 50 km, with peak ground acceleration (pga) bigger than 0.15 g at least in one horizontal component. Each of the recorded accelerograms is amplitude-scaled in such a way that the median spectrum of both *unidirectional* and *bidirectional* set match to the target elastic spectrum, which is the EC8 spectrum for soil type C shown in Figure 3.

The scaling procedure used for the *bidirectional ensemble* is the same of the one used for the *unidirectional ensemble*, but in this case both North-South and East-West components have been considered for the scaling procedure. The response spectrum at 5% damping calculated from the North-South and East-West components of each earthquake are combined with the *SRSS* rule.

4 COMPARATIVE EVALUATION OF THE NON LINEAR STATIC ANALYSIS

Lateral forces with a modal load pattern are applied to all models first in one direction and then in both directions. In the first case, the classical pushover analysis is performed, while in the second case bidirectional pushover analysis (BPA) is performed.

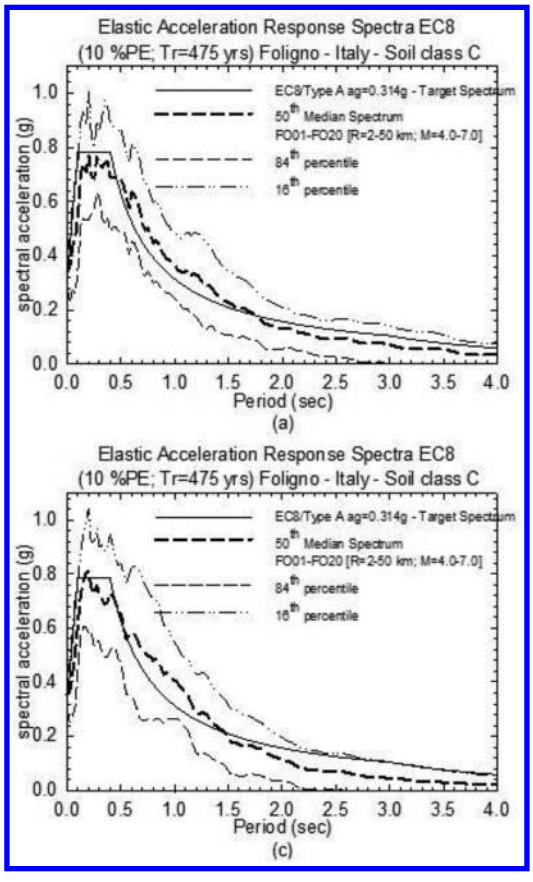

Figure 3. (a) Acceleration response spectrum of the 20 earthquake records used in the unidirectional analysis. (c) Acceleration and displacement response spectrum of the 20 earthquake records used in the bidirectional analysis.

4.1 *Comparison of pushover analysis vs. non linear response history analysis*

Pushover analyses are performed in the two horizontal directions with lateral loads based on the fundamental mode shapes in the relevant direction, i.e. x-components of the first mode shape is used in the X-direction, and Y-component of the second mode shape is used in the Y-direction.

Pushover analysis is performed in both North-South and East-West direction separately using the modified N2 method (Fajfar, 2005, Kreslin and Fajfar, 2011). The displacements of the center of mass of each floor of the buildings analyzed are evaluated using N2 pushover method and the results are compared with the median values of the displacements obtained by the time history analysis using the 20 earthquake records selected in previous section. The time history median results are identified in each plot with NRHA.

Numerical results at a given location are amplified by a correction factor calculated for each location. All models (six) have been analyzed. The accuracy of the proposed procedure is illustrated for example in

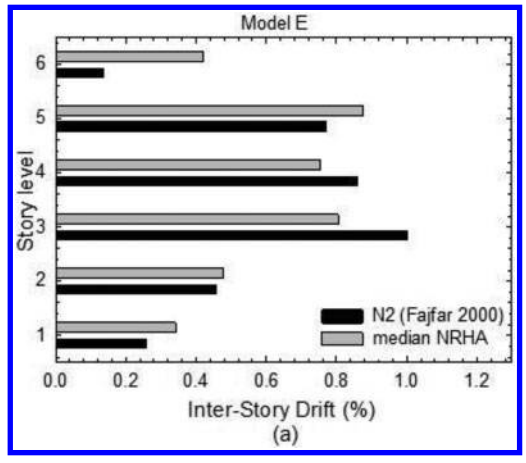

Figure 4. Pushover curves in the X direction of the analyzed models.

Figure 4 by comparing the maximum building interstory drifts of the traditional pushover analysis (N2) with the interstory drifts of the nonlinear response history analysis (NRHA). The floor relative rotation is evaluated comparing the ratio between the displacement measured at predefined corner points of the building and the displacement measured at the center of mass of the respective floor. The estimation of the floor relative rotations with the traditional N2 method is compared with the median time history response (NRHA) obtained from the 20 selected scaled records corresponding to the *unidirectional set*. In particular for the *E model* ($\alpha = 0.03$), which is symmetric with respect to a direction oriented at 45° with respect to the orthogonal axis X and Y, the floor displacement errors with respect to the time history analysis (NRHA) are respectively 11% at 6th floor, 3% at 5th floor, 2% at 4th floor 12% at 3rd floor and finally 16% and 9% at 2nd and 1st floor. The comparison shows a good approximation of the floor rotations in the upper stories, while differences are evident in the lower stories (Cimellaro et al., 2013).

4.2 *Assessment of the new bidirectional pushover analysis procedure vs. time history analysis*

In order to obtain accurate estimation of X and Y displacements when considering bi-directional simultaneous pushover analysis the ratio $\gamma = Y/X$ in the pushover lateral loads is considered.

In Figure 6 is shown the comparison of the top story (6th level) displacement for one of the six analyzed models. The top story total displacement and rotation obtained by the BPA is compared with the results of the nonlinear response history analysis (NRHA). In particular, the selection of the optimal lateral load distribution ratio γ that optimizes the X and Y displacement is obtained by minimizing the index $F(\gamma)$ which represents the sum of the differences of translational and rotational displacements at each floor between

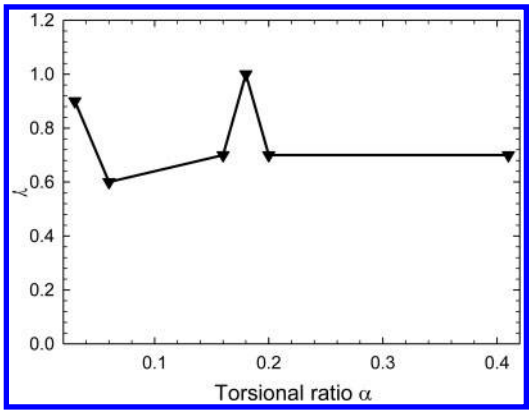

Figure 5. Optimal bidirectional ratio g = Y/X for different structural models.

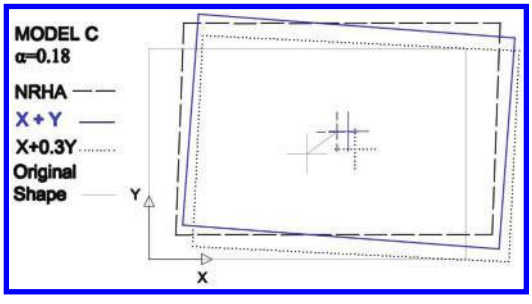

Figure 6. Comparison of time history analysis with different ratio of bidirectional pushover Analysis at 6th floor.

bidirectional pushover analysis (BPA) and nonlinear response history analysis (NRHA).

$$F(\gamma)=\sum_{1}^{6}\left[\left(X_{i\,TH}-X_{i\,PA}\right)^2+\left(Y_{i\,TH}-Y_{i\,PA}\right)^2+\left(\vartheta_{i\,TH}-\theta_{PA}\right)^2\right] \quad (6)$$

where X, Y = translational story displacement measured at the center of mass; $\theta_{R,i} = X_i/X_{cm,i}$ rotational story displacement where X_i is the maximum corner floor displacement in the X direction normalized with respect to $X_{cm,i}$ which is the floor center of mass displacement.

The optimal γ ratio obtained by minimizing the index F(γ) given in Equation (6) is plotted in Figure 5 for the different structural models considered in the analysis, while the optimal top story displacements obtained with the BPA are shown in Figure 6 and compared with the displacements obtained with the BPA using a γ ratio of 0.3 ($X + 0.3Y$) as suggested for linear dynamic analysis in the European seismic standard (CEN, 1994). Regardless the torsional ratio α, the γ ratio ranges between 0.6 and 1. This ratio is therefore different from the value provided in the European seismic provision which uses a value to combine earthquake records of 0.3. The relative rotation $\theta_{R,i}$ can be plotted for different torsional ratio α related to six different structural models considered. The floor relative rotation $\theta_{R,i}$ are evaluated for all bidirectional pushover lateral load ratios γ and compared with median relative rotations obtained at each floor by the bidirectional time history analysis for each model. Bidirectional pushover analysis ($X + 0.6Y$) shows better results with respect to the classical pushover analysis (N2) especially at the lower stories, while similar results in agreement with time history analysis and N2 method can be obtained at the upper stories.

5 CONCLUDING REMARKS

Nonlinear static procedures are less time-consuming than nonlinear response history analysis, therefore nowadays are extensively used by practicing engineers for virtually every type of building. However, since the majority of real structures are irregular, pushover methods need to be improved to take into account the torsional effects of buildings and the directivity of the seismic ground motion, before being implemented in design codes. In this paper an extension of the N2 method to overcome the torsional problem in plan and elevation of asymmetric buildings is proposed. The proposed bidirectional pushover analysis (BPA) method, applicable when bidirectional ground motion is considered, led to better results than the traditional N2 method when compared with nonlinear response history analysis (NRHA). In particular, the BPA method estimates accurately the response of the CM when the torsional effects are not relevant (Model E with $\alpha = 0.03$), while the response is overestimated when the torsional effects are relevant (Model F with $\alpha = 0.16$). Based on the numerical results provided from the analysis, it was found that the ratio $\gamma = Y/X$ equal to 0.3, which is provided by the European seismic code when bidirectional ground motion wants to be considered in the analysis, is not adequate when nonlinear static analysis is performed. Instead, the ratio $\gamma = Y/X$ equal to 0.6 for the bidirectional pushover analysis (BPA) is proposed. Using this ratio, floor mass center displacements have been estimated relatively accurately, while fair results have been obtained in the estimation of floor relative rotations. The reason of this discrepancy is probably due to the fact that the factor is obtained from the statistical analysis of linear dynamic simulations.

Seismic collapsing response analysis of wooden house retrofitted by ACM braces

T. Takatani
Department of Civil Engineering & Architecture, Maizuru National College of Technology

H. Nishikawa
Education and Research Supporting Centre, Maizuru National College of Technology

ABSTRACT: 3-D non-linear collapsing process analysis of two-story wooden house was conducted against several strong earthquake ground motions with the seismic intensity of 6+ to 7 level in order to investigate the seismic behaviour of the wooden house retrofitted by ACM braces. A non-linear behaviour of timber elements in wooden house during earthquake motion can be simulated by this collapsing analysis. As a result, seismic response of the wooden house depends on the seismic intensity of input earthquake ground motion in the collapsing analysis. Also, there seems to be a possibility that the wooden house with the upper structural seismic index value of less than 1.0 may be collapsed by a strong earthquake motion with 7 level.

1 INTRODUCTION

In recent years, major earthquakes in Japan caused serious damage to a great number of existing wooden houses built by some old seismic design codes before 1981. One of the authors has already developed an advanced seismic retrofitting method for existing wooden house using ACM bracing method which consists of Carbon Fiber Reinforced Plastic (CFRP) plate and steel plates (Takatani 2012). It is very important for a structural engineer to take account of a seismic response of wooden house in the design process of seismic retrofit and also to make an accurate evaluation of the seismic collapsing behaviour of the retrofitted wooden house during a strong earthquake ground motion. In this paper, 3-D seismic collapsing process analysis of wooden house based on the theory of the Distinct Element Method (Cundall et al. 1979) is conducted in order to accurately evaluate the seismic behaviour of wooden house with or without ACM bracing seismic retrofit. The effect of the seismic retrofit using ACM bracing method on the collapsing behaviour is numerically investigated. Five earthquake ground motions with the Japan Meteorological Agency (JMA) seismic intensity, $I_{\mathrm{JMA}} = 6+ \sim 7$, are used in this 3-D collapsing process analysis of a typical traditional two-story wooden house in Japan.

2 COLLAPSING ANALYSIS OF WOODEN HOUSE

Target of the collapsing process analysis in this paper is a Japanese traditional two-story wooden house built in 1961. The upper structural seismic index of this wooden house is 0.45 in the span direction. ACM bracing seismic retrofit can be designed so as to satisfy the upper structural seismic index of 1.0. Figure 1 shows the wooden house floor plans before and after seismic retrofit. This wooden house was retrofitted by outside, inside and corner ACM bracing techniques. Some red lines of X sign in Figure 1(b) mean ACM brace locations. Some types of ACM bracing seismic retrofit for wooden house have already developed by Takatani (2012).

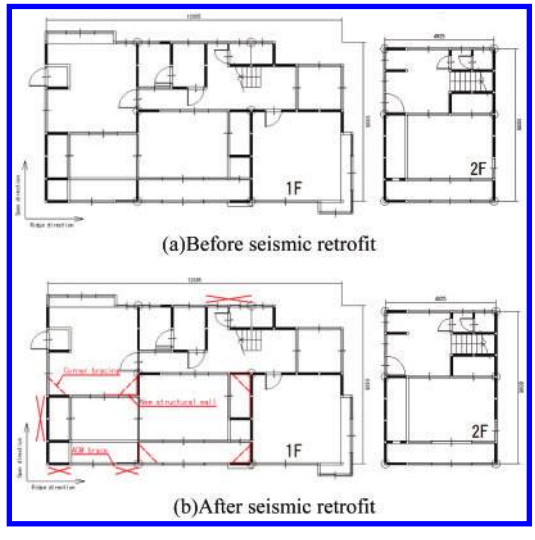

Figure 1. Floor plan of wooden house.

A collapsing process analysis software of "Wallstat" is conducted in order to investigate the seismic response behaviour and the collapsing process of wooden house during a strong earthquake ground

motion. This software has an original analysis technique (Nakagawa et al. 2010) using the basic theory of the Distinct Element Method.

Figure 2 illustrates a typical framing plan of Japanese two-story wooden house built by a traditional wooden-based building method. In the collapsing process analytical calculation, a wooden house can be modelled by a lot of timber elements such as beam and column connected with non-linear spring as shown in Figure 2, and also can be modelled by lumped mass and the weight of each floor in wooden house model can be obtained from each structural element as illustrated in Figure 3.

2.1 *Modelling of frame*

Timber frame is modelled by two elasto-plastic rotational springs (plastic hinge) and an elastic beam component as shown in the left-hand side of Figure 4. The spring can be defined by a relationship between the bending moment M and the angle of rotation θ with the skeleton curve indicated in the right-hand side of Figure 4. The bending moment starts to fall once if it is over the maximum bending moment, and the rotating spring changes to a pinned joint state at the point if the bending moment reaches 0, and then the beam component can be judged to have been broken.

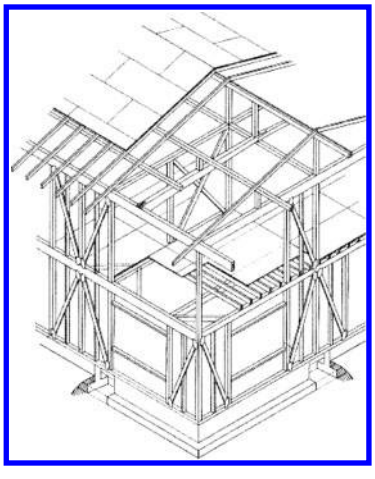

Figure 2. Framing plan of wooden house.

2.2 *Modelling of joint spring*

Joint spring can be modelled by both an elasto-plastic spring and a rotational spring as shown in Figure 5(a). Timber characteristic of the compression and tensile elasto-plastic spring consist of an elastic part and slip-type part indicated in Figure 5(b), and also timber characteristics of the rotational spring is assumed to be a slip-type relationship between ending moment M and angle of rotation θ shown in Figure 5 (c). When the elasto-plastic spring or the rotational spring of the joint exceeds the maximum structural strength or moment and their strength values becomes 0, the joint will be adjudged to have been broken and then the spring will be annihilated.

2.3 *Modelling of shear wall and bracing*

Vertical shear wall indicated in Figure 6 can be modelled by the replacement of truss component with a load-displacement non-linear relationship shown in Figure 8. Also, bracing shear wall illustrated in Figure 7 can be modelled by the replacement of compression and tensile truss components defined by a set of bi-linear and slip skeleton curve shown in Figure 8, too.

2.4 *Parameters of structural element*

In this paper, Young's modulus and the maximum bending moment of timber component are assumed to be 2,000 MN/m^2 and 10 kNm, respectively. External and internal walls in wooden house can be assumed to be lath mortal wall and clay wall, respectively. For seismic retrofit work, plywood is used as internal wall. Parameters of hysteretic characteristics of their walls are shown in Table 1. Parameters of stub tenon jointed at the interface between beam, column

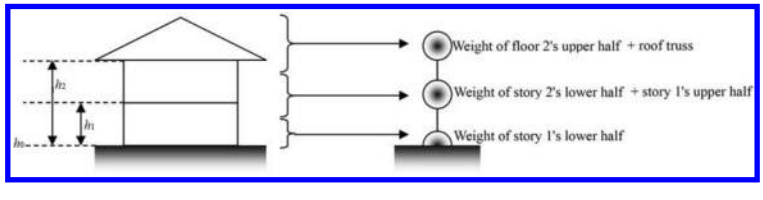

Figure 3. Weight of floor in the analytical model of wooden house (Nakagawa 2010).

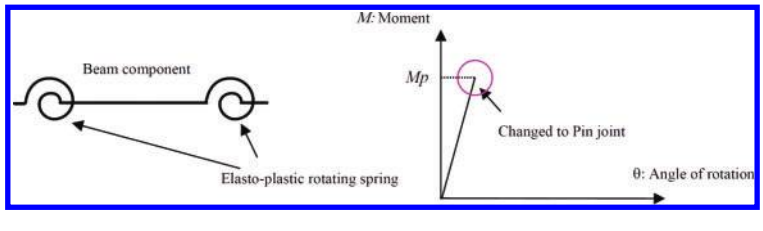

Figure 4. Schematic diagram and skeleton curve of frame spring (Nakagawa 2010).

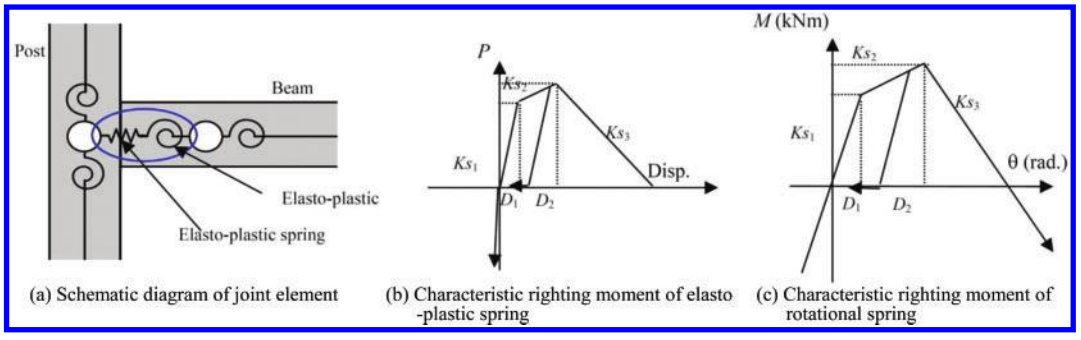

Figure 5. Outline of joint modelling (Nakagawa 2010).

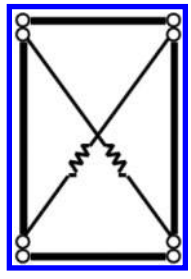

Figure 6. Shear wall spring.

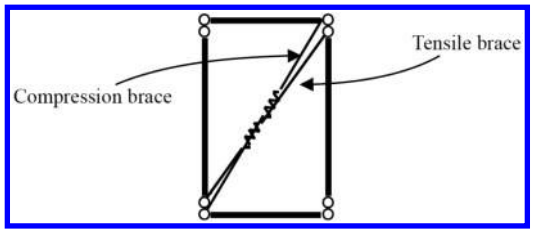

Figure 7. Outline of bracing shear wall.

and corner bracing used for seismic retrofit work are described in Table 2. Table 3 shows the parameters of hysteretic characteristics of timber brace and ACM brace element. This software has an original analysis technique (Nakagawa et al. 2010) using the basic theory of the Distinct Element Method, and can be taken into consideration the extremely non-linear properties of timber members breaking or being disperse. Nishikawa et al. (2012) conducted collapsing analysis of a two-story wooden house with and without ACM bracing seismic retrofit against some earthquake motions to investigate the effect of seismic retrofit of the wooden house.

3 EVALUATION OF COLLAPSING PROCESS OF WOODEN HOUSE

3.1 *Input earthquake motion*

Table 4 shows five earthquake records in K-NET and KiK-net systems used in this paper, which were obtained in the earth's crust between 2000 and 2008 in Japan and were the moment magnitude $M_W = 6.6 \sim 6.9$ with the seismic intensity of $I_{JMA} = 5 + \sim 7$. Three earthquake acceleration waves in Table 4 and their Fourier spectra are indicated in Figures 9 and 10, respectively. Three seismic intensities I_{JMA} are 6.3∼ 6.7 and their predominant frequencies are about 1 Hz.

3.2 *Collapsing process and seismic response*

Figure 11 illustrates collapsing behaviours before and after seismic retrofit of a wooden house against K-NET Ojiya in the Mid Niigata prefecture Earthquake in 2004. Wall elements in wooden house during earthquake are indicated in yellow, orange and red colours with the increase of damage degree of wooden house. In addition, as can be seen from the upper structural seismic index values in Table 5, the difference between the upper structure seismic index values before and after seismic retrofit have a significant effect on the seismic response against a strong earthquake motion, because the upper structural seismic index of the first floor in the ridge direction increases more than 0.2 by a seismic retrofit. Upper structure seismic index of wooden house means a ratio of the holding strength to the necessary one of wooden house, and also indicates the resistant strength against a strong earthquake motion with $I_{JMA} = 6 +$ level. Therefore, if the upper structural seismic index value is over 1.0, the retrofitted wooden house has an enough seismic resistant strength against a strong earthquake with the seismic intensity of $I_{JMA} = 6 +$ level. It is found from Table 5 that the wooden house after seismic retrofit doesn't have an enough seismic resistant strength. As can be found from the collapsing behaviour during K-NET Ojiya in Figure 11, the first floor of wooden house before seismic retrofit begins to destroy after 8 seconds and then collapses after 12 seconds. On the other hand, the damage degree of wooden house after seismic retrofit is slightly smaller than before seismic retrofit and then collapses after 12 seconds, too. This is because the displacement wave of K-NET Ojiya in Figure 9(a) was measured under a strong earthquake motion with the seismic intensity of $I_{JMA} = 7$ level and the amplitude of displacement was over 0.3 m.

Figure 12 illustrates collapsing behaviours before and after seismic retrofit of wooden house during K-NET Anamizu in the Noto Peninsula Earthquake in 2007. Although wooden house before seismic retrofit collapses after 16 seconds, wooden house after seismic

retrofit has no large damage after 50 seconds. This implies that the seismic retrofit has a significant effective effect on the collapsing behaviour against an earthquake with the seismic intensity of $I_{JMA} = 6 +$ level.

Figure 13 indicates collapsing behaviours before and after seismic retrofit of wooden house during KiK-NET Hino in the Western Tottori prefecture Earthquake in 2000. The first floor of wooden house before seismic retrofit in Figure 13(a) begins to destroy after 8 seconds and then collapses after 12 seconds. On the other hands, the damage degree of wooden house after seismic retrofit in Figure 13(b) is almost the same collapsing behaviour of wooden house before

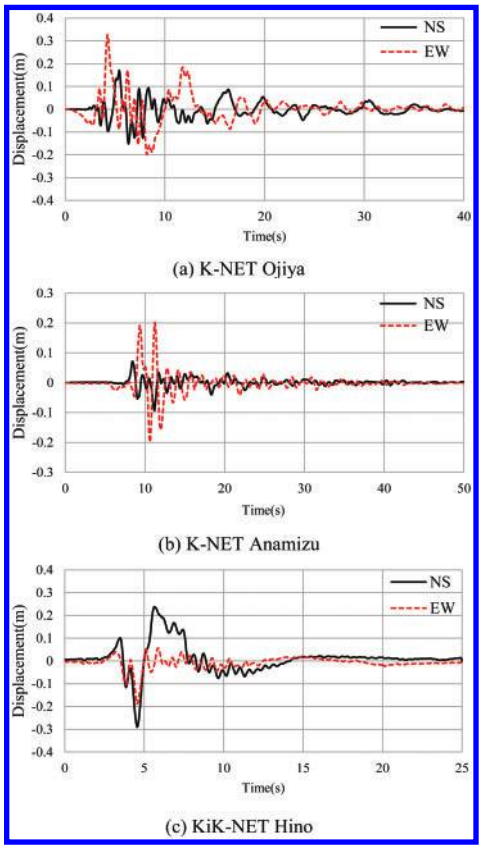

Figure 9. Displacement waves of input motion.

seismic retrofit. This is because the displacement wave of KiK-NET Hino in Figure 9(c) was measured under a strong earthquake motion with the seismic intensity of $I_{JMA} = 7$ level.

In this collapsing analysis, there are three wooden houses collapsed before seismic retrofit and two wooden houses collapsed after seismic retrofit against earthquake motions in Table 5. Because two earthquake motions, which was collapsed the wooden house after seismic retrofit, have seismic intensity of $I_{\mathrm{JMA}} = 7$, any other effective seismic retrofit countermeasure seems to be needed for a strong earthquake motion with the seismic intensity of $I_{JMA} = 7$. Consequently, the upper structural seismic index value of wooden house must be over 1.0.

4 CONCLUSIONS

In this paper, a structural analysis based on the Distinct Element Method was conducted in order to investigate the collapsing behaviour of wooden house during a strong earthquake ground motion and the seismic performance effect of ACM bracing method using e-plate. A traditional two-story wooden house was modelled before and after ACM bracing seismic retrofit, and the collapsing behaviour of the wooden house against some earthquake motions with the seismic intensity of $I_{\mathrm{JMA}} = 6 + \sim 7$ were investigated by 3-D seismic collapsing process analysis.

In summary, the following conclusions can be made based on the results presented in this paper.

(1) Seismic performance of an old wooden house retrofitted by ACM bracing method can be numerically confirmed by a collapsing process analysis. Seismic response of the wooden house greatly depends on the seismic intensity of input earthquake ground motion used in the collapsing analysis.
(2) There seems to be a possibility that the wooden house with the upper structural seismic index value of less than 1.0 is easily collapsed by a strong earthquake motion with the seismic intensity of $I_{JMA} = 7$ level even if the wooden house is retrofitted by ACM bracing method.
(3) As the wooden house retrofitted by ACM bracing method does not suffer severe damage against any earthquake ground motion with the seismic intensity of $I_{\mathrm{JMA}} = 6 +$ level, ACM bracing method for old wooden house may be one of the effective seismic retrofitting countermeasures.

Although the effect of earthquake ground motion spectrum on the seismic response of wooden house is not presented in detail in this paper, it is necessary for an intensive study on the effect of earthquake ground motion spectrum on the seismic response of the retrofitted wooden house during some earthquake ground motion wave data, which have the same level intensity with a different peak frequency in Fourier spectra. In addition, further investigation may be needed to simulate the seismic collapsing process phenomenon of an existing wooden house with or without seismic retrofit and make some concrete conclusions.

ACKNOWLEDGMENTS

The authors would like to thank the Japan Meteorological Agency and the National Research Institute for Earth Science and Disaster Prevention in Japan for their earthquake ground motion wave data in K-NET and KiK-net system.

Nonlinear behavior of submerged floating tunnels accounting for seaquake effects

Chunxia Shi, Marco Domaneschi & Luca Martinelli
Department of Civil and Environmental Engineering, Politecnico di Milano, Italy

ABSTRACT: Submerged Floating Tunnels, also known as Archimedes Bridges, are a new structural conceptual way for strait and waterways crossing, which are catching more and more worldwide attention. In this paper, a 3D finite element model is developed in a commercial finite element code, accounting for material and geometrical nonlinearities, soil-structure interaction and multiple-support seismic excitation, to give a broad angle view on the structural behavior under seismic motion. Elastic-plastic springs at tunnel shores, simulating passive control devices, are applied to reduce relative displacements between the tunnel and shores. Beside the traditional earthquake loading on the structure foundations' connections, the motion transmission from the seabed through the water (called *seaquake*) is newly introduced as an additional hydrodynamic pressure working on the floating tunnel. The velocity field due to seaquake is derived from its velocity potential which is deduced from the wave equation considering the boundary conditions. The force on the moving tunnel body in the oscillatory flow, simulating the seaquake, is modeled by using Morison's equations. A comparison between transient dynamic response in case of 'earthquake' and 'earthquake plus seaquake' is also given, which shows how seaquake loading affects the responses of anchor bars, shore connections and tunnel sections in terms of stresses, strains and displacements. The outcome indicates a larger displacement capacity is required to the control system in the mitigation of dangerous structural responses, as well as the significant role played by the seaquake loading source, and highlights the need of further investigations on seaquake effects.

1 INTRODUCTION

Submerged Floating Tunnels (SFTs), also named Archimedes Bridges, are a promising alternative to cross sea-straits, lakes and waterways. Entirely immersed at specific depth, they serve different types of traffic efficiently connecting the shores. A circular cross section is commonly adopted in SFTs' design and the tunnel, subject to positive buoyancy, is anchored at the seabed by suitable structural elements. The first proposal about SFTs was formulated by S. Preault in 1860. The concept caught the attention of several bridges and links specialists from Italy, Norway, China, Japan, USA and other countries, and is the object of a working group for SFTs established in 1989 (Ingerslev 2010).

Owing to the special siting of the SFT, several research fields have to be covered to give a thorough view of the dynamic loading and the resulting structural behavior, such as:

- seismic engineering analysis, studying both support-transmitted and fluid-transmitted loads,
- fluid-structure interaction, leading to the definition of forces due to sea waves and vortex shedding,
- vehicle-structure interaction, resulting in forces due to traffic loading,
- phenomena related to impact and explosions, for both internal and external events.

The study on the dynamic response of SFTs subjected to strong seismic motion made significant progress in the last decades (Di Pilato et al. 2008a, b, Martinelli et al. 2010, Martinelli et al. 2011, Shi et al. 2012a, b). The response due to hydrodynamic loads has been treated in detail in (Di Pilato et al. 2008b). In (Hong & Ge 2010), the SFT response to the accidental load due to the impact of a sinking boat is discussed. Fewer works have been found in the field of vehicle-structure interaction.

In seismic analysis, both the earthquake loads due to direct ground motion transmission to the structural supports and the so-called "seaquake" loading, due to the water transmission of compressive waves originated at the seabed, are worth more attention. Especially for seaquake, research work on SFTs has only been recently started (Shi & Martinelli 2013). However, a number of other different cases called for attention to the effects of propagating seismic waves in water due to seaquakes, and to the potential damaging effects that such waves may cause on offshore structures and floating systems (Hove et al. 1982). As a new type of external loading, this load works as a hydrodynamic pressure due to compression waves, since water cannot transmit a shear wave, traveling through the water and excited by the motion of the seabed during an earthquake.

Such complex loading conditions can induce dangerous responses in SFTs, about safety and reliability

performances. Structural control solutions can help to meet the required high standards of safety, mitigating the tunnels responses and protecting their structural elements. Moreover, several fruitful applications of passive and semi-active control systems to long span structures, such as cable-stayed and suspension bridges under seismic loading (Domaneschi 2010, 2012, Domaneschi & Martinelli 2012, Ismail et al. 2013), seem promising also when SFTs are considered.

In this paper, the first part is devoted to introduce the earthquake and seaquake motions. Then, a SFT model, simulated in the commercial finite element (FE) framework ANSYS, has been accounted for as a case study: it has been equipped with suitable passive control devices in the way of elastic-plastic axial springs which restrain the tunnel at the shores, and inelastic anchoring bars mooring the tunnel to the seabed. Finally, some conclusions are given about comparison between the cases of 'earthquake' and 'earthquake plus seaquake'.

2 SEISMIC MOTIONS

2.1 *Multiple-support earthquake loading*

The seismic excitation is applied at each ground connection points (shores and anchoring foundations) in the form of a multiple-support one. The stochastic modeling of the space-time variation of the seismic excitation is based on the Kanai-Tajimi power spectral density (PSD) modified by Clough and Penzien, which has been adopted to describe the seismic motion at a point. In addition, the coherency model of Luco and Wong was introduced representing the spatial variation of the ground motion.

The coherency function is defined in terms of the cross-power spectral density of ground acceleration $S_{i,j}(\xi_d, \omega)$ between two stations i and j at a separation distance ξ_d.

$$\gamma(\xi_d, \omega) = \frac{S_{i,j}(\xi_d, \omega)}{\left[S_{i,i}(\omega) \cdot S_{j,j}(\omega)\right]^{1/2}} \tag{1}$$

where ω is the circular frequency; $S_{i,i}(\omega)$, $S_{j,j}(\omega)$ the direct PSDs at the station sites.

Luco and Wong 1986 model was here adopted in the form:

$$\gamma(\xi_d, \omega) = \exp\left[-\left(\frac{\alpha_c \omega \xi_d}{v_s}\right)^2\right] \exp\left[i \frac{\omega \xi_d^L}{v_{app}}\right] \tag{2}$$

where ξ_d is the horizontal separation distance between two stations i and j, v_s the shear wave velocity, α_c a parameter controlling coherence decay, ξ_d^L the projected horizontal distance along the wave propagation direction, v_{app} the surface apparent velocity of "dominant" waves.

The adopted PSD function is the well-known modified Kanai-Tajimi spectrum of ground accelerations (Clough and Penzien 1975), expressed as (Monti et al. 1996)

$$S(\omega) = S_0 S_{CP}(\omega) = S_0 \frac{\omega_g^4 + 4\zeta_g^2 \omega_g^2 \omega^2}{(\omega_g^2 - \omega^2)^2 + 4\zeta_g^2 \omega_g^2 \omega^2} \frac{\omega^4}{(\omega_f^2 - \omega^2)^2 + 4\zeta_f^2 \omega_f^2 \omega^2} \tag{3}$$

where S_0 is the intensity of the ideal white noise process as bedrock acceleration, $S_{CP}(\omega)$ the normalized Clough-Penzien spectrum, ω_g and ζ_g the characteristic ground frequency and damping, ω_f and ζ_f parameters of an additional filter introduced to guarantee finite power for displacements.

The parameters in Equation 3, defining the modified Kanai-Tajimi power spectral density, have been selected according to the procedure presented in Martinelli et al. 2010 and Martinelli et al. 2011, to achieve acceleration time histories satisfying a code compatible response spectrum.

2.2 *Seaquake loading*

When seaquake effects are introduced, the hydrodynamic pressure is assumed associated with the water-transmitted seismic vibration from the seabed to the SFT. The velocity field due to seaquake is derived from its velocity potential. The velocity potential is deduced from the wave equation considering the boundary conditions (Hamamoto 1995). The force on the moving body in the oscillatory flow is modeled by using Morison equation (Chakrabarti 1987), which is adopted for simulating the seaquake loading on the tunnel.

3 SFT MODEL

3.1 *General outline and the control system*

In this paper, a prize-winning proposal for a SFT between Calabria and Sicily across the Messina strait in Italy is selected as case study. The model accounts for soil-structure interaction, geometrical and material non-linearities as well as for 3D multiple-support seismic excitation and seaquake.

The length of the proposed SFT project across the Messina Strait is 4680 m, the maximum depth is 325 m, and the location of the floating tunnel is set 40 m under the water level. Figure 1 shows the SFT's front and section views. The tunnel has a circular

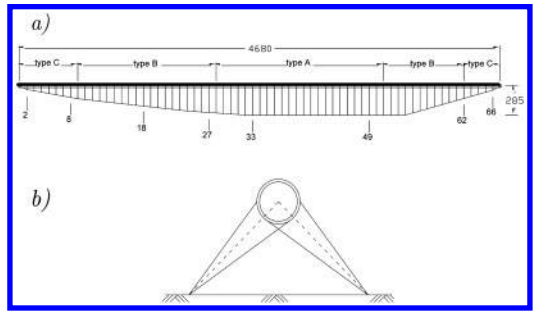

Figure 1. SFT, front view (a), section view (b).

composite steel-concrete section having a 15.95 m outside diameter. It is connected to the seabed by means of slender steel beams having hollow circular section and pile foundations.

For the supporting system, there are three kinds of bar sections along the whole length of the tunnel. The composite section is treated as an equivalent homogeneous one, having elastic modulus equal to 2.943×10^7 kN/m^2. The steel elastic modulus for the anchoring system is assumed equal to 2.06×10^8 kN/m^2, while the yielding stress and the hardening ratio are assumed respectively 210×10^6 N/m^2 and 0.02.

In light of the requirements of energy dissipation under severe seismic excitation, passive hysteretic control devices are suggested to be applied, acting in longitudinal direction at the tunnel's ends. These devices are implemented in the FE model as nonlinear elastic-plastic springs. Their design stiffness is derived from the yielding displacement and yielding force fixed respectively to 10 cm and 5% of tunnel weight. Additionally, the mooring system can have elastic-plastic behavior as well.

The role played by the passive control systems at the shores is twofold: first, to dissipate part of the seismic energy imparted to the SFT by the earthquake motion. This results attempts also to concentrate the inelastic deformation at specific and selected positions on the whole structure. The second aim of the control system is to decouple the structural motion from those of the shore, shifting the structural response to lower frequencies and, consequently, far from the higher frequencies characterizing the earthquake excitation. The expected consequence is to allow internal forces and stresses reductions at cost of larger structural displacements.

3.2 *The ANSYS implementation*

The ANSYS FE code is used to simulate the seismic response of the SFT by implementing a 3D model. In Figure 2, an illustration of the first natural vibration shape in transversal direction is depicted.

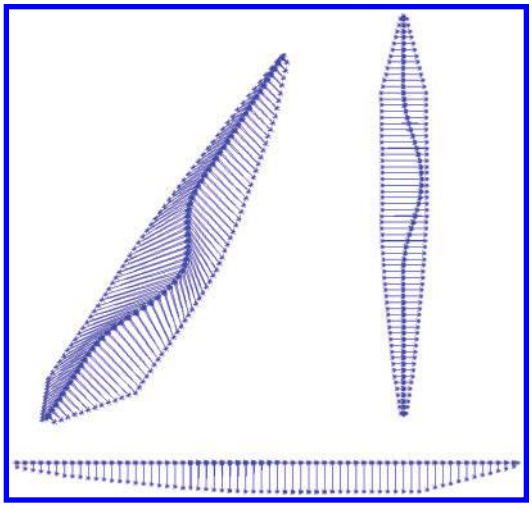

Figure 2. Mode shape of tunnel first transversal mode.

4 TRANSIENT ANALYSES

Two different loading conditions have been implemented for the dynamic analyses: the first accounts for the earthquake excitation, identified in the remaining of this section with the 'Eq' acronym, the second is the combination of both earthquake and seaquake excitations (identified with the 'Sq+Eq' notation). The transient dynamic responses of passive control devices, tunnels and anchor bars under such loading conditions are presented in the following sub-sections.

In the following figure legends (Figures 3–7), solid lines represent the responses under the combination of seaquake and earthquake excitations while dashed lines stand for the responses under earthquake alone.

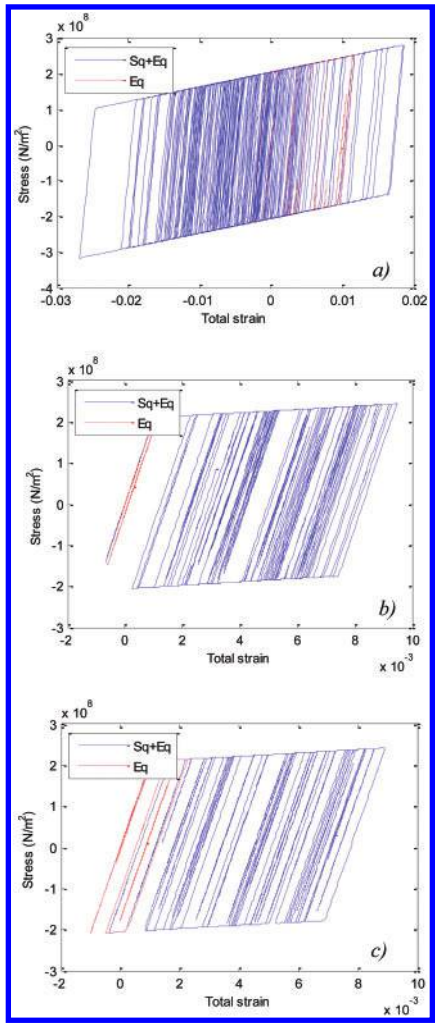

Figure 3. Strain-stress relationships of anchoring bars: the mid-section of bar close to the shore (a), at the quarter-span of tunnel (b), at the mid-span of tunnel (c).

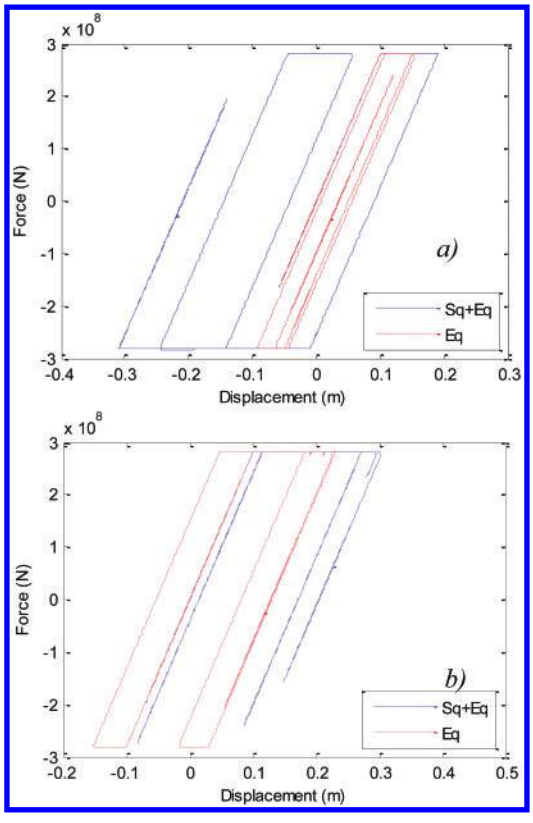

Figure 4. Elastic-plastic springs' nonlinear behaviors.

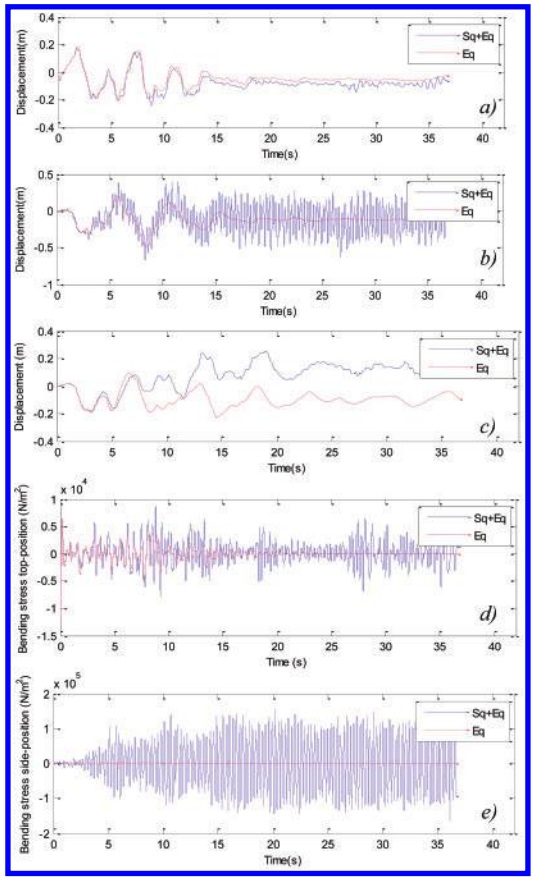

Figure 5. Tunnel section 1 (close to the shore). Transversal displacement (a), vertical displacement (b), longitudinal displacement (c), bending stress at top-position (d), bending stress at side-position (e).

4.1 *Response of anchoring bars*

In Figure 3, the inelastic behavior of the anchor bars is depicted. Figure 3a shows the strain-stress relationship at the mid-section of the bar close to the shore; Figure 3b gives the mid-section of the bar at the quarter-span of tunnel; meanwhile Figure 3c the mid-section of the bar at the mid-span of tunnel.

From the general overview of Figures 3a-c it arises that the bars close to the shore show ten times larger plastic deformations if compared with those at quarter-span and mid-span. The seaquake effect influences the behavior of the anchoring system, especially causing a significant strain increment in the bars at the middle span. Larger hysteretic cycles are induced by the 'Sq+Eq' loading.

4.2 *Passive control devices' response*

Figure 4 reports the longitudinal displacement-force paths for the devices at both tunnel ends.

From Figures 4a-b, the passive control devices, both in cases of 'Sq+Eq' and 'Eq', dissipate satisfactorily the seismic energy through hysteresis cycles. Larger displacements in 'Sq+Eq' than that in 'Eq' case can also be recognized, highlighting the more severe condition represented for the SFT by the coupled earthquake and seaquake excitation.

4.3 *Tunnel response*

Tunnel responses in terms of vertical (y axis), longitudinal (z) and transversal (x) absolute displacements, together with bending stresses (at top-position and side-position in the tunnel cross-section) are discussed in this subsection. Three locations along the longitudinal tunnel axis have been considered: close to the shore, at the quarter-span, and at the mid-span. The outcomes are depicted respectively in Figures 5–7.

The transversal displacements of tunnel sections near the shore, at the quarter-span of tunnel and at the mid-span of tunnel for the 'Sq+Eq' loading condition show similar time variation as those in the 'Eq' one, meaning that the vertical seaquake loading has small influence in the transversal direction for the inelastic model (Figure 5a, Figure 6a and Figure 7a).

The longitudinal displacements show a drift of the tunnel sections. Particularly, the tunnel section near the shore shows the largest drift, caused by the high yielding deformation in the anchoring bars at this position and the proximity to the dissipative control devices, see Figure 5(c), Figure 6(c) and Figure 7(c).

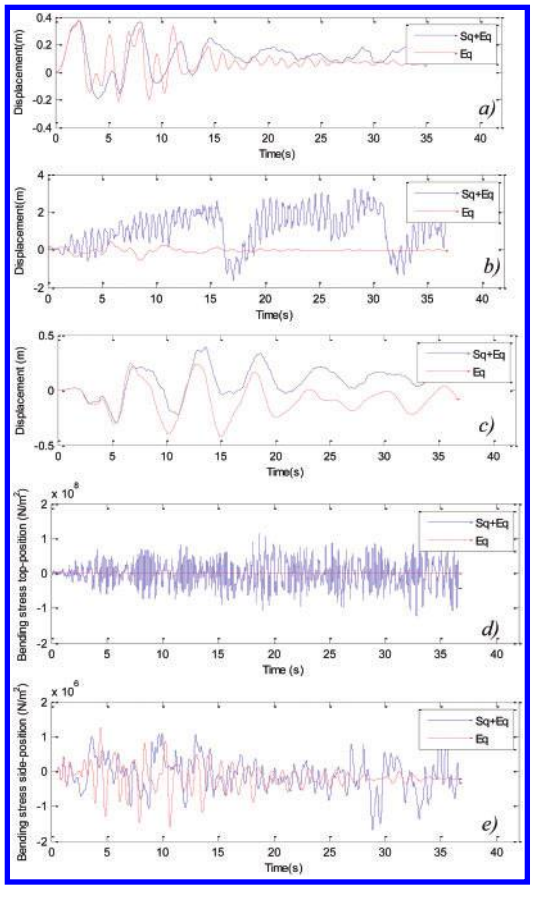

Figure 6. Tunnel section 18 (quarter-span). Transversal displacement (a), vertical displacement (b), longitudinal displacement (c), bending stress at top-position (d), bending stress at side-position (e).

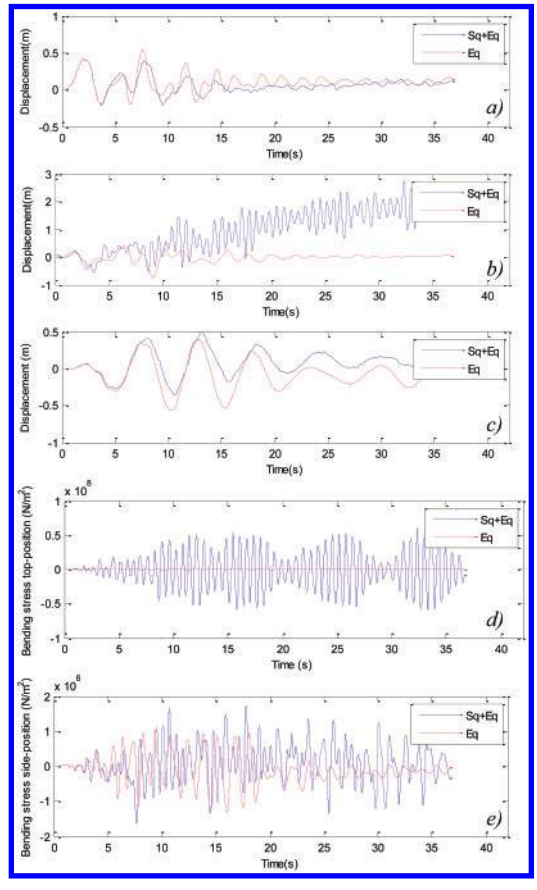

Figure 7. Tunnel section 33 (mid-span). Transversal displacement (a), vertical displacement (b), longitudinal displacement (c), bending stress at top-position (d), bending stress at side-position (e).

From Figures 5b-7b, the vertical displacements for the 'Sq+Eq' loading are larger than those in 'Eq' conditions, particularly at the quarter and the mid-span. Especially, the 'Sq+Eq' loading leads to larger values of the bending stress in the tunnel top-position (see Figures 5d–7d). Furthermore, taking a comparison between bending stress at the tunnel top-position in Figure 6d and Figure 7d, the seaquake effects enlarge the bending stress to a large degree, compared with only earthquake excitation.

Finally, comparing the bending stress in tunnel side-position at quarter-span and mid-span, see Figure 6e and 7e, the amplitudes in the 'Sq+Eq' case are close to those of the 'Eq' case, showing how the seaquake has little influence on the bending stress on the section side-position due to being these positions close to the neutral axis for bending when the bending moment acts in the vertical plane.

5 CONCLUSIONS

In this paper a SFT case study in a finite element software has been developed under different earthquake excitations, namely the multiple-support and the seaquake one. Dissipation devices have been implemented and, from the results so far obtained which relate to a single earthquake realization, they perform efficiently especially when both multiple-support and seaquake loading are considered together. As it concerns the other source of energy dissipation herein considered, that is to say energy dissipated by exploiting the inelastic behavior of the mooring system material, the anchoring bars largely exceed the yielding stress not only near the shore, where is can be expected due to the shorter length of the bars, but also at the quarter-span and mid-span along the tunnel.

The seaquake effect mainly induced a response in the vertical plane. Related to this aspect, it mainly affects the vertical displacement and the bending moment in the horizontal plane, and also this influences more the tunnel bending stress at the cross-section top position.

It can be thus inferred that seaquake effects will increase the probability of damage, both for the higher stress in the tunnel and for the higher deformation in the mooring bars. It follows that to this source of

excitation it should be paid a larger attention in the future designs.

An innovative solution for earthquake resistant hybrid steel-concrete systems with replaceable dissipative steel links

A. Zona, G. Leoni & A. Dall'Asta
Univesity of Camerino, Italy

T. Bogdan, C. Braham & H. Degée
University of Liège, Belgium

ABSTRACT: In this work innovative Hybrid Coupled Shear Walls (HCSW) are considered, their design is discussed, their efficiency and limitations evaluated by means of nonlinear static (pushover) analysis. Different numbers of storeys, wall geometries and design assumptions are studied in order to give an overview of situations of interest in European seismic prone areas. The design of an experimental test regarding the performance of the connection of a seismic link embedded in a concrete shear wall is presented. This study is part of a larger research project named INNO-HYCO (INNOvative HYbrid and COmposite steel-concrete structural solutions for building in seismic area) funded by the European Commission.

1 INTRODUCTION

Steel-concrete hybrid structures are of current limited application for construction in seismic areas, compared to classical steel-concrete composite structures. However, their use seems promising provided that suitable structural schemes and proper design methods are identified and developed. While the deformation demands for the steel and concrete components in traditional composite structures are in the same range (since concrete and steel are part of a same structural member), hybrid structures allow a more efficient design of both the reinforced concrete and the steel structural elements. In this context, the present paper proposes an innovative hybrid solution coupling concrete shear walls by steel link elements tailored to act as dissipative replaceable fuses. The concrete wall is designed to control the stiffness while the links are controlling the resistance and optimized for an efficient dissipation of the seismic energy. Preliminary design is discussed and efficiency and limitations of the system are evaluated by means of nonlinear static and dynamic analyses. Different numbers of storeys and different global geometries of the structural system are examined in order to give an overview of situations of interest in European seismic prone areas.

Objective of the research project INNO-HYCO (INNOvative HYbrid and COmposite steel-concrete structural solutions for building in seismic area), funded by the European Commission, is the study of steel-concrete hybrid systems obtained by coupling reinforced concrete elements (e.g., walls and shear panels) with steel elements (e.g., beams and columns). Such systems should permit to exploit both the stiffness of reinforced concrete elements, necessary to limit building damage under low-intensity earthquakes, and the ductility of steel elements, necessary to dissipate energy under medium- and high-intensity earthquakes. Such hybrid systems might represent a cost- and time-effective type of construction since: (i) simple beam-to-column connections could be used for the steel frame constituting the gravity-resisting part, (ii) traditional and well-known building techniques are required for the reinforced concrete and steel components.

2 COUPLED SHEAR WALL SYSTEMS

2.1 *Conventional systems*

Coupled shear wall systems obtained by connecting reinforced concrete shear walls by means of beams placed at the floor levels constitute efficient seismic resistant systems characterized by good lateral stiffness and dissipation capacity. Structural steel coupling beams (Figure 1) or steel-concrete composite coupling beams provide a viable alternative (e.g. El-Tawil et al. 2010), particularly for cases with restrictions on floor height. The coupling beam-wall connections depend on whether the wall boundary elements include structural steel columns or are exclusively made of reinforced concrete elements. In the former case, the connection is similar to beam-column connections in steel structures. In the past decade, various experimental programs (El-Tawil et al. 2010) were undertaken to address the lack of information on the interaction between steel coupling beams and reinforced concrete shear walls. Coupled shear wall systems suffer from being difficult to be repaired after strong earthquakes.

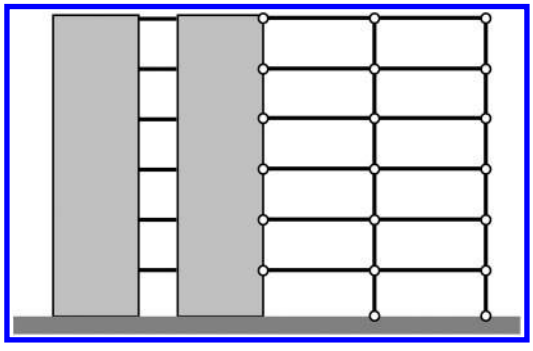

Figure 1. Example of conventional hybrid coupled shear wall system connected to a gravity-resisting steel frame with pinned beam-to-column joints.

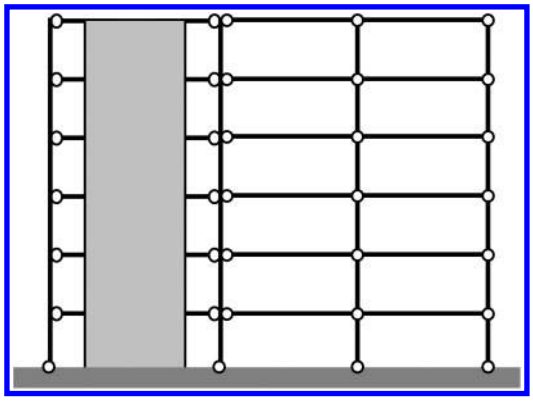

Figure 2. Example of innovative hybrid coupled shear wall system connected to a gravity-resisting steel frame with pinned beam-to-column joints.

2.2 *Innovative systems*

An example of innovative hybrid system is the reinforced concrete shear wall with steel links depicted in Figure 2. The connections between steel beams (links) and the side steel columns are simple: a pinned connection ensures the transmission of shear force only while the side columns are subject to compression/traction with reduced bending moments.

The structure is simple to repair if the damage is actually limited to the link steel elements. To this end, it would be important to develop a suitable connection between the steel links and the concrete wall that would ensure the easy replacement of the damaged links and, at same time, the preservation of the wall. Clearly, the proposed hybrid system is effective as seismic resistant component if the yielding of a large number of links is obtained.

3 DESIGN OF HCSW SYSTEMS

3.1 *Case study*

Two case studies are considered: 4-storey and 8-storey steel frames with the same floor geometry as shown in Figure 3. For each floor the vertical loads are $G_k = 6.5\,\text{kN/m}^2$ and $Q_k = 3.0\,\text{kN/m}^2$, while the floor total seismic mass is $1200\,\text{kNs}^2/\text{m}$. Interstorey height is $h = 3.40\,\text{m}$. The gravity-resisting frame has continuous columns (Table 1) pinned at the base. Beams (IPE500) are pinned at their ends. Steel S355 is used for columns, beams, and links. Selected materials for the reinforced concrete walls are concrete C25/30 and steel reinforcements S500.

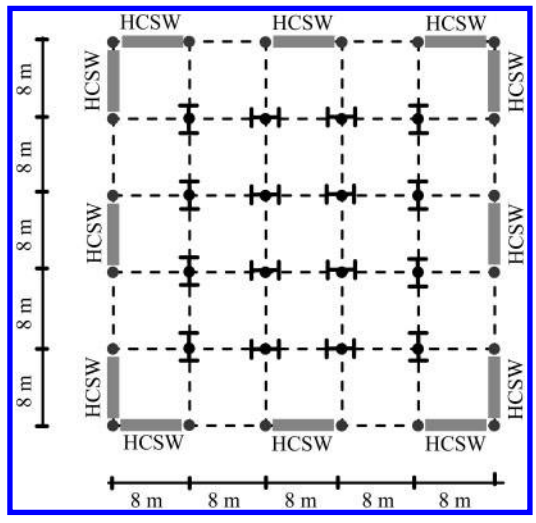

Figure 3. Floor geometry of the benchmark structures with positions of the HCSWs.

Table 1. Wide-flange cross sections of the columns of the vertical-resisting structure.

Storey #	4-storey case	8-storey case
8	–	HE 220 B
7	–	HE 220 B
6	–	HE 300 B
5	–	HE 300 B
4	HE 220 B	HE 450 B
3	HE 220 B	HE 450 B
2	HE 300 B	HE 450 M
1	HE 300 B	HE 450 M

The assumed seismic action is represented by the Eurocode 8 type 1 spectrum with $a_g = 0.25\,\text{g}$ and ground type C. Both verifications of the ultimate limit state (ULS) and of the damage limit state (DLS) are required.

3.2 *Preliminary design*

Preliminary designs based on the conventional force approach were made in order to identify possible optimal geometries. Two conditions were required in the design: (i) strength verification at ULS under the lateral forces derived from the design spectrum following the prescriptions in Eurocode 8.

A large number of HCSWs with different dimensions of the reinforced concrete shear walls and link lengths were evaluated and the seismic behaviour of the most promising designs was assessed through nonlinear static (pushover) analysis and multi-record incremental nonlinear dynamic analysis.

In the 4-storey case it is observed that reinforcements in the concrete wall yield together with yielding in bending of the steel links in the first three storeys. Afterwards, further plastic dissipation is fostered by the successive yielding in bending of the links at the last storey. Then the peak strength of the reinforced concrete wall is achieved leading to the maximum sustained base shear before leading the bracing system to failure due to failure of the reinforced concrete wall. A different seismic performance is observed in the 8-storey design, where the steel links at all storeys yield in bending before any damage in the reinforced concrete wall. Afterwards reinforcements yields and shortly afterwards all links yield in shear. The concrete peak strain is attained but the bracing system is still able to exhibit global hardening. Collapse is reached when the link at the fifth storey fails in combined banding and shear. Despite these differences, pushover verifications are satisfied (capacity displacement larger than target displacement) in both case studies. In addition, it is observed that the HCSW systems designed are not prone to soft storey formation, even when the yielding of the steel links is not simultaneous, thanks to the contribution of the reinforced concrete wall.

3.3 *Design based on rules inherited from other systems*

The results obtained in this first design stage directed the research towards the definition of a design approach that inherits recommendation for capacity design from other structural systems involving similar dissipative mechanisms in the links, i.e. eccentric braces in steel frames, as well as indication to reduce damages in the reinforced concrete wall. The design procedure attempted in this second stage of this research is subdivided in the following steps:

- Step 1: assign dimensions of the reinforced concrete wall by selecting height-to-length ratio and thickness;
- Step 2: design of the steel links based on bending and shear obtained from linear analysis (e.g. spectrum analysis) with assigned uniform overstrength; design of the steel side columns using the summation of the yield shear forces of the links (amplified with $1.1\gamma_{ov}$) as design axial force;
- Step 3: design of the wall longitudinal reinforcements to provide an assigned over-strength compared to the bending moment obtained from linear analysis; design of the transverse reinforcements to avoid shear collapse of the wall considering the maximum shear at the base derived from the limit condition of yielded steel links and yielded wall in bending; reinforcement detailing according to Eurocode 8 DCM rules.

The application of the above design rules and the necessity to limit the shear force at the base of the wall brought to the adoption of six HCSW systems for each direction (Figure 3). In order to investigate the main geometric and design parameters, 18 cases were designed, comprising three height-to-length ratios of the wall taken with constant thickness and relevant links (length 600 mm for the 4-storey case and 660 mm for the 8-storey case) designed with over-strength equal to one, longitudinal reinforcements in order to obtain three values of wall over-strength (1.00 in cases labelled as R10, 1.25 in cases labelled as R12, 1.50 in cases labelled as R15), as detailed in preliminary report “” produced by ULg. Reinforcement bars were concentrated in the lateral confined parts of the wall as for Eurocode 8 DCM rules. Significant quantities of longitudinal bars were required, especially for R15, in some cases exceeding Eurocode upper limits.

4 DESIGN OF DOWN SCALED CONNECTION

4.1 *General assumptions*

The tests aim to characterize the performance of the connection of a seismic link embedded in a concrete shear wall and the efficiency of the capacity design of such a system, with the objective of developing a plastic hinge in the replaceable part of the link, acting as a fuse, with all other components of the connection remain undamaged. For the materials, design values are used concrete C 25/30, steel grades (S275 for the link, S355 for the embedded part and S500 for reinforcements). The links are defined as being intermediate and the link stiffeners number is determined using a linear interpolation and the link rotation angle value θ_p. Face bearing plates are placed at the face of the concrete wall, in order to keep the integrity of the concrete part and for the yielding to take place in the profile section or rebars. The concrete wall dimensions are consistent with the experimental stand dimensions and the embedment length of the steel profile into the concrete part.

Two topologies are considered for what regards the embedment of the profile in the concrete shear wall and the connection of the replaceable part of the link to the embedded part.

– *Configuration No. 1 (Figure 4)* – The bending moment transferred by the link to the wall is resisted by shear studs, while the beam splice connection is placed at a distance of 100 mm from the top face of the concrete wall in order to allow an easy bolting of the removable part.

The design assumptions consists in forcing the creation of a plastic hinge in the replaceable part of the link and to capacity-design the part of the fixed part of the link embedded in the shear wall, the link-to-shear-wall connection and the bolted beam splice connection between the fixed and replaceable parts of the link.

The required number of shear studs is influenced by the value of the fore V, as shown in Figure 4. The

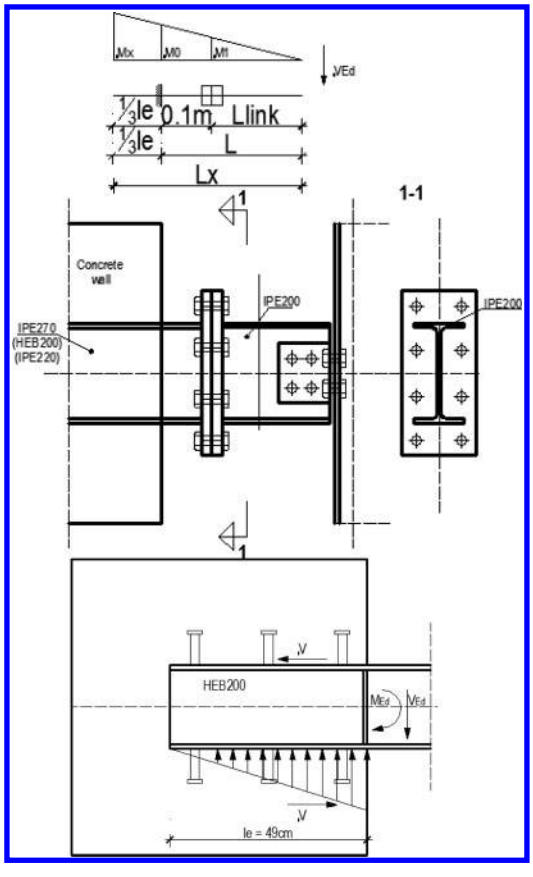

Figure 4. Configuration No. 1 – mechanical model.

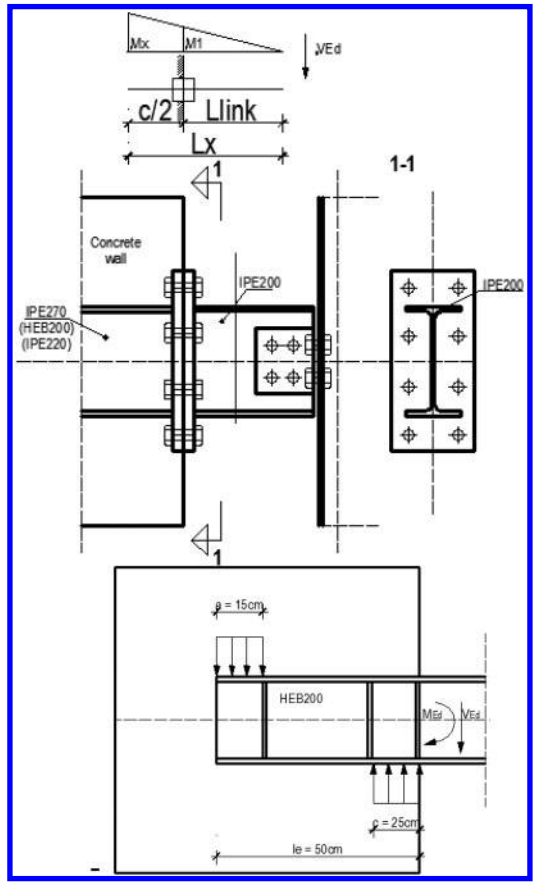

Figure 5. Configuration No.2 – mechanical model.

embedment length is determined using equilibrium equations of the mechanical model.

– *Configuration No. 2 (Figure 5)* – The bending moment transferred by the link to the wall is balanced by a couple of vertical forces. The connection link – embedded steel profile is placed at the top of the wall using threaded bushings.

The main differences with configuration 1 are:

- The positioning of the beam-splice connection of the fuse with the embedded part of the link. The end-plate is positioned right at the face of the shear wall, acting thus also as face bearing plate. Moreover, the connection is assumed to be realized in practice with threaded bushes instead of regular bolts;
- The assumed load transfer mechanism between the embedded part of the link and the concrete shear wall. In this case, no shear studs are used and a longer embedded part is considered in order to develop a static scheme where the applied bending moment is resisted by a couple of vertical load, activating the compression resistance of the contact profile-concrete.

According to the transfer mechanism, the embedded part of the profile is designed assuming conservatively that the bending moment increased linearly until the location of the first reaction force applied by the concrete on the profile.

The design of the beam splice connection has been realized with CoP, software developed by Universities of Aachen and Liege, based on the component method. The aimed and governing failure of the connection is failure of the steel bolts, before yielding of the beam flange of the profile.

5 SEISMIC BEHAVIOUR OF HCSW SYSTEMS

5.1 *Modelling assumptions and selected results*

The seismic behaviour of the designed HCSW systems was assessed through displacement-controlled nonlinear static analysis under applied lateral loads (pushover analysis), using the software FinelG. For the sake of simplicity, the evaluation of the seismic performances is based on a plane model of a single HCSW connected to two continuous columns equivalent to the relevant parts of the gravity-resisting steel frame, as shown In Figure 6 (4-storey case).

The reinforced concrete shear wall is represented by frame elements using a fibre description for the behaviour of the concrete in the longitudinal direction, allowing an accurate estimation of the behaviour

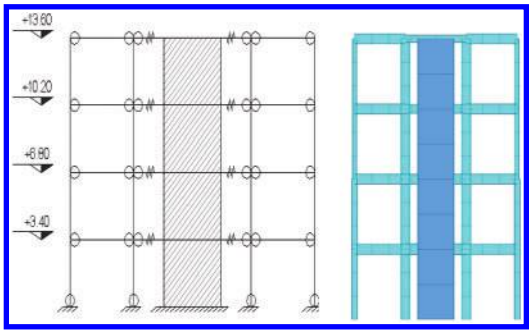

Figure 6. Numerical model.

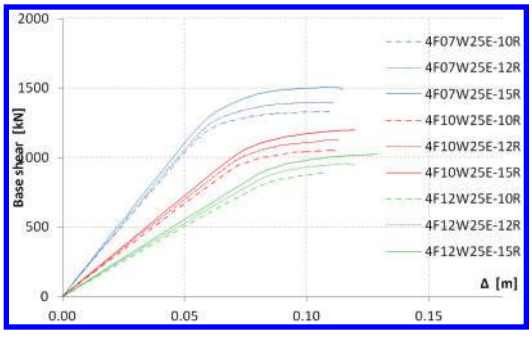

Figure 7. Pushover curve – global comparison.

in bending and thus of the possible plastic hinge at the bottom of the wall. Reinforcement of the shear wall is assumed to be sufficient to avoid a shear failure of the wall. The steel shear links are modelled using non linear frame elements for the bending contribution as well as non linear shear springs introduced at mid span of each steel link to account for the shear deformability of the link and for the possible yielding in shear of the links. This additional shear spring is required for a correct modelling of the system since most links are classified as intermediate according to EC8 definition and are thus more or less equally prone to shear or bending failure. Interaction between flexural and shear plastic deformations is considered in the post-processing of the results.

For all materials, the design values of the resistance are used ($f_{cd} = 20$ MPa, $f_{y,s} = 435$ MPa, $f_{y,p} = 355$ MPa). Steel behaviour is modelled by a bilinear elastic-perfectly-plastic law without strain hardening. Concrete is by a parabola-rectangle in compression and a linear behaviour in tension with tension stiffening. Particular values of the strain are $\varepsilon_{c2} = 0.002$ (end of the parabolic behaviour) and $\varepsilon_{cu2} = 0.0035$ (end of the rectangular behaviour). No confinement is considered for the concrete in compression.

Pushover curves (total base shear versus top displacement) for the 4-storey cases are shown in Figure 7, while for the 8-storey case is shown in Figure 8.

It is observed that increasing the wall over-strength has positive effects as the yielding of reinforcements and failure of the wall (attainment of the ultimate strain

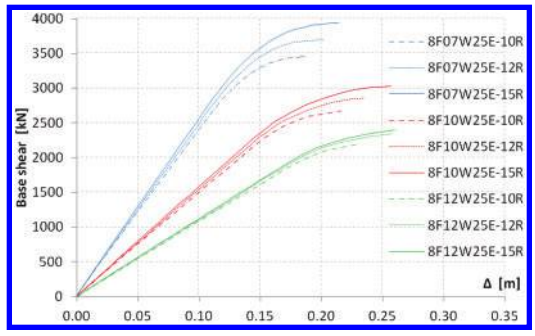

Figure 8. Pushover curves – global comparison.

in the concrete) are delayed, resulting in an increment of the lateral load capacity as well as in an increment of the global ductility of the HCSW systems. However, these benefits are obtained at the expenses of an often excessive congestion of reinforcements. It is also observed that a reduction of the wall aspect ratio allows a higher lateral load capacity as well as a higher ductility. Given that a reduction of the aspect ratio means smaller steel links and longer walls that allow more space for reinforcements, the design should be based in practice on a limitation of the wall aspect ratio, possibly limited to suggested values $H/l_w \leq 10$.

5.2 *ULS and DLS verifications*

Outcomes in terms of pushover curves presented in section 5.1 can be analyzed with respect to different ULS and DLS criteria. This allows in particular the calculation of specific performance points associated the activation with different limit states and hence, based on the N2 method proposed in Annex B of Eurocode 8, the calculation of the acceleration level corresponding to these performance points. In the present contribution, only preliminary assessments are given. The outcomes will be more deeply investigated in the next publications on the INNO-HYCO project. Three different limit states are taken into consideration:

- *ULS1: Maximum compressive strain reached in the concrete shear wall*. No confinement is conservatively taken into account. Accounting for the confining effect by imposing rules similar to those prescribed by EC8 for reinforced concrete walls could certainly improve the global behaviour of the system.
- *ULS2: Maximum rotation of the steel links*. In this preliminary assessment, indicative conservative values of the maximum possible rotation capacity are estimated according to the criteria proposed by FEMA 356 for seismic links in eccentrically braced structures. The values must be adjusted in a next stage on the base of experimental test results to be carried out in the context of the INNO-HYCO project.
- *DLS: Maximum allowable inter-storey drift.* Associated values of the acceleration should be referred to acceleration level for DLS, smaller than the reference design value of 0.25 g.

6 CONCLUDING REMARKS

A selection of results involving an innovative steel-concrete hybrid coupled shear wall systems developed under the European research project INNO-HYCO was briefly illustrated. The analysis of the case studies designed according to the adoption of existing rules in the Eurocodes has highlighted the potentialities of the proposed innovative HCSW systems, namely: it is actually possible to develop a ductile behaviour where plastic deformation are attained in the steel links and limited damage occurs in the reinforced concrete wall; the interstorey drifts up to collapse are quite regular regardless of the non-simultaneous activation of the plastic hinges in the steel links and/or in the reinforced concrete wall; the adopted design approach based on well-known concepts and procedures already available in the Eurocodes give a promising starting design solution, although it appears that using the behaviour factor proposed by Eurocode 8 for composite walls overestimates the deformation capacity of the HCSW, in particular for short walls. On the other hand, the following issues have been encountered: the designed solutions require additional studies to clarify the relationships between wall and links in order to provide additional design recommendations as integration of the Eurocodes; the slenderness of the HCSW systems needs to be better controlled in order to limit the negative effects of geometric nonlinear effects and improve the behaviour at the damage limit states. However, the sensitivity of the response to rotation capacity of the links and to confinement of the concrete needs also to be deeper studied, including in the context on time-history analysis. The upcoming developments of this research work involve the definition of a design procedure compatible with the current Eurocode 8 recommendations and in-depth experimental studies on the connections between reinforced concrete wall and replaceable dissipative steel links.

ACKNOWLEDGMENT

Support for this research from the European Commission, Research Fund for Coal and Steel, Steel Technical Group TGS 8 “Steel products and applications for building, construction and industry”, is gratefully acknowledged. H. Degée also acknowledges the support received from F.R.S.-FNRS.

Effectivenss of seismic protection by added damping: An energy approach

I. Ladar, O. Prodan & N. Chira
Technical University of Cluj-Napoca, Romania

ABSTRACT: The contribution proposes an analytical tool to assess the energy demand to be used in energy based structural design. An important step in energy based structural design is the assessment of energy demand that is going to take the unprepared structure into post-elastic incursions. While added damping may reduce this amount of energy, the designer is, still, uncertain of its efficacy. Proposed technique allows for an immediate and simple check of this efficacy. Several numerical studies have been performed on full scale steel multistory structures aiming at computation of energy components developed during seismic action. Also, a set of laboratory seismic tests have been conducted to the same objective on scaled down steel structures. Processed results have been synthetized into the proposed ratio for assessing the efficacy of added damping. Its values and time-variation emphasize allow for immediate conclusions and, possible, changes regarding the amount of added damping during the design activity.

1 INTRODUCTION

The objective of the present contribution is to introduce an energy approach to the assessment of effectiveness of passive protection of steel multistory structures equipped with passive seismic protection via added viscous damping. Numerical and experimental studies have been carried out to back up the assessment technique of the added viscous damping. Current techniques are, mainly, based on checking the values of several static and kinematical parameters against their code prescribed maximum values. This is the standard and correct way in the case of structure design. A rather popular approach is to compare the reduction in lateral displacements induced by seismic excitation. Indeed, the reduction – via seismic protection – in lateral displacements of shear multistory structures seismically induced is an easy, immediate and visible effect of any system of seismic protection. Nevertheless, the seismic response of structures is a broader concept that includes, beside classical components (such as stresses and deformations), synthetic and stronger components such energy quantities. Since Housner's pioneering work on energy approach to seismic input [1], several outstanding works and results have paved the way to present day energy based seismic design. Among the first objectives of the new field of research has been the assessment of seismic input energy [2], [3], [4], [5]. Next clear cut objective consists in exploiting the new analysis tool to assess the future damages that a prescribed earthquake will in inflict into a given structure [6], [7]. Based on possible seismic induced damages, the computation of structure capacity to dissipate the seismic input energy – the already popular – seismic energy demand became a new performance objective [8], [9]. As expected, the structures had to be equipped with industrial devices that increase their energy dissipating capacity. Almost entire scene has been set for the structural design based on energy approach while the results appeared continuously [10], [11], [12]. This is the most advanced stage in the new domain of energy based structural computation. The up to day level of energy approach to structural computation did not prevent a continuous research over the whole issue of the field. Present contribution belongs to the narrow topics of assessing the effectiveness of added viscous damping by using energy concepts and quantities. The supplementary damping is provided in the form of linear viscous damping by viscous dampers inserted into steel multistory structures. The assessment of effectiveness of seismic protection is not just a tool to check the quality of the final product (seismic protection). It is necessary in the more elaborated activity of structural design, mainly, in designing the (hysteretic) energy demand of future structure. Providing for energy demand (hysteretic dissipating capacity of designed structure) is a must of today structural engineering. The relevance of an adequate tool to measure the effectiveness of seismic protection system is generated by the importance of providing for energy demand in structural design activity. Since the seismic protection via energy dissipating equipment has been implemented, several "instruments" for assessing effectiveness of seismic protection have been proposed [13], [14]. Energy approach to structural computation requires an energy based technique to such an assessment. The contribution introduces such a scalar parameter that focuses on expressing the capacity of a structure to absorb seismic energy. If E_i is the seismic input energy and E_d is the total dissipated energy (by inherent and added damping), the quantity (E_i–E_d) expresses the energy that has to be "faced" by the

equipped structure through deformations. Since the structure has been provided with added damping, the deformations are allowed in the elastic domain only, usually limited by design codes to small values. The smaller the quantity (E_i–E_d) the smaller seismically induced elastic deformations. Consequently, the ratio $E_i/(E_i–E_d)$ is directly proportional to the capacity of designed structure to avoid plastic deformations and to keep elastic deformations inside the code provided limits. The contribution proposes the above ratio as a measure of the effectiveness of seismic protection by added damping. The proposed ratio is capable to express the effectiveness of added damping at every instant of seismic action. Usually, at the end of seismic action, the energy balance may be "reduced" to its simplest form (1)

$$E_d = E_i \tag{1}$$

since the kinetic energy E_k and elastic strain energy E_s do no longer contribute (due to their tendency to vanish towards to the end of seismic action) to the energy balance

$$E_k + E_s + E_d = E_i \tag{2}$$

valid at an instant t of seismic action. By expressing the effectiveness of added damping at every instant, an adequate seismic behavior of designed structure could be achieved over the entire duration of earthquake.

The contribution is structured into four parts: a general view of energy balance of multi degree of freedom steel structures, a theoretical study of a set of multistory steel structures via energy approach, a presentation of numerical results specific to energy approach associated to a set of laboratory tested structures seismically acted and finally, an emphasize on proposed technique of assessing the effectiveness of added damping together relevant concluding remarks.

2 ENERGY FORMULATION OF MDOF STRUCTURES UNDER SEISMIC ACTION

Classical technique regarding the dynamic model, energy components, energy balance equation of seismically acted shear multistory steel structures is adopted: the n – dimension vector of degrees of freedom u(t) together the associated velocities $\dot{u}(t)$ and accelerations ü(t), ground seismically induced acceleration $\ddot{u}_g(t)$, the nxn inertia matrix **M**, nxn damping matrix **C** (inherent Rayleigh type and added damping), the nxn stiffness matrix **K**, unit n vector dimension 1.

Modal analysis of damped free vibrations lead to the well-known modal results: eigen periods T_j, eigen circular frequencies ω_j, eigen n vectors Φ_j, modal nxn matrix Φ.

In what regards damping, the Rayleigh type damping matrix is processed from its proportional form (3)

$$\mathbf{C} = \alpha\cdot\mathbf{M} + \beta\cdot\mathbf{K} \tag{3}$$

to its diagonal form (4) following [15].

$$\mathbf{c} = \mathbf{\Phi}^T\cdot\mathbf{C}\cdot\mathbf{\Phi} \tag{4}$$

The relative energy components associated to seismic behavior over the entire duration t_c of the earthquake read:

Seismic input energy

$$E_i = -\int(\dot{\mathbf{u}})^T\cdot\mathbf{M}\cdot\mathbf{1}\cdot\ddot{u}_g(t)\cdot dt \tag{5}$$

Kinetic energy

$$E_k = \int(\ddot{\mathbf{u}})^T(t)\cdot\mathbf{M}\cdot\dot{\mathbf{u}}\cdot dt \tag{6}$$

Elastic strain energy

$$E_s = \int(\mathbf{u})^T(t)\cdot\mathbf{K}\cdot\dot{\mathbf{u}}(t)\cdot dt \tag{7}$$

Energy dissipated (inherent linear viscous and added viscous damping)

$$E_d = \int(\dot{\mathbf{u}})^T(t)\cdot\mathbf{c}\cdot\dot{\mathbf{u}}(t)\cdot dt \tag{8}$$

The relative energy balance equation takes the form:

$$E_k + E_s + E_d = E_i \tag{9}$$

Relative forms (5–8) of energy components and energy balance equation (9) have been adopted as the results of laboratory tests proved to be more accurate in the case of the values of relative story displacements/velocities/accelerations in what regards their measured and computed values. The computation of integral quantities has been performed following a linear integration procedure associated to a time interval $\Delta t = 0.02$ sec.

3 THEORETICAL STUDIES

Theoretical studies have been carried out on three structures six story one bay steel frames of the same general geometry (Fig. 1), while the lateral stiffness is gradually increased through higher stiffness values of

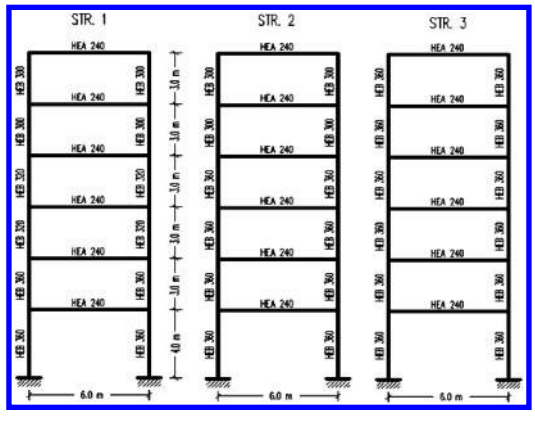

Figure 1. Steel frames STR1, STR2 and STR3.

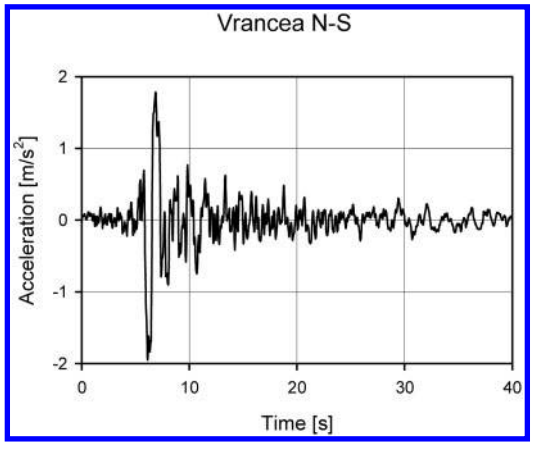

Figure 2a. Vrancea 1977 earthquake.

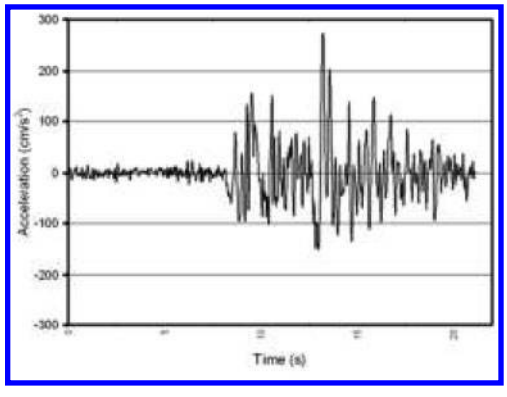

Figure 2b. Focsani 1986 earthquake.

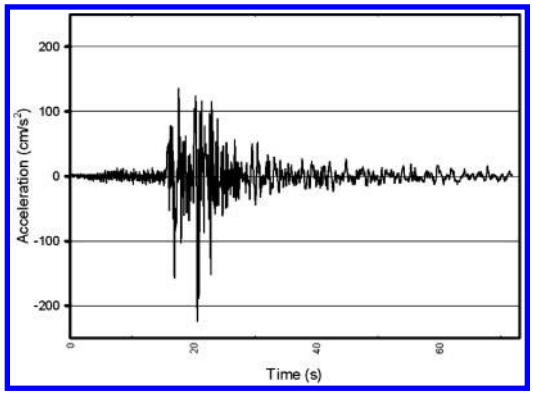

Figure 2c. Focsani 1990 earthquake.

the columns cross sections. The three structures have been designed for a peak seismic acceleration value of $a_g = 0.3\,g$ according to Romanian seismic code applied simultaneously with a gravitational loading of 60.0 kN/m on current beams and 40.0 kN/m on top beam. Several levels of damping have been considered: a reference level of 1.0% and two increased damping levels (ratio of critical damping ζ) of 5.0% and 9.0%, respectively. Story lateral displacements u_i ($i = 1 \div 3$)

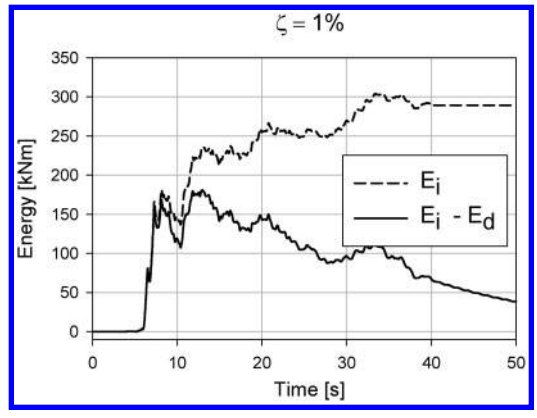

Figure 3. Energy quantities for $\zeta = 1\%$.

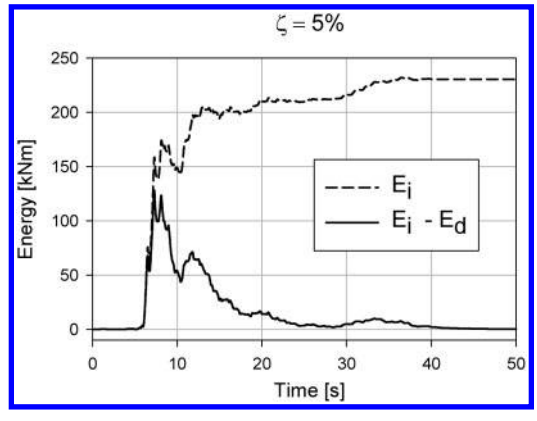

Figure 4. Energy quantities for $\zeta = 5\%$.

collected in the three degrees of freedom vector **u** ad to the general picture of dynamic MDFO model. Seismic actions are applied in the form of three recorded (in Romania) earthquakes: Vrancea 1977 (Figs 2), Focsani 1986 and Focsani 1990 – reference earthquakes in this country.

Modal and time history analyses of each frame under each earthquake have been performed and kinematical parameters (displacements, velocities and accelerations) associated to seismic behavior have been computed. The most relevant primary results (kinematical parameters) and processed parameters (energy quantities) results for the structure STR1 are presented (Figs 3–5). The area defined by E_i–E_d is the amount of energy the structure has to "face".

4 LABORATORY RESULTS

A set of three scaled down steel frames have been tested using a small seismic platform. A high flexibility has been provided to the tested frames to ensure large lateral deformations exclusively inside the elastic behavior of the tested structure. Dynamic model of the three story tested frame includes the lumped masses located in the frame joints (Fig. 6). The tests have been conducted in two cases: on the reference frames (no added

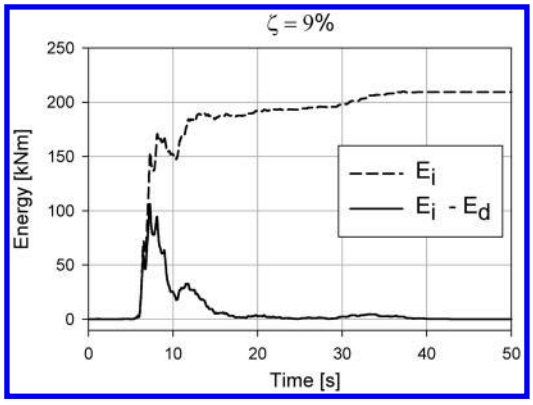

Figure 5. Energy quantities for $\zeta = 9\%$.

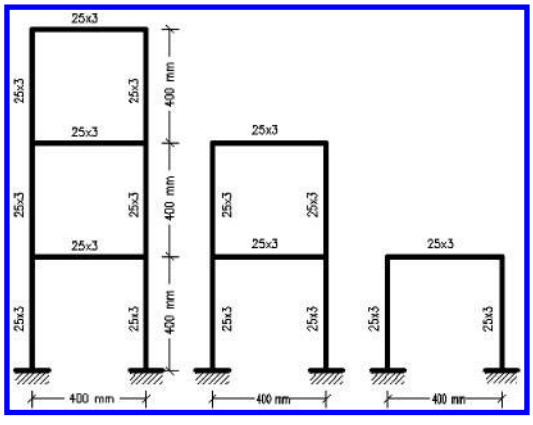

Figure 6. Laboratory tested frame. Geometry.

damping) and on the frame equipped with linear fluid viscous dampers (Fig. 7). Seismic load has been applied in the form of three recorded and processed accelerograms (Northridge 1994, Kobe 1995, Chi–Chi 1999) provided together with the shaking table.

Using digital transducers, the lateral displacements and accelerations have been recorded. In accordance to their values, the energy components are computed from equations (5–8). Variations of energy components E_i and $(E_i–E_d)$ for Kobe 1995 and Northridge 1994 emphasize their expected shape (Figs 8–9).

Proposed ratio (10) of effectiveness assessment and its variation in time have been graphically emphasized for Kobe-1995 earthquake (Fig. 10). The pseudoconstant amount of energy demand between $t = 2$ seconds and $t = 6$ seconds (Fig. 10) closely follows the shape of Kobe 1995 recorded and scaled earthquake

$$\varepsilon = (E_i - E_d)/E_i \qquad (10)$$

Variation (in time) of proposed ε for the reference structure (Fig. 10) expresses an almost constantly decreasing need of energy dissipating capacity (area under each of the two curves). Again, this shape is in accordance with the shape of accelerograms associated to the two earthquakes (a strong initial shock in the case

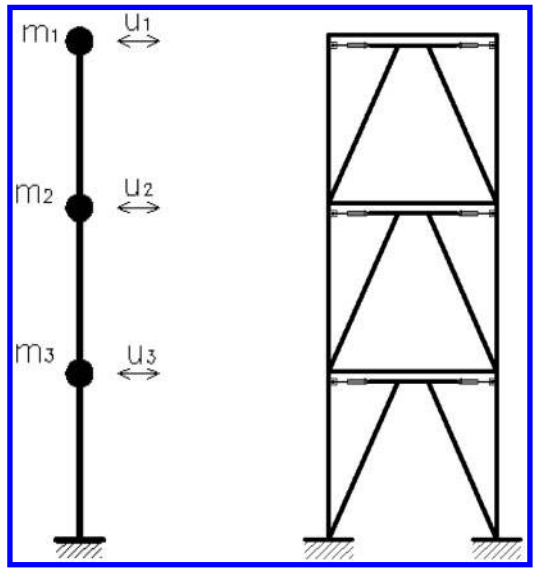

Figure 7. Dynamic model and the frame equipped with viscous dampers.

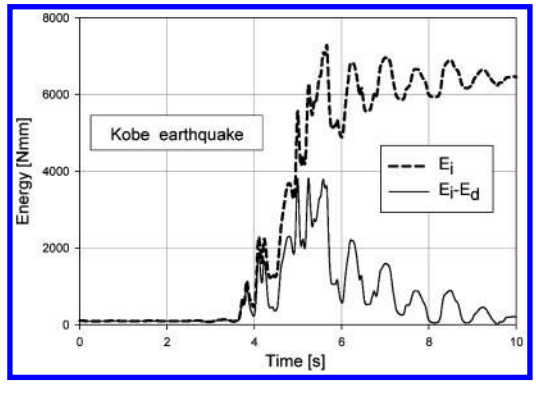

Figure 8. Reference 3 story structure.

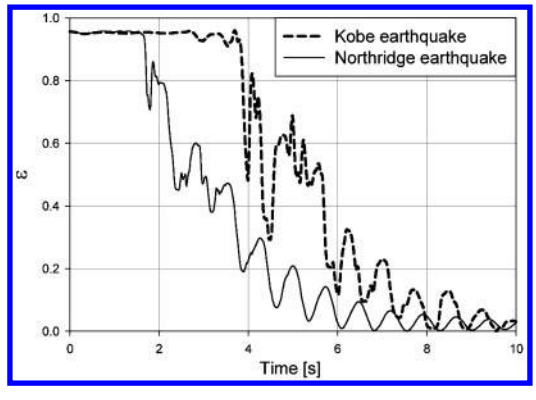

Figure 9. Reference 3 story structure.

of Northridge earthquake). Once this initial energy "hunger" is satisfied, the structure may carry on the remaining induced vibration motion. It may transmit a clear message to the structural engineer in what regards

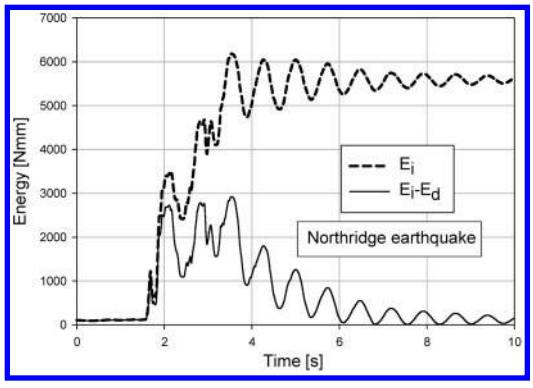

Figure 10. Effectiveness ε ratio. Reference structure.

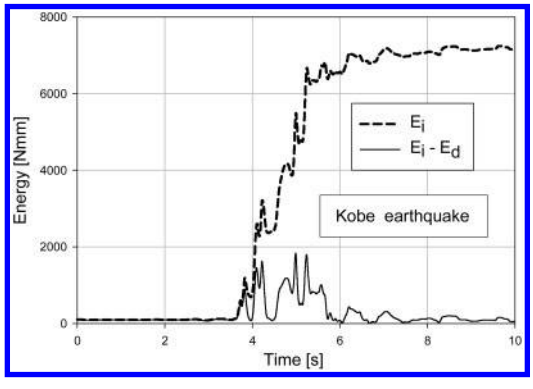

Figure 11. Structure with dampers.

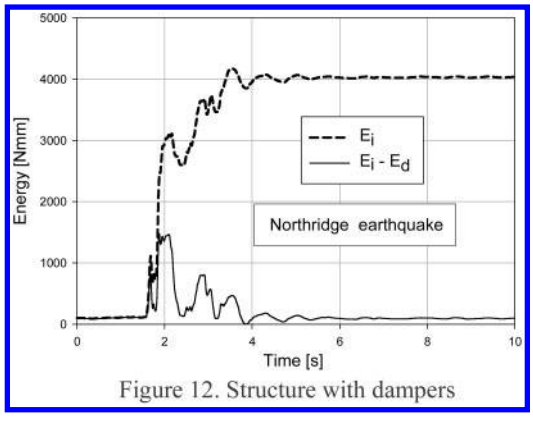

Figure 12. Structure with dampers.

the seismic protection in terms of required amount of added damping or energy absorbing devices.

Similar variations of energy quantities E_i and (E_i–E_d) for the case of structure equipped with fluid viscous dampers are, further presented (Figs 11–12). It can be noticed the small amount of energy absorbing capacity "uncovered". Indeed, the installed dampers (Fig. 7) are performing their "job" of providing energy absorbing capacity.

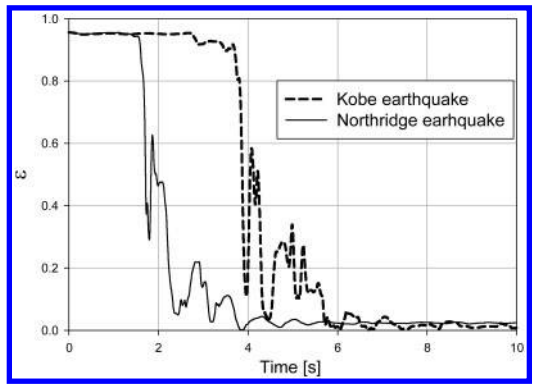

Figure 13. Equipped structure. Effectiveness ratio ε.

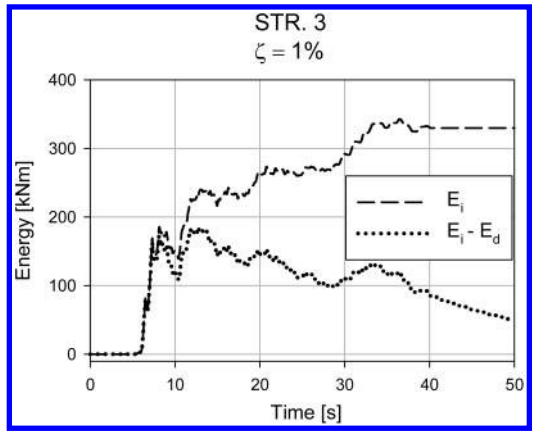

Figure 14. Energy quantities for $\zeta = 1\%$.

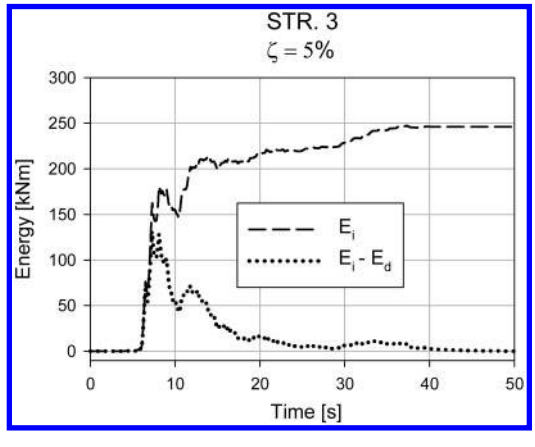

Figure 15. STR3 with $\zeta = 5\%$ damping.

A corresponding variation of proposed ratio ε for the case of structure equipped with fluid viscous dampers is presented in Figure 13.

Several other results obtained in terms of seismic input energy E_i, energy demand (E_i–E_d) in the case of structure STR3 are presented for critical damping ratio $\zeta = 1\%$ (Fig. 14), $\zeta = 5\%$ (Fig. 15) and $\zeta = 9\%$

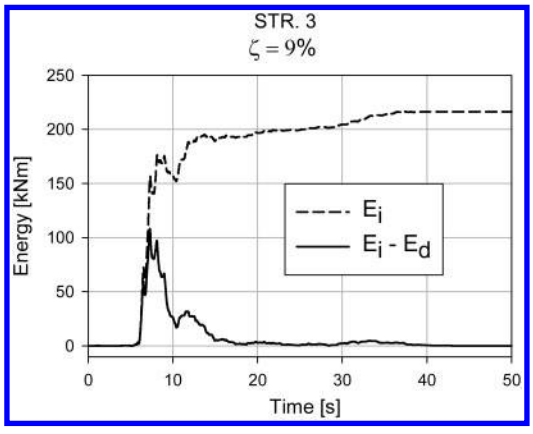

Figure 16. STR3 with $\zeta = 9\%$ damping.

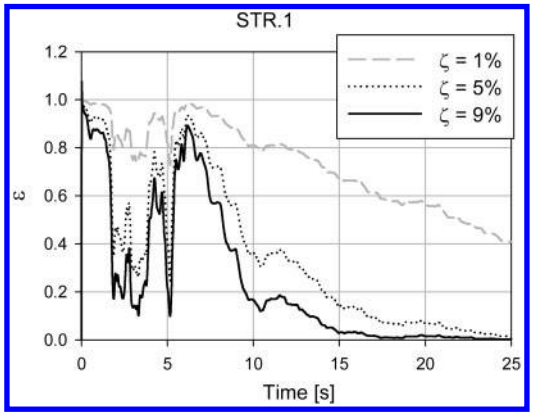

Figure 17. STR1. Effectiveness ratio ε.

(Fig. 16) are presented. The relevance of proposed effectiveness ratio ? in the case of structure STR1 for all three levels of damping, also, presented (Fig. 17).

5 CONCLUSIONS

A simple technique to assess the effectiveness of seismic protection via added damping has been proposed – in the form of energy ratio – and presented in several cases of full scale steel structures and scaled down models. Both, the values of proposed ratios and, mainly, their variation in time are capable of expressing the degree of reduction in the amount of dissipated energy by (inherent and added) viscous damping and the amount of energy that is still stored in the structure – the energy demand. The energy demand is a decisive criterion in the ingoing modern tendency of the energy based structural design. The time variation form of proposed ? ratio provides a direct, immediate, versatile and visual tool to assessing the structural weaknesses at every instant of seismic action. The possibility of assessing the contribution of added damping to seismic protection during the design process opens, in its turn, the opportunity of corroborating the added damping with an adequate (lateral, mainly) stiffness. Structural optimization regarding seismic response in terms of rigidity is an important aspect of modern design activity [16], [17], while the designer's option concerning stiffness is a decisive economical step in structural design process.

Seismic Safety Screening Method (SSSM) for slum clearance

P. Ozdemir Caglayan
Istanbul Technical University, Turkey

ABSTRACT: After October 23rd, 2011 M7.2 Tabanli-Van earthquake which caused damage in a widespread area across the Van province, government of Turkey announce that "revolutionary measures will be taken in the area of housing and public works with respect to the life safety in structures, and urban regeneration will be started soon". When the existing stock of RC buildings in Turkey with a large variety of design and construction defects is considered it is vital importance to use not only simplified but also reliable techniques, which can predict the seismic safety of the existing buildings in relatively shorter time. Seismic Safety Screening Method (SSSM), is an adaptation of the Japan Seismic Index Method considering "Specification for Buildings to be Built in Seismic Zones (2007)", some technical/non-technical properties of existing building stock in Turkey. The outcome of SSSM is the determination of buildings which are not safe enough to keep the life alive inside, or another words to decide the "Slum Clearance" by spending minimum time with reliable results.

1 INTRODUCTION

In the past, big earthquakes in Turkey have caused huge numbers of casualties and damage to structures. The Marmara earthquake in 1999 reportedly killed 17.480 persons; injured 23.781 persons and damaged 328,113 buildings in Marmara region. Though being a seismic country, earthquake-resistant standard has not been effectively applied to new constructions because of adequate control and being be unaware of earthquakes always occur suddenly without prior notice. There is a higher possibility of large number of buildings will not perform life safety level during a large seismic event. Recent earthquakes in Van province in 2011 were proved that above statement, unfortunately. Then, the government of Turkey announce that "Revolutionary measures will be taken in the area of housing and public works with respect to the life safety in structures" after October 23rd, 2011 M7.2 Tabanli – Van earthquake which caused damage in a widespread area across the Van province. They also declared that "regeneration of urban areas and slum clearance will be started soon". Turkey is an earthquake prone country where 92 % of total areas of 783,562 km^2 are located at seismic zone.

A high priority task of urban regeneration or of the slum clearance is to decide weak structures in terms of safety during the earthquakes. Determining the location of seismically vulnerable buildings structures in the current building stock is therefore a high priority task within the concept of urban renovation issues.

When the existing stock of buildings in Turkey with a large variety of design and construction defects is considered it is clear that it is practically impossible to carry out detailed structural analysis for all of the buildings. Therefore, it is vital importance to use not only simplified but also reliable techniques, which can predict the seismic safety of the existing buildings in relatively shorter time.

Seismic Safety Screening Method (SSSM), is an adaptation of the Japan Seismic Index Method, considering Turkish Earthquake Resistant Design Code and some technical or non-technical properties of existing building stock in Turkey such as older design standards, or non-engineered design, etc . The outcome of SSSM is the determination of buildings which are not safe enough to keep the life alive inside, or another words to decide the "Slum Clearance" by spending minimum time with reliable results.

The procedure presented in this paper is the secondary screening phase of a two-phase procedure for identifying potentially hazardous buildings. The first phase is much easier and used as a quick safety check to generate list of building stock and sort the inventory for the second stage.

Since reinforced concrete frame, shear wall or dual frame-shear wall structural systems are nationwide, the SSSM procedure is intended to be applicable for RC building types having number of stories free to vibrate (excluding basements) is 6 or less. Steel structures, precast structures, and other non-building structure types, however, are not covered by the procedure. SSSM is designed to calculate the capacity of a building in terms of seismic index of a building (I_S). Seismic index, I_S, will be compared with the demand of the seismicity in terms of required seismic index of a building (I_D).

Buildings identified by this procedure must be interiorly inspected. The detailed description of building characteristics based on the five basic parameters;

building location based on seismicity region and soil condition, number of floors, building plans (particularly a plan of the most critical floor), the floor height and occupancy type. The structural characteristics of the building are necessary for calculating the seismic capacity of buildings.

A large number of the buildings in Turkey have not received proper civil engineering service and they do not have any civil engineering drawings of the structural system. The data and information gathered after recent earthquakes indicated that average concrete compressive strength is as low as 10 MPa and the amount of longitudinal reinforcement bar is 1% of gross cross sectional area of columns with the tensile strength of 220 MPa on the large number of buildings. Both longitudinal and transverse bars are generally plain bars with large spacing between stirrups like 20~30 cm. Due to these facts some assumptions were made to simplify the quick assessment procedure. However, if blue prints and the construction material information are available actual values also could be used in this method.

The original method JSIM have been applied to a number of buildings damaged during 1992 Erzincan, 1998 Adana-Ceyhan and 1999 Marmara and Duzce Earthquakes. These results have been used for adaptation of the JSIM to SSSM depending on initially adopted seismic design code requirements. The calibrations of several coefficients in this method have been done after examining certain buildings in Zeytinburnu, and nine school building in Istanbul. Reliability of the method has been tested by analyzing buildings respect to requirement of "Specification for Buildings to be Built in Seismic Zones (2007)".

2 SEISMIC SAFETY SCREENING METHOD (SSSM)

Basic concept of SSSM and the original JSIM is the equal energy concept. In case of structures with relatively short natural period, dissipation energy is almost equal to maximum potential energy of the elastic system. Seismic index of a building, I_S value, is calculated by using Equation 1 below.

$$I_S = P \times D \times K \quad (1)$$

where P = seismic capacity index; D = structural irregularity index; and K = time dependent deterioration index.

Seismic index I_S is calculated with penalties if there is a irregularity or/and a deterioration on a building. I_S should be calculated separately for both earthquake directions for all critical stories of a building and the most unfavorable result should be compared with the required seismic index I_D. The required seismic index, I_D should be calculated by Equation 2.

$$I_D = P_0 \times B \times Z \times U \quad (2)$$

where P_0 = index for basic seismic demand; B = index for regional seismicity; Z = index for local soil conditions; and U = index for usage. Index B should be taken as 1.0 for high seismicity and never lower than 0.5 in any case. Index Z varies for soil conditions from 0.80 (for rock or stiff soil) to 1.00 (soft soil). Usage index, U is 1.0 for residential buildings, 1.5 for buildings to be utilized immediately after the earthquake.

Based on comparison of indices, the seismic safety of the building can be estimated. If for any of the comparison cases is $I_S < I_D$, then it is concluded that the performance of the building is not enough for life safety, and preventive measures should be taken.

Table 1. Classification of Vertical Members.

Elements	Definition	Ductility Index R
Columns	$h_0/D > 2.0$	$Rc = 1.0$
Short Columns	$h_0/D < 2.0$	$Rsc = 0.8$
Walls	shear wall	$R_w = 1.0$

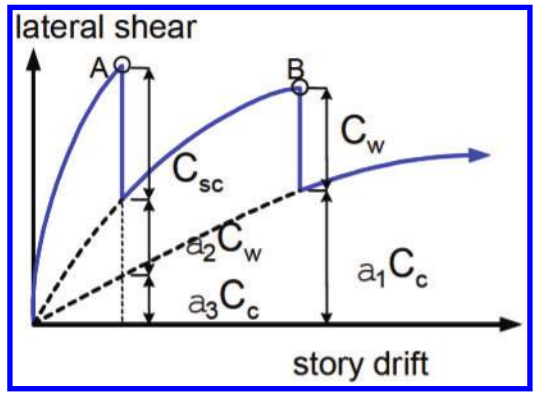

Figure 1. Displacement compatibility of vertical members.

2.1 *Seismic capacity index, P*

Seismic capacity index, P, is a function of strength index, C and ductility index, R. The C is computed with the lateral strength of vertical members based on the assumption that beams are strong enough and the expected structural damage on beams cannot be as important as vertical elements' damages. Vertical structural members are classified into three groups as columns, short columns and shear walls since ductile behavior of elements are different. The definitions of these groups are given in Table 1.

The calculation of P index differs at each floor of the building in accordance with Equation 3.

$$P_i = \frac{(n+1)}{(n+i)} \sum (a \times C) \times R \quad (3)$$

where n = number of stories of a building; i = number of the story where the calculation is done (for a ground floor i = 1); C = strength index of a vertical member, and R = ductility index, a = strength reduction factors due to displacement compatibility as shown Figure 1.

On the figure above C_c = strength index of a column; C_w = strength index of a shear wall; C_{sc} = strength index of a short column, and a1 = 0.7; a2 = 0.7; a3 = 0.5.

$$P = (n+1/n+i) * (C_{sc} + a_2 C_w + a_3 C_c) * R_{sc}$$
$$P = (n+1/n+i) * (C_w + a_1 C_c) * R_w \quad (4)$$
$$P = (n+1/n+i) * (C_c) * R_c$$

2.2 *Structural irregularity index, D*

Structural irregularity index is related with the irregularities in plan and irregularities in elevation of a building. In the "Specification for Buildings to be Built in Seismic Zones (2007)" six types of irregularities are described. Three of these are in plan and three in elevation. Since the seismic index, I_S is a production of three sub-indices (Eqn. 1) structural irregularity index, D, negatively affects the result. If building is an irregular structure, the seismic index, I_S could be reduced 40% by the structural irregularity index, D. The details of structural irregularity index, D will not be given in this study.

2.3 *Time dependent deterioration index, K*

Influence of structural defects such as deflection, cracking, and corrosion is taking into account with time dependent deterioration index, K on the seismic index, I_S. Site inspection is necessary for the estimation of the time dependent deterioration index, K. The seismic index, I_S could be reduced 30% by the time dependent deterioration index, K.

3 BASIC SEISMIC DEMAND INDEX, P_0

Seismic index of a building, I_S should be greater than the required seismic index, I_D. The basic seismic demand index, P_0 is the most critical parameter for the method. In TERDC-2007, Total Equivalent Seismic Load (base shear), V_t acting on the entire building in the earthquake direction considered will be determined by Equation 5 below:

$$V_t = \frac{W x A_0 x I x S(T)}{R_a(T)} \geq 0.10 x A_0 x I x W \quad (5)$$

where W = total weight of the building ($\Sigma G + nQ$); A_0 = effective ground acceleration coefficient; I = building importance factor; $S(T)$ = spectrum coefficient, $R_a(T)$ = seismic load reduction factor; and T = natural period of the building.

The lateral load carrying capacity of the ground floor, Q_g can be expressed by Equation 6 in the SSSM, and it should be greater than the base shear, V_t.

$$Q_g = P_g x W \;\; ; \;\; Q_g \geq V_t \;\; ; \;\; P_g \geq \frac{A_0 x I x S(T)}{R_a(T)} \quad (6)$$

where P_g = seismic capacity index of ground floor; and W = total weight of the building.

When a non-ductile ($R_a(T) = R = 4.0$), residential building ($I = 1.0$) is considered, whose natural period is relatively short and nearly matching with soil's natural period ($S(T) = 2.5$) and located on seismic zone 1 ($A_0 = 0.40$), its seismic capacity index of ground floor (P_g) should be equal to or greater than 0.25.

$$P_g \geq \left(\frac{0.40 x 1.00 x 2.5}{4} = 0.25 \right) \quad (7)$$

If we calculate the seismic index, I_s for the same case with assuming structural irregularity index, D and time dependent deterioration index, K equal to 1.0 we can say that I_s should be equal to or greater than 0.25. Then; the required seismic index, I_D value should be equal to 0.25 at least because the seismic index, I_s value will be judged against to the required seismic index, I_D value. If we repeat the same conditions ($B = 1$; $Z = 1$; $U = 1$) in Equation 2 to calculate I_D, the result implies that P_0 should be equal to 0.25 as the first approach.

$$I_s \geq I_D$$
$$\left(I_s = 0.25 x 1.0 x 1.0 x 1.0\right) \geq \left(I_D = P_0 x 1.0 x . 1.0 x 1.0 x 1.0\right) \quad (8)$$

The value of 0.25 is very conservative as a basic seismic demand index P_0 in case of buildings with high ductility. For calibration of this index, a pilot study was carried out in Zeytinburnu, Istanbul to the residential buildings and nine school buildings at different locations of Istanbul, but has a same hazard zone level 1. Calibration and validation of the seismic demand index P_0 and the whole procedure will be continuously done as more data becomes available, there for some school builds are under consideration from data of Van.

4 CALIBRATION

The value of the seismic capacity index, P has a fundamentally important effect on the decisions about the basic seismic demand index, P_0.

For the calibration of the SSSM, the results of nonlinear static analysis carried out for 12 of 2401 buildings are utilized for seismic safety during Istanbul Earthquake Master Plan Project.

In this study, nine reinforced concrete school buildings that can represent typical school buildings in Turkey are examined by SSSM. The analyses have been done by the seismic loads given in the Turkish Earthquake Resistant Design Code. The result was none of them were satisfying the code expectation. After retrofit designs of these buildings are done considering the seismic loads given by the Turkish Earthquake Resistant Design Code, SSSM is utilized once more for each of these retrofitted buildings. Then detailed structural analysis is carried out both for the existing and retrofitted states of these buildings. Finally a comparison of the results obtained by the quick seismic safety

Table 2. P values obtained for existing and retrofitted school buildings by SSSM.

	Existing			Retrofitted		
Code	P_x	$P_{y\ \min}$	$(V/W)_{x,y}$	P'_x	$P'_{y,\min}$	$(V/W)_{x,y}$
ANT	0,15	0,14	0,14	0,24	0,40	0,18
HAY	0,06	0,07	0,06	0,15	0,22	0,13
MHV	0,03	0,04	0,03	0,12	0,32	0,14
MSF	0,14	0,15	0,14	0,28	0,51	0,21
SB	0,17	0,25	0,17	0,32	0,58	0,22
UEML	0,18	0,25	0,18	0,35	0,77	0,23
RD	0,18	0,14	0,14	0,48	0,39	0,20
MEV	0,18	0,25	0,18	0,51	0,50	0,20
TIOK	0,10	0,12	0,10	0,35	0,38	0,17

evaluation method before and after retrofitted is presented. Since this comparison is separately carried out for each principal direction, an important amount of data is obtained in terms of the relation between results of the detailed structural analysis and quick evaluation method. Then the ratios of base shear force capacity to structural weight were calculated. The ratios for x and y directions (Vx/W, Vy/W) and the structural seismic capacity indices (Px, Py), which are the ratios of strength indices to the structural weight determined by SSSM are presented in Table 2.

5 CONCLUSIONS

Based on the proposed study in the paper the Seismic Safety Screening Method, SSSM, which is adopted and modified from Japanese Seismic Index Method, can be used to rank buildings according to their building performance indices. Estimation of the existing seismic safety levels for medium/low rise RC buildings due to the structural analysis. are in good agreement with the results obtained by the SSSM. Calibration and validation of the scores and the whole procedure will be continuously done as more data becomes available in different seismic regions.

Institute of Engineering, UNAM, Mexico

ABSTRACT: This paper presents the results of a comparative evaluation of the seismic performance of two RC bridge columns, one of a full cross section and the other of a hollow cross section. The full section specimen has a cross section of 120 × 80 cm and a height of 500 cm, whereas the hollow column has an interior section of 96 × 56 cm, and 12 cm for thickness. The specimens were subjected to a cyclic reversal loading pattern. Experimental tests were carried out in order to evaluate the performance of the specimens at the limit and ultimate stage; flexural and shear strengths, and ductility capacity were observed as well. Tests were performed at the laboratory of great structures of CENAPRED.

1 INTRODUCTION

Up to date, the results of a large amount of experimental works related to bridge piers under lateral loads indicate that the most brittle way of failure is produced by shear, where cracks with inclination produce the crushing and spalling of the concrete cover and the breaking and/or separation of the stirrups. Another form of failure is the loss of confinement at the plastic hinge zones, where flexure cracks, crushing and spalling of the concrete cover produce the buckling of the longitudinal reinforcement or a compression failure due to the deterioration at the plastic hinges. Also, it has been observed that pier element specimens fail because of the sliding of the longitudinal reinforcement splices; the degradation of the flexure capacity can quickly happen in zones where there are small joints and confinement is restricted (Priestley et al, 1996).

In Mexico, historically, failures of bridge structures due to earthquakes are unusual. Earthquake effects observed to date only show minor damage or partial failures of elements. More scarce are the studies on the structural evolution of bridges and their components, in spite of the policy implemented in the late 90's for the construction of high standards highways.

This work is intended to start a research line related to the laboratory experimental response of RC pier models for highway bridges. In a first stage the experimental response of two piers specimens under lateral loads that simulate the actions of an earthquake is studied. The work is aimed to compare the performance of highway bridge prototype pier models: one with a solid cross section of reinforced concrete, and another with a hollow cross section of the same material. These models are representative of columns used in the construction of bridges piers in Mexico. Results of the solid cross section model will be used to establish comparative parameters and differences in behavior with respect to the hollow cross section model. The influence of the void in the pier, the displacement capacity of the tested element as well as its pattern of damage and failure will be observed. In a second stage a reliable mathematical model will be developed and calibrated in order to reproduce the hysteretic behavior of laboratory models.

In the first part of this paper a brief description of the studied models is presented, as well as the experimental procedure used. Location of sensors for instrumentation, both external and embedded in the specimens, the device and load history, and the general test procedure are also described. This is followed by an analysis of some basic design and experimental parameters: strength, displacement, stiffness, degradation of stiffness and energy dissipation capacity; all of them from the perspective of the influence of the gap in the section of the pier column on the characteristics of response under lateral loads of the seismic type. Finally, the results of greater importance are presented.

The experimental work described herein was carried out at the Laboratory of Large Structures of the National Center for Disaster Prevention (LEG-CENAPRED).

2 DESCRIPTION OF THE MODELS

In order to achieve the objectives of the study, laboratory tests were carried out in two RC specimens

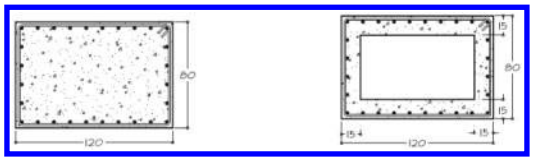

Figure 1. Cross section of the models studied. Dimensions and reinforcement.

of columns, one with a solid cross section and another with a hollow cross section; both specimens aimed to represent piers used in the construction of highway bridge substructures. Cross sections of the models are shown in Figure 1, whereas the nominal properties of the materials were: concrete for footing, $fc' = 350\,\text{kg/cm}^2$; concrete for pier $fc' = 300\,\text{kg/cm}^2$; and longitudinal and transverse steel, $fy = 4200\,\text{kg/cm}^2$; which are similar to those used in the construction of bridges.

The first model studied in the laboratory was the solid cross section model and herein will be referred as the "standard" or "pattern" model. This model has a longitudinal reinforcement ratio of 0.0148 and a ratio of volume of transverse reinforcement of 0.0040.

The second model studied, called herein "ch-01", had the same external dimensions than the "pattern" model, but with a hollow cross section and a wall thickness of 15 cm; it has a longitudinal reinforcement ratio of 0.0278, a ratio of volume of transverse reinforcement of 0.0081.

Both models were built using the regular procedures employed in this type of civil works. Steel bars of 25 mm were used for the longitudinal reinforcement being distributed uniformly in the cross section. For the transverse reinforcement, 13 mm bars were used. In both models a concrete cover of 5.0 cm was implemented.

In order to carry out a preliminary calibration of the models, using the values for confined concrete (Kent and Park, 1971), and the program BIAX (Wallace, 1989), moment-curvature relationships of the cross sections were obtained. Confined and unconfined regions considered in the analysis; moment curvature and interaction diagram obtained for the solid and hollow cross sections were obtained.

In the interaction diagram, it was easily observed that in order to consider the axial load in the experiments, its magnitude has to be very large to influence the results; also, from the moment-curvature graph, for a ultimate moment of 320 t-m corresponds a lateral load of 66.7 t and an ultimate displacement of 35 cm.

On the other hand, a 64 cm length for the plastic hinge was obtained using the expression provided by Priestley et al (1996). Also, a ductility factor of 8 was derived.

For the hollow section, the ultimate moments is 340.3 t-m for a lateral load of 70.9 t; the ductility factor is 11, and the plastic hinge length is the same as in the solid section.

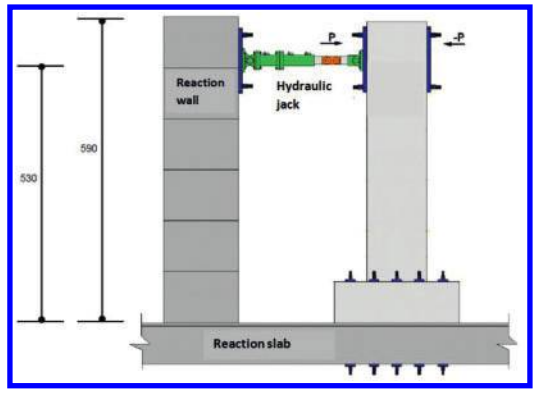

Figure 2. General array of the loading device (dim: cm).

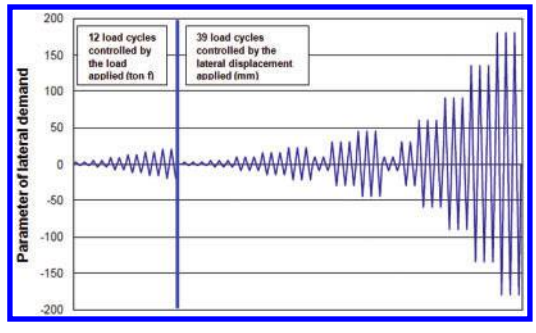

Figure 3. Load history.

3 LOAD HISTORY

Specimens were subjected to one-way reversible cyclic loading with a configuration of a cantilever load type, as shown in Figure 2.

Load history was designed to allow the observation of elastic and inelastic behaviors, as well as the "low cyclic fatigue" phenomena. Loading was initially defined considering 12 load controlled cycles, up to the theoretical cracking stress produced by flexural bending at the critical section of the pier (at the base). Once the lateral load corresponding to cracking was attained, the test was then controlled using the displacement of the point where the load was applied, and applying 39 additional load cycles with re-runs of three cycles for each range of amplitude. The graphical representation of the load history is shown in Figure 3.

During testing the magnitude of strains occurring in the longitudinal and transversal steel were recorded, allowing the identification of plastic hinges.

4 INSTRUMENTATION AND RECORDING SETUP

Instrumentation of the models comprised 126 strain gauges placed in the longitudinal and transverse reinforcing bars. The strain gauges were basically placed

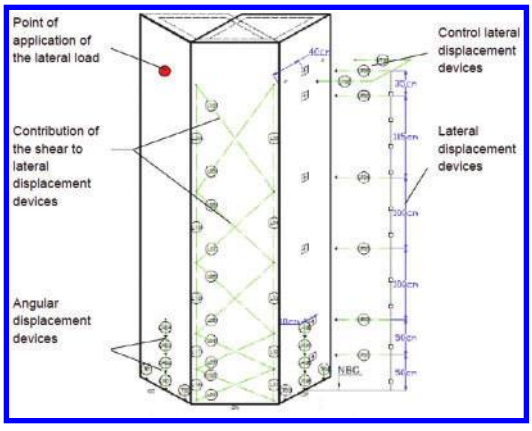

Figure 4. Graphic representation of the external instrumentation.

within the influence length of the plastic hinge, defined for this study as a section with a size equivalent to greater dimension of the cross section measured from the critical section. In a first instance, these recorded strains were aimed to identify the level of demand in the reinforcement, and therefore, their possible incursion in the yielding area.

Additionally, external instrumentation was used and it was conformed with LVDT's. The objective of this instrumentation is, in addition to control the test parameter or the displacement at the point of application of load, to identify characteristics of displacement, rotation, and contributions of the mechanisms of flexural bending and shear to the total displacement, among other issues.

The distribution of sensors is presented in Figure 4, whereas Figure 5 shows a general view of the load set-up during the test.

4.1 *General behavior of the models*

Load – displacement relationships

As a result of the application of the reversible cyclic lateral loading, load-displacement histories of the response of both models were obtained as shown in Figure 6. Two graphs are presented, one for the response of the two models in the range of elastic behavior (defined until the yielding of the longitudinal reinforcement), and the other one for the complete test, also for the two models, including the incursion on the inelastic range.

Analysis of the load – displacement graph in the range of elastic behavior (Figure 6) shows a difference in the initial stiffness between the two models. This fact produces a variation in the values of the lateral force associated with flexural cracking, as well as in the displacement magnitudes observed for these conditions. On the other hand, Figure 6.b shows a similar trend of behavior between the two models after incursioning in the inelastic range. Regarding the capacity of deformation and degradation of resistance for the same

Figure 5. General view of the model and testing set-up at LEG – CENAPRED.

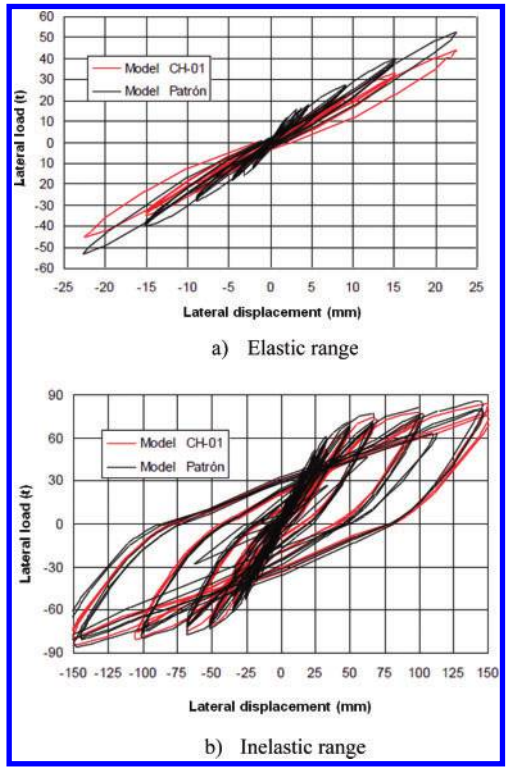

Figure 6. Lateral load-displacement behavior of the two models.

Table 1. Theoretical and experimental strengths of the models.

MODEL	MODEL	Solid model	Hollow model
Cracking	Experimental resistance (V_{crEXP}, t)	14.92	9.95
	Theoretical resistance (V_{crTEO}, t)	16.48	12.92
	V_{crEXP}/V_{crTEO}	0.92	0.77
	Experimental displacement (δ_{crEXP}, mm)	3.14	2.81
	Theoretical displacement (δ_{crTEO}, mm)	1.60	1.60
	$\delta_{crEXP}/\delta_{crTEO}$	1.96	1.48
Yielding	Experiemental resistance (V_{yEXP}, t)	44.17	44.06
	Theoretical resistance (V_{yTEO}, t)	40.64	40.44
	V_{yEXP} V_{yTEO}	1.09	1.09
	Experimental displacement (δ_{yEXP}, mm)	18.10	25.03
	Theoretical displacement (δ_{yTEO}, M-φ, mm)	26.90	26.00
	Theoretical displacement (δ_{yTEO}, Sugano, mm)	15.50	19.70
	$\delta_{yEXP}/\delta_{yTEO}$ (M-φ)	0.67	0.96
	$\delta_{yEXP}/\delta_{yTEO}$ (Sugano)	1.17	1.27

consecutive demands of displacement, no significant differences between the performance parameters of the two models were observed. Information on parameters such as degradation of instant stiffness, peak to peak degradation of stiffness, energy dissipation, coefficient of equivalent damping, among other important parameters of structural performance has not yet been processed, as well as other concepts that will be introduced in a future work.

Based on the analysis of similar graphs, together with the review of information recorded during the test and a review of the level of unit deformation required in the longitudinal steel reinforcement of the models, values of load and displacement associated with the first cracking of tension due to flexural bending, were identified, as well as the load magnitude associated with the manifestation of yielding of the longitudinal reinforcement. These values are presented in Table 1 for the two models.

On the other hand, based on moment-curvature (M-φ) relationships, theoretical values of the lateral forces associated with the first cracking and the first yielding, V_{cr}TEO and V_yTEO, respectively, were identified. Also, based on the theoretical relationship between flexural moment, curvature, rotation and deflection, theoretical deflections at cracking and yielding were derived and identified as δ_{cr}TEO and δ_yTEO, respectively. Additional displacement magnitudes at yielding were obtained using the empirical expressions of Sugano (AIJ, 1987). This one defined in Table 1 as δ_yTEO, Sugano.

Analysis of resistances shows that the dispersion between the experimental and theoretical values are slightly higher for the CH-01 model, mainly for the resistance at cracking with a difference of 23% between the experimental and the theoretical for the CH-01 model, and 9% for the standard model. Regarding the yielding resistance, the difference between the theoretical, and experimental value, for both models, is 9%; this is an expected behavior since after yielding the prevailing structural performance parameter is the amount of longitudinal steel reinforcement.

On the other hand, from the analysis of displacements, it is observed that the experimental state for cracking, nominally equal to the limit values of linear elastic behavior, was considerably higher than the theoretical: 96% for the pattern model and 48% for model CH-01. In this regard it is important to mention that the difference of initial stiffness, defined as the relationship between load and displacement at cracking due to tension by bending, is 34% higher than that of the pattern model; a difference of 28% was expected.

Analyzing the yielding condition or limit state of service, and calculating for the two models the experimental stiffness up to the yielding point, the ratio between the stiffness at the yield point (K_y) and the initial stiffness (K_{cr}) is equal to 0.51 and 0.50 for the pattern and CH-01 models, respectively; therefore, there is no difference in the parameter of degradation of stiffness between the two models considering only the limit points in the service range (cracking and yielding by bending).

4.2 *Cracking patterns*

Cracking patterns of the two models showed similar trends in the distribution and orientation of the cracks; no gross differential effect was identified due to the presence of the void in the model CH-01. Figure 7 shows the cracking pattern of the standard model at the final stage of the testing which was reached when the crushing of the fiber of maximum compression was observed.

The final mechanism of failure of both models was observed during the failure of the third stirrup at the critical section. This failure was observed at its bend of 135 degrees around the longitudinal corner bars. It is worth to mention that the manufacture of stirrups used in the two models was made using a mechanical bending device and complying with the radii of curvature specifications. Even so, damage in the area of the bend of the crossbar that shapes the stirrup was observed. This damage was observed previous to the lateral loading demand applied on the model.

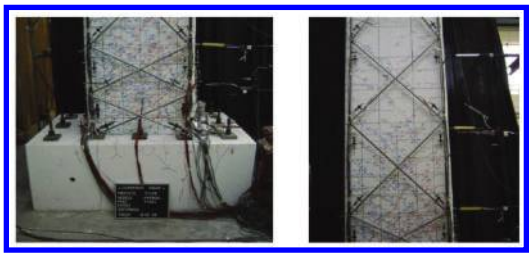

Figure 7a. Final cracking patterns on both models.

Figure 7b. Failure mode at the base of the standard model.

4.3 *Analysis of lateral displacements*

As indicated in Figure 8, regarding specifically the devices used to measure the configuration of lateral displacements of the models, experimental normalized deformed configurations for the two models were identified for the first ten cycles, corresponding to the applied load history controlled by the magnitude of the applied lateral force, in the interval of behavior previous to cracking due to tension by flexural bending. Using concepts of the theory of elasticity and strength of materials, expressions to calculate the deformed configuration of the models were derived. For each load cycle, Figures 12 presents a comparison of the deformed configurations of the models including the theoretical one.

Studying the distributions of displacements along the height of the models, and comparing with a theoretical configuration, it can be asserted that for the pattern model (solid cross section), its displacements are quite different from the theoretical values in a length of 100 cm near the base of the pier. The rest of the configuration shows a configuration similar to the theoretical.

On the other hand, although for a small number of cycles, the trend is the same for the CH-01 model as described for the standard model. For most of the cycles, the behavior observed/measured reasonably matches the theoretical behavior expected along the 100 cm near the base of the pier.

The difference between the observed behavior at the bottom of the pier can be assumed as a consequence of the greater geometric inertia and mass of the pattern model, which could generate a local rotation at

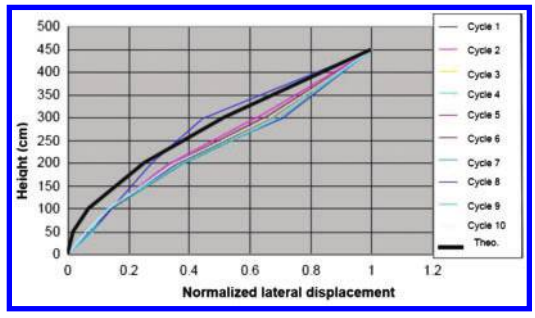

Figure 8a. Configuration of normalized lateral displacements for the pattern model, interval previous to cracking by flexure.

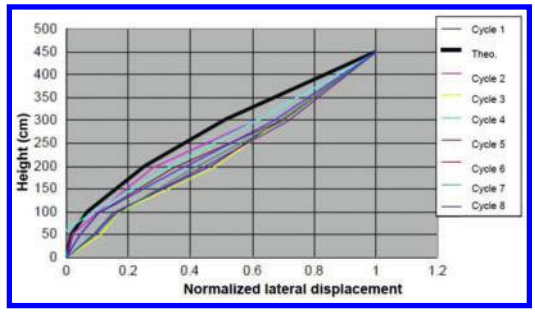

Figure 8b. Configuration of normalized lateral displacements for the CH-01 model, interval previous to cracking by flexure.

the base of the pier starting at load levels lower than those associated to flexural cracking, aspect that was not observed in the pier of the hollow section model. This aspect will have to be revised and, if necessary, confirmed with the analysis of external and internal information in the vicinity of the bases of the two models.

5 CONCLUSIONS

As a result of this experimental study, and taking into account only part of the information recorded with the external instrumentation, the most important conclusions can be summarized as follows:

(1) Regarding the mechanism of failure, the presence of the void in the section of the pier does not significantly modify the overall performance of the model. This is inferred from the direct comparison of the results of the solid section model with those of the hollow section;
(2) There are differences in performance characteristics between the models in the elastic range, between cracking and the first yielding due to flexural bending; more specifically, differences were observed in the cracking resistance and the values of initial stiffness and yielding, resulting

higher than those expected for the pattern model (solid section); and,

(3) From the analysis of the deformed configuration of the two models in the elastic range, a possible rotation of the base of the pattern model was observed, feature which was not fully observed in the CH-01 model, probably due to the large difference in inertia and mass between the models.

ACKNOWLEDGMENTS

The authors are grateful to technicians Pablo and Carlos Olmos-Ibarra, at LEG-CENAPRED, for their participation in the experimental testing. Also, enthusiastically, Jaime Lorenzo-Camargo provided assistance at the laboratory during his social service stage. Assistance of Salvador Barrios, Ivan I. León, Ronald Gomez, Joel Aragon, Raúl Sánchez and Oscar Rosales is appreciated as well.

Financial support for the manufacturing of the models was provided from remnants funds of a project sponsored by the Secretariat of Communications and Transport of Mexico to the Institute of Engineering at the National University of Mexico.

ABSTRACT: The safety and stability of Roller Compacted Concrete (RCC) dam under strong earthquake shaking has long been an issue of practical importance, and has attracted and continues to attract considerable research interest. In this paper the evaluation of seismic performance of RCC dam subjected to near-field and far-field earthquakes was undertaken. In this attempt, an RCC dam was modeled using the Finite Element (FE) software considering dam-reservoir interaction. Then dynamic analysis procedure has been performed via non-linear time history analysis. Verification of FE model was done with experimental data by a statistical test which the obtained results indicated a good conformity.The obtained seismic strain, stress and lateral displacement demonstrated that RCC dam include different seismic behavior subjected to near and far field earthquakes which the near-field earthquakes have more greater effects on the RCC dams in comparison with far-field earthquakes.

Keywords: Seismic performance, Finite Element Analysis (FEA), Roller Compacted Concrete (RCC) dam, Near-field and far-field earthquakes

1 INTRODUCTION

Roller compacted concrete (RCC) technology has revolutionized the dam construction industry during the past decades. The advantages of more economical and rapid construction brought these dams into the engineers' attention; hence seismic analysis of suchlike structures to assess its resistance during earthquake and some phenomena such as cracking has become important. It is recommended to perform nonlinear analysis based on fracture mechanics theory to assess performance of a new or an existing concrete dam with regard to dam safety [1,2].

The design of gravity dams constructed by RCC is similar to the design of concrete gravity dams constructed by conventional methods. The largest differences are in the used construction methods and in the composition of the concrete used to allow roller compaction [3]. Ground motion effect on RCC dams in the earthquake zone should be taken into account for the most critical conditions.

This paper aims to present the evaluation of RCC seismic performance against near-field and far-filed earthquakes.

2 FINITE ELEMENT MODEL AND ANALYTICAL DYNAMIC CHARACTERISTIC OF ZIRDAN DAM

Zirdan dam was taken place in Kajoo River in north of Chabahar city in Iran. Zirdan, is one of the gravity dams which was constructed by RCC method in 2011. (fig 1)

Using about 545,000 m^3 concrete which is contained two material (CVC and RCC). FE model of the dam that is shown in Figure 1 is 64.5 m high, with a sharp slope change on the upstream face at the level of 20 m and 35 m (fig 2,4).

In the finite element modeling of the RCC dam that is shown in Fig 2, openings are not considered in the modeling. In the finite element model of Zirdan Dam, the dam body is created firstly by the FEM software. In the dam body, areas are used. Each areas has 8 node and each node has three degree of freedoms: translations in the nodal x, y, and z directions. The finite element model of Zirdan Dam is developed considering reservoir. Reservoir affects the dynamic response of gravity dams considerably. So they must be well represented to obtain realistic result. In the model, the

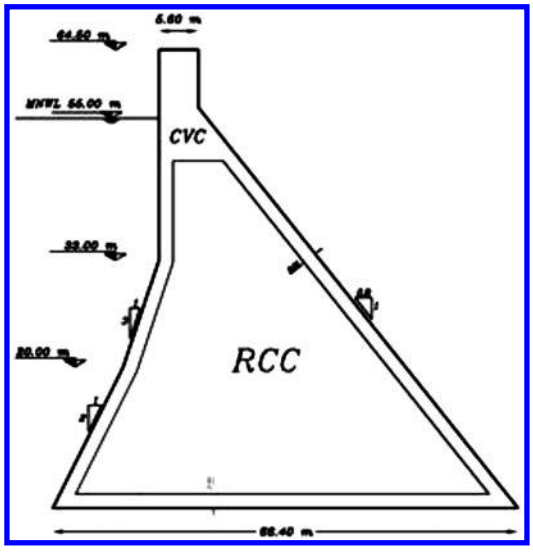

Figure 1. Zirdan Dam.

Figure 2. Zirdan Dam.

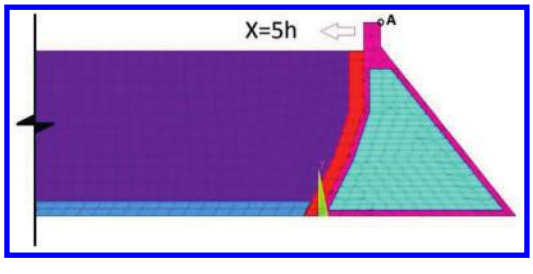

Figure 3. Zirdan Dam Finite Element model.

length of the reservoir is taken as much as fifth times of dam high to represent the impounded water [4]

In this Study, material properties assumed in the analyses are listed in Table 1.

3 AMBIENT VIBRATION AND GEOTECHNICAL TEST OF ZIRDAN DAM

Several vibration tests were conducted to Zirdan. Site classification and wave velocity of the dam foundation

Table 1. Material properties of Zirdan Dam.

were carried out during the tests. We classified the soil characteristics by USGS method and we assume the foundation soil type is Type A, and also we found out the design base earthquake (DBE) and Maximum credible earthquake (MCE).

4 VERIFICATION OF NUMERICAL MODEL

To Confirm the Validity of the numerical model we studied Koyna Dam researches [5].

Koyna Dam is a gravity dam in India that was damaged by during the earthquake in 1967, the Koyna Dam is considered a classic problem for experimental studies and validation of numerical procedure for predicting the seismic response of concrete gravity dams [6] for this purpose we made the FE model of Koyna dam (fig 5) to control the modal properties of Koyna dam and verify the FE Software , so for theses control we used the results of V. Valamanesh et al [7,8].

We analyzed the model of Koyna Dam and Compared the results in Table 2.

For this comparison we used SPSS Program by Mann-Whitney U method.

Mann-Whitney test is a statistics method for one of two samples of independence number and it is one of the most well-known non-parametric significance tests [9].

Mann-Whitney U test showed that asymp sig is 0.873 so it is clarified that Analytical mode shape of Koyna dam is convergence and we can trust on our outputs.

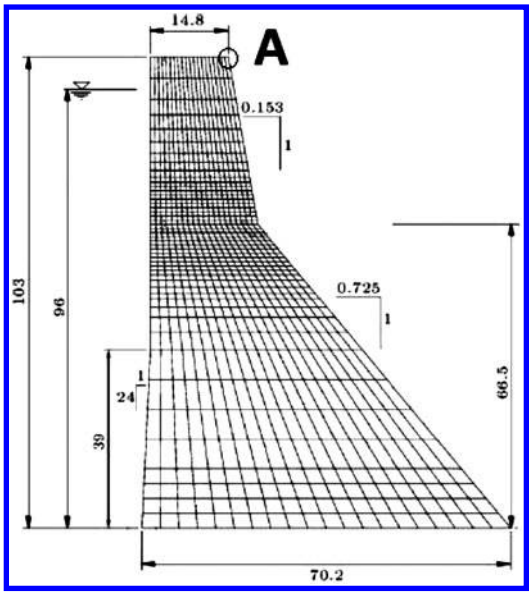

Figure 5. Koyna Dam.

5 MODEL ANALYSIS

First of all we must select the accurate records for time history method for near field and far field earthquakes, for this purpose we accumulated the seismic records data which are conformed to local soil characteristics. We must modify the accelerators to gain the best interaction between the foundation, dam and reservoir because the record doesn't match with Zirdan Dam location, to reach the target we studied faults and histories of the earthquakes then we recognized that we should amend the accelerators by MCE records.

On this inquiry we selected Northridge, Koceali and Whittier Narrows seismic records on FE Software and discussed on the lateral displacements on dam.

Near-filed earthquake means that the faults are very close to dam structure and it can be about 10 km or less,

In Figures 6 and 7 are showed that the lateral displacements of Point A on Zirdan Dam Via Near and far-field Northridge earthquake records.

It is denoted that the time the displacement of the near-field earthquake is greater than far field earthquake.

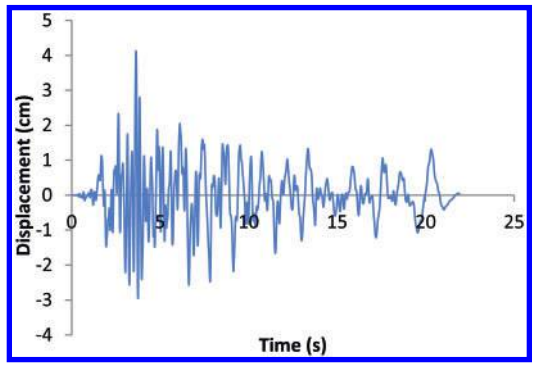

Figure 6. Lateral Displacement – Near-Field Northridge records.

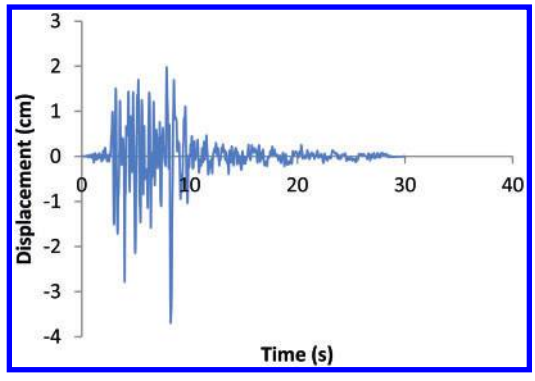

Figure 7. Lateral Displacement – Far-Field Northridge records.

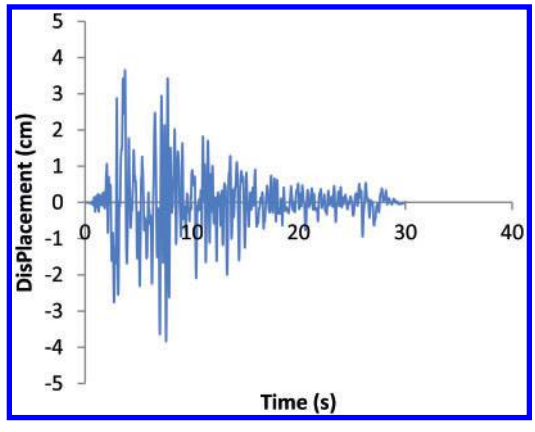

Figure 8. Lateral Displacement – Near-Field Koceali records.

In Figures 8 and 9 are showed that the lateral displacements of Point A on Zirdan Dam Via Near and far-field Koceali earthquake records.

It is showed that the maximum displacement of point A is happened in far filed earthquake that is denoted the point A moved towards the reservoir of dam.

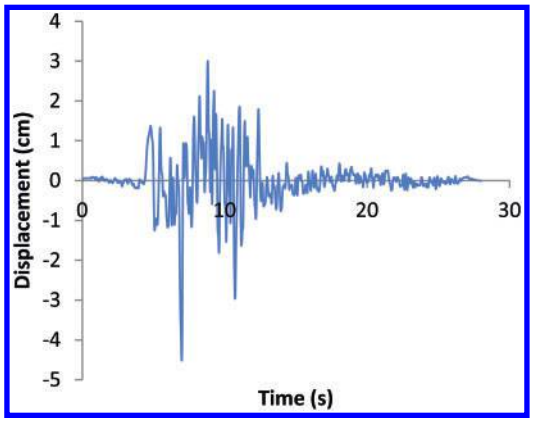

Figure 9. Lateral Displacement – Far-Field Koceali records.

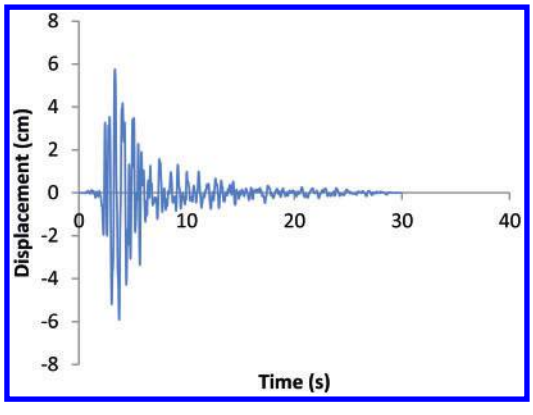

Figure 10. Lateral Displacement – Near-Field Whittier Narrows records.

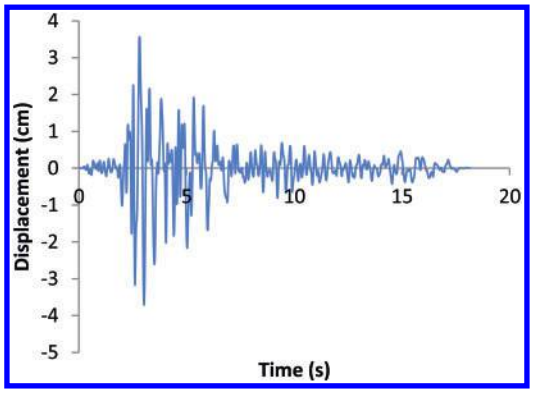

Figure 11. Lateral Displacement – Far-Field Whittier Narrows records.

In Figures 10 and 11 are showed that the lateral displacements of Point A on Zirdan Dam Via Near and far field Whittier Narrows earthquake records.

It is denoted that the time the displacement of the near field earthquake is greater than far field earthquake.

The obtained results were compared between near and far filed earthquakes that were modified.

6 CONCLUSIONS

This paper compares nonlinear seismic responses of RCC Dam – reservoir systems obtained for near field and far-field earthquakes by FE models on MCE records.

- The displacement of three near field and far-field seismic records were showed that near-filed earthquakes are much stronger than far field one indeed , although there are some lateral displacements that are excessive than near filed but the average of displacement is not.
- The direction of the displacement of far filed earthquake is showed that the maximum of movements are towards the reservoir so it can be very dangerous for dam stability.

Some advances in functionally graded materials

Luciano Nunziante
University of Napoli Federico II. Napoli. Italy

ABSTRACT: Some new solutions for mechanical response of composite circular cylinders are shown, by means of a mathematical treatment of Navier-Cauchy elasticity equations, based on suitable choice of Boussinesq-Somigliana Galerkin potentials. The set of Euler differential equations is transformed in to an algebraic one, by means of compatibility and equilibrium boundary conditions. All load cases de Saint-Venant like are solved. An homogenization technique is used to obtain particular stiffness features, by coupling of materials with Poisson modulus of opposite sign. Finally, the solution of technical problems is shown: design of optimum assembling aimed to maximize stiffness in cases of bending and shear, design of optical fibre sensors for distributed strain measurements, prediction of collapse load of concrete columns confined by Fiber Rinforced Polymers.

1 INTRODUCTION

1.1 *Composites and functionally graded materials*

Composites are highly inhomogeneous media made up of a matrix and of a reinforcement, designed to enhance overall mechanical properties and destined to optimize elastic stiffness or to gain resistance of the designed objects to face up mechanical actions or limiting damage effects, in cases of dynamic impact, wear, thermal loads, fatigue and fracture. Sometime the composite is made up by an assembling of several composite lamina, each of them constituted by a mono or two-phase component. Among Composites, Functionally Graded Materials (FGMs) are formed of two or more constituent phases with a continuously variable composition, where volume fraction of particles varies in one or several directions. FGMs possess a number of advantages that make them attractive in several applications, since they eliminate stress discontinuities of composites, avoiding delaminating effects, also mitigating thermal stress concentrations [1,2,3]. When the cylinder is strained symmetrically it was already shown by the Author [7] that all mechanical quantities can be obtained in closed form starting from the Navier-Cauchy elastic equilibrium equation of the single phase for vanishing body forces:

$$\nabla^2\mathbf{u}+1/(1-2\nu)\,grad\,div\mathbf{u}=-\mathbf{b}/\mu=0 \qquad (1)$$

where **u** is the displacement field, **b** are body forces, ∇^2 is the Laplacian operator; μ and ν are the first Lamè constant and the Poisson modulus of the material phase, respectively.

It is well known that for the problem at hand for the displacement **u** there exists a vector ***F*** (Boussinesq-Somigliana Galerkin potential) such that following equations hold true:

$$\mathbf{u}=\nabla^2\boldsymbol{F}-2(1-\nu)\,grad\,div\boldsymbol{F} \quad , \quad \boldsymbol{F}\in\mathcal{C}^{(4)} \, , \, \nabla^4\boldsymbol{F}=0. \qquad (2)$$

Figure 1. Structures in composites materials.

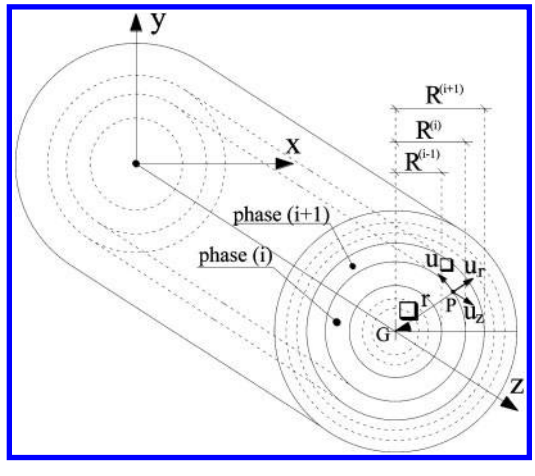

Figure 2. Composite Cylinder.

The problem of the whole composite cylinder was solved in analytical form [4,7,9] for a variety of load cases, by choosing suitable form for the potential of displacement of single material phase. From displacement, strains are obtained by differentiation and stresses by application of Hooke's law of linear elasticity. Finally on displacements and on stresses are applied constraints of continuity on the boundary surfaces between couples of material phases, expressing compatibility and equilibrium. These conditions follow the assumption of perfect bonding among constituting phases.

2 NEW SOLUTIONS FOR COMPOSITE CYLINDER UNDER SAINT-VENANT LOADS

For the already defined composed cylinder, were obtained new analytical elastic solutions, in presence of pure bending, and of bending and shear [7,9]. Also the well known literature's solutions for cases of axial force and of torque, were obtained, thanks to a unitary mathematical procedure starting from following assumptions:

a) Existence of a Love's function, [3] defining an irrotational potential giving displacement field for the case of axial force

$$\begin{aligned} u_r &= -(1/2)\left(\chi_{,rz}/\mu\right),\ \ u_\vartheta = 0, \\ u_z &= (1/2)\left[\left(\nabla^2\chi\right)/(\mu+\lambda)+\left(\chi_{,rr}+r^{-1}\chi_{,r}\right)/\mu\right] \end{aligned} \tag{3}$$

where χ is a bi-harmonic function satisfying equation $\nabla^4\chi = 0$

b) Existence of a solenoidal potential of displacement field for torque, bending moment and shear. As matter of fact, symmetry and skew-symmetry conditions on displacement in to the section allow to split in each phase displacement components in two parts: the first ones u_r, u_z symmetric, and the second one u_θ as skew-symmetric, so that the divergence takes in to account the relevant terms: $\nabla\cdot\mathbf{u} = g_1 + g_2$, where $g_1 = u_{r,r} + r^{-1}u_r + u_{z,z}$, is symmetric and $g_2 = r^{-1}u_{\theta,\theta}$, is skew-symmetric. Above Figure shows displacement's symmetry and skew-symmetry features respect to axes x and y for bending moment M_x. It was shown [7] that the integral of the divergence of displacement field over any cross section is equal to zero:

$$\int_\omega \nabla\cdot\mathbf{u}\, d\omega \tag{4}$$

The above integral condition (weak condition) corresponds to a vanishing volumetric change of cross-section and of whole solid. It was shown that

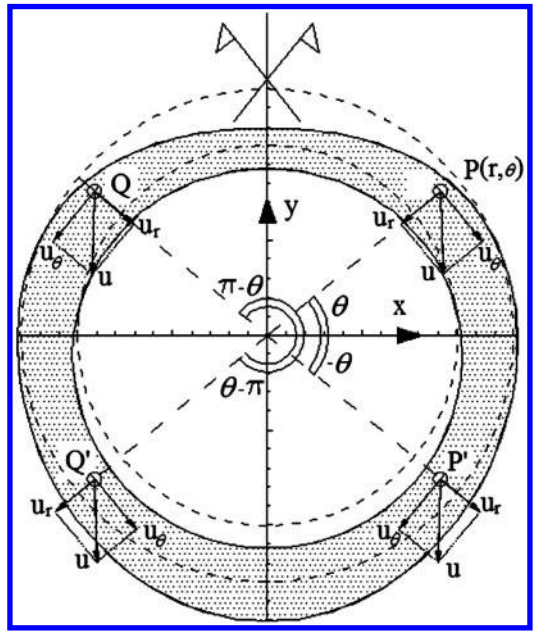

Figure 3. Symmetry and skew-symmetry features of displacement field in cross section of bending composite cylinder.

divergence of displacement can assume the unified expression:

$$\nabla\cdot\mathbf{u} = 1/4\ k\,\alpha^2\ \ 7-3\alpha\ \ z^{\alpha-1}y\ = \\ = \left\{\begin{array}{l} = 0, \alpha = 0, torque; = k\,y, \alpha = 1, bending; \\ = k\,y\,z, \alpha = 2, shear + bending \end{array}\right\} \tag{5}$$

By substituting above condition in to the Navier-Cauchy equations, resulting displacement field is obtained as the sum of the two following displacements

$$\mathbf{u} = \mathbf{u}^h + \mathbf{u}^p \tag{6}$$

where:

$$\begin{aligned} &u_r^h = r^{-1}G_{,\theta z},\ \ u_\theta^h = \left[\ 1/2\ r\nabla^2 G - G_{,r}\right]_{,z},\ \ u_z^h = -\ 1/2\ \left[\nabla^2 G\right]_{,\theta} \\ &u_r^p = \left[\alpha\ 3\mu+\lambda\ \ 7-3\alpha\ \ k\,z^{\alpha+1}\sin\theta\right]/\left[4\ 1+\alpha\ \ \mu\right] \\ &u_\theta^p = \left\{\frac{\alpha\,k\,z^{\alpha-1}\ \ 3\alpha-7}{\left[4\ 1+\alpha\ \ \mu\right]}\left[\alpha\ 1+\alpha\ \ 2\mu+\lambda\ r^2 - 3\mu+\lambda\ z^2\right]\cos\theta\right\} \\ &u_z^p = \left[\ \mu+\lambda\ \ 3\alpha-7\ \ \alpha\,k\,r\,z^\alpha\sin\theta\right]/\ 4\mu \end{aligned} \tag{7}$$

The first one $\mathbf{u}^h$ is characterized by divergence equal to zero (pure torsion), and corresponds to the solution of the homogeneous differential equation system, and is denoted by the symbol "h". This solution will not more treated in what follows.

The second one $\mathbf{u}^p$ is characterized by divergence equal to function reported in (5) with $\alpha \neq 0$, is a particular integral and will be denoted by the symbol "p" (bending and shear);

By substituting the components of displacement $\mathbf{u}^p$ corresponding to the "particular" solution in to the stress-strain relationships, were obtained for each phase the stress components related to this part of displacement with volumetric strain not locally vanishing:

$$\begin{aligned}
&\sigma_{rr}^p = -\Gamma\lambda\sin\theta,\ \sigma_{\theta\theta}^p = -\Gamma\ 4\mu+3\lambda\ \sin\theta,\\
&\sigma_{zz}^p = \Gamma\ 2\mu+\lambda\ \sin\theta,\ \tau_{r\theta}^p = \Gamma\ 2\mu+\lambda\ \cos\theta,\\
&\tau_{rz}^p = -\Gamma\ 2\mu z\sin\theta\ /\ \alpha r\ ,\\
&\tau_{\theta z}^p = \Gamma\left[-2\mu z^2+\alpha\ 2\mu+\lambda\ \ \alpha-1\ r^2\right]\cos\theta\ /\ \alpha\ r z\ ,\\
&\text{where } \Gamma = k\alpha^2\ 3\alpha-7\ r z^{\alpha-1}\ /4\ .
\end{aligned} \tag{8}$$

2.1 *Combined bending and shear force*

For the problem of bending and shear, functions $G^{(i)}$ are assumed as bi-harmonic in each phase. Also in this case the integral of divergence of solving displacement vanishes on every cross section. In presence of constant shear on the solid, shear stresses $\tau_{\theta z}^{(i)}, \tau_{rz}^{(i)}$ must be independent on z. Since the bending moment is linear along z direction, the remaining stresses depend linearly upon z direction. By applying the above hypotheses, we obtain [7,9] for each material phase function $G^{(i)}$ as:

$$\begin{aligned}
&G^{(i)} = \left(G_0^{(i)} + G_1^{(i)} z^2 + G_2^{(i)} z^4\right)\cos\theta,\\
&k^{(i)} = 2\left[2V_3^{(i)} - 9V_2^{(i)}\right]\Big/\Omega^{(i)}
\end{aligned} \tag{9}$$

the solving displacement field is finally obtained for each phase satisfying equilibrium and compatibility equations inside each generic *i-th* phase of multilayered cylinder subjected to shear and bending moment:

$$\begin{aligned}
u_r^{(i)} &= \left\{V_5^{(i)} + V_2^{(i)} z^2 + (1/2)V_4^{(i)} r^{-2} + \left(r^2/2\Omega^{(i)}\right)\left[V_3^{(i)}\left(\mu^{(i)} - \lambda^{(i)}\right) + 6V_2^{(i)}\lambda^{(i)}\right]\right\} z\sin\theta\\
u_\theta^{(i)} &= \left\{V_5^{(i)} + V_2^{(i)} z^2 - (1/2)V_4^{(i)} r^{-2} + \left(r^2/2\Omega^{(i)}\right)\left[6V_2^{(i)}\lambda^{(i)} - V_3^{(i)}\left(3\lambda^{(i)} + 5\mu^{(i)}\right)\right]\right\} z\cos\theta\\
u_z^{(i)} &= \left\{\begin{array}{l} V_6^{(i)} + -3V_2^{(i)} z^2 + V_7^{(i)} r^{-2}\left(1-\delta_{0i}\right) + \\ +\left(r^2/2\Omega^{(i)}\right)\left[3\left(2\lambda^{(i)} + 3\mu^{(i)}\right)V_2^{(i)} - \left(\lambda^{(i)} + \mu^{(i)}\right)V_3^{(i)}\right] \end{array}\right\} r\sin\theta
\end{aligned} \tag{10}$$

Above displacements produce by differentiation and by means of Hooke equations suitable expressions for strain and stress components. Under assumption of perfect contact at the cylindrical interfacial boundaries (no de-lamination or friction phenomena), equilibrium and compatibility equations at the interfaces between two generic adjacent phases allow to determine constants V_i. The followed mathematical approach reduces the Euler partial differential equation's system governing the elastic problem and relevant boundary conditions in to a simpler linear algebraic problem, where a prescribed number of coefficients have to be determined. The found analytical solutions allows to controlling the evolution of the local stress field inside each object's layer and at the material interfaces when volume fractions and elastic modulus of the constituents are prescribed.

2.2 *Homogenization of multilayered cylinder*

The derived analytical solutions lend themselves to define a homogenized one-dimensional beam-like model, representing the overall behavior of multilayered cylinder under the action of the DSV load conditions, by explicitly constructing the corresponding stiffness governing the elastic law among generalized beam stresses and strains. In case of bending, for the infinitesimal beam element under moment M_x the external virtual work becomes $dL_E = M_x\, d\phi(z)$ where $d\phi(z)$ is the flexural rotation increment. The inner virtual work is

$$dL_I = dz\sum_{i=0}^{n}\int_{\omega^{(i)}} \boldsymbol{\sigma}^{(i)} : \boldsymbol{\varepsilon}^{(i)} ds = \tag{11}$$

where

$$\begin{aligned}
&\Psi_\chi = \sum_{i=0}^{n}\int_{\omega^{(i)}} \boldsymbol{\sigma}^{(i)} : \boldsymbol{\varepsilon}^{(i)} ds = \sum_{i=0}^{n}\frac{4E^{(i)}I^{(i)}}{\left(1+\nu^{(i)}\right)}\\
&\cdot\left[\frac{U_4^{(i)2}\left(1-\delta_{0i}\right)}{R^{(i)4}R^{(i-1)4}} + \frac{4U_3^{(i)2} + \chi_0^2\left(3-\nu^{(i)}\right) - 8\chi_0 U_3^{(i)}\nu^{(i)}}{4\left(3-4\nu^{(i)}\right)}\right];
\end{aligned} \tag{12}$$

The curvature χ ,which is constant on the whole cross section in agreement with Bernulli's theory of beam, can be defined on each material phase as follows:

$$\begin{aligned}
&\chi = \varphi_{x,z} = \left[u_z^{(i)}/\left(r\sin\theta\right)\right]_{,z} = \chi_0 = const\\
&M_x = k_\chi\,\chi = k_\chi\,\varphi_{x,z} \ \Rightarrow\ d\varphi_x(z) = M_x\, k_\chi^{-1} dz
\end{aligned} \tag{13}$$

By means of Virtual Work Equation we obtain the overall bending stiffness k_χ of multilayered cylinder: $k_\chi = M_x^2\,\Psi_\chi^{-1}$ and the overall bending stiffness is $k_\chi = \Psi_\chi^{-1} = \sum_{i=0}^{n} E^{(i)}I^{(i)}\psi_\chi^{(i)}$ where $\psi_\chi^{(i)}$ is a correction term that depends on geometrical and mechanical parameters:

$$\psi_\chi^{(i)} = \eta_\chi^{(i)} \Big/ \left[\sum_{i=0}^{n} E^{(i)}I^{(i)}\eta_\chi^{(i)}\right]^2 = \left(dL_I^{(i)} / dL_I^2\right) / E^{(i)}I^{(i)} \tag{14}$$

where coefficient $\eta_\chi^{(i)}$ is given by following expression:

$$\begin{aligned}
&\eta_\chi^{(i)} = 1/E^{(i)}I^{(i)}\int_{\omega^{(i)}} \boldsymbol{\sigma}^{(i)} : \boldsymbol{\varepsilon}^{(i)} ds\ = 4/\left(1+\nu^{(i)}\right).\\
&\left[\frac{U_4^{(i)2}\left(1-\delta_{0i}\right)}{R^{(i)4}R^{(i-1)4}} + \frac{4U_3^{(i)2} + \chi_0^2\left(3-\nu^{(i)}\right) - 8\chi_0 U_3^{(i)}\nu^{(i)}}{4\left(3-4\nu^{(i)}\right)}\right]
\end{aligned}$$

where, without loss of generality, $U_3^{(i)}, U_4^{(i)}, \chi_0$ are coefficients to determine by setting $M_x = 1$. It is hence evident that, in the expression found for bending stiffness, an important role is covered by the value of Poisson modulus of each material phase. Following a similar procedure [4,7,9], the shear stiffness of homogenized composed cylinder was obtained as: $k_\gamma = \sum_{i=0}^{n} \mu^{(i)}\omega^{(i)}\psi_\gamma^{(i)}$ where $\omega^{(i)}$ is the area of i-th

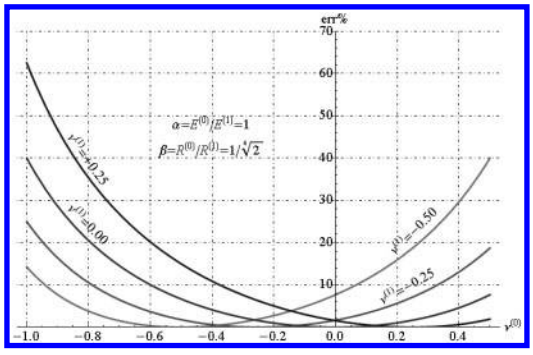

Figure 4. Error percentage of bending stiffness as function of different Poisson modulus values of materials.

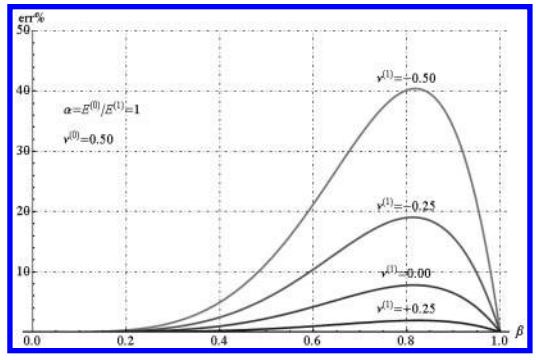

Figure 5. Error percentage of bending stiffness for different Poisson modulus values of materials, as function of radii ratio.

phase and $\psi_\gamma^{(i)}$ is a coefficient depending on geometrical and mechanical parameters of the i-th phase. Also for the shear stiffness a crucial role is covered by the elastic modulus (Lamè constants, and Poisson modulus) of each component phase. The numerical values of the found stiffness's expressions were tested on a two phase multilayered cylinder (a central core perfectly bonded to a sole surrounding hollow cylinder), for which relevant bending stiffness is $k_\chi = \Psi_\chi^{-1} = \sum_{i=0}^{n} E^{(i)} I^{(i)} \psi_\chi^{(i)}$ that was compared with the approximate bending stiffness of current literature $\bar{k}_\chi = \sum_{i=0}^{1} E^{(i)} I^{(i)}$, evaluated as the sum of the single phase's stiffness, ($I^{(i)}$ are the inertia, and $E^{(i)}$ the Young modulus of single phase, respectively). In order to stress the influence of Poisson's moduli, the error percentage between and $\bar{k}_\varepsilon$ was carried out by applying the formula $err\% = 100(k_\chi - \bar{k}_\chi)/\bar{k}_\chi$, that for pure bending gives:

$$err\% = \frac{400\,\alpha\,\beta^4\left(1+\beta^4\right)\left(\nu^{(0)}-\nu^{(1)}\right)^2}{\left[\beta^4(\alpha-1)+1\right]} \cdot \frac{1}{\left\{\left(\beta^4-1\right)\left(3-\nu^{(0)}-4\nu^{(0)2}\right)+\alpha\left(1+\nu^{(1)}\right)\left[\beta^4\left(4\nu^{(1)}-3\right)-1\right]\right\}} \tag{14}$$

where α, β are parameters expressing ratios between Young modulus and of radii of two phases, respectively.

By assuming same area and same Young's modulus for two phases: $\alpha = 1$, $\beta = 1/\sqrt[4]{2}$, the defined percentage error becomes following function of Poisson's modulus of two phases:

$$err\%\left(\alpha=1,\beta=\frac{1}{\sqrt[4]{2}}\right) = \frac{200\left(\nu^{(1)}-\nu^{(0)}\right)^2}{8+\nu^{(1)}\left(1-4\nu^{(1)}\right)-\nu^{(0)}\left(1+4\nu^{(0)}\right)} \tag{15}$$

Figure 4 shows that by coupling an external tube shoving negative values of Poisson modulus ν with a core cylinder with positive values of ν, the homogenized stiffness of composite can assume values greater than 40% respect the approximate averaging

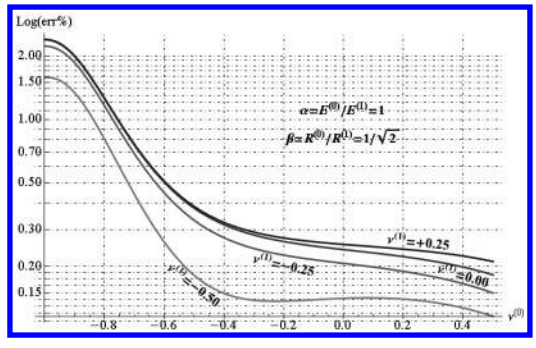

Figure 6. Error percentage of shear stiffness as function of different Poisson modulus values of materials.

value ($\alpha = E^{(0)}/E^{(1)} = 1$, $\beta = R^{(0)}R^{(1)} = 1/\sqrt[4]{2}$). Figure 5 shows same effect when it is assumed variable the ratio β between radii of phases, for negative values of Poisson modulus of external material ($\alpha = E^{(0)}/E^{(1)} = 1, = 0.5$). By means of the same homogenization procedure also the shear stiffness was obtained, which is given by:

$$\bar{k}_\gamma = 6\pi R^{(1)}\mu^{(1)}\left[\frac{\beta^2\mu^{(0)}\left(1+\nu^{(0)}\right)}{7+2\nu^{(0)}\left(7+4\nu^{(0)}\right)} + \frac{\left(1-\beta^2\right)\left(1+\beta^2\right)^2\left(1+\nu^{(1)}\right)}{\left[7+2\nu^{(1)}\left(7+4\nu^{(1)}\right)\right]\left(1+\beta^4\right)+\left[34+4\nu^{(1)}\left(17+8\nu^{(1)}\right)\right]\beta^2}\right] \tag{16}$$

and the relevant error percentage is given by formula

$$err\% = 100\left(k_\gamma - \bar{k}_\gamma\right)/\bar{k}_\gamma. \tag{17}$$

Following Figures 6 and 7 show the considerable growing of shear stiffness for particular chooses of mechanical and geometrical parameters, namely for Poisson modulus of components of opposite sign.

Above solutions were successfully applied to a few of technical problems aimed to maximize stiffness in cases of bending and shear, design of optical fibre sensors for distributed strain measurements, prediction of collapse load of concrete columns confined by Fiber Rinforced Polymers.

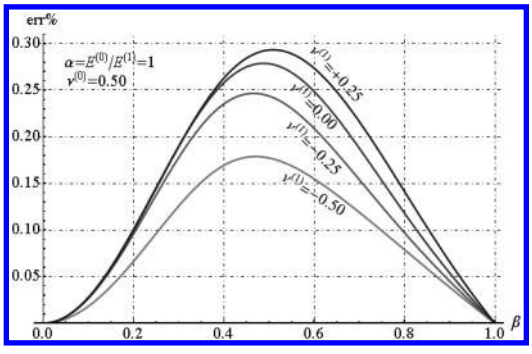

Figure 7. Error percentage of shear stiffness for different Poisson modulus values of materials, as function of radii ratio.

3 TECHNICAL APPLICATIONS

In the following, some applications of above theory are presented, that show interesting new results obtained by the Author, in a few of new fields of modern structural engineering.

3.1 *Optical fibre sensors for distributed strain readings*

New sensors for distributed readings, composed by a three phase Functionally Graded Cylinder [Figure 8] were studied by means of the above presented theory [5,6,8]. The optical fibre (Figure 8), a composed cylinder whose axis is x_3, is composed by an internal glass core, covered by a glass cladding and by a polymeric jacket. The external diameter can reach a few of hundreds of micrometers. For many engineering works of strategic significance like bridges, pipes, high rise buildings, dams and tunnels, safety should be continuously assessed over their complete lifetimes. Because optical fibre length reaches tens of kilometres, they can be used for the monitoring and safety assessment of these large structures.

When optical fibre is strictly bonded to the structure, its deformation follows that of the supporting object, and thanks to the strain, changes in to the density of the glass core occur. This effect con be read by means of distributed optical fibre sensors based on *stimulated Brillouin scattering* (SBS) that rely on the interaction between two light waves and an acoustic wave in the optical fibre. The measurement principle is based on the fact that the Brillouin frequency of the optical fibre is shifted when strain changes occur.

A necessary condition for a good reading of strain, is that the strain present in the object in the direction of axis x_3 on the external boundary of optical fibre, may be transmitted without decaying until the central core of sensor. This condition becomes the so-called mechanical condition of *no-decaying* of ε_{33} strain component in the radial direction [4], passing through the three material phases of sensor. The mechanics of the three-phase composed cylinder constituting the sensor was analysed, by imposing the inner constraint

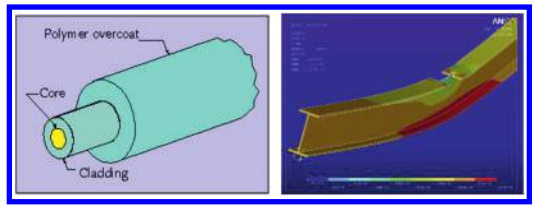

Figure 8. Optical Fibre. FEM analysis of bent defected beam.

Figure 9. Laboratory Tests on large beams.

of no-decaying of the ε_{33} strain component in radial direction. It was shown that under this internal constraint on deformation, only the following conditions of loads are allowed: a) radial pressures with linear variation in x_3 direction applied on the cylindrical external surface of sensor; b) axial force applied on two bases; c) uniform shear tractions applied on the cylindrical external surface of sensor in x_3 direction accompanied by equilibrating normal forces on bases of cylinder.

By means of this new mechanical solutions, and of an experimental optical-electronic apparatus, some laboratory tests on large steel beams and rods, were carried out to measure the strain profile all over the length of structure (Figure 9). This technique was then successfully utilised to predict the damage present in a bending beam, showing optimal accuracy and agreement between the read strains and the calculated ones. FEM numerical results were also utilised for assessment of experimental results (Figure 8).

3.2 *Load carrying capacity of reinforced concrete columns confined with fiber reinforced polymers*

By means of the above presented theory of composite cylinders [4,5], the elastic and ultra-elastic response of concrete columns confined by Carbon Fiber Reinforced Polymers (CFRP) was analyzed. The concrete column was modeled as a composed circular cylinder constituted by a concrete's central core with a surrounding tube of concrete in which are present axial steel reinforcements, surrounded by a CFRP thin bandage.

Under the hypotheses of axis-symmetrical boundary conditions, elasticity and perfect bond between the phases, analytical solutions for self-equilibrated axial forces applied at the extremities of the object were derived (Figure 10).

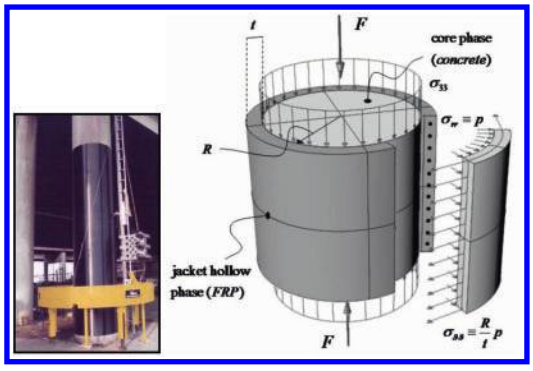

Figure 10. RC Column reinforced with FRP. Mechanical model.

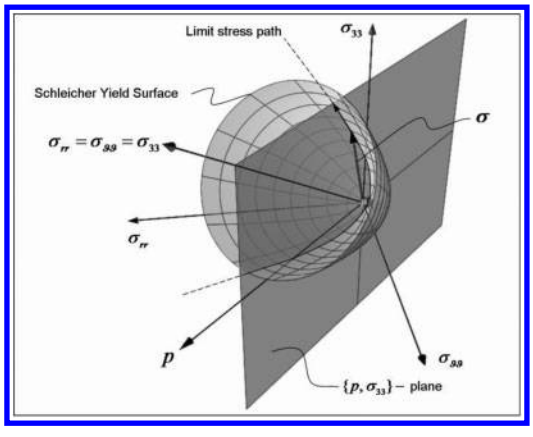

Figure 11. Limit stress path on Schleicher Yield surface.

The initial elastic analysis was based here on the hypotheses of isotropic response of concrete and on cylindrically anisotropy of FRP bandage. Also in this case, the differential Boundary Value Problem (BVP) of the three phase composite cylinder was reduced to the equivalent linear algebraic one, by means of a special matrix-like arrangement of the governing equations and invoking the Complex Potential Theory for anisotropic materials.

When axial load increases, the response of cylinder "moves" toward the post-elastic range in which the stress field in the core follows the Intrinsic Curve or Schleicher-like elastic-plastic behavior whit associate flow rule.

The cylindrically orthotropic hollow phase modeling FRP sheets surrounding reinforced concrete column obeys to an elastic-brittle Tsai-Hill anisotropic yield criterion. By means of this strategy, predictive formulae for estimating the overall collapse mechanism, the concrete ultimate compressive strength and the confining pressure effect were derived.

The obtained results were compared with several experimental literature data, highlighting good agreement with each other [5,6].

Also a formula for design thickness of confining FRP sheet was obtained, as well as an assessment formula for the whole reinforced column [5].

Numerical implementation of the Hoek-Brown material model with strain hardening

E.S. Sørensen, J. Clausen & L. Damkilde
Department of Civil Engineering, Aalborg University, Aalborg, Denmark

ABSTRACT: A numerical implementation of the Hoek-Brown criterion is presented, which is capable of modeling important aspects of the different post-failure behaviors observed in jointed rock mass. This is done by varying the material parameters based on the accumulated plastic strains. The implementation is for use in finite element calculations, and is based on the return mapping framework. The updated stress state is found in principal stress space based on the principles of boundary planes and a consistent constitutive matrix is found for better convergence of the global equilibrium iterations. The constitutive model is demonstrated on a simulation of a tunnel excavation and the results are compared with an analytical solution for a tunnel excavation in elastic-brittle rock material.

1 INTRODUCTION

Rock masses are often encountered within the fields of civil and mining engineering. Examples include tunnel excavations, foundations and slope stability problems. According to Hoek & Brown (1997), the post-failure behavior of rock masses falls into three categories. A very good quality hard rock mass tends to show an elastic-brittle behavior, where the strength drops rapidly once yielding occurs. Average quality rock mass is believed to show a strain-softening behavior, where the strength decrease with an increase in plastic strains. Rock mass of poor quality behaves in an elastic-perfectly-plastic fashion. The analytical solutions of a tunnel excavation provided by Sharan (2008) demonstrate the impact of an elastic-brittle behavior compared to a perfectly plastic behavior.

To model the strength of rock masses, the Hoek-Brown yield criterion is often applied (Hoek et al. 2002). This paper seeks to implement a Hoek-Brown material model able to incorporate all three post-failure behaviors for use in finite element calculations.

2 THE HOEK-BROWN CRITERION

The Hoek-Brown criterion has evolved from the original Hoek-Brown criterion used for hard rock masses into the more versatile generalized Hoek-Brown criterion, which states that plastic deformations develop once

$$\sigma_1' = \sigma_3' + \sigma_{ci}\left(m_b\frac{\sigma_3'}{\sigma_{ci}} + s\right)^a \tag{1}$$

where σ_1' is the largest effective principal stress, σ_3' is the smallest effective principal stress, σ_{ci} is the uniaxial compressive strength of the intact rock material and m_b, s and a are material parameters. Compression is taken as positive. Throughout the rest of this paper, effective stresses are implied and the primes will thus be left out for simplicity. The material parameters m_b, s and a and the Youngs modulus, E can be found based on the Geological Strength Index, GSI, the disturbance factor, D, and the intact rock parameter, m_i (Hoek et al. 2002), (Hoek & Diederichs 2006).

3 PLASTICITY FUNDAMENTALS

The basic theory behind plasticity relies on one or more yield functions, $f_1, \ldots, f_n$, which are scalar functions of the stress state, $\boldsymbol{\sigma}$, and some hardening parameters, $\boldsymbol{K}$. Plastic strains start to develop once the material reaches its yielding limit, which is defined by the yield criteria

$$f_i(\boldsymbol{\sigma}, \boldsymbol{K}) = 0, \quad i = 1, \ldots, n \tag{2}$$

Any combination of $\boldsymbol{\sigma}$ and $\boldsymbol{K}$ fulfilling one or more of the criteria leads to additional plastic straining. Any combination of $\boldsymbol{\sigma}$ and $\boldsymbol{K}$ resulting in negative values of all yield criteria does not result in additional plastic straining and any combination resulting in a positive value of any of the functions is inadmissible. The manner in which the plastic strains develop is governed by the plastic potential functions, $g_1, \ldots, g_n$, which are also functions of $\boldsymbol{\sigma}$ and $\boldsymbol{K}$, and the non-negative plastic multipliers $\lambda_1, \ldots, \lambda_n$, such that

$$d\boldsymbol{\varepsilon}^p = \sum_{i=1}^{n} \alpha_i \, d\lambda_i \frac{\partial g_i}{\partial \boldsymbol{\sigma}} \tag{3}$$

where α_i is 1 if yield criterion i is active, and 0 otherwise. The hardening parameters, $\boldsymbol{K}$, are functions of

the state variables, $\boldsymbol{\kappa}$, that define the internal state of the material

$$\boldsymbol{K} = \boldsymbol{K}(\boldsymbol{\kappa}) \tag{4}$$

The evolution of the state variables is defined by the evolution law

$$d\boldsymbol{\kappa} = \sum_{i=1}^{n} \alpha_i \, d\lambda_i \boldsymbol{k}_i(\boldsymbol{\sigma}, \boldsymbol{K}) \tag{5}$$

where $\boldsymbol{k}_1, \ldots, \boldsymbol{k}_n$ are some functions, that must be appropriately chosen.

Further details of the FE-method and plasticity can be found in Ottosen & Ristinmaa (2005), de Souza Neto, Perić, & O wen (2008) and Clausen (2007).

4 RETURN MAPPING

The numerical implementation relies on return mapping, which initially assumes that the strain increment, $\Delta\boldsymbol{\varepsilon}$, from the global equilibrium iterations, is entirely elastic, resulting in an elastic predictor stress increment

$$\Delta\boldsymbol{\sigma}^e = \boldsymbol{D}\Delta\boldsymbol{\varepsilon} \tag{6}$$

which combined with the initial stress state, $\boldsymbol{\sigma}^A$, results in a predicted elastic stress state

$$\boldsymbol{\sigma}^B = \boldsymbol{\sigma}^A + \Delta\boldsymbol{\sigma}^e \tag{7}$$

If the evaluation of one or more of the yield criteria with this stress state and the initial hardening parameters, $\boldsymbol{K}^A$, results in a positive value, the stress state is inadmissible, cf. figure 1.

To find the updated stress state, a plastic corrector, $\Delta\boldsymbol{\sigma}^p$, is introduced

$$\begin{aligned} \Delta\boldsymbol{\sigma}^p &= \boldsymbol{D}\Delta\boldsymbol{\varepsilon}^p = \boldsymbol{D}\sum_{i=1}^{n} \alpha_i \int_{\lambda_i^A}^{\lambda_i^C} \frac{\partial g_i}{\partial \boldsymbol{\sigma}} d\lambda_i \\ &\approx \sum_{i=1}^{n} \alpha_i \Delta\lambda_i \boldsymbol{D} \left.\frac{\partial g_i}{\partial \boldsymbol{\sigma}}\right|_C = \sum_{i=1}^{n} \alpha_i \Delta\lambda_i \boldsymbol{s}_i \end{aligned} \tag{8}$$

where (3) has been used. Thus, the plastic corrector is some linear combination of the directions

$$\boldsymbol{s}_i = \boldsymbol{D} \left.\frac{\partial g_i}{\partial \boldsymbol{\sigma}}\right|_C \tag{9}$$

given by each active yield surface. The updated stress state becomes

$$\boldsymbol{\sigma}^C = \boldsymbol{\sigma}^B - \Delta\boldsymbol{\sigma}^p = \boldsymbol{\sigma}^B - \sum_{i=1}^{n} \alpha_i \Delta\lambda_i \boldsymbol{s}_i \tag{10}$$

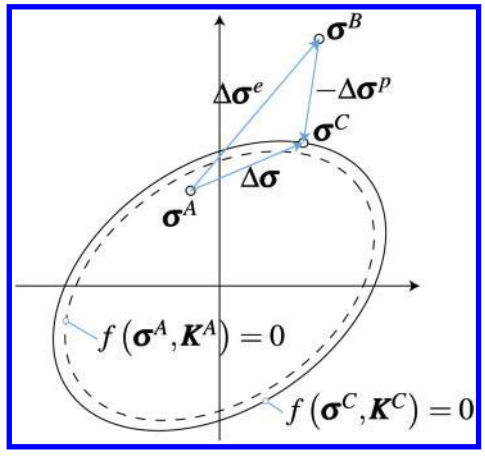

Figure 1. Sketch of the updating scheme.

In this regard, α_i is 1 for the yield criteria, which are satisfied for the updated stress state and zero otherwise. The updated stress state must fulfill

$$\alpha_i f_i\left(\boldsymbol{\sigma}^C, \boldsymbol{K}^C\right) = 0 \tag{11}$$

where $\boldsymbol{K}^C$ has been found from $\boldsymbol{\kappa}^C$, which in turn has been found using (5) such that

$$\boldsymbol{\kappa}^C = \boldsymbol{\kappa}^A + \sum_{i=1}^{n} \alpha_i \int_{\lambda_i^A}^{\lambda_i^C} \boldsymbol{k}_i d\lambda_i \approx \boldsymbol{\kappa}^A + \sum_{i=1}^{n} \alpha_i \Delta\lambda_i \, \boldsymbol{k}_i|_C \tag{12}$$

5 STRAIN HARDENING HOEK-BROWN MODEL

5.1 *Basic premises*

In order to implement the strain hardening Hoek-Brown model, the above mentioned aspects must be accounted for. With tension taken as positive, the Hoek-Brown criterion of (1) can be rewritten

$$f = \sigma_{\max} - \sigma_{\min} - \sigma_{ci}\left(s - m_b \frac{\sigma_{\max}}{\sigma_{ci}}\right)^a = 0 \tag{13}$$

where $\sigma_{\max}$ is the largest principal stress and $\sigma_{\min}$ is the smallest principal stress. Equation (13) forms a six-sided pyramid with curved sides in principal stress space along the hydrostatic axis, which bounds the allowable stress states, as seen on figure 2.

The plastic potential function is assumed to take the form of the Hoek-Brown criterion as well, however, the parameters are different from those of f, thus

$$g = \sigma_{\max} - \sigma_{\min} - \sigma_{ci_g}\left(s_g - m_{b_g} \frac{\sigma_{\max}}{\sigma_{ci}}\right)^{a_g} \tag{14}$$

The hardening parameters are comprised of

$$\boldsymbol{K} = \{\sigma_{ci}, m_b, s, a, \sigma_{sci_g}, m_{b_g}, s_g, a_g\} \tag{15}$$

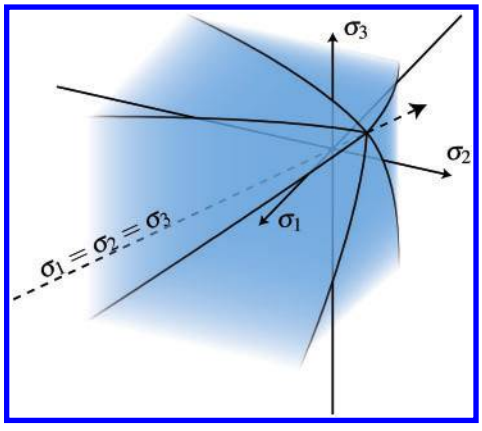

Figure 2. Sketch of Hoek-Brown criterion in principal stress space.

The state parameters, $\boldsymbol{\kappa}$, are assumed to be expressed by a single scalar value, $\bar{\varepsilon}^p$, called the accumulated plastic strain, which is assumed to evolve according to

$$d\bar{\varepsilon}^p = \sum_{i=1}^{n} \alpha_i \, d\lambda_i \tag{16}$$

i.e. $\boldsymbol{k}_i(\boldsymbol{\sigma}, \boldsymbol{K})$ is assumed to be 1, cf. (5). Thus, the change in accumulated plastic strain is the sum of the plastic multipliers involved. The state of the hardening parameters, $\boldsymbol{K}$, are found based on an arbitrary user defined set of points

$$\left(\bar{\varepsilon}_1^p, \boldsymbol{K}_1\right), \ldots, \left(\bar{\varepsilon}_k^p, \boldsymbol{K}_k\right) \tag{17}$$

Thus, the hardening parameters are found by linear interpolation between these points. If $\bar{\varepsilon}^p$ exceeds $\bar{\varepsilon}_k^p$, the hardening parameters are set according to the last point, and perfect plasticity is assumed during further plastic straining. Using this method, the model is able to simulate different kinds of behaviour, including elastic-brittle, strain hardening, strain softening and elastic-perfectly-plastic behaviour.

The return mapping scheme is carried out in principal stress space. This reduces the unknowns of $\boldsymbol{\sigma}^C$ from six to only three components, which can be visualized in a 3D space, and thus geometrical arguments can be applied. The predicted stress state, $\boldsymbol{\sigma}^B$, is thus transformed to principal stress space, denoted $\bar{\boldsymbol{\sigma}}^B$, and the corresponding updated stress state in principal stress space, $\bar{\boldsymbol{\sigma}}^C$, is found, which is then converted back to the original coordinate system, giving the updated stress state, $\boldsymbol{\sigma}^C$, that is of interest in the FE-model.

5.2 *Yield criterion regions*

Figure (3) shows the Hoek-Brown criterion seen from the hydrostatic axis.

If by definition we state that $\sigma_1 \geq \sigma_2 \geq \sigma_3$, when we transform $\boldsymbol{\sigma}^B$ to $\bar{\boldsymbol{\sigma}}^B$, then only surface f_1, f_2 and f_6 are of interest. There are four possible locations of

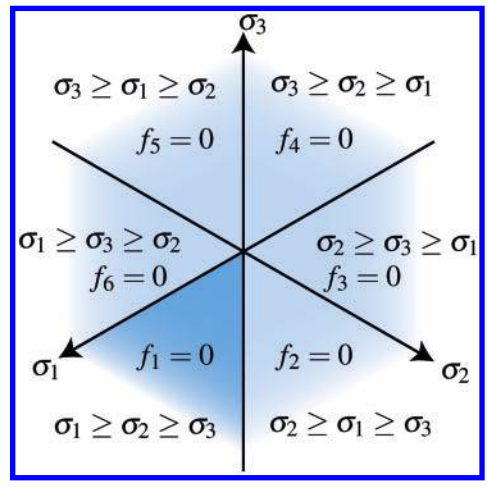

Figure 3. Sketch of Hoek-Brown criterion in principal stress space seen from the hydrostatic axis.

the updated stress state. Either the stress state lies on surface f_1, the intersection between f_1 and f_2, the intersection between f_1 and f_6 or the intersection of f_1, f_2 and f_6, known as the apex. Even though the apex point is comprised of all six yield criteria, only three of them are needed to form a basis for the plastic strains. Thus, we are dealing with three yield functions

$$f_1 = \sigma_1 - \sigma_3 - \sigma_{ci}\left(s - m_b\frac{\sigma_1}{\sigma_{ci}}\right)^a = 0 \tag{18}$$

$$f_2 = \sigma_2 - \sigma_3 - \sigma_{ci}\left(s - m_b\frac{\sigma_2}{\sigma_{ci}}\right)^a = 0 \tag{19}$$

$$f_6 = \sigma_1 - \sigma_2 - \sigma_{ci}\left(s - m_b\frac{\sigma_1}{\sigma_{ci}}\right)^a = 0 \tag{20}$$

with the appertaining plastic potentials g_1, g_2 and g_6. Because the updated stress state can be situated at four different locations, four different return algorithms are required. However, before they can be put to use, it must first be clarified, which one to use for a given predictor stress state.

This is handled in a similar fashion to Clausen & Damkilde (2008), with the use of boundary planes. By evaluating (9) along the boundaries of each yield criterion, the principal stress space is divided into regions. The updated stress state of a given predictor stress state belongs to the yield criteria f_i, where $\boldsymbol{s}_i$ define the region, in which the predictor stress state is located.

For the Hoek-Brown model, $\boldsymbol{s}_1$ is given by

$$\boldsymbol{s}_1 = \frac{E}{(1+\nu)(1-2\nu)}\begin{Bmatrix}(1-\nu)k_g - \nu \\ \nu k_g - \nu \\ \nu k_g - 1 + \nu\end{Bmatrix} \tag{21}$$

where

$$k_g = \frac{\partial g_1}{\partial \sigma_1} = 1 + a_g m_{b_g}\left(s_g - m_{b_g}\frac{\sigma_1}{\sigma_{ci_g}}\right)^{a_g - 1} \tag{22}$$

similarly $\boldsymbol{s}_2$ and $\boldsymbol{s}_3$ is given by

$$\boldsymbol{s}_2 = \left\{s_{1,2},\ s_{1,1},\ s_{1,3}\right\}^T,\ \boldsymbol{s}_3 = \left\{s_{1,1},\ s_{1,3},\ s_{1,2}\right\}^T \quad (23)$$

where $s_{1,k}$ is the k'th component of $\boldsymbol{s}_1$. From (21) and (22), it is seen, that $\boldsymbol{s}_i$ only depend on σ_1.

If perfect plasticity is assumed, the boundaries given by $\boldsymbol{s}_i$ does not change during plastic flow. However, if hardening plasticity is applied, the boundaries of each criteria as well as $\boldsymbol{s}_i$ change as the hardening parameters change. Since the hardening parameters of the updated stress state, $\boldsymbol{K}^C$, is unknown, these boundaries are also unknown. Nonetheless, by evaluating $\boldsymbol{s}_i$ with the initial hardening parameters, $\boldsymbol{K}^A$, the correct return algorithm can be estimated and applied. The resulting updated stress state and hardening parameters can then be used to check, whether the correct return algorithm has been employed. This is done if any of the return algorithms fail to converge. The new boundaries are calculated using the hardening parameters of the last iteration, $\boldsymbol{K}_l^C$, and if the predictor stress state has fallen into a new region, that return algorithm is applied. If that is not the case, then it is suggested to decrease the load step of the global finite element calculations and try again.

5.3 *Return to f_1*

If the predictor stress state is believed to return to $f_1 = 0$, then only one plastic multiplier is in play and only $\alpha_1 = 1$. This leads to four unknowns, namely the three principal stresses $\overline{\boldsymbol{\sigma}}^C$ and $\Delta\lambda_1$, which is sufficient to compute the accumulated plastic strain, $\overline{\varepsilon}^p$, and the updated hardening parameters. The solution is required to obey

$$\sigma_1^C = \sigma_1^B - \Delta\lambda_1 s_{1,1} \quad (24)$$

$$\sigma_2^C = \sigma_2^B - \Delta\lambda_1 s_{1,2} \quad (25)$$

$$\sigma_3^C = \sigma_3^B - \Delta\lambda_1 s_{1,3} \quad (26)$$

$$f_1\left(\overline{\boldsymbol{\sigma}}^C, \boldsymbol{K}^C\right) = 0 \quad (27)$$

cf. (10) and (11). However, since $\boldsymbol{s}_1$ only depends upon σ_1^C, the unknowns σ_2^C and σ_3^C are known once σ_1^C is known cf. (25) and (26). Thus we only need two equations, and with a little rewriting of (24), we obtain

$$\sigma_1^C - \sigma_1^B + \Delta\lambda_1 s_{1,1} = 0 \quad (28)$$

$$f_1\left(\overline{\boldsymbol{\sigma}}^C, \boldsymbol{K}^C\right) = 0 \quad (29)$$

This system of equations is solved using a Newton-Raphson iteration scheme, where

$$\boldsymbol{R}_l = \begin{Bmatrix} \sigma_{1,l}^C - \sigma_1^B + \Delta\lambda_{1,l} s_{1,1} \\ f_1\left(\overline{\boldsymbol{\sigma}}_l^C, \boldsymbol{K}_l^C\right) \end{Bmatrix} \quad (30)$$

until $|\mathrm{norm}(\boldsymbol{R}_l)| < \mathrm{TOL}$, where TOL is the required tolerance. $\boldsymbol{K}_l^C$ is interpolated from the points of (17) based on $\overline{\varepsilon}_l^{p,C}$ given by

$$\overline{\varepsilon}_l^{p,C} = \overline{\varepsilon}^{p,A} + \Delta\lambda_{1,l} \quad (31)$$

To start the iterations, an initial guess is needed. $\sigma_{1,0}^C$ is based on the σ_1 value that would fulfill (18) if $\sigma_3 = \sigma_3^B$ and $\Delta\lambda_{1,0}$ is assumed equal to 0. If $\sigma_{1,l+1}^C$ exceeds the current apex of the yield criteria, a fail safe is adapted in which

$$\sigma_{1,l+1}^C = \rho\sigma_{a,l+1}^C + (1-\rho)\sigma_{1,l}^C \quad (32)$$

where $\sigma_{a,l+1}^C$ is the current apex of the Hoek Brown criterion based on $\boldsymbol{K}_{l+1}^C$, and $\rho = 0.99$.

The solution of (28) and (29) does not ensure that $\sigma_1^C \geq \sigma_2^C \geq \sigma_3^C$. The solution is thus checked to ensure this. If it turns out that $\sigma_2^C > \sigma_1^C$, the return to f_1 & f_2 is applied. If $\sigma_3^C > \sigma_2^C$, the return to f_1 & f_6 is applied.

5.4 *Return to f_1 & f_2*

If the updated stress state resides on the intersection between f_1 and f_2, where $\sigma_1 = \sigma_2$, then two yield criteria are active, $\alpha_1 = \alpha_2 = 1$, and two multipliers, $\Delta\lambda_1$ and $\Delta\lambda_2$, are needed. Based on a similar procedure as the f_1 return, it ends up in three equations, with three unknowns

$$\sigma_1^C - \sigma_1^B + \Delta\lambda_1 s_{1,1} + \Delta\lambda_2 s_{2,1} = 0 \quad (33)$$

$$\sigma_1^C - \sigma_2^B + \Delta\lambda_1 s_{1,2} + \Delta\lambda_2 s_{2,2} = 0 \quad (34)$$

$$f_1\left(\overline{\boldsymbol{\sigma}}^C, \boldsymbol{K}^C\right) = 0 \quad (35)$$

Note that (34) corresponds to $\sigma_1^C = \sigma_2^C$, which ensures that $f_2(\overline{\boldsymbol{\sigma}}^C, \boldsymbol{K}^C) = 0$. This system is solved in a similar manner to the system of the f_1 return.

5.5 *Return to f_1 & f_6*

If the updated stress state resides on the intersection between f_1 and f_6, where $\sigma_2 = \sigma_3$, then two yield criteria are active, $\alpha_1 = \alpha_6 = 1$, and two multipliers, $\Delta\lambda_1$ and $\Delta\lambda_6$, are needed. Based on a similar procedure as above, it ends up in three equations, with three unknowns

$$\sigma_1^C - \sigma_1^B + \Delta\lambda_1 s_{1,1} + \Delta\lambda_6 s_{6,1} = 0 \quad (36)$$

$$\sigma_3^C - \sigma_2^B + \Delta\lambda_1 s_{1,2} + \Delta\lambda_6 s_{6,2} = 0 \quad (37)$$

$$f_1\left(\overline{\boldsymbol{\sigma}}^C, \boldsymbol{K}^C\right) = 0 \quad (38)$$

Again (37) corresponds to $\sigma_2^C = \sigma_3^C$, which ensures that $f_6(\overline{\boldsymbol{\sigma}}^C, \boldsymbol{K}^C) = 0$.

5.6 *Return to f_1, f_2 & f_6*

The return algorithm where the updated stress state resides on the apex, is comprised of three active yield criteria, f_1, f_2 and f_6, $\alpha_1 = \alpha_2 = \alpha_6 = 1$, and thus three plastic multipliers are also needed, $\Delta\lambda_1$, $\Delta\lambda_2$ and $\Delta\lambda_6$. However, the return algorithm is a little different than the other algorithms, because the location of $\overline{\boldsymbol{\sigma}}^C$ is known to coincide with the intersection of the three active yield criteria, where $\sigma_1^C = \sigma_2^C = \sigma_3^C = \sigma_a^C$. The apex, σ_a^C, is known once $\boldsymbol{K}^C$ is known. Thus only the three equations of (10) are needed to solve the problem, i.e.

$$\sigma_a^C - \sigma_1^B + \Delta\lambda_1 s_{1,1} + \Delta\lambda_2 s_{2,1} + \Delta\lambda_3 s_{3,1} = 0 \tag{39}$$

$$\sigma_a^C - \sigma_1^B + \Delta\lambda_1 s_{1,2} + \Delta\lambda_2 s_{2,2} + \Delta\lambda_3 s_{3,2} = 0 \tag{40}$$

$$\sigma_a^C - \sigma_1^B + \Delta\lambda_1 s_{1,3} + \Delta\lambda_2 s_{2,3} + \Delta\lambda_3 s_{3,3} = 0 \tag{41}$$

If associated flow is assumed, the apex of the yield criteria and the plastic potentials coincide. Since the gradient of the plastic potential tends toward infinity on the apex, cf. (22), the plastic multipliers must approach zero in order to give finite strains. For this reason, perfect plasticity is assumed in the associated case with a return to the apex.

5.7 *Consistent constitutive matrices*

It can be shown, that the consistent constitutive matrix is given by

$$\boldsymbol{D}^{epc} = \boldsymbol{D}^c - \boldsymbol{D}^c \sum_{i=1}^{n}\sum_{k=1}^{n} \alpha_i \alpha_k \left(\boldsymbol{A}^{-1}\right)_{ik} \frac{\partial g_i}{\partial \boldsymbol{\sigma}} \left(\frac{\partial f_k}{\partial \boldsymbol{\sigma}}\right)^T \boldsymbol{D}^c \tag{42}$$

where $\boldsymbol{A}$ is the $n \times n$ matrix given by

$$A_{ik} = \alpha_i \alpha_k \left(\left(\frac{\partial f_i}{\partial \boldsymbol{\sigma}}\right)^T \boldsymbol{D}^c \frac{\partial g_k}{\partial \boldsymbol{\sigma}} + \left(\frac{\partial f_i}{\partial \boldsymbol{K}}\right)^T \frac{\partial \boldsymbol{K}}{\partial \overline{\boldsymbol{\varepsilon}}^p} \right) + (\alpha_i - 1)(\alpha_k - 1)\,\delta_{ik} \tag{43}$$

where $\boldsymbol{D}^c$ is the modified elastic stiffness matrix and δ_{ik} is the Kronecker delta. For further details see Clausen (2007) and Ottosen & Ristinmaa (2005). Once perfect plasticity is reached, the modified consistent constitutive matrices mentioned in Clausen (2007) is used in the calculations.

6 EXAMPLE: TUNNEL EXCAVATION

The numerical implementation is tested on a simulation of a tunnel excavation. The simulation models 1 m of a tunnel with a radius, r_T, of 10 m along the tunnel axis, z, using axissymmetry, cf. figure 4. The extend of the model reach out to $r_{BC} = 300$ m from the tunnel axis. The excavation is simulated by reducing the pressure, p, on the tunnel wall from the in-situ

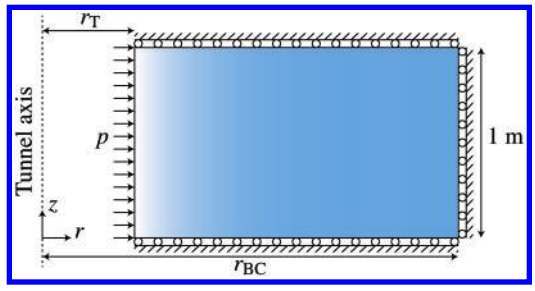

Figure 4. Sketch of the tunnel model.

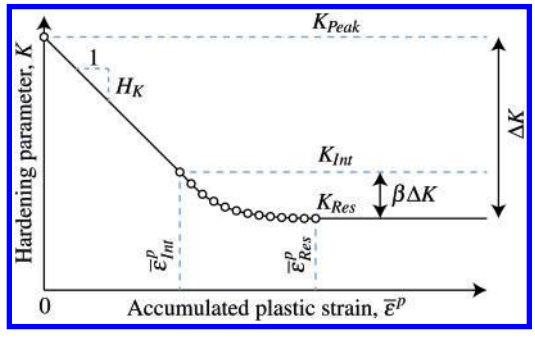

Figure 5. Evolution of the hardening parameters based on the accumulated plastic strain, $\overline{\varepsilon}^p$.

pressure, p_∞, to 0. The self weight of the rock material is neglected.

The parameters of the Hoek-Brown material are taken from example B of Sharan (2008). The parameters consists of peak parameters and residual parameters, cf. table 2. Notice however, that the numerical implementation is incapable of implementing the drop in Young's modulus described in Sharan (2008). Because of this, the peak modulus is assumed throughout the simulation, and the solution method in Sharan (2008) is utilized to get an analytical solution for an elastic-brittle rock material.

The plastic potential parameters are listed in table 2. These parameters result in non-associated flow and gives a constant dilation parameter, K_d, of 1.15, which makes comparing with the solution of Sharan (2008) possible.

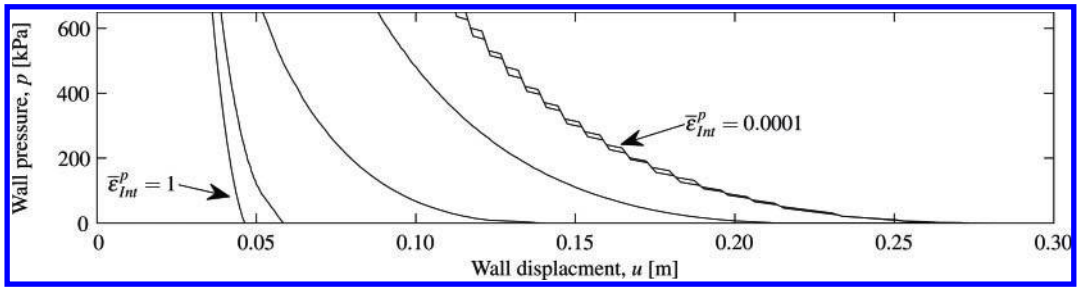

Figure 6. Tunnel wall movement, u, as a function of wall pressure, p. Notice that the curve for $\bar{\varepsilon}^p_{Int} = 0.0010$ and $\bar{\varepsilon}^p_{Int} = 0.0001$ almost overlap.

In the simulations, it is chosen, that during plastic straining, the hardening parameters drop from the peak parameters to the residual parameters according to figure 5.

As can be seen, the hardening parameters drop linearly from the peak value at zero plastic strain, to some intermediate value, K_{Int}, at some intermediate accumulated plastic strain, $\bar{\varepsilon}^p_{Int}$, followed by a non-linear evolution leading to perfect plasticity at $\bar{\varepsilon}^p_{Res}$. The intermediate value of the hardening parameter, K_{int}, is based on the parameter β, cf figure 5, which is set to 0.1. By setting the residual parameters equal to the peak parameters, perfect plasticity is achieved. The intermediate and residual accumulated plastic strains, $\bar{\varepsilon}^p_{Int}$ and $\bar{\varepsilon}^p_{Res}$, can be used to control the rate of softening. By letting these tend towards zero, an elastic-brittle behavior is achieved. $\bar{\varepsilon}^p_{Res}$ is chosen as $2\bar{\varepsilon}^p_{Int}$, and the simulation is performed for $\bar{\varepsilon}^p_{Int} = \{1; 0.1; 0.01; 0.005; 0.0025; 0.0010; 0.0001\}$, which spans an almost perfectly-plastic behavior, through strain softening to almost elastic-brittle behavior. Based on this, 300 points are calculated and used in the simulations, cf. (17). The model is meshed using 1600 linear-strain triangular elements with a gauss order of 13 and solved using a standard Newton-Raphson solution method with a maximum step length of $\Delta t = 5 \cdot 10^{-4}$, in order to get a detailed view of the equilibrium path, which can be seen on figure 6.

The analytical solution predicts a wall displacement of 0.0454 m in the elastic-perfectly-plastic case, and a wall displacement of 0.2789 m in the elastic-brittle case. The results from the finite element model results in a wall displacement between 0.0456 m and 0.2826 m respectively for $\bar{\varepsilon}^p_{Int} = 1$ and $\bar{\varepsilon}^p_{Int} = 0.0001$. A difference of 0.4% and 1.3% respectively. Further, the results of the simulations in between the elastic-perfectly-plastic and the elastic-brittle behaviour shows results between these two values, which is what would be expected.

The FE-simulations showed some mesh dependency, and the jagged nature of the more brittle rock simulations is believed to stem from a too coarse mesh. If the elastic predictor stress state falls just outside the yield surface, the yield surface shrinks very rapidly, and thus a large plastic multiplier is needed, which leads to large plastic strains. If the mesh is coarse, each gauss point represents a large portion of the model, and thus large displacements are also expected. If a finer mesh is employed, each gauss point represents smaller portions of the model, and thus smaller and more continuous displacements are expected. However, if a finer mesh is employed, the global equilibrium iterations become troublesome. This could perhaps be due to the stability issues surrounding numerical non-associated plasticity.

7 CONCLUSION

A strain hardening Hoek-Brown material model has been developed, which is capable of modeling many aspects of the observed behavior of jointed rock masses. A total of eight parameters are allowed to evolve based on the accumulated plastic strains. The model has been deployed on a FE-simulation of a tunnel excavation utilizing non-associated plasticity and the results obtained are in good agreement with the analytical solutions, however, some mesh dependency was observed.

Simulation of the mechanical behavior of W/Cu composites containing FGM related interpenetrating microstructures under consideration of phase dependent damage limits

S. Schmauder & U. Weber
Institute for Materials Testing, Materials Science and Strength of Materials (IMWF), University of Stuttgart, Stuttgart, Germany

ABSTRACT: Coarse isotropic interpenetrating microstructures are often found in powder metallurgically fabricated composites in the regime of 25%–75% volume fraction, or result from the infiltration of a porous material with a molten metal of a lower melting point. The phases in most of these technical composites are usually randomly arranged. Besides the volume fraction such an interpenetrating microstructure requires at least one further parameter called matricity to describe the material more precisely. The "matricity" describes the mutual circumvention of both phases and can be measured from a representative micrograph of a microstructure via an image analyzing system. In order to characterize the elastic and elastic-plastic properties of composites with interpenetrating microstructures a self-consistent unit cell model is applied. This so called matricity model is a combination of two self-consistent unit cells, which consider the enclosure of the phases of a two-phase microstructure. Thereby, in every cell, depending on the volume fraction, every phase is once considered as the matrix and as inclusion. The matricity model is applied on several ranges of volume fractions for a W/Cu composite. In addition a damage criterion based on critical normal stresses and on the von Mises stress is applied to predict load limits for the composite.

1 INTRODUCTION

1.1 *General*

Composites consisting of phases with strongly different properties have the potential to be used in new application fields as they comprise otherwise incompatible properties. While the deformation behaviour of inclusion-type microstructures has been successfully modeled in the past for brittle fiber or particulate reinforced metal matrix composites (Zahl & Schmauder & McMeeking, 1994, Dong & Schmauder, 1996a, Schmauder & Mishnaevsky, 2009) this was not achieved until recently in the case of interpenetrating microstructures where both phases are connected throughout the material. Such microstructures are typically observed in the composition range of 30–70% while inclusion type of microstructures are typical for dilute systems with phase volume fractions between 0–30%. Specifically, functionally graded materials can depict the full composition range in material transitions. As processing techniques are nowadays available to design material transitions, experience in modeling of the full composition range is still lacking. This paper is intended to bridge the gap in the case of W/Cu composites where the full compositional range is experimentally available from a powder-metallurgical route (Jedamzik & Neubrand & Rödel, 1997).

1.2 *Model*

The matricity model is used for the simulation of the elastic-plastic material properties of the W/Cu composite with phases α and β in this paper. In the case of an inclusion type of microstructure the self-consistent embedded cell model is applied which is described in (Dong & Schmauder, 1996a, b, c, Sautter, 1995, Zahl & Schmauder & McMeeking, 1994). The embedded cell model has been introduced to simulate the mechanical behaviour of composites with randomly distributed inclusions. The volume fraction of the inclusions is the main parameter in the model. To take the matricity M as a second microstructural parameter into account, the self-consistent embedded cell model has been extended by a second self-consistent embedded cell model (Figure 1). In this "matricity model" the parameter M can be defined in the same manner as the matricity is defined for a real microstructure: First the single phases are reduced to skeleton lines. The lengths of the skeleton lines of the inclusions (Figure 1; left: β, right: α) are zero as the inclusions are spherical and are, therefore, reduced to a point in the process of obtaining the matricity of the phase.

The lengths of the skeleton lines S_α and S_β in the matrices are given as the circumference of a circle with a diameter which is obtained from the arithmetic average of the diameter of the embedded cell and the

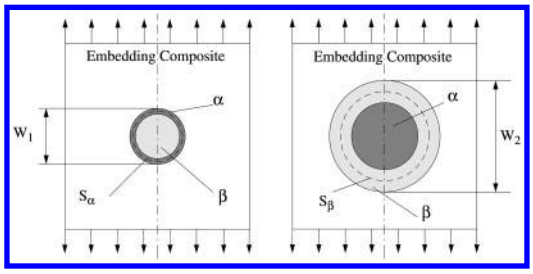

Figure 1. Matricity model (schematic) with skeleton lines (dashed) to adjust for the measured parameter "Matricity" in the model via the factors W_1 and W_2.

diameter of the inclusion phase (Figure 1; left: S_α, right: S_β). The diameters of the embedded cells are denominated as W_1 and W_2. The diameters of the inclusion part of the embedded cells depend on the volume fraction of the inclusions and the corresponding factors W_1 or W_2. The matricity M can be calculated as a function of the sizes of the embedded cells and the volume fraction of one of the two phases, as the volume fraction of the phases is held constant in both parts of the matricity model.

$$W_1 = W_2\left(\sqrt[3]{1-f_\beta}\right)\cdot\frac{1-M_\beta}{M_\beta\left(\sqrt[3]{f_\beta}+1\right)},\ W_2 = 1 \text{ for } M_\beta \geq 0.5$$
$$W_2 = W_1\left(\sqrt[3]{1-f_\alpha}\right)\cdot\frac{1-M_\alpha}{M_\alpha\left(\sqrt[3]{f_\alpha}+1\right)},\ W_1 = 1 \text{ for } M_\alpha \geq 0.5 \quad (1)$$

As can be seen in Figure 1, the volume fractions of the phases as well as the diameters W_1 and W_2 of the embedded cells are adjustable. To achieve a matricity M_i ($i = \alpha, \beta$) in the model, the measured volume fraction of the phases in the model is realized and the diameters W_1 and W_2 are calculated according to equation 1 (Leßle & Dong & Soppa & Schmauder, 1998). If the geometrical boundary conditions are modeled at a distance of about 5 times the radius of the embedded cell, they are of almost no influence on the model's mechanical behaviour. If the boundary conditions are kept remote, the embedded cell can be modeled with the surrounding composite in different manners. As the remote boundary conditions have almost no influence on the mechanical behaviour of the embedded cell it is assumed that the continuum mechanical stress-strain state in the embedded cell is hardly influenced as well. Taking this into account, a unit cell for a specific volume fraction can be used in each part of the matricity model. Moreover, due to the virtual independency from remote boundaries, it is not necessary to model the matricity as an absolute parameter of the FE-mesh. It is rather possible to introduce the matricity by adjusting weighting factors W_1 and W_2 only in the evaluation of the results from the inclusion type geometries. As the results have to be determined by an iterative procedure in about 3 to 5 iterations, the adjusting weighting factors W_1 and W_2 must be introduced in the evaluation of each iteration step.

The stress-strain curves of the two-phase composite are determined from the matricity model in the same iterative manner as it is done for the simple self-consistent embedded cell model: In each increment the components for stress and strain are determined. This is done by a weighted averaging of the stress and strain values over all integration points of both embedded cells in loading direction.

2 RESULTS AND DISCUSSION

2.1 *Microstructures and matricity*

W/Cu compositions in different ranges till 75% Cu were produced by a sintering and infiltration method (Jedamzik & Neubrand & Rödel, 1997).

The corresponding microstructures are presented in Figure 2. Besides the volume fraction, the second parameter, the so-called matricity parameter M which represents the degree of mutual interpenetration and circumvention of the phases and which was introduced by (Poech & Ruhr, 1993) is also given in the Figure. In the following, composites of two phases α and β are considered. Matricity is then defined as the ratio of the length of the skeleton lines of one phase, S_α, and the length of the skeleton lines of the participating phases:

$$M_\alpha = \frac{S_\alpha}{S_\alpha + S_\beta} \quad (2)$$

By definition, the sum of the matricities of all phases equals to one:

$$M_\alpha + M_\beta = 1 \quad (3)$$

To obtain the skeleton lines of a certain phase, this phase is selected within an image analysing system and the detected structure is reduced to a typically non-connecting line maintaining the topology. In Figure 2 the matricities have been determined for a graded W/Cu composite. The structure parameters, volume fraction f, and matricity M, have been determined to be: $M_{Cu} = 0.26$, 0.45, 0.59 and 0.72 for $f_{Cu} = 21\%$, 40%, 50% and 75%, respectively.

2.2 *Material properties*

To predict the stress-strain curves of the W/Cu composite with the corresponding volume fraction and matricities of the real microstructure using the matricity model, the elastic-plastic behaviour of the bulk materials W and Cu are needed. Because W can be assumed as a brittle metal, a pure elastic behaviour is assumed for this phase. The elastic-plastic properties of the Cu-phase are given in Table 1.

The tensile strength and the yield stress of the W- and Cu-phase, respectively, are used later on as critical damage stresses.

Figure 3 shows the calculated stress strain behaviour of the W/Cu composite for the given volume fractions and matricities of Cu (see Figure 2). As indicated

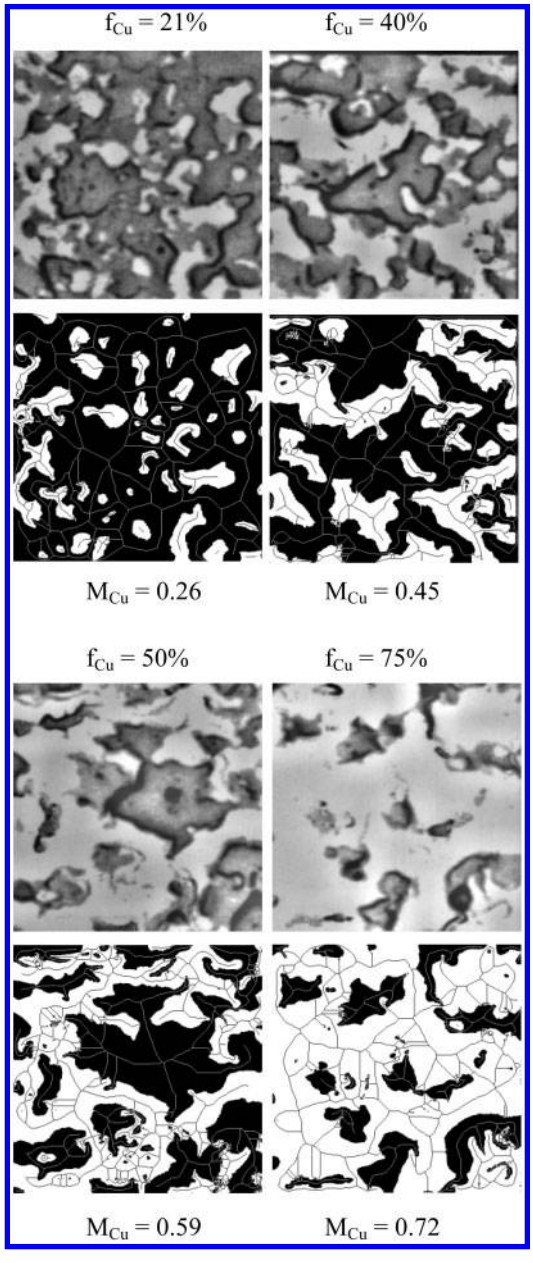

Figure 2. Microstructures and matricities (Cu-phase) of different W/Cu composites at different volume fractions of Cu.

in Figure 3, there is especially a strong variation in the mechanical behaviour of the W/Cu composite for $f_{Cu} = 40\%–50\%$. In order to derive later on limit curve at additional interpolation points, additional volume fractions of Cu have to be considered.

The unknown matricities for these additional volume fractions are determined by interpolation. In Figure 4 it can be seen, that there exists a nearly linear relationship between the two parameters f (volume fraction) and M (matricity).

Table 1. Material Properties of the Bulk Phases W and Cu: μ = Poisson's Ratio, E = Young's Modulus, σ_y = yield stress, R_m = tensile strenth, ε_{ue} = uniform elongation

Setting	μ	E (GPa)	σ_y (MPa)	R_m (MPa)	ε_{ue}
W	0.17	411	–	800	–
Cu	0.35	130	95	230	0.22

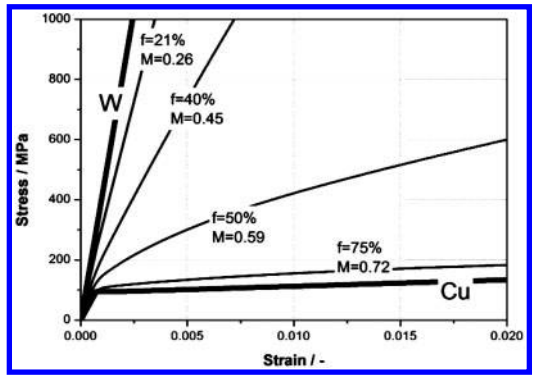

Figure 3. Calculated stress-strain curves of the W/Cu composite for selected compositions and according matricities (see Figure 2) (f = volume fraction of Cu, M = Matricity of Cu).

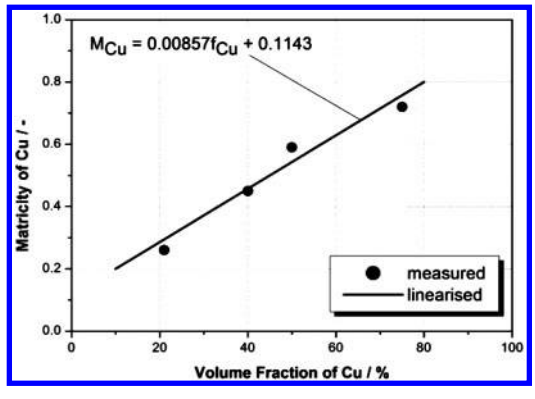

Figure 4. Correlation between volume fraction of Cu (f_{Cu}) and matricity of copper (M_{Cu}) for different W/Cu microstructures.

To close the gap of unknown stress-strain curves between 40% and 50% and between 50% and 75% volume fractions of Cu (see Figure 3), respectively, additional simulations are performed at $f_{Cu} = 46\%$ ($M_{Cu} = 0.51$) and $f_{Cu} = 60\%$ ($M_{Cu} = 0.63$). More model details and further results are given in Schmauder & Weber & Hofinger & Neubrand.

2.3 *Damage*

W/Cu composites are mostly applied as electrodes to erode, electrical contacts and welding electrodes.

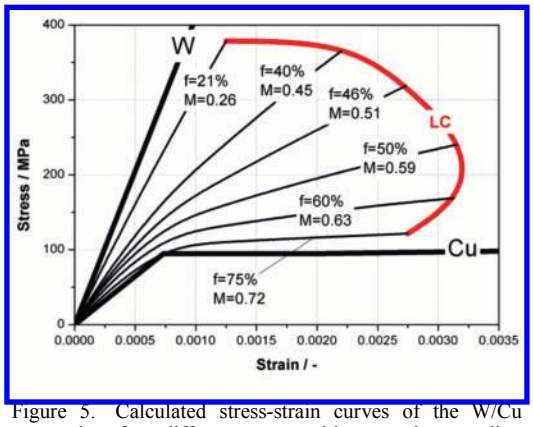

Figure 5. Calculated stress-strain curves of the W/Cu composite for different compositions and according matricities (f = volume fraction of Cu, M = matricity of Cu). LC = limit curve at which the averaged von Mises stress in the Cu-phase reaches 95 MPa.

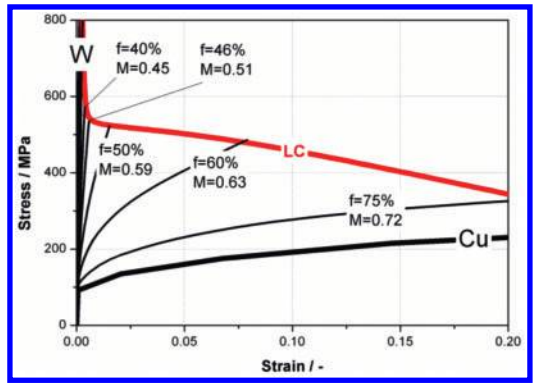

Figure 6. Calculated stress-strain curves of the W/Cu composite for different compositions and according matricities (f = volume fraction of Cu, M = matricity of Cu). LC = limit curve at which the averaged first principal stress in the W-phase reaches 800 MPa.

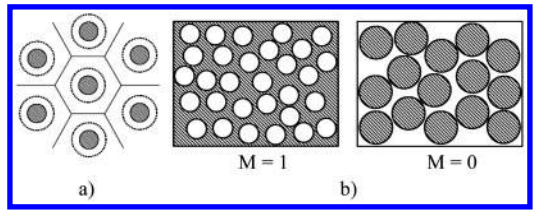

Figure 7. Independence of the volume fraction f and matricity M (schematically) of the shaded phase. a): Change of the volume fraction at constant matricity. b): Change of the matricity from M = 1 to M = 0 at constant volume fraction.

If the functionality of a sample requires limited plastic deformation during application, the loading limitation of the W/Cu composite is the yield stress of the Cu-phase. For this purpose, the averaged von Mises stress in the Cu-Phase is compared to the yield stress of Cu (=95 MPa) during the loading of the embedded cells. Figure 5 shows the calculated stress-strain curves of the W/Cu composite combined with the limit curve, which defines the state, where the averaged von Mises stress in the Cu-phase reaches the critical value (yield stress of copper) of 95 MPa. Because of the averaging of all integration points, which belongs to the Cu-phase, the limit curve admits some plastic deformation of the composite.

As expected, the deformation limit of the W/Cu composite depends on the volume fraction of the Cu-phase (Figure 5): For low copper volume fractions up to 40%, there exists nearly no change in the limit stress. For Cu volume fractions above 40% the limit stress (on the LC) decreases strongly. Overall, for the given requirements, the max. allowed strain of the W/Cu composite is limited to ~0.32%. For application, comparatively high stresses at comparatively high strains are feasible for a copper volume fraction in the range of 46%.

On the other hand, if plasticity in the Cu-phase of the W/Cu composite is tolerable but fracture of the brittle W-phase must be avoided in operation, the tensile strength of this phase (because of the assumed brittle behaviour) is the limitation. For this purpose the averaged first principal stress in the W-Phase is compared with the tensile strength of W (=800 MPa) during the loading of the embedded cells. According to Figure 5, Figure 6 shows the calculated stress-strain curves of the W/Cu composite and the limit curve, which defines the position where the averaged first principal stress in the W-phase reaches the critical value (tensile strength of W) of 800 MPa. As can be seen in Figure 6, the stress limit of the W/Cu composite depends again on the volume fraction of the Cu-phase: For low copper volume fractions up to 46%, there exists a broad decrease in the limit stress at low strains. For copper volume fractions in the range of 50%–75%, the limit stress changes linearly from ~500 MPa to ~300 MPa with large differences in the respective strains. In all cases, the yield stress of the copper phase is surmounted. Similar results were found in Schmauder & Weber & Reuschel & Willert, were this model was applied to an Al/TiO_2 composite.

Although, there exists a linear relation between the volume fraction f and the matricity M as experimentally found for different interpenetrating microstructures, these both microstructural parameters are independent. This is shown schematically in Figure 7.

In Figure 7a) the volume fraction of the shaded phase changes without any modification of the matricity of the white phase and therefore without change of the matricity of the shaded phase. In Figure 7b) the volume fraction of both phases in both rectangles is identical, but the matricity of the shaded phase changes from M = 1 (left) to M = 0 (right) and, therefore, for a given phase volume fraction the deformation behaviour of interpenetrating microstructures can be designed only by the variation of the matricity M. In the following, the matricity of the copper phase is varied at constant copper volume fraction of $f_{Cu} = 50\%$. According to Figure 5, Figure 8 shows the calculated stress-strain curves of the W/Cu composite combined

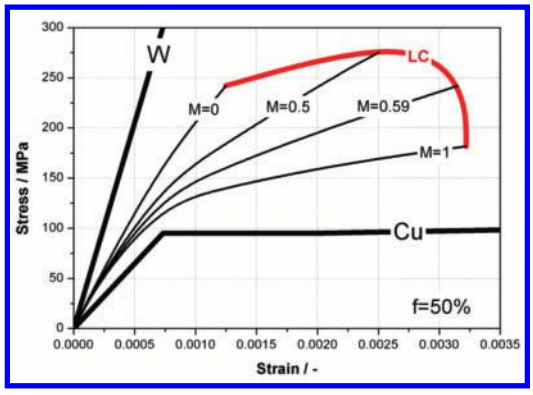

Figure 8. Calculated stress-strain curves of the W/Cu composite for a Cu volume fraction of f = 50% at different matricities M of the Cu-phase. LC = limit curve at which the averaged von Mises stress in the Cu-phase reaches 95 MPa.

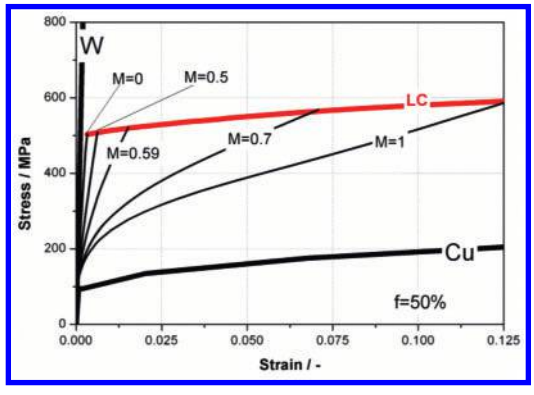

Figure 9. Calculated stress-strain curves of the W/Cu composite for a Cu volume fraction of f = 50% at different matricities M of the Cu-phase. LC = limit curve at which the averaged first principal stress in the W-phase reaches 800 MPa.

with the limit curve, which defines the state, where again the averaged von Mises stress in the Cu-phase reaches the critical value (yield stress of copper) of 95 MPa. After a slight increase from M = 0 to M = 0.5 (M = 0 denotes, that W is the pure matrix and Cu is the pure inclusion), the limit curve decreases rapidly at M > 0.5, where the copper phase plays more and more the role of the matrix. The highest strength at comparable strain are found for a Cu matricity M = 0.5.

According to Figure 6, Figure 9 shows for a given volume fraction of copper (f = 50%) the calculated stress-strain curves of the W/Cu composite combined with the limit curve, which defines the state, where the averaged first principal stress in the W-phase reaches the critical value (tensile strength of W) of 800 MPa. As can be seen in Figure 9, with increasing Cu matricity M, the limit curve allows more and more deformation at increasing strength. But again, in all cases, the yield stress of the copper phase is exceeded and plastic deformation occurs in the W/Cu composite. If plasticity is tolerable, the most suitable composition (high strength at high strain) is found at M = 1.

2.4 *Elastic properties*

Finally, the calculated elastic properties like Young's modulus E and Poisson's Ratio μ are shown in Figure 10. Here, E and μ are plotted vs. the volume fraction of copper for different W/Cu compositions, respectively. Because the Young's Modulus of W is higher and its Poisson's Ratio is lower than of Cu, the Young's Modulus E and the Poisson's Ratio μ of the W/Cu composite decreases and increases with increasing volume fraction f of Cu, respectively.

It is clearly seen, that there exists a nonlinear relation between both elastic properties and the volume fraction of Cu. The rule of mixture based on both limit volume fractions (f = 21% and f = 75%) would overestimate especially the Young's Modulus of the W/Cu interpenetrating microstructure.

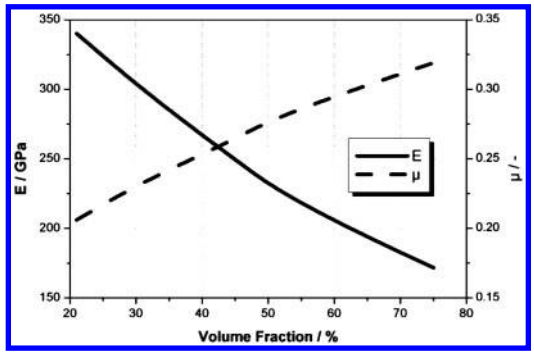

Figure 10. Correlation between volume fraction of Cu and the Young's Modulus E and Poisson's Ratio μ of the W/Cu composite.

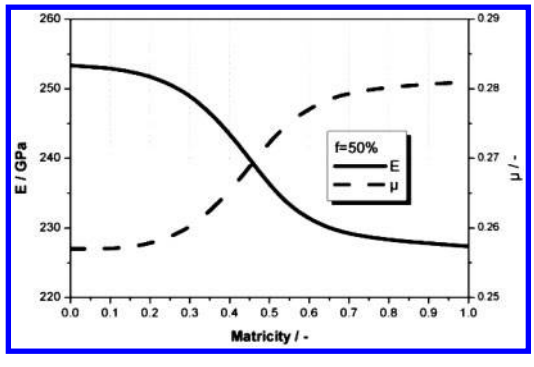

Figure 11. Correlation between the matricity of Cu and the Young's Modulus E and Poisson's Ratio μ of the W/Cu composite for a Cu volume fraction of f = 50%.

As mentioned above, the matricity of an interpenetrating microstructure is a powerful parameter to design materials with specific properties, especially in the plastic regime. But also the elastic properties are influenced by this parameter. In Figure 11, again the Young's Modulus E and the Poisson's Ratio μ are

shown as a function of the matricity of Cu for a giv-ven Cu volume fraction f = 50%.

An increasing matricity M of Cu means, that the Cu phase plays more and more the role of the matrix while the W-phase can more and more be regarded as the inclusion phase. Hence, with increasing M, the Cu properties predominate the composite behaviour and the values of E and μ tend towards the Cu-values, therefore, E and μ decreases and increases, respectively, with increasing M. Particular between M = 0.3 and M = 0.7 a clear change of E and μ can be detected. Comparable characteristics were also found for the plastic regime, where the hardening of the W/Cu composite changes dramatically between M = 0.5 and M = 0.7 (Figure 9).

3 CONCLUSION

The self-consistent matricity model was applied to systematically predict the elastic-plastic material properties of a full range of W/Cu compositions. In addition, a damage criterion based on the critical normal stresses and on the von Mises stress is applied. The results in the case of W/Cu (with one elastic and one elastic-plastic phase) can be summarized as follows.

Besides the volume fraction f, the matricity M of an interpenetrating microstructure, which describes the mutual circumvention of both phases influences the stress-strain behaviour of the investigated W/Cu composite especially in the range between M = 0.5 and M = 0.7 (M = matricity of Cu). It was found, that in experiments there exists nearly a linear relation between the matricity M and the volume fraction f. However, in principle, both microstructural parameters can be regarded to be independent.

If yielding of Cu is defined as damage criterion, the total deformation of the composite is limited to ~0.3% for $f_{Cu} = 50\%$. If fracture of the brittle W-phase should be avoided, the total composite deformation is limited to ~20%. As expected, also the elastic properties E and μ depend on the composition of the W/Cu composite: With increasing volume fraction of Cu, E decreases and μ increases, respectively.

It was also shown, that for a constant volume fraction of Cu ($f_{Cu} = 50\%$) the elastic-plastic behaviour of the W/Cu composite can be designed by varying the matricity of the copper phase. Considering a brittle damage criterion (no fracture of the W phase), the total deformation of the W/Cu composite is reduced to 12.5% but at much higher stresses as before. Concerning the elastic properties E and μ, a strong change was found in the range between $M_{Cu} = 0.3$ and $M_{Cu} = 0.7$ at $f_{Cu} = 50\%$.

Thus, the self-consistent matricity model is a powerful model to describe the elastic-plastic properties of interpenetrating microstructures and to design and adapt material properties for specific applications.

Determination of effective elastic constants of two phase composites

O. Bulut, N. Kadioglu & S. Ataoglu
Istanbul Technical University, Faculty of Civil Engineering, Istanbul, Turkey

M. Yuksek & E. Sancak
Marmara University, Faculty of Technical Education, Istanbul, Turkey

ABSTRACT: The objective of the present study is to determine the mechanical properties of the composite materials formed in two types. The first includes small particles in a matrix while the second involves thin fibers. During calculations a fictitious, homogeneous, linear-elastic and isotropic single material which is named as effective material is considered. The base of the theoretical calculation depends on the equality of the strain energies of the composite and the effective material under the same state of stress. Considering hydrostatic tension and simple torsion, the Bulk modulus and the shear modulus of the effective material have been calculated as a function of the concentration ratio, and the elastic constants of the components. Some experiments are also achieved for comparison. The volume ratio of the matrix is much bigger compared to the particles or fibers. This means that the present study deals with experiments for the low concentration ratios.

1 INTRODUCTION

In continuum mechanics, it is assumed that materials have a continuous volume without any hole and cover the all area of this volume. In the model presented here, the atomic structure of the material is ignored since the interatomic distances are very small compared to the dimensions of the body. However, some latest works prove that the micro-structure of a material and the interactions between them affect the macro-scale properties of the body. In other words, the mechanical properties of a material which are macro-properties of it are closely related to the micro-structure of it.

In this study, to observe the results of some changing in micro-structure on macro-scale properties, composites, including very small particles or very thin fibers in a matrix, are considered. So, this study serves to understand of the behavior of the composites at the same time. Composite materials are chosen for designing frequently due to their strength or other advantages.

Here, the particles and the fibers have at least one dimension in micro-level. The materials of both of the matrix and inclusions are considered as homogeneous, linear-elastic and isotropic. The volume concentration which is inclusion volume to total volume ratio is very small in considered composites. So, there are no interactions between them. Furthermore, inclusions distribute in the matrix homogeneously. Besides, the elastic constants of matrix material are very lower than those of fibers or particles.

Under the mentioned assumptions, a representative volume element (RVE) can be defined (Hashin, 1962). This volume represents the whole composites and it is different for the cases of the particles or fibers. It has two geometrical shapes, spherical and cylindrical, according to the type of composites and consists of two parts for both of them. The first part is matrix which has the greater volume and the second is inclusion which can be a single particle or a single fiber. The inclusions are assumed as a spherical and a cylindrical body, respectively. In another saying, matrix having spherical form includes particle and matrix in cylindrical geometry includes fiber. As it is stated in the mentioned article, it is assumed that the RVE is equivalent to a single effective body which has the same geometry with the RVE.

In this study, hydrostatic tension problem has been considered for the spherical RVE and for the equivalent effective body to obtain the effective Bulk modulus. Furthermore, simple torsion problem has been solved for the cylindrical RVE and its equivalence. This process is based on the equating the total strain energies of the RVE to that of the associated effective body.

2 DETERMINING OF THE EFFECTIVE BULK MODULUS ANALYTICALLY

2.1 *Strain energy of a spherical body in the state of hydrostatic tension*

A spherical body having radius b is loaded hydrostatic pressure τ_0 (Fig. 1). For convenience, the spherical coordinates (r, θ, φ) has been used for the solution.

The problem is spherically symmetric and whole quantities are independent from θ and φ. Displacement vector $\mathbf{u}$ has only radial component u_r. In spherical

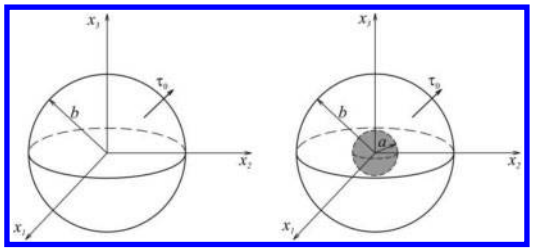

Figure 1. Spherical Bodies.

coordinates, nonzero components of the strain tensor $\boldsymbol{\varepsilon}$ are

$$\mathbf{u} = u_r \mathbf{e}_r \tag{1}$$

$$\varepsilon_{rr} = \frac{\partial u_r}{\partial r}, \varepsilon_{\theta\theta} = \varepsilon_{\varphi\varphi} = \frac{u_r}{r} \tag{2}$$

where ∂ shows the partial differential, $\mathbf{e}_r$ is the unit vector along the radial direction.

Using the constitutive equations in the theory of elasticity and considering the expressions (1) and (2) the nonzero components of the stress tensor are obtained as

$$\begin{aligned} \tau_{rr} &= (\lambda + 2\mu)\frac{\partial u_r}{\partial r} + 2\lambda\frac{u_r}{r} \\ \tau_{\theta\theta} &= \tau_{\varphi\varphi} = \lambda\frac{\partial u_r}{\partial r} + 2(\lambda + \mu)\frac{u_r}{r} \end{aligned} \tag{3}$$

where λ and μ are Lamé's constants. The equilibrium equations in terms of displacement vector is

$$(\lambda + 2\mu)\nabla\nabla\cdot\mathbf{u} - \mu\nabla\times\nabla\times\mathbf{u} = 0 \tag{4}$$

while the body forces are neglected (Malvern, 1969 & Sadd, 2005). Here, ∇ is the del operator and in spherical coordinates it is stated as (Moon & Spencer, 1961)

$$\nabla = \frac{\partial}{\partial r}\mathbf{e}_r + \frac{1}{r}\frac{\partial}{\partial\theta}\mathbf{e}_\theta + \frac{1}{r\sin\theta}\frac{\partial}{\partial\varphi}\mathbf{e}_\varphi \tag{5}$$

If the displacement vector given in the expression (1) is used in the expression (4) then

$$\frac{\partial}{\partial r}\left(\frac{\partial u_r}{\partial r} + 2\frac{u_r}{r}\right) = 0 \tag{6}$$

is obtained. This is a differential equation in the type of Euler-Cauchy. Then, the radial component of the displacement vector is obtained as

$$u_r = Ar + \frac{B}{r^2} \tag{7}$$

where A and B are the unknown constants. This solution is valid on the whole body so that at $r = 0$ the solution must be finite. This concludes that B is zero. The other boundary condition says that surface traction vector $\boldsymbol{t}$ is equal to $\tau_0\varepsilon_r$ on the boundary $r = b$. Writing these, using (2), (3) and (7), and using the outer normal of the boundary as $\boldsymbol{e}_r$

$$\begin{aligned} &t = \tau\cdot n = \tau_0\mathbf{e}_r \\ &\varepsilon_{rr} = \varepsilon_{\theta\theta} = \varepsilon_{\varphi\varphi} = A \\ &\tau_{rr} = \tau_{\theta\theta} = \tau_{\varphi\varphi} = A(3\lambda + 2\mu) = 3KA \\ &A = \frac{\tau_0}{3\lambda + 2\mu} = \frac{\tau_0}{3K} \end{aligned} \tag{8}$$

will be obtained. Here, K is the Bulk modulus and is stated as

$$K = \frac{3\lambda + 2\mu}{3} \tag{9}$$

Finally the total strain energy U accumulated on this body can be written using equation below.

$$U = \frac{1}{2}\int_V \tau_{ij}\varepsilon_{ij}dV \tag{10}$$

Here dV is the differential volume element which has to be written in spherical coordinates. When this integral is evaluated using the equations (2), (8) and (10), the result is obtained as

$$\begin{aligned} U &= \frac{1}{2}\int_{\varphi=0}^{2\pi} d\varphi\int_{\theta=0}^{\pi}\sin\theta d\theta\int_{r=0}^{b} r^2\left(\frac{\tau_0^2}{3K}\right)dr \\ &= \frac{2}{3K}\pi b^3\tau_0^2 \end{aligned} \tag{11}$$

The total volume of the sphere having radius b is

$$V = \frac{4}{3}\pi b^3 \tag{12}$$

So, if the expression (11) is re-written, then the strain energy comes as

$$U = \frac{1}{2K}V\tau_0^2 \tag{13}$$

2.2 *Strain energy of a spherical body including the co-centered spherical particle in the state of hydrostatic tension*

Here a spherical body having radius b including a spherical particle with radius a, centered on the same origin is considered (Fig. 1).

Using the expression (7), the displacement field for particle and matrix can be written as

$$u_r^P = A^P r + \frac{B^P}{r^2} \quad , 0 \le r \le a \tag{14}$$

$$u_r^M = A^M r + \frac{B^M}{r^2} \quad , a \le r \le b \tag{15}$$

Here, the letter "P" and "M" indicate the particle and the matrix, respectively. At $r=0$, the displacement must be finite so it is required that

$$B^P = 0 \tag{16}$$

The components of the strain and stress can be written using (14), (15) and (16) for particle and matrix, separately such that they are similar in the previous considered problem. There are three unknown A^P, A^M and B^M so three boundary conditions to determine them are

$$\tau_{rr}^M = \tau_0 \quad \text{at } r=b \tag{17}$$

$$u_{rr}^M = u_{rr}^P \quad \text{at } r=a \tag{18}$$

$$\tau_{rr}^M = \tau_{rr}^P \quad \text{at } r=a \tag{19}$$

If these conditions are written using the obtained stress and displacement components three equations occurs. These are

$$\left(3K^M\right)+B^M\left(-\frac{4\mu^M}{b^3}\right)=\tau_0 \tag{20}$$

$$A^M(a)+B^M\left(\frac{1}{a^2}\right)-A^P(a)=0 \tag{21}$$

$$A^M\left(3K^M\right)+B^M\left(-\frac{4\mu^M}{a^3}\right)-A^P\left(3K^P\right)=0 \tag{22}$$

The volume concentration of the included particle, c, is defined as the ratio of the volume of particle (V^P) to the volume of the total body (V). This is written as

$$c=\frac{V^P}{V}=\frac{(4/3)\pi a^3}{(4/3)\pi b^3}=\frac{a^3}{b^3} \tag{23}$$

Furthermore, if a constant D is used instead of (B^M/a^3) in the equations (20), (21) and (22), then these three equations can be solved for the unknown constants as

$$D=\tau_0\frac{K^M-K^P}{4\mu^M[K^M+(K^P-K^M)c]+3K^MK^P} \tag{24}$$

$$A^P=\tau_0\frac{4\mu^M+3K^M}{3\{4\mu^M[K^M+(K^P-K^M)c]+3K^MK^P\}} \tag{25}$$

$$A^M=\tau_0\frac{4\mu^M+3K^P}{3\{4\mu^M[K^M+(K^P-K^M)c]+3K^MK^P\}} \tag{26}$$

Now, the strain energy accumulated on the whole body can be written in terms of Bulk moduli, shear moduli and concentration ratio. To do this, the equation (10) is used for the two parts and the summation of results gives the energy. Here, the integrals are gotten over φ and θ from 0 to 2π and from 0 to π for both of the parts, respectively. The radius is changed from 0 to a for particle and from a to b for matrix. Using the stress and strain components, the equations (24), (25) and (26), and the expressions which are

$$4\pi\frac{b^3-a^3}{3}=V(1-c) \tag{27}$$

$$B^M=Da^3 \tag{28}$$

the total strain energy is calculated as

$$U=\frac{9}{2}[VcK^P(A^P)^2+VK^M(A^M)^2(1-c)] +6V\mu^MD^2c(1-c) \tag{29}$$

2.3 *Determining the effective bulk modulus*

The strain energy written in the expression (13) can be considered as the energy of effective material which must be equivalent to the RVE whose total strain energy was obtained in the expression (29). If these two strain energy are equated and rearranged for K^*, which is the effective Bulk modulus, then the result will be

$$\frac{1}{K^*}=\frac{1}{\tau_0^2}\{9[cK^P(A^P)^2+(1-c)K^M(A^M)^2] +12c(1-c)\mu^MD^2\} \tag{30}$$

Hashin used two materials for matrix and particle whose Bulk moduli are

$$K^M=418511.77MPa,\ K^P=172368.93MPa \tag{31}$$

Here, the variation of the Bulk modulus of composite materials obtained with these materials with respect to volume concentration is given in Figure 2.

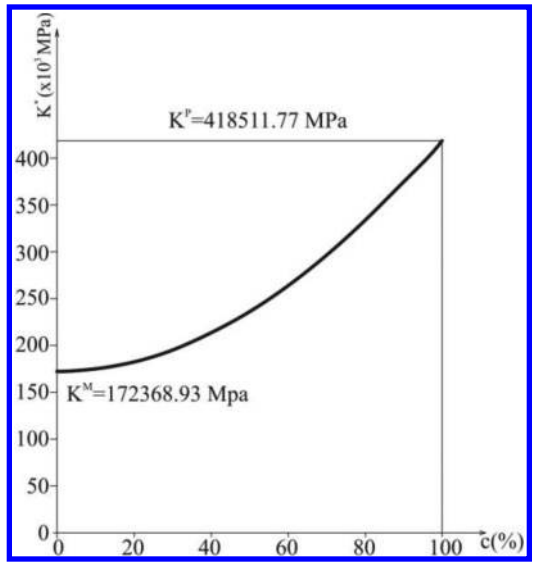

Figure 2. The variation of the Bulk modulus of composite including particle vs. volume concentration.

3 CALCULATION OF THE EFFECTIVE SHEAR MODULUS

3.1 *Simple torsion of a cylindrical body*

A single cylindrical body whose height and radius are h and b, respectively, has been considered (Fig. 3). There is a constant distributed moment m which is applied to this cylinder at both ends in x_3 direction which is the axis of the body. $M_0 = m\pi b^2$ is the total moment acting on both top and bottom surfaces. For convenience, the cylindrical coordinates (r, φ, z) will be used. The components of the stress tensor are zero except $\tau_{r\varphi}$, $\tau_{\varphi r}$, $\tau_{\varphi z}$ and $\tau_{z\varphi}$ in the cylindrical coordinates. Here, all unknowns of the problem are independent of φ and displacement vector has only u_φ component. A differential element having the height dz, and radius r is considered (Fig. 3).

$M_z + dM_z$ and M_z represent the resulting torsion moments at the top and bottom surfaces of this differential element, respectively. Let $\tau_{z\varphi}$ denotes the shear stress acting on the bottom surface. The resultant of this stresses is M_z. If this relation is written

$$M_z(r,z) = \int_{\varphi=0}^{2\pi} d\varphi \int_{r=0}^{b} \xi^2 d\xi \tau_{z\varphi}(\xi, z) \tag{32}$$

is obtained. Calculating r derivative of equation (32) gives

$$\tau_{z\varphi}(r,z) = \frac{1}{2\pi r^2}\frac{\partial M_z}{\partial r} \tag{33}$$

Additionally, the moment balance along the x_3 axis gives the equation below.

$$\tau_{r\varphi}(r,z) = -\frac{1}{2\pi r^2}\frac{\partial M_z}{\partial z} \tag{34}$$

These two shear stress expressed in (33) and (34) can be also written in terms of displacement components by using the relations between strains and displacements in cylindrical coordinates and using Hooke's Law as below.

$$\tau_{z\varphi} = \mu\frac{\partial u_\varphi}{\partial z} \quad , \quad \tau_{r\varphi} = \mu\left(\frac{\partial u_\varphi}{\partial r} - \frac{u_\varphi}{r}\right) \tag{35}$$

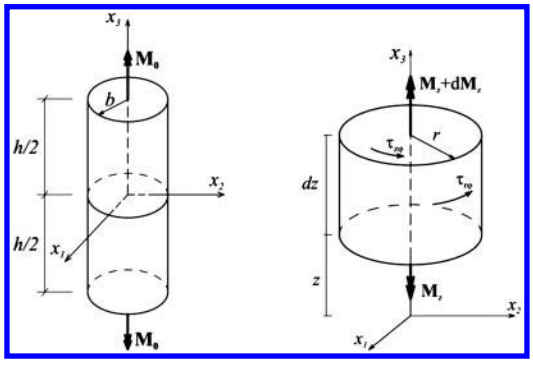

Figure 3. The cylindrical body and a differential element from that.

Using (33)–(35)

$$\frac{1}{2\pi r^2}\frac{\partial M_z}{\partial r} = \mu\frac{\partial u_\varphi}{\partial z} \tag{36}$$

$$-\frac{1}{2\pi r^2}\frac{\partial M_z}{\partial z} = \mu\left(\frac{\partial u_\varphi}{\partial r} - \frac{u_\varphi}{r}\right) \tag{37}$$

are found. Calculating r derivative of (36) and z derivative of (37), the following differential equations is obtained for M_z.

$$\frac{\partial^2 M_z}{\partial r^2} - \frac{3}{r}\frac{\partial M_z}{\partial r} + \frac{\partial^2 M_z}{\partial z^2} = 0 \tag{38}$$

The solution of this equation for this equation is

$$M_z = Cr^4 + B \tag{39}$$

M_z should vanish for $r = 0$ (Love, 1944 & Barber, 2004). Then, B becomes zero. M_z must be equal to M_0 for $r = b$. Writing this, the other constant is obtained as

$$M_z(r=b) = M_0 = m\pi b^2 \;\rightarrow\; C = \frac{m\pi}{b^2} \tag{40}$$

Substituting this into (39) and using this into the equations (33) and (34), the shear stresses obtained as well.

$$\tau_{r\varphi} = 0, \; \tau_{z\varphi} = \frac{2mr}{b^2} \tag{41}$$

So, the shear strain different from zero is also obtained using Hooke's Law as

$$\gamma_{z\varphi} = \frac{2mr}{\mu b^2} \tag{42}$$

The total strain energy accumulated in this cylinder can be calculated as

$$U = \int_{\varphi=0}^{2\pi} d\varphi \int_{z=0}^{h} dz \int_{r=0}^{b} \tau_{z\varphi}\gamma_{z\varphi} r dr = \frac{\pi h m^2}{\mu} \tag{43}$$

3.2 *Simple torsion of a cylindrical body including a coaxial cylindrical fiber*

In this subsection, the strain energy of a cylindrical body including a coaxial cylindrical fiber will be calculated under simple torsion (Fig. 4). The total torsion moment is divided to two parts. These parts M^M, M^F are gotten by the matrix and fiber, respectively.

The previous solution given in (39) for single cylinder can be used in here. For the fiber, the moment and nonzero shear stress and strain are written as

$$M_z^F = C^F r^4, \; \tau_{z\varphi}^F = \frac{2C^F r}{\pi} = \mu^F \gamma_{z\varphi}^F \tag{44}$$

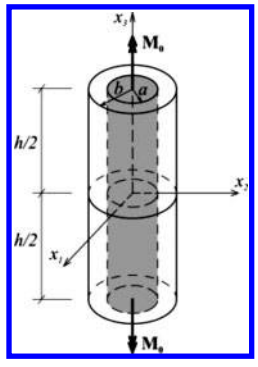

Figure 4. The cylindrical body including fiber.

Here, r may change from zero to a. For the matrix which has the geometry of hollow cylinder, the moment is

$$M_z^F = C^F r^4 + D^F \tag{45}$$

The shear stress and strain on that are the same as those in fiber totally except being the superscripts M. The total torsion moment on the surface due to these shear stresses is

$$\begin{aligned} &\int_0^a 2\pi\tau_{z\varphi}^F r^2 dr + \int_a^b 2\pi\tau_{z\varphi}^M r^2 dr = M_0 \quad \rightarrow \\ &C^F a^4 + C^M (b^4 - a^4) = M_0 \end{aligned} \tag{46}$$

This is the first equation for C^F, C^M and D^M constants. The common boundary for the matrix and fiber is at $r = a$. On that, surface traction vectors are equal for both matrix and fiber. This gives

$$C^F = C^M \frac{\mu^F}{\mu^M} \tag{47}$$

The solution of (46) and (47) are obtained as (Bulut, 2013)

$$\begin{aligned} C^F &= \frac{M_0 \mu^F}{\mu^F a^4 + \mu^M (b^4 - a^4)} \\ C^M &= \frac{M_0 \mu^M}{\mu^F a^4 + \mu^M (b^4 - a^4)} \end{aligned} \tag{48}$$

The strain energy is calculated as

$$U = \frac{b^4 m^2 \pi h}{a^4 (\mu^F - \mu^M) + b^4 \mu^M} \tag{49}$$

3.3 *Determining the effective shear modulus*

If the expression obtained in (43) which may be thought as effective shear modulus in the condition of changing μ to μ^* is equated to the expression (49), and the concentration ratio c is defined as (a^2/b^2) then the expression for the effective shear modulus will be obtained as

$$\mu^* = \mu^P c^2 + \mu^M (1 - c^2) \tag{50}$$

4 EXPERIMENTS

In order to compare the previous analytical results, the experiments of cylindrical composite samples having fibers whose radius in in micro level under simple tension have been realized. Here, polyester and Kevlar fiber are used as matrix and fibers, respectively.

Firstly, in order to determine the properties of used polyester or matrix material, cylindrical samples without any fiber have been molded. The radii and the heights of the samples are about 22 mm and 185 mm. A mold was manufactured to obtain the samples. When the samples were prepared, cobalt and methyl-ethyl-ketone (MEK) were used in the percentage of weight ratio of %0.05 and %0.25, respectively. To avoid of cracks or deformations on the samples due to the exothermic reactions causing thermal stresses were why the weight ratio of the hardener was low.

As the second step, the cylindrical composite samples which included 1% and 1.5% fibers with respect to the volume ratio have been prepared.

All samples have waited for a month and they have been put in an oven for post curing.

The simple tension tests have been realized by Instron 8802. The Young's moduli have been obtained from the stress-strain diagram of the test of these samples. Furthermore, a digital micrometer has been used for calculating the Poisson's ratios. The stress-strain curves of polyester sample without fiber and the samples including 1% and 1.5% fibers have been obtained. The slopes of the tangent to the initial portion of the curves have given the Young's moduli. These have been obtained as

$$\begin{aligned} E^M &= 1820 MPa \\ E_1^* &= 1832.6 MPa \\ E_{1.5}^* &= 1860.9 MPa \end{aligned} \tag{51}$$

Here, E_1^* and $E_{1.5}^*$ are shown the Young's moduli of the samples including 1% and 1.5% fibers, respectively.

The Poisson's ratios have been calculated as

$$\upsilon^M = 0.27\,,\ \upsilon_1^* = 0.25\,,\ \upsilon_{1.5}^* = 0.23 \tag{52}$$

5 COMPARISON OF THE ANALYTICAL AND EXPERIMENTAL RESULTS

Because of the geometry of the experimental samples, the results obtained from experiments have been compared with the analytical solution which is given in (50). To use this relation, the shear moduli of the matrix and fibers must be obtained.

The Young's modulus and the Poisson's ratio of Kevlar fibers have been gotten from the literature as

$$E^F = 10^5 MPa\,,\ \upsilon^F = 0.33 \tag{53}$$

Table 1. The results and errors.

Vol. ratio	μ_t (MPa)	μ_d (MPa)	Error (%)
%1	720.223	733.04	1.78
%1.5	724.832	756.46	4.36

The shear moduli of the matrix and fiber can be calculated from the expressions (51), (52) and (53) by using

$$\mu = \frac{E}{2(1+\upsilon)} \tag{54}$$

So, these are

$$\mu^M = 716.535MPa\,,\ \mu^F = 37593.98MPa \tag{55}$$

The shear moduli of the composites including 1% and 1.5% fibers can be calculated using the equation (50) as

$$\mu_{t1}^* = 719.688MPa\,,\ \mu_{t1.5}^* = 724.832MPa \tag{56}$$

The shear moduli of associated composites obtained experimentally are

$$\mu_{d1}^* = 733.04MPa\,,\ \mu_{d1.5}^* = 756.46MPa \tag{57}$$

The subscript t shows the results from theoretical solution whilst the letter $d$defines the experimental results.

Obtained results have been shown in Table 1.

As it can be shown here, the mean value of the error between analytical and experimental solution is %3.07.

The variation of the value of the shear modulus of composites with respect to volume concentration obtained by analytically and experimentally has been graphed in Figure 5.

6 RESULTS

In this study, the Bulk modulus of composites including particles and the shear modulus of composites including fibers have been obtained in terms of elastic constants of matrix and particle or fiber and the volume concentration, analytically. Although

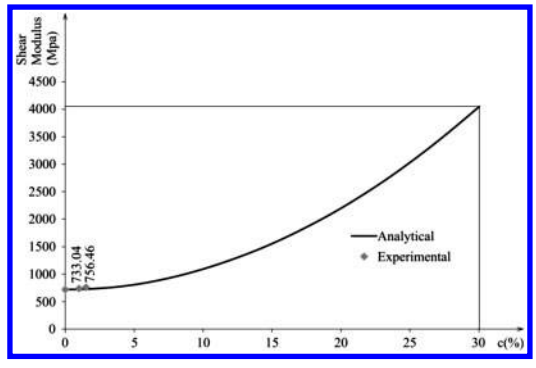

Figure 5. The variation of the shear modulus with volume ratio.

experiments have not been realized yet for preceding composite, the analytical results are in accordance with the experimental results in Hashin's article (Hashin, 1962).

The difference in this study is that the expressions of elastic constants for composites having long thin cylindrical fibers have been obtained. So, for a constant volume concentration value, a constant single value can be obtained for an associated composite.

The drawn graph shows accordance so that experimental results for the latter prove that the analytical solution is acceptable.

ABSTRACT: This paper deals with the computational homogenization of magneto-electric composites consisting of piezoelectric and piezomagnetic phases. Applying a computational homogenization scheme we calculate the effective magneto-electric coupling coefficients which arise as strain-induced product properties. The numerical procedure is based on the Finite Element Method, used for the discretization of a substructure of the heterogenous microscale. After analysing a periodic composite, we discuss the applicability of the homogenization procedure for the calculation of the effective properties of particulate magneto-electric composites obtained from experimental measurements.

1 INTRODUCTION

The magneto-electric (ME) coupling effect has attracted special attention during the last decades. Materials exhibiting coupling between magnetic and electric fields allow for many new intelligent applications, for instance as magnetic-field sensors or electric-write magnetic-read memories (Eerenstein et al. 2007). The latter application would combine the advantages of Ferroelectric and Magnetoresistive Random Access Memories (FeRAM and MRAM, respectively) resulting in a Magneto-Electric Random Access Memory (MERAM). Such device could be realized by using materials that possess both spontaneous magnetization and polarization coupled to one another (Bibes and Barthélémy 2008). Since these materials exhibit at least two distinct ferroic states (ferroelectricity and ferromagnetism, often accompanied by ferroelasticity) they belong to the class of ME multiferroics. In recent years, ME multiferroics have been studied intensively, see e.g. Schmind (1994), Schmind (2008). Works which discuss the basic experimental observations and also present theoretical investigations of the underlying phenomena are given by e.g. Cheong and Mostovoy (2007) and Khomskii (2009). Since the coupling between the two ferroic quantities in intrinsically multiferroic materials is in general weak, the range of possible applications is still quite narrow, c.f. Hill (2000). Furthermore, the obtainable ME coupling is limited as pointed out by Brown et al. (1968) who discuss an upper bound of the possible ME coefficient formulated in terms of the magnetic permeability and the electric permittivity. Thus, the design of ME composite materials becomes relevant, see e.g. Nan (1994), Eerenstein et al. (2006), Nan et al. (2008), Srinivasan (2010), Wang et al. (2010), Priya et al. (2007), Ryu et al. (2002). Such composite structures consist of individual electroactive and magnetoactive phases and the ME coupling enters the material as a *product property* (van Suchtelen 1972). A product property can be defined as a property of the composite which is not present in none of the composite phases, but which arises as product of the interaction between the individual phases. In an ME composite the interaction between the two phases is driven by strain: on the one hand, an applied electric field induces a deformation of the electroactive material which is transferred to the magnetoactive material. The deformation of the magnetoactive material then induces a magnetic reaction. On the other hand, an applied magnetic field deforms the magnetic phase which then induces strain-driven polarization in the electric phase. The latter phenomenon is often termed the direct ME effect, while the former describes the converse ME effect, see e.g. Wang et al. (2010).

In contrast to single-phase multiferroics, composite structures can show very pronounced ME coupling. Experiments on sintered granular composites and laminate structures have been performed and an ME coefficient of up to 90 V/cm *Oe* has been observed in the range of the electro-mechanical resonance. This is three to five orders of magnitude higher than the coupling observed in a typical single-phase material (Fiebig 2005). The production processes of ferromagnetic/ferroelectric heterostructures are manifold and can be optimized by nanotechnological methods, see e.g. Ramesh and Spaldin (2007) and Martin

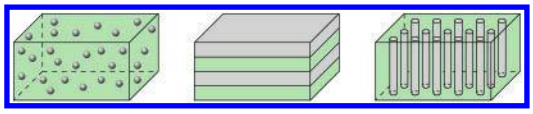

Figure 1. Typical ME composites: 0-3, 2-2, and 1-3 composite.

et al. (2010). Some typical composite structures are depicted in Figure 1.

As a convention, we will denote the type of the composites as follows. The first number indicates the spatial connectivity of the magnetoactive phase and the second number indicates the connectivity of the electroactive phase.

The determination of the effective behavior of ME composites is therefore of great interest. In this context, homogenization methods play an important role for the description of micro-heterogeneous materials since they allow for the characterization of material properties on different scales. Many theoretical investigations have been conducted in order to study the effective behavior of ME composites. The work Harshé et al. (1993b) presents a micro-mechanical approach for the estimation of the ME effect in 3-0 and 0-3 composites. Similar to that, Harshé et al. (1993a) discuss the effective response of 2–2 laminate composite structures. Huang and Kuo (1997) and Srinivas et al (2006) determine the effective properties of ME composites with ellipsoidal inclusions by using a Mori-Tanaka method. For the determination of the effective behavior by using a self-consistent approach see Srinivas and Li (2005). Camacho-Montes et al. (2009) calculate the ME coefficient of 1–3 composites on the basis of asymptotic homogenization. In the work Bichurin et al. (2003) the ME effect of 2–2 structures is analyzed in the low-frequency range. Corresponding results for electro-mechanical resonance are given in Bichurin et al. (2003). For an overview see Bichurin et al. (2010). In Nan et al. (2005) 1–3 and 2–2 ME composites are analyzed with regard to magnetic-field induced electric polarization. The influence of the mechanical boundary condition on the ME effect is discussed in Shi et al. (2004).

The present paper aims at the numerical characterization of ME composites based on computational homogenization. We will derive a numerical procedure based on the Finite Element Method in order to compute the overall ME coefficient of two-phase composites consisting of piezoelectric and piezomagnetic phases, cf. also Lee et al. (2005). The method will be applied to the computation of the effective ME properties of idealized microstructures as well as of realistic microstructures obtained from experiments. The outline of the paper is as follows. In chapter 2 the theoretical framework will be provided where the procedure for the determination of the effective properties will be discussed in detail. In chapter 3 the effective response of several composites including ideal and realistic microstructures will be computed. Chapter 4 closes the paper with a short conclusion.

2 THEORETICAL FRAMEWORK

In the following chapter, the continuum-mechanical framework for the simulation of ME materials is described briefly. We will start with writing down the fundamental balance equations and the underlying kinematical assumptions, whereby we restrict ourselves to small deformations such that the geometric linear theory can be applied. The numerical method for the determination of the overall constitutive response will be discussed, where we confine our attention to the computation of the ME coupling coefficients. After that, we will write down the periodic boundary conditions. Finally, we outline the constitutive relations of the individual phases of the composite, which respectively exhibit the piezoelectric and piezomagnetic coupling.

2.1 *Magneto-electro-mechanical boundary value problem and scale transition*

Let the body under consideration be denoted as $\mathcal{B} \subset \mathbb{R}^3$ and parameterized in space with coordinates $\mathbf{x}$. Then, the basic kinematical quantities are given by the linear strain tensor, the electric field, and the magnetic field defined by

$$\varepsilon = \nabla^s \mathbf{u}, \quad \mathbf{E} = -\nabla\phi, \quad \text{and} \quad \mathbf{H} = -\nabla\varphi, \tag{1}$$

respectively. Herein, $\mathbf{u}$, ϕ, and φ denote the displacement field and the scalar electric and magnetic potential. The fundamental balance equation are given by the balance of linear momentum

$$\nabla \cdot \boldsymbol{\sigma} + \mathbf{f} = \mathbf{0}, \tag{2}$$

the Gauß's law of electrostatics

$$\nabla \cdot \mathbf{D} = q \tag{3}$$

and the Gauß's law of magnetostatics

$$\nabla \cdot \mathbf{B} = 0, \tag{4}$$

where we have introduced the Cauchy stress tensor σ, the vector of body forces $\mathbf{f}$, the vector of dielectric displacements $\mathbf{D}$, the density of free charge carriers q and the vector of the magnetic induction $\mathbf{B}$.

In order to compute the effective response of the ME composite we analyze a representative volume element (RVE) of the actual body, which has to be imagined as periodically embedded into a higher scale macroscopic continuum. The RVE is driven by boundary conditions that arise as a consequence of macroscopic fields. These boundary conditions have to be *energetically consistent* and can be derived by exploring a *scale transition* between the scales. For this purpose, we first decompose the microscopic fields into constant macroscopic fields $\overline{\bullet}$ and fluctuation parts $\widetilde{\bullet}$ as

$$\boldsymbol{\xi} = \overline{\boldsymbol{\xi}} + \widetilde{\boldsymbol{\xi}} \quad \text{with} \quad \boldsymbol{\xi} := [\boldsymbol{\varepsilon}, \boldsymbol{\sigma}, \mathbf{E}, \mathbf{D}, \mathbf{H}, \mathbf{B}]\,. \tag{5}$$

Energetic consistence is then ensured by postulating a generalized macrohomogeneity condition of the form

$$\overline{\boldsymbol{\sigma}} : \dot{\overline{\boldsymbol{\varepsilon}}} + \overline{\mathbf{D}} \cdot \dot{\overline{\mathbf{E}}} + \overline{\mathbf{B}} \cdot \dot{\overline{\mathbf{H}}} = \frac{1}{V} \int_{\mathrm{RVE}} (\boldsymbol{\sigma} : \dot{\boldsymbol{\varepsilon}} + \mathbf{D} \cdot \dot{\mathbf{E}} + \mathbf{B} \cdot \dot{\mathbf{H}}) \, dv \,, \tag{6}$$

in this context we refer to Schröder (2009), Schröder and Keip (2010), (2011), (2012) or Keip and Schröder (2011). Periodic boundary conditions that fulfill this condition are

$$\begin{aligned} \widetilde{\mathbf{u}}(\mathbf{x}^+) = \widetilde{\mathbf{u}}(\mathbf{x}^-) \quad &\text{and} \quad \mathbf{t}(\mathbf{x}^+) = -\mathbf{t}(\mathbf{x}^-) \,, \\ \widetilde{\phi}(\mathbf{x}^+) = \widetilde{\phi}^-(\mathbf{x}^-) \quad &\text{and} \quad Q(\mathbf{x}^+) = -Q(\mathbf{x}^-) \,, \\ \widetilde{\varphi}(\mathbf{x}^+) = \widetilde{\varphi}(\mathbf{x}^-) \quad &\text{and} \quad \zeta(\mathbf{x}^+) = -\zeta(\mathbf{x}^-) \,, \end{aligned} \tag{7}$$

where $\mathbf{x}^+$ and $\mathbf{x}^-$ denote points on the opposite faces of a periodic unit cell. After the solution of the boundary value problem, we can compute the homogenized macroscopic response by averaging over the microscopic fields over the RVE. In a more general case, the macroscopic quantities hace to be defined in terms of surface integrals. For simplicity we restrict ourselves to suitable volume averages as

$$\begin{aligned} \overline{\boldsymbol{\varepsilon}} &= \frac{1}{V} \int_{\mathcal{B}} \boldsymbol{\varepsilon} \, dv, \quad \overline{\boldsymbol{\sigma}} = \frac{1}{V} \int_{\mathcal{B}} \boldsymbol{\sigma} \, dv \\ \overline{\mathbf{E}} &= \frac{1}{V} \int_{\mathcal{B}} \mathbf{E} \, dv, \quad \overline{\mathbf{D}} = \frac{1}{V} \int_{\mathcal{B}} \mathbf{D} \, dv \\ \overline{\mathbf{H}} &= \frac{1}{V} \int_{\mathcal{B}} \mathbf{H} \, dv, \quad \overline{\mathbf{B}} = \frac{1}{V} \int_{\mathcal{B}} \mathbf{B} \, dv \,. \end{aligned} \tag{8}$$

For a more general definition of macroscopic quantities in terms of suitable surface integrals we refer to Schröder (2009).

2.2 *Constitutive framework and effective ME coefficient*

For the analysis of the effective ME behavior of the composite, we suppose a linear piezoelectric and a linear piezomagnetic material response of the individual phases on the microscale. To be specific, we consider the phases to be transversely isotropic and use the constitutive framework proposed in Schröder and Gross (2004) such that each phase is characterized by a preferred direction denoted by the vector $\mathbf{a}$. This preferred direction can be imagined as the fixed direction of remanent polarization and magnetization of the two ferroic phases. Without going into detail we write down the constitutive behavior for each of the two phases as

$$\begin{aligned} \boldsymbol{\sigma} &= \mathbb{C} : \boldsymbol{\varepsilon} - \mathbf{e}^T \cdot \mathbf{E} - \mathbf{q}^T \cdot \mathbf{H} \\ -\mathbf{D} &= -\mathbf{e} : \boldsymbol{\varepsilon} - \boldsymbol{\epsilon} \cdot \mathbf{E} - \boldsymbol{\alpha}^T \cdot \mathbf{H} \\ -\mathbf{B} &= -\mathbf{q} : \boldsymbol{\varepsilon} - \boldsymbol{\alpha} \cdot \mathbf{E} - \boldsymbol{\mu} \cdot \mathbf{H} \end{aligned} \tag{9}$$

where $\mathbb{C}$, $\boldsymbol{\epsilon}$, $\boldsymbol{\mu}$, $\mathbf{e}$, $\mathbf{q}$, and $\boldsymbol{\alpha}$ denote the constant material moduli of the individual phase. Here, it has to be emphasized that for each of the two phases the ME coupling modulus is zero: $\boldsymbol{\alpha} \equiv \mathbf{0}$. However, the overall macroscopic ME modulus of the composite $\overline{\boldsymbol{\alpha}}$ is in general non-zero since it is activated by the electric- or magnetic-field induced deformation of the microstructure. This macroscopic property is defined as

$$\overline{\boldsymbol{\alpha}} = \frac{\partial \overline{\mathbf{B}}}{\partial \overline{\mathbf{E}}} = \left[\frac{\partial \overline{\mathbf{D}}}{\partial \overline{\mathbf{H}}} \right]^T . \tag{10}$$

3 NUMERICAL EXAMPLES

The following chapter contains two numerical examples for the calculation of the ME coefficient. In detail, we consider an idealized three-dimensional RVE as well as a two-dimensional part of a real microstructure obtained from an experiment. First, in order to verify the performance of the implemented model, the strain-induced ME coefficient of the 3D ideal RVE is compared to results from the literature. After that the formulation is applied to the discretized morphology of a sample of a real microstructure. Here we will analyze if the numerical results coincide with the coupling behavior obtained from experimental measurements. All computations will be performed in consideration of periodic boundary conditions.

3.1 *Ideal 3D microstructure*

In order to verify the model we will compare the results of the model to data from the literature given by the work of Lee et al. (2005). In this contribution, a periodic RVE with a piezomagnetic matrix consisting of cobalt ferrite ($CoFe_2O_4$) and a piezoelectric cylindrical inclusion consisting of barium titanate ($BaTiO_3$) is considered. The preferred directions of the two phases are assumed to point into the positive vertical direction. Figure 2 shows an illustration of the discretized RVE. The material parameters of the two phases are taken from Lee et al. (2005) and listed in table 1.

For validation of the results two numerical examples with 40% and 60% volume fraction of the inclusion are performed. For the computation we consider a macroscopic electric field $\overline{E}_3$ which is applied to the RVE using periodic boundary conditions. Since the preferred directions of both materials are oriented in x_3-direction, a pronounced coupling as a result of the applied field is activated: due to the electric field, the piezoelectric inclusion reacts with an elongation which is transferred to the piezomagnetic matrix. The deformation then leads to a magnetic reaction of the piezomagnetic matrix. This strain-induced ME coupling can be quantified by determining the quotient of the magnetic induction and the electric field following (10). For this purpose, the volume average of the magnetic induction $\overline{B}_3$ is determined by using (8). The calculation was carried out for the two volume fractions of the piezoelectric inclusion. The resulting

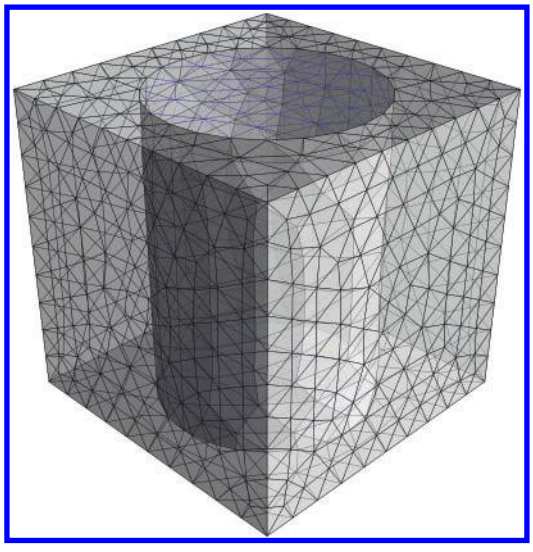

Figure 2. Piezomagnetic cube with piezoelectric cylindrical inclusion of the periodic microstructure.

Table 1. Material parameters for $BaTiO_3$ and $CoFe_2O_4$.

Parameter	$BaTiO_3$	$CoFe_2O_4$
$\mathbb{C}_{11}\ [\frac{N}{mm^2}]$	$16.6 \cdot 10^4$	$28.6 \cdot 10^4$
$\mathbb{C}_{12}\ [\frac{N}{mm^2}]$	$7.7 \cdot 10^4$	$17.3 \cdot 10^4$
$\mathbb{C}_{13}\ [\frac{N}{mm^2}]$	$7.8 \cdot 10^4$	$17.05 \cdot 10^4$
$\mathbb{C}_{33}\ [\frac{N}{mm^2}]$	$16.2 \cdot 10^4$	$26.95 \cdot 10^4$
$\mathbb{C}_{44}\ [\frac{N}{mm^2}]$	$4.3 \cdot 10^4$	$4.53 \cdot 10^4$
$\epsilon_{11}\ [\frac{mC}{kVm}]$	$112 \cdot 10^{-4}$	$0.8 \cdot 10^{-4}$
$\epsilon_{33}\ [\frac{mC}{kVm}]$	$126 \cdot 10^{-4}$	$0.93 \cdot 10^{-4}$
$\mu_{11}\ [\frac{N}{kA^2}]$	5	-590
$\mu_{33}\ [\frac{N}{kA^2}]$	10	157
$e_{31}\ [\frac{C}{m^2}]$	-4.4	0
$e_{33}\ [\frac{C}{m^2}]$	18.6	0
$e_{15}\ [\frac{C}{m^2}]$	11.6	0
$q_{31}\ [\frac{N}{kAmm}]$	0	$5.803 \cdot 10^2$
$q_{33}\ [\frac{N}{kAmm}]$	0	$6.997 \cdot 10^2$
$q_{15}\ [\frac{N}{kAmm}]$	0	$5.5 \cdot 10^2$

ME-coefficients arise as $\alpha_{33}^{40\%} = 2.671 \cdot 10^{-9}$ [s/m] and $\alpha_{33}^{60\%} = 2.503 \cdot 10^{-9}$ [s/m] for 40% and 60% volume fraction, respectively. This is in good agreement with the results from Lee et al. (2005).

3.2 *Realistic 2D microstructure*

In the second example, we analyze the ME behavior of a real composite microstructure. The morphology of the ME composite consists of a piezoelectric matrix ($BaTiO_3$) with embedded particulate piezomagnetic inclusions ($CoFe_2O_4$), where the surface

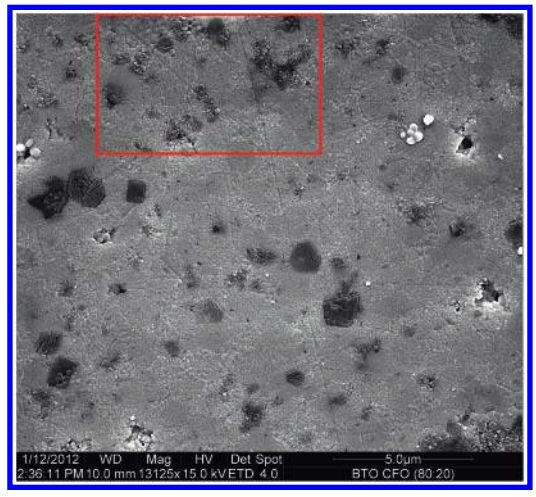

Figure 3. The real microstructure obtained by microscopy.

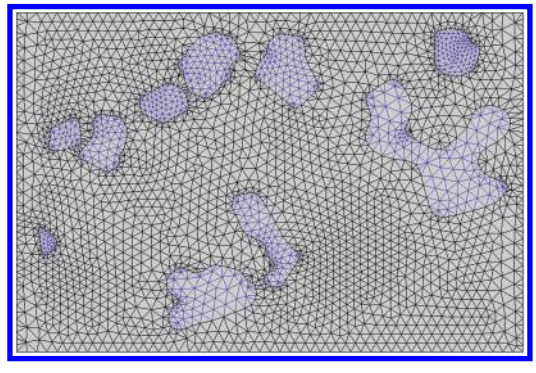

Figure 4. The discretized part of the real microstructure.

fraction of the piezomagnetic inclusions can be constituted with 16%; it is depicted in Figure 3. The experimental microstructure was discretized with triangular finite elements with quadratic shape functions and the preferred directions of the two phases are assumed to point in positive x_2-direction. The discretized microstructure is depicted in Figure 4.

In order to analyze the ME coefficient of the microstructure we apply an external electric field in positive vertical direction under plane-strain conditions. Analogously to the three-dimensional example, the deformation of the piezoelectric matrix is transferred to the piezomagnetic particles, so that a magnetic induction is generated. The resulting distributions of the microscopic electric field E_2, dielectric displacement D_2, magnetic field H_2, and magnetic induction B_2 are depicted in Figures 5 and 6.

By using (8) for the magnetic induction $\overline{B}_2$ together with (10) we obtain the effective ME coefficient $\alpha_{22} = 3.893 \cdot 10^{-11}$ [s/m]. This is not in agreement with the measurements of Etier et al. (2012), who measured an effective ME coefficient of $\alpha_{22} = 4.4 \cdot 10^{-12}$ [s/m]. This deviation might be

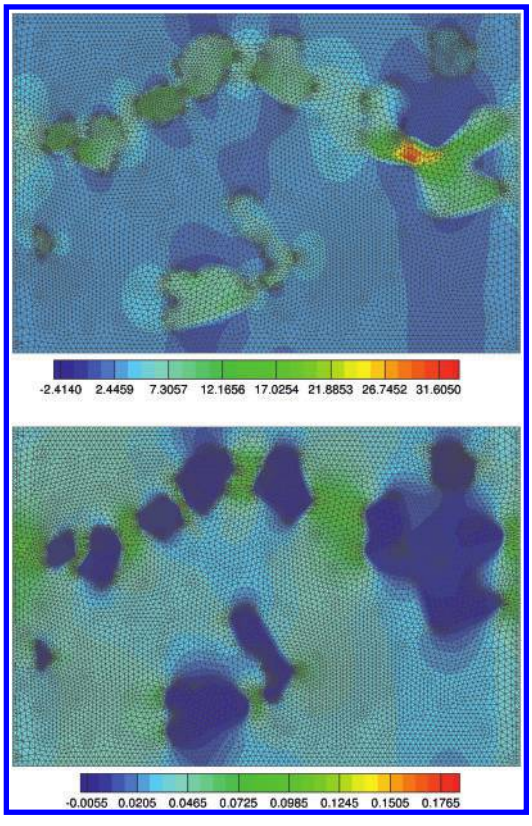

Figure 5. Distribution of the electric fields and dielectric displacement in x_2-direction.

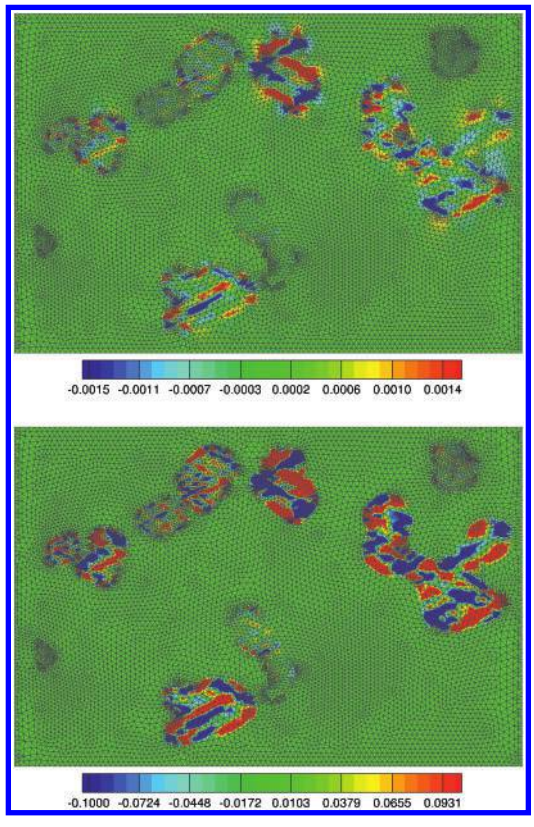

Figure 6. Distribution of the magnetic fields and magnetic induction in x_2-direction.

explained by the fact that we have assumed an ideal microscopic microstructure in which the preferred directions of the two materials point in vertical direction. In the experiment such situation is very hard to achieve since the composite has to be polarized so that the resulting remanent polarization network will differ from the ideal assumption. Furthermore, we have assumed fully activated piezoelectric and piezomagnetic coupling in the individual phases of the composite. This can be constituted as an ideal assumption as well. Both assumptions will not be fulfilled in the experiment. Another influence may arise from the two-dimensional approximation of the originally particulate three-dimensional microstructure.

4 CONCLUSION

In the present paper, the strain-induced magneto-electric coupling of two-phase magneto-electric composites consisting of piezoelectric barium titanate and piezomagnetic cobalt ferrite is analyzed numerically. First we verified the formulation by comparing the magneto-electric coefficient of a fiber-matrix composite to data from the literature. After that the formulation was applied to the computation of the magneto-electric coupling behavior of a realistic microstructure obtained from an experiment. We considered a two-dimensional discretization of the morphology of the composite microstructure. The computed magneto-electric coupling coefficient is in insufficient agreement with the coefficient obtained in the experiment. This deviation was explained by the assumption of a complete uni-directional, ideal polarization of the piezoelectric matrix and magnetization of the piezomagnetic inclusions, respectively. Such ideal situation can hardly be realized in an experiment. In order to describe the behavior of realistic magneto-electric composites more accurately the definition of different orientations for multiple parts of the microstructure should be implemented. This can be achieved by simulating the electric polarization process.

Microstructural image-based modelling of weld failure

O. Barrera & A.C.F. Cocks
Department of Engineering Science, University of Oxford, UK

E. Tarleton
Department of Materials, University of Oxford, UK.

ABSTRACT: This paper deals with the constitutive modelling of one of the phenomena affecting welding failure: Hydrogen Embrittlement (HE). The focus of the HE model is on dissimilar weld interfaces in AISI8630/IN625. Fractography of dissimilar weld interfaces in AISI8630/IN625 shows that cracks propagate in a carbides (M_7C_3)-rich region called the "featureless" region located on the Nickel side of the weld. Our model takes into account the effect of hydrogen on the material behaviour as the result of a combined HELP (Hydrogen Enhanced Local Plasticity) and HID (Hydrogen Induced Decohesion) mechanism where: (i) hydrogen enhanced dislocation mobility promotes a reduction of the flow stress in the matrix and the development of dislocation structures at the M_7C_3 carbides which increases the stress on the particles; and (ii) the presence of hydrogen also results in a reduction in the cohesive strength of the carbide/matrix interface. Here TEM images of the carbides-rich region are converted into a finite element mesh through an image-based mesh generation scheme. Simulations of the response of these structures show that in regions where the hydrogen content is high, the cohesive strength decreases, and microcracks form at the carbide-matrix interface that lead to microvoid formation. The amount of deformation then increases in a localized region adjacent to the region where (a) hydrogen content is high and (b) the carbide/matrix interface has debonded. As deformation proceeds the pores enlarge and link to form cracks which generate the failure surface.

1 INTRODUCTION

1.1 *Hydrogen embrittlement in dissimilar weld interfaces*

Dissimilar metal butter-welded joints are commonly used by the oil and gas industries to join a range of structural components such as valves, connectors or manifolds to carbon steel pipes, as they allow a welded connection between high strength hardenable carbon forged steel or non-hardenable pipe line steel to Nickel alloy components. A series of catastrophic failures of AISI 8630 steel/IN625 Nickel alloy dissimilar-metal welds has highlighted the need for further investigations on the role of hydrogen on the fracture process of the components (Fenske 2010).

One of the outstanding issues in hydrogen cracking of welds is to link micromechanical processes to the macroscopic fracture behaviour of the system. Recent TEM and SEM studies (Fenske 2010) have revealed detailed information about the microstructure in the vicinity of the fusion boundary of 8630/625 dissimilar welds and the fracture morphologies which alternates between a flat cleavage-like morphology and a highly irregular cratered structure. Figure 1 (Kitaguchi & Lozano-Perez 2012) shows a simplification of the interface microstructure of a 8630/625 dissimilar weld, (Beaugrand et al. 2009, Dodge et al. 2012), i.e. at the interface between the steel and the buttering. Three major regions can be distinguished:

a. The heat affected zone (HAZ) in the parent steel side close to the interface consists of a fine decarburised zone. This zone is mostly ferritic.

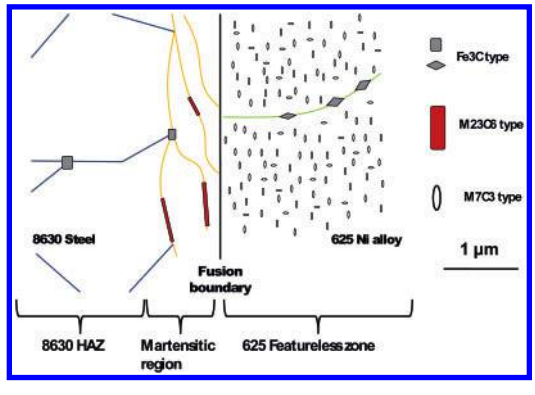

Figure 1. Schematic summary of interface microstructure 8630/625 showing the different types of precipitates that are present.

b. A martensitic iron rich region (about 1 μm wide) on the steel side close to the fusion boundary. This zone exhibits a BCT structure.
c. A FCC carbide (M_7C_3)-rich region (about 20 μm wide) in the nickel side, previously wrongly identified as a "featureless zone", that plays an important role in the macroscopic fracture behaviour of the system in a hydrogen environment. The volume fraction has been estimated to be about 15% and the dimension of the major axis of the carbides is about 40 nm as seen in Fig. 3. Fig. 2 (Dodge & Mililtitsky 2012) shows a fractured sample of an AISI8630/IN625 dissimilar weld exposed to a hydrogen rich environment. The crack path with respect to the interface structure of Fig. 1 is shown in Fig. 2, which has sections within (a) the HAZ, (b) the martensitic region and (c) the featureless zone. Despite the crack initiation location not being precisely identified (Fenske 2010, Beaugrand et al. 2009, Dodge et al. 2012) and is still subject to debate, there is general agreement that the presence of M_7C_3 carbides in the "featureless zone" provides a low energy path for crack propagation.

The fracture morphology of this region consists of terrace-cleavage or quasi cleavage features (Fig. 2). More in-depth studies of this type of fracture have revealed that the planes along which the cracks propagate are not known cleavage planes. The planes contain ridges that are almost parallel to the crack propagation path. These ridges are related to sub-surface intense and highly localized deformation bands (Martin 2011). The fracture surface appears to be generated by ductile processes, enhanced and localized to well defined slip bands by hydrogen (Martin et al. 2011). The fracture morphology within the featureless zone, which is produced only in the presence of hydrogen, is consistent with a hydrogen-induced decohesion (HID) mechanism along the M_7C_3-matrix interface succeeded by strain localization between the particles (HELP). This suggests that the effect of hydrogen on the material toughness is a result of a synergistic effect of HELP and HID mechanisms: (i) with hydrogen enhancing dislocation mobility, promoting softening and strain localization; (ii) and the combined effect of increased stress on the M_7C_3 carbides due to the enhanced plastic deformation and the effect of hydrogen on the interface cohesive properties promoting decohesion at the particle/matrix interface. In this paper we use the model developed by Barrera & Cocks (2013) in which preliminary analyses carried out on a unit cell representing the matrix/carbide system are discussed. The results showed that the HELP and HID mechanisms act synergistically. When the combined HELP+HID mechanism occurs, microcracks form at the matrix/carbide interface due to a decohesion process followed by localization of plastic flow responsible for the link-up of the micro-cracks.

Here we generate an image-based mesh of the featureless region (Figure 1) in order to explore the model presented in Barrera & Cocks (2013) when dealing with the real microstructure of the carbides-rich

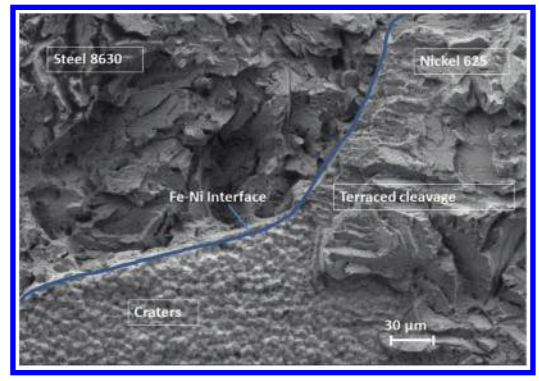

Figure 2. SEM image of fracture morphology of interface microstructure 8630/625 showing different morphologies: "Craterlike" and terraced cleavage-type.

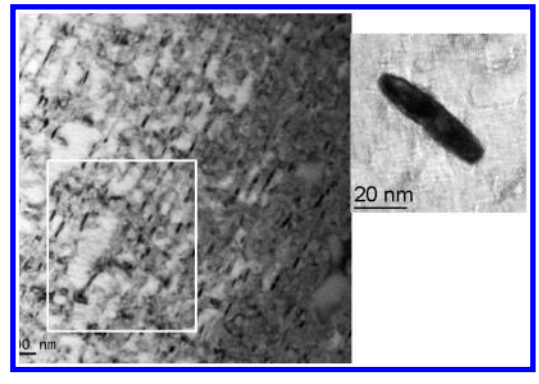

Figure 3. TEM image of the featureless zone schematically shown in Fig. 1.

region. The TEM image of the multi-carbide region in Fig. 3 is converted into a finite element mesh. A layer of cohesive elements is then assigned at the carbide/matrix interface to allow investigations of the deformation and decohesion processes (Tarleton et al. 2012).

2 CONSTITUTIVE MODELLING OF THE FEATURELESS REGION

We use the experimental observations discussed in the introduction to guide the development of models which simulate the effect of hydrogen on the material response in the carbide-rich region of Fig. 3. These observations suggest that cracks nucleate at the interface of the M_7C_3 particles in the featureless zone under the high stresses generated locally. These interfacial cracks link with each other and the main crack through localised, intense, plastic deformation. Central to the development of the model is the use of a cohesive modelling approach (CZM). Cohesive elements can be imagined as interface elements with a thickness close to zero embedded in continuum elements. Fracture

occurs at the interface between the CZM and continuum elements. One of the key properties of CZM is the definition of the traction-separation (T-δ) law. In this paper a cohesive element formulation is proposed in which the T-δ law is a function of hydrogen content and the plastic deformation of the surrounding material. We assume a single bilinear relationship in which the traction increases linearly to a peak value σ_c and then decreases to zero at an opening δ_c. We assume that the initial stiffness and critical displacement δ_c are not influenced by the hydrogen, but the cohesive strength depends on both the hydrogen content and the local accumulated plastic strain; i.e.

$$\sigma_c = \sigma_c^0 \Phi(c) - \alpha \mu_m f_p^{1/2} \epsilon^p \tag{1}$$

where σ_0^c is the cohesive strength in the absence of hydrogen and $\Phi(c)$ is a function of the hydrogen concentration, c. Here we assume a simple linear relationship for $\Phi(c)$: $\Phi(c) = (\xi - 1)c + 1$ where $\xi < 1$ is a softening parameter. The second term in eq. 1 arises from consideration of the short range stress generated on a particle from prismatic dislocation loops punched out from the particle to accommodate the inelastic strain, where α is a constant, μ_m is the shear modulus of the matrix, f_p is the volume fraction of the carbides and ϵ^p the effective plastic strain. This model has been implemented as a user element (UEL) in the commercial finite element code Abaqus (Barrera & Cocks 2013). Following Liang & Sofronis (2003) we also assume that the constitutive response of the matrix is a function of the hydrogen content. We assume an isotropic model in which the yield strength σ_Y is given by:

$$\sigma_Y = \sigma_0^H \left(1 + \frac{\epsilon^p}{\epsilon^0}\right)^{\frac{1}{n}} \tag{2}$$

where $\sigma_0^H = \Psi(c)\sigma_0$ is the initial yield strength in the presence of hydrogen that decreases with increasing hydrogen concentration. $\Psi(c)$ is a monotonically decreasing function of hydrogen concentration. ϵ^0 is the initial yield strain in the absence of hydrogen, ϵ^p is the plastic strain and n is the hardening exponent which is considered not to be affected by hydrogen. For simplicity, we will ignore swelling due to introduction of hydrogen into a material. Eq. 2 has been implemented as a UMAT user routine in Abaqus (Barrera & Cocks 2013).

3 IMAGE-BASED MESH GENERATION OF THE FEATURELESS REGION

Here the aim of the work is to model the multi-carbide "featureless" region in Fig. 3 by using an image-based approach. Tarleton et al. (2012) developed and implemented an algorithm capable of converting a binary image of the microstructure into a finite element mesh. The algorithm is currently capable of generating a 2D mesh. Let us consider an image of a single ellipsoidal carbide surrounded by matrix material as shown in the higher magnification of Fig. 3; the image is reconstructed in such a way that the particle is identified by a polygon. Salient pixels forming the polygon vertices need to be identified first and pixel connectivity is then used in order to reproduce each polygon as seen in Fig. 4. The geometry is then used to generate a finite element mesh in Fig. 5 by using the Abaqus python scripting interface. A layer of cohesive elements is then assigned at the carbide/matrix interface (Fig. 6) in order to study in detail the micromechanical processes associated with hydrogen embrittlement within the featureless region. In Fig. 7 we show the RVE highlighted in Fig. 3. Fig. 8 shows the FEM mesh of this RVE which contains 113 carbides. Fig. 9 shows a higher magnification of the lower left corner of Fig. 8. The mesh consists of 46,300 plain strain elements (CPE4) and 2,900 cohesive-user defined elements. The carbides shown in black are modelled as linear elastic with a Young's modulus of 400 GPa and Poisson's ratio of 0.3. The matrix is represented by blue elements in Fig. 8. The constitutive response is

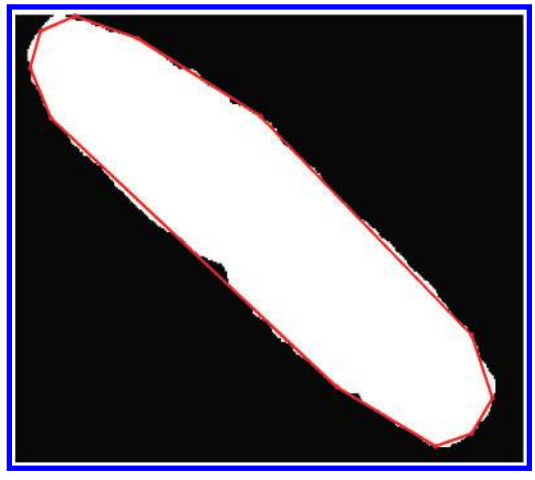

Figure 4. TEM image after processing and polygon representing the geometry of the carbide in Fig. 3.

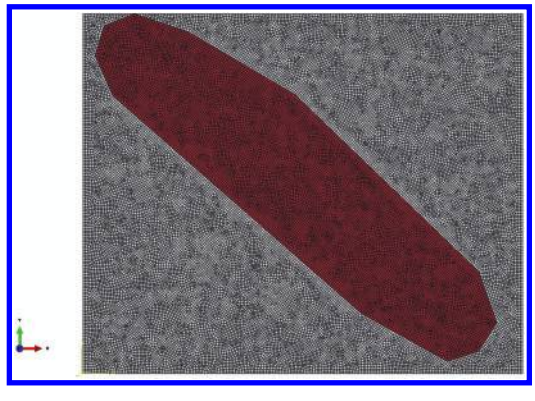

Figure 5. Finite element mesh of the single carbide of Fig. 3.

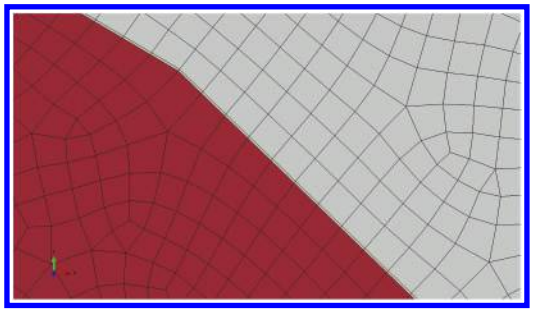

Figure 6. An higher magnification of Fig. 5 showing a layer of cohesive elements at the carbide/matrix interface.

described in eq. 2, the initial yield strength (in the absence of hydrogen) σ_c^0 is 200 MPa, which reduces to 40 MPa at the maximum hydrogen content. Young's modulus is equal to 200 GPa and the hardening exponent $n = 10$. The cohesive user elements are shown in their damaged shape in Fig. 8. These elements are assigned at the carbide/matrix interface to simulate the evolution of the decohesion phenomenon occurring during the deformation process. The damage variable d is also shown in Fig. 8. Damage $d = 0$ corresponds to an undamaged interface, i.e. the carbide has not de-bonded from the matrix, $d = 1$ represents complete failure of the interface i.e. carbides are effectively substituted by pores (white spaces in Fig. 8). The cohesive law parameters are: stiffness $K = 200$ MPa/nm, failure displacement $\delta_c = 2$ nm. The cohesive strength of the UEL in the absence of hydrogen σ_0^c is equal

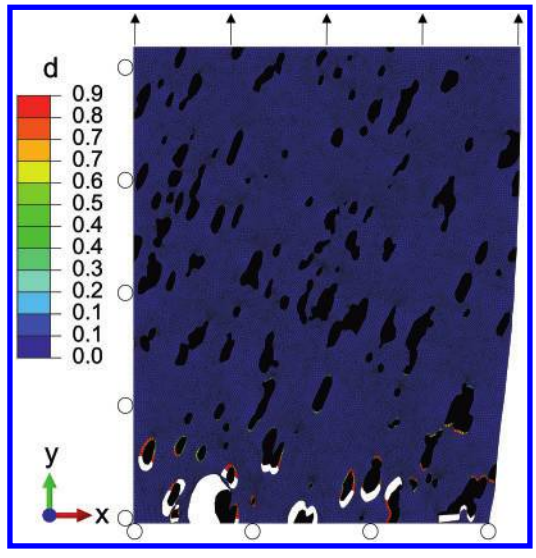

Figure 8. Finite element mesh of the RVE of Fig. 7. The figure shows the deformed mesh at the macroscopic uniaxial strain $\epsilon = 1.4$. The coloured contours give the extent of damage development, d at the carbide/matrix interface. Some cohesive elements have failed with local plastic deformation resulting in separation of the matrix from the carbides creating the white regions in the figure. The deformation is scaled by a factor of 4 for clarity.

to 200 MPa. σ_c (eq. 1) will decrease with increasing hydrogen content and due to the fact that hydrogen enhanced dislocation mobility promotes the development of dislocation structures at the M_7C_3 carbides which increases the stress on the particles; the FE analysis does not give this contribution to the local stress. We take this into account by reducing the apparent macroscopic cohesive strength. This is described by eq. 1 (Barrera & Cocks 2013).

4 DISCUSSION

The aim of the paper is to investigate the role of the hydrogen in the micromechanical failure process occurring in the "featureless zone" of the dissimilar weld interface in AISI8630/IN625. As discussed in Sec. 1 the "featureless" region shown in Fig. 3 plays a major role in the fracture behaviour of this type of interface. The reason is the presence of a fine distribution of high atomic number M_7C_3 carbides. The volume fraction has been estimated to be 12%. The carbides show an ellipsoidal shape and the dimension of the major axis varies from 20 nm–40 nm as seen in Fig. 3. The RVE in Fig. 8 is subjected to displacement boundary conditions such that the macroscopic uniaxial strain is increased at a constant rate up to 1.4%. We apply a gradient of hydrogen content $c = 1 - \frac{y}{L}$. We assume that the hydrogen in the normal interstitial sites (i.e. matrix) is in equilibrium with the hydrogen at the carbide/matrix interface. In the area where the

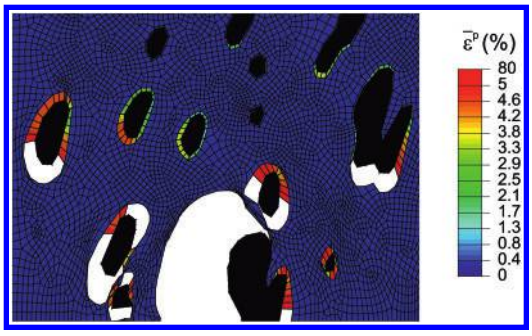

Figure 9. Higher magnification of the lower left corner of Fig. 8.

hydrogen is highly localized (i.e. lower part of Fig. 8) (i) the cohesive strength of the interface is also reduced as summarized in Eq. 1 and (ii) the material softens as consequence of Eq. 2. Therefore there are two phenomena occurring:

(i) The presence of the hydrogen facilitates the decohesion process (HID). In those regions where the carbide-matrix interface is weak, the debonding mechanism of the carbides from the matrix is shown in Fig. 8. Effectively, as a result of the deformation process due to the loading conditions and the hydrogen content, the carbides decohere from the matrix forming pores (if complete decohesion occurs d = 1) or the interface becomes damaged (i.e. partial decohesion $0 < d < 1$). The larger carbides tend to fail completely becoming pores and the smaller carbides experience partial debonding.

(ii) The presence of hydrogen enhances localization of plastic flow (HELP) in those areas where (a) the hydrogen concentration is high (i.e. material softens) and (b) the carbide-matrix interface has debonded. Fig. 10 shows the distribution of the equivalent plastic strain at the end of the deformation process. Softening occurs in the area where high concentration of hydrogen is present (i.e. lower part of Fig. 9). A macroscopically ductile process is also confirmed by the necking region in Fig. 9. As the material deforms, small microvoids (of the size of the carbides or less) form. As the deformation process proceeds the pores enlarge and link to form a crack. Cracks then link up due the highly localized plastic flow. At this point the fracture process can be very fast and can generate a fracture surface that might appear brittle, i.e. reasonably flat with the detailed cavitation process not evident on micrograph at the scale of that shown in Fig. 2, and plastic flow confined to a thin localized band which can occasionally terminate creating wisps on the failure surface. This phenomenon could explain the presence of the "terraced cleavage like" fracture surface of Fig. 2 which show evidence of wisps on the surface.

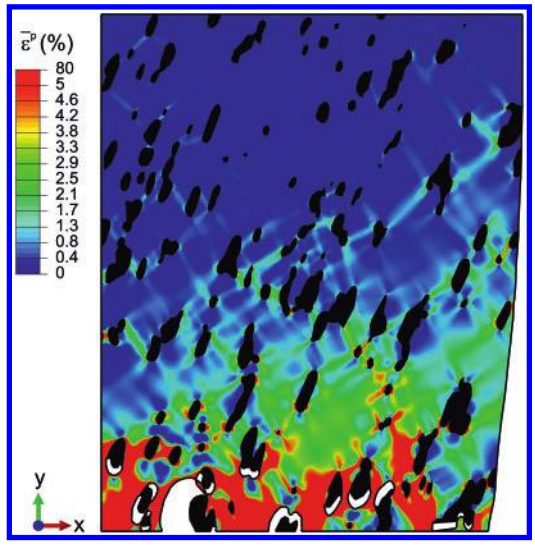

Figure 10. Equivalent plastic strain evolution of RVE in Fig. 8.

5 CONCLUSIONS

A model of the failure process of a dissimilar AISI8630/IN625 weld has been proposed. The model developed here is based on a classical continuum mechanics formalism. The scale of the particles is such, however, that the interaction of the particles with discrete dislocations and the dislocation structures generated around the particles must be taken into account in determining the constitutive response of the matrix and interface region. The work presented in this paper is based on experimental observations of the microstructure and fracture morphology that reveal that cracks nucleate at the interface of the M_7C_3 particles in the "featureless zone" under the high stresses generated ahead of a crack tip succeeded by strain localization between the particles linking these interfacial cracks with each other. The combined effect of hydrogen on the material toughness is a result of a synergistic effect of HELP and HID mechanisms: (i) with hydrogen enhancing dislocation mobility, promoting softening and strain localization; (ii) and the combined effect of increased stress on the M_7C_3 carbides due to the enhanced plastic deformation and the effect of hydrogen on the interface cohesive properties promoting decohesion at the particle/matrix interface. We simulate (1) the failure process at the interface of the M_7C_3 particles and the matrix by use of a cohesive modelling approach (CZM) whose T-δ law is a function of hydrogen content and the plastic deformation of the surrounding material. We also assume (2) that the constitutive response of the material is a function of the hydrogen content. (1) and (2) have been implemented in UEL and UMAT subroutines in Abaqus. The results show that in regions where the hydrogen content is high, the cohesive strength decreases and

microcracks occur that might lead to microvoid formation. The amount of deformation then increases in a localized region adjacent to the region where (a) the hydrogen content is high and (b) the carbide/matrix interface has debonded. As deformation proceeds the pores enlarge and link to form cracks and the intense localized plastic flow links-up the cracks and microcracks formed at adjacent carbides. The failure surface then consists of planes of intense plastic deformation, connected by small regions of decohesion around the particles, which is consistent with the morphology of failure surfaces (Fig. 2) generated as the result of crack growth through the featureless zone.

Flame straightening application on structural steels: Effects on mechanical and fracture properties

R. Lacalle, J.A. Álvarez, D. Ferreño, J. Portilla, E. Ruiz, B. Arroyo & F. Gutiérrez-Solana
University of Cantabria, Santander, Spain

ABSTRACT: In this paper, the influence of the flame bending procedure on the microstructure of three very different structural steels (S235 JR, S460 ML and S690 QL, respectively), widely used for the construction of metallic structures, is analysed. The consequences of the heat treatment on the mechanical and fracture properties were characterised through tensile, micro-hardness Vickers and Charpy impact tests; in addition, some elastic-plastic fracture tests were performed on precracked Charpy specimens manufactured with the S235 JR steel. The relationship between the microstructural features and the material mechanical and fracture behaviour was studied in depth in all cases. For a proper understanding of the microstructural consequences of this straightening heat treatment, it was necessary to develop a Finite Element numerical model.

1 INTRODUCTION

The flame straightening (or flame bending) technique is widely used for the control of geometric distortions or tolerance deviations in steel parts caused by the manufacturing or welding processes; it is also used to repair damaged elements; nevertheless, many aspects of the process remain as uncertainties: the question of the effects induced by the heating process on the microstructure and, as a consequence, on the mechanical and fracture properties is currently an important open issue (Avent 1989, 1992, 1995, 1998, 2000). The present contribution analyses the influence of the flame bending procedure on the material properties of three very different structural steels (S235 JR, S460 ML and S690 QL, respectively), widely used for the construction of metallic structures for buildings or bridges. First, the microstructural and metallurgical changes induced by the flame heating were studied; then, the mechanical properties were assessed. Finally, the influence of the bending process on the fracture properties was determined.

2 OBJECTIVES OF THE RESEARCH

To the knowledge of the authors of the present paper, little research has specifically addressed the influence of the flame bending technique on the microstructure and mechanical or fracture properties of steels. For these reasons, the experimental scope of the present contribution was designed with the purpose of analysing the influence of the heat straightening process on three very different structural steels: S235 JR, SA460 ML and S690 QL. In order to fully understand the microstructural changes that take place in the material as a consequence of the surface heating caused by the flame, a Finite Elements (FE) numerical model was developed. Only through a numerical technique is it possible to take into account the many factors participating in the process (material properties, heat flux of the flame, trajectory and speed of the torch, location of the material point to be analysed, etc.).

3 MATERIALS

The three following structural steel grades (EN 10025 2004) were studied in this research: S235 JR, S460 ML and S690 QL. The microstructure of S235 JR and S460 ML consists of ferrite and perlite whereas S690 QL steel shows a microstructure of bainite and tempered bainite. The specified chemical compositions of the steels (EN 10025 2004) are included in Table 1. For the microstructural analysis of the consequences induced by the flame heat treatment, the material specific Fe-C phase diagram should be considered. For this reason, it is necessary to take into consideration the changes induced by the alloying elements (Baik 1961) of the three materials analysed on the basic Fe-C diagram.

Table 1. Specified chemical composition (% wt.) of the steels analysed in the research (EN 10025 2004).

Grade	C	Mn	Si	Ni	S	Cr	P
S235JR	≤0.17	≤1.40	–	–	≤0.035	–	≤0.035
S460ML	≤0.16	≤1.70	≤0.6	≤0.8	≤0.02	≤0.3	≤0.025
S460ML	≤0.2	≤1.70	≤0.80	≤2.0	≤0.010	≤1.5	≤0.20

4 EXPERIMENTAL RESULTS

4.1 *Chemical composition*

The chemical compositions of the three steels studied are given in Table 2. The comparison between these results and the limits of the material specification (Table 1) shows that the chemistry satisfies in all cases what is established there.

4.2 *Microstructure*

S235 JR steel: In Figure 1, two micrographs showing the microstructure of the non-heated S235 JR steel at two different depths in the plate (0.5 and 10 mm, respectively) can be appreciated. In Figure 2, two micrographs (with different magnification), taken from a depth of 0.5 mm, show the microstructure of the heated S235 JR steel. Two relevant microstructural effects were detected: first, Figure 2(a), the grain has experienced a noticeable refinement: (from $20 \pm 4\,\mu m$ to $14 \pm 4\,\mu m$). Second, tertiary cementite precipitates are appreciated in some grain boundaries, see Figure 2(b).

S460 ML steel: In Figure 4, two micrographs taken from a depth of 0.5 mm, show the microstructure of the non-heated S460 ML steel. A combination of proeutectoid ferrite (white) and perlite (black) can be clearly seen, In this case, the elongated non-symmetrical disposition of grains created by the rolling process is evident even in this near-to-surface micrograph. Concerning the microstructure of the flame treated S460 ML steel, a micrograph obtained at a depth of about 0.5 mm is shown in Figure 4. The alteration of the morphology of the grains is highlighted in this image; moreover, larger non uniformity is present in the grain size distribution. These features are a consequence of the recrystallization induced by the flame heating process.

S690 QL steel: The microstructure of the non-heated S690 QL steel can be seen in Figure 5 (this micrograph was taken at a depth of 15 mm). A combination of bainite and ferrite constitutes the microstructure of this material, in accordance with what is expected (see above). Although the maximum temperature reached during the heating in this case is only 688°C, the material has undergone a second tempering, superimposed on the original one, (Fig. 6a). No

Table 3. Summary of the results of the Vickers hardness tests.

Material	As received	After heating	Variation (%)
S235 JR	147 ± 6	147 ± 11	0
S460 ML	198 ± 4	172 ± 11	−13
S690 QL	291 ± 7	215 ± 21	−26

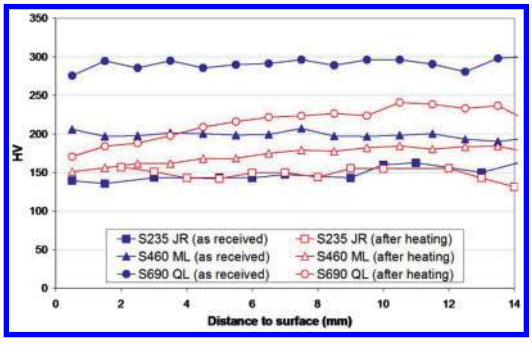

Figure 7. Results of the Vickers tests performed through the thickness of the plates, prior to and after heating, for each steel grade.

modification in the grain size or shape is appreciated, which is consistent with the fact that the maximum temperature is below T_{Ac1}.

4.3 *Mechanical characterisation*

Vickers hardness tests: The tests were performed across the thickness of the specimen below the surface heated by the flame. The average results of these tests are summarized in Table 3 and graphically represented in Figure 7. 235 JR did not undergo any substantial change in hardness; on the other hand, both S460 ML and S690 QL steels became softer as a consequence of the heat treatment experienced. On average, the Vickers hardness decrease in these materials is up to 13% and 26%, respectively.

Tensile tests: One non-heated specimen plus one heated specimen were obtained for each material (ASTM E8 2005). The tests were performed at room temperature (~20°C). The load vs. elongation curves were recorded up to fracture; from them, the stress

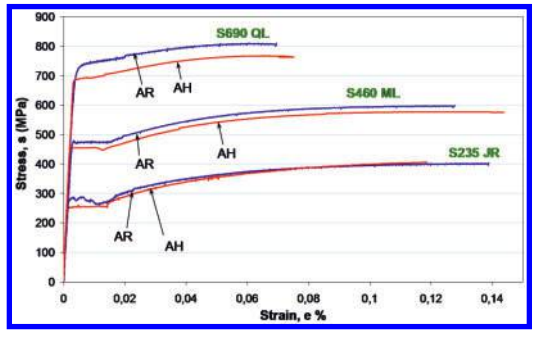

Figure 8. Stress vs. strain curves (as received and flame heated condition).

	e_U (%)	6.9	7.5	8.7

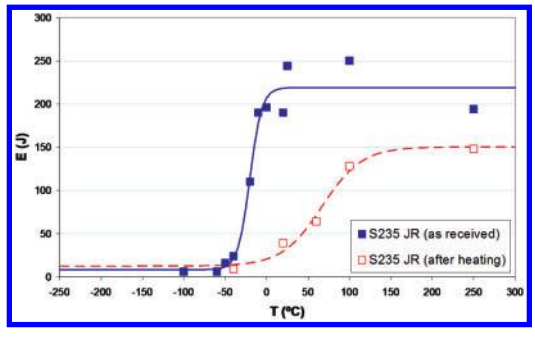

Figure 9. CVN curves (energy vs. temperature) for S235 JR steel (as received and after heating condition).

vs. strain (engineering variables) curves, represented in Figure 8, were calculated; the main mechanical parameters (Table 4). The curves clearly show that the influence of the flame heating on the mechanical response is strongly material dependent: following the same tendencies that were appreciated in the previous section, the flame treatment hardly modifies the properties of S235 JR steel, whereas the change in the other materials varies from moderate (S460 ML) to noticeable (S690 QL).

Fracture characterisation: The experimental results, expressed in terms of the absorbed energy vs. test temperature (ASTM E23 2005), are included in Figure 9

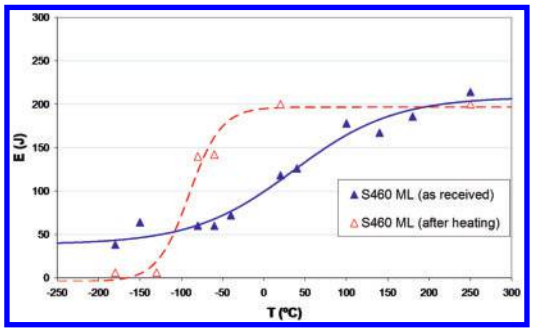

Figure 10. CVN curves (energy vs. temperature) for S460 ML steel (as received and after heating condition).

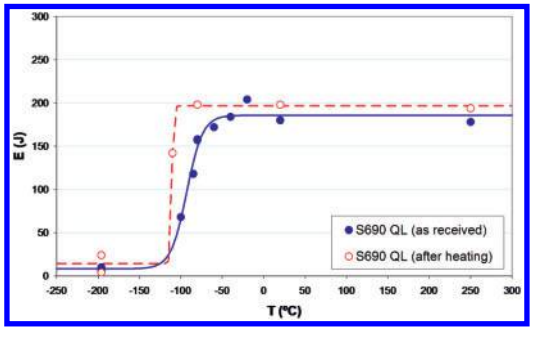

Figure 11. CVN curves (energy vs. temperature) for S690 QL steel (as received and after heating condition).

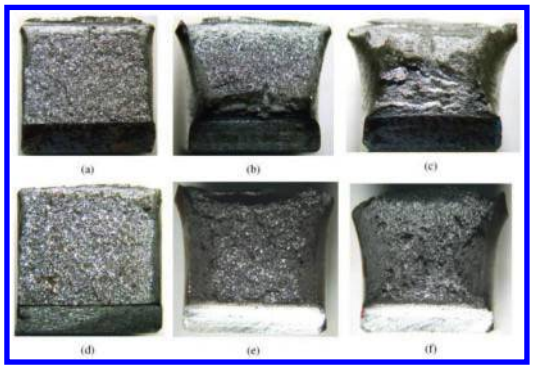

Figure 12. Macrographs showing the fracture surfaces of the S235 JR CVN specimens. As received condition: (a) −50°C, (b) 20°C, (c) 250°C. Flame heated condition: (d) −40°C, (e) 60°C, (f) 100°C.

(S235 JR), Figure 10 (S460 ML) and Figure 11 (S690 QL). To facilitate the subsequent analysis, the CVN curves were fitted to a hyperbolic tangent curve.

The curves included in Figures 9 to 11 clearly show that the influence of the flame heating on the fracture response is, again, strongly material dependent. The S235 JR steel has undergone a marked embrittlement as a consequence of the flame heating. The influence of

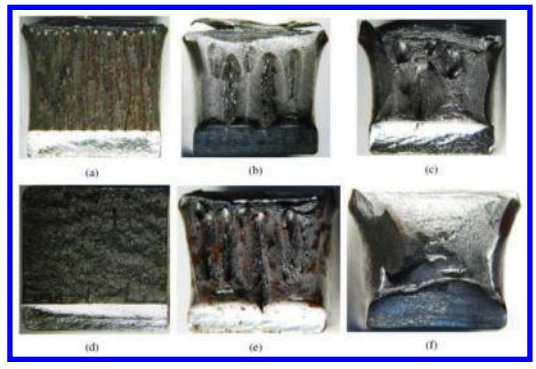

Figure 13. Macrographs showing the fracture surfaces of the S460 ML CVN specimens. As received condition: (a) −150°C, (b) 40°C, (c) 140°C. Flame heated condition: (d) −135°C, (e) −60°C, (f) 250°C.

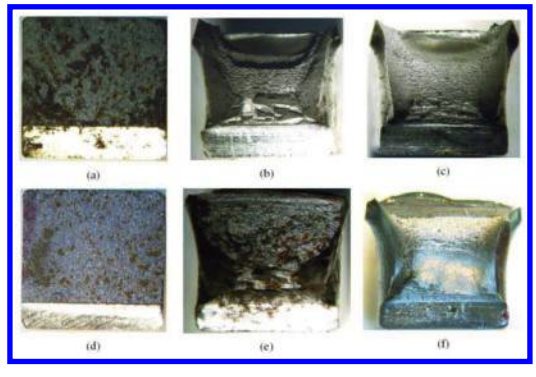

Figure 14. Macrographs showing the fracture surfaces of the S690 QL CVN specimens. As received condition: (a) −196°C, (b) −60°C, (c) 20°C. Flame heated condition: (d) −196°C, (e) −110°C, (f) 250°C.

the flame on the S460 ML steel is certainly more complex (Fig. 10) as a complete modification in the shape of the curve occurred. Finally, the fracture behaviour of the S690 QL grade hardly modified as a consequence of the flame heating process (Fig. 11). Some representative macrographs of the fracture surfaces can be appreciated in Figure 12 (S235 JR), Figure 13 (S460 ML) and Figure 14 (S690QL).

Extended characterisation of the S235 JR steel: The S235 JR steel has undergone a noticeable embrittlement as a consequence of the flame heating. To analyse this feature, the J-integral as an energy release rate (Anderson 1995, Kanninen 1985) has been used in this research (ASTM E1820 2005). In this sense, two S235JR CVN specimens (one in the as-received condition and the other in the flame treated condition) were precracked through fatigue (to induce the presence of an initial sharp crack, a_0) and subsequently tested at room temperature in three-point bending; the fracture resistance curves, which are represented in Figure 15, were obtained. The curves highlight the significant difference in fracture response between the original and the heat treated S235 JR material.

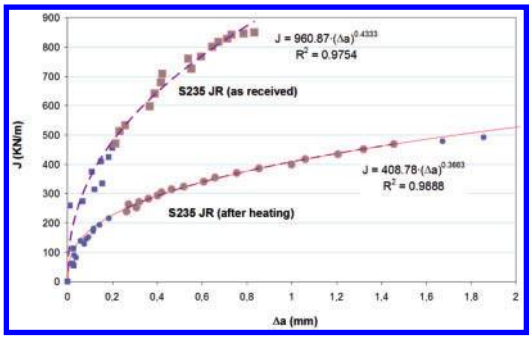

Figure 15. Fracture resistance curves (J-integral vs. crack extension, Δa) obtained for the S235 JR steel comparing the as received response with the flame treated behaviour.

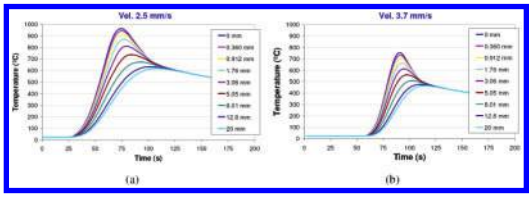

Figure 16. Finite Elements temperature vs. time curves as a function of the depth in the plate. (a) 2.5 mm/s (S235 JR and S460 ML steels); (b) 3.7 mm/s (S690 QL steel).

5 ANALYSIS AND DISCUSSION OF EXPERIMENTAL RESULTS

5.1 *S235 JR steel*

As shown by the Finite Element results (ANSYS 2011), Figure 16 (a), this material remains at a temperature higher than ~750°C ($T_{AC1} = 714$°C; $T_{AC3} = 846$°C) for at least 10 seconds in the 3 mm band closest to the surface. This process, which may be considered as an "intercritical annealing", causes the partial dissolution of pearlite which, in turn, as a result of the subsequent cooling, may lose its laminar (banded) structure (Fig. 2a) previously appreciated in the original microstructure (Fig. 1a). A second appreciable aspect is caused by the high temperature reached, exceeding $T_{AC3} = 846$°C, by the material in the 2 mm band nearest the surface. This process results in the transformation of the existing phases in austenite, this phenomenon being known as a "full annealing". A third point to notice here is the formation of "tertiary cementite" as a result of the cooling conditions to which the material is subjected. As shown by the FE model, see Fig. 16(a), the cooling rate below 600°C is very slow at any depth, thus enabling the formation of such a microstructure; indeed, the time for the temperature to decrease from 600°C to 400°C is substantially longer than 100s. This feature is shown in Figure 2b.

5.2 *S460 ML steel*

As demonstrated above, this steel shows a strongly deformed microstructure because of the rolling process, Fig. 3(a). The consequences of the heating experienced by the steel depend on the temperature reached. As the upper surface band of the plate exceeded the temperature $T_{Ac1} = 704$°C, the material was subjected to an intercritical or full annealing treatment, depending on whether the steel reached the temperature $T_{Ac3} = 859$°C. These two treatments lead to the formation of austenite as well as the recrystallization of ferrite, Figure 4.

The profile of Vickers tests in Figure 7 shows that there is no noticeable change in hardness with the depth in the as-received condition. The heated material, in turn, shows a tendency to a softer behaviour in the proximity of the surface; this can be explained as a consequence of the recrystallization induced by the flame heating process which is particularly intense on the surface of the plate. The consequences of the recrystallization also become evident when comparing the tensile response of the material in the as-received condition and after heating. These features are reflected in the fracture response of the material, as can be seen in Figure 10, when an improvement in fracture toughness is evident in the treated material as compared with the original condition.

5.3 *S690 QL steel*

As indicated above, the speed of the torch in this case was significantly higher than the other steels. This fact results in a lower maximum temperature and different cooling patterns. The analysis represented in Figure 16(b) states that, as no point in the plate has reached the temperature T_{AC1}, this martensitic-bainitic material was subjected to a tempering heat treatment.

Figure 7 shows that this material has undergone an intense change in hardness due to the flame heating. This has its corresponding counterpart in the tensile characterisation. This behaviour is perfectly reasonable in view of the second tempering detected in the microstructural investigation. Nevertheless, the fracture response is only slightly affected by the changes in microstructure.

6 CONCLUSIONS

As can be appreciated, the influence of the flame straightening procedure on the microstructure, mechanical or fracture behaviour clearly depends on the nature of the steel receiving this sort of heat treatment. These results provide clear evidence that it is not possible to determine a priori the consequences of the heat straightening on a specific steel; rather, they must be experimentally obtained on a case by case basis. Regardless of this, the experimental results reported in this study allow different families of steels to be distinguished and, from this, the following set of general recommendations to be stated: In general, when

the critical (T_{Ac3})/intercritical (between T_{Ac1} and T_{Ac3}) temperature is reached, the subsequent cooling rate must be controlled to avoid the formation of martensite. In addition, in order to prevent the formation of tertiary cementite in low carbon ferritic-pearlitic steels, low cooling rates below 650°C must be avoided.

The conventional treatises recommend not exceeding the critical temperature of dissolution of pearlite to avoid the possible harmful consequences of the flame straightening treatment. The literature, however, makes no reference to the particular characteristics of the material or heat treatment such as cooling rate. This work has revealed the importance of these and other aspects and how, in some cases, the general recommendations lead to undesirable results.

ABSTRACT: This contribution presents a method to construct three-dimensional Statistically Similar RVEs (SSRVEs) for the simulation of the mechanical response of dual-phase steel (DP steel). DP steels have enhanced material properties such as high ductility and high strength compared to conventional steels. Since these properties originate in the microstructure of the material, it should be incorporated in the numerical calculations in order to account for these microstructural effects. This can be accomplished by using the FE^2 – method, however for an efficient computation SSRVEs with a reduced complexity compared to the real microstructure have to be defined. These SSRVEs still represent the mechanical response of the material accurately. The method for the construction of SSRVEs is based on a least-square functional considering suitable statistical measures describing the inclusion morphology of the real microstructure. In numerical examples, the mechanical response of the SSRVE is compared to the response of the real microstructure.

1 INTRODUCTION

Advanced high strength steels enable engineering applications where both, high strength and high damage tolerance are required such as encountered in the fields of mobility, manufacturing and safety. One specific type of such materials is dual phase steel. Here, the improved material properties originate from the interaction of the individual constituents in the microstructure, which is composed of a soft ferrite matrix with hard martensite inclusions, cf. N. Peranio and Raabe (2010). Thus, the direct incorporation of the microstructure into the model is desirable, which can be achieved using direct micro-macro approaches, such as the FE^2 method, see e.g. C. Miehe (1999), W. Brekelmans (1998), Schröder (2000). In the context of this method, a microscopic boundary value problem is solved at each evaluation point of the macroscopic boundary value problem, with a RVE reflecting the real microstructure on the microscale. These require commonly very complex discretizations if a RVE is chosen as a direct representation of a real material microstructure due to the complex morphology of the microstructure itself. A way to obtain more efficient calculations using this scheme is the application of Statistically Similar RVEs (SSRVEs), see Balzani et al. (2010), J. Schröder (2011), which have a lower complexity than the aforementioned RVEs taken directly from real microstructures but which still represent the mechanical response of the material accurately. The construction of the SSRVEs is based on the assumption that selected statistical measures describing the microstructure morphology of the real material are similar to statistical measures describing the SSRVE. Some possible descriptors are the basic scalar-valued parameters, see Ohser and Mücklich (2000), such as the volume fraction and integral of mean curvature, furthermore higher order statistical measures as the n-point probability function and lineal path function. The spectral density has been shown to be correlated to the two-point probability function, see Parzen (1992). In previous studies for two-dimensional SSRVEs, see Balzani et al. (2010), it has been found that certain statistical measures show a better performance for the application in this method than others, see J. Schröder (2011). Hence, in our construction method, the volume fraction, spectral density and lineal path function are chosen as appropriate statistical measures to describe the microstructural morphology. A method for the determination of substructures that are statistically similar to more complex two-phase microstructures has been proposed in Povirk (1995) where a least-square functional is minimized taking into account the power spectral densities of the real microstructure and the substructure with a fixed inclusion geometry. From here, the basic idea for the construction method of the SSRVEs is the minimization of a least-square functional considering the aforementioned appropriate statistical measures for

the SSRVE and the real microstructure. For the construction of 3D SSRVEs a parameterization of the inclusion morphology using different numbers of rotationally non symmetric ellipsoids is incorporated. The minimization problem is carried out applying a differential evolution algorithm for global optimization using the optimization package Mystic, see M.M. McKerns et al. (2011). Numerical examples are given to show the performance of the method.

2 STATISTICALLY SIMILAR RVES

In Finite-Element simulations based on the FE^2 approach, the boundary value problem on the microscale is built up by a RVE. This RVE commonly is determined by the smallest possible subvolume of a microstructure which is still able to represent the macroscopic mechanical response of the complete microstructure. However, this smallest possible substructure of a material is usually still too complex for efficient FE^2 calculations due to the large number of degrees of freedom originating from the discretization of the complex morphology of the microstructure. The basic idea in this context is to replace the RVE by a periodic microstructure composed of periodically arranged unitcells, see Figure 1.

The effort of calculating the complete periodic microstructure can then be reduced to only computing the periodic unitcell, if periodic boundary conditions are applied.

A least-square functional is formulated considering suitable statistical measures describing the morphology of the inclusion phase of the real microstructure and the SSRVE. This functional is minimized to obtain a SSRVE which emits the lowest error in statistical measures compared to the real microstructure. We consider the general minimization problem

$$\gamma^\star = \operatorname{argmin}\left[\mathcal{L}(\gamma)\right] \quad \text{with} \tag{1}$$

$$\mathcal{L}(\gamma) = \sum_{i=1}^{nsm} \omega_i \left[\mathcal{P}_i^{real} - \mathcal{P}_i^{SSRVE}(\gamma)\right]^2 \tag{2}$$

wherein $\mathcal{P}^{real}$ and $\mathcal{P}^{SSRVE}$ denote the suitable statistical measures describing the inclusion morphology computed for the real microstructure and the SSRVE.

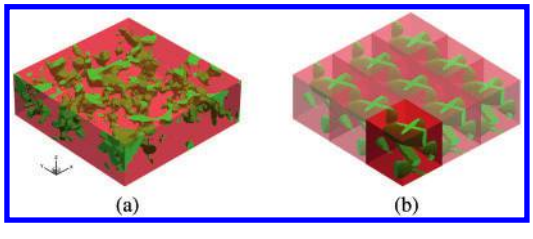

Figure 1. Schematic illustration of the basic concept, red indicating the matrix phase, green indicating the inclusion phase: (a) usual RVE with arbitrary inclusion morphology and (b) periodic microstructure with SSRVE.

The total number of statistical measures taken into account is described by *nsm* and ω represents the weighting factor of the individual statistical measures. The morphology of the inclusion phase of the SSRVE is described by a parameterization vector γ, which will be explained in Section 2.3. $\gamma^\star$ is considered the representation of the real microstructure.

2.1 *Statistical measures*

There exists a large number of statistical measures to describe the morphology of a single phase in a multiphase material, an overview can be found in Mücklich (2000). In our case we seek for measures to describe the inclusion phase in a two-phase matrix-inclusion composite, such as a DP steel. A very basic but yet important measure is the volume fraction defined by

$$\mathcal{P}_V = \frac{V_I}{V} \tag{3}$$

where V_I and V denoting the volume of the inclusion phase and the volume of the total composites, respectively. This parameter has been shown to play an important role in the method, cf. Balzani, Brands, Schröder & Carstensen 2010) and has to be considered to obtain satisfying results. A further statistical measure is the spectral density which is defined by the multiplication of the discrete Fourier transformation with its conjugate complex

$$\mathcal{P}_{SD}(n_x, n_y, n_z) := \frac{1}{2\pi N_x N_y N_z} \left|\mathcal{F}(k_x, k_y, k_z)\right|^2 \tag{4}$$

with the discrete Fourier transformation given by

$$\mathcal{F}(n_x, n_y, n_z) := \sum_{k_x=1}^{N_x} \sum_{k_y=1}^{N_y} \sum_{k_z=1}^{N_z} \exp\left(2\pi i \left(\frac{n_x\ k_x}{N_x} + \frac{n_y\ k_y}{N_y} + \frac{n_z\ k_z}{N_z}\right)\right) \chi(k_x, k_y, k_z). \tag{5}$$

The maximal number of pixels in each dimension of the considered binary data set are given by N_x, N_y and N_z, and the indicator function χ is defined by

$$\chi(k_x, k_y, k_z) := \begin{cases} 1 \text{ if point } x \text{ is in incl. phase} & (6) \\ 0 \text{ else} & (7) \end{cases}$$

with the point $x(k_x, k_y, k_z)$ in the binary data set. The coordinates in frequency domain are n_x, n_y and n_z. The spectral density captures periodicity information of a microstructure and is related to the two-point probability function, see Parzen (1992). It is considered a measure of higher order compared to the scalar valued basic parameters.

The lineal path function is another measure of higher order giving information about the probability

that line segments with different lengths and orientations are entirely located in one phase of the material. A complete computation of a lineal path function is expensive, therefore we use a template containing a certain number of line segments with distinct orientations which are analyzed instead of the whole set of possible line segments. The lineal path function is computed based on the indicator function

$$\lambda := \begin{cases} 1 \text{ if } \overrightarrow{\boldsymbol{x_1 x_2}} \text{ is in inclusion phase} & (8) \\ 0 \text{ else,} & (9) \end{cases}$$

with the line segment $\overrightarrow{x_1 x_2}$. For periodic and ergodic microstructures, the lineal path function is calculated by

$$\mathcal{P}_{LP}(m,k,l) := \frac{1}{N_x N_y N_z} \sum_{p=1}^{N_x} \sum_{q=1}^{N_y} \sum_{o=1}^{N_z} \lambda \qquad (10)$$

with $\lambda := \lambda(p+m, q+k, o+l)$ and (m,k,l) defining the oriented line segments in the template.

2.2 *Proposed method*

The outlined statistical measures cover important information about the morphology of the inclusion phase of the microstructure. With these measures in hand, the least-square functional for the minimization process is obtained as

$$\mathcal{L}(\gamma) = \omega_V \left(\mathcal{P}_V^{real} - \mathcal{P}_V^{SSRVE}(\gamma)\right)^2 \qquad (11)$$

$$+ \omega_{SD} \sum_{k_x,k_y,k_z} \left(\mathcal{P}_{SD}^{real} - \mathcal{P}_{SD}^{SSRVE}(\gamma)\right)^2 \qquad (12)$$

$$+ \omega_{LP} \sum_{p,q,o} \left(\mathcal{P}_{LP}^{real} - \mathcal{P}_{LP}^{SSRVE}(\gamma)\right)^2 \qquad (13)$$

with the weighting factors $\omega_V = 1$, $\omega_{SD} = 1$ and $\omega_{LP} = 1000$, which were found to give reasonable results.

2.3 *Parameterization of inclusion phase morphology of SSRVEs*

For the parameterization of the inclusion phase in the SSRVE, a varying number of non rotationally symmetric ellipsoidal inclusions is chosen. One ellipsoidal inclusion is described by a set of nine parameters $[x_c\ y_c\ z_c\ \psi\ \theta\ \phi\ r_1\ r_2\ r_3]$, which are defined as described in Figure 2. The first three entries x_c, y_c and z_c describe the center point of the inclusion, the Euler angles ψ, θ and ϕ measure a rotation of the coordinate system of the ellipsoid and r_1, r_2 and r_3 define the radii of each semi axis of the ellipsoid. Depending on the number of ellipsoidal inclusions in the SSRVE, the vector γ contains one data set for each ellipsoidal inclusion.

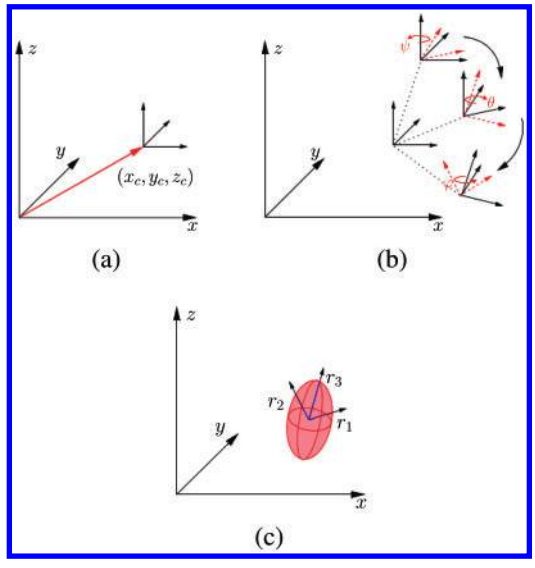

Figure 2. Illustration of parameterization of one ellipsoidal inclusion in SSRVE: (a) center coordinates of ellipsoid, (b) rotation by Euler angles, (c) radii on semi axis.

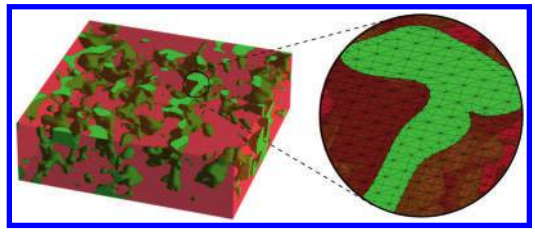

Figure 3. Reconstruction of DP steel microstructure and discretization.

3 NUMERICAL EXAMPLES

For a representation of a real DP steel microstructure, four 3D SSRVEs with different numbers of inclusions are generated. The reconstruction of a DP steel microstructure is obtained from 3D EBSD FIB-based serial sectioning measurements, cf. M. Calcagnotto and Raabe (2010), carried out in coorporation with the Max Planck Institut für Eisenforschung, Düsseldorf, for details on the method see e.g. N. Zaafarani (2006). Details of the serial sectioning and 3D reconstruction method has been described by S. Zaefferer (2008). Figure 3 shows the microstructure which was discretized with 8.5 mio. dof and 10-noded tetrahedrons, the structure measures $15.9 \times 16.45 \times 5$ micrometers. The size of the SSRVEs is calculated on the basis of the statistical measures of the real microstructure. Since the lineal path function captures length information, it can conflict with the measure of volume fraction, if the size of the SSRVE is not chosen large enough. In this contradicting case, in the minimization process, the size of

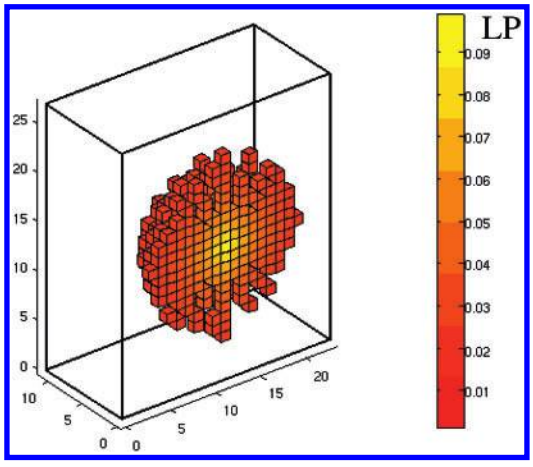

Figure 4. Illustration of lineal path function for a lower threshold of 2% probability.

the average ellipsoidal inclusion in the real microstructure, estimated from the lineal path function, would be larger than the volume fraction allows the inclusion to be. The average size of an ellipsoidal inclusion is estimated using a threshold of 2% probability, excluding small probabilities, to obtain an average ellipsoidal inclusion. The corresponding lineal path function representing the average ellipsoidal inclusion can be seen in Figure 4. Calculating the volume of this ellipsoid based on the measurements of the semi axes, V_{aver}, the size of a cubic SSRVE can be determined for the desired number of inclusions, respectively, by

$$\mathcal{P}_V^{real} = \frac{n_{inc}\, V_{aver}}{V^{SSRVE}}, \tag{14}$$

$$\rightarrow l_x = l_y = l_z = \sqrt[3]{\frac{n_{inc}\, V_{aver}}{\mathcal{P}_V^{real}}}. \tag{15}$$

For an analysis of the performance of the method, SSRVEs with one, two, three and five inclusions are constructed using the method described. The minimization process is carried out using the parallel optimization environment Mystic, cf. M.M. McKerns et al. (2011). Figure 5 shows the obtained SSRVEs and the corresponding error measures in the statistical measures are summarized in table 1.

A decrease of the errors of the statistical measures with increasing number of inclusions is clearly detectable from Table 1. The increase of complexity in the morphology of the microstructure leads to a closer fit of the statistical measures to the ones of the real microstructure. The performance regarding the mechanical response of the SSRVEs compared to the real microstructure is tested in four basic virtual experiments, tension in x-direction, tension in z-direction, shear of xz-plane in x-direction (xy) and shear of yz-plane in y-direction (yx). For comparative means, a

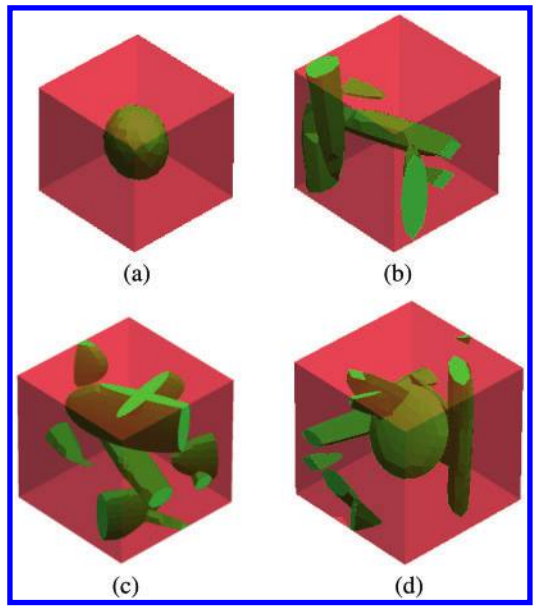

Figure 5. SSRVEs constructed for DP steel microstructure with (a) $n_{inc} = 1$, (b) $n_{inc} = 2$, (c) $n_{inc} = 3$ and (d) $n_{inc} = 5$.

Table 1. Error in statistical measures of calculated SSRVEs.

SSRVE	$\mathcal{L}[10^{-2}]$	$\mathcal{L}_V[10^{-4}]$	$\mathcal{L}_{SD}[10^{-3}]$	$\mathcal{L}_{LP}[10^{-4}]$
$n_{inc} = 1$	8.432	485.29	4.5	0.31
$n_{inc} = 2$	0.98	32.07	3.5	0.031
$n_{inc} = 3$	0.53	3.37	3.3	0.017
$n_{inc} = 5$	0.38	3.03	2.0	0.015

relative error measure is calculated for each virtual experiment by

$$\tilde{r}_j = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left[r_j^{(i)}\right]^2} \tag{16}$$

with

$$r_j^{(i)} = \frac{\bar{\sigma}_{j,i}^{real} - \bar{\sigma}_{j,i}^{SSRVE}}{\bar{\sigma}_{j,i}^{real}}, \tag{17}$$

j indicating the virtual experiment, the individual and total number of evaluation point i and n, respectively and $\bar{\sigma}$ being the macroscopic stress. An overall average error is computed by

$$\tilde{r} = \sqrt{\frac{1}{4}\left(\tilde{r}_x^2 + \tilde{r}_z^2 + \tilde{r}_{xy}^2 + \tilde{r}_{yx}^2\right)}. \tag{18}$$

Figure 6 shows the errors of the mechanical response of the SSRVEs compared to the real microstructure. For the tension test in x-direction, all

Table 2. Error in [%] of mechanical response for virtual experiments comparing SSRVEs to real microstructure and number of elements in discretization.

SSRVE	n_{ele}	$\tilde{r}_x$	$\tilde{r}_z$	$\tilde{r}_{xy}$	$\tilde{r}_{yx}$	$\tilde{r}$
$n_{inc}=1$	2851	5.3	4.6	5.5	5.5	5.24
$n_{inc}=2$	5015	0.5	3.6	4.4	4.4	3.60
$n_{inc}=3$	18835	0.5	1.8	1.5	1.3	1.36
$n_{inc}=5$	20413	0.5	2.1	2.6	2.6	2.13

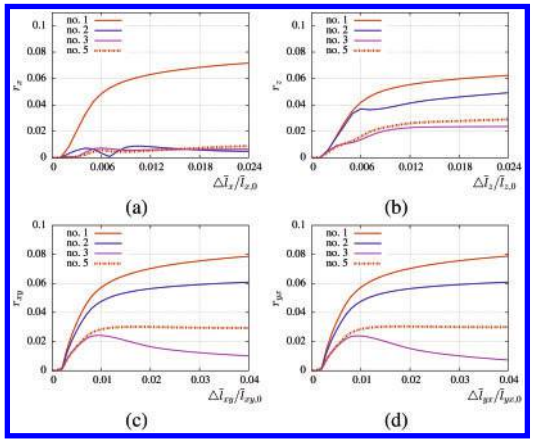

Figure 6. Error of mechanical response for virtual experiments: (a) tension x-, (b) tension in z-direction, (c) shear of xz plane in x-direction and (d) shear of yz plane in y-direction.

SSRVEs except for the single inclusion one can represent the real microstructure response accurately. For the tension test in z-direction, a separation of the curves for the SSRVEs with one and two inclusion while the other two remain lowest with the SSRVE with three inclusions having a slightly lower error. In the shear tests the error of SSRVE no. 3 emits the lowest error.

The summary of the results in Table 2 shows a decrease in the mechanical error in most virtual experiments with increase of number of inclusions, SSRVEs with three and five inclusions both having an overall error around 2%, the SSRVE with three inclusions even having a lower error, $\tilde{r}=1.36$, than the one with five inclusions. Increasing the number of inclusions from one to two inclusions leads to a large descent in the mechanical error, which was also seen for the statistical measures. A further increase of the number of inclusions up to three leads to a lower mechanical error. Increasing the number of inclusions to five does not improve the mechanical error although the error in the statistical measures decreased. Looking at the number of elements used to discretize the SSRVEs, an increasing value n_{ele} can be found with increasing number of inclusions in the SSRVE. From Figure 5, it can be found that the increase from three to five inclusions does not lead to an obvious increase of visible complexity, only slightly more elements for a discretization were needed.

4 CONCLUSION

A method for the construction of 3D SSRVEs is proposed using the volume fraction, spectral density and lineal path function to describe the morphology of the inclusion phase. From the here presented results, it can be seen that with increasing complexity of the SSRVE, i.e. increasing number of inclusions in the SSRVE, a lower error measure in the statistical measures and also, for an increase up to three inclusions, a lower error in the mechanical results can be seen. A further increase to five inclusions leads to a lower error in the statistical measures, however, no decrease in the mechanical error can be detected. This finding leads to the assumption that for the characterization of the real microstructure, the statistical measures chosen to represent the real microstructure are reasonable but not perfectly complete, since some hidden information may remain undetected. Thus, the incorporation of more statistical measures to represent the microstructure can be promising. Possible candidates are Minkowski functionals, which carry further statistical information.

A study of local mechanical properties of 304L SS welded joints subjected to cyclic straining using depth-sensing instrumented indentation

Duyi Ye & Feng Mi
Institute for Process Equipments, Zhejiang University, Hangzhou, China

Xiaoxia Yin
Institute for Architecture Design, Huaxin Consulting Co., Ltd, Hangzhou, China

ABSTRACT: In this paper, a series of experiments including low-cycle fatigue tests, depth-sensing indentation measurements, optical microscopy examinations, etc. were carried out to study the local mechanical properties and microstructures in particular zones of 304L SS welded joints subjected to cyclic straining. An analytical algorithm proposed by Dao et al. was utilized to estimate the basic mechanical properties (E, σ_y and n) in various regions of the welded joints from the indentation load-displacement data. It is shown that in the as-welded condition, the weld metal has a higher strength but lower stiffness and plasticity than does the base metal, while the material within HAZ exhibits a significant gradient of the mechanical properties. A strain amplitude-dependent variation in the local mechanical properties in particular joint regions was also obtained for the cyclically deformed welded joints. Optical microscopy examinations show that the microstructure in particular regions of 304L SS welded joints is not only decided by the metallurgical condition resulting from the welding process, but also determined by the strain amplitude applied during cyclic deformation.

1 INTRODUCTION

In welded structures, welded joints are generally known as potential 'weakest links' due to weld defects or microstructural in-homogeneities which bring about the local changes in the mechanical properties and thus result in difficulties in fatigue strength analysis of welded structures, since the stress distribution and crack behavior in welded joints are strongly dependent on the mechanical in-homogeneity (Filacchioni et al. 2002, Lee et al. 2007, Kim et al. 2007). Accordingly, comprehensive understanding of the local mechanical properties in welded joint zones, including the weld metal (WM), heat-affected zone (HAZ) and base metal (BM), as well as their variations during fatigue loading is of vital importance for the design of the welded structures against fatigue failure.

So far, a variety of methods for determining the local mechanical properties of welded joints have been developed. One of the widely applied methods is microhardness measurement that can determine the transverse profiles of the deformation resistance across the joints (Naderi et al. 2008, James et al. 2009). The conventional microhardness testing, however, can only provide qualitative data instead of further information regarding the basic mechanical properties such as Young's modulus, yield stress, strain hardening exponent, etc in welded joint zones. These basic mechanical parameters are essential for the fatigue strength analysis of welded joints subjected to cyclic external forces (Fuchs & Stephens 1980). For this reason, methods to characterize joint zone properties based on uni-axial tension test using mini- or micro-specimens have been developed in recent years (Rafal et al. 2009, Fuller et al. 2008, Rao et al. 2010). It has been found (Fuller et al. 2008), however, that preparing isolated mini-tensile specimens from the welded joints is frequently connected with certain difficulties and restrictions in practical applications due to the small-size of joint zones. For instance, in most cases the size of the HAZ does not exceed fractions of millimeter, and, additionally, its shape often makes it difficulties to produce an isolated specimen for tensile testing. It has also been indicated (Rafal et al. 2009, Boroński 2006) that the tensile tests using isolated mini-specimens can not take into account the interaction of welded joint zones on each other during the joint loading. This interaction may significantly affect the mechanical behavior of welded joints especially in the case of time-altering loadings as cyclic straining.

Depth-sensing indentation (DSI) technique, developed over the last decade, has been regarded as a power tool for the mechanical measure of small-volume materials or engineering surfaces (Giannakopulos & Suresh 1999). Much recent research (Giannakopulos & Suresh 1999, Oliver & Cheng 1984, Dao et al. 2001, Ye et al. 2007) also led to the development of numerous analytical methods for estimating the basic mechanical properties such as Young's modulus, yield stress, strain hardening exponent, etc. from the indentation load-displacement data. Among these analytical methods, an analytical

algorithm proposed by Dao et al (Dao et al. 2001) has been regarded as the representative one due to its more accordant estimations with the measured mechanical properties (Ye et al. 2011, 2012). Since DSI has various merits in practical applications, such as less destructive, quick to perform, and only a relatively small piece of material is required in testing, it provides a promising method for determining the local mechanical properties of welded joints. This is the motive of the present research work to apply the depth-sensing indentation tests and combine with Dao et al's analytical algorithm to study the local mechanical properties of 304L SS welded joints subjected to low-cycle fatigue (LCF) loadings so as to develop a local mechanical properties-based approach for the fatigue strength analysis of welded components under alternative service conditions.

2 EXPERIMENTAL DETAILS

The material used in the present study was 304L stainless steel (SS). Its actual chemical composition in weight percent was listed in Table 1. Solution-annealed base plate of 304L SS, 18 mm in thickness, was joined along the plate rolling direction by manual metal arc welding using 316L SS and Inconel 182 electrodes. The configuration of the joint groove was double-V shaped and the weld was completed in 15 passes with a voltage of 24V, a current of 100 A. Subsequent to welding, the weldments were examined, non-destructively, by X-ray to ensure their soundness. Cylindrical specimens having 12 mm gauge length and 10 mm diameter were cut from the acceptable weldments in such a way that they contained portions of the base metal, heat-affected zone and weld metal.

Experiments for the present study consist mainly of (1) room-temperature constant amplitude low-cycle fatigue (LCF) tests of 304L SS welded joint specimens, and (2) depth-sensing indentation measurements in particular zones of the fatigue failure joint specimens. Details of experimental procedures are described as follows.

Fully reversed total-axial-strain-controlled LCF tests were conducted at room temperature in air on 304L SS as-welded joint specimens using a MTS 810 servohydraulic testing system. Tests were conducted at various strain amplitudes in the range of $\pm 0.5\%$ to $\pm 1.2\%$ at a constant total strain rate of $4 \times 10^{-3}\ s^{-1}$. In this study the fatigue life (N_f) of welded joint specimens is defined as the number of cycles required to reduce the maximum stress (σ_{max}) to a value of 3/4 times the peak value experienced during previous cycles.

Table 1. Chemical compositions (wt. %) of the material investigated.

C	Mn	Si	S	P	Cr	Ni	Mo	Cu	N
0.03	2.0	0.75	0.03	0.045	18.7	10.15	0.07	0.19	0.1

Samples for the depth-sensing indentation measurements were sectioned to the required size along the longitudinal direction of both the as-welded and fatigue failure 304L SS joint specimens comprising the WM, HAZ and BM zones. The cut sections were then polished using different grads of emery papers. Final polishing was done using a diamond compound ($1\ \mu m$ particle size) in the disc polishing machine. To reveal the microstructure, the polished samples were etched for 30 s in a solution containing 70% HNO_3. Depth-sensing indentation measurements were performed using a dynamic ultra microhardness tester (Shimadzu DUH201S) equipped with a Vickers diamond indenter. In this study, a maximum indentation load of 500 mN and a dwell-time of 15 s were utilized. Throughout the indentation tests, the loading rate was kept at 200 mN/min. Taking into account the in-homogeneity of the local mechanical response in welded joint zones, indentation measurements were performed as the following ways. In the case of the as-welded joint sample, an indentation array consisting of 5×30 measures that contained portions of the base metal, heat-affected zone and weld metal was utilized. The mean results for each equivalent position were then calculated. In the case of fatigue failure joint specimens, at least 15 indentations were measured at randomly selected places in each joint zone to provide statistical representative results. During indentation testing, both the indentation load (P) and displacement (h) were continuously recorded as an indenter was driven into the sample (loading segment) and then withdrawn from it (unloading segment). The raw data were then used to construct the indentation load-depth ($P-h$) curves.

Microstructures in particular zones of both the as-welded and fatigue failure 304L SS joint specimens were observed by optical microscopy (OM). In this study, a quantitative measurement of the ferrite/martensite content in particular joint zones was also performed using a commercial magnetic instrument (MP30 Ferriscope), in which at least 11 measurements for each joint zone were recorded.

3 RESULTS

3.1 *Mechanical property distributions across the as-welded 304L SS joint zones*

Five lines of indents along the longitudinal direction of the as-welded 304L SS joint sample were illustrated in Figure 1. This figure also allowed us to identify the BM, HAZ and WM regions as well as their approximate dimensions. In Figure 1, a much less size of the indent compared to the dimension of the individual joint zone was observed, indicating thereby that the indentation load-depth ($P-h$) curve measured in this study is exactly an indication of the local elasto-plastic response of the joint zone materials. Figure 2 presents typical $P-h$ curves measured in the BM, HAZ and WM regions, respectively. For the sake of clarity, only one curve for each joint zone was presented in this

figure. As it is seen in Figure 2, not only the magnitude but also the shape of $P-h$ curves changes significantly with the joint zone, indicating that for the present 304L SS welded joint, the indentation response is highly sensitive to the details of the metallurgical condition resulting from the welding process.

In terms of the above experimental $P-h$ curves, the basic mechanical properties (σ_y, n and E) in particular zones of the as-welded 304L SS joint sample can be estimated using Dao et al's analysis algorithm. Figure 3 shows the estimated mechanical properties (σ_y, n and E) plotted as a function of the measured positions across the welded joint regions, where each data point represents an average of 5 values and error bar are ± 1 standard deviation. As it is seen in this figure, various mechanical parameters (σ_y, n and E) exhibit relatively little variation in BM and WM regions, but significant variation within HAZ. In comparison to the base metal, the weld metal shows a higher yield stress (σ_y) and strain hardening exponent (n) but a lower Young's modulus (E), while the material within HAZ exhibits gradient-distribution mechanical properties. The significant variation in the local mechanical properties across the joint is mainly attributed to the welding-altered microstructures in welded joint zones, which will be analyzed in the subsequent section.

3.2 *Fatigue mechanical properties in particular zones of 304L SS welded joints*

Figure 4 shows typical indentation load-depth ($P-h$) curves measured in the base metal, heat-effect zone and weld metal of the 304L SS joint specimens cycled to failure at two representative low and high strain amplitudes ($\pm 0.5\%$ and $\pm 1.2\%$). As it is seen in this figure, with increased strain amplitudes, the curvature of the loading curves tends to increase, as a whole, while the contact depth at the maximum load and the residual depth after complete unloading exhibit decreasing characteristics for various joint regions investigated. The above observations indicate that for the 304L SS welded joints under investigation the indentation response is also highly sensitive to

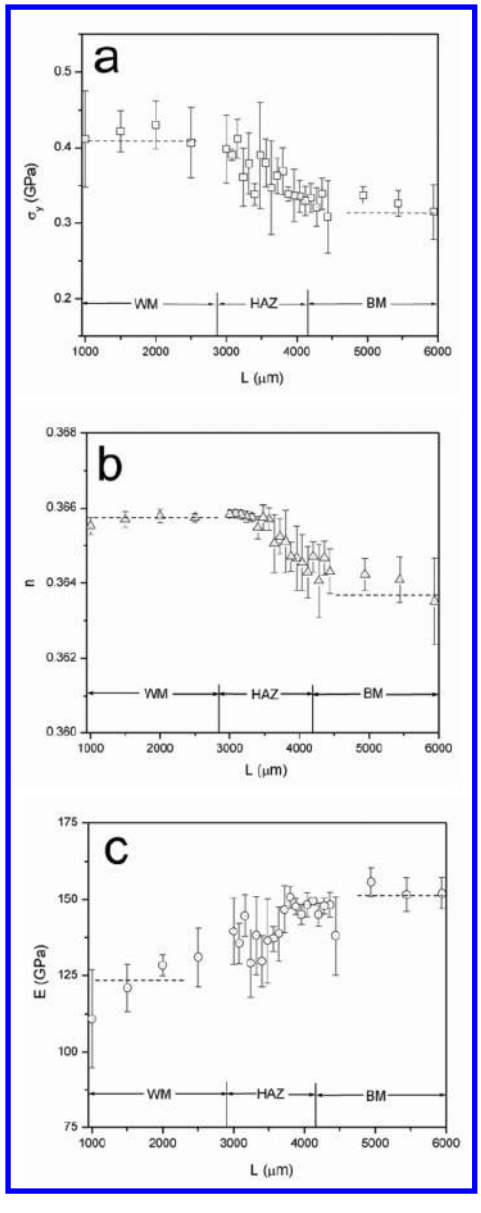

Figure 3. Distributions of the basic mechanical properties across the as-welded 304L SS joint regions: (a) yield stress (σ_y); (b) strain hardening exponent (n); (c) elastic modulus (E).

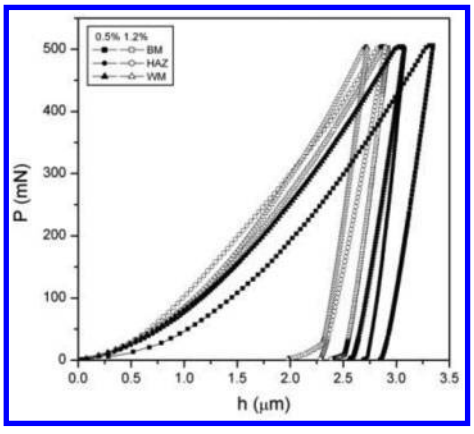

Figure 4. Typical indentation load-depth ($P-h$) curves in particular zones of fatigue failure 304L joint specimens.

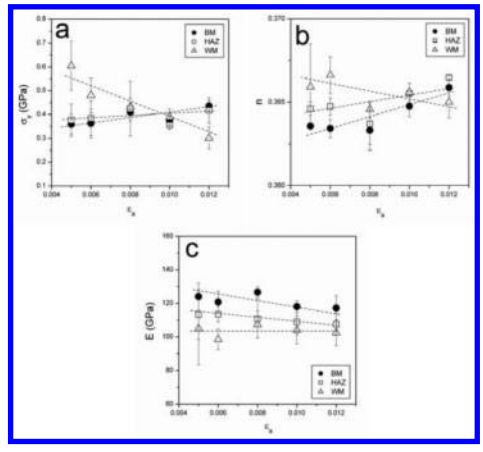

Figure 5. Dependence of the basic mechanical properties on the applied strain amplitudes: (a) yield stress (σ_y); (b) strain hardening exponent (n); (c)Young's modulus (E).

the strain amplitude applied during low-cycle fatigue loadings.

In this study, the basic mechanical properties (σ_y, n and E) in three different zones of fatigue failure joint specimens were also estimated using Dao et al's analysis algorithm combined with the measured $P-h$ curves. Figure 5 shows the values of σ_y, n and E plotted as a function of the applied strain amplitude in the base metal, heat-effect zone and weld metal, where each data point represents an average of 15 values and the error bars are ± 1 standard deviation. This figure reveals that with increasing strain amplitudes, the yield stress (σ_y) and strain hardening exponents (n) display increase in both BM and HAZ regions but decrease in WM region, while Young's modulus (E) exhibits decreasing characteristic in various joint regions investigated. This strain amplitude-dependent variation in the basic mechanical properties in particular joint zones essentially results from the strain amplitude-dependent variation in the microstructures in the welded joints during cyclic straining, which will also be discussed subsequently.

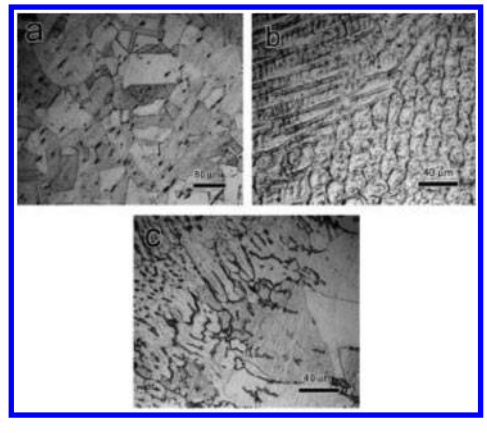

Figure 6. Microstructures in particular zones of the as-welded 304L SS joint sample: (a) base metal; (b) weld metal; (c) interfacial region close to HAZ.

3.3 *Microstructures in particular zones of 304L SS welded joints in both as-welded and cyclic straining conditions*

In order to seek for the micromechanisms responsible for the variation in the local mechanical properties of the present 304L SS welded joints, microstructural examinations were performed in particular zones of both the as-welded and fatigue failure joint specimens.

Figure 6 shows the optical micrographs of the base metal, weld metal and their interfacial regions close to HAZ of 304L SS joint sample in the as-welded condition. Note in Figure 6a that the microstructure of the base metal consists of equiaxed austenitic grains with small amount of δ – ferrite in the form of stringers. The weld metal exhibits a fine duplex austenite-ferrite microstructure (Figure 6b), where δ – ferrite with cellular and dendritic morphologies has been clearly observed. In addition, extensive precipitations of carbides and oxides are also visible preferentially on the boundaries between the austenite and ferrite phases. In Figure 6c, the microstructure of the interfacial region close to HAZ is predominantly vermicular or intercellular, although ferrite stringers are occasionally observable in some of the austenite grains.

Figure 7 summarizes representative microstructures in particular regions of fatigue failure 304L SS joint specimens tested at low and high strain amplitudes ($\pm 0.5\%$ and $\pm 1.2\%$). At low strain amplitude of 0.5%, the austenitic grains in the base metal contain a few slip bands (Figure 7-1a). Additionally, martensitic phase appeared as blocks or islands are also visible in some austenitic grains. In weld metal discrete slip bands with one slip system are found in the majority of the grains (Figure 7-1b). In the interfacial regions close to HAZ, small dark needles assumed to be deformation-induced martensite are

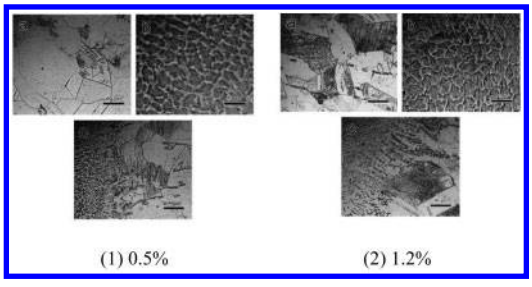

Figure 7. Microstructures in particular zones of the fatigue failure 304L SS joint specimen tested at 0.5% and 1.2%: (a) base metal; (b) weld metal; (c) interfacial region close to HAZ.

also observed (Figure 7-1c). At high strain amplitude of 1.2%, in addition to the localized single slip bands, multiple slip modes with intersecting bands on different planes, penetrating the whole grains, are found commonly in both the base metal (Figure 7-2a) and weld metal (Figure 7-2b) as well as their interfacial regions close to HAZ (Figure 7-2c). In some austenitic grains the slip bands become unrecognizable due to their high density in the base metal. Meanwhile, martensite with different morphologies and distributions has also been, more or less, observed over several austenite grains.

The above microstructural observations indicate that for the present 304L SS welded joints the microstructure in welded joint zones is not only decided by the metallurgical condition resulting from the welding process, but also determined by the strain amplitude applied during cyclic straining.

4 DISCUSSIONS

As indicated (Sireesha et al. 2000), during welding some metallurgical changes, such as (a) segregation during solidification, (b) distribution of elements during phase changes, and (c) precipitation of secondary phase particles, take place in welded joint zones. In the case of austenitic stainless steel (SS) weldments, owing to the non-equilibrium rapid solidification condition in welding process, the peak temperature in fusion zone is much higher than the upper limit of phase balance between δ – ferrite and γ – austenite (Folkhard 1984). Because of high cooling rate in the fusion zone, the possibility of ferrite to austenite transformation is low and some ferrites are remained at grain boundaries. According to Fuller et al (Fuller et al. 2008), presence of δ – ferrite at grain boundaries may prohibit grain growth and decrease the grain size. Consequently, in the present 304L SS welded joint the incomplete phase transformation during welding results in the formation of the observed a fine duplex austenite-ferrite microstructure in the weld metal region (see Figure 6b). With increasing distance from the fusion boundary, the cooling rate tends to decrease due to the thermal gradient between the joining faces and electrodes. The reduced cooling rate leads to decreasing the amount of grain boundary ferrite, which results in the formation of a partially mixed zone with a higher semicontinuous δ – ferrite content near the interface close to HAZ, as seen in Figure 6c, where the vermicular or intercellular ferrite structure is mostly because of the effects of dilution from the base metal. As it has been indicated (Folkhard 1984, Bhanu et al. 1990, Sharifitabar et al. 2011), in austenitic SS weldements the formation of δ – ferrite is an important aspect to take into account for their mechanical behavior. The δ – ferrite was found to induce an increased number of dislocation sources which act as barriers to the mobile dislocations and cause an increase in the deformation resistance (Lee et al. 2007). Several reports (Rho et al. 1998 & Hong et al. 2002) also revealed the deleterious effect of increased δ – ferrite content on resistance of fracture of weld metals. The cause was traced to the tendency for cracks to propagate preferentially along the δ – ferrite or δ/γ interface. In this study, magnetic measurements indicated the amount of the average δ – ferrite in the weld metal region to be about 2.4% and in the base metal region to be about 1.4%. The higher percentage of ferrite content in the WM region, with its many transformed phase boundaries, is believed to offer a greater resistance to plastic flow than does the relatively coarser austenitic structure of the base metal, which may be responsible for the higher local strength and strain hardening capacity in the weld metal than in the base metal, as seen in Figures 3a and 3b. Additionally, the carbide precipitations formed at grain boundaries and within grains in the weld metal will also contribute to the increase in the local strength due to the interactions between dislocations and precipitates during deformation. Since δ – ferrite is basically different from austenite matrix in its crystallography and chemical composition, stress concentration may occur at the δ/γ interface owing to strain incompatibility (Fuller et al. 2008). The high stress concentration at δ/γ interfaces promotes microcrack initiation and results in the reduction in the local stiffness. Accordingly, in the present 304L SS welded joint, the higher volume fraction of ferrite in the WM region may also become a primary factor responsible for the observed reduction in the stiffness property in the weld metal, as shown in Figure 3c, since the larger amount of δ – ferrite provides more δ/γ interfaces that imply more possible sites for crack initiation. In this study, a significant gradient of the local mechanical properties has also been observed within HAZ (see Figures 3a, 3b and 3c), which is thus mostly associated with the microstructure gradient resulting from the inhomogeneous metallurgical changes during welding process. The severe property gradient in HAZ also suggests that the tensile test using mini- or microspecimens extracted from the welded joint regions, as mentioned previously, can only provide an averaged mechanical measurement of the entire HAZ due to the fact that the dimension of the micro-tensile specimen is usually much larger than the size of the microstructure. In other words, the instrumented indentation-based

mechanical testing would provide a more reasonable approach for studying the local mechanical properties of welded joints.

As shown in the present study, the microstructure in particular regions of 304L SS welded joints undergoes strain amplitude-dependent change during low-cycle fatigue loadings. With increased strain amplitudes, both the number of micro-shear bands and activated slip systems showed increase in welded joint zones (see Figure 7). Additionally, more and thicker deformation-induced martensite was also observed at the intersections of the slip bands especially in the base metal. In this study, magnetic measurements in particular zones of the fatigue failure joint specimens revealed that with increase in strain amplitude, the volume fraction of martensite displayed increase in the base metal, but slight decrease in the weld metal. Since micro-shear band boundaries and martensite formations both impede dislocation motion and lead to a strengthening effect (Lee et al. 2007), with increasing strain amplitudes, the increase in the number of micro-shear bands and the volume fraction of martensite transformation gives rise to the increase in the local strength and strain hardening capacity in the base metal, as seen in Figures 5a and 5b. On the other hand, numerous previous investigations (Bhanu et al. 1990) also showed that at high strain amplitude, the dislocation structure in the weld metal tended to wall and cell arrangements. Since cellur structure provides a larger mean free path for dislocations, softening may take place in the weld metal in this case. Accordingly, in this study, as the applied strain amplitude increased, the decrease in the local strength and strain hardening capacity in the weld metal, also shown in Figures 5a and 5b, is mostly associated with the softening of the material resulting from annihilation of dislocations or arrangement of dislocations into cells/subgrains during cyclic straining. The nucleation of microcracks/microvoid at δ/γ interfaces during cyclic straining, as well as their increase in the number with increased strain amplitudes, will be responsible for the strain amplitude-dependent degradation in the local stiffness of the present joint region materials (see Figure 5c).

5 CONCLUSIONS

(1) The indentation response is highly sensitive to the details of the metallurgical condition resulting from the welding process. For the present investigated welded joint, not only the magnitude but also the shape of $P-h$ curves changes significantly with the joint zone.
(2) The weld metal has a higher yield stress (σ_y) and strain hardening exponent (n) but a lower Young's modulus (E) than does the base metal, while the material within HAZ exhibits a significant gradient of the mechanical properties.
(3) In the as-welded condition, the microstructure of the base metal consists of equiaxed austenitic grains with small amount of δ – ferrite. The weld metal exhibits a fine duplex austenite-ferrite microstructure. The microstructure of the interfacial region close to HAZ is predominantly vermicular or intercellular. The above microstructural features play an important role in deciding the local mechanical properties in different joint zones.
(4) With increasing strain amplitudes, the yield stress (σ_y) and strain hardening exponents (n) display increase in both BM and HAZ regions but decrease in WM region, while Young's modulus (E) exhibits decreasing characteristic in various joint regions investigated.
(5) The microstructure in particular regions of 304L SS welded joints undergoes strain amplitude-dependent change during low-cycle fatigue loadings, which is essentially responsible for the strain amplitude-dependent variation in the local mechanical properties of the present welded joints.

Biological tissue mechanics with fibres modelled as one-dimensional Cosserat continua. Applications to cardiac tissue in healthy and diseased states

K. Sack & S. Skatulla
Department of Civil Engineering, University of Cape Town, South Africa

C. Sansour
Division of Materials, Mechanics, and Structures, The University of Nottingham, UK

ABSTRACT: Classically, the elastic behaviour of biological tissues is modelled using anisotropic strain energy functions which are supposed to capture the averaged behaviour of the matrix and the fibres. The strain energy function can be derived via representation theorems for anisotropic functions as shown in Wang (1970), Zheng (1994) and Holzapfel (2004). Alternatively, a superimposed continuum approach can be adopted where the matrix is considered as an isotropic material but the fibres are taken as superimposed one-dimensional continua (Karšaj[1], Sansour, & Sorić 2008). The latter approach allows for the inclusion of any number of families of fibres. In either case the state of stress in the fibres is one-dimensional and is parallel to the fibre tangent. Hence, fibre thickness is not a parameter in the formulation. Biological tissues, however, exhibit strong variations in fibre thickness defining different fibre hierarchies where the thickness can have a significant influence. This is especially true in inhomogeneous bending and shear-related states of stress.

To overcome this shortcoming, in this paper the approach of superimposed continua is extended. While the matrix is still considered as an isotropic continuum, the fibres are modelled as one-dimensional Cosserat continua. Hence, bending and shearing of fibres, in addition to stretching, become meaningful and fibre thickness becomes a material parameter.

The muscle fibres are enmeshed in a collagen network. Both, the fibre and the collagen material, are associated each with individual strain energy functions which are combined within a homogenization approach. In this way, a three-dimensional state of stress and strain of the complex myocardial tissue can be addressed. Presently, only the linear elastic representation for the strain energy function of the muscle fibre tissue are considered.

1 INTRODUCTION

Cardiovascular disease is the leading cause of death in the developed world accounting for 40% of all human mortality. Modelling the mechanical behaviour of the heart to improve our understanding of cardiovascular disease has been a scientific endeavour for the last 30 years. The proliferation of inexpensive high performance computing power has enabled more sophisticated simulation tools that can facilitate and guide the development of modern therapies.

Fundamental to this endeavour is the understanding and accurately describing the material and mechanical behaviour of the cardiac tissue is of great importance. Over the last 15 years constitutive models have introduced phenomenological properties as a means overcome the complex structure on a macro and micro scale (Costa et al. 2001), (Schmid, H.H. 2006) and (Holzapfel and Ogden 2009). This approach usually incorporate a large number of material parameters. A problem with this approach is the shortage of experimental data suitable for detailed parameter estimation. Increasing attempts to include the micro-structural influences directly have emerged with the hope that this will reduce, albeit not remove, the dependency on material parameters and the complicated strategies used to approximate them.

To date, the leading strain invariant-based stored energy functions only include limited micro structure considerations. Nothing has yet emerged to include an actual micro-structure on a kinematics level that influence macro-deformations in a coupled-physics behaviour.

Adopting the work of Sansour & Skatulla (2008), which successfully illustrated the increased accuracy of a three-dimensional Cosserat micro-structure in deformations of fibre orientated sheets, into the description of cardiac tissue is the objective of this paper. We consider the material response to be obtained by a homogenisation scheme superimposing

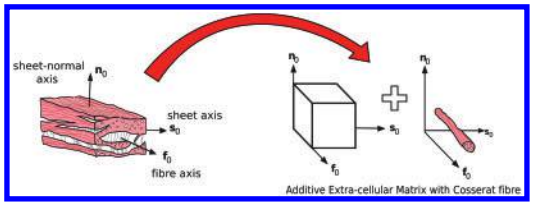

Figure 1. The material properties of cardiac tissue can be modelled as additive contributions from the extra-cellular matrix and Cosserat fibres.

the material behaviour of fibre/fibre bundles, modelled as Cosserat rods, and extra-cellular matrix, modelled as an isotropic elastic material.

2 DEFORMATION AND STRAIN

Let the deformation $\phi(\boldsymbol{X},t)$ be a mapping from the reference state of the body $\mathcal{B}$ with $\boldsymbol{X}\in\mathcal{B}$ to the current configuration at a specific time $\mathcal{B}_t$. If $\boldsymbol{X}$ and $\boldsymbol{X}$ are the respective coordinates of the reference state $\mathcal{B}$ and the current configuration $\mathcal{B}_t$, then the deformation gradient is given by:

$$\boldsymbol{F}=\mathrm{Grad}(\boldsymbol{x}) \tag{1}$$

Where Grad is the gradient operator acting with respect to the reference configuration $\boldsymbol{X}$. Given $\vartheta^i, i=1,2,3$, the co-variant curvilinear coordinate system parametrizing $\mathcal{B}$, we define, $\boldsymbol{G}_i$, the co-variant tangent vectors spanning the tangent space $\mathcal{TB}$ by:

$$\boldsymbol{G}_i=\frac{\partial \boldsymbol{X}}{\partial \vartheta^i} \tag{2}$$

In the classical Cosserat continuum every material point P is assigned a rotational field independent of displacements, enriching the continuum with additional degrees of freedom. We can express this rotational field $\boldsymbol{R}\in SO(3)$ explicitly (Sansour and Skatulla 2008):

$$\boldsymbol{R}(\vartheta^i,t)=1+\frac{\sin|\boldsymbol{\gamma}|}{|\boldsymbol{\gamma}|}\boldsymbol{\Gamma}+\frac{\cos|\boldsymbol{\gamma}|}{|\boldsymbol{\gamma}|^2}\boldsymbol{\Gamma}^2 \tag{3}$$

where $\boldsymbol{\gamma}$ denotes the rotation vector and $\boldsymbol{\Gamma}(\vartheta^i,t)\in so(3)$ is a skew a skew symmetric tensor with $\boldsymbol{\gamma}$ as its axial vector.

The *Cosserat* continuum features two strain measures. The first *Cosserat* strain tensor is a stretch-like tensor given by:

$$\boldsymbol{U}(\vartheta^i,t)=\boldsymbol{R}^T\boldsymbol{F} \tag{4}$$

where it should be noted, that unlike it's classical counterpart, is not symmetric in general. The second *Cosserat* strain measure is a change of curvature strain tensor given by:

$$\boldsymbol{K}(\vartheta^i,t)=-\frac{1}{2}\boldsymbol{\epsilon}:(\boldsymbol{R}^T\boldsymbol{R}_{,i})\otimes\boldsymbol{G}_i \tag{5}$$

For the purpose of modelling one dimensional Cosserat rods, consider a one-dimensional fibre continuum mapped by the coordinate $s=s(\vartheta^i)$. As such the fibre is assumed to be embedded in three dimensional space. The fibre deformation gradient is given by:

$$\boldsymbol{F}^{(s)}=\frac{\partial \boldsymbol{x}}{\partial \vartheta^i}\frac{\partial \vartheta^i}{\partial s}\otimes\hat{\boldsymbol{V}}_F=\boldsymbol{v}_F\otimes\hat{\boldsymbol{V}}_F \tag{6}$$

where $\boldsymbol{V}_F$ denotes a co-variant vector in fibre direction and $\hat{\boldsymbol{V}}_F$ its contra-variant equivalent. The fibre direction in the current configuration is expressed by $\boldsymbol{v}_F=\boldsymbol{F}\boldsymbol{V}_F$. In this sense, $\boldsymbol{F}^{(s)}$ is the projection of the deformation gradient $\boldsymbol{F}$ in direction of the fibre. A corresponding structural tensor is written as $\boldsymbol{M}_F=\boldsymbol{V}_F\otimes\hat{\boldsymbol{V}}_F$ representing the one-dimensional fibre continuum allowing us to alternatively express $\boldsymbol{F}^{(s)}=\boldsymbol{F}\boldsymbol{M}_F$

Similarly, we find associated strain measures $\boldsymbol{U}^{(s)}$ and $\boldsymbol{K}^{(s)}$, respectively, for the *Cosserat* fibre continuum:

$$\begin{aligned}\boldsymbol{U}^{(s)} &= \boldsymbol{R}^T\boldsymbol{F}^{(s)}=U_1^{(s)}\boldsymbol{V}_F\otimes\hat{\boldsymbol{V}}_F+\ldots\\ &\quad U_2^{(s)}\boldsymbol{A}_1\otimes\hat{\boldsymbol{V}}_F+U_3^{(s)}\boldsymbol{A}_2\otimes\hat{\boldsymbol{V}}_F \qquad (7)\\ \boldsymbol{K}^{(s)} &= -\frac{1}{2}\boldsymbol{\epsilon}:\boldsymbol{R}^T\frac{\partial\boldsymbol{R}}{\partial\vartheta^i}\frac{\partial\vartheta^i}{\partial s}\otimes\hat{\boldsymbol{V}}_F=\\ &= K_1^{(s)}\boldsymbol{V}_F\otimes\hat{\boldsymbol{V}}_F+\ldots\\ &\quad K_2^{(s)}\boldsymbol{A}_1\otimes\hat{\boldsymbol{V}}_F+K_3^{(s)}\boldsymbol{A}_2\otimes\hat{\boldsymbol{V}}_F \qquad (8)\end{aligned}$$

where $\boldsymbol{A}_i$ are the unit vectors defining the cross-fibre orientations in the reference configuration such that $(\boldsymbol{V}_F,\boldsymbol{A}_1,\boldsymbol{A}_2)$ spans an orthonormal basis.

3 VARIATIONAL PRINCIPLE

As a first approach of the theory we explore the use of a linear constitutive law, allowing us to determine if the model can suitable capture deformation in the small strain strain range before investigating the computationally demanding requirements of testing a nonlinear constitutive based model.

We look at establishing a stored energy function relating to the fibrous material and the extra cellular matrix $\psi(\boldsymbol{U},\boldsymbol{K})$ as an additive function of the two material components as follows:

$$\psi=v_m\psi_{matrix}(\boldsymbol{U})+v_f\psi_{fibre}(\boldsymbol{U}^{(s)},\boldsymbol{K}^{(s)}) \tag{9}$$

where v_m and v_f are the respective volume fractions for the matrix and fibre components, such that $v_m+v_f=1$. Additionally, we define ψ_{fibre} as a decoupled function of the two fibre Cosserat strain measures.

$$\psi_{fibre}(\boldsymbol{U}^{(s)},\boldsymbol{K}^{(s)})=\psi_I(\boldsymbol{U}^{(s)})+\frac{l^2}{12}\psi_{II}(\boldsymbol{K}^{(s)}) \tag{10}$$

where linear hyperelastic material behaviour is assumed for both, the fibre and the matrix continuum, and l is the so called *characteristic length* of the underlying micro-structure. Assuming symmetry in cross fibre directions, they can be expressed as:

$$\begin{aligned} \psi_I(\boldsymbol{U}^{(s)}) &= \frac{1}{2}\left(EAU^{(s)2}_1 + GAU^{(s)2}_2 + GAU^{(s)2}_3\right) \\ \psi_{II}(\boldsymbol{K}^{(s)}) &= \frac{1}{2}\left(GJK^{(s)2}_1 + EI_2K^{(s)2}_2 + EI_2K^{(s)2}_3\right) \end{aligned} \quad (11)$$

where E is Young's modulus G is the shear modulus, J and I_2 are the second moments of area corresponding to torsion and bending and A is the cross sectional area of the fibre bundle. In this sense, the characteristic length, l, is incorporated directly in the cross sectional area, $A = \frac{\pi l^2}{4}$ and the second moments of area $I_2 = J/2 = \frac{\pi l^4}{32}$.

This allows us to express a variational principle as:

$$\delta\Psi = \int_{\mathcal{B}} \{\boldsymbol{n} : \delta\boldsymbol{U} + \boldsymbol{m} : \delta\boldsymbol{K}\}\, \mathrm{d}V - W_{ext} \quad (12)$$

where the force stress tensor, $\boldsymbol{n}$ and the couple stress tensor, $\boldsymbol{m}$, given by:

$$\begin{aligned} \boldsymbol{n} &= v_m \frac{\partial \psi_{matrix}}{\partial \boldsymbol{U}} + v_f \frac{1}{A}\frac{\partial \psi_I}{\partial \boldsymbol{U}} \\ \boldsymbol{m} &= v_f \frac{1}{A}\frac{l^2}{12}\frac{\partial \psi_{II}}{\partial \boldsymbol{K}} \end{aligned}$$

are work conjugate to $\boldsymbol{U}$ and $\boldsymbol{K}$ respectively. Note that the contributions from the fibre have been normalized by the cross sectional area.

4 APPLICATION TO CARDIAC TISSUE

A regularly functioning, healthy heart is consists mainly of myocardial fibres, occupying roughly two thirds of the volume (Cleutjens 1996), and an extracellular matrix (ECM). The ECM has various components, most notably collagen fibrils: composed 85% of type I, 11% type III and 3% type V (Caulfield and Janicki 1997), which are responsible for the structural support and contributes to the mechanical stiffness of the problem. Other minor components include elastin, various cells and proteins as described in Weber et al. (1988) and Jugdutt (2003).

In a regular cardiac cycle, the heart undergoes four distinct phases: passive filling, isovolumetric contraction, ejection and isovolumetric relaxation. When analysing the pressure-volume relation of the left ventricle, these four cycles form a closed loop. This initial research will focus on modelling the passive filling stage, whereby the left ventricle volume cavity and internal pressure increases to accommodate the inflow of oxygenated blood. In this phase the healthy cardiac tissue performs as a nonlinear hyperelastic orthotropic material (Usyk, Mazhari, & McCulloch 2000).

4.1 *Calibration*

To model the fibres as Cosserat 1D rods embedded in a 3D ECM space, we will need to be able to separate the material properties into their respective components. While there is experimental data available for cardiovascular tissue; most notably Demer and Yin (1983) and Dokos et al. (2002), who performed biaxial and shearing properties respectively, the data sets proved unsuitable for linear model parameter calibration due to the highly nonlinear material behaviour.

Rather, we calibrated our model using a previously verified model of the rat left myocardium that employed the orthotropic based relations. Calibration employed specific computational experiments investigating simple tension, pure shear and four point bending, where appropriate Dirichlet boundary conditions are applied restraining displacement and rotational fields. The latter only applies for the Cosserat continuum-based approach. We are able to calibrate our model parameters for both the linear, isotropic ECM and the Cosserat fibre in the small strain range.

The samples of comparison tissue specimens were composed utilizing the constitutive implementation of Usyk et al. (2000). The strain energy function is expressed as:

$$\Psi_{Usyk} = C\frac{(e^Q - 1)}{2} + C_{compr}(J\ln J - J + 1) \quad (13)$$

with $Q = b_{ff}E^2_{ff} + b_{ss}E^2_{ss} + b_{nn}E^2_{nn} + b_{fs}(E^2_{fs} + E^2_{sf}) + b_{fn}(E^2_{fn} + E^2_{nf}) + b_{ns}(E^2_{ns} + E^2_{sn})$.

This treats cardiac tissues as nonlinear, orthotropic and nearly incompressible. Herein, E_{ij} are the components of the *Green* strain tensor $\mathbf{E}$. The parameters b_{ij} are constants which determine the contribution of each strain component to the strain energy:

Table 1. Strain energy function coefficients for Usyk-based model.

Parameter	Value
b_{ff}	2.8
b_{ss}	1.0
b_{nn}	1.0
b_{fs}	6.4
b_{fn}	1.0
b_{ns}	1.0

The indices refer to components aligned with fibre axis, f, sheet axiss s, and sheet-normal axis, n. Additionally the scaling parameters for healthy tissue $C = 1$ kPa and $C_{comp} = 100$ kPa were used. For more details on this model and it's calibration, one can consult (Legner et al. 2013).

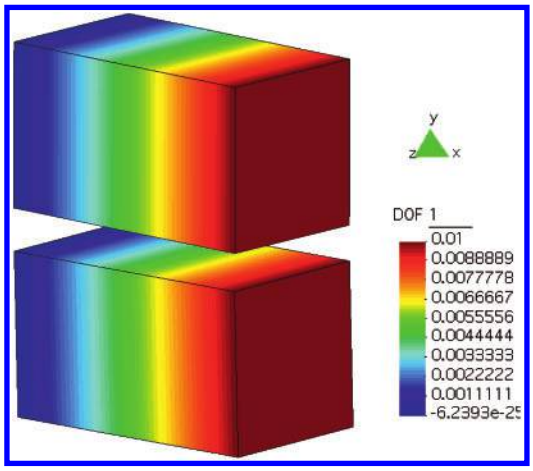

Figure 2. Deformation of Usyk-based (upper) and Cosserat (lower) for simple extension. Three of the six surface were unconstrained, allowing for extension in the direction of loading and contraction in orthogonal directions, while still enforcing a point of zero deformation.

4.2 *Initial results*

The corresponding Cosserat based model was successfully calibrated in each experiment (simple tension, pure shear and four-point bending) to within a tolerance of 0.05% of comparable stresses (or in the case of bending, with midpoint deflection). Figure 2 shows the deformation result of the Usyk-based and Cosserat based materials after calibration.

The following parameters are a result of the healthy tissue calibration:

Table 2. Material properties for Cosserat based constitutive law, modelling healthy cardiac tissue.

Parameter	Symbol	Fibre	EC matrix
Axial stiffness	E (kPa)	10.82	7.10
Shear Stiffness	G (kPa)	4.49	2.37
Characteristic length	l	0.59	–

It should be noted that the condition of near incompressibility is assumed for the isotropic ECM, as such Poisson's ration ν is modelled as 0.4999. This allows us to calibrate for only E_{ECM} and calculate G_{ECM} accordingly.

Following a myocardial infarction, the cardiac tissue experiences ischemia. The subsequent changes in tissue state and behaviour can be categorized into various stages: Acute, necrotic, fibrotic and remodelling. In the early phase of the infarct healing (acute ischemia), the tissue experiences a decrease in passive mechanical properties in the infarcted region (Holmes et al. 2005). The initial healing phase before necrosis was deliberately chosen as the micro structure of the cardiac tissue is mostly unchanged, removing the need for altering the volume ratios. To simulate this in

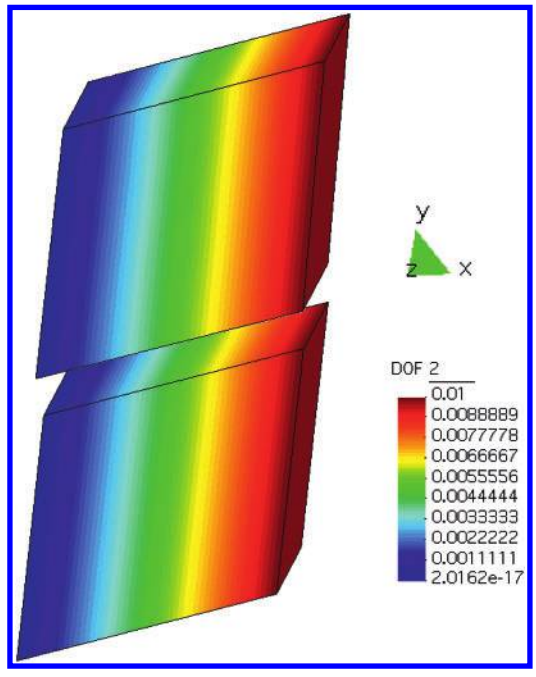

Figure 3. Shear deformation of Usyk-based (upper) and Cosserat (lower) for the pure shear experiment. Only the deformation in the direction of the applied shearing force is presented as the other deformation are trivial.

our comparison specimens, we employ the approach of Kortsmit et al. (2012), where the scaling coefficient in the Usyk formulation is reduced accordingly to $C = 0.44$ kPa.

The calibration of the Cosserat model applied to the above mentioned diseased state followed the same procedure as the healthy state and produced the following parameters:

Table 3. Material properties for Cosserat based constitutive law, modelling cardiac tissue in diseased state.

Parameter	Symbol	Fibre	EC matrix
Axial stiffness	E (kPa)	4.10	3.22
Shear Stiffness	G (kPa)	2.03	1.07
Characteristic length	l	0.851	–

In figure 3 the deformation results of the Usyk-based and Cosserat based materials are presented, for the model's calibration in the diseased state.

5 DISCUSSION

It was found through the calibration process that enforcing boundary conditions on the rotational degrees of freedom is essential to establish a well defined generalized continuum.

Mention must be made to the increase in the calibrated Cosserat characteristic length, l, from the healthy to diseased state. As the stress components in 12 have been normalized with respect to A, the primary function of l is to scale the stiffness contributions associated with flexure. In the case of calibration for bending, the weakened diseased material is especially susceptible to bending deformation and l subsequently compensates.

An interesting case to explore would be in the later stages of healing, where the diseased tissue microstructure changes. A significant portion of the cardiomyocytes would have decayed through necrosis and the volume content of the extra cellular matrix increases, with a rising contribution from collagen (Jugdutt & Amy 1986), making the infarct *stiffer*. As the volume fractions in the Cosserat continuum are explicit in the formulation it would allow for more realistic physical representation of the material, directly.

Application of the Cosserat fibre-based anisotropy model to the heart would require $\boldsymbol{V}_F$ defined for each material point $P(\xi, \eta, \theta)$. With respect to geometric boundary conditions along with displacement restraints one would apply to the base of the LV, our proposed approach also allows direct enforcement of rotational boundary conditions restraining the twist of the left ventricle. This enables the rest of the domain to experience more realistically the complex deformation modes including stretching, shearing, twisting and bending.

6 CONCLUSIONS

This initial investigation into the feasibility of using the Cosserat continuum to model cardiac tissue, illustrates the successful capability in capturing the material response in the small strain deformation range.

The linear model is not suitable to realistically capture the deformation behaviour of biological tissue which is characterized by large strains, and must be replaced with a nonlinear, preferably exponential form of (11).

The future investigation of this work, lies in the implementation of the nonlinear model, capable of capturing larger strain deformations and the application to more realistic geometries.

Buckling analysis of thin composite plates reinforced by carbon nanotubes (CNTs) using finite strip methods (F.S.M)

M. Pazoki & M. Azhari
Department of Civil Engineering, Isfahan University of Technology, Isfahan, Iran

A. Heidarpour
Department of Civil Engineering, Monash University, Australia

ABSTRACT: Due to high mechanical strength, Carbon Nanotubes (CNTs) as single walled carbon nanotubes, are being considered as Nano scale fibers to enhance the performance of polymer composite materials. An improvement of the physical properties of polymer Nano-composites, based on Carbon Nanotubes (CNTs), is devoted to a good dispersion and strong interactions between the matrix and the filler. Theoretical studies indicate that the tensile modulus of multi-walled nanotubes may reach 1 TPa.In the present study, the composite rectangular thin plate reinforced with Single-Walled Carbon Nanotubes (SWCNTs) is subjected to axial and biaxial loads and the critical buckling load of plate is calculated using Classical Plate Theory (CPT). Finite Strip Method (F.S.M) is employed to derive buckling equations. The Mori-Tanaka method is further used to calculate the effective elastic modulus of composites having aligned oriented straight CNTs. Furthermore the effect of CNTs agglomeration is investigated when CNTs are dispersed non- uniformly in the polymer matrix. The effects of aspect ratio and the edge conditions on the critical buckling load are also considered.

Keywords: Buckling, Mori-Tanaka, Nano composite, Carbon Nanotubes (CNTs), Finite Strip Method

1 INTRODUCTION

Since the discovery of carbon nanotubes(CNTs) by Ijima in 1991 (Iijima, 1991), several research works have been conducted by using CNTs in different areas of science and technology. Nowadays, due to the increasing need for materials with different mechanical properties, the use of Nano materials including Nano composites has been extended into the industry. These composites consist of two phases: the matrix phase and the phase composed of Nano-scale morphologies. Good mechanical and thermal properties of these materials could have important effects on the composite strength. Among the Nano-materials, Carbon nanotubes (CNTs) are noticeable. Due to lower resistance of the matrix phase relative to the reinforced phase, when the plate undergoes different loads the loads are transferred to the reinforcement phase (Yakobson et al., 1996, Yu et al., 2000, Zhang et al., 2002).

Griebel et al. compared experimentally the effect of aligned CNTs in polymer reinforcement (Griebel and Hamaekers, 2004). They concluded that for a constant compressive force, if the direction of nanotube axis is parallel to the force direction, the polymer composite would have higher resistance against the exerted force. Also, if the compressive force is perpendicular to nanotube axis, the composite longitudinal modulus would be improved slightly compared to bare polymer matrix. In the case of non-directional compressive loads, randomly arranged nanotubes will give better invariant modulus in comparison to the aligned ones (Griebel and Hamaekers, 2004). Formica et al. studied the vibrational properties of carbon nanotube reinforced composites (CNTRC) by means of an equivalent continuum model and Shelby-Mori-Tanaka approach (Formica et al., 2010).

Alibeigloo (Alibeigloo, 2012) continued the research by investigating the buckling of functionally graded Nano-composites aligned by SWCNTs subjected to uniaxial and biaxial in-plane loadings based on the first-order shear deformation theory (FSDT).

Hitherto, there is no available theoretical study investigating the buckling of plates reinforced by randomly oriented CNTs using finite strip method. In this paper, considering the enhanced mechanical properties of carbon nanotubes, buckling analysis of composite plates reinforced with randomly oriented CNTs are investigated. For the buckling analysis of plates under in plane loads and different boundary condition, the finite strip method (FSM) is used. FSM was developed by Cheung (Cheung, 1976). This method is efficient for plate analysis of all loading and support conditions. Finite strip method is based on the harmonic functions where the plate is divided into limited strips. Comparison of the present results for the plate

buckling coefficient for 0% volume fraction of CNTs (0% CNTs) with those obtained by other theoretical studies have shown the good accuracy of the present method.

2 THEORETICAL METHOD

2.1 *Eshelby-Mori-Tanaka method*

In the present study, the Eshelby-Mori-Tanaka method is used to determine the properties of the composites reinforced with carbon nanotubes. This method is based on the Eshelby equivalent inclusion idea and the average stress method (Mori and Tanaka, 1973, Benveniste, 1987). Therefore, the following equation expresses the tensor of effective elastic moduli $\mathbf{D}^*$:

$$\mathbf{D}^* = (V_m \mathbf{E}_m + V_{CNT} (\mathbf{E}_{CNT}^T \mathbf{A}))^T (V_m \mathbf{I} + V_{CNT} \mathbf{A})^{-1} \quad (1)$$

Where, $\mathbf{V}_m$ and $\mathbf{V}_{CNT}$ represent the volume fractions of matrix and CNTs phase, respectively. Also, $\mathbf{E}_m$ and $\mathbf{E}_{CNT}$ are the tensors of elastic moduli for each phase, $\mathbf{I}$ is the demonstrator of the fourth-order unit tensor and $\mathbf{A}$ is the partial concentration factor ($\varepsilon_{CNT} = A\varepsilon_m$), where ε_{CNT} and ε_m are the strain matrices for each phase and $\mathbf{A}$ is given by the following equation such that:

$$\mathbf{A} = (\mathbf{I} + \mathbf{S}^T \mathbf{E}_m^{-T} (\mathbf{E}_{CNT} - \mathbf{E}_m))^{-1} \quad (2)$$

In Eq. (2) $\mathbf{S}$ is the fourth-order Eshelby tensor (Eshelby and Eshelby, 1957), which is expressed as:

$$S_{ijkl} = \frac{5\nu - 1}{15(1-\nu)} \delta_{ij}\delta_{kl} + \frac{4 - 5\nu}{15(1-\nu)} (\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) \quad (3)$$

in ν is Poisson's ratio of matrix phase.

2.2 *Composites reinforced with randomly oriented, straight CNTs*

Figure 1 shows the orientation of straight CNT nanotubes in two different coordinate systems denoted by angles α and β. The global (X_1, X_2, X_3) and local (X_1', X_2', X_3') coordinate systems are shown in Figure 1.

The transformation matrix components a_{ij} forms a relationship between global and local coordinate systems such that:

$$e_i = a_{ij} e_j \quad (4)$$

In which, the transformation matrix $\mathbf{a}$ is obtained from:

$$\mathbf{a} = \begin{bmatrix} \cos\beta & -\cos\alpha\sin\beta & \sin\alpha\sin\beta \\ \sin\beta & \cos\alpha\cos\beta & -\sin\alpha\cos\beta \\ 0 & \sin\alpha & \cos\alpha \end{bmatrix} \quad (5)$$

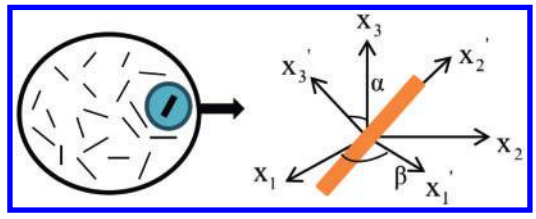

Figure 1. Randomly oriented carbon nanotubes.

Carbon nanotubes are distributed in matrix by a probability density function P(α, β) in which the overall probability is unit:

$$\int_0^{2\pi} \int_0^{\pi/2} P(\alpha,\beta) \sin\alpha d\alpha d\beta = 1 \quad (6)$$

For plenary randomly oriented CNTs with uniform distribution in the matrix volume P(α, β) is equal to $\pi/2$.

According to Eshelby-Mori-Tanaka method, the relations between the CNTs strain (ε_{CNT}) and stress (σ_{CNT}), and the matrix stress (σ_m) are (Huang et al., 2004):

$$\begin{cases} \boldsymbol{\varepsilon}_{CNT}(\alpha,\beta) = \mathbf{A}(\alpha,\beta)^T \boldsymbol{\varepsilon}_m = \mathbf{A}(\alpha,\beta)^T C_m^{-T} \boldsymbol{\sigma}_m \\ \boldsymbol{\sigma}_{CNT}(\alpha,\beta) = \mathbf{E}_{CNT}^T \mathbf{A}(\alpha,\beta)^T \boldsymbol{\varepsilon}_m = (\mathbf{E}_{CNT}^T \mathbf{A}(\alpha,\beta)^T C_m^{-1})^T \boldsymbol{\sigma}_m \end{cases} \quad (7)$$

where $\mathbf{A}(\alpha, \beta)$ is expressed by Eq. 2. Thus, the average strain and stress of randomly oriented CNTs in matrix are given by:

$$\begin{cases} \{\varepsilon_{CNT}\} = (\int_0^{2\pi} \int_0^{\pi/2} P(\alpha,\beta) \mathbf{A}(\alpha,\beta) \sin(\alpha) d\alpha d\beta)^T \varepsilon_m \\ \{\sigma_{CNT}\} = (\int_0^{2\pi} \int_0^{\pi/2} P(\alpha,\beta) (\mathbf{A}(\alpha,\beta)^T C_m^{-1}) \sin(\alpha) d\alpha d\beta)^T \sigma_m \end{cases} \quad (8)$$

Finally, according to the Eshelby-Mori-Tanaka method, the relations between average stress and strain of isotropic composites can be written as:

$$\begin{cases} \boldsymbol{\sigma} = f_m \boldsymbol{\sigma}_m + f_r \boldsymbol{\sigma}_r \\ \boldsymbol{\varepsilon} = f_m \boldsymbol{\varepsilon}_m + f_r \boldsymbol{\varepsilon}_r \end{cases} \Rightarrow \boldsymbol{\sigma} = \boldsymbol{D}^* \boldsymbol{\varepsilon} \quad (9)$$

This indicates that the composite reinforced with randomly oriented (and straight) CNTs is isotropic.

3 BUCKLING ANALYSIS

3.1 *Displacement field*

The Kirchhoff theory is used to investigate thin plates. In this theory, the out-of-plane displacements of the plate, w, is expressed as:

$$w_{ij} = \sum_{i=1}^{4} \sum_{i=1}^{m} (N_i(x) Y_j \delta_{ij}) \quad (10)$$

in which, δ is the nodal displacement vector, Y_j is the longitudinal term which is given by:

$$Y_j(y)=\sin\left(\frac{\lambda_j y}{L}\right)\qquad \lambda_j=j\pi \tag{11a}$$

when both ends are simply supported, and

$$Y_j(y)=\sin\frac{\lambda_j y}{L}-c_j\sinh\frac{\lambda_j y}{L},\quad \lambda_j=\frac{4j+1}{4}\pi,\quad c_j=\frac{\sin\lambda_j}{\sinh\lambda_j} \tag{11b}$$

when one end is simply supported and the other is fixed, and

$$Y_j(y)=\sin\frac{\lambda_j y}{L}-\sinh\frac{\lambda_j y}{L}-c_j\left(\cos\frac{\lambda_j y}{L}-\cosh\frac{\lambda_j y}{L}\right)\qquad \lambda_j=\frac{2j+1}{2}\pi,\quad c_j=\frac{\sin\lambda_j-\sinh\lambda_j}{\cos\lambda_j-\cosh\lambda_j} \tag{11c}$$

when both ends are fixed.

In Eqs. 11, L is the length of strip and $j=1,2,\ldots,m$. In Eq. 10, N_i is the Hermitian transverse shape functions expressed as

$$\begin{cases} N_1(x)=1-3\bar{x}^2+2\bar{x}^3 & N_2(x)=x(1-2\bar{x}+\bar{x}^2) \\ N_3(x)=3\bar{x}^2-2\bar{x}^3 & N_4(x)=x\left(\bar{x}^2-2\bar{x}\right) \end{cases}\qquad \bar{x}=x/b \tag{12}$$

where b is width of strip.

3.2 *Total potential energy* Π

The total potential energy of the plate is defined as summation of strain energy and the work done by the applied load. The strain energy $\boldsymbol{U}$ for each strip of the plate is given by:

$$U_f=\frac{1}{2}\{\delta_f\}^T\left[K_f\right]\{\delta_f\} \tag{13}$$

where the elements of the stiffness matrix $[K_f]$ are obtained from:

$$\left[K_{f\,ij,mn}\right]=\iint_\Omega\left[B_f\right]_{ij}^T\left[D_f\right]\left[B_f\right]_{mn}dxdy \tag{14}$$

in which $\mathbf{B_f}$ is the strain matrix and the vector $\{\varepsilon_f\}$ can be expressed as

$$\{\varepsilon_f\}=\left[B_f\right]\{\delta_f\} \tag{15}$$

In Eq. (14) $\mathbf{D_f}$ represents the elastic matrix given by:

$$\left[D_f\right]=\frac{Eh^3}{12(1-\nu^2)}\begin{bmatrix}1 & \nu & 0\\ \nu & 1 & 0\\ 0 & 0 & (1-\nu)/2\end{bmatrix} \tag{16}$$

The work done by the applied load can be written as:

$$V_p=\frac{1}{2}\{\delta_f\}^T\left[K_g\right]\{\delta_f\} \tag{17}$$

in which the geometric matrix $[K_g]$ for each strip is defined as:

$$\left[K_{g\,ij,mn}\right]=\iint_\Omega\left[B_g\right]_{ij}^T\left[\sigma_g\right]\left[B_g\right]_{mn}dxdy \tag{18}$$

where σ_g is the in-plane stress matrix determined by:

$$\left[\sigma_g\right]=\begin{bmatrix}\sigma_x & \sigma_{xy}\\ \sigma_{xy} & \sigma_y\end{bmatrix} \tag{19}$$

3.3 *Eigenvalue equation*

Using the principle of virtual work minimization of the total potential energy results in the eigenvalue equation such that

$$\left(\left[K_f\right]-\sigma_0\left[K_g\right]\right)\{\delta\}=\{0\} \tag{20}$$

in which σ_0 is the buckling parameter.

4 ILLUSTRATION

In this study, Polystyrene and SWCNTs are matrix and reinforcement phase of composite plate, respectively. The Young's modulus of polystyrene and SWCNTs are assumed to be $E_m=1.9$ GPa and $E_{CNT}=1$ TPa, respectively and the Poisson's ratio for both of them is taken as $\nu=0.3$.

Many scholars have attempted to analyze the buckling of plates by different numerical methods such as the finite strip method (Mizusawa, 1993) and exact solution (Hosseini-Hashemi et al., 2008).

Table 1 shows the local buckling coefficients of plates under various loadings and boundary conditions while the magnitude of the length to width (a/b) ratio is equal to 1. The buckling coefficients have also been compared with the finite strip method (Mizusawa, 1993) and the exact solution (Hosseini-Hashemi et al., 2008).

By comparison of the present results with the results obtained by F.S.M and exact solution method for uniaxial and biaxial load, it can be seen that the method proposed in this paper is accurate for 0% CNTs (Table 1). Due to high modulus elasticity of carbon nanotubes, the local plate buckling coefficients is increase when the volume fraction of carbon nanotubes increases.

Table 2 presents the results for buckling of the plates with different boundary conditions under uniaxial loading where the length to width ratios (a/b) is assumed to be 1. It can be seen that the use of reinforcing CNTS is effective for increasing the loading of the plate and results in the increase of plate strength.

Figures 2 and 3 depict the variations of the local buckling coefficient (K) of composite plates under uniaxial pressure with different volume fractions of CNTs and various length to width ratios (a/b). The boundary conditions are assumed to be simply supported (Fig. 2) or fully clamped (Fig. 3).

SFSF	0.95	1.33	2.88	4.86

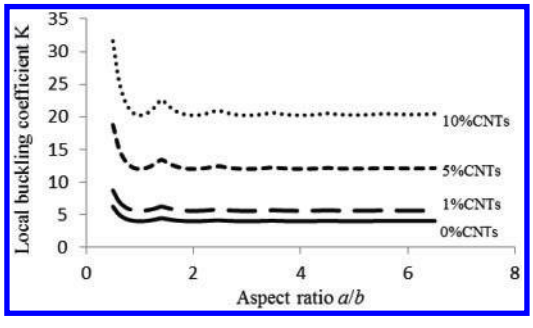

Figure 2. Local buckling Coefficient for simply condition.

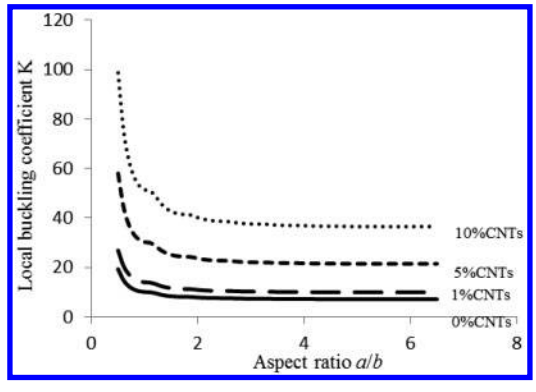

Figure 3. Local buckling Coefficient for clamped condition.

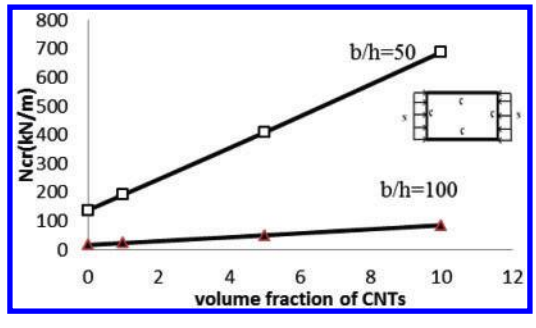

Figure 4. Critical buckling load for clamped plate.

It can be seen from Figures 2 and 3 that the local buckling coefficient decrease when the length to width ratio of the plate increase. From the other side, it can be easily seen that CNTs can considerably increase the plate resistance against buckling.

The effect of the value of the width to thickness ratio (b/h) on the buckling of composite plates is shown in Figure 4. It can be seen that the critical buckling load (N_{cr}) of the fully clamped composite plate increases when the volume fraction of CNTs increase or when the value of width to thickness ratio decreases.

5 CONCLUSIONS

In this study the buckling analysis of thin plates reinforced with randomly distributed single-walled carbon nanotubes (SWCNTs) using the finite strip method was investigated. To obtain the elastic modulus of the composite plates, Mori-Tanaka theory was employed. This theory proposes an analytical method to obtain the internal stress of the composite plates. It was shown that when the volume fraction of carbon nanotubes in

the composite plates increases, the stiffness and critical buckling load of the composites increase which is due to the high modulus elasticity of carbon nanotubes. Also, it has been shown that by reducing the width to thickness ratio and the critical buckling load increases.

Identification of nonlinear hyperelastic material parameters for healthy myocardial tissue via an inverse method based on modelling the passive filling stage of the cardiac cycle

M. Essack & S. Skatulla
CERECAM and the Department of Civil Engineering, University of Cape Town, South Africa

ABSTRACT: In order to fully comprehend the function of biological tissue in the context of the canine left ventricle, it is required that proper material parameters are identified that govern the materials behaviour according to a particular set of constitutive laws. For the purposes of this research, the passive filling stage of the cardiac cycle is modelled with a non linear hyperelastic orthotropic material law (Usyk, Mazhari, & McCulloch 2000). Inherent to this constitutive law are eight material parameters namely A, A_{compr} and b_{ij}, where i, j $\in$ (1, 2, 3). In order to calibrate the material parameters of this model to experimental data, or any patient specific application for that matter, a nonlinear optimization algorithm in the form of the Bounded Levenberg-Marquardt algorithm, with the additional option of a line search is implemented in the in-house modelling software SESKA. In order to test the algorithm implementation, pseudo experimental data are generated with a set of assumed to be true parameters for a canine ellipsoidal left ventricle geometry. Consequently, the implemented algorithms ability to converge towards this true set of parameters from a number of different initial starting points is tested. For the case of the conventional Bounded Levenberg-Marquardt algorithm implementation, material parameters converge quickly towards the true values provided that the initial guess for parameters is close enough to the true set. However, for initial parameter guesses that are far from the true values, parameters may converge to a ridge in the cost function, which does not represent a minimum in the cost function surface. Furthermore, when the conventional Levenberg-Marquardt algorithm is combined with a line search, parameters are more likely to converge towards a local minimum within a well defined range, regardless of whether the initial parameter guess is good or not. However, it should be noted that the line search does not assure convergence of material parameters to a global minimum in the cost function, it just prevented convergence of parameters towards ridges in the cost function.

1 INTRODUCTION

In order to fully comprehend the function of biological tissue in the context of the left ventricle, it is required that proper material parameters are identified that govern the materials behaviour according to a particular set of constitutive laws.

Despite continued progress in the treatment of infarcted myocardium within the left ventricle, current treatments continue to be challenged to consistently improve myocardium function for extended durations. Improved approaches for myocardium repair rests upon the ability to more fully comprehend and simulate its functions. Consequently, appropriate material parameters need to be derived for both healthy and infarcted myocardium within the left ventricle.

Although it is the ultimate objective of this line of research to identify material parameters for both the healthy and diseased states of the left ventricle, this paper is limited to only the healthy case. In addition, only the passive filling phase of the left ventricle cardiac cycle is considered, and the associated passive material parameters that govern this phase of the cardiac cycle.

Many methods have been proposed in order to identify the material properties of passive myocardium, however, this research shall focus on a fairly new field, involving updating methods of inverse modelling (Avril, Bonnet, Bretelle, Grdiac, Hild, Ienny, Latourte, Lemosse, Pagano, Pagnacco, & Pierron 2007). Such methods involve the computation of displacement, strain, stress, pressure or volume fields numerically (i.e. using computer simulations), using initial estimates or guesses for material parameters defined in the particular constitutive law chosen. The actual constitutive material parameters are then identified by minimizing a cost function, which compares available strain, displacement, stress, pressure or volume measurements from experimental testing, to the corresponding results simulated via an FEM analysis.

In addition, minimization of the cost function is conducted via the use of an optimization algorithm. Since the number of material parameters that need to be identified within the passive filling stage of the

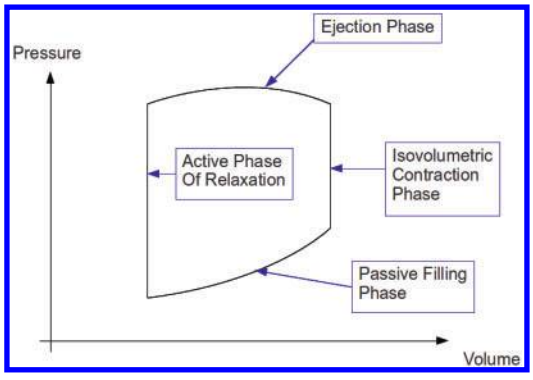

Figure 1. Idealized representation of the left ventricle cardiac cycle.

cardiac cycle is small, it was deemed adequate to utilize a local, gradient based algorithm based on the Levenberg-Marquardt algorithm (Marquardt 1963), with the option of an additional line search algorithm, in order to ensure convergence of parameters to at least a local minimum of the cost function, within a predefined range (Yu 2004). This algorithm is implemented in the in-house modelling software SESKA, which is also used to generate the required simulated data fields that are core to the cost function.

Consequently, this paper shall outline the portions of the cardiac cycle that have been modelled, followed by an exploration of what inverse modelling entails. Next, methods for material parameter identification shall be explored, followed by an outline of the conventional Levenberg-Marquardt and modified Levenberg-Marquardt algorithms implemented in SESKA. Finally, the results of numerical simulations of the passive filling stage of a ellipsoidal canine left ventricle geometry shall be presented, followed by a discussion of key observation of the behaviour of the optimization algorithm in terms of its convergence properties towards a unique set of material parameters.

2 MODELLING THE CARDIAC CYCLE

Figure 1 is an illustration of an idealized cardiac cycle, which is similar to what would be simulated via a computational analysis. In addition, figure 2 is an illustration of the idealized canine ellipsoidal left ventricle model, which was constructed using the preprocessing software GID, and was used for all numerical simulations in this paper. In addition, the left ventricle model is disrcretized with sixty six particles, and comprises of sixty six tetrahedral elements.

It is clear from figure 1 that the cardiac cycle is split into various phases. In the following section only the passive filling stage of the cardiac cycle shall be explained (Niederer & Smith 2009). In addition, the constitutive model that is implemented in the cardiac mechanics module of SESKA, in order to simulate the passive filling phase shall be introduced.

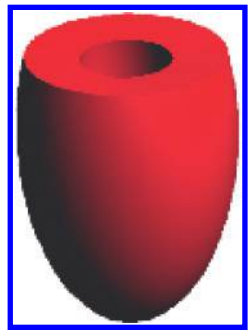

Figure 2. Ellipsoidal left ventricle geometry.

2.1 *Passive filling*

This is the first phase of the cardiac cycle and is also referred to as diastole. In this phase the left atrium and the mitral valve open, allowing blood to fill the ventricle. Consequently, the left ventricle cavity volume increases and the pressure increases as more blood causes the ventricle to inflate. During this phase, healthy myocardial tissue is modelled as a non linear hyperelastic orthotropic material (Usyk, Mazhari, & McCulloch 2000).

3 MATERIAL PARAMETER IDENTIFICATION

In the previous section, the passive filling phase of the cardiac cycle was explained, as well as the constitutive law that is implemented in the cardiac mechanics module of SESKA in order to simulate it.

Within the passive filling phase of the cardiac cycle, the behaviour of myocardial tissue is simulated using a non linear hyperelastic orthotropic material model with the following strain energy function (Usyk, Mazhari, & McCulloch 2000).

$$W = A(e^{Q} - 1)/2 + A_{compr}\Big\{ det[U]\,ln(det[U]) - det[U] + 1)\Big\} \quad (1)$$

Where:

$$Q = b_{11}\hat{E}_{11}^2 + b_{22}\hat{E}_{22}^2 + b_{33}\hat{E}_{33}^2 + b_{12}(\hat{E}_{12}^2 + \hat{E}_{21}^2) + b_{13}(\hat{E}_{13}^2 + \hat{E}_{31}^2) + b_{23}(\hat{E}_{23}^2 + \hat{E}_{32}^2) \quad (2)$$

Firstly, E_{ij} (i,j $\in$ (1,2,3)) are components of the Green strain **E**, and the right stretch tensor is denoted by U.

From the strain energy function illustrated by equation 1, it is clear that the behaviour of healthy myocardial tissue within the passive filling stage depends on eight material parameters, namely; A, A_{compr}, and b_{ij}, where i,j $\in$ (1,2,3). However, the stiffness of the myocardial tissue is primarily governed by parameters A and A_{compr}. Consequently, parameters b_{ij} which govern the anisotropy of the material are neglected from

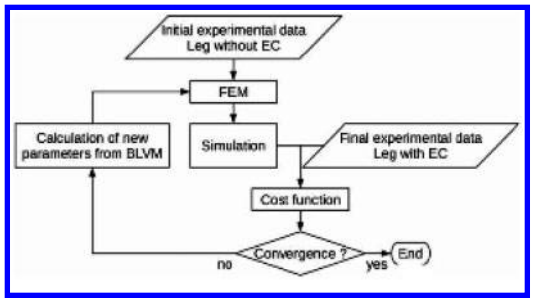

Figure 3. Schematic of updating methods of inverse modelling.

the numerical optimization, and only the main stiffness parameters; A and A_{compr} are optimized for during the passive filling of the cardiac cycle.

Consequently, parameters A and A_{compr} are identified via an inverse method which shall be explained briefly in the following section.

3.1 *Inverse modelling*

Identification of constitutive parameters A and A_{compr} was conducted using numerical simulations (using SESKA) in combination with experimental measurements of kinematic field variables, i.e. pressure, volume data relating to the passive filling stage of the cardiac cycle. This method of parameter identification is referred to as an updating method of inverse modelling (Avril, Bonnet, Bretelle, Grdiac, Hild, Ienny, Latourte, Lemosse, Pagano, Pagnacco, & Pierron 2007). The basic schematic of updating methods of inverse modelling is illustrated in figure 3.

For the purposes of this paper, pseudo experimental data for the passive filling stage of the cardiac cycle is generated, instead of using actual data, as the objective is to ascertain whether the optimization algorithm (which shall be explained in detail later in this paper) performs as required. This pseudo experimental data is generated using a set of assumed to be true material parameters for the constitutive law found in literature (Usyk, Mazhari, & McCulloch 2000).

Finally, an important component of updating methods of inverse modelling is that an objective cost function, that is to be minimized, must be formulated, and the nature of this cost function shall be explained in the following sections.

3.1.1 *Choice of an objective cost function*

The cost function to be minimized can be constructed from the simulated and targeted volumes at each pressure step of the passive filling stage of the cardiac cycle (Avril, Bonnet, Bretelle, Grdiac, Hild, Ienny, Latourte, Lemosse, Pagano, Pagnacco, & Pierron 2007). This cost function is illustrated in equation 3 below.

$$J^2(\boldsymbol{\theta}) = \frac{1}{2}\sum_{i=0}^{i=N-1}\left[\left(V_i^e - V_i^s(P_i;\boldsymbol{\theta})\right)^2\right] \quad (3)$$

Where V_i^e and $V_i^s(P_i;\boldsymbol{\theta})$ represent the experimentally measured and simulated left ventricle cavity volumes, taken at a particular pressure step P_i within the passive filling phase and given a certain set of material parameters $\boldsymbol{\theta}$.

Minimization of the cost function (equation 3) is conducted using an optimization algorithm, therefore allowing material parameters to be derived. Such optimization algorithms shall be explored in the following section.

3.2 *Choice of optimization algorithm*

The minimization of equation 3 involves the use of a non linear optimization algorithm. Since the number of material parameters that need to be identified within the passive filling stage of the cardiac cycle is small, it was deemed adequate to utilize a local, gradient based algorithm based on the Bounded Levenberg-Marquardt algorithm or BLVM (Levenberg 1944), with the option of an additional line search algorithm (Yu 2004), in order to ensure convergence of parameters to at least a local minimum of the cost function, within a predefined parameter range.

3.2.1 *The standard non-linear bounded Levenberg-Marquardt algorithm*

The standard non-linear bounded Levenberg-Marquardt algorithm flexibly updates the material parameters between the Gradient descent and Gauss Newton update methods (Gavin 2011), based on the following parameter update equation. ($\boldsymbol{\delta\theta}$).

$$\left[\boldsymbol{J}^T\boldsymbol{J} + \lambda \mathrm{diag}\left(\boldsymbol{J}^T\boldsymbol{J}\right)\right]\boldsymbol{\delta\theta} = \mathbf{J}^{\mathbf{T}}\left[\left(\mathbf{V}^{\mathbf{e}} - \boldsymbol{V}^{\boldsymbol{s}}(\boldsymbol{\theta})\right)\right] \quad (4)$$

In equation 4 above, λ is a positive scalar. It is clear that for large values of λ the Levenberg-Marquardt parameter update tends to that produced by the Gradient Descent method. However, for small values of λ the Levenberg-Marquardt parameter update tends to that produced by the Gauss Newton method. Consequently, the algorithm exhibits fast convergence of the material parameters ($\boldsymbol{\theta}$) towards a local minimum. Also, $\boldsymbol{V}^s(\boldsymbol{\theta})$ represents a vector of simulated cavity volumes produced via an FEM analysis, and $\boldsymbol{V}^e$ represents a vector of experimentally measured cavity volumes corresponding to the same pressure step P_i in the passive filling stage of the cardiac cycle. In addition, $\boldsymbol{\theta}$ represents a vector of material parameters pertaining to the constitutive law utilized (Usyk, Mazhari, & McCulloch 2000). Furthermore, the right hand side of equation 4 represents the cost function gradient vector, whose components ($\frac{\partial J^2(\boldsymbol{\theta})}{\partial \theta_i}$) represent the gradient of the cost function ($J^2(\boldsymbol{\theta})$) with respect to a particular material parameter θ_i.

In addition, $\boldsymbol{J}$ is the Jacobian matrix, which represents the sensitivity of the simulated field (volume fields in the context of this research) to small perturbations in the material parameters. The Jacobian can be approximated numerically using finite differences

(equation 5) or alternatively using a higher order difference (equation 6), the later ensuring better numerical stability of the algorithm at smaller parameter increments, in other words it approximates the Jacobian matrix accurately upto a term of order equal to h^2, where h represents a small perturbation in θ_i. Consequently, the second Jacobian implementation results in a better conditioned Jacobian matrix. In addition, the second Jacobian implementation is constructed specifically for modelling the cardiac cycle, because it appeared that the first order finite differences Jacobian matrix was ill conditioned even at larger parameter perturbations of 10^{-3}. Also, in equation 5 and 6 below the jth element of $\boldsymbol{\delta\theta}_j$ is the only non zero element and is set to a value of $\epsilon_2(1+|\theta_i|)$ (Gavin 2011), where ϵ_2 is some small value, say 10^{-6}.

$$J_{ij} = \frac{V_i^s(P_i;\boldsymbol{\theta}+\boldsymbol{\delta\theta}_j) - V_i^s(P_i;\boldsymbol{\delta\theta}_j)}{\|\boldsymbol{\delta\theta}_j\|} \tag{5}$$

Or alternatively;

$$J_{ij} = -\frac{V_i^s(P_i;\boldsymbol{\theta}+2\boldsymbol{\delta\theta}_j) - 4V_i^s(P_i;\boldsymbol{\theta}+\boldsymbol{\delta\theta}_j)}{2\|\boldsymbol{\delta\theta}_j\|} - \left\{ \frac{V_i^s(P_i;\boldsymbol{\delta\theta}_j)}{2\|\boldsymbol{\delta\theta}_j\|} \right\} \tag{6}$$

Consequently, a new set of material parameters can be found by solving the set of linear equations represented by equation 4, and adding this new parameter update to the old set of parameters, as illustrated in equation 7 below.

$$\theta_{\mathrm{i}}^{\mathrm{new}} = \theta_{\mathrm{i}} + \delta\theta_{\mathrm{i}} \tag{7}$$

Next, meaningful parameter constraints are applied to the new parameter vector, such that the inequality in equation 8 below holds true, thus giving a new set of material parameters for the iteration.

$$\theta_{\mathrm{i}}^{\mathrm{min}} < \theta_{\mathrm{i}}^{\mathrm{new}} < \theta_{\mathrm{i}}^{\mathrm{max}} \tag{8}$$

where θ_i^{min} represents the lower range of θ_i, and θ_i^{max} represents its upper range.

Finally the cost function (equation 3) is evaluated at the new set of material parameters $J^2(\boldsymbol{\theta}^{\mathrm{new}})$, and compared to the value at the old set of parameters $J^2(\boldsymbol{\theta}^{\mathrm{old}})$.

If the new cost function value is less than the old, then the parameters are in fact moving in a descent direction, towards a local minimum, hence λ is decreased by a factor of eleven (Gavin 2011), and the new set of material parameters replaces the old set for the next iteration of the algorithm. If the new cost function is greater than the old, then λ is increased by a factor of nine (Gavin 2011), and the old parameters are kept for the next iteration of the algorithm.

However, the main disadvantage of this algorithm is that the parameter values tend to oscillate endlessly,

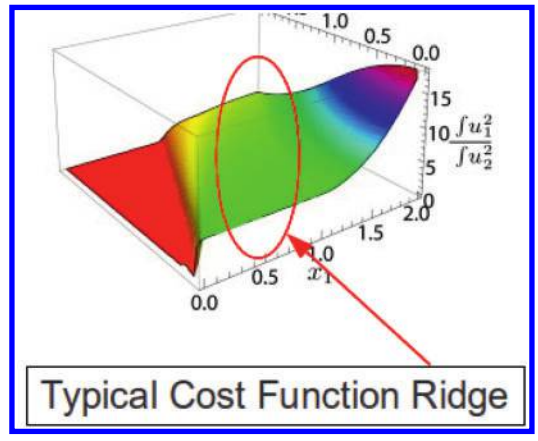

Figure 4. Illustration of a typical ridge in a cost function surface.

if a ridge in the cost function is obtained (Dubuis, Avril, Debayle, & Badel 2011). A ridge is a portion of the cost function surface where the absolute value of the maximum component of the cost function gradient vector ($|\max(\frac{\partial J^2(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}})|$) is close to zero, but does not represent a local minimum in the cost function. Such a surface can be compared to an inflection point in a two dimensional function. Consequently, if the cost function values on such a surface are small (i.e. close to zero) it may appear that the algorithm has converged to a local minimum, however, this set of parameters does not correspond to those which would minimize the cost function represented in equation 3. Figure 4 illustrates a typical ridge in a cost function of two variables.

Consequently, in order to avoid the problems associated with cost function ridges, an additional formulation of the conventional Levenberg-Marquardt algorithm (Yu 2004) was considered, which incorporates a line search. The additional line search was proposed in order to assist the algorithm in avoiding convergence to parameters that would produce a ridge in the cost function, where its gradient is close to zero. The details as to how this line search algorithm is incorporated into the Levenberg-Marquardt algorithm shall be discussed in the following section of this paper.

3.2.2 *Modified Levenberg-Marquardt algorithm*

This modified Levenberg-Marquardt algorithm accepts an initial guess of material parameters $\boldsymbol{\theta}$, then calculates the parameter update $\boldsymbol{\delta\theta}$ and a new parameter set $\boldsymbol{\theta}^{\mathrm{new}}$ according to equation 4 and 7 respectively. Parameter constraints are then applied according to equation 8 giving a set of new parameters for the iteration. The cost function (equation 3) is then computed at this new set of parameters and compared to that at the initial set. If the new cost function is less than the old, then λ is decreased by a factor of eleven. However, if the cost function at the new set of parameters is greater than that with the old set, then instead of increasing λ by a factor of nine (as in the conventional Bounded

Levenberg-Marquardt algorithm), a line search is initiated to ensure that a final new parameter $\boldsymbol{\theta}_{i+1}^{new}$ is calculated such that the cost function value is always moving in a descent direction, hence ensuring that the algorithm always converges to a local minimum in the cost function surface, within a predefined parameter range.

The line search works by accepting the parameter update calculated via equation 4 (i.e. $\boldsymbol{\delta\theta}$), and using it as a descent direction. Next, a new step size η_{i+1} is computed using a regula falsi or secant procedure as illustrated in equation 9 below.

$$\eta_{i+1} = \eta_i - \frac{\eta_i - \eta_{i-1}}{J^2(\boldsymbol{\theta}^i) - J^2(\boldsymbol{\theta}^{i-1})} J^2(\boldsymbol{\theta}^i) \tag{9}$$

Where;

$$\boldsymbol{\theta}^i = \boldsymbol{\theta} + \eta_i \boldsymbol{\delta\theta} \tag{10}$$

$$\boldsymbol{\theta}^{i-1} = \boldsymbol{\theta} + \eta_{i-1} \boldsymbol{\delta\theta} \tag{11}$$

Note that for equation 9, $\eta_0 = 0$ and η_1 must be chosen such that the following inequality holds true.

$$\eta_1 < \min\left[\max\left(\left|\frac{\theta_i^{max} - \theta_i}{\delta\theta_i}\right|\right), \max\left(\left|\frac{\theta_i^{min} - \theta_i}{\delta\theta_i}\right|\right)\right] \tag{12}$$

If the above inequality does not hold true for η_1 (which is the maximum step size) then the step size η_1 shall move parameters to a new set that lies outside the specified parameter range, thus equation 9 no longer holds. If the equality represented in equation 12 holds true, then a new parameter ($\boldsymbol{\theta}^{i+1}$) is then calculated as follows.

$$\boldsymbol{\theta}^{i+1} = \boldsymbol{\theta} + \eta_{i+1} \boldsymbol{\delta\theta} \tag{13}$$

Next the value of the cost function (equation 3) is then evaluated at the new material parameter $J^2(\boldsymbol{\theta}^{i+1})$ and compared to the initial value of the cost function at the initial set of parameters $J^2(\boldsymbol{\theta})$. The line search iteration is terminated if the new cost function is less than the initial value multiplied by a factor ϵ_3 (which is set to a default value of 0.9), in other words, the line search has found a new descent direction that moves the parameters towards those which would produce a local minimum in the cost function. In this case the new parameter $\boldsymbol{\theta}^{i+1}$ is used as the starting parameter for the next iteration of the Levenberg-Marquardt type algorithm.

4 BENCHMARKING AND TESTING OF ALGORITHM IMPLEMENTATIONS

4.1 *Generation of Pseudo experimental data*

Both optimization algorithms explored in the sections above are implemented in C++ in the in-house modelling software SESKA. For the purpose of testing each optimization algorithm, pseudo experimental data was generated for an ellipsoidal canine left ventricle model (figure 2), which was constructed using the preprocessing software GID. Table 1 lists the set of assumed to be true parameters, for the non linear hyperelastic orthotropic material model (equation 1), used to simulate myocardial tissue of the canine left ventricle. The simulated pressure, volume, data (figure 5) for the passive filling stage of the cardiac cycle, obtained using the above set of true material parameters was taken as the experimental data for testing purposes.

Table 1. True material parameter values used to generate experimental data.

Parameter	Value
A	0.88 kPa
A_{compr}	150 kPa
b_{11}	−6
b_{22}	−5
b_{33}	9
b_{23}	12
b_{13}	12
b_{12}	−6

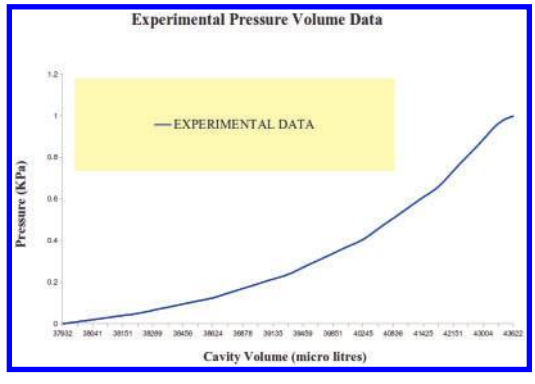

Figure 5. Pseudo experimental data for the passive filling stage of the cardiac cycle.

Table 2. Initial parameter guesses.

Parameter	Case 1	Case 2	Case 3
A (kPa)	0.11	0.5	1.0
A_{compr} (kPa)	51	200	230

4.2 *Testing tegime*

Simulations were first run using the conventional Bounded Levenberg-Marquardt algorithm with three different starting parameters (table 2), and then separately using the modified Levenberg-Marquardt Algorithm with the same three different initial starting

parameters. Bear in mind that only parameters A and A_{compr} were optimized for, hence parameters b_{ij} are excluded from table 2, as they are the same as those values in table 1 for each simulation run.

4.3 *Results and discussion of numerical simulations*

Before the results of numerical simulations are presented, a few definitions from earlier on in this paper shall be revised in order to facilitate better understanding of the results and discussions presented in the following sections. Firstly, $J^2(\boldsymbol{\theta}^{\text{final}})$, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ represent the cost function value and the absolute value of the maximum component of the cost function gradient vector (respectively) at the final set of material parameters $\boldsymbol{\theta}^{\text{final}}$. If both $J^2(\boldsymbol{\theta}^{\text{final}})$, as well as $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ are close to zero (i.e. less than 10^{-7}) then the final set of material parameters produced a local minimum in the cost function. However, if $J^2(\boldsymbol{\theta}^{\text{final}})$ is large (i.e greater than or equal to 10^{-2}, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ is close to zero (i.e. less than 10^{-7}) then the final set of material parameters produced a ridge in the cost function.

4.3.1 *Conventional bounded Levenberg-Marquardt algorithm*

Referring to table 2, the first set of initial material parameters was taken as $A = 0.11$ KPa and $A_{compr} = 51$ kPa. After nine iterations of the algorithm, parameters converged to $A = 0.645$ kPa and $A_{compr} = 300$ kPa, at which point the $J^2(\boldsymbol{\theta}^{\text{final}})$ was 10^{-8}, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$, had a value of 10^{-7}. Consequently, it appears that the algorithm converged to a local minimum in the cost function. This set of parameters is however not a global minimum, as it is already known that the parameters that produce a global minimum in the cost function are $A = 0.88$ kPa and $A_{compr} = 150$ kPa.

For the next calculation, initial material parameters were taken as $A = 0.5$ kPa and $A_{compr} = 200$ kPa (table 2). After 40 iterations of the algorithm, the algorithm exited without a converged set of parameters, as the maximum number of iteration was set as twenty multiplied by the number of parameters. The final set of parameters was $A = 0.7$ kPa and $A_{compr} = 170$ kPa and $J^2(\boldsymbol{\theta}^{\text{final}})$ was 10^{-2}, at which point $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ had a value of 10^{-9}. Consequently, it appears that the algorithm has found a ridge in the cost function, as the maximum cost function gradient component is near zero, whereas, the value of the cost function is comparatively larger, and it this ridge that prevents the conventional Levenberg-Marquardt algorithm from moving in a consistent descent direction towards a local minimum.

Finally, the initial material parameters were taken as $A = 1.0$kPa and $A_{compr} = 230$ kPa. After six iterations of the algorithm, parameters converged to $A = 0.88$ kPa and $A_{compr} = 150$ kPa, at which point $J^2(\boldsymbol{\theta}^{\text{final}})$ was 10^{-12}, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ had a value of 10^{-10}. Consequently, it appears that the algorithm converged to a global minimum in the cost function. This set of parameters is a global minimum, as it is already known that the parameters that produce a global minimum in the cost function are $A = 0.88$ kPa and $A_{compr} = 150$ kPa. Table 3 is a summary of the results discussed in the section above. Finally, figure 6 illustrates a plot of the simulated pressure volume curves for each set of final parameters represented in table 3.

Table 3. Initial parameter guesses and final parameters found based on the conventional bounded Levenberg-Marquardt algorithm.

Parameter	Case 1	Case 2	Case 3
A^{initial} (kPa)	0.11	0.5	1.0
$A^{\text{initial}}_{\text{compr}}$ (kPa)	51	200	230
A^{final} (kPa)	0.645	0.7	0.88
$A^{\text{final}}_{\text{compr}}$ (kPa)	300	170	150
$J^2(\boldsymbol{\theta}^{\text{final}})$	10^{-8}	10^{-2}	10^{-12}
$\lvert\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{\text{final}}})\rvert$	10^{-7}	10^{-9}	10^{-10}
Result	Local Minima	Cost Function Ridge	Global Minima

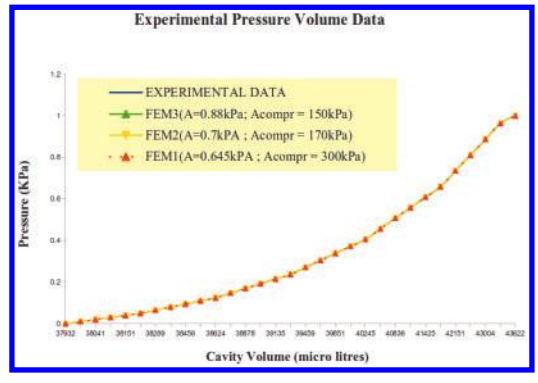

Figure 6. Plot of experimental and simulated pressure volume curves.

4.3.2 *Modified Levenberg-Marquardt algorithm*

Starting at an initial set of material parameters of $A = 0.11$ kPa and $A_{compr} = 51$ kPa (from table 2). After four iterations of the algorithm, parameters converged to the same local minimum of $A = 0.645$ kPa and $A_{compr} = 300$ kPa, which is also found by the standard Levenberg-Marquardt algorithm, and consequently $J^2(\boldsymbol{\theta}^{\text{final}})$ was also 10^{-8}, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ also had a value of 10^{-7}. Consequently, this seems to illustrate that the set of parameters, $A = 0.645$ kPa and $A_{compr} = 300$ kPa definitely produces a local minimum in the cost function.

Table 4. Initial parameter guesses and final parameters found based on Modified Levenberg-Marquardt algorithm.

Parameter	Case 1	Case 2	Case 3
A^{initial} (kPa)	0.11	0.5	1.0
$A^{\text{initial}}_{\text{compr}}$ (kPa)	51	200	230
A^{final} (kPa)	0.645	0.88	0.88
$A^{\text{final}}_{\text{compr}}$ (kPa)	300	150	150
$J^2(\boldsymbol{\theta}^{\text{final}})$	10^{-8}	10^{-8}	10^{-12}
$\lvert\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{\text{final}}})\rvert$	10^{-7}	10^{-7}	10^{-10}
Result	Local Minima	Global Minima	Global Minima

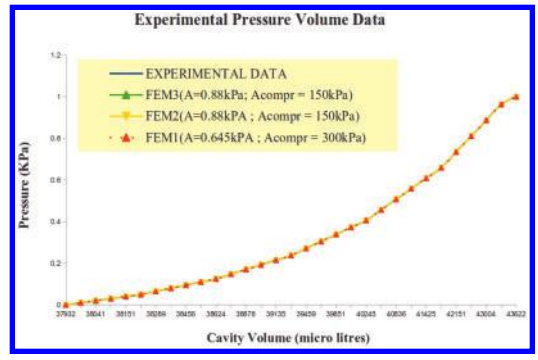

Figure 7. Plot of the experimental and simulated pressure volume curves.

Next, a new calculation was initiated with an initial set of material parameters of $A = 1.0$ kPa and $A_{compr} = 230$ kPa (from table 2). As was the case for the standard Levenberg-Marquardt algorithm, parameters converged to $A = 0.88$ kPa and $A_{compr} = 150$ kPa, and consequently $J^2(\boldsymbol{\theta}^{\text{final}})$ was also 10^{-12}, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ also had a value of 10^{-10}. Consequently, this example again illustrates the ability of the algorithm to converge consistently to the global minimum, provided that the initial guess for material parameters is good, i.e close to the true set which would produce a global minima in the cost function.

For the final calculation, initial material parameters are $A = 0.5$ kPa and $A_{compr} = 200$ kPa (table 2). After 10 iterations, the algorithm exited with a converged set of parameters of $A = 0.88$ kPa and $A_{compr} = 150$ kPa. At this final set of parameters $J^2(\boldsymbol{\theta}^{\text{final}})$ was 10^{-8}, and $|\max(\frac{\partial J^2(\boldsymbol{\theta}^{\text{final}})}{\partial \boldsymbol{\theta}^{xtfinal}})|$ had a value of 10^{-7}. Consequently, whereas material parameters tended to oscillate within a cost function ridge for the conventional bounded Levenberg-Marquardt algorithm, the line search was able to move the parameters away from this ridge, and in a descent direction, ensuring that the material parameters converged to a local minimum within a predefined parameter space. In this case the parameters that the algorithm converges to do in fact produce a global minimum in the cost function, however, it is important to note, that the line search simply ensures convergence to a local minimum, and does not always ensure convergence to a global minimum within a predefined parameter space. Table 4 below summarizes the results discussed in the section above. Finally, figure 7 illustrates a plot of the simulated pressure volume curves for each set of final parameters represented in table 4.

5 CONCLUSIONS

For the purposes of this research, the passive filling stage of the cardiac cycle was modelled with a non linear hyperelastic orthotropic material law (Usyk, Mazhari, & McCulloch 2000). Inherent to this constitutive law are eight material parameters namely A, A_{compr} and b_{ij}, where i, j $\in (1, 2, 3)$. In order to calibrate these material parameters for the canine left ventricle geometry, to experimental data, or any patient specific application for that matter, a non-linear optimization algorithm in the form of the Bounded Levenberg-Marquardt algorithm, with the additional option of a line search is implemented in the in-house modelling software SESKA.

In order to test the algorithm implementation, pseudo experimental data was generated with a set of assumed to be true parameters for the canine ellipsoidal left ventricle geometry. Consequently, the implemented algorithms ability to converge towards this true set of parameters from a number of different initial starting points was tested.

For the case of the conventional Bounded Levenberg-Marquardt algorithm implementation, it is found that parameters converged quickly towards the true values, provided that the initial guess for parameters is close enough to the true set. However, for initial parameter guesses that are far from the true values it is noticed that parameters may converged to a ridge in the cost function, which does not represent a minimum in the cost function surface.

However, using the modified Levenberg-Marquardt algorithm, which incorporates a line search, assisted the algorithm in always converging to a set of parameters, within a well defined range, which produces a local minimum in the cost function, regardless of whether the initial parameter guess was good or not. However, it should be noted that the line search did not assure convergence to a global minimum in the cost function, it just prevents convergence of parameters towards ridges in the cost function, in fact, the use of the line search illustrated the presence of multiple local minima of the cost function within the defined parameter space.

Consequently, due to the existence of multiple minima within a predefined parameter range, it would be prudent to test the uniqueness of any one particular set of parameters derived via the conventional or modified Levenberg-Marquardt type algorithms. One way of testing the uniqueness of a solution would be to make use of a non parametric boot strapping technique (Sun, Sacks, & Sellaro 2003).

Finally, in this paper only the passive filling stage of the cardiac cycle has been modelled for the case of healthy myocardial tissue. However, the optimization algorithms presented in this paper are intended to be applied to the remaining portions of the cardiac cycle (isovolumetric contraction, ejection and relaxation, as illustrated in figure 1) in order to provide a means of calibrating material parameters for any patient specific cardiac model to patient specific data, for the case of both healthy, and diseased myocardium.

Numerical properties of second order integration algorithms for plasticity models

M. Jahanshahi
Department of Civil Engineering, School of Science and Engineering, Sharif University of Technology, International Campus, Kish Island, Iran

ABSTRACT: Investigating the behavior of materials in plastic limit is very important in different fields of engineering. Due to the simplicity of implementation and numerical stability, implicit types of algorithms are conventionally used to deal with plasticity problems. The backward Euler method as a first order accurate algorithm has proven very efficient for integrating the rate form of differential equations governing the behavior of different plasticity models. However, it is desirable to have algorithms with superior performance and quadratic rate of convergence compared with backward Euler method. Many second order integration algorithms have been proposed in the literature which are majorly focused on metal plasticity with isochoric dominant behavior in post yielding range and various types of hardenings. The J_2 plasticity model can be mentioned as a good example. It is also possible to present second order algorithms for material models with pressure sensitive behavior such as soil and concrete. The aim of this work is to present a comparison between classical backward Euler method and second order algorithms that are proposed in the literature for different types of plasticity models. The efficiency of algorithms is investigated through iso-error maps and error graphs.

1 INTRODUCTION

The evolution of implicit integration algorithms dates back to the pioneering work of Wilkins (1964). The algorithm that he developed was actually a backward Euler type of algorithm for the integration of first order ordinary differential equations as a function of time. Backward Euler algorithm has been used successfully in the work of many authors and has proven its applicability in many research and commercial Softwares. Midpoint rule algorithm was first proposed in the work of Ortiz & Popov (1985). They also presented a method for investigating the stability of this type of algorithm which was later modified and corrected in the work of Simo & Govindjee (1991). Double step algorithms as known today were introduced by Simo (1998), but were not elaborated until recently. Artioli et al. 2007a used double step methods for linear hardening and a type of nonlinear hardening in some detail, Artioli et al. 2007b. Jahanshahi (2012a) modified second order integration algorithms to account for generalized form of isotropic hardening and formulated a variant of double step integration scheme for nonlinear hardening, Jahanshahi (2012b).

Single step algorithms for plasticity models with different types of nonlinearities are well developed in the literature. The complexity that arises in deriving the algorithmic setup and tangent operators for double step algorithms makes it hard to apply them for arbitrary hardening rules. However, considering the fact that double step algorithms are second order accurate and thus have better convergence properties compared with the classical backward Euler method makes them appealing in various engineering applications.

The aim of this work is to present a rather brief discussion on the formulation of double step integration algorithms for plasticity models with general isotropic and kinematic hardening. Tangent operators and an investigation of numerical properties are presented as well. The behavior of algorithms is compared with backward Euler method as benchmark and the convergence history is studied through iso-error maps and error graphs.

The paper is organized as follows. In section 2 the time continuous model based on which double step integration algorithms are developed is presented. The formulation of integration algorithms as well as the enforcement of consistency condition is discussed in section 3. In section 4 tangent operators that are essential for quadratic rate of convergence are discussed briefly. Finally in section 5 the behavior of algorithms is investigated using numerical examples. Efficiency and accuracy of algorithms are studied through iso-error maps and error graphs.

2 TIME CONTINUOUS MODEL

In this work we consider an associative von Mises plasticity with nonlinear isotropic and kinematic hardening within the infinitesimal range. If the stress and strain

tensors are split into deviatoric and volumetric parts we can write

$$\boldsymbol{\sigma} = \boldsymbol{s} + p\mathbf{1} \qquad \text{with} \qquad p = \frac{1}{3}\text{tr}(\boldsymbol{\sigma}) \tag{1}$$

$$\boldsymbol{\varepsilon} = \boldsymbol{e} + \frac{1}{3}\theta\mathbf{1} \qquad \text{with} \qquad \theta = \text{tr}(\boldsymbol{\varepsilon}) \tag{2}$$

$$p = \kappa\theta \tag{3}$$

where tr is the trace operator, $\mathbf{1}$, $\boldsymbol{s}$, $\boldsymbol{e}$, p and θ are, respectively, the second order identity tensor, the deviatoric stress and strain tensors, the volumetric stress and strain terms and finally κ is the bulk modulus.

Based on the splitting mentioned above, the equations of the model can be written as:

$$\boldsymbol{s} = 2G(\boldsymbol{e} - \boldsymbol{e}^p) \tag{4}$$

$$\boldsymbol{\xi} = \boldsymbol{s} - \boldsymbol{\beta} \tag{5}$$

$$f = \|\boldsymbol{\xi}\| - \sqrt{\frac{2}{3}}K(\bar{e}^p) \tag{6}$$

$$\dot{\boldsymbol{e}}^p = \gamma\boldsymbol{n} \tag{7}$$

$$\dot{\boldsymbol{\beta}} = \frac{2}{3}H'(\bar{e}^p)\gamma\boldsymbol{n} - \gamma b\boldsymbol{\beta} \tag{8}$$

$$\dot{\bar{e}}^p = \sqrt{\frac{2}{3}}\gamma \tag{9}$$

$$\gamma \geq 0, \quad f \leq 0, \quad \gamma f = 0 \tag{10}$$

where G is the shear modulus, $\boldsymbol{e}$ is the total deviatoric strain, $\boldsymbol{e}^p$ is the plastic strain whose trace is zero, $\boldsymbol{\xi}$ is the relative stress, $\boldsymbol{\beta}$ is the center of yield surface in stress deviator space (back stress, f is the von Mises yield function, $\boldsymbol{n}$ is the normal to the yield surface, $\bar{e}^p$ is the equivalent plastic strain, the functions $K'(\bar{e}^p)$ and $H'(\bar{e}^p)$ are called the isotropic and kinematic hardening modulus respectively and b is the material constant. Finally, equations (10) are the so called Kuhn-Tucker conditions.

The kinematic hardening as prescribed by equation (8) is of nonlinear type due to the presence of the extra term $-\gamma b\boldsymbol{\beta}$. If this term is omitted the kinematic hardening becomes linear as it is widely used in the literature. Moreover, nonlinear forms can be considered in the definition of $K'(\bar{e}^p)$ and $H'(\bar{e}^p)$ in which a saturation hardening term of exponential type can be appended to linear terms, Simo & Hughes (1998). The forms employed in this work are

$$h(\bar{e}^p) = \overline{K}_\infty - \left[\overline{K}_\infty - \overline{K}_0\right]\exp(-\delta\,\bar{e}^p) + \overline{H}'\,\bar{e}^p$$

$$\begin{aligned} K(\bar{e}^p) &= \beta\, h(\bar{e}^p) \\ H(\bar{e}^p) &= (1-\beta)\, h(\bar{e}^p), \quad \beta \in [0,1] \end{aligned} \tag{11}$$

where, $\overline{K}_\infty$, $\overline{K}_0$, δ and $\overline{H}'$ are material constants and β provides a modulation between pure kinematic ($\beta = 0$) and pure isotropic ($\beta = 1$) hardening.

3 INTEGRATION ALGORITHMS

The loading history over the interval $[0, T]$ is divided into N subintervals. An intermediate time interval is therefore represented by $\Delta t = t_{n+1} - t_n$. The midpoint instant $t_{n+\alpha}$ for each subinterval $[t_n, t_{n+1}]$ is chosen such that $t_n \leq t_{n+\alpha} \leq t_{n+1}$ and

$$\alpha = \frac{t_{n+\alpha} - t_n}{\Delta t} \tag{12}$$

Given the variables $\{\boldsymbol{s}_n, \boldsymbol{e}_n, \boldsymbol{e}^p_n, \boldsymbol{\beta}_n, \bar{e}^p_n\}$ at time t_n and the deviatoric strain $\boldsymbol{e}_{n+1}$ at time t_{n+1}, the objective is to compute the variables at time t_{n+1}.

The difference between second order integration algorithms lies in the way the governing differential equations are integrated. In single step algorithms usually a midpoint rule is applied to midpoint instant $t_{n+\alpha}$ while in double step algorithms the return mapping procedure is performed twice per time interval, first at $t_{n+\alpha}$ and then at t_{n+1}. In the first step, a backward Euler integration is performed over the subinterval $[t_n, t_{n+\alpha}]$. The results are extrapolated to time instant t_{n+1} and projected onto the yield surface if necessary, Artioli et al. 2007a.

It was mentioned that applying a backward Euler method over the subinterval $[t_n, t_{n+\alpha}]$ constitutes the first step. Therefore the algorithmic setup for the first step can be formulated as follows.

$$\begin{aligned} &\boldsymbol{e}^p_{n+\alpha} = \boldsymbol{e}^p_n + \lambda_1\boldsymbol{n}_{n+\alpha} \\ &\boldsymbol{s}_{n+\alpha} = 2G(\boldsymbol{e}_{n+\alpha} - \boldsymbol{e}^p_{n+\alpha}) \\ &\boldsymbol{\beta}_{n+\alpha} = \frac{1}{1+b\lambda_1}\left(\boldsymbol{\beta}_n + \sqrt{\frac{2}{3}}\Delta H_{n+\alpha}\boldsymbol{n}_{n+\alpha}\right), \; \Delta H_{n+\alpha} = H(\bar{e}^p_{n+\alpha}) - H(\bar{e}^p_n) \\ &\boldsymbol{\xi}_{n+\alpha} = \boldsymbol{s}_{n+\alpha} - \boldsymbol{\beta}_{n+\alpha} \\ &\bar{e}^p_{n+\alpha} = \bar{e}^p_n + \sqrt{\frac{2}{3}}\lambda_1, \; \lambda_1 = \Delta t\,\gamma_{n+\alpha} \end{aligned} \tag{13}$$

If the kinematic hardening is linear it is sufficient to set b to zero in equation $(13)_3$. It is initially assumed that the evolution of variables over the time interval $[t_n, t_{n+\alpha}]$ is elastic and if the trial values violate the consistency condition a plastic correction is employed. Based on the elastic hypothesis the trial step is

$$\boldsymbol{e}^{p,\text{trial}}_{n+\alpha} = \boldsymbol{e}^p_n$$

$$\begin{aligned} &\boldsymbol{s}^{\text{trial}}_{n+\alpha} = \boldsymbol{s}_n + 2G\Delta\boldsymbol{e}_{n+\alpha}, \; \Delta\boldsymbol{e}_{n+\alpha} = \boldsymbol{e}_{n+\alpha} - \boldsymbol{e}_n \\ &\boldsymbol{\beta}^{\text{trial}}_{n+\alpha} = \boldsymbol{\beta}_n \\ &\boldsymbol{\xi}^{\text{trial}}_{n+\alpha} = \boldsymbol{s}^{\text{trial}}_{n+\alpha} - \boldsymbol{\beta}^{\text{trial}}_{n+\alpha} \\ &\bar{e}^{p,\text{trial}}_{n+\alpha} = \bar{e}^p_n \end{aligned} \tag{14}$$

If the trial relative stress violates the consistency condition, i.e. if

$$\left\|\boldsymbol{\xi}^{\text{trial}}_{n+\alpha}\right\| - \sqrt{\frac{2}{3}}K\left(\bar{e}^{p,\text{trial}}_{n+\alpha}\right) > 0 \tag{15}$$

a plastic correction according to the following equations should be applied.

$$
\begin{aligned}
&\boldsymbol{e}^{p}_{n+\alpha} = \boldsymbol{e}^{p,\text{trial}}_{n+\alpha} + \lambda_1 \boldsymbol{n}_{n+\alpha} \\
&\boldsymbol{s}_{n+\alpha} = \boldsymbol{s}^{\text{trial}}_{n+\alpha} - 2G\lambda_1 \boldsymbol{n}_{n+\alpha} \\
&\boldsymbol{\beta}_{n+\alpha} = \frac{1}{1+b\lambda_1}\left(\boldsymbol{\beta}^{\text{trial}}_{n+\alpha} + \sqrt{\frac{2}{3}}\Delta H_{n+\alpha}\boldsymbol{n}_{n+\alpha}\right) \\
&\boldsymbol{\xi}_{n+\alpha} = \boldsymbol{\zeta}_{n+\alpha} - \left(2G\lambda_1 + \frac{\sqrt{2/3}}{1+b\lambda_1}\Delta H_{n+\alpha}\right)\boldsymbol{n}_{n+\alpha} \\
&\bar{e}^{p}_{n+\alpha} = \bar{e}^{p,\text{trial}}_{n+\alpha} + \sqrt{\frac{2}{3}}\lambda_1
\end{aligned}
\tag{16}
$$

where $\boldsymbol{\zeta}_{n+\alpha}$ is defined as follows.

$$
\boldsymbol{\zeta}_{n+\alpha} = \boldsymbol{s}^{\text{trial}}_{n+\alpha} - \frac{1}{1+b\lambda_1}\boldsymbol{\beta}^{\text{trial}}_{n+\alpha} \tag{17}
$$

The plastic multiplier λ_1 is calculated by enforcing the consistency condition at time instant $t_{n+\alpha}$. The procedure is schematically shown in figure 1.

As the second step, the results of the first step are extrapolated to time instant t_{n+1}, Artioli et al. 2007a. If it is assumed that the evolution of variables over the time interval $[t_n, t_{n+1}]$ is linear, then the extrapolation can be performed by expressing the quantities at time instant t_{n+1} in terms of the quantities at time instants t_n and $t_{n+\alpha}$. The variables obtained in this way constitute the trial state for the second step. Therefore the trial state can be written as

$$
\begin{aligned}
&\boldsymbol{e}^{p,\text{trial}}_{n+1} = \frac{1}{\alpha}\boldsymbol{e}^{p}_{n+\alpha} - \frac{1-\alpha}{\alpha}\boldsymbol{e}^{p}_{n} \\
&\boldsymbol{s}^{\text{trial}}_{n+1} = \frac{1}{\alpha}\boldsymbol{s}_{n+\alpha} - \frac{1-\alpha}{\alpha}\boldsymbol{s}_{n} \\
&\boldsymbol{\beta}^{\text{trial}}_{n+1} = \frac{1}{\alpha}\boldsymbol{\beta}_{n+\alpha} - \frac{1-\alpha}{\alpha}\boldsymbol{\beta}_{n} \\
&\boldsymbol{\xi}^{\text{trial}}_{n+1} = \frac{1}{\alpha}\boldsymbol{\xi}_{n+\alpha} - \frac{1-\alpha}{\alpha}\boldsymbol{\xi}_{n}
\end{aligned}
\tag{18}
$$

$$
\bar{e}^{p,\text{trial}}_{n+1} = \frac{1}{\alpha}\bar{e}^{p}_{n+\alpha} - \frac{1-\alpha}{\alpha}\bar{e}^{p}_{n}
$$

Similar to the first step, a plastic correction as specified by the following equations would be required if the trial relative stress $\boldsymbol{\xi}^{trial}_{n+1}$ violates the yield condition.

$$
\begin{aligned}
&\boldsymbol{e}^{p}_{n+1} = \boldsymbol{e}^{p,\text{trial}}_{n+1} + \lambda_2 \boldsymbol{n}_{n+1} \\
&\boldsymbol{s}_{n+1} = \boldsymbol{s}^{\text{trial}}_{n+1} - 2G\lambda_2 \boldsymbol{n}_{n+1} \\
&\boldsymbol{\beta}_{n+1} = \frac{1}{1+b\lambda_2}\left(\boldsymbol{\beta}^{\text{trial}}_{n+1} + \sqrt{\frac{2}{3}}\Delta \bar{H}_{n+1}\boldsymbol{n}_{n+1}\right) \\
&\boldsymbol{\xi}_{n+1} = \boldsymbol{\zeta}_{n+1} - \left(2G\lambda_2 + \frac{\sqrt{2/3}}{1+b\lambda_2}\Delta \bar{H}_{n+1}\right)\boldsymbol{n}_{n+1} \\
&\bar{e}^{p}_{n+1} = \bar{e}^{p,\text{trial}}_{n+1} + \sqrt{\frac{2}{3}}\lambda_2
\end{aligned}
\tag{19}
$$

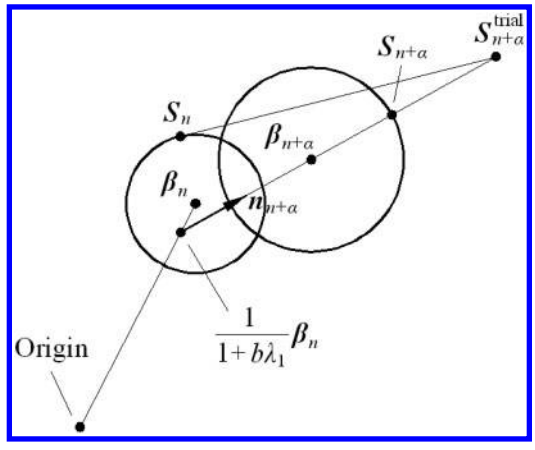

Figure 1. Stress updating procedure for the first step, Jahanshahi (2012b).

The plastic multiplier λ_2 is calculated by enforcing the consistency condition at time instant t_{n+1}. A detailed description of the stress updating procedure outlined above can be found in Jahanshahi (2012b).

4 TANGENT OPERATOR

In order to preserve the quadratic rate of convergence of the Newton-Raphson method used to solve the elastoplasticity problem under consideration, the tangent operator should be consistent with the corresponding integration algorithm. For single step algorithms such as backward Euler method or midpoint rule it is rather trivial to derive the corresponding tangent operator. However for double step algorithms, the procedure of deriving tangent operator can be tedious and complex depending on the type of nonlinearity being used (linear/nonlinear isotropic/kinematic hardening).

It can be shown that in the case of linear kinematic hardening and general form of isotropic hardening ($b = 0$) the tangent operator takes the following form, Jahanshahi (2012a).

$$
\begin{aligned}
&\mathbf{C}^{ep} = \kappa \mathbf{1}\otimes\mathbf{1} \\
&+2G\left[\left[1-A-\left(1-\bar{A}\right)C\right]\left(\boldsymbol{I}-\frac{1}{3}\mathbf{1}\otimes\mathbf{1}\right)\right. \\
&-\left[\left(\bar{A}-\bar{B}\right)C-\left(A-B\right)\right]\boldsymbol{n}_{n+\alpha}\otimes\boldsymbol{n}_{n+\alpha} \\
&-\left(1-\bar{A}\right)\left(D-C\right)\boldsymbol{n}_{n+1}\otimes\boldsymbol{n}_{n+1} \\
&\left.-\left[\left(\bar{A}-\bar{B}\right)\left(D-C\right)\left(\boldsymbol{n}_{n+1}:\boldsymbol{n}_{n+\alpha}\right)-\bar{C}\right]\boldsymbol{n}_{n+1}\otimes\boldsymbol{n}_{n+\alpha}\right]
\end{aligned}
\tag{20}
$$

where $\boldsymbol{n}_{n+\alpha}$ and $\boldsymbol{n}_{n+1}$ are respectively the outward normals to the yield surface at time instants $t_{n+\alpha}$ and t_{n+1}. A to D and $\bar{A}$ to $\bar{C}$ are parameters which are defined as follows.

$$
A = \frac{2G\lambda_1}{\left\|\boldsymbol{\xi}^{\text{trial}}_{n+\alpha}\right\|},\quad B = \left[1+\frac{H'(\bar{e}^{p}_{n+\alpha})+K'(\bar{e}^{p}_{n+\alpha})}{3G}\right]^{-1} \tag{21}
$$

$$C = \frac{2G\lambda_2}{\left\|\xi_{n+1}^{\text{trial}}\right\|},\quad D = \left[1 + \frac{H'(\bar{e}_{n+1}^{p}) + K'(\bar{e}_{n+1}^{p})}{3G}\right]^{-1} \tag{22}$$

$$\bar{A} = \frac{1}{\left\|\xi_{n+\alpha}^{\text{trial}}\right\|}\left(2G\lambda_1 + \sqrt{\frac{2}{3}}\Delta H_{n+\alpha}\right) \tag{23}$$

$$\bar{B} = \left[1 + \frac{H'(\bar{e}_{n+\alpha}^{p})}{3G}\right]B \tag{24}$$

$$\bar{C} = \frac{H'(\bar{e}_{n+1}^{p}) - H'(\bar{e}_{n+1}^{p,\text{trial}}) + K'(\bar{e}_{n+1}^{p})}{3G}B \tag{25}$$

If the kinematic hardening is of nonlinear type ($b \neq 0$) the procedure that is required to derive $\mathbf{C}^{ep}$ is more involved. One can refer to Jahanshahi (2012b) for an elaboration.

5 NUMERICAL EXAMPLES

In this section, iso-error maps and a numerical example are used to investigate the behavior of the double step integration algorithm compared with backward Euler method. Both algorithms have been implemented into a C++ program based on standard concepts in finite element analysis, Bathe (1996).

The elastic properties of material are taken as $E = 7000$ MPa, $\nu = 0.3$, and the material constants are $\overline{K}_\infty = 35$ MPa, $\overline{K}_0 = 30$ MPa, $\delta = 0.1$, $\overline{H}' = 280$ MPa, $\beta = 0.8$ and $b = 1$.

5.1 *Iso-error maps*

Iso-error maps are extensively employed by researchers as a procedure to systematically assess the accuracy of a proposed algorithm. In the literature, iso-error maps are generated by applying a set of normalized strains in principal directions. A detailed description be found in Simo & Hughes (1998).

The iso-error maps corresponding to point **C** of the yield surface in figure 2 are shown in figures 3 and 4 and are generated for $\alpha = 0.5$.

The error range for each iso-error map is divided into 10 error levels. Regarding figure 3, it can be concluded that the accuracy of backward Euler method as a first order accurate algorithm is quite acceptable showing low error levels for large time steps. It also should be emphasized that the simplicity of implementation as well as the efficiency with regard to computational effort make this algorithm numerically attractive.

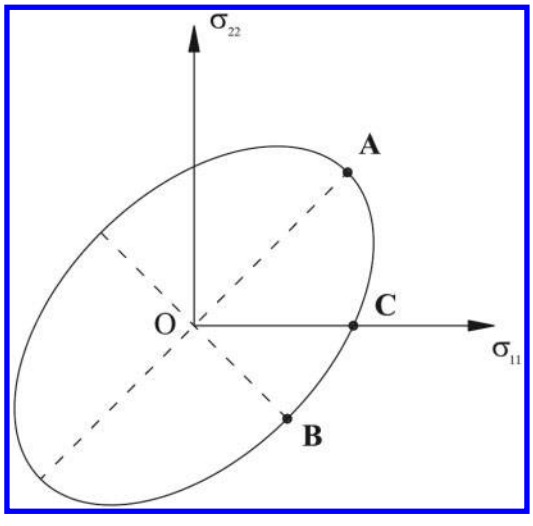

Figure 2. Plane strain yield surface. Points for iso-error maps.

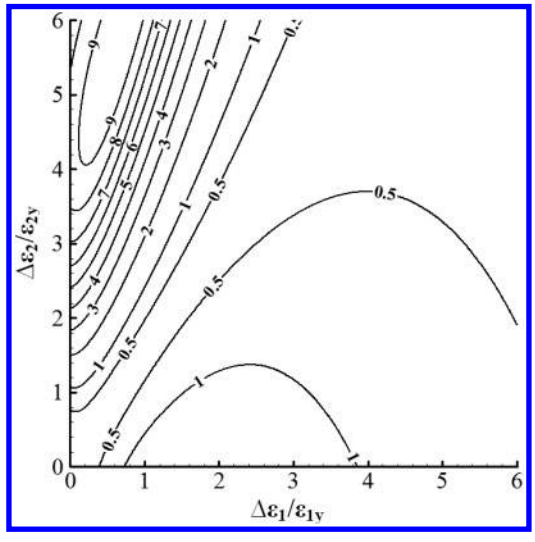

Figure 3. Iso-error maps for point **C** of the yield surface using backward Euler method, Jahanshahi (2012b).

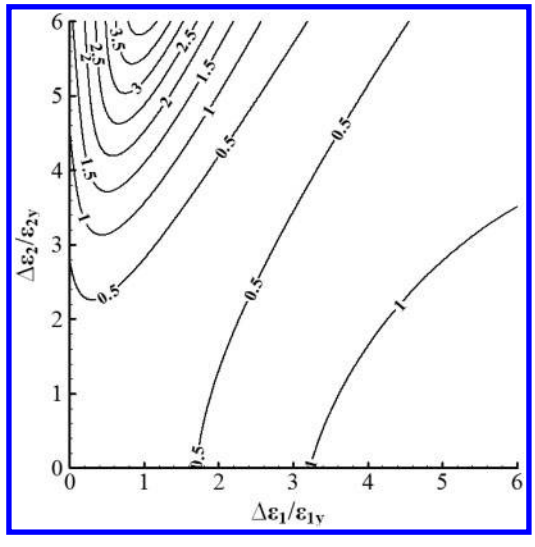

Figure 4. Iso-error maps for point **C** of the yield surface using double step algorithm, (Jahanshahi 2012b).

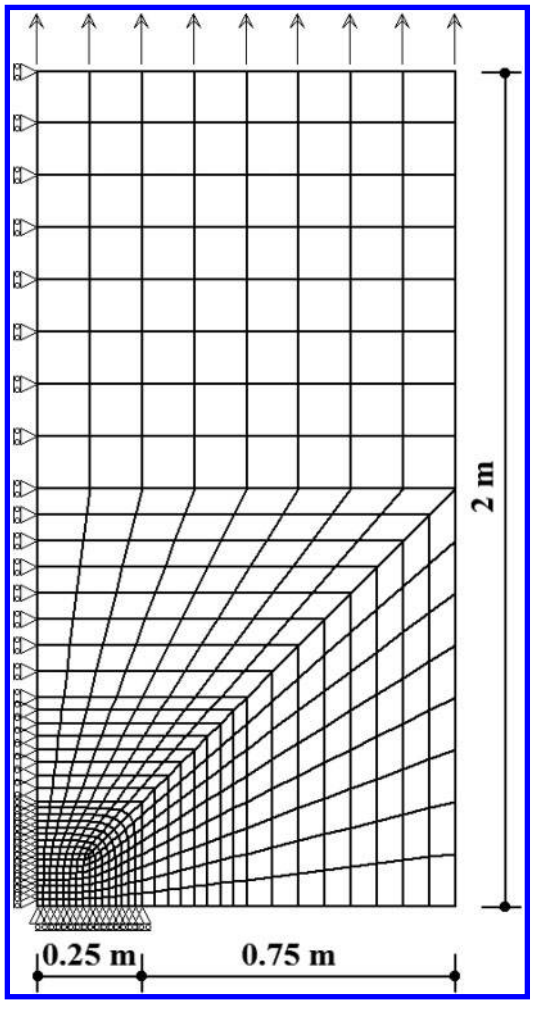

Figure 5. Finite element model for one quarter of double-notched plate, Jahanshahi (2012b).

Comparing figures 3 and 4 one can see that the maximum error using backward Euler method is 9% while for the double step algorithm it is 4.2%. A literature survey shows that for proportional loading (points **A** and **B** in figure 2) the maximum error and the difference between maximum error values from the backward Euler method and the double step algorithm are lower than the case of non-proportional loading presented here. Based on this observation it can be conferred that the double step algorithm has a superior performance compared with backward Euler method.

5.2 *Double-notched plate subject to cyclic load*

A plate with two symmetrical notches in plane strain condition is considered as a numerical example to investigate the performance of the double step integration algorithm briefly discussed in previous sections, Jahanshahi (2012b). The finite element model for one quarter of the plate is shown in figure 5. A total of

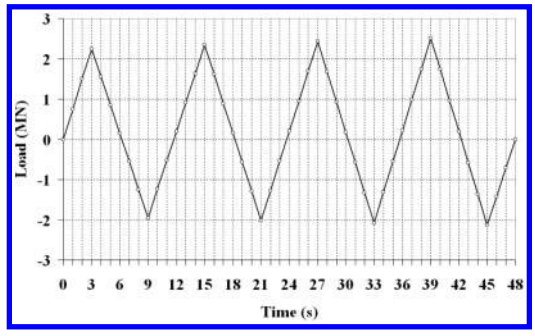

Figure 6. Variation of cyclic load applied to double-notched plate, Jahanshahi (2012b).

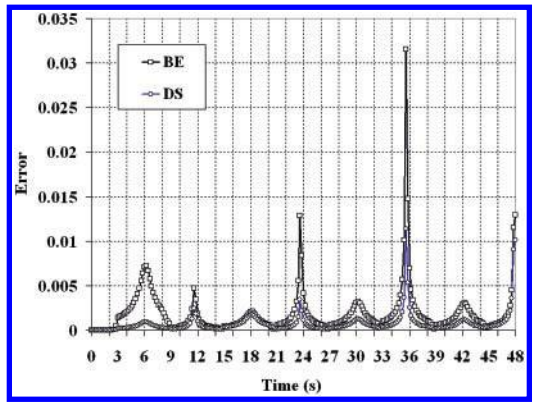

Figure 7. Error graph for BE and DS algorithms applied to double-notched plate with cyclic load and $\alpha = 0.8$, Jahanshahi (2012b).

512 quadrilateral plane strain elements with 4 integration points and linear displacement interpolation along each direction are used to model the plate. The variation of point loads that are applied to indicated nodes is shown in figure 6. The loading program comprises of four cycles of tension and compression and it takes 4 s. For the first cycle, the intensity of load increases to 2.25 MN at $t = 3$ s and drops to -1.95 MN at $t = 9$ s. In subsequent cycles, the maxima of load increases gradually both in tension and compression. In the last cycle it increases to the maximum of 2.50 MN at $t = 39$ s and drops to the minimum of -2.15 MN at $t = 45$ s. Finally, the value of load increases again until it becomes zero at $t = 48$ s.

An error graph is provided in figure 7 to compare the results of algorithm for $\alpha = 0.8$. BE and DS in this figure refer respectively to backward Euler method and double step algorithm. The residual stresses that remian in plate after completing the loading program are shown in figure 8. Regarding the error graph the following observations can be made:

- The maximum error for the double step algorithm is 64 percent lower than the maximum error for backward Euler method.

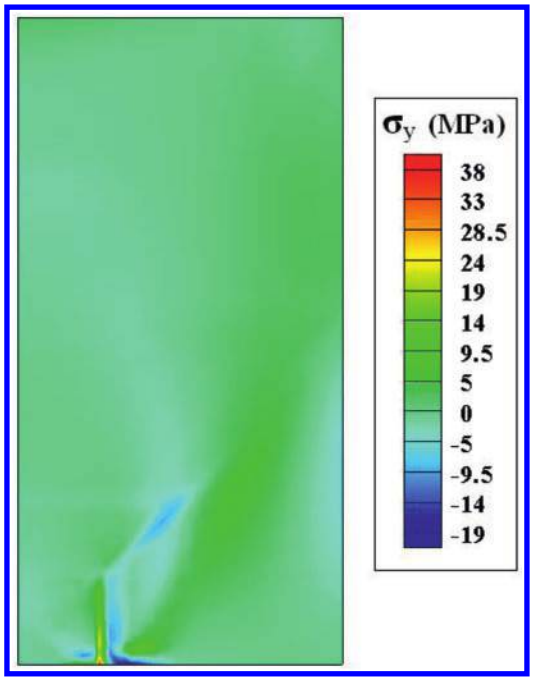

Figure 8. Residual stresses in double-notched plate. Jahanshahi (2012b).

- In addition to maximum error, the error of double step algorithm is lower than the backward Euler method at all points during the loading program.

6 CONCLUSIONS

Second order integration algorithms have been shown by many authors to have better convergence properties compare with backward Euler method. In this paper a double step integration scheme is presented for linear/nonlinear isotropic and kinematic hardening. Based on numerical examples it was shown that the behavior of this type of algorithm is superior to backward Euler method. It should also be emphasized that the number of numerical operations that have to be performed also increases but this extra computational effort is offset by using large time steps.

Numerical experience shows that under sever loading conditions where most parts of the medium under consideration plasticize, the double step algorithm demonstrates its efficiency compared with classical methods such as the backward Euler method. However under moderate loading conditions where only small parts of the medium enter the plastic limit the difference between the two methods might not be very noticeable.

A layered shell element for the thermal analysis of plates exposed to non-uniform heating

A.E. Jeffers
University of Michigan, Ann Arbor, MI, USA

ABSTRACT: This paper describes a heat transfer element that has been formulated to model the 3D thermal response of plates subjected to non-uniform heating. Unlike existing elements, the present formulation uses a combination of finite element and control volume techniques to discretize the plate into layers that are each characterized by a temperature field that is lumped at the mid-section of the layer. In plane, the temperature field is interpolated from nodal values as quadratic. Although a combination of finite difference and finite element approximations is used, the element equations are in a form that can readily be implemented in a finite element code. Verification studies demonstrate that the element exhibits excellent accuracy and rapid convergence. Comparisons to continuum elements illustrate that the proposed element also results in considerable cost savings. The element also facilitates the transfer of temperature data to a structural analysis because both models utilize the same mesh.

1 INTRODUCTION

As illustrated in Figure 1, the simulation of structures in fire involves three sequentially coupled processes: 1) a fire analysis to determine the thermal boundary conditions at the structural surface, 2) a conduction heat transfer analysis to determine the temperatures in the structure, and 3) a structural analysis to determine the force-deformation response of the structure. For structural design, research has historically focused on post-flashover fire exposures, in which the fire behavior is described in terms of a uniform gas temperature. This assumption is valid for most building structures, in which compartments are relatively small and the fuel distribution is fairly uniform. However, fully developed compartment fire models have been questioned due to their inability to capture fire spread that occurs naturally in large, open compartments (Stern-Gottfried et al. 2010).

As a result, significant efforts are underway to study structural response under non-uniform fire exposures, including the coupling of structural models to computational fluid dynamics codes (Chen et al. 2011, Tondini et al. 2012). The coupling of a high-resolution fire simulation to a low-resolution structural model poses a number of challenges due to the severe disparities in spatial and temporal scales between the various models (Prasad & Baum 2005), as shown in Figure 1.

One of the primary challenges to studying structural response under non-uniform heating is that there is no direct way to model the thermal response of the structure in a way that is compatible with the finite elements that are typically used in structural analysis (Jeffers and Sotelino 2009). Consequently, an analyst must conduct a high-resolution heat transfer analysis using computationally expensive continuum elements and perform an intermediate calculation to resolve the temperature data to a form that is compatible with the structural elements (i.e., frame and shell elements) that are used to evaluate the mechanical response of the structure. This approach involves excessive computational costs, making the simulation approach impractical for most engineering applications.

To overcome the limitations of current techniques for modeling heat transfer in structures, this paper introduces a novel heat transfer finite element for evaluating the thermal response of non-uniformly heated plates. Using the approach of Jeffers & Sotelino (2009), a combination of finite element and control volume methods are used to discretize the temperature field in the plate heat transfer element. In particular, temperatures over the plate's thickness are modeled in high-resolution using a finite difference grid while temperatures in plane are modeled in low-resolution using quadratic interpolation functions. The result is a layered plate heat transfer element that is capable of capturing the complete 3D thermal response. The formulation emphasizes compatibility between the thermal and structural models because the heat transfer element uses the same layering technique that is used in mechanics-based plate and shell elements to model distributed plasticitity (Ramm & Matzenmiller 1988, Buchter et al. 1994, Wriggers et al. 1996). The resulting element efficiently simulates the 3D thermal response while facilitating the transfer of data between the thermal and structural models due to the compatibility between the finite element meshes.

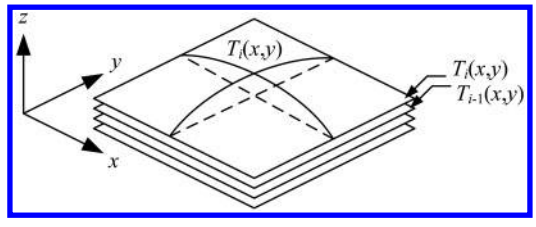

Figure 3. Quadrature temperature field in layer i.

This paper provides a summary of the element formulation and results of the verification studies that were conducted to evaluate the plate heat transfer element. Additional details can be found in the paper by Jeffers (2013).

2 ELEMENT FORMULATION

As illustrated in Figure 2, the plate heat transfer element is discretized into n layers. The thickness t_i of layer i is assumed to be relatively small such that the temperature field is lumped in each layer. As a result, the temperature field in layer i is reduced to a 2D temperature field that varies only in plane, as illustrated in Figure 3. A combination of finite element and control volume techniques can be employed to arrive at a set of equations that account for heat transfer across the layers in the element.

In particular, the weak form of the governing energy conservation equation in layer i is given as

$$\int_{V_i}\left[\rho C\frac{\partial T}{\partial t}-\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right)-\frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)-\frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right)\right]dV_i=0 \qquad (1)$$

where ρ = mass density, C = specific heat, k = conductivity, T = temperature, t = time, and V_i = volume of layer i.

Because the thickness of layer i is relatively small, it can be assumed that the temperature gradient $\partial T/\partial z$ is approximately zero over the depth of the layer. Thus, the 3D temperature field $T(x, y, z, t)$ is replaced by a 2D layer temperature $T_i(x, y, t)$ that only varies in plane (Figure 3). To satisfy the energy balance, however, additional terms must be introduced into the governing equation to account for heat transfer by conduction from the adjacent layers $i-1$ and $i+1$. Thus, Equation 1 becomes

$$\int_{V_i}\left[\rho C\frac{\partial T_i}{\partial t}-\frac{\partial}{\partial x}\left(k\frac{\partial T_i}{\partial x}\right)-\frac{\partial}{\partial y}\left(k\frac{\partial T_i}{\partial y}\right)-Q\right]dV_i + \int_A\left(k\frac{\partial T}{\partial z}\right)\Big|_{i-}dxdy-\int_A\left(k\frac{\partial T}{\partial z}\right)\Big|_{i+}dxdy=0 \qquad (2)$$

The first term in Equation 2 results from substituting the layer temperature $T_i(x, y, t)$ into Equation 1 while the remaining terms account for the flux that enters the bottom and top surfaces of layer i by conduction from the adjacent layers. Symbols $i-$ and $i+$ represent the boundaries between layers (i.e., at $i-1/2$ and $i+1/2$, respectively). Note that heat transfer by conduction occurs normal to the element's xy plane and therefore the energy flow is integrated over plate's area A.

The heat transfer by conduction from the adjacent layers can be approximated as finite differences, i.e.,

$$\left(k\frac{\partial T}{\partial z}\right)\Big|_{i-} = k_{i-}\left(\frac{T_i - T_{i-1}}{z_i - z_{i-1}}\right), \left(k\frac{\partial T}{\partial z}\right)\Big|_{i+} = k_{i+}\left(\frac{T_{i+1} - T_i}{z_{i+1} - z_i}\right), \quad (3)$$

where k_{i-} and k_{i+} = effective conductivities at the layer interfaces, which are calculated by averaging the thermal resistances of adjacent layers (Jaluria & Torrance 2003). In Equation 3, z_i is the location at which the layer temperature is lumped in the z-direction. For interior layers, z_i coincides with the mid-height of the layer. For exterior layers, z_i coincides with the surface of the element to provide greater accuracy in modeling the thermal boundary conditions at the element's surface (Jaluria & Torrance 2003).

Note that Equation 2 only applies to interior layers in which heat is transferred by conduction from an adjacent layer. For exterior layers (i.e., the layers at the top and bottom surface of the plate), the appropriate boundary conditions must be applied to simulate prescribed temperature, flux, convection and/or radiation boundary conditions. These terms are given by Jeffers (2013).

The finite element method is applied to Equation 2 by assuming that the temperature field $T_i(x, y)$ in layer i is interpolated from the nodal temperatures $\mathbf{T}_i$ using element shape functions $\mathbf{N}$, i.e.,

$$T_i(x, y) = \mathbf{N}\,\mathbf{T_i}. \quad (4)$$

As shown in Figure 3, a quadratic temperature field is assumed here, resulting in a nine-node heat transfer element.

Equation 4 is substituted into Equation 2, and the Galerkin finite element method is employed. After some manipulation, the governing equations for an interior layer i are given by

$$\mathbf{c_i}\dot{\mathbf{T}}_\mathbf{i} + \mathbf{k_i}\mathbf{T_i} - \left(\mathbf{k_{i-}}\mathbf{T_{i-1}} + \mathbf{k_{i+}}\mathbf{T_{i+1}}\right) = \mathbf{r_i}, \quad (5)$$

Where

$$\mathbf{c_i} = \int_A \mathbf{N}^T \rho C t_i \mathbf{N} dxdy \quad (6)$$

$$\mathbf{k_i} = \int_A \mathbf{N_{,x}}^T k t_i \mathbf{N_{,x}} dxdy + \int_A \mathbf{N_{,y}}^T k t_i \mathbf{N_{,y}} dxdy + \mathbf{k_{i-}} + \mathbf{k_{i+}} + \mathbf{h_i} \quad (7)$$

$$\mathbf{k_{i-}} = \int_A \mathbf{N}^T \frac{k_{i-}}{z_i - z_{i-1}} \mathbf{N}^T dxdy \quad (8)$$

$$\mathbf{k_{i+}} = \int_A \mathbf{N}^T \frac{k_{i+}}{z_{i+1} - z_i} \mathbf{N}^T dxdy \quad (9)$$

$$\mathbf{h_i} = \int_S \mathbf{N}^T (h + h_r)\mathbf{N} dS \quad (10)$$

$$\mathbf{r_i} = \int_S \mathbf{N}^T q_s'' dS + \int_S \mathbf{N}^T (hT_\infty + h_r T_{sur}) dS \quad (11)$$

In Equations 5–11, t_i = thickness of layer i; $\mathbf{N}_{,x}$ and $\mathbf{N}_{,y}$ = derivatives of the shape function matrix with respect to x and y, respectively; h = convection heat transfer coefficient and T_∞ = fluid temperature (for a convection boundary condition); h_r = linearized radiation heat transfer coefficient and T_{sur} = temperature of surroundings (for a radiation boundary condition); q_s'' = surface flux (for a prescribed flux boundary condition).

For exterior layers, Equation 5 is modified to include the appropriate boundary conditions specified at the top or bottom surface of the plate. For a prescribed flux, the following term is added to $\mathbf{r_i}$:

$$\mathbf{r_{qb}} = \int_A \mathbf{N}^T q_b'' dxdy. \quad (12)$$

For a convection boundary condition, the following terms are added to $\mathbf{k_i}$ and $\mathbf{r_i}$, respectively:

$$\mathbf{h_b} = \int_A \mathbf{N}^T h \mathbf{N} dxdy, \ \mathbf{r_{hb}} = \int_A \mathbf{N}^T h T_\infty dxdy. \quad (13)$$

For a radiation boundary condition, the following terms are added to $\mathbf{k_i}$ and $\mathbf{r_i}$, respectively:

$$\mathbf{h_{rb}} = \int_A \mathbf{N}^T h_r \mathbf{N} dxdy, \ \mathbf{r_{hrb}} = \int_A \mathbf{N}^T h_r T_{sur} dxdy. \quad (14)$$

Equation 5 represents the temperature in layer i, which is dependent on the temperatures in the adjacent layers $i-1$ and $i+1$. The governing equations for the entire element are obtained by assembling the n layers (with temperatures described in terms of m nodal temperatures) over the element's domain. The resulting element has $n \times m$ degrees of freedom. After assembly, the element equations have the form

$$\mathbf{c}\dot{\mathbf{T}} + \mathbf{k}\mathbf{T} = \mathbf{r} \quad (15)$$

where $\mathbf{c}$ = heat capacity matrix, $\mathbf{k}$ = conductivity matrix, $\mathbf{r}$ = an array of thermal loads, $\mathbf{T}$ = an array of nodal temperatures, and $\dot{\mathbf{T}}$ = first derivative of temperatures with respect to time. Note that, although a combination of finite element and control volume methods were used in the element formulation, the governing equations in Equation 15 are in a form that can readily be implemented into a finite element program.

3 VERIFICATION

The element was implemented in *ABAQUS* (2010) as a user-defined element to verify the element formulation. A series of verification cases were devised to evaluate the element's accuracy in simulating various cases of non-uniform heating.

Two cases are shown here to demonstrate the element's ability to simulate 2D and 3D heat transfer. Both cases consider a rectangular steel plate

with dimensions 2 m, × 1 m, × 10 cm. The steel was assumed to have density $\rho = 7{,}833\ \text{kg/m}^3$, conductivity $k = 54$ W/m-K, and specific heat $C = 465$ J/kg-K. Material properties were assumed to be independent of temperature. Results from the proposed heat transfer element were compared to high-resolution finite element analyses conducted in *ABAQUS* using linear 2D and 3D continuum elements.

3.1 *Two-dimensional heat transfer*

To evaluate the heat transfer over the section, the plate was given an initial temperature of 0°C and the top surface was instantaneously fixed at 100°C, while the remaining surfaces were maintained at 0°C. The nature of the heating induced a temperature field that varied in two dimensions over the cross-section. The shell element was assigned seven layers over the depth, and a convergence study was carried out to determine the influence of increasing the number of elements along the width of the plate.

Mid-surface temperatures were evaluated at times $t = 10$ s, 50 s, 170 s, and at steady state (i.e., $t = 10{,}000$ s). Figure 4 shows the results at steady state. Under the prescribed boundary conditions, the temperature varies non-uniformly. From Figure 4, it can be seen that the shell element converges rapidly, with excellent agreement achieved with eight elements over the width of the plate.

To better illustrate the level of accuracy achieved by the shell model, the L_2-norm error was calculated for each mesh. These errors are given in Table 1 at various times. Initially, the temperature gradient is quite significant, resulting in somewhat large errors at $t = 10$ s. As time progresses, the temperature profile smoothes out and the quadratic shell element provides an improved prediction of the thermal response. The data in Table 1 indicates that excellent accuracy is achieved with as few as eight elements over the width, with errors less than three percent for times greater than 50 s.

Simulation times were recorded for various finite element meshes to demonstrate the efficiency of the new heat transfer element. The converged finite element solution was based on a 2D heat transfer analysis conducted in *ABAQUS* using four-node continuum elements. The high-resolution model used rectangular elements that were 1 cm × 1 cm. Consequently, the 2D heat transfer analysis required 1,111 temperature degrees of freedom (DOFs). The analysis using the shell elements involved a 3D analysis of the plate with elements arranged in four meshes: 1 × 1, 2 × 2, 4 × 4, and 8 × 16. The corresponding numbers of degrees of freedom are given in Table 2 along with the recorded simulation times. Note that the simulation times for the shell models were on the same order of magnitude as the high-resolution 2D finite element analysis.

3.2 *Three-dimensional heat transfer*

To study the element's ability to capture a temperature field that varies in three dimensions, an analysis was conducted for a plate subjected to a non-uniform surface flux. The plate was given an initial temperature of 0°C and then heated by the boundary conditions illustrated in Figure 5. In particular, one-fourth of the top surface of the plate was subjected to a prescribed flux of 30 kW/m^2 while the remainder of the top surface was cooled by convection, with the fluid temperature $T_\infty = 0$°C and a heat transfer coefficient

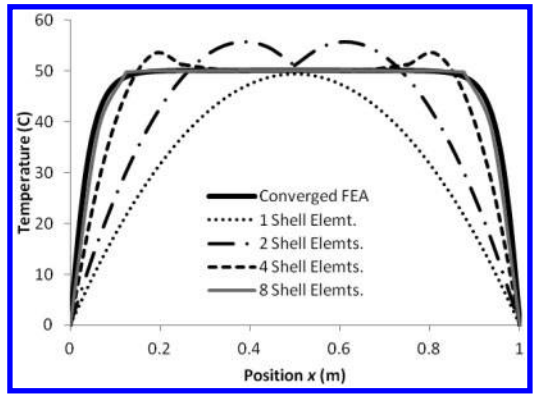

Figure 4. Mid-surface temperature at steady state for plate subjected to 2D heating of cross-section.

Shell Element		
1 × 1	63	0.6
2 × 2	175	0.6
4 × 4	567	0.6
8 × 16	3,297	2.3

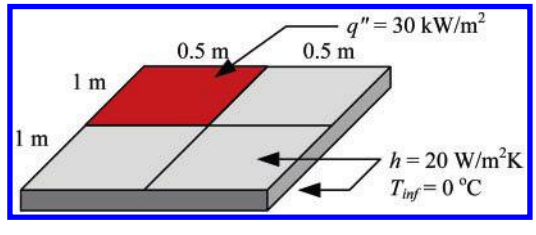

Figure 5. Boundary conditions for 3D heat transfer case.

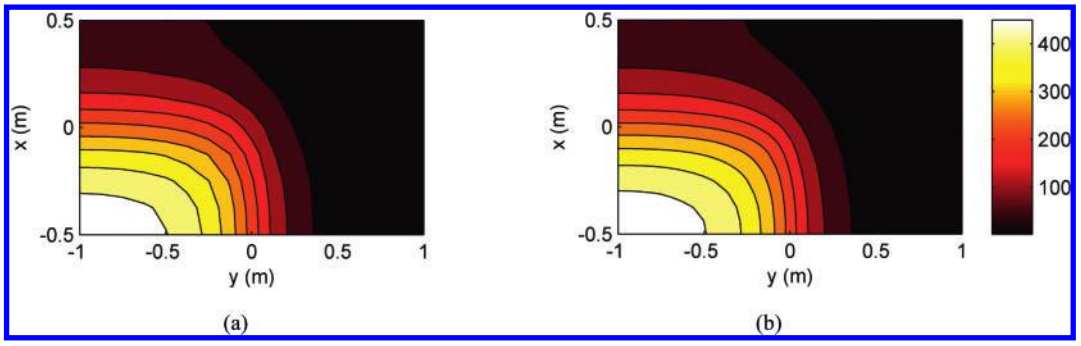

Figure 6. Steady-state temperature contours at the mid-surface of the plate, (a) 4 × 8 elements, and (b) 8 × 16 elements.

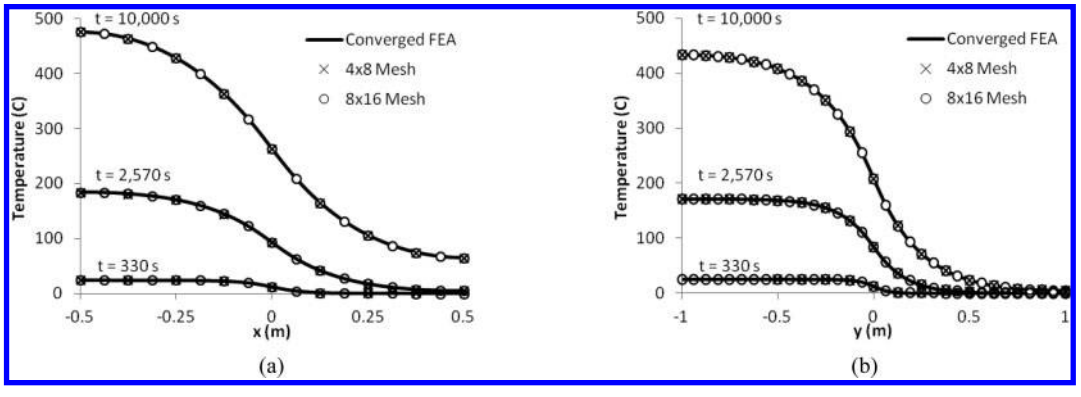

Figure 7. Comparison of mid-height temperatures at various times, (a) y = −0.75 m, and (b) $x = 0.25$ m.

$h = 25\ \mathrm{W/m^2K}$. The bottom surface of the plate was cooled by the same convective boundary condition. The sides of the plate were treated as insulated. Note that the temperatures are non-uniform over the thickness of the plate as well as along the surface under this heating.

The shell elements were arranged in two meshes: 4 × 8 and 8 × 16. The temperature contours calculated at the mid-surface at steady state are presented in Figure 6 for the two meshes of plate heat transfer elements. Qualitative comparisons between Figure 6 and results computed using a high-resolution mesh of continuum elements indicated good agreement in the predicted thermal response.

To better assess the accuracy of the analyses, temperatures were plotted along two paths at the mid-surface of the plate: 1) along $y = -0.75$ m, and 2) along $x = -0.25$ m. These results are shown in Figures 7a and 7b, respectively, for times $t = 330$ s, 2570 s, and 10,000 s. Note that the results from the plate heat transfer element agree very well with the high-resolution finite element analysis.

Simulation times were recorded in Table 3 for each analysis to provide a means of assessing the efficiency of the shell model. From the data presented in Table 3, it is clear that the shell element offers substantial savings in computational costs, with the 8 × 16 mesh requiring 2.6 s whereas the high-resolution finite element analysis required several minutes to run. It is important to realize that these savings would be magnified when larger and more complex structural systems are analyzed.

8 × 16	3,297	2.6

4 CONCLUSIONS

In this paper, a novel heat transfer element was formulated to provide an accurate and efficient means for predicting the temperature field in non-uniformly heated shells. The formulation used a combination of finite element and control volume techniques to discretize the temperature field into 2D layers that were coupled by a finite difference approximation of the transverse flux. While the element uses a combination of techniques, the layers can be assembled into

a set of element equations that are in a form that can readily be implemented into a finite element analysis. The present study focused on a nine-node quadratic element, although the formulation is valid for linear elements as well. On-going research is being done to extend the formulation to shells with more complex (i.e., curved) geometries.

Two verification examples were presented here to demonstrate the capabilities of the proposed element. The results indicate that the element rapidly converges with the use of more elements. While not shown here, more layers can be used to provide greater accuracy in predicting large thermal gradients over the depth of the element.

Comparisons to high-resolution finite element analyses demonstrate that the shell element presented here offers substantial cost-savings in the 3D analysis of plates subjected to non-uniform heating. These savings will be amplified when the heat transfer element is coupled with a mechanics-based shell element to perform thermo-structural analyses of non-uniformly heated structures. In addition to offering significant computational savings, the element also greatly simplifies that transfer of data from the heat transfer analysis to the structural analysis because the element's mesh is compatible with existing elements for distributed plasticity analysis of shells.

ABSTRACT: The Finite Element Method (FEM) is the dominant tool in the field of structural analysis. Typical engineering tasks imply "off-line" FEM computations with high accuracy set as the primary simulation objective. However, in many areas of applications, such as Multi-Body System (MBS) dynamics or virtual reality simulators, high numerical efficiency with respect to time becomes an aspect of similar importance as the accuracy itself. Furthermore, adequate modeling in the field of the applications mentioned requires the consideration of geometrically nonlinear effects. As a response to those requirements, the authors propose a simplified co-rotational FEM formulation, the essence of which is to account for rigid-body rotation on the element level. The development is briefly presented for solids and shells. A set of examples have been chosen to demonstrate the features of the proposed FEM formulation.

1 INTRODUCTION

A number of methods have been developed with the aim of predicting the physical behavior of deformable objects with very high level of accuracy. The finite element method (FEM), as the dominant tool in the field of structural analysis, has deservedly gained the reputation of the 'state-of-the-art method'. Typical engineering tasks require models and computations that provide an authentic representation of the real world. The solutions are obtained through "off-line" FEM computations with the accuracy set as the primary simulation objective. For small deformations and displacements a linear analysis is conducted. For larger deformations and displacements, particularly rotations, rigorous geometrically nonlinear FEM formulations are used, which involve a significantly larger numerical effort compared to the linear analysis.

However, in many areas of application, such as MBS-FEM integration (Zehn 2005) or virtual reality simulators (Erleben et al. 2005), the efficiency of computing nonlinear deformational behavior becomes an objective of similar or maybe even greater (real-time simulators) importance than the accuracy itself. For computation of multi-body system dynamics over longer time-intervals and with geometrical nonlinearities included, so-called co-simulations (MBS-FEM) based on commercially available software packages can be used (Kalmykov et al. 2001, Busch & Schweizer 2010). This, however, requires a rather expensive data transfer in each time-step of numerical integration as well as synchronization of different software products (with different types of data storage, structure and solver), which implies rather long computational times with numerical instability as a potential problem as well. Similarly, FEM software packages do offer means to conduct computations for different types of virtual reality simulators, but with computational times much longer than required for the purpose of simulations at interactive frame rates. Hence, both the mentioned applications impose the strong demand for rather efficient computations with geometrical nonlinearities included.

This paper offers a simplified co-rotational FEM formulation designed to response to the challenges of the aforementioned and similar applications. The essence of the formulation is given for solid and shell elements and several examples are provided to give an idea of achievable results.

2 THE IDEA BEHIND THE PROPOSED CO-ROTATIONAL FEM FORMULATION

The linear FEM is highly efficient and numerically stable but accurate only for rather small deformations and displacements. Rigorous nonlinear FEM offers high accuracy of predicted deformational behavior, but is significantly slower than the linear FEM and the numerical stability of computation may also be an issue.

The co-rotational FEM proposed by the authors is supposed to combine the advantages of both approaches. The general idea behind the formulation arises from the principles of incorporating flexible bodies in Multi-Body-System (MBS) dynamics. To achieve high computational efficiency, the overall motion of a flexible body in an MBS program is decomposed into large rigid-body motion and a small deformation described with respect to the body-fixed reference frame. This local reference frame is actually attached to the body and performs the same rigid-body motion as the body itself. Hence, it excludes large rotation from the motion, thus allowing extraction of the deformable motion (in the average sense), which might be, on the other hand, just a small portion of the overall motion.

The idea is simply extended so that each element of the finite-element assemblage is assigned a local reference system, with respect to which the behavior of the element remains entirely linear. In this manner, deformations of a body, characterized by large local rotations of sub-domains with respect to the remaining of the body, are easily handled. The approach permits the computation of the linear stiffness matrices of single elements in a step prior to simulation. Over the course of simulation, it is necessary to extract the rigid-body motion of each element and use it to update the element stiffness matrices and to compute the internal forces. Hence, the numerical effort is significantly reduced and the numerical stability is notably improved compared to the rigorous geometrically nonlinear FEM, with the accuracy somewhat but for many purposes not significantly reduced.

3 THE CO-ROTATIONAL FEM WITH SOLID ELEMENTS

3.1 *Handling the translational degrees of freedom*

Solid elements result from discretization of structural elements viewed as continua. The mutual property of solid elements is that they describe the displacement field by means of nodal translations as degrees of freedom. Typical representatives of this group of finite elements are tetrahedral and hexahedral elements.

The linear tetrahedral element is well-known for its rather stiff behavior, which accounts for its disadvantage. Its major advantage, on the other hand, is the ability to mesh any geometry. The description of this finite element is widely available in literature (e.g. (Bathe 1997)) and, for the sake of brevity, it is not given here, but the element is used to elaborate the proposed co-rotational formulation. The very essence of the formulation is computation of the internal forces of the element, $\{F_e\}$ according to the following expression:

$$\{F_e\} = \mathbf{R}_e \mathbf{K}_e \left(\mathbf{R}_e^{-1} \{x_e\} - \{x_{0e}\} \right) \quad (1)$$

where $\{x_e\}$ and $\{x_{0e}\}$ are the current and initial element configurations (i.e. nodal coordinates), respectively, $\mathbf{R}_e$ is the rigid-body rotational matrix and $\mathbf{K}_e$ the linear element stiffness matrix. It will be worthwhile to give the interpretation of this equation by means of Figure 1. The first term in the parenthesis on the right-hand side of the equation yields the current element configuration rotated back to the original element orientation. Observing Figure 1, that configuration is obtained when the deformed element is rotated backwards through $\mathbf{R}_e^{-1}$. Thus, the entire term in the parenthesis gives the rotation-free nodal displacements. Multiplied with the linear element stiffness matrix, $\mathbf{K}_e$, the element internal (elastic) forces with respect to the original element configuration are obtained. Finally, what remains is to rotate the internal forces to the current element configuration, which is achieved by multiplication with the element rotational matrix, $\mathbf{R}_e$.

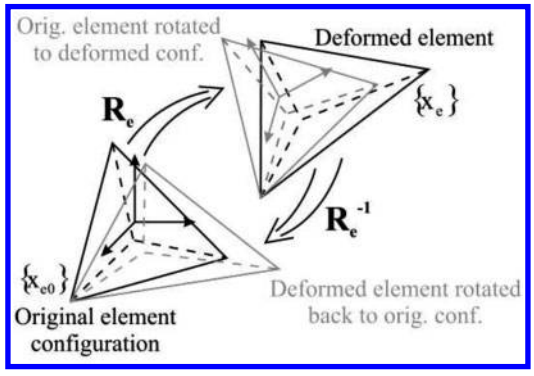

Figure 1. Decomposition of element's motion into rotation and deformation.

Finally, it should be noted that, regarding the linear tetrahedral element, there is a unique matrix that transforms the initial element configuration into the current one. Polar decomposition of this matrix yields the rotation matrix $\mathbf{R}_e$. With other element types, a kind of averaged rotation matrix has to be computed for the presented approach.

3.2 *An example with the tetrahedral element*

An example is given below to demonstrate the achievable accuracy with the simplified co-rotational approach. The considered structure is a part of a Volkswagen car's sliding door hinge. The boundary conditions are defined as fixed nodes over the surface of the holes designed for the hinge pin and a rather large excitation force, the direction of which can be seen in Figure 2. The depicted boundary conditions resemble the case when a car door opens quickly and hits against the bump stops. The induced force is large enough to cause large, geometrically nonlinear deformations. The deformation can be visually inspected in Figure 3 from different perspectives. It should be emphasized that the deformation is inspected in Figure 3 from different perspectives. It should be emphasized that the deformation is depicted in its actual size, i.e. with the deformation scaling factor equal to 1.

4 IMPLEMENTION OF A SHELL ELEMENT INTO THE CO-ROTATIONAL FORMULATION

4.1 *Handling the rotational degrees of freedom*

The efficient simulation of global deformational behavior of thin-walled structures is driven by the recognition that the nature of their global behavior allows condensation of the complex 3D field to the essential ingredients of the structural response described by a 2D approach. For this purpose, the authors use recently developed 9-node degenerate shell element (Marinkovic 2007) (Fig. 5).

The degenerate shell element has 3 translations and 3 rotations at each of the 9 nodes in the global coordinate system (x, y, z). The translations are handled in exactly the same manner as in the case of solid elements. To determine an average rotation of the element, an element local reference frame is introduced as depicted in Figure 5. The reference frame is determined by the element mid-node (node 9) and the mid-side nodes 5 and 6. The same nodes are used in both the original and the current configuration. As a matter of fact, one may define a tetrahedron by using those nodes and a point along the axis obtained by a cross-product of axes $\vec{v}_{95}$ and $\vec{v}_{96}$. This allows the use of exactly the same procedure as for the tetrahedral element to extract the rotation matrix.

The update of the rotational degrees of freedom is where the actual complexity with the shell element resides within a geometrically nonlinear formulation. The rotations do not share the same properties with the translations and cannot be simply rotated as it is done with the translations. Instead, the incremental rotations computed in each time-step are used to update the shell normals at each node. This is done by computing the

incremental rotation matrices of the shell normals as (Argyris 1982):

$$\mathbf{Q} = \mathbf{I} + \frac{\sin\gamma}{\gamma}\mathbf{S} + \frac{1}{2}\left(\frac{\sin\gamma}{\gamma}\right)^2 \mathbf{S}^2 \tag{2}$$

$$\text{with } \gamma = \sqrt{\theta_1^2 + \theta_2^2 + \theta_3^2} \tag{3}$$

$$\text{and } \mathbf{S} = \begin{bmatrix} 0 & -\theta_3 & \theta_2 \\ \theta_3 & 0 & -\theta_1 \\ -\theta_2 & \theta_1 & 0 \end{bmatrix} \tag{4}$$

where θ_1, θ_2 and θ_3 are the 3 incremental global rotations at the node. The rotation matrix $\mathbf{Q}$ is further used to update the orientation of the shell normal. By means of the inverse of the element rotation matrix, $\mathbf{R}_e^{-1}$, the updated normal is rotated back to the original configuration and the local 2 rotations are determined and used to compute the internal moments with respect to the original configuration. Finally, the internal moments are rotated to the current configuration using $\mathbf{R}_e$. Once both the internal forces and moments are computed and the element stiffness matrix is updated by means of rotation matrix, a static or dynamic computation may proceed.

4.2 *An example with the shell element*

A rather simple example is given below in order to compare the results by the rigorous geometrically nonlinear FEM and by the presented co-rotational FEM. In the original configuration, the considered structure's geometry is flat (50 × 30 × 3 mm) and considering the boundary conditions and the load, it could have been described as a plate (Fig. 7). The material is steel.

However, upon the deformation has been initiated, the behavior of the considered structure is actually that of a shell and the membrane effects gain more on importance as the deformation proceeds. The force of F = 12 kN is chosen so that significant geometrically nonlinear effects are observable in structural behavior. The deformation can be visually assessed in Figure 8 from different perspectives. Again, the deformation is shown in its actual size (scaling factor set to be 1) with both the initial and deformed configuration depicted.

The resulting displacements in the global x- and z-directions are summarized in the form of diagrams given in Figure 9. The z-displacement of the point of force application exceeds 25 mm, which is more than a half of the structure's length. The geometrically nonlinear effects are obvious in the obtained results. One may notice somewhat larger differences in the nonlinear results obtained with shell elements compared to the differences in the nonlinear results obtained with the tetrahedral element (Fig. 4). This fact is worth of discussion. There are a couple of reasons for this. Actually, one of the reasons has already been mentioned. Namely, the linear tetrahedral element has the unique rotation matrix, which describes the rotational motion of the element accurately. This is not the case with the full biquadratic shell element, i.e. in this case the matrix describing the rigid-body rotation is an averaged rotation matrix and this aspect certainly affects the accuracy. An additional reason should be sought in the differences in the shell element formulation used by the authors and the one from ABAQUS. The shell element from ABAQUS is an 8-node element with reduced integration and an hourglass control. The element applied here is the full biquadratic element with full integration implemented. Those differences in the element formulations actually lead to small differences in linear results as well, whereas the tetrahedral elements are identical and yield identical linear results.

5 FIELDS OF APPLICATION

The presented co-rotational FEM formulation offers a combination of the features originating from the linear and geometrically nonlinear FEM. It is more efficient and stable than the rigorous geometrically nonlinear FEM and covers geometrical nonlinearities up to a great extent. The authors use this formulation in a combination with an iterative preconditioned conjugate gradient solver. The solver provides further means to perform a "trade-off" between the accuracy and numerical effort by simply limiting the number of iterations in the solver. The solver is also a good choice for dynamic computations. Namely, the efficiency of the iterative solver can be noticeably improved by a reasonable choice of the starting vector of the iterative process. This is particularly interesting in dynamics with the system of equations solved for nodal velocities. The nodal velocities typically do not change dramatically within a time-step and, therefore, a good choice would be to take the nodal velocities from the previous time-step as a starting vector for the iterative solver in the next time-step. This improves the numerical efficiency of simulation as fewer iteration steps are needed to arrive to the solution.

With those features, the presented FEM formulation may find its application in all the systems where high numerical efficiency and consideration of geometrical nonlinearities are required and where a trade-off between the accuracy and computational efficiency may also be an option. Consideration of elastic structures in MBS dynamics is typically resolved in modal space, which intrinsically covers only linear deformations. However, adequate simulations of many structures require consideration of geometrical nonlinearities in order to reach a reasonable accuracy. An example of such a structure is the rear car axle shown in Figure 10. The crank arms of the axle may perform an average rotation of up to 15° over the course of the axle's deformation caused by a fast change of the car's driving direction. Simulation of such a deformation by means of a linear model yields results of insufficient accuracy for the prediction of the turning curve of the car.

Another interesting field of application is in virtual-reality simulators. A distinctive example of such a simulator would be a surgery simulator, particularly for the laparoscopic surgery. It is a type of surgery that minimizes the damage to surrounding tissue caused by reaching the location of intervention. Very difficult conditions (no direct contact with the operation site, 2D "on-screen" surgery monitoring, limited movability of surgery tools) give rise to a relatively high rate of surgeon errors with less experienced surgeons performing laparoscopic surgeries and, hence, adequate training tools are needed. They require plausible real-time simulation of internal organs' behavior. In this application, the real-time requirement has obviously the highest priority, while the accuracy requirement is not defined in terms of numbers and may be jeopardized as long as the on-screen behavior appears realistic to human perception. In many commercially available devices this goal is achieved by means of the simplest approach, namely the mass-spring systems, to realize geometrically nonlinear real-time simulations. The formulation presented in this paper offers a more sophisticated approach to simulate internal organs' deformation (Fig. 11) and still realizable in real-time.

In the entertainment industry, there is an ever growing tendency to use physics-based animation in order to achieve a higher degree of realism. In this field, the graphics requirements are always on the high end of achievable with the current hardware technology and, hence, highly efficient solutions are also sought for the background physics. The presented co-rotational FEM can also find its application in this field. Figure 12 shows deformations of a dog model over the

Figure 10. A model of a rear car axle used by VW for MBS dynamics.

Figure 11. Screen-shots from a real-time simulation of liver deformations determined by the presented co-rotational FEM.

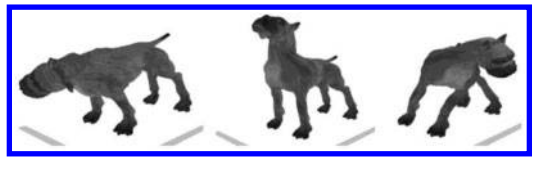

Figure 12. Screen-shots from an interactive simulation with a dog model.

course of an interactive simulation computed with the presented approach.

6 CONCLUSIONS

The paper presents the fundamental idea of the simplified co-rotational FEM formulation that covers geometrical nonlinearities by accounting for rigid-body rotation on the element level. It has been demonstrated that the method combines the advantages of the linear and geometrically nonlinear FEM. It permits performing a great deal of computation prior to the simulation, thus offering high numerical efficiency and stability. Regarding the accuracy, the limit of application of the presented approach depends on the requirements in the field of application and on the character of deformation. Rather high accuracy can be expected in the cases where local rotations dominate in the geometrically nonlinear behavior, while strains remain small. Deformational behavior with larger strains involved would require modification of the presented approach.

The formulation has been presented for solid and shell elements, the latter being more demanding due to the rotational degrees of freedom. Computing an average element rotation is an ambiguous issue for most elements. The linear tetrahedron is one of the rare elements with a unique rotation matrix. This is the major reason why this element yields very high agreement between the results obtained with this formulation and the results obtained by the rigorous geometrically nonlinear FEM. More attention should be given to the aspect of element rotation in the future work.

Several possible fields of application have been briefly discussed. The list includes MBS dynamics and the applications where interactive dynamics is required. However, this list is definitely not exhaustive. The features of modern hardware render this approach even more attractive, as the applied solver offers great parallelization potential. To take the full advantage of hardware's computation power, the computation could be switched from CPU to GPU (graphics processing unit), as modern GPUs contain a number of processors and give a massive floating-point computation power expressed in teraflops (10^{12} floating-point operations per second). This would certainly expand the list of possible applications of the presented approach.

Finite element modelling of shear tab connections including damage simulation

A. Mirzaei & C.A. Rogers
McGill University, Montréal, Canada

R. Tremblay
École Polytechnique de Montréal, Montréal, Canada

ABSTRACT: A common approach to connect steel beams to columns is to use shear tabs. Numerous laboratory test programs of these connections have been completed; however, the development of finite element models that accurately capture their behaviour lags behind. A series of full-scale lab tests were carried out at McGill University on "standard" and "non-standard" shear tab connections. The results from these tests were used in the development of a finite element model that is capable of simulating the response of the connection under load; predict the ultimate resistance and the progression of failure. The intent is to use the model for the future evaluation of shear tabs under extreme loading conditions such as combined axial and vertical forces. Previous finite element modelling of shear tabs lacked damage simulation capability, did not include the effect of weld tearing, and as such often overestimated the connection resistance. This paper will summarize the development of a finite element simulation model and provide a comparison with the laboratory results.

1 INTRODUCTION

1.1 *Shear tabs*

Single plate beam web connections, also known as shear tabs or fin plates, are one of the more common simple connections used in the steel construction industry. Shear tab connections are typically specified due to their cost efficiency, as well as ease of fabrication and installation on the construction site. They are usually used to connect girder beams to columns and secondary beams to girders. The connecting plate is welded to the supporting member in the fabrication shop. The connection between the supported beam's web and the steel plate is made by means of field-installed bolts.

1.2 *Research program*

The current design procedure used for shear tabs in Canada (CISC, 2010) is based on the research carried out by Astaneh (1989) and Astaneh et al. (1989); it has not been further developed. This approach is only applicable to shear tabs with one vertical row of 2 to 7 bolts connected to a rigid support (e.g., the flange of a W section column) or a flexible support (e.g., the web of a column or a girder) by using E49 fillet welds and A325 bolts. The current Canadian approach does not cover the usage of multiple vertical rows of bolts or the use of configurations with more than 7 bolts per vertical row. The size and thickness of the shear tab is further limited due to design restrictions. The existing design approach also does not address the application of combined shear and axial forces on the connection.

The objective of the global research project involves the development of shear tab design and detailing provisions to be used in Canada. It comprises full-scale laboratory testing and finite element (FE) modelling. The advantage of using finite element simulation is that the load level can easily be changed and more cases can be investigated in less time and with less cost compared to full-scale testing. The FE models described herein will be used in future studies to investigate the performance of the same shear tab connections under extreme loading conditions such as an axial plus gravity loading scenario. The validity of the FE models was verified by using data obtained from full-scale testing.

2 FULL-SCALE LAB TESTING

2.1 *Overview*

A series of full-scale laboratory tests was carried out by Marosi et al. (2011a, b) at McGill University on "standard" and "non-standard" shear tab connections subjected to gravity loads. Data collected from the tests were used to calibrate the FE models capable of simulating the test procedure and predicting the performance and ultimate shear resistance of the same tested shear tab connections.

2.2 *Test setup*

The test configuration used by Marosi et al. is shown in Figure 1 and its functionality schematic is illustrated in Figure 2. The shear tabs were shop welded to a W360x196 ASTM A992 Grade 50 ($F_y = 345$ MPa) column which was secured to the strong floor, minimizing column movement and rotation. The shear tabs, ASTM A572 Grade 50 ($F_y = 345$ MPa) hot rolled plate, were fillet welded on both sides using a flux-cored arc welding (FCAW-G) process along with an additional shielding gas (CO_2) and an E71T (480 MPa) electrode. An ASTM A992 Grade 50 ($F_y = 345$ MPa) test beam (Table 1) was used to transfer the forces from the actuators to the connection. A 12 MN actuator was responsible to create the main shear force in the connection. To eliminate friction and permit free rotation between the actuator head and the test beam's top flange a half steel cylinder, steel plate and roller system was used. The end of the beam was attached to a 269 kN actuator which limited the vertical displacement in order to control the rotation of the connection. ASTM A325 snug tight bolts, placed at a 76 mm spacing both vertically and horizontally (when applicable), were used to connect the shear tab to the test beam. A lateral bracing system was used which simultaneously allowed the test beam to displace vertically without lateral movement as illustrated in Figure 1. A target rotation of 0.02 rad for the W310 and 0.015 rad for the W610 and W920 beam connections at the predicted ultimate shear resistance was used for the loading protocol. A displacement based loading approach was used in which the relative displacement rate of the two actuators was controlled to attain the target rotation. A range of instrumentation was used to measure vertical, horizontal and rotational movements of the shear tab, test beam and column. To monitor the change in strain throughout the steel plate, strain gauges were installed on the shear tabs. The connection shear force was determined based on the data from load cells attached to the actuators. Table 1 contains a summary of the six test configurations that that were modelled in ABAQUS; additional information on the testing can be found in Marosi et al. (2011a, b).

Figure 1. Test setup used for Test #2 (Marosi et al. 2011a,b).

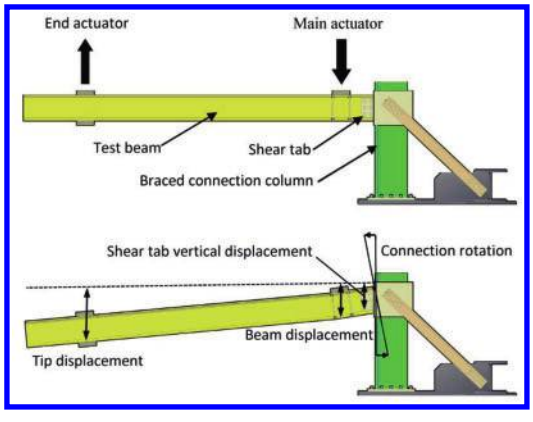

Figure 2. General schematic of the test functionality.

3 MATERIAL PROPERTIES

3.1 *Coupon testing and simulation*

In order to obtain an accurate FE simulation, material properties were determined by performing coupon tests on specimens cut from the plates and beams used for the connection tests by Marosi et al. Four coupons were extracted from the beam's flanges, three from the web, and three for each shear tab specimen. The

Table 1. Shear tab specimens tested by Marosi et al. (2011a, b).

Test No.	Shear tab size mm	Beam size	Bolt size mm	Row and number of bolts	Fillet weld size mm
1	228 × 89 × 6	W310 × 60	19	1 × 3	6
2	228 × 165 × 10	W310 × 60	19	2 × 3	6
7	456 × 102 × 8	W610 × 140	22	1 × 6	6
8	456 × 178 × 16	W610 × 140	22	2 × 6	10
13	760 × 102 × 10	W920 × 223	25	1 × 10	6
15	760 × 178 × 22	W920 × 223	25	2 × 10	14

results from the coupon tests were available in terms of engineering stress-strain curves. Since the FE package (ABAQUS) requires true stress-strain curves as an input, the coupon tests were modelled in ABAQUS such that the material model could be accurately calibrated with the test information. Tests were not conducted for the bolt material property; the nominal properties were converted into true stress and strain input instead. For the fillet welds, the same elastic and plastic data from the corresponding shear tab specimen were used, but with different damage parameters that were calibrated with the shear tab test data.

3.2 *Damage simulation*

The results from testing showed that the performance of the shear tabs was dependent on the ductility of the steel plate and the strength of the connecting weld. In tests where the weld started to tear, the shear tab continued to carry shear force until a point at which either cracks developed in the plate itself between the bolt holes or the weld was excessively fractured. For shear tabs in which the ultimate resistance was governed mainly by net area plate fracture with no tearing in the welds, the FE models without damage simulation could still approximate the ultimate shear resistance with reasonable accuracy. In contrast, for shear tabs that experienced weld tearing, the FE model without damage simulation overestimated the shear resistance and stiffness of the connection. Based on this initial observation a damage model was deemed essential for shear tab FE simulation since the failure mode is not necessarily known a priori.

The material damage simulation model is illustrated in Figure 3. At the onset of loading the material behaves elastically until it reaches point 1 (yielding point). Subsequently, the material experiences plastic deformation until it reaches point 2 at the ultimate stress level. At this point the damage parameter (D) is incorporated in the analysis. A ductile damage for metals initiation criterion was utilized, which is a function of triaxiality, fracture strain and strain rate. Determination of the damage parameters requires accurate measurement of the fractured coupons and recorded data of the post ultimate behaviour; therefore, for simplicity it was assumed for different levels of triaxiality that the fracture strain is 0.21 at a strain rate of 0.01/s. The damage initiation criterion controls when damage initiates and has no effect on the material unless equipped with damage evolution capability. Damage evolution controls the stiffness degradation parameter (D) by using an energy approach which is based on the fracture energy required for failure. Beyond point 2, through to point 3, the D parameter increases, leading to stiffness degradation (softening) of the material. At point 4, $D = 1.0$ which means the stiffness is absent, and as such the material cannot develop any stress. Generally steel never reaches point 4, therefore another parameter called the maximum stiffness degradation is used to determine where the material fails; it can be determined based on the post ultimate coupon test information. In cases where the data was not available a maximum stiffness degradation of 0.5 was used. Once D reaches its specified limit, an option exists to remove the degraded elements from the global stiffness matrix or to keep them in the system although having a degraded stiffness. Element removal results in a modification to the global system stiffness and gives the ability to redistribute stresses in the connection to compensate for the loss of stiffness, at weld fractures for example (Simulia, 2011).

As an example, Figure 4 shows the effect of the damage model in the simulation of a coupon extracted from the shear tab specimen used in Test #2; Figure 5 shows the corresponding stress-strain curve.

4 CONNECTION FINITE ELEMENT MODEL

4.1 *General simulation strategy*

A 3D solid finite element model was used for simulation, which includes the beam, column, shear tab, bolts, washers, welds and load blocks (Figure 6). The different components of the test setup modelled in ABAQUS were assumed to be homogeneous and deformable solids. For mesh design, two different element types were used for modelling. An 8-node cubic 3D element with full linear integration (C8 element) was used to model most parts except for locations where the geometry conditions had curvature involved (such as the bolts or the curve between the flange and web of the beam). A 6-node linear triangular prism 3D element (C3D6 element) was used to model these geometric conditions. The lateral brace mechanisms used in the full-scale testing were simulated by applying a boundary condition to the beam flanges to prevent lateral displacements but allow for other degrees of freedom to displace and rotate. The loading generated from the main actuator and tip actuator was applied as a displacement boundary condition to the load blocks that have a frictionless interaction defined at their interface with the beam's flange. The load block had the feature to rotate freely as it displaces to simulate the half cylinder–roller system used for applying the main load in the lab tests.

To allow for weld tearing, the mesh assembly in Figure 7 was used. The problem with classical FE models is that all the components are usually modelled as one individual part, which would result in shared nodes between the shear tab, weld and supporting member. This would limit the ability to capture the shear tab separation from the column and would result in incorrect stresses in the weld leading to over-estimated shear resistance of the connection. To resolve this issue the steel plate, including an interface layer of 2 wedge elements on each side, was assembled as a separate part distinct from the column. The interface layer of wedge elements, which physically would be part of the weld, was tied with a tie constraint to the fillet weld. A contact interaction was also used between the vertical edge of the plate and the column flange which included a separation allowance. By using this technique and applying the damage properties to the shear tab and weld, tearing simulation was made possible. Once damaged, the weld was able to tear resulting in separation of the shear tab on top and a more accurate compression stress distribution at the bottom of the shear tab due to contact with the column. The thickness of the wedge layer was minimized while still satisfying mesh quality requirements. By utilizing damage and weld tearing in the simulation, the final deformed shape of the FE models showed significant improvement in the failure progression of the connection compared to preliminary FE models which lacked these features.

The element removal feature was used for the fillet weld properties in all tests, but was not used in the shear tab mesh for some tests. Removing an element from a mesh that is part of an interaction property (such as a contact) causes numerical instability. The software

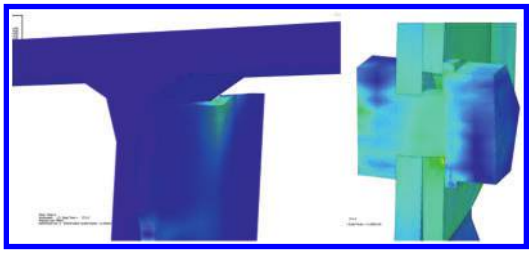

Figure 8. Cross sectional view of the contact between the shear tab and the test beam (left), stress distribution in a bolt (right).

was still capable of reassigning the interaction surfaces after element removal but the procedure would not always be executed to completion due to numerical instability. Initial modelling attempts included the element removal feature in the plate but when numerical instabilities occurred it was itself removed, while the stiffness degradation was kept functional. Using the damage modelling in the simulation increased the running time but resulted in a more realistic behaviour of the connection as compared with laboratory tests.

4.2 *Contact interactions*

The FE model included many contact interactions. These contacts were assigned tangential behaviour with a friction coefficient of 0.3 and normal behaviour with separation allowance; all were defined as surface-to-surface contacts. Bearing simulation at bolt surfaces was achieved by the contact between a bolt's outer surface and the surface of the inner hole on the beam web and the shear tab. The diameter used for the bolt was the same as the diameter of the hole on the shear tab. The reason for selecting the same diameter is that in the FE model the 2 mm space gap between the bolts with the holes cannot exist due to continuity of the interaction surfaces. Since each bolt was assembled as an individual part in the FE assembly, this technique allowed for stability of the assembly at the initial stage of the analysis. Figure 8 shows a cross section of a bolt from the FE model for Test #1. The contour shows the von Mises stress distributed inside the bolt which is caused mainly due to shear stress.

Other contacts simulated were: contact between the shear tab and the beam web, washers with the shear tab, and the shear tab with the column flange. Additional contacts that were observed during lab testing were also embedded in the models such as the contact of the top of the shear tab with the curve between the beam flange and web (Figure 8). Based on observations during testing tearing of the fillet welds was influenced by the contact between the top of the shear tab and this region of the beam.

5 RESULTS

The FE models were capable of simulating the behaviour and progressive damage observed in the six shear tab tests by Marosi et al. Most of the FE model analyses where able to run completely but some terminated at just over 90% of the testing procedure due to numerical instabilities after damage evolution. Figure 9 compares the final deformed shape of the shear tab specimen of Test #1 with its corresponding FE model (bolts have been removed to show the plate deformation). The shear tab experienced flexural and shear plastic yielding between the bolt line and the fillet weld. Weld tearing can be observed on top of the shear tab in both the model and test. Figure 10 demonstrates net area failure simulation in the FE models, which in this case was combined with weld fracture. During testing cracks developed in the shear tab between the four centre bolt holes. The same damage progression was observed in the FE model (with damaged element removal capability), which demonstrates the ability of the model to simulate net area failure.

The shear tab vertical displacement and connection rotation versus the shear force were selected as the

*Actuators reached maximum stroke prior to connection failure

criteria for comparing the response from FE simulation with the lab test results. Figure 11 demonstrates the response curves of Test #13. Some alterations are observed in the deformation due to the simulation technique, slippages between the components during the testing process, errors in the instrumentation, equipment, etc. Nevertheless, in terms of connection shear resistance the FE models were able to predict the ultimate shear resistance of the connection with a very good accuracy. Table 2 contains a listing comparing the predicted (by hand calculation), tested and FE simulated shear resistance of the test configurations. The predicted shear resistance was calculated based on Marosi et al.'s modified AISC (2005) extended shear tab method using a resistance factor, ϕ, of 1.0 and actual material properties from coupon testing. The predicted shear resistances underestimated the measured resistances of the connections whereas FE simulation results are all very close to the experimental results.

6 CONCLUSION

A series of finite element models representing six full-scale shear tab tests were created to replicate the laboratory testing procedure and connection configuration. The simulation strategy with appropriate material properties and equipped with a damage model was able to simulate weld tearing and net area fracture of the connections. The results showed the capability of ABAQUS to closely match the shear tabs behaviour observed in previous test programs, which has provided confidence in the models and their potential use for the evaluation of other loading scenarios.

Nonlinear static and dynamic analysis of an electrically-actuated microbeam modelled by means of the strain gradient elasticity theory

Pierpaolo Belardinelli & Stefano Lenci
Department of Civil and Building Engineering, and Architecture, Polytechnic University of Marche, Ancona, Italy

ABSTRACT: The main goal of this work is to investigate the static and the dynamic behaviour of an electrically-actuated microbeam modelled by means of the strain gradient elasticity theory. Considering the nonlinearities due to the mid-plane stretch and of the applied electric force, a numerical solution for the static response is obtained by the differential quadrature method including also the features introduced by the non-classical continuum theory. A parametric analysis confirms the well-known hardening effect generated by a tensile applied axial load and highlights the variation of the deflection with respect to the high-order material parameters. We propose an approximate model, for the electric force acting on the microbeam, using the Chebyshev method. An accurate model, so that the error is spread smoothly over the domain, is then analysed with a single-degree-of-freedom model. Particular attention is paid to find the influence of the high-order length scale material parameters, introduced by the non-classical theory, that progressively modify the oscillating behaviour.

1 INTRODUCTION

Control and design of Micro-electro-mechanical systems (MEMS) is, nowadays, a fundamental step in widely different engineering fields. Other than mechanical application, as micro switches, micro-electromechanical silicon resonators (Mestrom, Fey, van Beek, Phan, & Nijmeijer 2008), biological and biomedical applications have become field of particular interest with widespread use in a variety of activities.

The mechanical modeling of an electrically-actuated microbeams, is, often, based on the classical mechanics (Abdel Rahman, Younis, & Nayfeh 2002). Recently, the modeling in microstructures is moving towards the non-classical continuum theories (Kahrobaiyan, Asghari, Rahaeifard, & Ahmadian 2011). The deformation, when the characteristic length is on the micro scale order, has been shown to be size dependent (Yang, Chong, Lam, & Tong 2002), and high-order elastic theories can catch this phenomena. The non-classical approach increments the order of the governing differential equations introducing high-order length scale material parameters (Fleck & Hutchinson 1997, Mindlin & Tiersten 1962). This work wants to apply the modified strain-gradient elasticity proposed by (Lam, Yang, Chong, Wang, & Tong 2003) at an electrically-actuated clamped-clamped microbeam.

Other aim of this work is to derive an alternative, more efficient, method to approximate the electric actuation. Although with few terms of a Taylor series we cannot achieve an uniform error, we want to show, using the Chebyshev method, how to limit the error into a specified constrains. The purpose is, thus, to formulate an expression that can be successfully applied in all prescribed domains with a limited and reduced approximation error. The work done in (Younis, Abdel-Rahman, & Nayfeh 2003) shows a comparison between a more complicated exact solution and the Taylor series approximation. The method of differential quadrature, introduced by Bellman (Bellman, Kashef, & Casti 1972) is here used to analyse the static behaviour of the electromechanical model. It works approximating all the partial derivatives by a weighted linear sum of the function values at given discrete points. We also investigate, in the last section of the paper, on the discretized dynamical problem with a Galerkin procedure, evaluating the single-degree-of-freedom response as function of different parameters.

2 PROBLEM FORMULATION

The strain energy density (here named s), considering the strain-gradient elasticity theory, is a function both of the strain tensor ε_{ij} and of the second-order deformation gradient tensor η_{ijk}, defined respectively as:

$$\varepsilon_{ij} = \frac{1}{2}\left(u_{i,j} + u_{j,i}\right), \quad \eta_{ijk} = u_{k,ij}, \tag{1}$$

being u_i the components of the displacement vector. The Einstein's notation for partial derivatives is used. Considering the variation of the strain energy:

$$\delta s = \frac{\partial s}{\partial \varepsilon_{ij}}\delta\varepsilon_{ij} + \frac{\partial s}{\partial \eta_{ijk}}\delta\eta_{ijk}, \tag{2}$$

we can identify, as suggested in (Mindlin 1965), the Cauchy stress tensor $\sigma_{ij} = \partial s / \partial \varepsilon_{ij}$ and of the double stress tensor $\tau_{ijk} = \partial s / \partial \eta_{ijk}$.

The double stress tensor and the second-order deformation gradient can be recasted in such a way that:

$$\delta s = \sigma_{ij}\delta\varepsilon_{ij} + \tau^{(0)}_{ijk}\delta\eta^{(0)}_{ijk} + \tau^{(1)}_{ijk}\delta\eta^{(1)}_{ijk} + \tau^{a}_{ijk}\delta\eta^{a}_{ijk} \tag{3}$$

where with the apexes ^{s} and ^{a}, $^{(0)}$ and $^{(1)}$, are indicated the symmetric and antisymmetric, trace and traceless parts of the tensors. The second-order virtual work density can be rearranged using the dilatation gradient γ_i, the deviatoric stretch gradient $\eta^{(1)}_{ijk}$ and the symmetric part of the rotational gradient χ^s_{ij}, which are defined by:

$$\gamma_i = \varepsilon_{mm,i},$$
$$\eta^{(1)}_{ijk} = \frac{(\varepsilon_{jk,i} + \varepsilon_{ki,j} + \varepsilon_{ij,k})}{3} - \frac{\delta_{ij}(\varepsilon_{mm,k} + 2\varepsilon_{mk,m})}{15} \tag{4}$$

$$- \frac{[\delta_{jk}(\varepsilon_{mm,i} + 2\varepsilon_{mi,m}) + \delta_{ki}(\varepsilon_{mm,j} + 2\varepsilon_{mj,m})]}{15}, \tag{5}$$

$$\chi^s_{ij} = \frac{1}{2}(e_{ipq}\varepsilon_{jp,q} + e_{jpq}\varepsilon_{ip,q}). \tag{6}$$

δ_{ij} is the Kronecker delta and e_{ijk} the Levi-Civita alternating tensor, see Section 2.2 of (Lam, Yang, Chong, Wang, & Tong 2003) for details.

By the previous developments, the first variation δs of the strain energy becomes

$$\delta s = \sigma_{ij}\delta\varepsilon_{ij} + p_i\delta\gamma_i + \tau^{(1)}_{ijk}\delta\eta^{(1)}_{ijk} + m^s_{ij}\delta\chi^s_{ij} \tag{7}$$

where the conjugate static terms σ_{ij}, p_i, $\tau^{(1)}_{ijk}$, m^s_{ij} are defined by the constitutive functions (Zhao, Zhou, Wang, & Wang 2012):

$$\sigma_{ij} = 2\mu\left(\varepsilon_{ij} + \frac{\nu}{1-2\nu}\varepsilon_{mm}\delta_{ij}\right), \tag{8}$$

$$p_i = 2\mu l_0^2\gamma_i, \tag{9}$$

$$\tau^{(1)}_{ijk} = 2\mu l_1^2\eta^{(1)}_{ijk}, \tag{10}$$

$$m^s_{ij} = 2\mu l_2^2\chi^s_{ij}. \tag{11}$$

l_n $(n = 0; 1; 2)$ are the material length parameters related, respectively, to p_i, $\tau^{(1)}_{ijk}$ and m^s_{ij}; ν is the Poisson's ratio and μ the Lamé's second parameter.

We use the extended Hamilton's principle, to get the equations of motion for an electrically-actuated slender microbeam:

$$\delta\int_{t_1}^{t_2}(T - \Pi + W_{nc} + U_e)\,dt = 0, \tag{12}$$

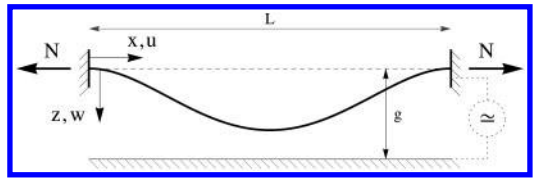

Figure 1. 1-D model for the electrically-actuated microbeam.

where T and Π are the kinetic and the elastic energy, while W_{nc} and U_e represent the non-conservative energy and the electric potential energy stored in the parallel plate capacitor. The kinetic energy of the beam in its variational form, being u and w the longitudinal and the transversal displacements (see Figure 1), is given by:

$$\delta T = \int_0^L \rho A\,(\dot{u}\delta\dot{u} + \dot{w}\delta\dot{w})\,dx \tag{13}$$

The dot is used to represent time differentiation. Integrating by parts in time with the assumption that the true and the varied paths coincide at t_1 and t_2 ($\delta u(x,t_1) = \delta u(x,t_2) = 0$ and $\delta w(x,t_1) = \delta w(x,t_2) = 0$) we have:

$$\delta T = -\rho A\int_0^L (\ddot{u}\delta u + \ddot{w}\delta w)\,dx. \tag{14}$$

The variation δW_{nc} due to the mechanical damping c, is expressed by:

$$\delta W_{nc} = \int_0^L (-c\dot{w})\,\delta w dx. \tag{15}$$

The variational form of the electric energy in a parallel plate capacitor reads (Fargas Marques, Costa Castello, & Shkel 2005):

$$\delta U_e = -\frac{1}{2}\int_0^L \left(\frac{\varepsilon_0\varepsilon_r bV^2}{(g-w)^2}\delta w\right)dx. \tag{16}$$

The elastic energy variation is represented by the volume integral of the strain energy density given in (7):

$$\delta\Pi = \int_V \left(\sigma_{ij}\delta\varepsilon_{ij} + p_i\delta\gamma_i + \tau^{(1)}_{ijk}\delta\eta^{(1)}_{ijk} + m^s_{ij}\delta\chi^s_{ij}\right)dV. \tag{17}$$

The mechanical problem, associated to the analysed slender microbeam, is formulated under the assumption of the nonlinear Euler-Bernoulli theory. Considering a second order axial stretch, the only non-null component of the strain tensor is:

$$\varepsilon_{xx} = \frac{\partial u}{\partial x} + \frac{1}{2}\left(\frac{\partial w}{\partial x}\right)^2 - z\frac{\partial^2 w}{\partial x^2} \tag{18}$$

in which the last term on the right hand side of the equation represents the deformation curvature of the beam. The higher-order deformations are given by (4, 5, 6) using ε_{xx}:

$$\begin{aligned}
&\gamma_x = \varepsilon_{xx,x} = \frac{\partial^2 u}{\partial x^2} + \frac{\partial w}{\partial x}\frac{\partial^2 w}{\partial x^2} - z\frac{\partial^3 w}{\partial x^3},\\
&\gamma_z = \varepsilon_{xx,z} = -\frac{\partial^2 w}{\partial x^2},\\
&\eta^{(1)}_{xxx} = \frac{2}{5}\varepsilon_{xx,x}, \qquad \eta^{(1)}_{xxz} = \eta^{(1)}_{zxx} = \eta^{(1)}_{xzx} = \frac{4}{15}\varepsilon_{xx,z},\\
&\eta^{(1)}_{xyy} = \eta^{(1)}_{xzz} = \eta^{(1)}_{yxy} = \eta^{(1)}_{yyx} = \eta^{(1)}_{zxz} = \eta^{(1)}_{zzx} = \frac{1}{5}\varepsilon_{xx,x},\\
&\eta^{(1)}_{yyz} = \eta^{(1)}_{yzy} = \eta^{(1)}_{zyy} = -\frac{1}{15}\varepsilon_{xx,z}, \qquad \eta^{(1)}_{zzz} = -\frac{1}{5}\varepsilon_{xx,z},\\
&\chi^s_{xy} = \chi^s_{yx} = \frac{1}{2}\varepsilon_{xx,z}.
\end{aligned} \tag{19}$$

The higher-order stresses component acting on the beam can be found inserting (19) into the constitutive functions (9, 10, 11); moreover for the only non-zero term in Cauchy stress tensor we have:

$$\sigma_{xx} = E\left(\frac{\partial u}{\partial x} + \frac{1}{2}\left(\frac{\partial w}{\partial x}\right)^2 - z\frac{\partial^2 w}{\partial x^2}\right). \tag{20}$$

with E the Young's modulus (Akgoz & Civalek 2011).

The variational form of the elastic energy, after an integration along the thickness and the width of the beam, using primes to indicate spatial derivatives, becomes:

$$\begin{aligned}
\delta\Pi = \int_0^L &[D_1 w''\delta w'' + D_2 w'''\delta w''' +\\
&+EA\left(u' + \frac{1}{2}w'^2\right)(\delta u' + w'\delta w') + D_3(u'' + w'w'')\times\\
&\times(\delta u'' + w''\delta w' + w'\delta w'')]\,dx
\end{aligned} \tag{21}$$

with:

$$\begin{aligned}
&D_1 = EI + \mu A\left(2l_0^2 + \frac{8}{15}l_1^2 + l_2^2\right),\\
&D_2 = \mu I\left(2l_0^2 + \frac{4}{5}l_1^2\right), \qquad D_3 = \mu A\left(2l_0^2 + \frac{4}{5}l_1^2\right).
\end{aligned} \tag{22}$$

After some parts integrations, we get the governing equations of motion; we can also specify the boundary conditions in such way that all the terms due to the integrations by parts vanish. The equations:

$$w = w' = 0 \quad \text{at} \quad x = 0, L \tag{23}$$

and

$$w'' = 0 \quad \text{at} \quad x = 0, L. \tag{24}$$

are respectively the classical (equation (23)) and non-classical (equation (24)) transverse boundary conditions, associated with the microbeam clamped at both edges. For the longitudinal direction we take

$$u(0,t) = 0 \quad \text{and} \quad u(L,t) = LN_0 \tag{25}$$

for the classical boundary conditions, while

$$\left(u' + w'^2/2\right)' = 0 \quad \text{at} \quad x = 0, L \tag{26}$$

are the higher order ones.

Using equations (14, 15, 16, 21), separating the transverse and longitudinal equation and, finally, condensing the longitudinal equation of motion into the vertical equation, as frequently used in slender microbeam with negligible longitudinal inertia (Rega 2004), we have:

$$\begin{aligned}
&\rho A\ddot{w} + c\dot{w} + D_1 w^{iv} - D_2 w^{vi} =\\
&= EA\left(N_0 + \frac{1}{2L}\int_0^L w'^2 dx\right)w'' + \frac{\varepsilon_0\varepsilon_r b V^2}{2(g-w)^2}.
\end{aligned} \tag{27}$$

2.1 *Dimensionless problem*

Introducing the following dimensionless variables:

$$w^* = \frac{w}{g}, \quad x^* = \frac{x}{L}, \quad t^* = \sqrt{\frac{\rho A L^4}{D_1}}t, \tag{28}$$

the dimensionless form for the governing equation is:

$$\begin{aligned}
&\frac{\partial^4 w^*}{\partial x^{*4}} - \alpha_3\frac{\partial^6 w^*}{\partial x^{*6}} + c\frac{\partial w^*}{\partial t^*} + \frac{\partial^2 w^*}{\partial t^{*2}} =\\
&= \left(N + \alpha_1\int_0^1\left(\frac{\partial w^*}{\partial x^*}\right)^2 dx^*\right)\frac{\partial^2 w^*}{\partial x^{*2}} + \frac{\alpha_2 V^2}{(1-w^*)^2}.
\end{aligned} \tag{29}$$

The previous equation takes into account, through the parameter N, an externally applied load, while the geometric nonlinearity due to the axis elongation is also considered by means of the integro-differential term. The associated dimensionless boundary conditions are:

$$w^* = \frac{\partial w^*}{\partial x^*} = \frac{\partial^2 w^*}{\partial x^{*2}} = 0 \quad \text{in} \quad x^* = 0, 1. \tag{30}$$

The dimensionless constants and parameters in (20) are defined as follows:

$$\begin{aligned}
&\alpha_1 = \frac{EAg^2}{2D_1}, \quad \alpha_3 = \frac{D_2}{D_1 L^2}, \quad c = \frac{\hat{c}L^4}{\sqrt{\rho A L^4 D_1}},\\
&N = \frac{EAN_0 L^2}{D_1} \qquad \alpha_2 V^2 = \frac{bL^4\varepsilon}{2D_1 g^3}V^2,
\end{aligned} \tag{31}$$

where $V(t) = V_{dc} + V_{ac}(t)$ is the applied electric voltage.

In the following sections we work with dimensionless variables avoiding the upper stairs for the sake of simplicity.

3 SOLUTIONS APPROACH

Neglecting all time dependences in (29), we get the steady state problem:

$$w_s^{iv} - \alpha_3 w_s^{vi} - \left[N + \alpha_1 \int_0^1 {w'_s}^2 dx\right] w_s'' = \frac{\alpha_2 V_{dc}^2}{(1-w_s)^2}, \quad (32)$$

where $w_s = w_s(x)$ is the nondimensional static transversal deflection. The static boundary conditions are:

$$w_s = w_s' = w_s'' = 0 \quad \text{at} \quad x = 0, 1. \quad (33)$$

We solve numerically the static problem with the differential quadrature method approximating the derivative of the function at a specific grid point by a linear weighted summation of all the grid point values over the whole computational domain.

In order to solve the problem given by equations (29, 30), we look for a solution that is the sum of a static (w_s) and a dynamic (w_d) response of the system:

$$w(x,t) = w_s(x) + w_d(x,t). \quad (34)$$

Now we look for an optimal approximation series of the last term on the right side of equation (29), containing the dynamic term at the denominator. We write:

$$\frac{\alpha_2 V^2}{(1 - w_d/(1-w_s))^2} = \alpha_2 V^2 \sum_{k=0}^{\infty} \tilde{c}_k P_k \quad (35)$$

in which $\tilde{c}_k$ are the series coefficients, and $P_k = P_k\left(\frac{w_d}{(1-w_s)}\right)$ are the series polynomials. A classic approach consists of using the Taylor series expansion ($P_k = \left(\frac{w_d}{1-w_s}\right)^k$), which is characterized by a very small error around the center of the expansion. The alternative applied in this work is represented by the use of the Chebyshev polynomials ($P_k \propto \cos\left(k \arccos\left(\frac{w_d}{1-w_s}\right)\right)$), spreading smoothly the error over the domain. Using (34) and retaining up to the third order ($k = 3$) term in the power series (35) we have:

$$\begin{aligned} &w_s^{iv} + w_d^{iv} - \alpha_3 w_s^{vi} - \alpha_3 w_d^{vi} + c\dot{w}_d + \ddot{w}_d + \\ &- \left[N + \alpha_1 \int_0^1 \left({w'_s}^2 + 2w'_s w'_d + {w'_d}^2\right) dx\right](w_s'' + w_d'') = \\ &= \frac{\alpha_2 (V_{dc}^2 + 2V_{dc}V_{ac} + V_{ac}^2)}{(1-w_s)^2} \sum_{i=0}^{3} \frac{c_i}{(1-w_s)^i} w_d^i, \end{aligned} \quad (36)$$
