$$T_{HF} = 6.35t - 160 \quad (42 \le t \le 110) \quad (2a)$$
$$T_{HF} = 12.11t - 790 \quad (110 < t) \quad (2b)$$
$$T_{CF} = 6.07t - 230 \quad (55 \le t) \quad (2c)$$

3) LSF wall lined on both sides by two layers of plasterboard with glass fibre used as cavity insulation (Test 3*).

$$T_{HF} = 11.17t - 490 \quad (53 \le t) \quad (3a)$$
$$T_{CF} = 4.92t - 225 \quad (66 \le t \le 96) \quad (3b)$$
$$T_{CF} = 12.04t - 915 \quad (96 < t) \quad (3c)$$

4) LSF wall lined on both sides by two layers of plasterboard with rockwool used as cavity insulation (Test 4*).

$$T_{HF} = 10.2t - 435 \quad (53 \le t) \quad (4a)$$
$$T_{CF} = 4.06t - 165 \quad (66 \le t) \quad (4b)$$

5) LSF wall lined on both sides by two layers of plasterboard with cellulose fibre used as cavity insulation (Test 5*).

$$T_{HF} = 8.94t - 360 \quad (53 \le t \le 106) \quad (5a)$$
$$T_{HF} = 19.83t - 1530 \quad (106 < t) \quad (5b)$$
$$T_{CF} = 3.83t - 150 \quad (66 \le t \le 106) \quad (5c)$$
$$T_{CF} = 17t - 1550 \quad (106 < t) \quad (5d)$$

6) LSF wall lined on both sides by two layers of plasterboard with glass fibre used as external insulation (Tests 1 & 2).

$$T_{HF} = 0.001007t^3 - 0.1605t^2 + 12.15t - 205 \quad (43 \le t) \quad (6a)$$
$$T_{CF} = 0.0904t^2 - 9.56t + 350 \quad (61 \le t) \quad (6b)$$

7) LSF wall lined on both sides by two layers of plasterboard with rockwool used as external insulation (Tests 3 & 6*).

$$T_{HF} = -0.000212t^3 + 0.0931t^2 - 5.47t + 100 \quad (71 \le t) \quad (7a)$$
$$T_{CF} = 0.0586t^2 - 6.69t + 260 \quad (81 \le t) \quad (7b)$$

8) LSF wall lined on both sides by two layers of plasterboard with cellulose fibre used as external insulation (Test 7*).

$$T_{HF} = -0.000286t^3 + 0.1024t^2 - 2.92t - 100 \quad (71 \le t) \quad (8a)$$
$$T_{CF} = 0.0846t^2 - 9.5t + 320 \quad (81 \le t) \quad (8b)$$

4 FINITE ELEMENT MODELS

A finite element model of LSF wall studs (Fig. 2) was developed with appropriate thermal and structural boundary conditions to simulate the behaviour of LSF wall studs under standard fire conditions and to determine the FRR. Finite element analyses were conducted under steady state conditions. Here, the

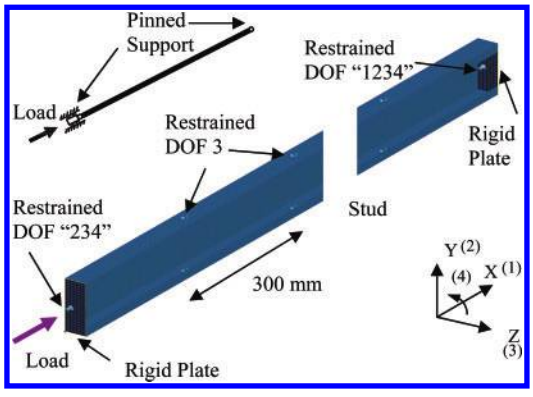

Figure 2. Loading and boundary conditions used in FEA.

non-uniform temperature distributions in the steel stud cross-section were raised to the target levels at any given time during the standard fire and then maintained. A load was then applied in increments until the failure of LSF wall stud.

Based on other numerical studies and the experimental behaviour of LSF wall studs, one of the two central studs that had the vertical plasterboard joint against it was considered in the analyses. Pinned support conditions were simulated for studs using rigid plates while an axial compressive load was applied at the section centroid at one end as shown in Figure 2. It was assumed that the plasterboards screw-fixed to both flanges provided sufficient lateral restraint until the failure of studs (Kaitila 2002, Feng et al. 2003 and Zhao et al. 2005).

S4R shell element type with a 4 mm × 4 mm mesh size was selected based on detailed convergence studies. Nominal mechanical properties and idealised time-temperature profiles using the predictive equations were used (Equations 1–8). The yield strength and elastic modulus reduction factors at elevated temperatures and the stress-strain curves were based on the predictive equations developed in Dolamune Kankanamge & Mahendran (2011). The strain hardening material model was used for steels with gradual yielding type stress-strain curve except for G250 steels at 20°C, 100°C and 200°C for which an elastic-perfect plastic material model was used (Dolamune Kankanamge & Mahendran 2011) as they had a well defined yield point. The coefficient of thermal expansion given in Eurocode 3 Part 1.2 (2005) was used.

The first eigen mode of the elastic buckling analyses was used to introduce the initial geometric imperfection with an amplitude of 0.006b. The residual stresses were not considered in the modelling of studs under fire conditions since they are insignificant at elevated temperatures.

Under fire conditions, many steady state analyses conducted in close time intervals led to a load ratio (ultimate load of stud in fire conditions / ambient temperature capacity) versus failure time (FRR) curve for the LSF wall systems. Figure 3 shows this curve for the

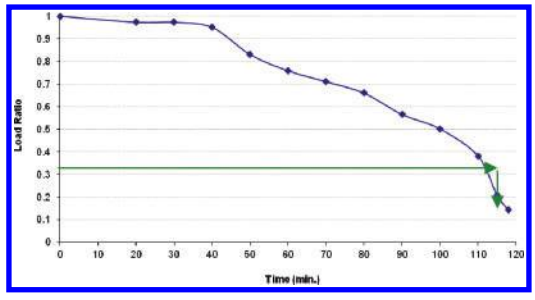

Figure 3. Variation of load ratio with time.

case of LSF wall with glass fibre external insulation. As shown in the figure, the failure time for Test 1 with a load ratio of 0.2 was obtained as 115 minutes. The main advantage of FEA with steady state conditions is that figures such as Figure 3 can now be used to obtain the fire resistance rating (failure time) for any given load ratio. Table 3 gives the failure times predicted by FEA under steady state conditions for all the tests. These comparisons show that the developed finite element model accurately predicts the ultimate capacities and failure times of LSF wall studs subjected to axial compression under standard fire conditions. Further details on the development and validation of the finite element model can be found in Gunalan and Mahendran (2013).

The results from finite strip analyses (CUFSM) and tests (Gunalan et al., 2013) were used to validate the results of finite element analyses (FEA). The validated finite element model was used in a detailed parametric study into the fire performance of LSF wall panels using a 90 × 40 × 15 stud section.

5 SIMPLIFIED DESIGN METHOD BASED ON THE CRITICAL HOT FLANGE TEMPERATURE

Lawson (1993) adopted the so-called limiting temperature method used for hot-rolled steel structures to cold-formed thin-walled steel structures. In this method the limiting temperature is defined as a function of the load ratio of the structural member. The load ratio is the ratio between the load on the member at the fire limit state and the load carrying capacity of that member under ambient conditions. Kolarkar (2010) proposed simple design rules to determine the failure times of LSF walls by combining the yield stress reduction factors and idealised time-temperature profiles. The critical temperature (ie. the maximum hot flange temperature at failure) corresponding to a load ratio (strength reduction factor) was used with idealised time-temperature profiles to obtain the approximate failure times of each type of wall specimen.

In this study FEA results of eight wall configurations (Table 2) were used to determine the critical temperature of LSF wall studs. Figure 4 shows the variation of load ratio with hot flange temperature at failure for LSF walls with glass fibre, rockwool and

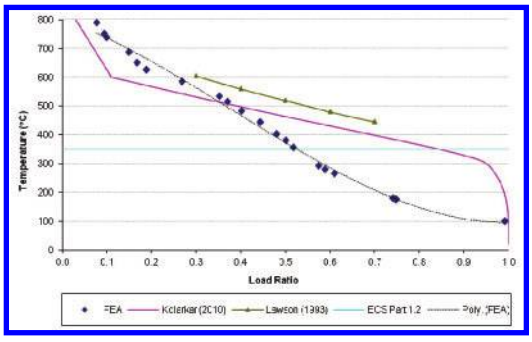

Figure 4. 1.15 mm G500 steel studs lined on both sides by two layers of plasterboards with cavity insulation.

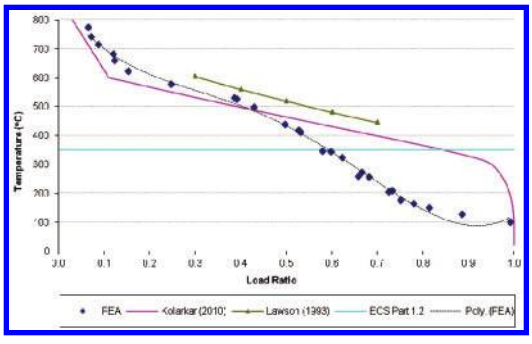

Figure 5. 1.15 mm G500 steel studs lined on both sides by two layers of plasterboards with external insulation.

cellulose fibre used as cavity insulations for 1.15 mm G500 steel studs. It is interesting to note the plots for different insulations merged together. This clearly indicates that the failure temperature of LSF wall studs does not depend on the type of insulation. In other words the effect of using different types of insulation is simply to delay the time to reach the same hot flange temperatures in the LSF wall studs. Similar behavior was observed in externally insulated wall panels as well (Fig. 5). The results of cavity and externally insulated wall panels did not merge when they were plotted together. This indicates that the arrangement of insulations and plasterboards influences the failure temperature although the type of insulation does not. Similar behavior was also observed for LSF wall studs made of G250 1.15 mm and 1.95 mm steels.

Eurocode 3 Part 1.2 (2005) recommends a limiting temperature value of 350°C irrespective of the load ratio as shown by a horizontal line in Figures 4 and 5. This did not agree with the FEA results. Kolarkar's (2010) and Lawson's (1993) design methods were also found to be unsuitable. Therefore it was decided to propose a new set of equations (Equations 9 to 20) to determine the critical hot flange temperatures at failure. These equations represent the temperature values ranging from 100°C to 800°C where T is the critical hot flange temperature in °C and LR is the load ratio. The load ratio was more than 0.90 when the hot flange temperature was below 100°C. Similarly the load ratio was less than 0.10 when the hot flange temperature was above 800°C. They were not included in the proposed equations.

1.15 mm G500 steel studs lined on both sides by A single layer of plasterboard

$$T = 1298LR^3 - 1894LR^2 - 14LR + 708 \quad (9)$$

Two layers of plasterboard

$$T = -527LR^3 + 895LR^2 - 1166LR + 825 \quad (10)$$

Two layers of plasterboard with cavity insulation

$$T = 196LR^3 + 428LR^2 - 1379LR + 854 \quad (11)$$

Two layers of plasterboard with external insulation

$$T = 870LR^3 - 1291LR^2 - 260LR + 768 \quad (12)$$

1.15 mm G250 steel studs lined on both sides by A single layer of plasterboard

$$T = -1300LR^3 + 2312LR^2 - 1927LR + 934 \quad (13)$$

Two layers of plasterboard

$$T = -1113LR^3 + 2583LR^2 - 2367LR + 968 \quad (14)$$

Two layers of plasterboard with cavity insulation

$$T = 863LR^3 - 990LR^2 - 581LR + 804 \quad (15)$$

Two layers of plasterboard with external insulation

$$T = 314LR^2 - 1136LR + 891 \quad (16)$$

1.95 mm G250 steel studs lined on both sides by A single layer of plasterboard

$$T = 866LR^2 - 1712LR + 938 \quad (17)$$

Two layers of plasterboard

$$T = 5455LR^4 - 10681LR^3 + 6727LR^2 - 2244LR + 868 \quad (18)$$

Two layers of plasterboard with cavity insulation

$$T = -1162LR^3 + 2085LR^2 - 1811LR + 920 \quad (19)$$

Two layers of plasterboard with external insulation

$$T = -708LR^3 + 1846LR^2 - 1995LR + 921 \quad (20)$$

In the simplified method proposed here to predict the fire resistance rating of LSF wall systems, Equations 9 to 20 predicting the limiting hot flange temperature of LSF wall studs are used with Equations 1 to 8 giving the idealised hot flange time-temperature

profiles. For one of the 24 LSF wall systems considered here (3 LSF wall stud cases with different steel grades and thicknesses X 8 wall configurations as shown in Table 2) with a given load ratio (LR), the limiting hot flange temperature can be found first by using Equations 9 to 20, which can then be used in Equations 1 to 8 to find the time required to reach the calculated limiting hot flange temperature. This is the fire resistance rating in minutes (stud failure time) for the selected wall system. Table 3 shows the fire resistance rating (failure times) of LSF walls predicted by the simplified method proposed in this section and the corresponding FEA and test results. This table shows that the results agree well.

6 CONCLUSIONS

This paper has presented the details of an investigation into the fire performance of LSF wall panels based on an extensive finite element analysis based parametric study and the results. The LSF wall panels with eight different plasterboard-insulation configurations were considered under standard fire conditions. This paper has developed two sets of equations to predict (1) the hot flange temperature as a function of time during a standard fire and (2) the critical (failure) hot flange temperature as a function of load ratio for LSF wall systems with varying plasterboard-insulation configurations. It then proposes a simplified design method to predict their fire resistance rating based on these two sets of equations.

Fire resistance assessment of steel structure exposed to fire for differentiated safety requirements

M. Maślak
Cracow University of Technology, Cracow, Poland

ABSTRACT: An alternative evaluation technique, helpful in fire resistance assessment of steel structure exposed to fire is presented and discussed in detail. The proposed calculation methodology deals with the probability-based approach and it is connected with the identification of the most probable failure point. Furthermore, the influence of model uncertainty, describing the steel mechanical properties reduction ratio under fire, is taken into account in this analysis. Conclusively, the critical steel temperature is obtained as the reliable safety measure for which the failure probability may not be accepted. Various levels of the acceptable failure probability can be assumed in such study. In the presented paper they are specified by the adoption of the adequate value of required reliability index β. The design algorithm, proposed by the author, is illustrated by simple example of uniformly heated unrestrained steel beam.

1 INTRODUCTION

The classical safety condition, commonly specified in many standards to determine ultimate limit state for considered structural member, deals with the comparison between two conclusive design values. The first one is usually identified for the reliable action effect, whereas the second - for the member resistance associated with this effect. It is a general knowledge that such approach is only the simplification of more detailed fully probabilistic calculation technique and, as a consequence, it leads to the solutions being always safe but frequently overestimated. However, this reassuring conclusion does not have to be correct in relation to structural analysis made for the accidental fire situation, therefore it seems to be advisable to look for the new, better justified algorithm which could be suggested for application in structural safety analysis for members under fire conditions. The aim of this paper is to present an alternative probability-based design methodology helpful in the evaluation of critical temperature of steel members exposed to fire. This temperature is connected to the point-in-fire-time when the considered member, with constant level of external loading, reaches fire resistance limit state under monotonically increasing steel temperature. Let us notice that such limit state does not mean the immediate member collapse but only the fire moment when the member failure probability becomes too high to be acceptable. The additional advantage of the proposed methodology is the possibility to take into account differentiated safety requirements being specified by means of the adoption of various levels of acceptable failure probability. Such concept is realized by the acceptance of particular values of required reliability index β. The design algorithm discussed in the presented paper is illustrated in detail by simple example of uniformly heated unrestrained steel beam.

2 THE PROPOSED DESIGN METHODOLOGY

2.1 *Alternative failure definition*

Let the failure be the case, defined for random realization, when random value of the reliable action effect becomes at least equal (or higher) to suitable random member resistance, associated with such effect and reduced because of the influence of high material temperature Θ_a. It means that for fire conditions then occurs $E_{fi} \geq R_{fi,\Theta}$. Furthermore, let us assume that the value of the reliable action effect is constant during the whole of fire time because there are no constraints for potential thermal deformations and owing to that no additional internal forces and moments are generated. Such definition leads to the conclusion that even if the random value of the conclusive action effect E_{fi} is unsafely high but at the same time the random member resistance $R_{fi,\Theta}$, compared to this effect, still remains higher, then this situation should be treated as fully acceptable in context of the structural safety analysis and, as a consequence, no failures are identified in the considered structure. Analogously, the same interpretation can be made for member resistance not large enough if only the corresponding action effect remains sufficiently small. As a result, the failure probability $p_f = P(E_{fi} \geq R_{fi,\Theta}) < p_{f,ult}$ is estimated. Its value is limited by the probability $p_{f,ult}$, being the maximum acceptable and specified, for example, as dependents on the assumed reliability class RC (according to EN 1990).

2.2 *Specification of limit state condition*

In further analysis only the simple case is discussed when both the action effect E_{fi} and the member resistance $R_{fi,\Theta}$ are random variables described by normal probability distribution (Maślak 2013). To obtain the value of the reliability index β considered random variables must be transformed into the standardized space. It is sufficient to take:

$$u_E = \frac{E_{fi} - m_E}{\sigma_E} \quad \text{and} \quad u_R = \frac{R_{fi,\Theta} - m_R}{\sigma_R} \tag{1}$$

which means that:

$$E_{fi} = m_E + u_E \sigma_E \quad \text{and} \quad R_{fi,\Theta} = m_R + u_R \sigma_R \tag{2}$$

In those formulae m_E and m_R are the suitable mean values, specified for the action effect and for the member resistance, respectively, whereas σ_E and σ_R are the adequate Gaussian standard deviations. As a consequence of such specification, the limit state condition, identified for considered value of Θ_a, leads to the linear equation:

$$R_{fi,\Theta} - E_{fi} = 0 \rightarrow m_R - m_E + u_R \sigma_R - u_E \sigma_E = 0 \tag{3}$$

To standardize this formula the quantity $\Xi = \sqrt{\sigma_E^2 + \sigma_R^2}$ is previously defined. As a result of its application one obtains:

$$\begin{aligned} &(m_R - m_E)/\Xi + (\sigma_R/\Xi)u_R - (\sigma_E/\Xi)u_E = \\ &= \beta + \alpha_R u_R - \alpha_E u_E = 0 \end{aligned} \tag{4}$$

Let us notice that such formula contains not only the reliability index equal to $\beta = (m_R - m_E)/\Xi$ but also the coefficients $\alpha_E = \sigma_E/\Xi$ and $\alpha_R = \sigma_R/\Xi$ being the direction cosines of the strain line connecting the origin of the Cartesian coordinate system (u_E, u_R) with the most probable failure point (closest to the origin and localized on the limit state surface). The value of $\Theta_{a,cr}$ is understood as the lowest steel temperature for which the beam failure probability p_f may not be accepted. This means that in the ultimate limit state occurs $\beta = \beta_{req}$. The required value β_{req} is explicitly connected with the maximum acceptable probability $p_{f,ult}$. Values of such index can be adopted adequately for the assumed safety requirements. In the example presented below three of them are examined in detail: $\beta_{req} = 4.3$ for range, $\beta_{req} = 3.8$ for moderate (ordinary) and $\beta_{req} = 3.3$ for minor required safety level. They are taken directly from the standard EN 1990 as those determining particular reliability classes: RC1, RC2 and RC3, respectively.

3 NUMERICAL EXAMPLE

3.1 *Description of the analysed steel beam*

To make easier interpretation of the methodology recommended by the author the case of unrestrained and simply supported steel beam is analysed in detail (Maślak 2012a). It is assumed that the span length is set at $L = 6$ m. Furthermore, the beam is made of the S235 grade steel and the IPE300 cross-section (belonging to class 1 according to EN 1993-1-1), for which $W_{pl} = 628\,\text{cm}^3$, is adopted for the study. The permanent load g and only one variable load q, both uniformly distributed, are applied to the beam. Let us assume that all considered external loads are random variables with normal probability distribution. In the presented example one has: $\overline{g} = 5$ kN/m, $\sigma_G = 0{,}3$ kN/m, $\overline{q} = 12$ kN/m, $\sigma_Q = 1{,}5$ kN/m, $\psi_2 = 0{,}3$ (ψ_2 is the ratio reducing the characteristic value of variable action to its quasi-permanent equivalent). Member resistance is proportional to the steel yield point, being the random variable with log-normal probability distribution $LN(\breve{f}_y, \upsilon_f)$. Its median value $\breve{f}_y$ can be estimated assuming that $\upsilon_f = 0.08$ – in accordance with numerous statistical data:

$$\begin{aligned} &\breve{f}_y = f_{y,k}\, exp(2\upsilon_f) = 235\, exp(2 \cdot 0{,}08) = \\ &= 275.8\ \text{MPa} \end{aligned} \tag{5}$$

Steel yield point is reduced if the beam is subject to fire exposure (reduction factors $k_{y,\Theta}$ are assumed according to the standard EN 1993-1-2):

$$f_{y,k,\Theta} = k_{y,\Theta} f_{y,k} = k_{y,\Theta} \breve{f}_y\, exp(-2\upsilon_f) \tag{6}$$

In further analysis the hypothesis that υ_f does not depend on the steel temperature is accepted. Such statement leads to the conclusion that:

$$\breve{f}_{y,\Theta} = k_{y,\Theta} \breve{f}_y \tag{7}$$

Moreover, it is assumed that the steel temperature monotonically rises during fire; nevertheless, at each particular fire moment the member temperature distribution is always uniform both in considered cross-section and along the beam length. This model is adequate for fully developed fire conditions and in general it may be qualified as the conclusive in structural analysis. Such simplification allows to conclude that also the plastic bending modulus W_{pl} does not change under fire exposure. Consequently, the median value of beam resistance can be calculated as follows:

$$\begin{aligned} &\breve{R}_{fi,\Theta} = W_{pl} k_{y,\Theta} \breve{f}_y = 628 \cdot 10^{-6} \cdot k_{y,\Theta} \cdot 275.8 \cdot 10^3 = \\ &= 173.20 k_{y,\Theta}\ \text{kNm} \end{aligned} \tag{8}$$

As one can see, the bending modulus W_{pl} as well as the reduction factor $k_{y,\Theta}$ are treated as deterministic parameters; however, their variability is added to the global coefficient of variance υ_R calculated for the resistance. Let the symbol υ_f^2 denote the variance of steel yield point, υ_A^2 – the variance of beam geometrical dimensions, υ_k^2 – the variance resulting from the uncertainty of a model describing mechanical properties of

steel under fire conditions. In this example it is adopted that $\upsilon_f = 0.08$ and $\upsilon_A = 0.06$ which is also consistent with many statistical estimates, made also in Poland. Furthermore, let us assume that $\upsilon_k = 0.10$. According to the suggestion given by Holicky (Holicky 2005) it is statistically legitimate to use even $\upsilon_k = 0.10$–0.30. Consequently, for such accepted data one obtains:

$$\upsilon_R = \sqrt{\upsilon_f^2 + \upsilon_A^2 + \upsilon_k^2} = \\ = \sqrt{0.08^2 + 0.06^2 + 0.10^2} = 0.141 \quad (9)$$

Recalculation the log-normal resistance parameters into Gaussian characteristics gives:

$$m_R = \bar{R}_{fi,\Theta} = \tilde{R}_{fi,\Theta} \exp\left(\upsilon_R^2/2\right) = \\ = 173.20 k_{y,\Theta} \exp\left(0.141^2/2\right) = 174.93 k_{y,\Theta} \text{ kNm} \quad (10)$$

$$\sigma_R = \bar{R}_{fi,\Theta} \sqrt{\exp\left(\upsilon_R^2\right) - 1} = \\ 174.93 k_{y,\Theta} \sqrt{\exp\left(0.141^2\right) - 1} = 24.79 k_{y,\Theta} \text{ kNm} \quad (11)$$

Similarly, for the action effect one has:

$$m_E = \bar{E}_{fi} = \left(\bar{g} + \psi_2 \bar{q}\right) L^2/8 = \\ = (5 + 0.3 \cdot 12) 6^2/8 = 38.7 \text{ kNm} \quad (12)$$

$$\sigma_E = \sqrt{\sigma_G^2 + \psi_2^2 \sigma_Q^2}\, L^2/8 = \\ = \sqrt{0.3^2 + 0.3^2 \cdot 1.5^2}\, 6^2/8 = 2.43 \text{ kNm} \quad (13)$$

3.2 *Evaluation of critical temperature by the standard approach*

At the beginning of the analysis it is necessary to show that the considered beam safely carries all applied loads for the conditions of persistent design situation (without any fire influences). In fact, according to classical approach given in the standard EN 1990 one can obtain that:

$$g_k = \bar{g} + 1.64\sigma_G = 5 + 1.64 \cdot 0.3 = 5.49 \text{ kN/m} \quad (14)$$

$$q_k = \bar{q} + 1.64\sigma_Q = 12 + 1.64 \cdot 1.5 = 14.46 \text{ kN/m} \quad (15)$$

$$E_d = \left(\gamma_G g_k + \gamma_Q q_k\right) L^2/8 = \\ = (1.35 \cdot 5.49 + 1.5 \cdot 14.46) 6^2/8 = 130.96 \text{ kNm} \quad (16)$$

$$E_d < R_d = W_{pl} f_{y,k}/\gamma_M = \\ = 628 \cdot 10^{-6} \cdot 235 \cdot 10^3/1.0 = 147.58 \text{ kNm} \quad (17)$$

The design value of the action effect estimated for accidental fire situation is significantly lower:

$$E_{fi,d} = \left(g_k + \psi_2 q_k\right) L^2/8 = \\ = (5.49 + 0.3 \cdot 14.46) 6^2/8 = 44.23 kNm \quad (18)$$

Let us notice that, according to Eq. (17):

$$R_{fi,\Theta,d} = 147.58 k_{y,\Theta} \text{ kNm} \quad (19)$$

because $\gamma_{M,fi} = \gamma_M = 1.0$.

The ratio $\rho(\Theta_a) = E_{fi,d}/R_{fi,\Theta,d}$ can be adopted as a measure helpful in the evaluation of critical beam temperature $\Theta_{a,cr}$ for which $\rho(\Theta_{a,cr}) = 1,0$. The results of the analysis are shown in Table 1.

Finally, by linear interpolation, one obtains:

$$\Theta_{a,cr} = 600 + \frac{(700 - 600)(1.0 - 0.638)}{1.303 - 0.638} = \\ = 654.4\ ^{o}C \quad (20)$$

3.3 *Application of the probability-based approach proposed in the presented paper*

Substituting values taken from Eqs. (10 ÷ 13) to Eq. (3) yields in turn:

$$174.93 k_{y,\Theta} - 38{,}7 + 24.79 k_{y,\Theta} u_R - 2.43 u_E = 0 \quad (21)$$

$$\Xi = \sqrt{\sigma_E^2 + \sigma_R^2} = \sqrt{24.79^2 k_{y,\Theta}^2 + 2.43^2} = \\ = \sqrt{614.54 k_{y,\Theta}^2 + 5.90} \quad (22)$$

Let us assume that the safety requirements are ordinary and $\beta_{req} = 3.8$ (for the reliability class RC2 and for the reference period equal to 50 years – according to EN 1990). Detailed results obtained owing to the application of Eq. (4) are presented in Table 2.

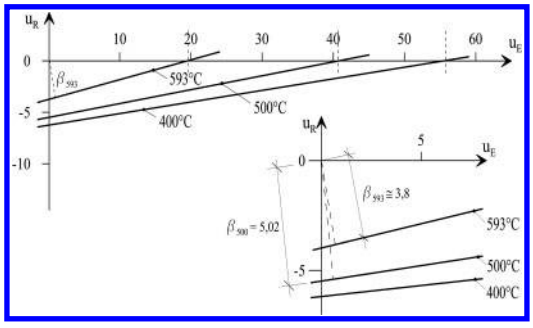

Figure 1. Graphical interpretation of the reliability index $\beta_{593} \cong 3.8$ leading to the evaluation $\Theta_{a,cr} \cong 593°C$ (see Table 2).

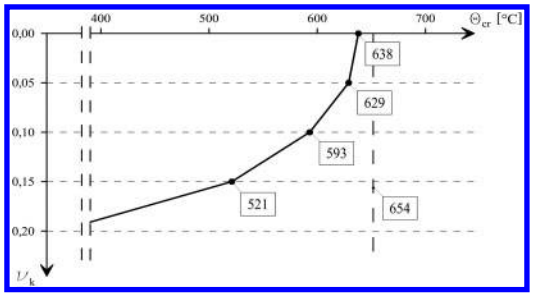

Figure 2. Resultant values of the temperature $\Theta_{a,cr}$ in relation to the adopted level of model uncertainty when the value $\beta_{req} = 3.8$ is assumed.

As one can see the value of $\Theta_{a,cr}$, estimated using proposed methodology, is equal to $\Theta_{a,cr} \cong 593\,°C$. The geometrical interpretation of such solution is given in Figure 1. It is noteworthy that the coefficients $\alpha_E = \sigma_E / \Xi$ and $\alpha_R = \sigma_R / \Xi$ change with the steel temperature growth and, as a result, inclination of the limit state line is also unstable.

3.4 *Assessment of beam critical temperature for differentiated safety requirements*

Basing on the data collected in Table 2 one can assess also the beam critical temperature specified for the other safety requirements, different than those accepted as the ordinary ones. Let us assume firstly that $\beta_{req} = 4.3$ which is an equivalent of the range required safety level. It is easy to see that the adequate critical temperature is then equal to $563°C$. Similarly, for the adoption of the minor required safety level and, in consequence, making the assumption that the index $\beta_{req} = 3.3$ one can obtain the searched temperature being much lower than previously indicated and equal to $619°C$. All obtained solutions, characteristic for particular assumed safety requirements, are shown in the diagram presented in Figure 2.

3.5 *Influence of model uncertainty*

The value of the temperature $\Theta_{a,cr} \cong 593\,°C$, obtained as a result of the application of alternative probability-based design procedure for ordinary safety requirements, is much more conservative in relation to the other, resulted from using the classical standard analysis. The main reason of such difference is the consideration of inevitable model uncertainty by joining to global variance of beam resistance an additional component $\upsilon_k = 0{,}10$. It seems to be informative to analyse more precisely the influence of various levels of model uncertainty on the resultant critical temperature assessment. To do this selected values of variability υ_k are adopted to detailed examination, particularly: 0.00; 0.05; 0.10; 0.15 and 0.20 (Maślak 2012b). As a consequence Eq. (8) is simplified to the form:

$$\upsilon_R = \sqrt{0.08^2 + 0.06^2 + \upsilon_k^2} = \sqrt{0.01 + \upsilon_k^2} \tag{23}$$

Let us notice that as a result of the correction of υ_R many other values connected to beam resistance simultaneously change, especially m_R, σ_R and even Ξ. On the other hand, no parameters dealing with the action effect are corrected in such approach. Consequently, formulae describing the limit state condition, adequate for the formula previously specified as Eq. (21), are now defined by the following equations:

- if $\upsilon_k = 0.00$:

$$174.07k_{y,\Theta} - 38.7 + 17.45k_{y,\Theta}u_R - 2.43u_E = 0 \tag{24}$$

- if $\upsilon_k = 0.05$:

$$174.29k_{y,\Theta} - 38.7 + 19.58k_{y,\Theta}u_R - 2.43u_E = 0 \tag{25}$$

- if $\upsilon_k = 0.10$:

$$174.93k_{y,\Theta} - 38.7 + 24.79k_{y,\Theta}u_R - 2.43u_E = 0 \tag{26}$$

- if $\upsilon_k = 0.15$:

$$176.03k_{y,\Theta} - 38.7 + 31.94k_{y,\Theta}u_R - 2.43u_E = 0 \tag{27}$$

- if $\upsilon_k = 0.20$:

$$177.60k_{y,\Theta} - 38.7 + 40.29k_{y,\Theta}u_R - 2.43u_E = 0 \tag{28}$$

It is easy to see, by interpretation of the solutions collected in succeeding tables (Tables 2–6), that for ordinary safety requirements occurs:

- if $\upsilon_k = 0.00$ than $\Theta_{a,cr} \cong 638°C$ (see Table 3),
- if $\upsilon_k = 0.05$ than $\Theta_{a,cr} \cong 629°C$ (see Table 4),
- if $\upsilon_k = 0.10$ than $\Theta_{a,cr} \cong 593°C$ (see Table 2),
- if $\upsilon_k = 0.15$ than $\Theta_{a,cr} \cong 521°C$ (see Table 5),
- if $\upsilon_k = 0.20$ than $\Theta_{a,cr} < 400°C$ (see Table 6).

As one can see, taking $\upsilon_k = 0.20$ leads to the inequality $\beta = 3.44 < \beta_{req} = 3.8$ which means that the safety condition can be unsatisfied even just before reaching the steel temperature equal to $\Theta_a = 400°C$. In this point-in-fire-time any reduction of steel yield point is

not yet performed ($k_{y,\Theta} = 1.0$) so, as a consequence, any decrease of beam cross-section resistance has not occurred.

Such result leads to the unexpected conclusion that the considered beam cannot carry all external loads applied just from the beginning of the fire, even if the accidental load combination rule is adopted to the study. Let us notice that quite a different conclusion was reached previously, regarding the behaviour of the same beam but dealing with persistent design situation – all loads applied to this beam were safely carried under such conditions. Comparison of both above conclusions leads to the formal inconsistency, indeed, and as a consequence allows to give the recommendation to adopt the level of model uncertainty with great thought, conservatively in general but never more than enough.

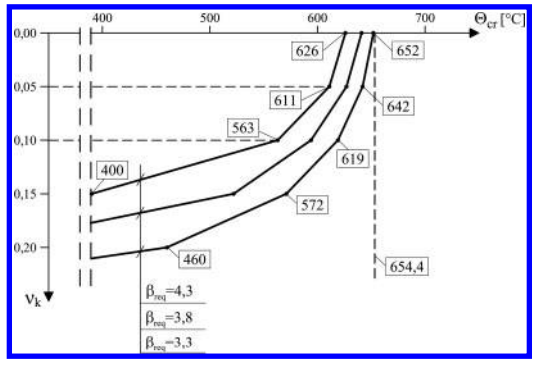

Figure 3. Resultant values of the temperature $\Theta_{a,cr}$ in relation to the adopted level of model uncertainty, obtained for diferrentiaded safety requirements.

Evaluations of beam critical temperature, completed in the considered example for the ordinary required safety level, are presented in detail in Figure 2. It is important that all those values are much more restrictive in relation to the solution obtained previously as an effect of the application of classical standard approach (marked in this diagram by the dashed line).

Moreover, in Figure 3 the similar presentation is made, but it is prepared taking into account the results obtained for differentiated safety requirements. As one can see, quantitative differences between the obtained solutions seem to be essential.

4 CONCLUDING REMARKS

The example presented in this paper shows that the alternative probability-based approach, recommended by the author for application in engineering practice, can be effectively used to assess the reliable value of critical temperature of steel structural members exposed to fire. Solutions obtained in this way seems to be better justified in relations to those resulted from the implementation of classical standard calculation technique because no representative values of considered random variables are established and calibrated. Moreover, the failure is defined more rationally. The fact that all evaluations of critical temperature $\Theta_{a,cr}$ being the results of practical use of proposed methodology are more restrictive in comparison to the adequate solutions obtained owing to the application of classical

standard design technique must be underlined. This means that such standard approach, commonly used in practice, gives in this field the safety assessments being in general too optimistic and, as a consequence, inaccurate.

ABSTRACT: A large experimental and modeling program concerning fire tests on timber connections under various mechanical loadings was performed in France since 1999. Numerical models, simulating the thermo-mechanical behavior of these tested connections were developed and validated on the basis of experimental results. The developed model is sufficiently relevant to realize parametrical studies on timber connections. Then, considering the four main parameters influencing the fire resistance of the connections (type and diameter of fasteners, thickness of timber members and load ratio), the model is used to analyze the combined influence of these factors and to realize a complete numerical experimental design. The thicknesses of the timber beam elements commercially available and the fastener diameters commonly used in timber structures are considered. This numerical experimental design, taking into account a predominant loading case of timber connections in fire situation, allows obtaining a simplified analytical formula giving the possibility to predict easily the fire resistance of the connection configuration studied.

1 INTRODUCTION

The use of timber for buildings is actually encouraged by environmental concerns. However, as wood is a combustible material, fire safety represents a main area of investigation to support this development. Indeed, the knowledge of the thermo-mechanical behavior of timber structures remains insufficient. Timber is the structural material for which the studies relative to the properties and the tools of simulation under fire exposure are the least numerous.

In timber structures, the connections are the weakest zones among the various structural components. The analysis of the fire behavior of these connections is complex due to the influence of several parameters (geometry combining various materials, fasteners types, different thermo-physical and thermo-mechanical properties). The design procedure given in Eurocode 5 (EN 1995-1-2) for timber connections in fire situation is based on a limited number of experimental and numerical results. The calculation method proposed to estimate the fire resistance of the connections has a limited range of application (not more than 30 or 40 minutes according to the connection type) and does not allow obtaining precise or safe results (Audebert et al 2010a).

To improve the knowledge of the behavior of timber connections in fire, a large experimental and modeling program began in France in 1999 (Dhima 1999, Audebert 2010b). Complying with the actual architectural trends and high strength requirements, timber connections using dowel-type fasteners and slotted-in steel plates were mainly studied. This research concerned connections using bolts, dowels or a combination of both and subjected to various loading types (tension parallel-to-grain, tension with an angle to the grain and bending). The experimental results were used to validate a numerical model simulating the thermo-mechanical behavior of the tested connections. The validation is based on the comparison between the calculated and the measured values of temperatures and fire duration resistances. Considering the large number of connections tested and the comparisons with the numerical models, the model developed can be considered sufficiently relevant to be used as a basis for a numerical experimental design.

In the present study, the main parameters affecting the fire resistance of timber connections are defined and a numerical experimental design approach is adopted. In a first part, the experimental results of the tests on timber connections under fire exposure realized since 1999 are exposed. These results allow

determining the factors influencing the fire resistance of the connections and show the existence of a dominant loading case for fire situation. Then the numerical model used to realize the numerical experimental design is briefly presented and some numerical results are given to show the precision ad the accuracy of the simulation. Finally, a complete numerical experimental design is done for a steel-to-timber connection configuration. The results are commented and a simplified analytical formula is obtained, giving the possibility to predict easily the fire resistance of the connection configuration studied.

2 EXPERIMENTAL RESULTS

In this section, the geometrical configurations of timber connections tested in France since 1999 are presented and the experimental results of fire duration resistances are commented.

2.1 *Fire tests*

The fire tests were conducted following the evolution of the temperatures of a conventional fire ISO 834. For each specimen, the temperatures are measured by thermocouples situated along the fasteners, inside the timber members and on the slotted-in steel plates. The protocol for mechanical loading under fire exposure was defined by the standard NF-EN 26891. After a preloading up to 40% and unloading to 10% of N_u (N_u is the failure load given by tests in normal conditions), the specimen was reloaded to the value of $F = \eta_{fi} * N_u$, retained as the loads in fire situation. Then, the fire exposure was started and the load ratio η_{fi} kept constant throughout the exposure to fire until the failure of the connection. The end of the fire tests is defined when a significant acceleration of the measured displacements is observed.

All the tests were realized on connections made with glulam members of resistance class GL24h. The steel elements used in the connections are the fasteners and the plates.

2.1.1 *Timber connections in tension parallel-to-grain*

These tests concern double shear steel-to-timber connections with a variable number of fasteners (bolts or dowels) subjected to a parallel-to-grain tension. The choice of the tested connections aimed at covering the most used real applications and at comparing the various types of connections under fire exposure. The connections satisfy the requirements of spacing and size for dowelled and bolted timber connections of the EN 1995-1-2. The variable parameters studied were the thickness of the timber members (50, 60, 75 and 95 mm), the diameter of the fasteners (12, 16 and 20 mm), the load ratio in fire situation (10 to 90% of N_u). Two examples of the geometrical configurations tested are shown on figures 1 and 2. In Table 1 are given

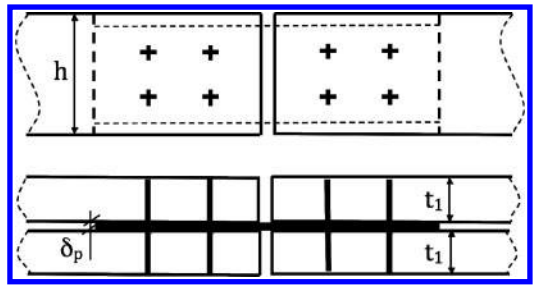

Figure 1. Geometry of a connection made with 4 dowels.

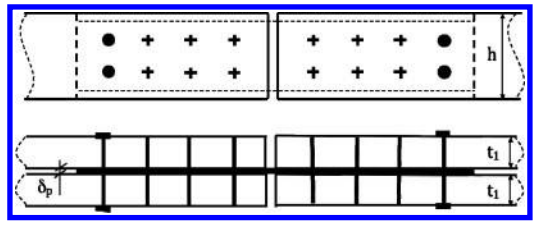

Figure 2. Geometry of a connection made with 6 dowels and 2 bolts.

Table 1. Experimental fire resistance of the connections (parallel-to-grain tension).

N°	Nb	d mm	t_1 mm	η_{fi} % N_u	$t_{fi,exp}$ min
1	2 × 4 bolts	12	50	46	17
				91	10
2	2 × 8 bolts	12	50	41	18
				83	11
3	2 × 16 bolts	12	50	40	18
				80	13
4	2 × 8 bolts	20	60	37	22
				75	15
5	2 × 16 bolts	20	60	37	23
				73	16
6	2 × 6 dowels + 2 × 2 bolts	12	75	10	54
				30	39
7	2 × 6 dowels + 2 × 2 bolts	16	75	10	55
				20	41
				30	36
8	2 × 6 dowels + 2 × 2 bolts	20	75	10	52
				30	37
9	2 × 6 dowels + 2 × 2 bolts	20	95	10	90
				30	45

the fire duration resistances of the tested connections and their geometrical characteristics.

These results show that timber connections can reach fire resistance upper than 30 minutes when load ratios lower than 30% of N_u are applied. Comparing the results for connections 7 and 8, it can be noted that increasing the fasteners diameter from 16 to 20 mm does not allow improving the fire resistance. For the connection 6, the use of fasteners with diameter 12 mm does not reduce the fire resistance of the connections. So, the thickness of the timber members seems

to be the predominant factor for the fire resistance of the timber connections. This comment has been confirmed by experimental results of timber-to-timber connections (Audebert et al. 2013). The fire resistance values obtained for tests 6 to 9 are higher than those obtained with tests 1 to 5. This is due to the values of load ratios and the increase of the thickness of timber members. Moreover bolt type fasteners play a negative role in the fire resistance of the connections (Audebert et al. 2012).

2.1.2 *Timber connections in tension with an angle to the grain*

These tests concern connections subjected to a perpendicular-to-grain tension or a tension with an angle of 45° to the grain. To compare the results of these tests to those of timber connections tested under a parallel-to-grain tension, the size of the connections were taken close to those retained in the design of connections 6 to 9. To avoid the negative effect played by the bolts on the fire resistance, only dowel type fasteners were used in the connections. Four dowels are used.

The geometrical configurations tested are illustrated on figures 3 and 4. Table 2 presents the experimental values of fire resistance $t_{fi,exp}$ depending on the load ratio η_{fi}.

Despite the low strength of wood material in perpendicular-to-grain direction, high values of fire resistance were obtained in this loading case. The results show also high values of fire resistance in tension with an angle to the grain of 45° (connections 13 and 14). The fire resistances of these connections are close to those of equivalent connections tested under a perpendicular-to-grain tension while being always lower.

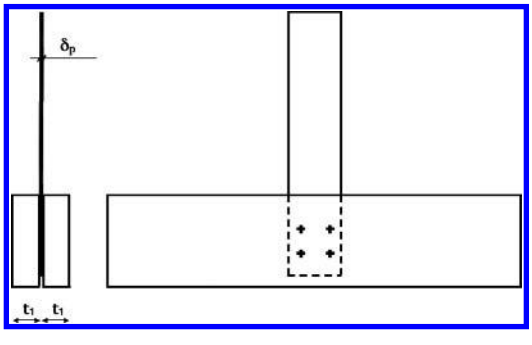

Figure 3. Steel-to-timber connections tested in tension perpendicular to the grain.

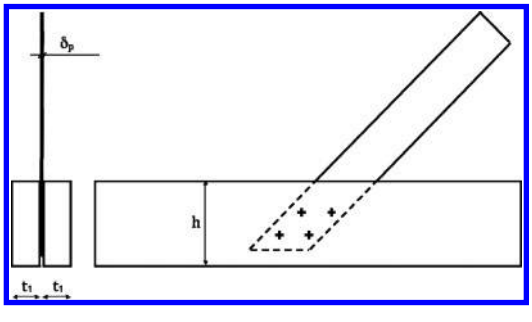

Figure 4. Steel-to-timber connections tested in tension with an angle of 45° to the grain.

2.1.3 *Timber connections in bending*

Two types of steel-to-timber connections were tested. These connections are constituted by two timber beams, connected by a slotted-in steel plate and 6 dowels of diameter 16 mm. Two dowel configurations were tested (figure 5). Table 3 summarizes the experimental results for these connections.

As for timber connections subjected to a transversal tension, high fire resistances, close to one hour, were obtained.

Table 2. Experimental fire resistance of the connections (tension with an angle to the grain).

N°	Load angle	d mm	t_1 mm	η_{fi} $\%N_u$	$t_{fi,exp}$ min
10	90°	16	75	10	71
				30	48

				45	50

2.2 *Conclusion on the experimental program*

This testing program allows concluding on the main parameters influencing the fire resistance of the connections. It appears that the timber members thicknesses and the load ratio applied are the two main factors influencing the fire resistance. Moreover, from the various experimental results presented, the load parallel to grain appears predominant in the design of the connections in fire situation. It would mean that, in term of fire resistance, a connection configuration designed with regard to the tension parallel-to-grain following the recommendations of EN 1995-1-1, would be, de facto, checked for all the loading types.

3 NUMERICAL MODELING

In this section, the main assumptions retained to develop the numerical modeling of the tested connections are presented. The model is developed in two steps using the MSC-MARC software.

3.1 *Heat transfer modeling*

The numerical simulations of heat transfer within the connections are performed considering the evolutions of the thermo-physical properties such as the thermal conductivity and the specific materials. The thermo-physical properties of steel are taken from EC 3 (EN 1993-1-2) and those of wood are chosen with a sensitivity analysis (Audebert et al. 2010a). For the thermal calculations, it is assumed that all the interfaces between the components are in perfect contact with continuous meshing.

The heat transfer model was validated for each tested connection by comparison of its calculated values with the measured charring rates and temperatures using thermocouples. The results obtained by the numerical model were in good agreement with the experimental values (Audebert et al. 2010a, Audebert 2010b).

3.2 *Thermo-mechanical modeling*

In the mechanical modeling, steel plates and dowels are considered with isotropic elastic-plastic behavior according to the von-Mises criterion. The mechanical behavior of wood was considered with transverse isotropy. The evolution of the plastic deformations was taken into account using the 3D Hill yield criterion, associated to the Tsaï-Wu failure criterion in the case of connections with transversal loadings, to take into account the dissymmetric behavior of the material in tension and compression. The evolution of the mechanical properties with temperature is considered using the reduction coefficients provided by the Eurocodes.

The mechanical model takes into account the material and geometrical nonlinearities, and the contact evolutions. The meshing is discontinuous and differs from that of the heat transfer. A procedure has been developed to make the transposition of the temperatures calculated with thermal meshing to the mechanical meshing. The thermo-mechanical model was validated by comparison with the experimental results. The comparison concerns the evolutions of the connection slip versus the time of exposure to fire (figure 6). From these evolutions, the fire resistance duration is determined. The fire resistance times obtained by the numerical model are always lower than those obtained from the experimental tests with a mean relative error of about 15%. Based on these results, the thermo-mechanical model is considered sufficiently accurate to represent safely the behavior of the connections exposed to fire.

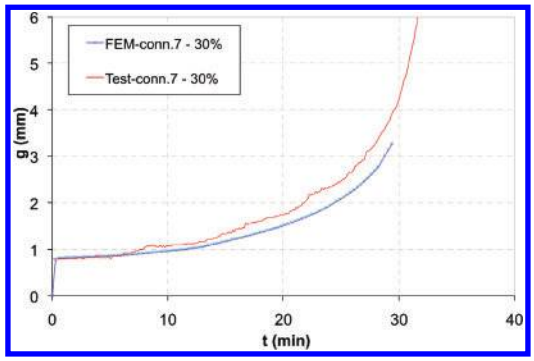

Figure 6. Comparison of numerical and experimental load-slip curves (connection $7 - \eta_{fi} = 30\%N_u$).

4 NUMERICAL DESIGN APPROACH

4.1 *Numerical experimental design*

The experimental results show that the fire resistance of the connections is influenced by three main parameters, which are the diameter of fasteners, the thickness of timber members and the load ratio. These three parameters represent the three factors of which the combined influence will be studied in the numerical design. Other influencing parameter is the type of fasteners used: dowel or bolt. In the practice, bolts are commonly used in association with dowels to connect timber elements. Their function is to prevent the separation of the connected members. The use of one bolt with three dowels (for four fasteners) is common and this distribution is mentioned in Eurocode 5 (EN 1995-1-1). The influence of this ratio bolts/dowels on the fire resistance of timber connections was studied (Audebert et al. 2012). It appears that the presence of one bolt for four fasteners reduces by about 15% the fire resistance comparing to a connection assembled only with dowels (figure 7).

Thus, the numerical experimental design is realized for dowelled steel-to-timber connections loaded in tension parallel to grain. This loading case is predominant in the design of the connection for fire situation. The geometrical configuration studied is identical to

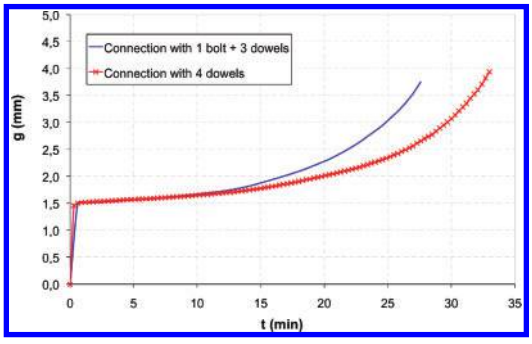

Figure 7. Influence of the presence of one bolt on the slip-time curves evolution of a timber connection.

the one presented in figure 2 but with dowels only. The number of fasteners is kept constant for all the studied configurations (2 × 8 dowels). The decrease of fire resistance generated by a bolt under fire exposure can be estimated by the introduction of a specific reduction coefficient.

Three different values are considered for the diameter of dowels (12, 16 and 20 mm) to cover the common fastener diameters used in timber structures. Six values of timber member thickness are retained to take into account the thicknesses commercially available. Two values are considered for the load ratio (10 and 30%). It is necessary to realize, at least, 36 simulations to obtain a complete factorial design considering the influence of each parameter. The interaction term between the three parameters (d-t_1-η) is neglected. Table 4 summarizes the numerical experiments and the corresponding calculated fire resistance durations ($t_{fi,sim}$).

From these numerical values of calculated fire resistance, a polynomial function is fitted according to the three selected parameters, using the least squares method on Matlab. The exponential relation between the load ratio and the fire resistance proposed by EN 1995-1-2 is kept. Indeed, this relation corresponds to the tendency observed with the experiments. Then, the polynomial function of Equation (1) is chosen:

$$\tilde{t}_{fi} = 31.92 - 1.79d + 1.03t_1 - 7.51\ln(\eta) + 0.003d \cdot t_1 + 0.49d \cdot \ln(\eta) - 0.24t_1 \cdot \ln(\eta) \quad (1)$$

Considering the fire resistance of the 36 calculated connections, the Equation (1) gives a mean relative error equal to 7.85% (Equation (2)).

$$\|\varepsilon\| = \frac{\left\| t_{fi,sim} - \tilde{t}_{fi} \right\|}{\left\| t_{fi,sim} \right\|} = 7.85\% \quad (2)$$

In Equation (1), the interaction term $d.t_1$ is weighted by a low coefficient. This interaction can be neglected. The final Equation (3) is then obtained:

$$\tilde{t}_{fi} = 27.32 - 1.51d + 1.07t_1 - 7.51\ln(\eta) + 0.49d \cdot \ln(\eta) - 0.24t_1 \cdot \ln(\eta) \quad (3)$$

Table 4. Numerical experimental design and simulated fire resistance durations.

N°	d mm	t_1 mm	η $\%N_u$	$t_{fi,sim}$ min
1	12	55	10	33.1
2		55	30	18.4
3		75	10	48.0
4		75	30	18.4
5		95	10	57.2
6		95	30	31.8
7		115	10	62.0
8		115	30	42.6
9		135	10	79.6
10		135	30	37.0
11		160	10	90.0
12		160	30	42.9
13	16	55	10	32.3
14		55	30	15.3
15		75	10	42.8
16		75	30	24.6
17		95	10	56.7
18		95	30	35.4
19		115	10	68.0
20		115	30	45.0
21		135	10	80.0
22		135	30	43.3
23		160	10	81.8
24		160	30	44.0
25	20	55	10	31.7
26		55	30	15.2
27		75	10	43.2
28		75	30	23.2
29		95	10	48.3
30		95	30	31.8
31		115	10	63.0
32		115	30	43.0
33		135	10	75.5
34		135	30	45.0
35		160	10	90.0
36		160	30	40.5

With the mean relative error:

$$\|\varepsilon\| = \frac{\left\| t_{fi,sim} - \tilde{t}_{fi} \right\|}{\left\| t_{fi,sim} \right\|} = 7.87\% \quad (4)$$

This formula is elaborated from the numerical models of dowelled connections. To take into account the reduction of fire resistance due to the use of one bolt for four fasteners, a reduction coefficient of 15% can be applied to the formula.

Using Equation (3), design abacuses can be drawn. The graphical representations are obtained for each given diameter. Figure 8 shows an example of these abacuses for a dowel diameter of 16 mm.

These abacuses give the possibility to obtain easily the duration of fire resistance of a connection knowing only the value of the three parameters retained.

The analytical formula presented in Equation (3) is used to estimate the fire resistance of the tested connections 6 to 9 (Table 1). As these connections are made with bolts and dowels, the reduction coefficient

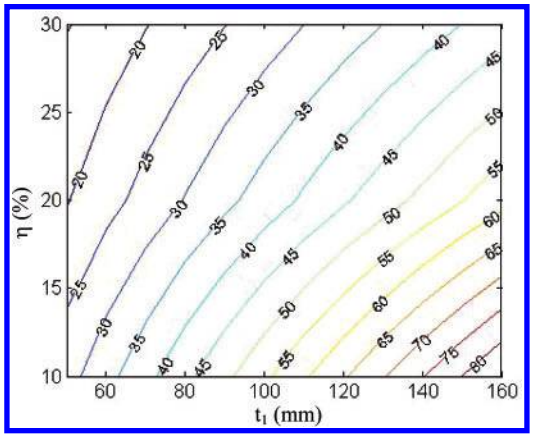

Figure 8. Abacus of the fire resistance of connections for fastener diameter d = 16 mm.

Table 5. Fire resistance of connections: calculated values (Eq. 3), experimental values and Eurocode 5 values.

N°	η_{fi} % N_u	$t_{fi,exp}$ min	$t_{fi,calc}$ min	ε_1 (%)	$t_{d,fi}$ min	ε_2 (%)
6	10	54	38.7	28	31.6	41
	30	39	20.0	49	18.4	53
7	10	55	37.4	32	31.6	43
	20	41	26.7	35	23.2	43
	30	36	20.3	44	18.4	49
8	10	52	36.1	31	31.6	39
	30	37	20.9	44	18.4	50
9	10	90	43.8	51	31.6	65
	30	45	24.7	45	18.4	59

of 15% to take into account the negative effect of the bolt is applied. The calculated fire resistances ($t_{fi,calc}$) are compared to the experimental ones ($t_{fi,exp}$) and to the values of the fire resistances $t_{d,fi}$ determined with the actual simplified calculation method, the "Reduced Load Method" provided by EN 1995-1-2 (Table 5).

Table 5 shows that Equation (3) allows obtaining fire resistance values of connections closer to the experimental values in comparison with the method provided by Eurocode 5 (relative errors of 39% and 49%). The error can be explained partly by the mechanical properties of the timber. Indeed, the experimental numerical design was made with normalized mechanical properties of timber corresponding to resistance class GL24h. These standardized mechanical properties underestimate significantly the real mechanical properties. For example, for connections 6 to 9, the standardized mechanical properties of timber underestimate the measured mechanical properties $f_{c,0}$ and f_v by 53% and 75% respectively.

The numerical experimental design approach presented in this study is being improved to take into account the resistance class of timber, the number of fasteners and the connection configurations exclusively made with bolts. This approach will be extended to various other geometrical configurations usually used in timber constructions.

5 CONCLUSIONS

The study presented a review of results of a large experimental program conducted in France on the fire resistance of timber connections. These results allowed to determine the main parameters influencing the fire resistance and allowed to identify a predominant loading case in fire situation. The results were used to elaborate a precise numerical model simulating the thermo-mechanical behavior of the connections. As this model is sufficiently accurate, it is used to realize parametrical studies on timber connections in fire situation. Thus, a numerical experimental design approach is performed on a common connection configuration. This numerical design allows obtaining a simplified analytical formula to calculate the fire resistance of the connections giving more precise results than the actual standards.

Performance of reinforced concrete structures in post-earthquake fire

B. Behnam & H. Ronagh

M. Ashraf
School of Engineering and IT, The University of New South Wales, Canberra, Australia

ABSTRACT: Post earthquake fire (PEF) can lead to the collapse of buildings that are partially damaged in a prior earthquake that occurred immediately before the fire. Most standards for the design of structures against earthquake ignore the possibility of post earthquake fire and hence buildings designed following these codes could be vulnerable under PEF. An investigation based on FEMA 356 is performed here on the performance based safety level of structures designed to the ACI code after they are subjected to an earthquake load with the PGA of 0.30 g. This is followed by a fire analysis of the weakened structure from which the time it takes for the weakened structure to collapse is calculated. The results show that the vulnerability of structures increases dramatically when a deformed structure is exposed to PEF. While the investigation is for a certain class of structures (intermediate reinforced concrete frame, 3 stories), the results confirm the need for the incorporation of post earthquake fire in the process of analysis and design.

1 INTRODUCTION

Earthquakes cause catastrophic damages to civilization but post-earthquake events resulting from the shock, such as fire, could potentially make things a lot worse. The effects of post-earthquake fire (PEF) on buildings are two-fold; one is the damage due to the burning of non-structural material, which possesses material value, and the other is the damage that can be caused due to excessive structural loads on the building Chen et al (2004). The structures are usually not designed for these additional loads and this could be significant when combined with the earthquake damage (even if moderate) leading to the collapse of buildings. On the other hand, structural elements are normally designed to satisfy a specific level of safety or performance. Fire is considered as one of the most problematic conditions and therefore, the provision of appropriate fire safety measures is essential. In general, fire resistance rating is defined as a period of time for which the integrity of a member subjected to fire is maintained to resist applied loads. This definition is correlated with various factors, one of which is the type of building that is being designed. The purpose of fire rating is not only to provide adequate time to evacuate trapped people under the fire, but to reduce the possibility of any conflagration Taylor (2003). Fire-resistance ratings are usually presented in national building codes such as NRCC (2005) and IBC (2006) but are not suitable for the post-earthquake fire. This is an important point because the vulnerability of earthquake-damaged structures exposed to post earthquake fire is much more than the fire itself. This is because earthquake excitation may produce residual lateral deformation as well as residual stresses on the members Mousavi et al (2008). Both active and passive fireproofing systems such as sprinklers and fire control systems may become seriously damaged during an earthquake and the fire resistance of the structure could reduce by a considerable margin. The fire resistance is defined as a time at which the element is unable to resist applied loads such as gravity loads Kodur and Dwaikat (2007). Evaluation of structural performance under PEF condition is an important issue that has to be scrutinized carefully. PEF resistance of a building is dependent on various factors including the deformed geometry and the degradation in stiffness resulted from earthquake Zaharia and Pintea (2009). In reinforced concrete structures, in addition to the aforementioned factors, the effects of level of damage including tensile cracking, removal of rebar cover and compressive crushing on PEF resistance should be considered as well. Assuming ductile behavior of RC elements, a typical moment-curvature relationship can be idealized to separate stages Kwak and Kim (2010). While it seems that tensile cracking, as the first stage of cracking, has no significant effect on the PEF resistance, major cracking as a result of removal of rebar cover or crushing of concrete in compression could drastically reduce the PEF resistance Ervine et al (2009).

Della Corte et al (2003) investigated unprotected steel moment-resistant frames and their response subjected to fire following an earthquake. Assuming

elastic perfectly plastic behavior for steel and considering P-Δ effect with P from gravity loads and Δ from the earthquake, the fire resistance was evaluated. It is worth noting that the degradation of stiffness was ignored in Della Corte et al.'s work. Further study on steel frames was carried out by Zaharia and Pintea (2009). They investigated two different steel frames, designed for two various return periods of ground-motion; 2475 years return period and 475 years. The seismic response of the structures was then evaluated by a pushover analysis. While the frame designed for the 2475 years return period remained elastic in the pushover analysis, the weaker frame designed for 475 years return period sustained notable inter storey drift. They then performed a fire analyses on both frames, which confirmed that the fire resistance of the structures considering their deformed state under earthquake is notably lower than the structures that do not have any history of deformation prior to the application of the fire. Mostafaei and Kabeyasawa (2010) investigated PEF resistance of reinforced concrete structure with shear wall. The model was first subjected to the Kobe 1995 earthquake on a shaking table. The damage sustained by the structure was quantified by the method of observation as well as using a developed method called Axial-Shear-Flexure Interaction (ASFI), as proposed by Kabeyasawa and Mostafaei (2007), followed by a numerical thermal analysis to find the temperature rise in and around both the seriously damaged and the intact sections subjected to fire. Fire loading was then applied to the damaged structure considering the effect of concrete degraded compressive strength. The results showed that the ability of the structure to sustain gravity loads in the damaged components is considerably lower in comparison to the intact components. In the same year, Faggiano and Mazzolani (2011) investigated steel structures exposed to post earthquake fire. They performed coupled analyses consisting of both earthquake and fire. Based on the FEMA356 procedure, Faggiano and Mazzolani (2011) developed a method for evaluating the performance of buildings subjected to earthquake, suggesting fire performance levels for various conditions of fire. In the coupled analyses, both residual deformation and degradation of mechanical characteristics were applied. However, the method can be more effective for steel structures, because as was previously mentioned, in reinforced concrete structures, seriously damaged sections play an important role on PEF resistance. Recently, Ervine et al (2012) conducted an experimental and a numerical study on a reinforced concrete element subjected to conventional loads followed by a fire load. Applying two concentrated vertical loads on the specimen and recording the subsequent deflection, the created cracks were observed through the member. The model was then subjected to fire load to find the effect of created cracks on the changes of thermal propagation inside the section. The results showed that minor tensile cracking would not considerably change the heat penetration inside the section. They concluded that fire resistance of the intact specimen and the minor damaged specimen are roughly identical. However, exposing the rebar directly to fire, i.e. in case of crushing of cover, considerably changes both the thermal and the structural behavior of the specimen. Another study on this issue was recently undertaken by Bhargava et al (2010) on the fire resistance of an earthquake damaged RC frame. A nearly full-scale portal frame was firstly loaded by the relevant gravity loads and then subjected to a cyclic lateral load based on the Indian standard in a quasi-static fashion. Moreover, load-controlled mode was considered to meet 2% drift corresponding to the Life Safety performance level as described in FEMA 356 code. The crack widths were then observed using optical tools, non-destructive tests and ultrasonic method. A computational analysis was also performed using the finite element package ABAQUS for making a comparison between the test and the analytical results. The results showed a good conformity with FEMA356 descriptive definition of damage levels at various performance levels as such Immediate Occupancy (IO) and Life Safety (LS). It was suggested that the results of quasi-static cyclic test can be used for the subsequent fire analysis.

More recently, Behnam and Ronagh (2012a, b) investigated the effects of prior damage on the PEF resistance of RC portal frames. The results showed that there was minor difference between the fire resistances of the fire alone situation and the situation where the frames are pushed to the IO level of performance under PEF. However, a significant difference was observed between the fire only situation and the situation where the frames are pushed to arrive at LS or CP levels of performance under PEF. The results also showed that fire resistance decreases more significantly when beams are exposed to fire in comparison to column exposure. In separate studies, they proposed different engineering solutions in order to improve the PEF resistance of existing structures and those to be constructed in future (Behnam and Ronagh 2012c, 2013).

Inspired by the aforementioned studies, the current research numerically investigates the PEF resistance of an RC frame designed for Life Safety performance level. The reported study includes a sequential analysis comprising both earthquake and the post-earthquake fire.

2 SEQUENTIAL ANALYSIS

A sequential analysis is used to appropriately analyze a structure under post-earthquake fire. Fig. 2 schematically shows the stages of a nonlinear sequential analysis. The first stage of loading is the application of gravity loads, which are assumed to be static, uniform and constant throughout the analysis. A pseudo earthquake load, in addition to the gravity loads, follows in a push over fashion reaching its maximum value and returning back to zero in a short time. The pattern chosen for the pseudo earthquake load is similar to pushover analysis with a difference that the structure

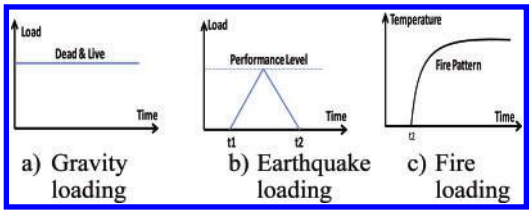

Figure 1. Stages of the sequential analysis.

is unloaded after reaching certain level of load. It is assumed that the maximum level of earthquake load corresponds to life safety level of FEMA356. This assumption is in line with the seismic design philosophy in which the performance level of structures shall not exceed life safety level when subjected to the "Design earthquake". Therefore, the structure is pushed to this life safety level and then is unloaded. It should be noted that no dynamic effects are considered in this study. Finally, as can be seen in Fig. 1, the fire load is applied to the structure after the lateral load is unloaded. Prior to fire loading, properties of structures are set to the reference temperature, but during fire, mechanical properties change with temperature.

In this research, incorporating the pattern shown in Fig. 1 and using SAP2000 for the pushover analysis and SAFIR (Franssen 2011) for the fire analysis, sequential seismic and fire analyses are performed.

3 PUSHOVER ANALYSIS

The static pushover analysis is one of the nonlinear static methods that are used for analyzing structures subjected to seismic loads. This method is becoming a popular tool for seismic performance evaluation of existing and new structures (Cardone et al 2009). In this method, using a specific load pattern, the structure is pushed to arrive at a displacement called the target displacement. The target displacement serves as an estimate of the global displacement that the structures is expected to experience in a design earthquake often represented by the roof displacement at the center of mass of the structure. In this study, a vertical distribution of loads proportional to the shape of the fundamental mode in the direction under consideration is used. Building performance is a combination of the performance of both structural and nonstructural components. According to FEMA356, the structural performance level is divided into four main categories: Operational (O), Immediate Occupancy (IO), Life Safety (LS) and Collapse Prevention (CP), which represent states of minor damage to notable damage.

4 FIRE FRONTIERS

Life Safety performance level is considered in the current study for the seismic analysis prior to fire loading. Structures experiencing plastic deformations do not return to their initial condition as residual deformation remains within the structure. Using the definition of lumped plasticity, the potential locations of high plasticity are introduced by plastic hinges in SAP2000 (2002).The moment-rotation behavior of each plastic hinge follows FEMA definition. These definition in a concrete cross section are required for the post-earthquake fire analysis, because variation of temperature across the section is highly dependent on the state of damage (Ervine et al, 2012). In FEMA356, it is stipulated that in the Life Safety performance level, extensive damage is observed in beams and columns, resulting in spalling of cover and mostly in the areas of created plastic hinges. The experimental tests conducted by Sharma et al. and Meada et al. also showed the good agreement between the FEMA prescriptive definition of damage state with the experiments (Behnam & Ronagh 2012c, 2013).

5 FIRE PATTERNS

Several methods have been proposed to determine the thermal actions produced by a fire within a compartment (Ramesh and Tan 2007 and Lundin 2005). These methods are established either using parametric fires called time-temperature curves such as those mentioned in ISO 834, and ASTM E119 (based on experiment and tests) or using natural fire which rely mainly on the volume of the produced gas by the combustible materials within a covered space such as those stated in SEI and ASCE. Both models, i.e. the time-temperature curve and the natural fire, are represented assuming a fully developed fire. The produced temperature resulted from burning combustible materials are lumped into one single parameter (Drysdale 2011).

A finite element method (FEM) based program SAFIR is used in the current study to calculate the fire resistance of the selected models. The program performs nonlinear analyses on one, two or three dimensional structures considering both geometrical and material nonlinearity. The analyses can be performed under ambient or elevated temperature. The stress-strain relationships for various materials as well as their thermal characteristics are embedded in the software according to Eurocodes. Meanwhile, accounting for thermal action in a structure, both 'time-temperature curves' and 'natural fire' can be used. Structures that are exposed to fire are analyzed in two stages – thermal analysis and structural analysis. In the thermal analysis, the temperature within a cross-section at every thermal step is stored to be used for the subsequent structural step. For the purpose of this study, the time-temperature curve according to ISO 834 without cooling phase is used as shown in Fig. 2.

6 CASE STUDIES

A reinforced concrete frame designed for PGA of 0.35 g is chosen for the current study, which is loaded and designed based on ACI 318-08 code; the properties of the designed frame are presented in Fig. 3.

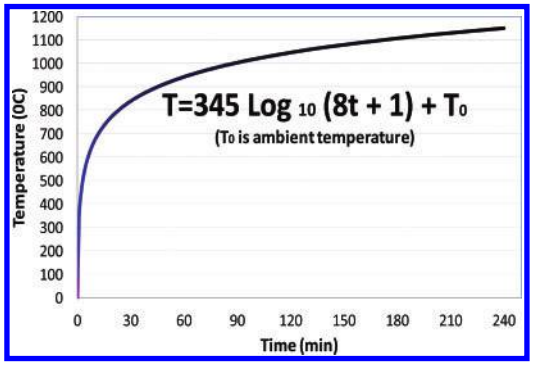

Figure 2. Fire pattern according to ISO834.

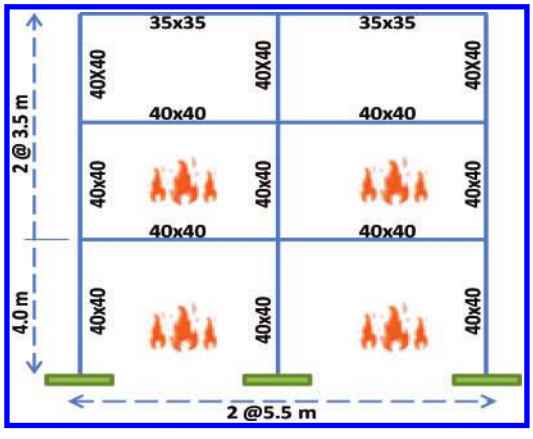

Figure 3. Geometric properties of selected case.

The structure is made of normal strength concrete with compressive strength of 25 MPa and longitudinal and transverse reinforcing bars with a yield stress of 400 MPa. The frame is dimensioned for the load combinations of 7.5 kPa dead load and 2.2 kPa live load. Combination of total dead load and 20% of live load is used to find the mass for calculating the earthquake load (ACI 318, 2008). The plastic hinge length (L_P) could be determined using a number of available methods; the formula proposed by Park and Paulay (1975) formula has been used due to its simplicity yet widely accepted accuracy. The plastic hinge length L_P is taken equal to $0.5H$ and H is the section height.

The model has been exposed to a standard fire (ISO834 curve) scenario for 4 hours. Concrete moisture content is assumed to be 2% for thermal analysis. The thermal expansion coefficients of rebar and that for concrete are taken as $12 \times 10^{-6}/°C$ and $10 \times 10^{-6}/°C$ respectively, whilst the Poisson's ratio of concrete is taken as 0.2. To achieve a clear understanding of the behavior, fire analysis was performed for the undamaged frame i.e. before occurrence the ground-motion. It must be noted that while exterior side of external columns is not exposed to fire, all sides of interior columns are subjected to high-temperature. Meanwhile, three sides of beams are exposed to fire as the top face is assumed to be protected by the concrete slab.

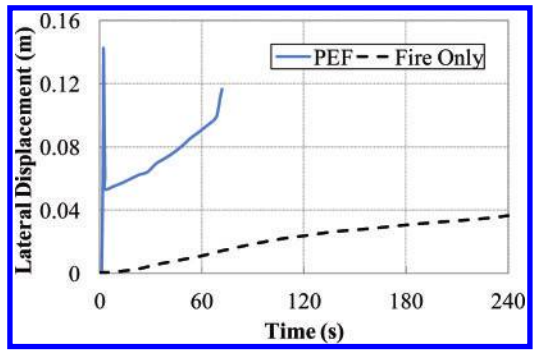

Figure 4. PEF resistance of the frame. Note: 2nd story lateral displacement plotted.

7 RESULTS

The sequential analysis comprises of three main stages that are gravity loading, followed by seismic pushover analysis, and finally post earthquake fire. In seismic analysis, the structure is subjected to a monotonically increasing lateral load to attain a certain level of drift. According to seismic codes philosophy, it is expected that ordinary structures like residential buildings remain at life safety level of performance. According to ASCE 7-10, the drift limit of 2% is used to control the lateral displacement of structures with the first period greater than 0.70 second. FEMA assumes that controlling this limit adequately provides for the life safety performance of a structure. The first modal period of the selected cases is greater than 0.70 seconds, thus, the selected structures are pushed to 0.02 drift. SAP2000 program is used for utilizing nonlinear pushover analysis with the hinges defined according to FEMA 356.

Fig. 4 plots displacement against time for the cases considered referring to the fire resistance of the frames for both scenarios (fire and PEF). The fire resistance is defined as the time at which the displacements, either globally (i.e. the drift of a certain point) or locally (i.e. the deformations at the middle of a beam), go beyond the chosen thresholds. The thresholds have been identified by the curve for displacements versus time step merging towards a vertical asymptote by 1% error. These thresholds implicitly represent the definition of fire resistance of a member as described earlier, where the member is not able to resist the initially applied gravity loads (Kodur and Dwaikat 2007).

It is obvious that the fire resistance of the damaged frame is much lower than the intact frame. While the fire resistance rating for the undamaged frame is around 4 hours, that for the PEF situation is only around 55 minutes. The collapse mechanism in fire alone scenario is local collapse, typically originating from the collapse of beams, whilst it fails in global fashion in PEF scenario causing a considerable lateral

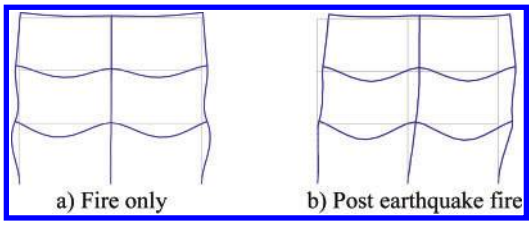

Figure 5. Collapse mechanism.

movement in the columns. Fig. 5 schematically shows two types of stated collapse failures.

8 CONCLUSION

Post-earthquake fire is one of the most problematic situations in seismic regions. The current paper presents a sequential nonlinear analysis for post earthquake fire. A three story RC frame was selected and designed for a PGA of 0.35 g, which was pushed to the maximum allowable inter-story drift and is assumed to satisfy the Life Safety performance level. Pushover curve was extracted for use in subsequent analysis. In addition, 1st and 2nd floor were subjected to fire. Sequential loading consisting of gravity and lateral loads followed by fire was a key aspect of the study conducted using FE package SAFIR. P-Δ effect and residual lateral deformations as well as degradation in stiffness were considered in SAFIR. Defining damaged sections – in terms of spalling of cover – in thermal analysis was another aspect considered in the fire analysis. The patterns of the damaged members were inspired from the descriptive definition of FEMA356 for building designed for the Life-Safety level of performance and the results of experimental tests. The following remarks can be made from the observations:

- While the fire resistance of the frame in the fire only situation was around 240 minutes, it considerably declined to around 55 minutes in post-earthquake fire. Thus it is obvious that structures suffering damage from earthquake loads could have significantly lower fire resistance than the undamaged structures. This could be the result of residual lateral displacements, the degradation in strength and stiffness, the direct heating of the steel reinforcement as a result of removal of cover that exacerbate the effects of fire.
- Two types of collapse mechanisms were observed during the fire analyses. While the global collapse occurred in the frames subjected to fire after an earthquake, the local collapse happened for the fire only case. The global collapse is mostly because of considerable lateral movement of the columns, whilst the local collapse occurs because of beam failure.
- The investigation performed herein represents a certain class of structures; further studies are required, either numerical or experimental, on different levels of performance and structures subjected to post-earthquake fire in order to develop a better understanding of this important issue.

Behaviour of structural steel subjected to post-earthquake fire

S. Sinaie, A. Heidarpour & X.L. Zhao
Department of Civil Engineering, Monash University, Melbourne, Australia

ABSTRACT: The mechanical response of a structural element not only depends on the inherent properties of the materials which constitute the element, but also on the history of any previously applied loads. An important instance is the response of steel structures subjected to post-earthquake fire, whereby the behaviour of steel at high temperatures is highly dependent on the existence and intensity of any prior cyclic load. While the individual effects of cyclic and thermal loadings on structural steel have been widely investigated in the literature, the effect of their sequential action is yet to be determined. This research aims to yield a fundamental understanding of the effect of a prior history of cyclic loads on the proceeding monotonic properties of grade 300PLUS steel at high temperatures. Results indicate that the effect of prior cyclic loads should be induced into fire resistant guidelines.

1 INTRODUCTION

Behaviour of structural steel not only depends on the innate properties of the material itself, but also on the history of loads it has already sustained. In other words, the responsive outcome of a certain type of load (e.g. monotonic) acting on a steel sample may differ if the sample had previously been subjected to another type of load. This is an example of what is further referred to as multi-phase loading history. In this work, multi-phase loading history is defined as the sequential action of different types of loads, whereby each type invokes a disparate behaviour of the material.

From a crystallographic point of view, the behavioural change in subsequent phases of an multi-phase loading history is due to the rearrangement of the dislocation structure during the previous phase (Kitayama et al., in press). On the other hand, from a modelling perspective, the memory of this history is preserved in the internal variables of the model, e.g. the hardening variables of a constitutive plasticity model (Lubliner 1990).

This work addresses the changes that cyclic loading induces on the subsequent response of steel under monotonic loads at high temperatures, or in other words, the post-cyclic thermal response of structural mild steel. While the individual effect, and the combined simultaneous effect of cyclic loading and thermal loading have been widely examined in the past (Kent & Park 1973, Outinen & Mekelainen 2002, Dusikia et al. 2007), research on their sequential effect in the form of a multi-phase loading history is scarce. An instance of such research is the work of Song et al. (2012).

Understanding post-cyclic thermal response at the material scale provides the means to the understanding of post-earthquake fire response at the structural scale. While design codes provide expressions for the mechanical properties of steel as a function of temperature for fire-resistant design, post-earthquake fire-resistant design of steel structures requires more knowledge about the multi-phase behaviour. The experimental work carried out in this research aims to address this phenomenon. The following sections briefly describe the test setup as well as the experimental results.

2 TEST PROGRAM

2.1 *Test setup*

All specimens used in this study were made from grade 300PLUS steel taken from the flange of 200UB22.3 hot rolled sections (BHP 1998). The preparation of the samples is consistent with the requirements of ASTM E606-92(1998). The specimen geometry is illustrated in Figure 1. Both faces of the specimens were grinded to give uniform thickness and a smooth finish across the entire surface. Specimens were restrained by means of two 12 mm high strength bolts at each end. the mechanical properties of the material at ambient state are given in Table 1.

In Table 1, E is the elastic modulus. σ_y and ε_y represent the yield stress and yield strain, respectively. σ_u and ε_u are the ultimate stress and ultimate strain, respectively. $H_{2.0}$ is the tangent modulus at $\varepsilon = 2.0\%$ where strain hardening initiates.

2.2 *Cyclic phase*

For the cyclic phase, a specifically built fixture was used to prevent the specimens from buckling about

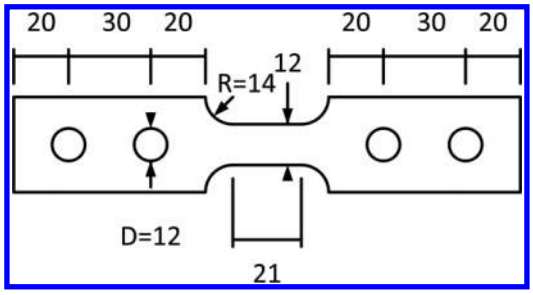

Figure 1. Sample geometry and dimensions in millimetres.

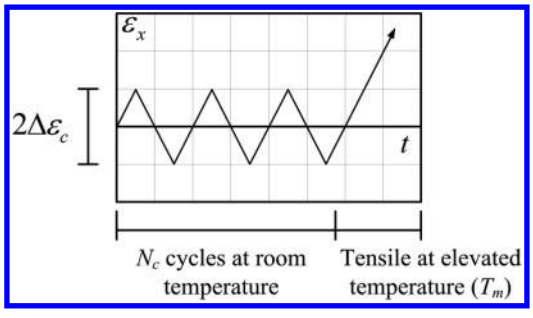

Figure 2. Multi-phase loading history including a cyclic phase at ambient state and a monotonic tensile phase at elevated temperature.

the weak axis. This fixture was comprised of two 12 mm plates with aligned holes in order to be fastened by appropriate bolts. The inner faces of these two plates which would be in contact with the specimen were polished and greased to yield minimum friction. Loads were applied by an Instron test machine (model 5892) with a 100 kN capacity. Axial force values were attained by the machine's built-in transducer, while strains were accumulated by a non-contact MTS laser extensometer (model LX1500). Tests were carried out in displacement control, however, the displacement rates were adjusted such that strain rates never exceeded 10^{-4} s^{-1}, which guarantees rate-independent behaviour. Figure 2 illustrates the loading history applied to the samples, where the number of cycles (N_c) and their amplitude ($\Delta\varepsilon_c$) are considered as variables for different test cases.

2.3 *Monotonic tensile phase at elevated temperature*

The anti-buckling fixture was removed prior to starting this phase of the test. The temperature was raised by means of an Instron thermal chamber (model 3119-408). The temperature of the sample was logged using

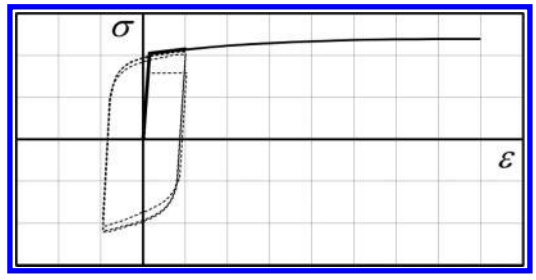

Figure 3. Multi-phase response of steel under strain-controlled cyclic load followed by a monotonic tensile load.

three thermocouples at three different heights of the sample's gage length. Loading was initiated after the temperature of these three points had stabilized with a gradient of less than 2%. Again, with the loading being in displacement control, the displacement rate was accordingly adjusted to limit the resulting strain rates to a rate-independent range. Strains were accumulated as before using the noncontact laser extensometer. Loading as well as data accumulation (at a frequency of 4 Hertz) was continued until failure. However, only the data attained up to the formation of necking will be presented.

3 TEST RESULTS

Five different combinations of $(\Delta\varepsilon_c, N_c)$ where used: that is $(0\%, 0)$, $(1\%, 3)$, $(1\%, 9)$, $(2\%, 3)$ and $(2\%, 9)$. The first combination represents a simple tensile test and is only expressed in this form for consistency. Hence, each sample's label will be expressed in the form AXCY, where A indicates amplitude and X is substituted with the value of amplitude ($\Delta\varepsilon_c$) in percentage strain and C indicates cycle and Y is substituted with N_c. For example, A1C9 represents a sample with a history of being subjected to 9 cycles of 1% strain amplitude. Each $(\Delta\varepsilon_c, N_c)$ combination is coupled with four different temperatures (T_m), namely Room temperature, 150°, 300° and 450° Celsius.

Figure 3 illustrates the typical behaviour of steel under the case of a cyclic-tensile multi-phase loading history. In this figure, the dashed line indicates the strain-controlled cyclic behaviour, whereby cyclic hardening is evident. While this figure shows only three cycles, it is worth noting that the cyclic hardening effect is observed to get stabilized around the sixth cycle, and by the ninth cycle a completely stabilized hysteresis loop is experienced. The solid line in this figure represents the response under the subsequent monotonic tensile phase of loading.

With the properties of the monotonic phase being of primary interest, Figure 4 is presented to indicate the selected properties. In this figure, $\sigma_{0.2}$ indicates the proof stress while $\varepsilon_{0.2}$ represents its corresponding strain. The ultimate stress and its corresponding strain are denoted by σ_u and ε_u, respectively and W represents the work per unit volume from the origin of the

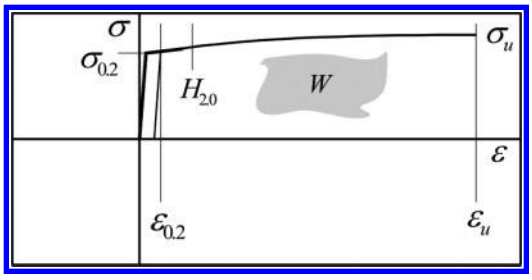

Figure 4. Mechanical properties of the post-cyclic tensile phase.

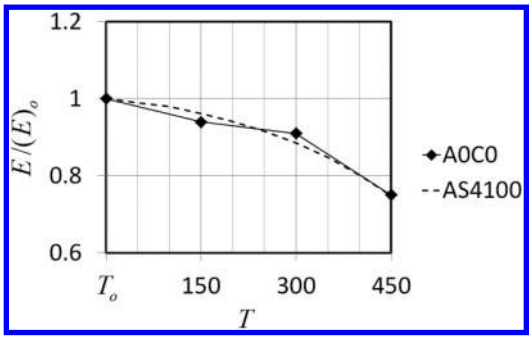

Figure 5. Variation of elastic modulus with temperature.

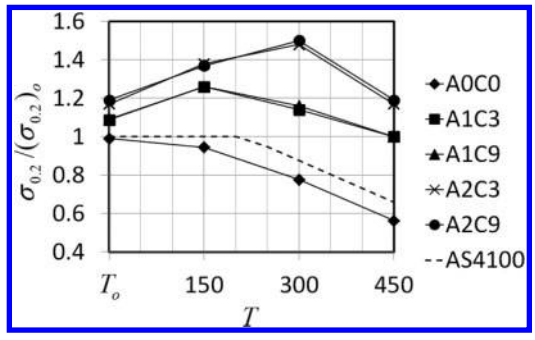

Figure 6. Variation of proof stress with temperature.

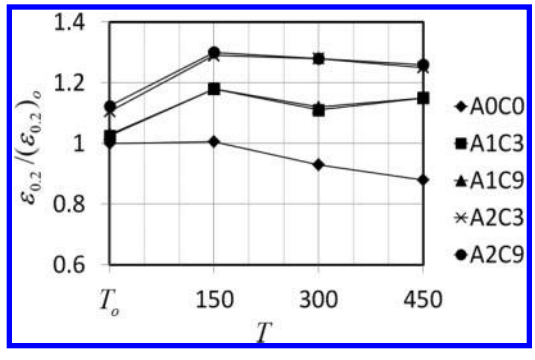

Figure 7. Variation of the strain corresponding to proof stress with temperature.

solid line up to the point of ultimate stress. In addition, with $\varepsilon = 2\%$ being the strain at which strain hardening initiates under a standard tensile test at ambient state, the tangent modulus $H_{2.0}$ at $\varepsilon = 2\%$ is also indicated as a variable of interest.

Before presenting the results, it is worth mentioning that given the common chemical composition of structural mild steel, this material gains hardened properties as the temperature rises up to about 150° C. However, the hardened properties tend to diminish as the temperature reaches 380° C, which afterwards, the material starts to soften. This behaviour was witnessed in the test program and is observed in the following results.

Figures 5–11 illustrate the variation of each of the aforementioned monotonic-phase variables as a function of temperature and cyclic-phase parameters, i.e. T_m, $\Delta\varepsilon_c$ and N_c. All values are normalized using their corresponding value for A0C0 at ambient temperature (denoted by the 'o' subscript).

Figure 5 shows the variation of the elastic modulus against temperature. The monotonic decrease of elastic modulus as the result of increasing temperature is the expected behaviour. The dashed line in this figure is the graph of the expression given by the Australian standard (AS4100 1998). It can be seen that the results obtained by experiment show good agreement with the design code expression.

The variation of the proof stress ($\sigma_{0.2}$) with temperature is presented in Figure 6. This figure shows that for the case with no previous cyclic history (i.e. A0C0), the proof stress monotonically decreases as temperature increases. However, for all other cases (which had previous cyclic histories), as the temperature increases, the value of $\sigma_{0.2}$ exhibits an initial increase followed by a decrease. Also shown in this figure, by the dashed line, is the graph of the expression given by AS4100 for the yield stress. The test results and design code expression are rather consistent, both in terms of value and variation pattern.

Figure 7 illustrates the variation of the strain corresponding to the proof stress, denoted by $\varepsilon_{0.2}$, with temperature. For the case with no cyclic history (A0C0), a monotonic decrease is observed. This is not the case for tests with previous cyclic histories and for these cases, the variation of $\varepsilon_{0.2}$ with temperature doesn't present a specific pattern. However, it is evident that the amplitude of the strain controlled cycles ($\Delta\varepsilon_c$) has a significant effect on $\varepsilon_{0.2}$. Moreover, what can be understood from Figures 6 and 7 is that the number of cycles does not affect the proof stress and the corresponding strain.

Illustrating the variation of the ultimate stress with temperature, Figure 8 can be considered as one of the most important results regarding post-cyclic thermal response. It has already been mentioned that this type of steel tends to attain hardened properties up to a temperature of 150° C. This is clearly evident in Figure 8. However, this figure demonstrates that a similar behavioural pattern also exists for samples which have a history of cyclic loading. Moreover, this figure shows a small increase of σ_u with the increase of cyclic loading parameters ($\Delta\varepsilon_c$ and N_c). While this increase in σ_u

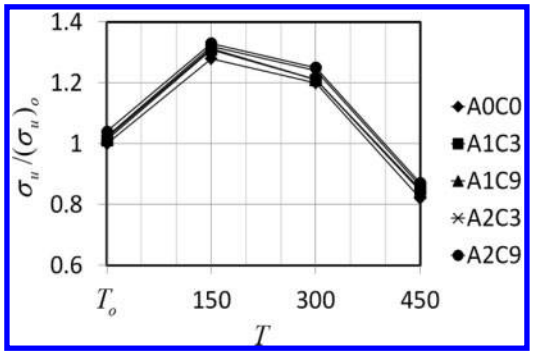

Figure 8. Variation of ultimate stress with temperature.

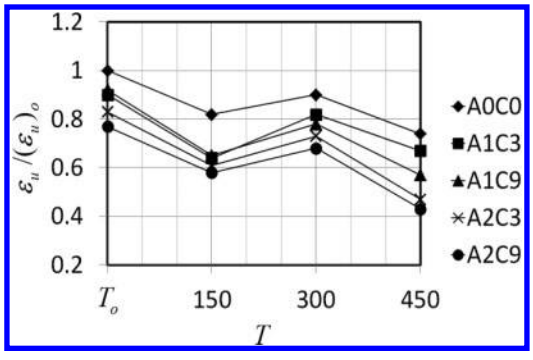

Figure 9. Variation of ultimate strain with temperature.

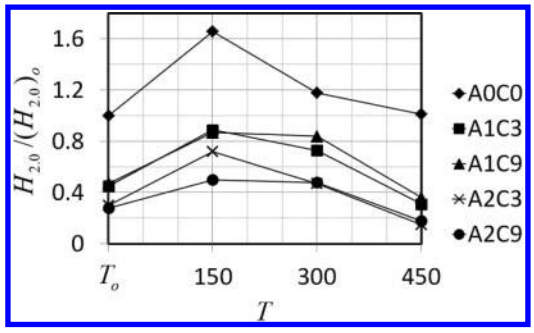

Figure 10. Variation of tangent modulus (at 2% strain) with temperature.

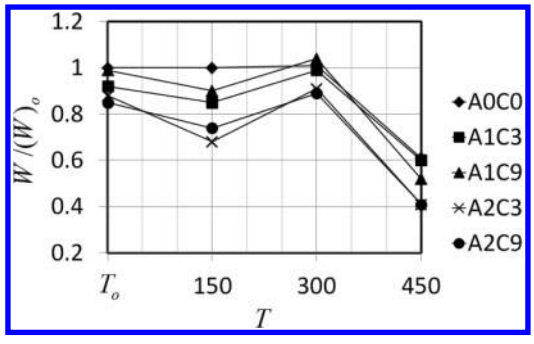

Figure 11. Variation of work per unit volume with temperature.

is small compared to the value of σ_u at temperatures up to 380° C, it becomes more prominent as the value of σ_u decreases with temperature. It appears that the value of σ_u for a post-cyclic thermal scenario can be obtained by adding the value of σ_u for a given temperature without a cyclic history (A0C0) to the increase that σ_u exhibits as the result of cyclic loads alone. This can be quite useful for design purposes, eliminating the need for exhaustive calculations.

As the counterpart for σ_u, the variation of ε_u with temperature is illustrated in Figure 9. This figure shows a fluctuation of the ultimate strain with rising temperature for A0C0 (no previous cyclic history). With the presence of a cyclic history, the same pattern is followed, however, with a significant drop in the value of ε_u as the cyclic-phase loading parameters are increased. It seems that further tests at higher temperatures must be carried out in order to gain a more definite understanding of these variations (These tests are currently being carried out at Monash University).

Figure 10 shows the variation of $H_{2.0}$ with temperature. This figure shows that for A0C0, the value of $H_{2.0}$ initially increases and then decreases with rising temperature. A nearly similar pattern is followed by other cases with a previous cyclic history, however, with lower values of $H_{2.0}$ as the cyclic-phase loading parameters ($\Delta\varepsilon_c$ and N_c) are increased.

Figure 11 illustrates the variation of work per unit volume against temperature. For A0C0, an almost constant value of W is observed for temperatures up to 300° C. However, W tends to decrease as the temperature passes 300° C. A different pattern is observed for cases with previous cyclic history. While these cases follow a similar pattern, they result in lower values of W, especially as $\Delta\varepsilon_c$ increases.

4 CONCLUSIONS

The aim of this research was to gain a fundamental understanding of the effect of a prior history of cyclic loads on the subsequent monotonic properties of a specific type of structural steel known as grade 300PLUS at elevated temperatures. For this purpose, steel specimens were initially subjected to a number of strain-controlled load cycles, and then monotonically loaded in tension at different temperatures until failure. With the number of cycles and strain amplitude serving as variables for the cyclic stage, and temperature being the variable for the monotonic stage, their combined influence on the mechanical properties of structural steel was examined.

The following conclusions can be drawn from the experimental results.

– Regarding the variations illustrated in Figures 8 and 9, the fact that the variations of σ_u and ε_u do not change pattern as a result of a previous cyclic history, but only shift in value, has great implications in view of developing design guidelines. This feature

allows the superposition of the individual effects of cyclic loads and thermal loads, in order to get the effect of their sequential combination.
- Whether ductility is viewed as the ratio of $\varepsilon_{0.2}/\varepsilon_u$, or work per unit volume (W), or simply by comparing combinations of $(\sigma_u, \varepsilon_u)$, it is evident that the existence of a previous cyclic phase decreases the ductility of the proceeding monotonic phase. This decrease is combined with the changes caused by elevated temperature. Therefore, it is reasonable to say that the sequential effect of cyclic load and temperature may lead to situations more severe than when the rise in temperature had not been preceded by a cyclic load. This indicates the fact that new formulations need to be developed for a post-earthquake fire-resistant design.
- Further tests should be conducted at higher temperatures in order to get a better understanding of the variations of $\varepsilon_{0.2}$ and ε_u. These test are currently being carried out at Monash University.

ACKNOWLEDGEMENT

The research work presented in this paper was supported by the Australian Research Council through a Discovery Project (DP1096454) awarded to the second author.

Target reliability for engineering structures

M. Holický
Klokner Institute, Czech Technical University, Prague, Czech Republic

ABSTRACT: The target reliability levels recommended in national and international documents vary within a broad range, while the reference to the cost of construction and failure consequences is mentioned only very vaguely. In some documents the target reliability index β is indicated for one or two reference periods (1 year and 50 years) without providing an appropriate link to the design working life. This contribution attempts to clarify the relationship between the target reliability levels, structural costs, failure consequences, reference period, the design working life and the discount rate. The theoretical study based on probabilistic optimization is supplemented by recommendations useful for code developers and practicing engineers. It appears that the optimal reliability level depends primarily on the construction costs, failure costs and relative cost for improving structural safety, and less significantly on the discount rate and the time to failure. In design based on the partial factor method, it is recommended that the characteristic values of the basic variables be defined independently of the design working life; to specify the design values on the bases of optimal reliability index; and to derive the partial factors from the specified design values and defined characteristic values.

1 INTRODUCTION

The target reliability levels recommended in various national and international documents for new structures are inconsistent in terms of the recommended values and criteria according to which the appropriate values are to be selected. Almost no recommendations are available for temporary structures. In general, optimum reliability levels can be obtained by considering both the cost of the structure and the expected cost of failure over the design working life.

The design working life is understood as an assumed period of time for which a structure is to be used for its intended purpose without any major repair work being necessary. Indicative values of design working life (10 to 100 years for different types of new structures) are given in EN 1990 (2002). Recommended values of reliability indexes are given for two reference periods, 1 year and 50 years (see Table 1), without any explicit link to the design working life that generally differs from the reference period, while no specific indicative values are available for temporary structures.

It should be emphasized that the reference period is understood as a chosen period of time used as a basis for statistically assessing time variable basic random variables and the corresponding probability of failure. The concept of reference period is therefore fundamentally different from the concept of design working life. Confusion is often caused when the difference between these two concepts is not recognized.

It should be recognized that the couple of β values (for 1 year and 50 years) given in Table 1 for each reliability class correspond to the same reliability level. Practical application of these values, however, depends on the time period considered in the verification, which may be linked to available probabilistic information concerning time variant basic variables (imposed load, wind, earthquake, etc.). It should be noted that the reference period of 50 years is also accepted as the design working life for common structures (see discussion by Diamantidis (2009)).

For example, considering a structure of reliability class 2 having a design working life of 50 years, the reliability index $\beta = 3.8$ should be used, provided that probabilistic models of basic variables are available for this period. The same reliability level is achieved when a reference period of 1 year and a target of $\beta = 4.7$ are applied using the theoretical models for a reference period of one year. Thus, when designing a structural member, similar dimensions (reinforcement area) would be obtained considering $\beta = 4.7$ and basic variables related to 1 year or $\beta = 3.8$ and basic variables related to 50 years.

A more detailed recommendation concerning the target reliability is provided by ISO 2394 (1998) where the target reliability indexes are indicated for the whole design working life without any restriction concerning its length, and are related not only to the consequences, but also to the relative costs of safety measures (see Table 2).

Similar recommendations are provided in the JCSS (2001) Probabilistic Model Code (Table 3). Recommended target reliability indexes are also related to both the consequences and to the relative costs of safety measures, though for a reference period of

Table 1. Reliability classification in accordance with EN 1990 (2002).

Reliability classes	Consequences of structural failure	Reliability index β for reference period		Examples of buildings and civil engineering works
		1 year	50 years	
RC3 – high	High	5.2	4.3	Bridges, public buildings
RC2 – normal	Medium	4.7	3.8	Residences and offices
RC1 – low	Low	4.2	3.3	Agricultural buildings

Table 2. Examples of life-time target reliability indexes β in accordance with ISO 2394 (1998).

Relative costs of safety measures	Consequences of failure			
	small	some	moderate	great
High	0	1.5	2.3	3.1
Moderate	1.3	2.3	3.1	3.8
Low	2.3	3.1	3.8	4.3

Table 3. Tentative target reliability indexes β (and associated target failure rates) related to one year reference period and ultimate limit states in accordance with JCSS (2001).

Relative costs of safety measures	Minor consequences of failure	Moderate consequences of failure	Large consequences of failure
Large	$\beta = 3.1$ ($p \approx 10^{-3}$)	$\beta = 3.3$ ($p \approx 5 \times 10^{-4}$)	$\beta = 3.7$ ($p \approx 10^{-4}$)
Normal	$\beta = 3.7$ ($p \approx 10^{-4}$)	$\beta = 4.2$ ($p \approx 10^{-5}$)	$\beta = 4.4$ ($p \approx 5 \times 10^{-6}$)
Small	$\beta = 4.2$ ($p \approx 10^{-5}$)	$\beta = 4.4$ ($p \approx 5 \times 10^{-6}$)	$\beta = 4.7$ ($p \approx 10^{-6}$)

1 year. The consequence classes in JCSS (2001) (similar to those in EN 1990, 2002) are linked to the ratio ρ defined as the ratio $(C_{str} + C_f)/C_{str}$ of the total cost induced by a failure (cost of construction C_{str} plus direct failure costs C_f) to the construction cost C_{str} as follows:

- Class 1 Minor Consequences: ρ is less than approximately 2; risk to life, given a failure, is small to negligible and the economic consequences are small or negligible (e.g. agricultural structures, silos, masts);
- Class 2 Moderate Consequences: ρ is between 2 and 5; risk to life, given a failure, is medium and the economic consequences are considerable (e.g. office buildings, industrial buildings, apartment buildings);
- Class 3 Large Consequences: ρ is between 5 and 10; risk to life, given a failure, is high, and the economic consequences are significant (e.g. main bridges, theaters, hospitals, high rise buildings).

However, it is not quite clear what is meant in JCSS (2001) by "the direct failure costs". This term indicates that there may be some other "indirect costs" that may affect the total expected cost. Here it is assumed that the failure costs C_f cover all additional direct and indirect costs (except the structural costs C_{str}) induced by the failure. The structural costs are considered separately and related to the costs needed for an improvement of safety (costs per unit of decision parameter C_1).

Both documents ISO 2394 (1998) and JCSS (2001) seem to recommend reliability indexes that are lower than those given in EN 1990 (2002) even for the "small relative costs" of safety measures. It should be noted that EN 1990 (2002) gives the reliability indexes for two reference periods (1 and 50 years) that may be accepted as the design working life for common structures (see also a discussion provided by Diamantidis (2009)). ISO 2394 (1998) recommends indexes for "life-time, examples", thus related to the design working life, without any restrictions, while Probabilistic Model Code by JCSS (2001) provides reliability indexes for the reference period of 1 year.

However, a clear link between the design working life and the target reliability level is not apparent from any of the above-mentioned documents. Thus, it is not clear which target reliability index should be used for a given design working life different from 50 years (say 10 years).

The basic aim of this contribution is to clarify the link between the design working life and the reliability index and to provide guidance for specification of the target reliability level for a given design working life. The submitted theoretical study based on probabilistic optimization is supplemented by practical recommendations. This contribution is an extension of the previous study by Holicky and Retief (2011).

2 GENERAL PRINCIPLES OF PROBABILISTIC OPTIMIZATION

Probabilistic optimization is based on a fundamental form of the objective function (not covering monitoring and maintenance) expressed as the present value of the total expected cost $C_{tot}(x, q, n)$

$$C_{tot}(x,q,n) = C_{str} \sum_1^n P_f(x,i) + C_f \sum_1^n P_f(x,i) Q(q,i) + \\ + C_0 + x\, C_1 \qquad (1)$$

Here x denotes the decision parameter of the optimization (a parameter of structural resistance), q is the annual discount rate (e.g. 0.03, an average long run value of the real annual discount rate in European countries), n is the number of years to the failure, which may differ from the design working life (specified usually as 50 or 100 years).

Further, $P_f(x, i)$ is the failure probability in year i, $Q(q, i)$ is the discount factor dependent on the annual

discount rate q and the year number i, C_0 is the initial cost independent of the decision parameter x and failure (a quantity not affecting the optimization), and C_1 is the cost per unit of the decision parameter x (a structural parameter quantity affecting the structural resistance and optimization).

Note that the design working life may generally differ from the time to failure denoted by the number of years n and considered here as an independent variable affecting the probability of failure. Maintenance and possible repair of the structure is not included in the objective function (1) and these aspects are to be considered in further studies.

Assuming independence failure events in subsequent years, the annual probability of failure $P_f(x, i)$ in year i may be approximated by the geometric sequence

$$P_f(x,i) = p(x)\,(1 - p(x))^{i-1} \tag{2}$$

The initial annual probability of failure $p(x)$ is dependent on the decision parameter x. Note that annual failure probabilities can be assumed to be independent when failure probabilities are chiefly influenced by time-variant loads (climatic actions, traffic loads, accidental loads). Then the failure probability $P_{fn}(x)$ during n years can be estimated by the sum of the sequence $P_f(x, i)$, that can be expressed as

$$P_{fn}(x,n) = 1 - (1 - p(x))^n \approx n\,p(x) \tag{3}$$

Note that the approximation indicated in equation (3) is fully acceptable for small annual probabilities $p(x) < 10^{-3}$.

The discount factor of the present value of the expected future costs in year i is considered in the usual form as

$$Q(q,i) = 1/(1+q)^i \tag{4}$$

Thus, the cost of malfunctioning C_f is discounted by the factor $Q(q, i)$ depending on the discount rate q and the point in time (year number defined as i) when the loss of structural utility occurs.

Considering equations (2) and (4) the total costs $C_{tot}(x, q, n)$ described by equation (1) this may be written in a simplified form as

$$C_{tot}(x,q,n) = C_{str}\,n\,p(x) + C_f\,p(x)\,PQ(x,q,n) + \\ + C_0 + x\,C_1 \tag{5}$$

Here the total sum of expected malfunction costs during the period of n years is dependent on the product of the present value of malfunction cost C_f, the annual probability $p(x)$ and a sum of the geometric sequence having the quotient $(1 - p(x))/(1 + q)$, denoted as the time factor $PQ(x, q, n)$:

$$PQ(x,q,n) = \frac{1 - \left[\frac{1-p(x)}{1+q}\right]^n}{1 - \left[\frac{1-p(x)}{1+q}\right]} \tag{6}$$

In general the total cost $C_{tot}(x, q, n)$ depends on the costs C_0, C_1, C_f, the annual probability of failure $p(x)$, the discount rate q and the design working life n. Note that for small probabilities of failure $p(x)$ (for appropriate structural parameter x) and very small (zero) discount rate q, the time factor $PQ(x, q, n) \approx n$.

The necessary condition for the minimum of the total cost follows from (1) as

$$\frac{\partial C_{tot}(x,q,n)}{\partial x} = C_{str} \sum_{i=1}^{n} \left[\frac{\partial P_f(x,i)}{\partial x}\right]_{x=x_{opt}} + \\ + C_f \sum_{i=1}^{n} Q(q,i) \left[\frac{\partial P_f(x,i)}{\partial x}\right]_{x=x_{opt}} + C_1 = 0 \tag{7}$$

Equation (8) represents a general form of the necessary condition for the minimum of total cost $C_{tot}(x, q, n)$, the optimum value x_{opt} of the parameter x and the optimum annual probability of failure $p_{opt} = p(x_{opt})$. The optimum probability for the total design working life $T_d = n$ years follows from equation (7) as

$$\sum_{i=1}^{n} Q(q,i) \left[\frac{\partial P_f(x,i)}{\partial x}\right]_{x=x_{opt}} + \\ + (\rho - 1) \sum_{i=1}^{n} Q(q,i) \left[\frac{\partial P_f(x,i)}{\partial x}\right]_{x=x_{opt}} = -\frac{C_1}{C_f} \tag{8}$$

Equation (8) represents a general form of the necessary condition for the minimum of total cost $C_{tot}(x, q, n)$, the optimum value x_{opt} of the parameter x and the optimum annual probability of failure $p_{opt} = p(x_{opt})$. The optimum probability for the total design working life $T_d = n$ years follows from equation (3) as

$$P_{fn,opt} = 1 - (1 - p_{opt})^n \approx n\,p_{opt} \tag{9}$$

The corresponding optimum reliability index $\beta_{opt} = -\Phi^{-1}(P_{fn,opt})$. These quantities are in general dependent on the cost ratio C_f/C_1, discount rate q and the design working life n.

3 FAILURE PROBABILITY OF A GENERIC STRUCTURAL MEMBER

Consider a generic structural member described by the limit state function $Z(x)$

$$Z(x) = x\,f - (G + Q) \tag{10}$$

Here x denotes a deterministic structural parameter (e.g. the cross-section area), f the strength of the material, G the load effect due to permanent load and Q the load effect due to variable load. Theoretical models of the random quantities f, G and Q considered in the following example are given in Table 4 (adopted from JCSS (2001) and Holicky (2009)).

Table 4. Theoretical models of the random variables f, G and Q (annual extremes).

Variables	Distribution	Mean	Standard deviation	Coef. of variation
f	Lognormal	100	10	0.10
G	Normal	35	3,5	0.10
Q	Gumbel	10	5	0.50

Considering the theoretical models given in Table 4, the reliability margin $Z(x)$ may be well approximated by the normal distribution $\Phi_{Z(x)}$ that provides sufficient accuracy. The annual failure probability $p(x)$ is then given as

$$p(x) = \Phi_{Z(x)}(Z(x) = 0) \tag{11}$$

In equation (11) the normal distribution is evaluated for $Z(x) = 0$; then for $x = 1$ and $n = 50$ the probability $P_{fn}(1, 50) \approx 6.7\ 10^{-5}$ and corresponding $\beta \approx 3.8$.

4 AN EXAMPLE

The following example illustrates the general principles, as well as a special case of probabilistic optimization. To simplify the analysis, the total costs $C_{tot}(x, q, n)$ given by equation (5) are transformed to the standardized form $\kappa_{tot}(x, q, n)$ given as

$$\kappa_{tot}(x,q,n) = \frac{C_{tot}(x,q,n) - C_0}{C_1} = \\ = p(x)C_{str}/C_1\left[n + (\rho - 1)PQ(x,q,n)\right] + x \tag{12}$$

Here ρ denotes the cost ratio $(C_{str} + C_f)/C_{str}$ of the sum of cost and failure costs $(C_{str} + C_f)$ to structural costs C_{str}.

The annual probability of failure $p(x)$ considered here for a general structural member is given by equation (11). However, the following procedure may be applied for any relevant dependence of the failure probability $p(x)$ expressed as a function of a suitable structural parameter x.

In the example, illustrated in Figure 1, it is assumed that the discount rate is $q = 0.03$ and the year number when the failure occurs is $n = 50$. Under these assumptions, Figure 1 shows the variation of the total standardized costs $\kappa_{tot}(x, q, n)$ (given by equation (12)), and the optimum reliability index β_{opt}, with structural parameter x. The optimal values $x_{opt}(q, n)$ of the structural parameter x, given by equation (8), are indicated by the dashed vertical lines. Indicated values of $\beta = 2.6$, 3.2, 3,5 correspond to annual rates 3,7, 4.2 and 4.4 recommended by JCSS (2001) (Table 3) for "normal relative costs of safety measures".

Note that the cost ratio $\rho = (C_{str} + C_f)/C_{str} = 1$ describes the extreme case when the failure costs C_f are negligible, $C_f \approx 0$, and the failure consequences

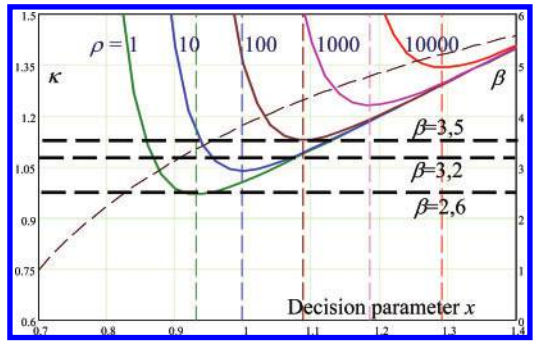

Figure 1. Variation of the total standardized cost $\kappa_{tot}(x, q, n)$ and the optimum reliability index β_{opt} with the decision parameter x for $q = 0.03$, $n = 50$, $C_{str}/C_1 = 100$ and selected cost ratios ρ.

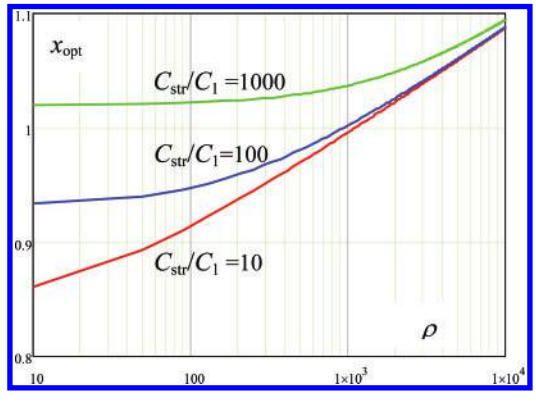

Figure 2. Variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the number of years n for the cost ratios $C_f/C_1 = \rho = 100$ and selected discount rates $q = 0.01, 0.03, 0.05$.

are confined to the structural costs C_{str}. Assuming the conditions considered in Figure 1 ($q = 0.03$, $n = 50$, $C_{str}/C_1 = 100$) the corresponding optimal reliability index $\beta_{opt} \approx 3.3$.

5 THE OPTIMAL RELIABILITY INDEX

The optimal decision parameter x_{opt} given by equation (8) is indicated in Figure 2.

The optimal reliability index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ depends in general on the discount rate q, the time to failure (number of years) n, and on the two cost ratios C_{str}/C_1 and $\rho = (C_{str} + C_f)/C_{str}$. Note that the failure C_f is discounted to the present price.

The dependence of $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ on q and n seems to be insignificant. This is well illustrated by Figure 3.

Figure 3 shows the variation of the optimal reliability index β_{opt} with the time to failure (number of years) n for the cost ratios $C_f/C_1 = \rho = 100$ for selected discount rates $q = 0.01$, 0.03 and 0.05. The optimal reliability index β_{opt} is almost independent

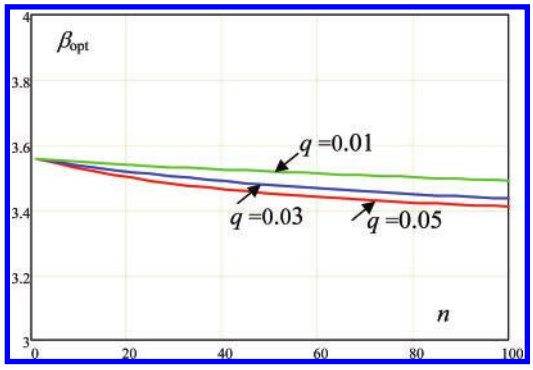

Figure 3. Variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the number of years n for the cost ratios $C_f/C_1 = \rho = 100$ and selected discount rates $q = 0.01, 0.03, 0.05$.

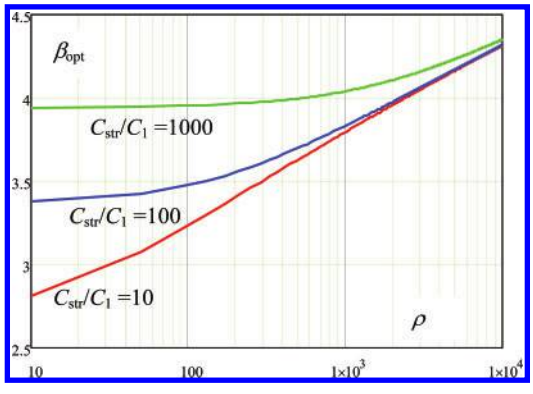

Figure 4. Variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the cost ratio $\rho = (C_{str} + C_f)/C_{str}$ for $q = 0.03$, $n = 50$, and selected ratios $C_{str}/C_1 = 10, 100, 1000$.

of q and n. Thus, as a conservative approximation, the target β can be determined considering a small discount rate q (for example 0,01) and a minimum number of years n (say 10).

The following Figure 4 shows variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the cost ratio ρ for $q = 0.03$, $n = 50$, and selected ratios $C_{str}/C_1 = 10, 100, 1000$.

Similarly, Figure 5 shows the variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the cost ratio C_{str}/C_1, for $q = 0.03$, $n = 50$, and selected ratios and for $\rho = 10, 100, 1000$.

The variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the cost ratio C_{str}/C_1, shown in Figure 5, slightly differs from the variation with the ratio ρ, indicated in Figure 1. This difference is due to the effect of the discounting of the failure consequences C_f. Nevertheless, the optimal reliability level depends also on the costs C_1 (in addition to the costs C_{str} and C_f). That is why the recommendation provided by ISO and JCSS consider also "the relative costs of safety measures". Nevertheless, the indicated values of the ratio $\rho = (C_{str} + C_f)/C_{str}$ within the interval from 2 to 10 seem to be rather low.

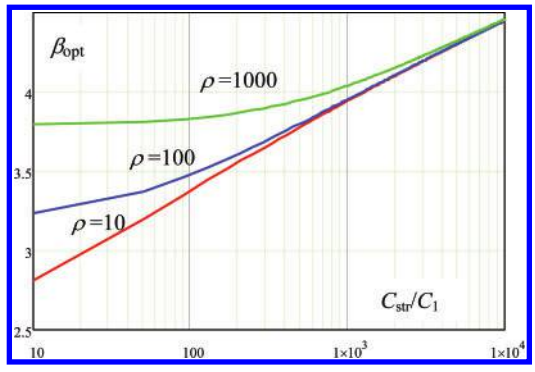

Figure 5. Variation of the index $\beta_{opt}(q, n, C_{str}/C_1, \rho)$ with the cost ratio C_{str}/C_1 for $q = 0.03$, $n = 50$, and selected ratios $\rho = (C_{str} + C_f)/C_{str} = 10, 100, 1000$.

The optimization results shown in Figures 2, 3 and 4 clearly indicate that the optimal reliability index β_{opt} depends primarily on both the cost ratios C_{str}/C_1, and $\rho = (C_{str} + C_f)/C_{str}$. For the cost ratios $C_f/C_1 = \rho = 100$ (a reasonable estimate) the optimal reliability index β_{opt} is about 3.5, and that corresponding to probability of failure is 2.3 10^{-4}.

However, when the cost ratios are small (say $C_f/C_1 = \rho = 10$), the optimal index β_{opt} is about 2.8, and that corresponding to probability of failure is 2.6 10^3, and is thus about ten times greater.

It is interesting to mention that the actual reliability level observed in common design using the partial factor method is quite conservative (Holicky and Schneider (2001)), and often corresponds to the reliability index β above 5.

6 CONCLUSIONS AND RECOMMENDATIONS

The available documents and codes for structural design do not provide a clear link between the design working life and the target reliability level, and no recommendations are offered to specify the target reliability index for temporary and long life structures.

It has been shown that the target reliability of structures can be derived from theoretical principles of probabilistic optimization considering the objective function as the total costs expressed as a sum of the initial costs C_0, the marginal costs x C_1 (where $x$denotes decision parameter and C_1 the incremental cost of decision parameter x), and the failure consequences consisting of the construction costs C_{str} and failure costs C_f (the loss of structural utility at the time of failure), these being taken into account by the cost ratio $\rho = (C_{str} + C_f)/C_{str}$. The failure cost C_f is discounted considering an annual discount rate q and the time to failure (number of years) n. In such a way the total cost is affected by the discount rate q and the number of years n.

An example of probabilistic optimization of a generic structural member clearly shows (see Figure 1, 4 and 5) that the optimal reliability level, reliability index β, depends primarily on:

- the structural costs C_{str},
- failure costs (malfunctioning costs) C_f,
- costs for improving structural safety C_1.

Less significant seem to be the discount rate q (about 0.03) and the time to failure n (figure 3).

It is recommended that the obtained results be considered in the development of design codes based on the partial factor method as follows:

- to specify the reliability level taking into account the optimal reliability index,
- to define the characteristic values of the basic variables as time independent quantities,
- to determine the design values on the basis of the specified reliability index design working life,
- to determine the partial factors considering the design and characteristic values.

It should be stated that further investigations are needed in order to include the costs of monitoring and the repair of structures, to improve assessment of failure consequences and to illustrate the application of general results in practical design.

ACKNOWLEDGEMENT

This study is an outcome of the research project GAČR P105/12/0589: "Probabilistic optimisation of the target structural reliability".

Reliability evaluation and design of steel frames with BRBs under severe earthquakes

Y.S. Liu, G.Q. Li & X.K. Guo
Tongji University, Shanghai, China

ABSTRACT: The steel Buckling-Restrained Braced Frame (BRBF) is a promising earthquake resisting structural system. However, the reliability assessment and design method of the structure still needs to be studied deeply for practical use. In this paper, inter-story and roof drift of the structure are chosen as the damage indexes to assess the reliability of the structural system. Firstly, the equivalent linearization method is introduced; then extensive time history analyses are conducted according to the seismic code of China. By combining the equivalent linearization method with the statistical characteristics of the elastoplastic displacement of the structure, the probability density function of the displacement can be determined, and the failure probability of the structure with different performance levels can be obtained. Finally, the proposed reliability evaluation method is illustrated by an example and the reliability design method of the structure under severe earthquake is given for the reference of engineering design.

1 INTRODUCTION

The buckling restrained brace (BRB) is generally composed of a ductile steel core that carries axial load and a constraining element that prevents the core from buckling under compression. The steel core is designed to yield in both tension and compression that can dissipate a significant sum of energy in earthquakes. After the Northridge (1994) and Kobe (1995) earthquakes, BRBs have been quickly accepted (Uang, 2004 and Xie, 2005) and the buckling restrained braced steel frames (BRBFs) also have become a very promising structural system to resist seismic load. Many researchers have conducted study on the design method of BRBFs. B. Asgarian and H.R. Shokrgozar (2009) used static pushover analysis and nonlinear incremental dynamic analysis to study BRBFs with various stories and different bracing configuration including diagonal. Over-strength, ductility and response modification factor *R* of BRBFs were evaluated. Choi and Kim, et al. (2006) developed the performance-based design method of BRBF based on the energy-balance concept. The errors associated with the energy-balance concept were identified and corrected by implementing proper correction factors. Also, they (Choi and Kim, et al., 2006) proposed an energy-based seismic design procedure for BRBFs using hysteretic energy spectra and accumulated ductility spectra. The procedure is based on the premise that the gravity load-resisting elements, such as beams and columns, are designed to remain elastic during earthquakes, and all the seismic input energy is dissipated by the buckling-restrained braces. However, the proposed design methods mentioned above are all deterministic schemes. The seismic reliabilities of the BRBFs are unknown. Lin, et al. (2010) evaluates the seismic reliability of eccentrically braced frame (EBF) and BRBF systems in comparison with that of moment-resisting frame (MRF) systems. The results show that the effectiveness of braced frames can vary significantly with ground motions and building rises. The added braced frames help to reduce story drifts, decreasing the probability of failure against ordinary ground motions. In China, seismic design of building is based on the frequent earthquake level, and collapse check is performed by nonlinear time-history analysis adopting several ground motions (GB 50011, 2010). The design concept cannot determine seismic reliability of structures under severe earthquakes.

For practical purpose, there is a pressing need to propose an easy way to assess the collapse probability and propose a design procedure of BRBFs considering the stochastic factors, such as ground motion, site category and structural arrangement. In this paper, inter-story and roof drift of the structure are chosen as the damage indexes to assess the reliability of the structural system. By combining the equivalent linearization method with the statistical characteristics of the elastoplastic displacement of the structure, a method to make reliability assessment and design of BRBF is presented.

2 DEFINITION OF LIMIT STATE

Performance-based seismic design (PBSD) is developed very fast in the recent decades, purpose of which is to ensure that the structure has different

Table 1. Performance levels in terms of roof drift θ_r.

Level	Performance	State	Limitation/%
1	Safe, immediate use	No damage	<0.2
2	Can be used after minor repair	Minor damage	<0.5
3	Structural damage, much repair needed	Medium damage	<1.5
4	Cannot be repaired	Severe damage	<2.5
5	Collapse	Collapse	>2.5

Table 2. Performance levels against inter-story drift θ_i.

Level	Severe earthquake
1	Almost no damage, $\theta_i > [\theta_e]$ a little
2	Minor damage, $\theta_i < 2[\theta_e]$
3	Obvious plastic, $\theta_i \approx 4[\theta_e]$
4	No serious damage, $\theta_i < 0.9[\theta_p]$

performance levels against different seismic hazard probabilities. However, definition of performance index varies among different researchers, such as story drift, energy dissipation capacity, damage and multi-parameter index. The most accepted and used is story drift, including inter-story and roof drift, with its convenience and directness for practical use. Displacement-based seismic design is the most important way to realize the PBSD methodology. In this paper, the limit state of BRBF at different performance levels is expressed as

$$G = D - [D] \le 0 \tag{1}$$

where D is the displacement of the story (inter-story and roof drift), $[D]$ is the displacement limitation according to performance levels. By comparing and summarizing the achievement of SEAOC (1995), ATC(1996) and FEMA(1996), Smith (2001) suggests that the performance of structures can be classified in terms of roof drift as shown in Table 1.

Performance-based seismic design is also developed in China, which is recently presented in the Seismic Design Code for Buildings (GB 50011, 2010) after Wenchuan earthquake in 2008. The performance of structure is divided into four levels according to the inter-story drift and seismic hazard, as shown in Table 2, where $[\theta_e]$ is the elastic inter-story drift limitation (1/250 for BRBFs), $[\theta_p]$ is the plastic inter-story drift limitation (1/50 for BRBFs).

3 SIMPLIFIED METHOD TO CALCULATE INELASTIC DISPLACEMENT OF BRBF

3.1 *Equivalent linear method*

Equivalent linear method is proposed to predict the peak elasto-plastic displacement response of structures in earthquakes. By using different principles of equivalence, the equivalent linear method consists of secant stiffness method (Rosenblueth, 1964), Hwang (1996) empirical coefficient method, average stiffness and energy method (Iwan, 1979), etc. The methodology is basically dependent on assuming that energy absorbed by the elasto-plastic structure equals to that dissipated by the damping of a corresponding elastic structure. Meanwhile, the fundamental period is modified to reflect stiffness decrease of the structure. The peak elasto-plastic displacement response can be easily estimated by linear analysis of the equivalent elastic structure with the modified design response spectrum. To compare with the nonlinear time history analysis, the calculating time is reduced dramatically. The equivalent linear method is adopted by FEMA273&274 and the Seismic Design Code for Buildings (GB 50011,2010) of China.

3.2 *Equivalent damping ratio and period*

According to the Seismic Design Code for Buildings of China (GB 50011, 2010), the equivalent damping ratio ζ_{eq} provided by the energy dissipation elements can be estimated as

$$\zeta_{eq} = W_p / (4\pi W_s) \tag{2}$$

where W_p is the hysteretic energy dissipated by structural elements in one cycle of the expected displacement; W_s is the total strain energy at the expected displacement.

The skeleton curve of BRBF is shown in Figure 1, which can be considered as combination of load-displacement curve for Frame and BRBs. W_p and W_s are illustrated in Figure 2, when the expected displacement U_m is achieved.

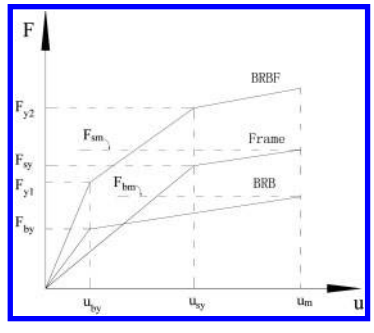

Figure 1. Skeleton curve.

where F_{by} is the story shear capacity provided by BRBs; u_{by} is the story displacement when BRB yields; F_{sy} is the yield capacity of frame; u_{sy} is the yield displacement of frame; U_m is the expected displacement of BRBF; F_{y1} is the story shear force of BRBF when the BRB yields; F_{y2} is the story shear force of the frame when the BRBF totally yields; F_{bm} is the story shear capacity provided by BRBs at U_m; F_{sm} is the story shear capacity provided by the frame at U_m.

The total damping ratio of the BRBF structure contains two parts, i.e., viscous damping ratio ζ_e and equivalent damping ratio ζ_{eq}, which is shown as

$$\zeta_P = \zeta_e + \zeta_{eq} \tag{3}$$

where ζ_e is 0.05 for analysis in severe earthquakes.

The frequency ω_r of structure with damping ratio ζ can be calculated as

$$\omega_r = \omega\sqrt{1-\zeta^2} \tag{4}$$

where ω is the fundamental frequency without damping ratio ζ.

So, the elasto-plastic period of structure T_p can be given by

$$T_p = T_e\sqrt{1-\zeta_e^2}/\sqrt{1-\zeta_p^2} \tag{5}$$

where T_e is the fundamental period of the elastic model without damping ratio ζ.

3.3 *Modified design response spectrum*

When the equivalent damping ratio and period are got, the elastic design response spectrum can be modified to consider the hysteretic energy dissipated by BRBs. The design response spectrum adopted by the Seismic Design Code for Buildings (GB 50011, 2010) is shown in Figure 3.

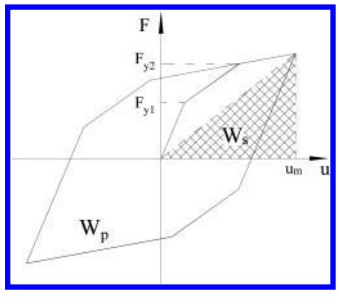

Figure 2. Hysteretic curve.

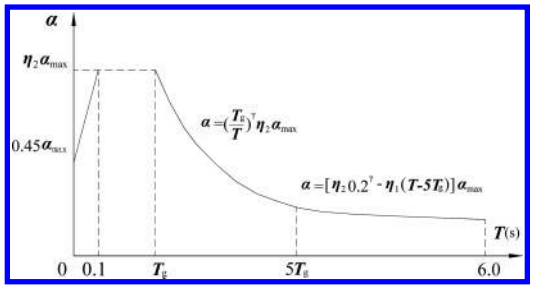

Figure 3. Design response spectrum in GB 50011.

where α is the horizontal earthquake influence factor, α_{max} is the maximum value of α, η_1, η_2 and γ is the modification parameters (GB 50011, 2010), T_g is characteristic period.

4 STATISTICAL CHARACTERISTICS OF ELASTO-PLASTIC DISPLACEMENT OF BRBF

4.1 *Sampling models*

Five sampling models are used to obtain the statistical characteristics elasto-plastic displacement of BRBFs. The stories are 1, 3, 6, 9 and 12 respectively, fundamental periods of which vary from 0.2 s to 1.8 s. First story height of the models is 4 m, while the other stories are 3.6 m high. The dead load is 5 kN/m^2, and the live load is 2 kN/m^2. The steel of frames is Q345B, while the BRBs' core is Q235B. Layout of the models is shown in Figure 4 and section properties are show in Table 3.

4.2 *Ground motions*

To reflect the randomness of ground motions, 120 earthquake records are collected and divided into 4 groups according to the characteristic period T_g, as the input ground motions to make nonlinear time history analysis of the sampling models. Response spectrum of the ground motions is shown in Figure 5, the damping ratio of which is 0.05 (take site type I for example).

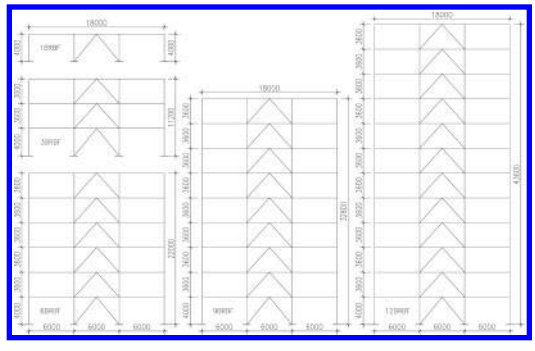

Figure 4. Layout of the sampling models.

Table 3. Section properties of sampling models.

Model	Beam (HN)	Middle Column(□)	Side Column(□)	BRB
1BRBF		250 × 250 × 16	200 × 200 × 16	200 × 10
3BRBF-1		250 × 250 × 16	200 × 200 × 16	200 × 20
3BRBF-2		250 × 250 × 16	200 × 200 × 16	150 × 10
3BRBF-3		250 × 250 × 16	200 × 200 × 16	100 × 10
6BRBF-1/2		300 × 300 × 16	250 × 250 × 16	300 × 20
6BRBF-3/4	300 × 175	300 × 300 × 16	250 × 250 × 16	200 × 20
6BRBF-5/6	× 8 × 11	300 × 300 × 16	250 × 250 × 16	100 × 20
9BRBF-1/3		300 × 300 × 25	300 × 300 × 20	150 × 20
9BRBF-4/6		300 × 300 × 25	300 × 300 × 20	100 × 20
9BRBF-7/9		300 × 300 × 25	300 × 300 × 20	100 × 20
12BRBF-1/4		300 × 300 × 25	300 × 300 × 20	150 × 20
12BRBF-5/8		300 × 300 × 25	300 × 300 × 20	150 × 20
12BRBF-9/10		300 × 300 × 25	300 × 300 × 20	100 × 20

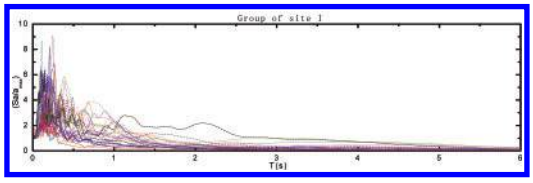

Figure 5. Response spectrum of the ground motions (site I).

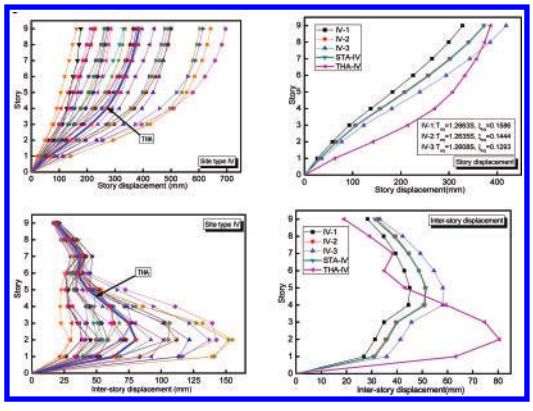

Figure 6. Displacement response of 9BRBF at site IV.

4.3 *Sampling results and statistical characteristics*

According to the Seismic Design Code for Buildings of China (GB 50011,2010), the peak ground acceleration (PGA) is adjusted to 620 gal for 9-level of seismic hazard in severe earthquake. By 600 times nonlinear time history analysis of the sampling models in total, the statistical characteristics of the BRBFs can be obtained and the accurateness of simplified method to calculate the inelastic displacement is also examined. To take the 9BRBF as an example, the displacement response (inter-story and roof) at site type IV is shown in Figure 6, where STA is static average value of the displacement, THA is time history average value of the displacement.

From the simulating results, it can be noticed that:

(1) The roof displacement obtained by simplified method is close to that of the average value from 30 times nonlinear history analysis.

(2) The position of maximum inter-story displacement predicted by simplified method is different from that of nonlinear time history analysis. Also, the maximum inter-story displacement by simplified method is smaller than the result from nonlinear time history analysis.

Statistical analysis is made for the roof and inter-story displacement of the BRBFs based on the sample points. The typical cumulative probability distribution curve and probability density curve of the BRBFs are shown in Figure 7. It can be seen that probability distribution model of elasto-plastic displacement of the BRBFs is most like the lognormal distribution model in severe earthquakes.

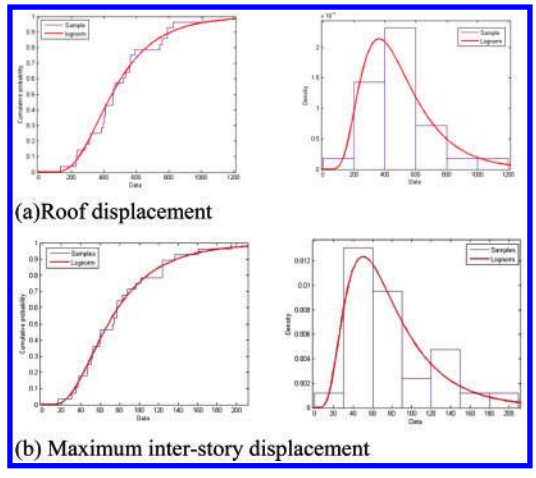

Figure 7. Displacement response probability distribution of 12 BRBF at site IV.

5 SEISMIC RELIABILITY ASSESSMENT METHOD OF BRBF

5.1 *Probability description of elasto-plastic displacement*

As mentioned above that the roof and maximum inter-story drift are lognormally distributed, so the random variation D (roof drift D_r and maximum inter-story drift D_i) can be determined by

$$D=\lambda\varphi D_d \tag{6}$$

where λ is a random factor, the mean value is 1.0 and the standard deviation is the variation of displacement response; φ is the uncertainty calculation factor, D_d is the displacement obtained by the simplified method, which is a deterministic value.

The probability density function of D is determined by

$$f(d)=\begin{cases}\dfrac{1}{\sqrt{2\pi}\sigma d}e^{\frac{(\ln d-\mu)^2}{2\sigma^2}}, & d>0\\ 0, & \text{other}\end{cases} \tag{7}$$

The cumulative distribution function of D is determined by

$$F(d)=\int_0^d f(x)dx=\Phi\left(\frac{\ln d-\mu}{\sigma}\right)/\sigma d \tag{8}$$

where σ is the standard deviation, $\sigma=\mu\delta$; μ is the mean value, calculated by equation (9); δ is the variation, got by equation (10).

$$\mu=\mu_\lambda\times\mu_\varphi\times\overline{D} \tag{9}$$

Where μ_λ is the mean value of λ, μ_φ is the mean value of φ.

$$\delta=\sqrt{\delta_\lambda^2+\delta_\varphi^2} \tag{10}$$

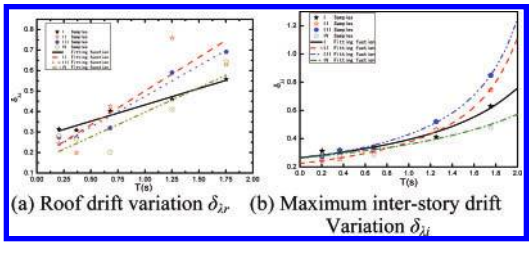

Figure 8. Fitting function of δ_λ.

Where δ_λ is the variation of λ, δ_φ is the variation of φ. δ_λ can be obtained by least square method to fit the samples from numerical simulations. The samples are shown in Table 4 and Table 5, and the fitting functions are shown in Figure 8.

5.2 *Uncertainty of the calculation model*

Difference between the displacements obtained from the two methods can be described by the uncertainty calculation factor φ, which is the ratio of THA to STA. Considering the two damage indices (roof drift and maximum inter-story drift), φ_r and φ_i are the uncertainty calculation factors for roof drift and maximum inter-story drift, respectively. Simulation samples are shown in Table 6 for φ_r and Table 7 for φ_i based on the 600 times nonlinear analysis. The statistical characteristics of φ_r and φ_i is shown in Figure 9.

5.3 *Seismic reliability assessment method*

When the probability density function of D is determined, the seismic reliability of BRBFs can be assessed by integration according to the limit state of performance levels as shown in Table 1 and Table 2. The seismic reliability assessment method is illustrated through a numerical example as below.

Table 6. Simulation samples of φ_r.

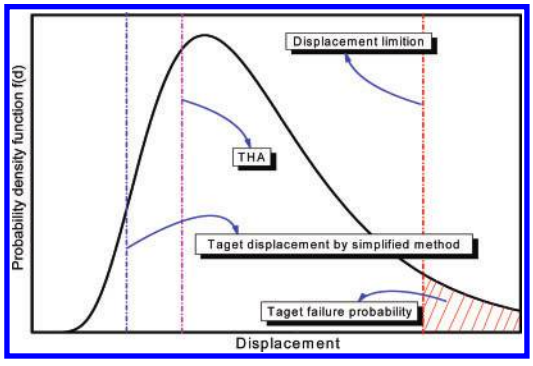

Figure 11. Seismic reliability design procedure of BRBFs.

6 SEISMIC RELIABILITY DESIGN METHOD OF BRBF

The seismic reliability design procedure of BRBFs is inverse against the reliability assessing process, which consists of the steps as follows (see Figure 11):

(1) to assess the seismic risk loss and determine the target reliability;
(2) to configure the BRBF and calculate the fundamental period T_1 of the structure;
(3) to determine the displacement probability density function;
(4) to obtain the target displacement meeting with the simplified method;
(5) to use the simplified method to estimate the displacement of BRBF;
(6) to compare the calculated displacement by step (5) with the target displacement by step (4);
(7) to adjust the structure till the calculated displacement meeting the target value.

7 CONCLUSIONS

In this paper, the seismic reliability assessment and design method of BRBFs is proposed by combining the equivalent linearization method with the statistical characteristics of the elastoplastic displacement of the structure. It can be found that:

(1) the equivalent linearization method to estimate the roof drift of BRBFs is better than that of the inter-story drift of BRBFs.
(2) the roof, inter-story, and maximum inter-story drift of BRBFs in severe earthquakes distribute likely lognormal.
(3) the variation of roof and inter-story drift increases with the fundamental period of BRBFs.
(4) BRBFs in site type IV has the highest failure risk among the four site types.
(5) the proposed method to assess seismic reliability of BRBFs is easy to be applied for practical use.

ABSTRACT: The present paper addresses reliability analysis of corroding pipelines also considering system reliability effects. The analysis is performed by utilization of enhanced Monte-Carlo simulation methods which have been found to be very efficient for quantification of system reliability in the case of multiple components with arbitrary correlation levels. The example studies in the paper comprise corrosion defects which are both independent and correlated.

1 INTRODUCTION

Corrosion of ageing pipelines is found to be a significant problem both onshore and within the subsea area. In order to determine the remaining time in service for such pipelines, it is required that deterministic capacity models are established as well as associated probability models for the key parameters. Having obtained these models, a proper reliability analysis and risk assessment can be performed.

The importance of this issue is reflected by the large number of associated publications in the existing literature. Some examples of probabilistic reliability analyses are found in the papers by Ahammed & Melchers (1996), Ahammed (1998), Caleyo et al. (2002), Lee et al. (2006), Santosh et al. (2006), Li et al. (2009a), Li et al. (2009b), Pandey (1998), Zhou (2011) and Hasan et al. (2012). Examples of relevant historic and more recent design guidelines are respectively ANSI/ASME B31G (1980) and DNV (2010).

As discussed in more detail below, there are significant differences between the applied probabilistic models which are employed in the various reliability analysis. This applies in particular to the statistical parameters which are employed for characterization of the internal pressure and the corrosion defects. Furthermore, in most cases a single corrosion defect is analysed. Only brief comments are usually given with respect to the system modeling that will be required in order to account for multiple defects.

In a few cases system analyses are performed by means of Ditlevsen bounds for estimation of failure probability for series systems. In the present paper, system modeling is focused upon both with respect to method of analysis and computational results.

2 METHOD FOR SYSTEM RELIABILITY ANALYSIS

2.1 *Basic formulation*

The enhanced Monte Carlo (MC) based method for estimation of system reliability which is applied for the present study is further described in Naess et al. (2009). The aim of this method is to reduce computational cost while maintaining the advantages of crude MC simulation. This applies in particular when dealing with complex systems. The key idea is to exploit the regularity of the tail probabilities. Based on results obtained from small Monte-Carlo samples for moderate levels of reliability this regularity enables prediction of far tail failure probabilities.

The motivation behind this approach is that systems with multiple and complex failure modes or limit states are often exceedingly difficult to analyze using traditional methods of structural reliability. On the other hand, even if direct MC does not suffer from this problem, it is computationally burdensome for small probabilities. This gives rise to the idea of sampling in a different less reliable range and performing a statistical tail extrapolation. A related idea is presented by Bucher (2009).

The fundamentals of the Naess et al. (2009) method are as follows. A safety margin $M = G(X_1, , X_n)$ expressed in terms of n basic variables, is extended

to a parameterized class of safety margins using a scaling parameter λ ($0 \le \lambda \le 1$):

$$M(\lambda) = M - E(M)(1-\lambda) \tag{1}$$

The failure probability is then assumed to behave as follows:

$$p_f(\lambda) = \text{Prob}\,(M(\lambda) \le 0) \underset{\lambda \to 1}{\approx} q(\lambda)\exp\{-a(\lambda-b)^c\} \tag{2}$$

where the function $q(\lambda)$ is slowly varying compared with the exponential function $\exp\{-a(\lambda-b)^c\}$. Clearly, the relevant failure probability $p_f = p_f(1)$ can be obtained from values of $p_f(\lambda)$ for $\lambda < 1$. It is now far easier to estimate the (larger) failure probabilities $p_f(\lambda)$ for $\lambda < 1$ accurately than the relevant value itself, since they require less simulations. Fitting the parametric form (2) for $p_f(\lambda)$ to the estimated values would then provide an estimate of the target value by extrapolation. The viability of this approach is demonstrated by both analytical and numerical examples e.g. in Naess et al. (2009) and Naess et al. (2010).

2.2 *System reliability analysis*

Using Monte Carlo methods for system reliability analysis has several attractive features, the most important being that the failure criterion is relatively easy to check almost irrespective of the complexity of the system. In order to limit the amount of computational effort that may be involved, it is hence useful to extend the above approach to systems.

Let $M_j(\lambda) = G_j(X_1, \ldots, X_n, \lambda), j = 1, \ldots, m$ be a set of m given safety margins expressed in terms of n basic variables and a single design parameter λ. The series system reliability expressed in terms of the failure probability can then be written as,

$$p_f(\lambda) = \text{Prob}\left(\cup_{j=1}^{m}\{M_j(\lambda) \le 0\}\right) \tag{3}$$

while for parallel systems,

$$p_f(\lambda) = \text{Prob}\left(\cap_{j=1}^{m}\{M_j(\lambda) \le 0\}\right) \tag{4}$$

In general, any system can be written as a series system of parallel subsystems. The failure probability would then be given as,

$$p_f(\lambda) = \text{Prob}\left(\cup_{j=1}^{l} \cap_{i \in C_j}\{M_i(\lambda) \le 0\}\right) \tag{5}$$

Here each C_j is a subset of $\{1, \ldots, m\}$, for $j = 1, \ldots, l$. The C_js denote the index sets defining the parallel subsystems. We then make the assumption that $p_f(\lambda)$ can also be represented as in Eq. (7) for the system reliability problems.

2.3 *Implementation*

The method to be described in this section is based on the assumption expressed by Eq. (2). For practical applications it is implemented in the following form:

$$p_f(\lambda) \approx q(\lambda)\cdot\exp\left\{-a(\lambda-b)^c\right\} \quad \text{for } \lambda_0 \le \lambda \le 1 \tag{6}$$

for a suitable value of λ_0. An important part of the method is therefore to identify a suitable range for λ so that the right hand side of Eq. (7) represents a good approximation of $p_f(\lambda)$ for $\lambda \in [\lambda_0, 1]$.

For a sample of size N of the vector of basic random variables $\boldsymbol{X} = (X_1, \ldots, X_n)$, let $N_f(\lambda)$ denote the number of samples in the failure domain of $M(\lambda)$. The estimate of the failure probability is then

$$\hat{p}_f(\lambda) = \frac{N_f(\lambda)}{N} \tag{7}$$

The coefficient of variation C_v of this estimator is

$$C_v\left(\hat{p}_f(\lambda)\right) = \sqrt{\frac{1-\hat{p}_f(\lambda)}{\hat{p}_f(\lambda)N}} \tag{8}$$

A fair approximation of the 95% confidence interval for the value $\hat{p}_f(\lambda)$ can be obtained as $\text{CI}_{0.95}(\lambda) = (C^-(\lambda), C^+(\lambda))$, where

$$C^{\pm}(\lambda) = \hat{p}_f(\lambda)\left(1 \pm 1.96 C_v(\hat{p}_f(\lambda))\right) \tag{9}$$

Assuming now that we have obtained empirical Monte Carlo estimates of the failure probability, the problem then becomes that of optimal use of the information available. By plotting $\log|\log \hat{p}_f(\lambda)/q(\lambda)|$ versus $\log(\lambda - b)$, it is expected that an almost perfectly linear tail behavior will be obtained according to Eq. (2). Recalling that the function $q(\lambda)$ was assumed to be slowly varying compared with the exponential function $\exp\{-a(\lambda-b)^c\}$ for relevant values of λ, it is now tentatively proposed to replace $q(\lambda)$ by a suitable constant value, q say, for tail values of λ, say $\lambda \ge \lambda_1 (\ge \lambda_0)$. Hence, we will investigate the viability of the following simpler version of Eq. (2):

$$p_f(\lambda) \approx q\exp\{-a(\lambda-b)^c\} \quad \text{for } \lambda_1 \le \lambda \le 1 \tag{10}$$

for a suitable choice of λ_1.

The problem of finding the optimal values of the parameters q, a, b, c is carried out by optimizing the fit on the log level by minimizing the following mean square error function with respect to all four arguments (Naess and Gaidai, 2009),

$$\text{F}(q,a,b,c) = \sum_{j=1}^{M} w_j\left(\log \hat{p}_f(\alpha_j) - \log q + a(\alpha_j - b)^c\right)^2 \tag{11}$$

where $\lambda_1 < \cdots < \lambda_M$ denotes the set of λ values where the failure probability is empirically estimated. w_j denotes a weight factor that puts more emphasis on the more reliable estimates.

A Levenberg–Marquardt least squares optimization method (Gill et al., 1981) is applied for the present minimization. Although this method generally works well, it may be simplified by exploiting the structure of F. It is realized by scrutinizing Eq. (16) that if b and c are fixed, the optimization problem reduces to a standard weighted linear regression problem. That is, with both b and c fixed, the optimal values of a and $\log q$ are found using closed form weighted linear regression formulas in terms of $w_j, y_j = \log \hat{p}_f(\lambda_j)$ and $x_j = (\lambda_j - b)^c$.

The optimal values of a and q are then given by the following relations,

$$a^*(b,c) = -\frac{\sum_{j=1}^{M} w_j (x_j - \bar{x})(y_j - \bar{y})}{\sum_{j=1}^{M} w_j (x_j - \bar{x})^2} \tag{12}$$

and

$$\log q^*(b,c) = \bar{y} + a^*(b,c)\bar{x} \tag{13}$$

where

$$\bar{x} = \sum_{j=1}^{M} w_j x_j \,/ \sum_{j=1}^{M} w_j, \quad \bar{y} = \sum_{j=1}^{M} w_j y_j \,/ \sum_{j=1}^{M} w_j.$$

The Levenberg–Marquardt method may now be used on the function $\tilde{F}(b,c) = F(q^*(b,c), a^*(b,c), b, c)$ to find the optimal values b^* and c^*, and then the corresponding a^* and q^* can be calculated from Eqs. (13) and (14).

3 EXAMPLES

3.1 *General*

An adequate reliability formulation for a corroding pipeline system requires that the time variation of both the internal pressure and the corrosion damage are taken into account. If the largest defect throughout the time period which is applied in combination with the highest pressure during the same period a conservative estimate of the failure probability for a single pipe cross-section will result. This model is frequently applied in the literature.

A convenient and quite accurate simplification is to apply the distribution of the annual maxima of the internal pressure (instead of the extreme pressure during the entire period). This distribution is then combined with the distribution of the corrosion damage during the same year (instead of the distribution of the largest defect during the period under consideration). This modeling can also be combined with the system reliability formulation to reflect the possibility that failure may occur at one out of a multiple of different defects.

In this approach, the probability distribution of the total population of corrosion defects is applied for each of the cross-sections (instead of that for the single largest defect at a given point in time). Hence, the possibility of failure at a number of "competing" cross-sections is properly represented through the series system model. This formulation is applied as the basis for the numerical studies in the present paper.

In many of the reliability studies found in the literature, the probability distribution of the instantaneous (normal) operation pressure is applied instead of the distribution for the extreme pressure during a specified time interval. The reason for this is a bit unclear and also it creates difficulties when trying to establish a reference time period for the calculated probability of failure (unless some characteristic short-term duration of the pressure is specified, i.e. of the order of minutes or hours).

In the present paper, the probability distribution of the annual extreme pressure is applied as discussed above. Representation of the annual maximum pressure then should than be based on the maximum instantaneous pressure (MAIP) which in general is higher than the maximum allowable operation pressure (MAOP). The mean value of the former pressure is typically given by means of a bias factor times the latter, typically 1.05 or 1.07.

The failure function which is presently applied for a pipeline cross-section where a corrosion defect is present is expressed as follows:

$$g(X) = \left\{ 2 \cdot m_f s_y \left(\frac{t}{D}\right) \frac{1 - \left(\frac{d}{t}\right)}{1 - \left(\frac{d}{tM}\right)} - p_a \right\} \tag{14}$$

Here, s_y is the yield stress of the steel material and m is a multiplying factor which converts yield stress into flow stress. This expression is based on a rectangular or nearly rectangular defect shape, with a defect depth of d and a defect length of L. The pipe wall thickness is designated by t and the pipe diameter by D. The quantity p_a is the internal overpressure that is acting at the relevant cross-section.

The quantity M is the Folias factor (also known as the bulging factor). The expressions which are applied for the Folias factor are as follows, Kiefner and Vieth (1990):

$$M = \left(1 + 0.6275\frac{L^2}{Dt} - 0.003375\frac{L^4}{D^2 t^2}\right)^{\frac{1}{2}} \quad \text{for } \frac{L^2}{Dt} \le 50$$

$$M = \left(0.032\frac{L^2}{Dt} + 3.3\right) \quad \text{for } \frac{L^2}{Dt} > 50 \tag{15}$$

For pipeline steels, the value of the conversion factor above, i.e. m, is usually taken to be between 1.10 and 1.15. This shows that there is also uncertainty in the value of m. In order to take this uncertainty into consideration, m, is represented as a random variable.

It is referred to Ahammed & Melchers (1996) as well as ANSI/ASME B31G (1984) and Kiefner & Vieth (1990) for further details associated with the present formulation. Clearly, it would be relevant to introduce an additional model uncertainty factor to reflect differences between observed versus calculated pressure levels at failure. However, this topic has not been pursued in the present study due the illustrative scope of the computed results.

A refined reliability analysis should distinguish between different types of failure modes with different consequences. This is discussed in more detail by Zhou (2011). Distinction is made between small leaks, large leaks and burst. Clearly, the latter will represent the failure mode with the worst consequence. In the present paper a more simplistic approach with only the single type of failure mode (which is defined by the failure function given above) is applied. Hence, the effect of a more refined sub-division will need to be studied as part of future investigations.

3.2 *Example 1: Single corrosion defect*

In order to illustrate the above concepts, a pipeline with known corrosion defects was analysed. This reflects the situation where defect dimensions are known from measurements by 'intelligent' tools. The random variables considered in this study are presented in Table 1 along with the typical statistical values and distribution functions for the variables. The distribution functions and statistical values were mainly based on those found in Ahammed and Melchers (1996). In the present paper, the intention is mainly to illustrate how the simulation procedure can be applied for the analysis of pipeline corrosion reliability. The distributions should hence be adopted to the available information for a specific application.

In the present study, the effect of applying different types of distributions for the internal pressure is investigated. The base case analysis corresponds to the pressure having a Gaussian distribution as indicated by the letter N in Table 1. In addition, results for a pressure distribution corresponding to the Gumbel distribution are also computed.

The case with a Gaussian pressure distribution and a single corrosion defect is first considered. A counting

Table 1. Random variables and statistical properties.

	Variable		Properties

* N: Normal (Gaussian) LN: Lognormal

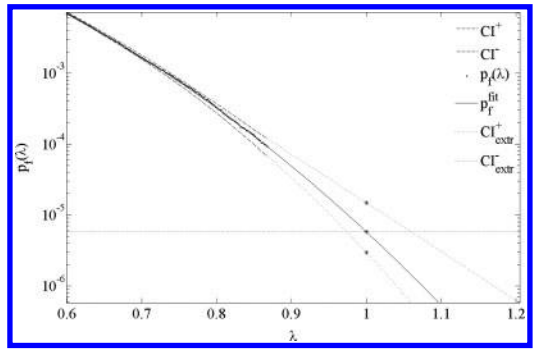

Figure 1. Extrapolation of failure probability from sampled values to relevant failure probability level. Mean value of internal pressure is 7 MPa.

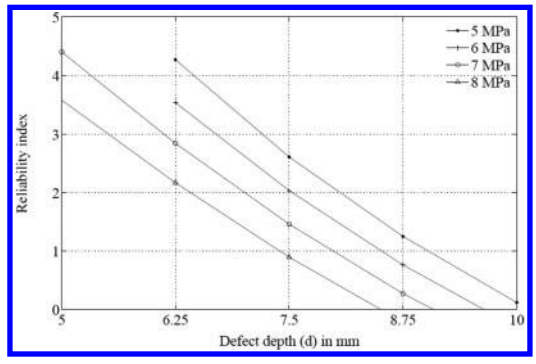

Figure 2. Failure probability as a function of mean values of internal pressure and defect depth. Pressure distribution is Gaussian.

of the observations with negative values of the failure function, N^- is performed for each value of the parameter lambda.

The simulated results for different values of lambda together with extrapolation to the relevant probability level are shown in Figure 1. It is seen that the failure probability which corresponds to $\lambda = 1$ is of the order of $3.0\ 10^{-5} +/- 0.4\ 10^{-5}$ with the best estimate being $2.0\ 10^{-5}$. It is noted that this probability is somewhat lower/higher than the value which was obtained based on performing a Taylor series expansion of the failure function around the mean point, see Ahammed & Melchers (1996).

3.3 *Parametric studies for a single defect*

The effect of varying the mean values of the pressure and the defect depth is also investigated. The results for a Gaussian pressure distribution as a function of the mean value of the pressure (from 5 MPa and upwards) and the mean value of the defect depth are shown in Figure 2. It is seen that the combination of low internal pressure and small defect depths give very high reliability levels, while a high internal pressure and large defects give very low reliability levels (with failure being almost a certain event).

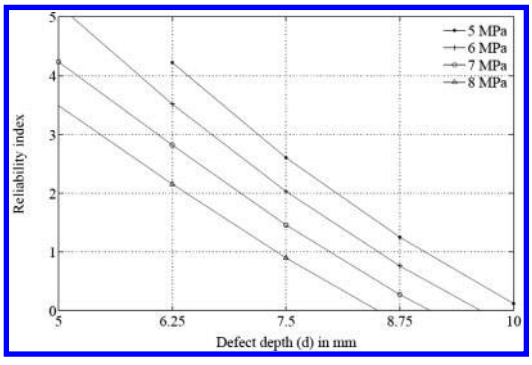

Figure 3. Failure probability as a function of mean values of internal pressure and defect depth. Pressure distribution is of the Gumbel type.

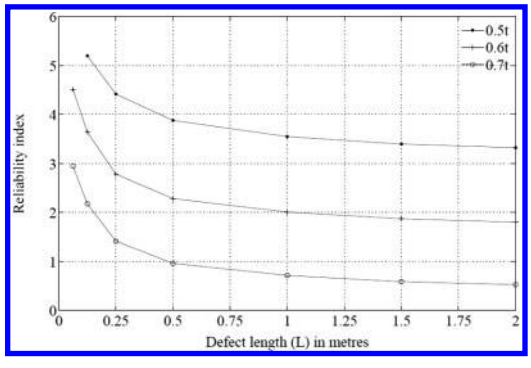

Figure 4. Failure probability as a function of mean values of defect depth and defect length. The former is normalized by wall thickness. Pressure distribution is of the Gumbel type.

Corresponding results for a pressure distribution of the Gumbel type are shown in Figure 3. Slightly lower reliability levels than for the Gaussian model are observed for the smallest defect depths. However, it should be noted that as the Gumbel model should refer to an annual extreme pressure as discussed above, the mean value should be significantly higher than for Gaussian distribution if the latter is intended to represent the normal operation pressure. This would result in much larger differences for the associated reliability levels.

The effect of varying the mean value of the defect length is illustrated by the results in Figure 4. It is seen that the reliability level decreases quite rapidly for the left part of the diagram but decreases very slowly for the right part of the diagram.

3.4 *Example 2: Multiple corrosion defects and effect of correlation*

The series system effect is illustrated by the curves in Figure 5. The lowermost (red) curve corresponds to results for a single defect, while the uppermost (green) curve corresponds to 100 defects. Since the coefficient of variation for the internal pressure is quite low

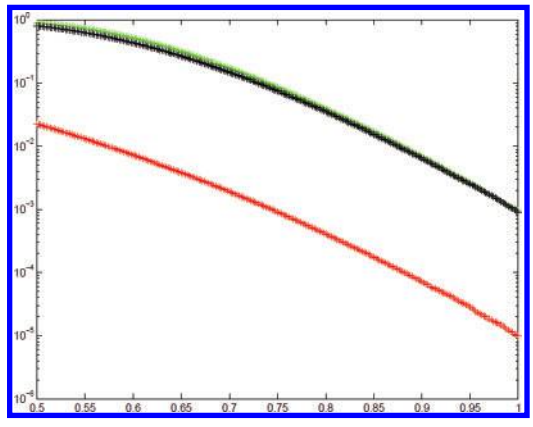

Figure 5. Failure probability of single defect (lowermost red curve) versus 100 defects (uppermost black curve). Application of independent versus fully correlated pressure at each cross-section is given by the upper green versus black lines.

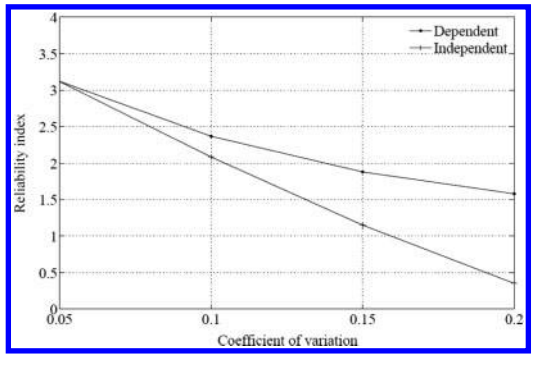

Figure 6. Failure probability of single (lowermost red curve) for system with 100 corrosion defects as function of C.o.V. for internal pressure. Independent (uppermost curve) versus dependent (lower curve) failure events. Correlation coefficient is equal to 0.04 for a C.o.V. of 0.05 and equal to 0.42 for a C.o.V of 0.2. (avg. pressure = 7 MPa).

(i.e. 0.05) the results for the case where the correlation between the failure events is taken into account are quite similar to the case with independent components. In fact, it is almost not possible to distinguish the upper blue (correlated events) versus the upper green (independent events) curves. However, this is not the case when the coefficient of variation for the internal pressure increases as shown by the results in the next section (see Figure 6).

The effect of correlation between the individual failure events is next investigated by increasing the coefficient of variation for the internal pressure. The results are shown in Figure 6 for a C.o.V. in the range from 0.05 to 0.2.

4 CONCLUSIONS

The present paper deals with application of an enhanced Monte Carlo simulation method to pipeline

systems with multiple corrosion defects. The presence of such multiple defects requires that a system analysis is performed. Furthermore, the effect of correlation between the failure events is highlighted. The failure probability decreases strongly as the degree of correlation increases as expected. However, the degree of correlation needs to be higher than around 0.2 before this effects starts to have any influence. For low values of the correlation coefficient the system failure probability can simply be obtained by multiplying the failure probability for a single defect (based on the ensemble probability distribution for the corrosion defect dimensions) with the total number of defects.

As mentioned, the present study is mainly intended as an illustration of how systems reliability analysis can be applied to corroded pipelines. There are multiple topics to be addressed in more detail as part of future work. Just a few examples are differentiation of failure modes and the effect of introducing model uncertainty factors as discussed above.

Some practical aspects of statistics methods of estimation reliability computed for existing silo constructions

M. Kaminski & M. Maj
Institute of Building Engineering, Technical University of Wrocław, Poland

ABSTRACT: The authors of this paper who are members of the research team in the Institute of Building Engineering of the Technical University of Wroclaw, for more than 40 years have been carrying out researches on silos for bulk materials. They had big influence on preparing polish silo codes . These investigations were carried out on silo batteries, free-standing silos and silo models. The researches include the evaluation of value of pressure and temperature field on the silo wall as well as temperature gradient, registration of simultaneity of these loads The researches include either the evaluation of influences of the wall stiffness and wall inclination on pressure changes, parameters connected with silo strength and geometry etc. According to the data of the mentioned above parameters values the evaluation and estimation of density function of these random values and first, second order statistics were calculated based on Level-1, Level-2 reliability methods. These experimental data were subjected to statistical accounts. The data obtained from calculations can be used in designing similar silos and in preparing silo codes. The experimental results and theoretical considerations help to determine the degree of safety of silos construction. Some aspects of the estimation of safety factors and values of partial safety coefficients are presented in this paper.

1 THE BASIC EQUATION OF RELIABILITY

The basic equation of reliability of silo wall can by described in following equation

$$R \geq S \quad , \tag{1}$$

where R-construction resistance, S-loadings acting on construction. This equation is used by engineers in stresses quantities, or resultant forces. Forces are compressive or tensile or bending moments. Generally in Limit State Design R is regarded as a strength S as stresses. In Serviceability Limit State R is allowable deflection or a allowable scratch and S is static deflection or calculated scratch. R is not simply limits stresses and S is not simply loads of snow, winter, pressure etc. Equation (1) has not simple, i. e, the linear form. It involves many parameters appropriate for the loads and strength. Equation (1) can be written in the following formula

$$R - S \geq 0, \tag{2}$$

or knowing that right side of equation (2) is function we can define function of safety or reliability by:

$$f(R - S) \geq 0, \tag{3}$$

Function f(R − S) is depended of many variables, generally X variables which are random values. We can write it as sequence variables X_i:

$$X = (X_i) \tag{4}$$

X_i variables are associated one with another with formula of reliability (1). They form a set Ω of variables in the inequality (1). The reliability measure is the probability of survival P_B, calculated as

$$P_B = \int_{\Omega} f_X(X)dx \tag{5}$$

where $f_z(X)$, is the probability density function of the variables X_i, $X = (X_i) = (\Delta T, p_h, T, w, a_{ct} \ldots, h, t, a, f_{cd}, f_{yd},,a_{th}..)$, Ω is the safe set (Figure 1). There are the following X_i

a) parameters connected with acting loads "***S***" ΔT-temperature gradient across the silo wall, p_h-horizontal pressure caused by grain pressure, aeration and homogenisation, concentrated loads, T-temperature field on the silo wall caused by storage grain, insolation and daily temperature variation, w-displacement caused by for example shrinkage, wind, a_{ct}-other extreme loads, etc.,

b) parameters connected with silo wall strength "***R***" D-silo diameter, α-temperature coefficient, h-thickness of the silo wall, EJ-wall stiffness, s-distance between the horizontal bars, f_{yd}-strength of bars, f_{cd}-strength of concrete, a_1-concrete cover, ϕ-diameter of bars, A_{s1}-area of bars, e_{s1}-eccentricity, x_{eff}-height of compressed concrete area, quantity of reinforced horizontal and vertical bars, adhesion of bars to concrete, quality of lap splices, type and quality of wall strengthening, openings in the silo wall, imperfections, cracks, steel corrosion, technical condition of concrete, i.e. carbonisation, etc.

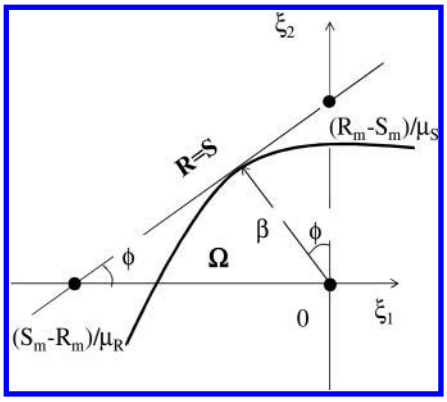

Figure 1. Index β as a minimum of distance between tangent to limit state surface and central point; area Ω is safety state of construktion computing methods.

Generally calculation of probability P_B employs probability of failure as a measure and require a knowledge of the joint distribution of all random value parameters. It is Level-3.

Probability of non failure can be written in terms of safety margin Δ:

$$f(R-S)=\Delta=R-S\geq 0, \tag{2}$$

is $P_B=P(\Delta>0)$. As an alternative to P_B, a reliability index is often defined as $\beta_B=\Phi^{-1}(P_B)=-\Phi^{-1}(P_F)$, where $P_F=1-P_B=\int_F f_X(x)dx$ is failure probability and F is the failure set. β is interpreted as minimum distance between central point and limit state surface (Figure 1). In general this integral cannot be computed analytically. Method solving this integral is rather difficult because of its complexity. There are many based on simplification and additional assumptions (Madsen,1986, Hasofer & Lind 1974, Faber, 2006,. Borges & Castanheta, 1971). Sometimes we can simplified problem to the basis variables which are jointly normally distributed and the failure surface is a hyperplane then the failure probability is simply $P_F=\Phi(-\beta_C)$ where β_C is second order moment reliability index for safety problem. We can use in the place of β_C another reliability indexes as for example general β_G or (Hasofer & Lind 1974) reliability index β_{HL}. In another words we can use methods of Level-2 or even Level-1 to evaluated index of reliability.

The limit condition $\Delta=0$ implicate reliability index

$$\beta\leq \tilde{\Delta_m}/\mu_d \tag{3}$$

and

$$\Delta_m=(R_m-S_m)/((\mu_R{}^2+\mu_S{}^2)^{1/2}) \tag{4}$$

where R and S with index m denotes mean value of R and S, μ denotes standard deviation. If are used standardized variables $\xi_i=(x_i-x_{im})/\mu_I$ then β is the shortest distance to limit surface (Figure 1)

$$\beta=(R_{mr}-S_m)/\sqrt{(\mu_R{}^2+\mu_S{}^2)} \tag{5}$$

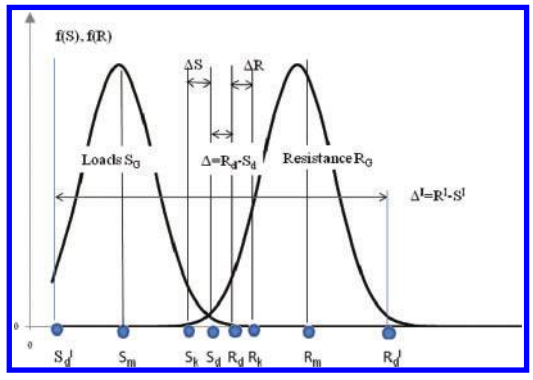

Figure 2. Safety for $\Delta=$R-S, Δ is minimum safety margin (certainty of safety) and Δ^I as certainty of construction destruction.

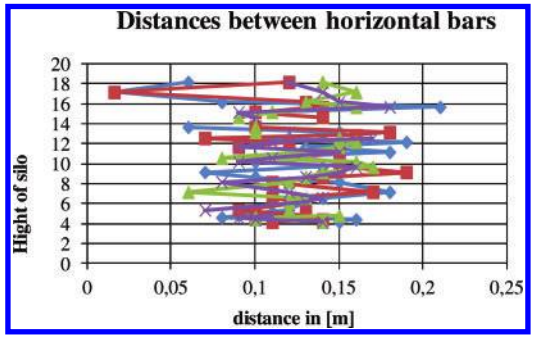

Figure 3. Random value of distances between horizontal bars.

When R and S are separated than index β in Level-2 is divided to two indexes for resistance and action consecutively

$$(S-S_m)/\mu_S\geq\beta_S,\ (R-R_m)/\mu_R\geq\beta_R \tag{6}$$

Simplifying safety phenomenon $\Delta=R-S$ to one dimension space margin of safety area Δ is shown on Figure 2 where $\Delta S=S_d-S_k$, $\Delta R=R_d-R_k$. For example certainty of construction destruction (e.g. during silo demolition) is Δ^I. From the equations, it is clear that it is very important to know the distribution of random variables.

2 RANDOM DATA OF SILO QUANTITIES

The problem gets complicated when we do not have full knowledge of the distributions of random variables. From our investigation we received distribution of basic variables which are shown on Figure 3–14 researches we get the frequency distributions of random variables presented on figures values of quantities as pressure and strength parameters were investigated on rape stored in full scale silo (Borcz & Maj & Trochanowski 1995) and (Kamiński & Maj 2000, 2006). Characteristics value of experimental data are

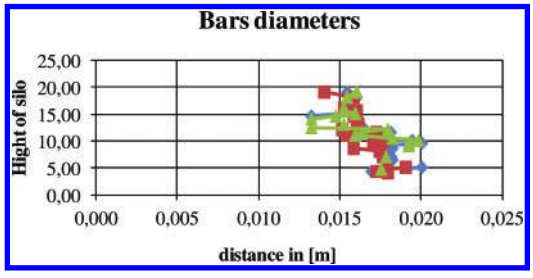

Figure 4. Random value of bars diameter.

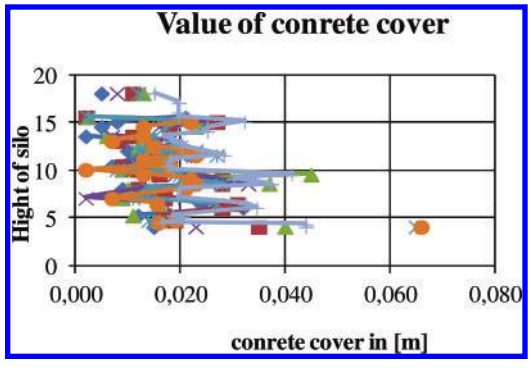

Figure 5. Random value of concrete cover.

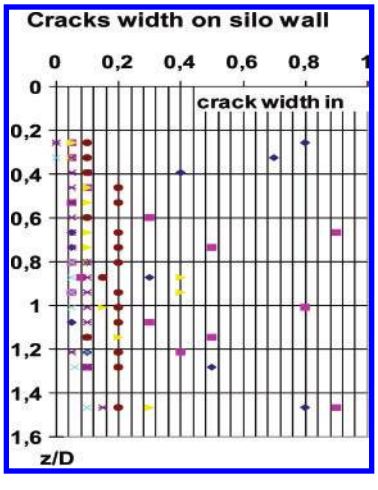

Figure 6. Distribution of random value of cracks width.

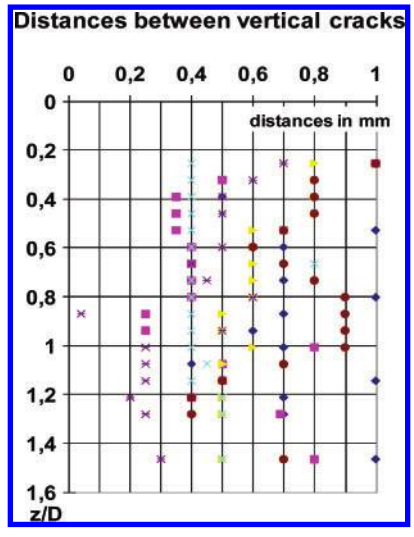

Figure 7. Distribution of random value of distances of vertical cracks.

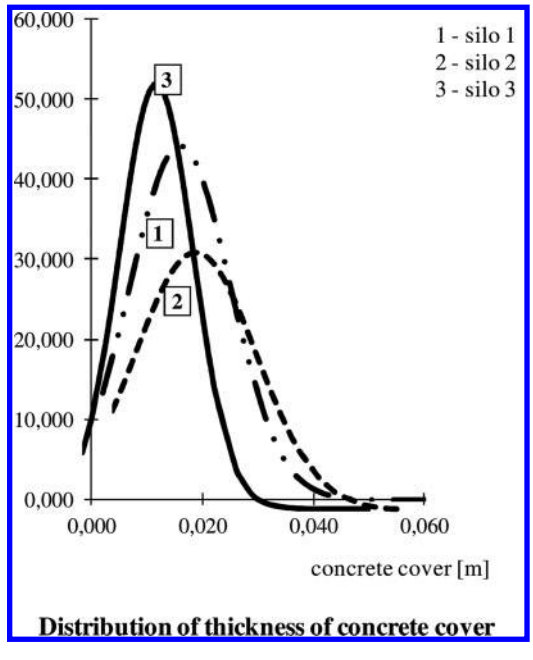

Figure 8. Density functions of thickness of concrete cover.

computed based on kind and richness of data collection. Same results obtained by Authors research team based on special constructed measurement sensors. Some of them were placed in for rape, investigated on full scale silo silo wall and bottom, some worked as sensors sounds (Borcz & Maj, 2002). Thereafter there are some mistakes of passing data's signals through interfaces in experimental devices (Leciejewski & Maj, 2013), and the range of mistakes is even 10–20%. So additional random value is the technical way of getting dates form experiment. Another problem of value of variation coefficient is selection of probability density function or distribution function (Gaussian, Gumbel, Rayleigh, empirical, extreme, etc.) to calculate mean, characteristic values of random data. Skewness of density function, double modal functions (Figure 9) etc can change the value of calculating statistics. The variation of value of measured pressure on rape silo (Borcz Maj, & Trochanowski, 1995) are shown on Figure 12, 13. Model of interaction between live loads and silo wall has influence of value of calculating pressure in concrete and steel bars. The very important is influence of cracks, changing

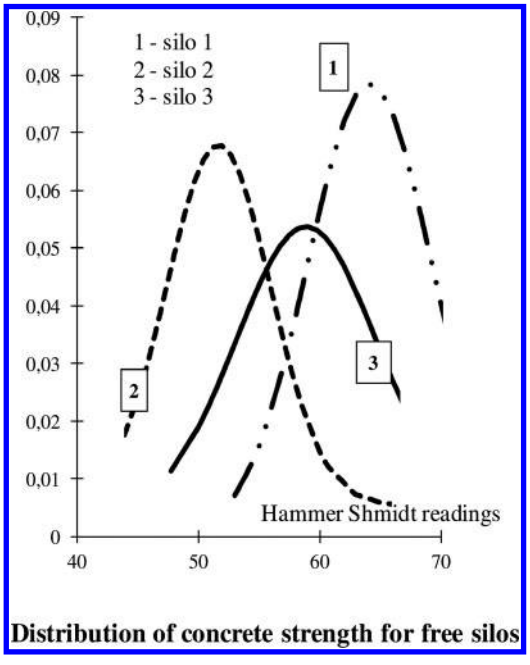

Figure 9. Concrete strength as a random value.

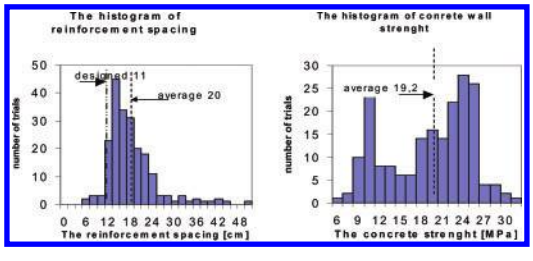

Figure 10. Histograms of strength parameter of cement.

width construction and its stiffness, no homogeneity of geometry etc. Variation of typical material strength parameters are shown on Figure 3–10. The presence of imperfection is shown on Figure 11. As follows limited values R_{di}, S_{di} (e.g. design values) and R_{ki}, S_{ki} (characteristic values) are usually calculated from linear formulas:

$$(S\text{-}S_m)/\mu_S \geq \beta_S, \tag{7}$$

$$(R\text{-}R_m)/\mu_R \geq \beta_R \tag{8}$$

with help of β_{Si}, β_{Ri} indexes (Madsen 1986). It implies separated load and material coefficients as γ_{fi}, γ_{mi} according as follows $\gamma_{fi} = S_{mi}/S_{ki}{}^*(1 + \beta_{Si}{}^*\nu_{Si})$; $\gamma_{fi} = (1 + \beta_{Si}{}^*\nu'_i)/(1 + t_S{}^*\nu_i)$; $\gamma_{mi} = (1 + \beta_{Ri}{}^*\nu'_i)/(1 + t_R{}^*\nu_i)$, where β_{Si}, β_{Si}-reliability indexes, ν_i-coefficient of variation, ν'_i-coefficient of variation is increased because of sensitivity on parameter changes μ_a, $\nu'_i = (\mu_i^2 + \mu_a^2)^{1/2}/(S_{mi})$, μ_a-standard deviation regarding to material fluctuation, t_S-calibration coefficient, e.g. probability quintile.

From this formula we see that the most important influence on safety index β and γ_{fi}, γ_{mi} has

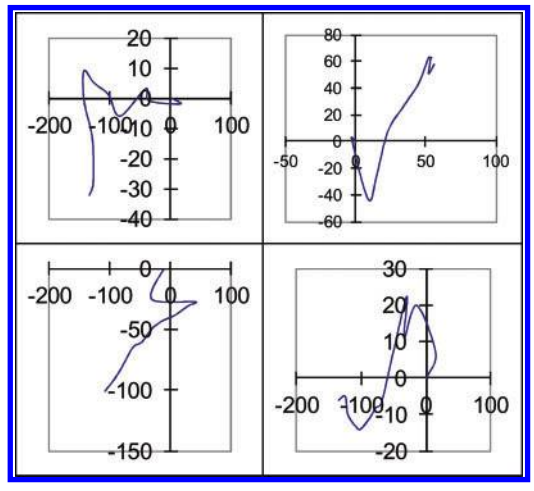

Figure 11. Imperfection of the geometric center of silo.

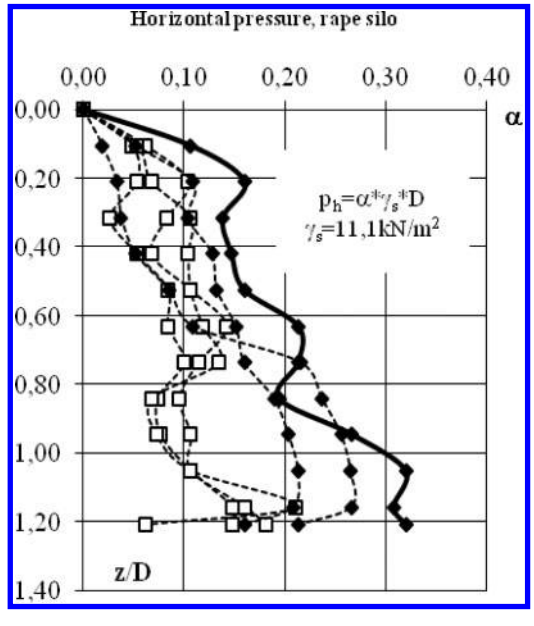

Figure 12. Distribution of random value of horizontal pressure.

coefficients of variation ν_i ν'_i. Some of loads and strength parameters are very susceptibility on changes and their value are variable. The variation exemplify values of standard coefficients k_i increasing or decreasing characteristic values. E.g. coefficients of: dead, live, extreme, dynamic loads $k_{QA} = 1{,}0\text{-}2$; loads simultaneous $k_{Acfi} = 0{,}6\text{-}1{,}0$; material: steel, concrete, cooperation $k_{mat} = 1{,}1\text{-}1{,}5$; construction dimension correction during its life $k_{ccs1} = 1{,}0\text{-}1{,}3$; consequence of destruction $k_{ccc} = 1{,}0\text{-}1{,}5$; performance factor $k_{wc} = 1{,}0\text{-}1{,}4$; material fatigue buckling $k_{mf} = 1{,}1\text{-}1{,}5$; construction validity, durability $k_{cim} = 1{,}0\text{-}1{,}3$; mode of constriction destruction $k_{cc} = 1{,}0\text{-}1{,}3$; periodic control $k_{ccon} = 1{,}0\text{-}1{,}3$; imperfections

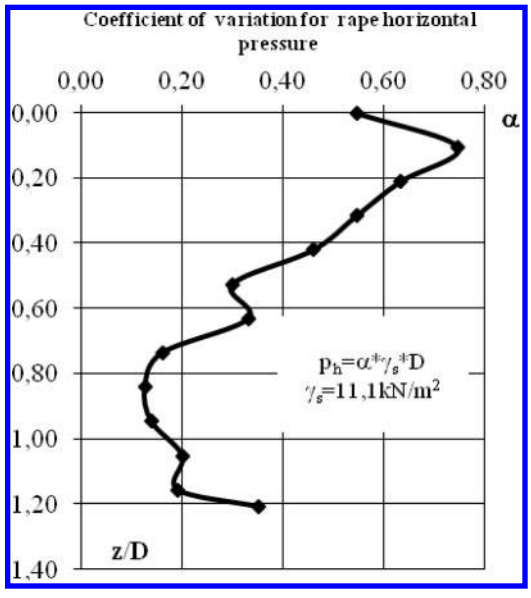

Figure 13. Coefficient of variation for pressure of in full scale rape silo.

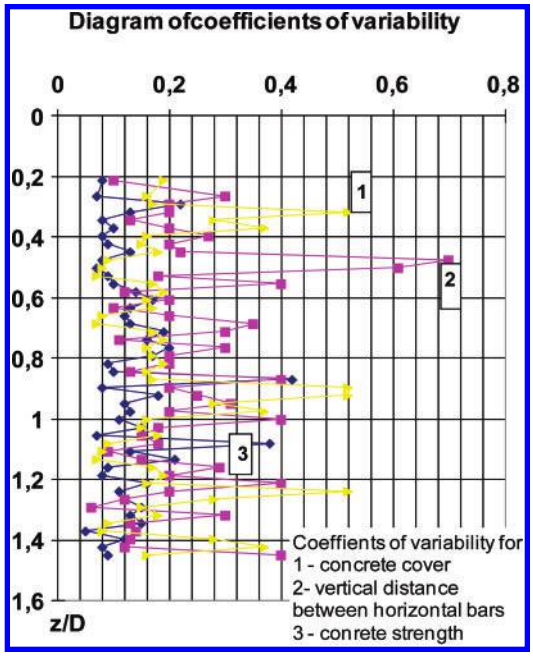

Figure 14. Distribution of coefficients of variably for concrete cover, concrete strength, vertical distances between bars.

$k_{cim} = 1,0\text{-}1,4$; adequacy of applied static models, calculating mistakes $k_{mis} = 1,0\text{-}1,5$. Another solution for $\Delta = R - S$ is evaluate global reliability index $\boldsymbol{\varpi}$: in equation

$$R^k \geq \boldsymbol{\varpi} S^k \tag{9}$$

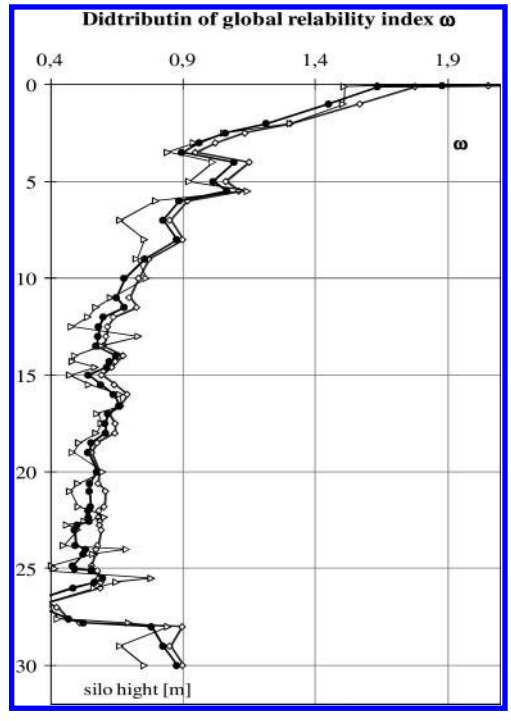

Figure 15. Distribution of global reliability index ω.

where S^k, R^k are characteristic value of S and R. It is simple method FORM with using calibration method in SORM. Results of calculation of this coefficient $\boldsymbol{\varpi}$ for repaired rape silo are presented in (Kaminski & Maj, 2000, 2006) and on Figure 15 Value of this index verify from 0,4 to 1,4. Another coefficient of construction safety is described by β, the reliability indices interval: $\beta = z_m/\sigma_z$ and reliability index of risk failure $p_f = \Phi(-\beta)$ where z_m i the mean value of function Δ, σ_Δ is standard deviation of Δ, $\Phi(-\beta)$ is Laplace function. For $\Delta_m \geq \beta^*\sigma_z$ construction work in safe area. Coefficient β is equal in European standards $3,7 \div 6,7$, $p_f = 10^{-3} \div 3 \cdot 10^{-8}$. Coefficient β can be separated to two β_R and β_S connected with strength and loads. According to (Pawlikowski, Jaskulski, Wiliński, 2004), there are three classes of safety coefficients RC1, RC2, RC3 but in we can use either RC0 class. In the last proposal, in case typical for silo loads, where live loads are greater than dead, and when $p(R \leq R_d;\ S \geq S_d) = \max$, R and S are independent (index d is design level) $\beta = 3,7$ ($p_f = 10\text{-}4$), $\beta_S = 2,59$ ($p_f = 0,005$), $\beta_R = 2,96$ ($p_f = 0,0015$).

3 CONCLUSIONS

The value of safety global factor $\boldsymbol{\omega}$ for the investigated and new designed silos is included within the range 0,9-7 which depends on the silo exploitation mode and "silo conditions", Kaminski & Maj 2006.

Reliability index β depends on kind of stored material, construction geometry etc should be individual calculated. It is useful to separate β to β_R and β_S.

ABSTRACT: Resistances of civil engineering structures are primarily dependent on material properties, geometry and uncertainties associated to an applied resistance model. While materials and geometry can be relatively well described, the resistance model uncertainty is not yet well understood. The present contribution proposes a general concept of the model uncertainty. Factors affecting results obtained by tests and models and influences of actual structural conditions are overviewed. In a numerical study statistical characteristics of the uncertainties in resistance of reinforced concrete members are then provided. Simple engineering formulas are considered. To facilitate practical applications the partial factors for the model uncertainties are derived using a semi-probabilistic approach.

1 INTRODUCTION

Safety formats for the analysis of reinforced concrete structures were investigated in numerous previous studies; see e.g. Bertagnoli et al. (2004), Schlune et al. (2011), Sykora & Holicky (2011), Allaix et al. (2012) and Cervenka (2012). It was indicated that structural resistances can be predicted by appropriate modelling of material properties, geometry variables and uncertainties associated with a model under consideration. The effect of variability of materials and geometry is relatively well understood and was extensively addressed by the aforementioned studies. However, better description of model uncertainties is desired.

The submitted study is thus aimed at the model uncertainties. A general concept is proposed and selected influencing factors are illustrated by examples concerning resistance of reinforced concrete members. Statistical characteristics of the model uncertainties are summarized from available data considering simple engineering formulas (beam models, section-oriented approaches). To facilitate practical applications the partial factors for model uncertainties related to various types of the analysis are derived using a semi-probabilistic approach.

2 MODEL UNCERTAINTY

2.1 *General concept*

According to JCSS (2011) the model uncertainty is generally a random variable accounting for effects neglected in the models and simplifications in the mathematical relations. Model uncertainties can be related to:

- Resistance models (based on simplified relationships or complex numerical models),
- Models for action effects (assessment of load effects and their combinations).

The model uncertainty can be obtained from comparisons of physical tests and model results. Actual structural conditions not covered by tests should be taken into account if needed. Obviously the model uncertainty should be associated with a computational model under consideration. General concepts of model uncertainty applicable to both resistance and load effect models are indicated in Figure 1. The significance of factors affecting tests, model results and actual structural conditions depends substantially on an analysed structural member or load effect.

2.2 *Factors affecting the uncertainty related to resistance models*

Examples of factors affecting the uncertainty related to resistance models are given in Table 1. Similar list could be provided for load effect models. However, only resistance models are addressed hereafter.

In general the following aspects should be considered in the assessment of the model uncertainty:

- Test conditions should be correctly defined and test results properly evaluated.
- The uncertainty of a resistance model is dependent on the failure definition (maximum load, strain, deflection, crack width etc.). Here it is assumed that the maximum load is to be estimated by a model. Larger variability of the model uncertainty is anticipated for other failure criteria.

– It should always be assured that a specimen fails in an investigated failure mode; e.g. when the model uncertainty in shear is investigated beams failed in bending should not be considered.

2.3 *Assessment*

In this study the model uncertainty θ is considered to be a random variable. The multiplicative relationship for θ is assumed in accordance with JCSS (2011):

$$R = \theta \, \mathrm{R}_{\mathrm{model}}(\mathbf{X}) \tag{1}$$

where R = response of a structure – actual resistance estimated from test results and structural conditions; $\mathrm{R}_{\mathrm{model}}$ = model resistance – estimate of the resistance based on a model; and $\mathbf{X}^{\mathrm{T}} = (X_1, \ldots, X_m)$ is the vector of basic variables X_i.

Realistically assuming a lognormal distribution with the origin at zero (hereafter simply "lognormal distribution") for R and $\mathrm{R}_{\mathrm{model}}(\cdot)$, the model uncertainty is also lognormal. Its characteristics can be assessed using standard statistical techniques such as the Method of moments, Maximum likelihood method or Bayesian updating. An alternative procedure of the assessment of the model uncertainty is provided in Annex D of EN 1990 (2002). This method, based on the regression analysis and the Least Square Method, is focused on estimation of a regression coefficient rather than on the assessment of statistical characteristics of a random variable according to the JCSS definition. That is why the EN 1990 procedure is not considered hereafter.

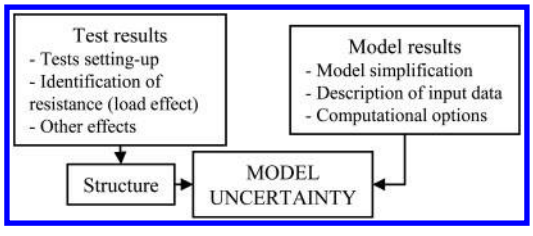

Figure 1. General concept of the model uncertainty.

Note that an additive relationship or combination of the multiplicative and additive formulas may be used to assess the model uncertainty, JCSS (2011). In more advanced analyses the model uncertainty may be represented by functions of several auxiliary random variables $\boldsymbol{\theta}$ and variables $\mathbf{X}$ as considered e.g. by Song et al. (2010).

The model uncertainty θ in general depends on basic variables $\mathbf{X}$. Influence of individual variables on θ can be assessed by a regression analysis as described e.g. by Ditlevsen & Madsen (1996). It is also indicated that the model describes well the essential dependency of R on $\mathbf{X}$ only if the model uncertainty:

– Has either a suitably small coefficient of variation (how small is the question of the practical importance of the accuracy of the model) or
– Is statistically independent of the basic variables.

It may also be important to define ranges of the input parameters $\mathbf{X}$ for which the accepted model uncertainty is valid. Such intervals should be established on the basis of:

Table 1. Examples of factors affecting the uncertainty related to resistance models.

Factors	Partial factors	Explanation	Examples
Test results	Tests setting-up	Differences between laboratory and in situ conditions	– accuracy of test method (accuracy of gauges, friction, assembly stiffness) – deviations of individual tests (variability of particular conditions) – boundary conditions (supports of specimens) – loading conditions (transfer, speed) – temperature, moisture conditions – size effect (scale of tests)
	Identification of resistance	Vagueness in failure indicator	– ultimate strength – strain, deflection – crack width
	Other effects	Effects not covered by tests	– time variant effects (time dependent material properties)
Structure	–	Actual structural conditions (may not always be known)	– boundary conditions (supports, continuous members) – loading conditions (transfer, combination of shear and bending moments) – temperature, moisture conditions - size effect (actual size)
Model results	Model simplification	Simplifications and approximations of model under consideration	– assumed stress distributions, constitutive laws – boundary conditions – bond between concrete and reinforcement – size effect
	Description of	Assumptions concerning input data actual values of variables not measured	– internal dimensions – tensile strength – fracture energy – plastic strain
	Computational options	Choices to be made by analysts in setting-up of model	– discretisation – type of finite elements – boundary conditions (simplifications made by analysts)

– Admissible ranges of **X** for the model (for instance limits on a reinforcement ratio) and
– Simplifications in modelling of θ (for instance when θ can be considered independent of the basic variable in a specified interval).

2.4 *Model uncertainty methodology*

The main properties of uncertainties in resistance models can be treated in the following steps, starting off from the resistance model and model uncertainty observations, ending up at a reliability function on which the design function is based:

1. The database of observations or test results, including all test parameters required for repeating of the tests and calculating the resistance by the model under investigation forms the basis of model uncertainty assessment.
2. The range of parameters for the dataset, such as material strength classes or geometry, defines the range of strict applicability of the derived model uncertainty.
3. Statistical treatment of model uncertainty observations includes proof of unbiased sampling and goodness of fit tests.
4. Deviations from such statistical treatment of model uncertainty observations introduce uncertainties which should be accounted for.
5. Additional uncertainties are introduced when the model uncertainty derived from experiment is applied to the design function as expressed in terms of the resistance model and related design rules.
6. Derivation of a generic model uncertainty for a given failure mode and design function includes provision for additional uncertainties resulting from the scope of application allowed by the procedure, such as structural and material classes, geometry including amount of steel and detailing rules.
7. The model uncertainty is furthermore dependent on the safety format of the design function across the scope of application, including the effects of predefined characteristic values and (material) partial factors.

Examples of this process were given by Huber (2005), Dithinde et al. (2011), Mensah (2012) and Sykora & Holicky (2012).

3 UNCERTAINTIES RELATED TO THE MODELS PROVIDED IN EN 1992-1-1

The numerical part of this contribution is focused on the uncertainties related to resistance models for reinforced concrete structures provided in EN 1992-1-1 (2004). It is assumed that the uncertainties of action effects can be treated separately. Model resistances of structural members exposed to compression, bending, and shear (members without and with special shear reinforcement distinguished) are given as follows:

$$R_{model}(\mathbf{X}) = b^2(\alpha_{cc} f_c + \rho_l f_y) \tag{2a}$$

$$R_{model}(\mathbf{X}) = \rho_l b\, d f_y [d - 0.5\rho_l\, d\, f_y / (\alpha_{cc} f_c)] \tag{2b}$$

$$R_{model}(\mathbf{X}) = \max[0.18k\,(100\rho_l f_c)^{1/3} b_w d;\quad 0.035k^{3/2} f_c^{1/2} b_w d] \tag{2c}$$

$$R_{model}(\mathbf{X}) = \max_{1 \le \cot\xi \le 2.5}\{\min[\rho_w b_w z f_{yw} \cot\xi,\ \alpha_{cw} b_w z \nu f_c / (\cot\xi + \tan\xi)]\} \tag{2d}$$

where b = width; $b_w = b$ is the minimum width between tension and compression chords; d = effective depth; f_c = concrete compressive strength; f_y and f_{yw} are yield strengths of reinforcement (longitudinal, shear); $k = \min[1 + \sqrt{(200\text{ mm} / d)};\ 2.0]$; $z \approx 0.9d$ is the inner lever arm; $\alpha_{cc} = 1$ is the coefficient accounting for long-term effects on concrete strength; $\alpha_{cw} = 1$ is the coefficient taking account of the state of the stress in the compression chord; $\nu = 0.6(1 - f_c / 250\text{ MPa})$ is the strength reduction factor for concrete cracked in shear; ξ = angle between concrete compression struts and the main tension chord; and ρ_l and ρ_w are the longitudinal/shear reinforcement ratios.

Note that the symbol ξ is introduced here instead of θ used in EN 1992-1-1 (2004) to avoid confusion with the symbol for model uncertainty. Neither the partial factor γ_C nor the characteristic value of f_c are applied in Equations (2). For shear without special shear reinforcement (such as stirrups or inclined bars, hereafter referred to as "shear reinforcement" to simplify the text), no axial compressive force is considered.

Statistical characteristics of the uncertainties related to the resistance models in Equations (2) obtained in several studies are provided in Table 2. The mean of the model uncertainty indicates a systematic deviation of the model from test results (bias). The following comments are made:

– Available experimental data are not supplemented by sufficient information on test conditions (see Figure 1 and Table 1) which are thus not appropriately accounted for; uncertainties due to description of input data may concern uncertain effective depth and material properties,
– Effects of actual structural conditions are unknown and not included,
– Computational options (Figure 1 and Table 1) seem to be irrelevant since simple structural members are considered.

Some of the studies are based on overlapping experimental results and thus are partly dependent. It follows from Table 2 that a broad agreement is mostly achieved for failure modes where several results are available.

The considered studies also provided a valuable insight into factors affecting the model uncertainties for bending and shear. As background information for the paper by Holicky et al. (2007) the analysis of experimental data revealed no significant statistical correlation between the model uncertainty and any of the basic variables influencing flexural resistance (including

[1] Validated to comply with the model uncertainty factors in Eurocodes, draft of bulletin on semi-probabilistic methods for verifications of RC structures by *fib* SAG7.

reinforcement ratio $0.25\% < \rho_l < 3.5\%$ and concrete compressive strength 17 MPa $< f_c <$ 45 MPa).

For shear resistance of members without shear reinforcement a research team at the University of Stellenbosch concluded that the model uncertainty:

- Is significantly decreasing with the ratio of the shear span to the effective depth $a/d$and the effective depth d while
- It is not subject to trends with the other shear parameters.

The results were limited to the range of $2.9 < a/d$ as deep beam and shear bond failures are expected for lower values of a/d in accordance with O'Brien & Dixon (1995). For lower a/d the shear resistance is likely to be underestimated since the positive contribution of an arch action is neglected in the Eurocode model. Cladera & Marí (2004a) reported decrease of the model uncertainty with d and also with ρ_l which does not comply with the conclusions of the South African team confirmed later by Sykora & Holicky (2012). It is emphasised that the failure of members without shear reinforcement is sudden and brittle and adequate reliability should be assured.

For shear resistance of members with shear reinforcement Cladera & Marí (2007) and Mensah (2012) indicated that the model uncertainty significantly decreases with an increasing strength of shear reinforcement $\rho_w f_{yw}$. Influences of the other basic variables are much lower. In addition Cladera & Marí (2004b) noted that influence of the amount of shear reinforcement is not linearly proportional to the shear strength and the truss model in EN 1992-1-1 (2004) may be unconservative for highly reinforced concrete members ($\rho_w f_y > 2$ MPa). These conclusions are confirmed by a more recent study of the authors where a significant trend of μ_θ with $\rho_w f_{yw}$ is observed (Table 2). Figure 2 shows variation of θ with $\rho_w f_{yw}$

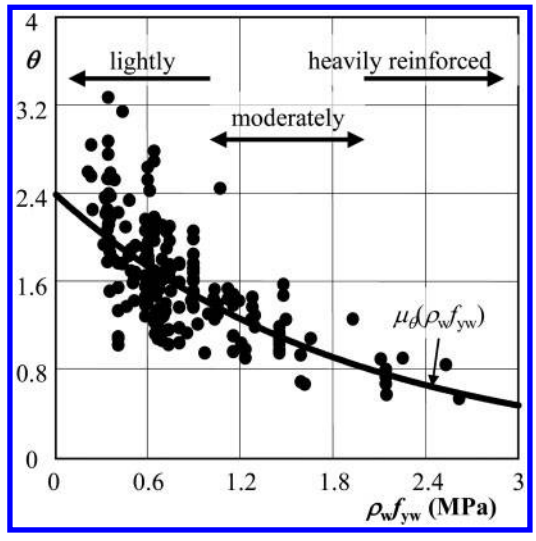

Figure 2. Variation of θ with $\rho_w f_{yw}$ and the trend of μ_θ.

and the trend of the mean value of θ based on an exponential regression. The influence of the strength of shear reinforcement on the coefficient of variation of the model uncertainty is less significant. A significant bias of the model uncertainty is primarily attributed to a limit for the angle ξ.

4 MODEL UNCERTAINTY FACTOR FOR DETERMINISTIC VERIFICATIONS

For deterministic reliability verifications EN 1990 (2002) introduces the partial factor γ_{Rd} to describe the uncertainty associated with the resistance model ("design value of the model uncertainty"). In accordance with fib SAG 9 (2010) the model uncertainty factor γ_{Rd} for reinforced concrete structures can be obtained as a product of:

$$\gamma_{Rd} = \gamma_{Rd1}\ \gamma_{Rd2} \tag{3}$$

where γ_{Rd1} = partial factor accounting for model uncertainty; and γ_{Rd2} = partial factor accounting for geometrical uncertainties.

EN 1992-1-1 (2004) provides no specific recommendations concerning model uncertainties. EN 1992-2 (2005) introduces the global safety format for a nonlinear analysis with the recommended model uncertainty factor of 1.06. However, Sykora & Holicky (2011) indicated that such a factor is low and should be increased in most cases depending on relevant failure mode (bending, shear, compression). In accordance with fib SAG 9 (2010) $\gamma_{Rd1} = 1.05$ for concrete strength and $\gamma_{Rd1} = 1.025$ for reinforcement may be assumed in common cases. However, larger model uncertainty needs to be considered for punching shear when concrete crushing is dominating.

A value of $\gamma_{Rd2} = 1.05$ may be assumed for geometrical uncertainties of the concrete section size or

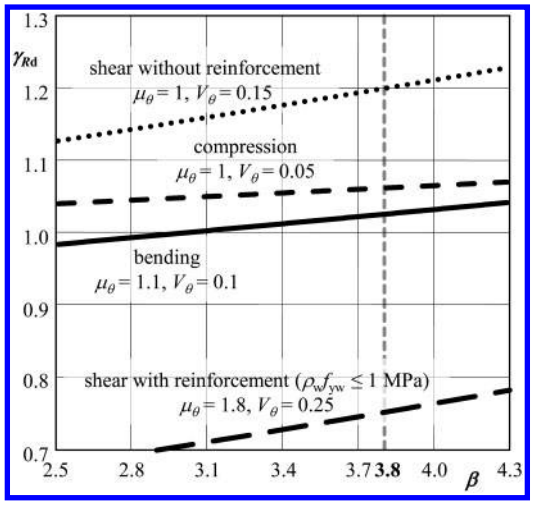

Figure 3. Variation of the partial factor γ_{Rd} with β for $\alpha_R = 0.32$.

reinforcement position. When measurements of an existing structure indicate insignificant variability of geometrical properties, $\gamma_{Rd2} = 1.0$ may be accepted.

Alternatively, the partial factor γ_{Rd} can be obtained from the following relationship based on a lognormal distribution:

$$\gamma_{Rd} = 1 / [\mu_\theta \exp(-\alpha_R \beta V_\theta)] \quad (4)$$

where α_R = FORM sensitivity factor; and β = target reliability index according to EN 1990 (2002). Assuming the probabilistic models for the model uncertainty given above (with rounded statistical characteristics), variation of the partial factor γ_{Rd} obtained from Equation (4) with the target reliability β and $\alpha_R = 0.32$ ("non-dominant resistance variable") is indicated in Figure 3.

It follows from Figure 3 that the model uncertainty factor γ_{Rd} is close to unity for the well-established models of flexural and axial compression resistances. The partial factor then drops below unity for the shear model for the members with shear reinforcement due to the high value of $\mu_\theta(\rho_w f_{yw} \leq 1\,\text{MPa})$. For $\beta = 3.8$ the model uncertainty factor of about 1.2 is obtained for the shear model for the members without shear reinforcement.

The selection of $\alpha_R = 0.32$ deserves additional comments. Leading and accompanying actions (with $\alpha_E = -0.7$ and $\alpha_E = -0.4 \times 0.7 = -0.28$) are distinguished in EN 1990 (2002) while $\alpha_R = 0.8$ is recommended for resistance variables. When the uncertainty factor γ_{Rd} and material factor γ_m are assessed separately for $\alpha_R = 0.8$, conservative designs may be obtained. Taerwe (1993) and ISO 2394 (1998) considered the model uncertainty as a non-dominant resistance variable and accepted the reduction $\alpha_R = 0.4 \times 0.8 = 0.32$. Note that the α_R-value significantly affects the partial factor γ_{Rd} (Sykora et al. (2013)).

5 DISCUSSION AND OUTLOOK OF FURTHER RESEARCH

This study indicates that the uncertainties related to the resistance models for reinforced concrete structures should be further investigated. Basically two classes of models should be distinguished:

- Engineering models with strictly defined assumptions (beam and sectional approaches),
- Complex models based on general principles of structural mechanics with much wider options and potentially higher uncertainties.

The following steps of research concerning the uncertainties in resistance models are foreseen:

1. *Data acquisition*. For structural members actual resistances will be obtained from available experimental tests. When experimental data is little or missing, test values are to be found by interpretation of test results in different conditions (simpler structural members), using different software tools and verification methods. Yet, this will introduce an additional uncertainty. The test results might be associated with weights reflecting types and frequencies of structures designed in practice.
2. *Uncertainties related to different test methods and actual structural conditions* will be assessed; use of expert judgements will often be inevitable.
3. *Uncertainties affecting model results*. Particularly for numerical models significance of the three partial factors affecting "model results" is to be assessed to provide background information for development of further guidelines.
4. *Differentiation of the model uncertainty* with respect to complexity of the task, failure mode, underlying structural models and level of control will be proposed. Appropriate probabilistic description will be suggested and the partial factors for model uncertainties derived.

For deteriorating structures the resistance model should inevitably incorporate degradation effects that may be a source of additional uncertainties and should be also quantified within the further research; Tanner et al. (2011) provided the first insight.

6 CONCLUDING REMARKS

Description of uncertainties related to resistance and load effect models can be a crucial problem of reliability analyses. The present paper focused on the uncertainties in resistance models of reinforced concrete structures reveals that:

1. The model uncertainty should be related to test uncertainties, to actual structural conditions and computational model under consideration.
2. In common cases actual resistance can be estimated as a product of the model uncertainty and resistance obtained by the model.
3. Uncertainties related to models provided in EN 1992-1-1 (2004) can be described by the following

statistical characteristics and partial factors (when combining different failure modes a less favourable model uncertainty may apply):

- Axial compression without effects of buckling: mean $\mu_\theta \approx 1$; coefficient of variation $V_\theta \approx 0.05$; model uncertainty factor $\gamma_{Rd} \approx 1.05$,
- Bending: $\mu_\theta \approx 1.1$; $V_\theta \approx 0.1$ and $\gamma_{Rd} \approx 1.05$,
- Shear of the members without special shear reinforcement: $\mu_\theta \approx 1$; $V_\theta \approx 0.15$ and $\gamma_{Rd} \approx 1.2$,
- Shear of the members with special shear reinforcement:
  - lightly reinforced beams ($\rho_w f_{yw} \leq 1$ MPa): $\mu_\theta \approx 1.8$; $V_\theta \approx 0.25$ and $\gamma_{Rd} \approx 0.75$,
  - moderately reinforced beams (1 MPa $< \rho_w f_{yw} \leq 2$ MPa): $\mu_\theta \approx 1.25$; $V_\theta \approx 0.25$ and $\gamma_{Rd} \approx 1.1$,
  - heavily reinforced beams (2 MPa $< \rho_w f_{yw}$): $\mu_\theta \approx 0.8$; $V_\theta \approx 0.2$ and $\gamma_{Rd} \approx 1.6$ (particularly these values are indicative since they are based on eight test results only).

Sabaratnam Loganathan
Deputy Global Discipline Director, PDG – Structural, Director PDG – Structural Assets, HATCH, Brisbane, Australia

ABSTRACT: Safety in Design is an integral part of the design process for industrial and mining structures. Safety in design is a philosophy which integrates risk management into the design process to identify and address safety issues over the whole of life (by elimination or minimization) and to communicate hazards and residual risks to "downstream" users. Hazards and risks associated with both work practices and structural safety are required to be considered. Solutions to reduce safety risks may require higher level structural analysis and/or rigorous measurements to verify design assumptions, minimize uncertainties and/or ongoing monitoring during the construction and operation phases. Engineering challenges, opportunities and lessons learnt from a number of taxing projects are presented.

1 INTRODUCTION

"Safety in Design" is defined as the integration of hazard identification and risk assessment methods early in the design process to eliminate or minimize risks throughout the life cycle of the structure or plant being designed and communicating hazards and risks to "downstream" users [modified from Safe Work Australia, 2006]. Prevention through design, HSE in design, safety by design, safe design and designing for safety are alternative expressions/terminology for Safety in Design.

Various studies have shown that design plays a role in accidents and that designers can do more to prevent such accidents [Safe Work Australia, 2004], [Bennett, 2004].

There are many reasons for Safety in Design approaches to be adopted by structural engineers:

1. It is the right thing to do, from a general engineering ethics standpoint. HATCH, the employer of the authors, has the implementation of Safety in Design principles as one of the main components of the company HSEC policy, and "No Harm' philosophy.
2. Most large mining and resource companies have Safety in Design principles directly embedded into their safety policies/standards. These embedded elements may relate to compliance with legislative requirements, requirements to undertake risk assessments for new designs, consideration of the structure/plant life cycle, identification of critical components, documentation of operating limits and design data, and reviews of design for use, maintenance and construction. Requirements for dealing with fatal or catastrophic risks may also involve Safety in Design principles.
3. Various government bodies around the world are enforcing the implementation of Safety in Design practices through various legislative instruments. Some typical examples can be found in [Safe Work Australia, 2012], [Department of Mines and Petroleum, 2010].

Structures for the mining and resource industries operate in an aggressive environment. Many types of these structures are subjected to "abnormal" or unusual operational loads during their service life and these structures are generally required to survive these abnormal events without compromising safety. As such Safety in Design is warranted for mining and resource structures, and in particular in the design of service life extension/risk reduction strategies for existing structures.

This paper will present the engineering challenges and lessons learnt from a Safety in Design perspective for a number of challenging projects. A "broad" definition of "Safety in Design", and "designer" is adopted throughout this article.

2 HAZARD IDENTIFICATION AND RISK MANAGEMENT FOR SAFETY IN DESIGN

Identification of hazards and management of risks forms a central pillar of Safety in Design. Risk management principles are well established in the mining and resource industries with specific publications to supplement general risk management publications such as ISO 31000. Briefly, the context of the risk assessment is defined, hazards are identified, risks evaluated against a tolerance criteria, and additional controls implemented where necessary. This

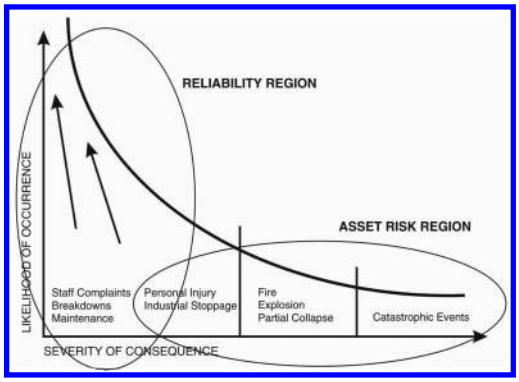

Figure 1. General distribution of probability vs consequence.

is generally undertaken by an experienced multi-discipline team with staged risk reviews and in parallel with client operability, maintainability and/or constructability reviews.

Although this process appears to be straight forward for structural engineering, it in fact requires structural engineers with appropriate experience, skills, knowledge, attitude and professionalism to carry out these tasks to achieve the correct outcomes.

The context for the hazard identification and risk management process is important. A general profile of all the hazards for a particular design will generally yield a distribution with the two extremes being low frequency, high consequence technical/process safety hazards, as opposed to high frequency, low consequence hazards generally slips, trips and falls. The source of these hazards can also range from the operation, maintenance and systems of work associated with the equipment/plant supported on the structure, adjacent items, through to the structure itself. Safety in Design generally requires that more than one hazard identification/risk management methodology is required to cover the full range of issues.

Several publications giving an overview of Safety in Design are available [Safework Australia 2012], [Workcover NSW, 2001] as a starting point.

These can be supplemented with recommendations from codes of practice and guidance material, which deal with good practice on issues as plant, steel or concrete construction, bridge beams, and bins/silos. Further information on hazards specific to the resources industry can be obtained from industry initiatives, safety alerts/bulletins from various government agencies or from reports relating to major or fatal accidents.

A major source of hazards often overlooked is the structure itself. Hazards relating to the construction of the structure or maintenance/operability of associated equipment may be well known, however the structure itself requires regular cleaning, maintenance, in particular maintenance of the protective coatings, and ongoing structural integrity inspections.

The ongoing structural integrity management of numerous types of structures for the resource

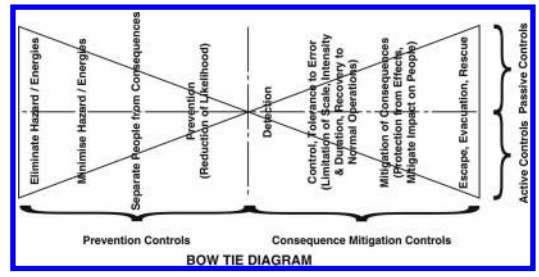

Figure 2. PFEEER mapped on a bow tie diagram.

industries are important. The selected structural configuration should consider potential failure modes, the ability to detect early signs of structural distress in critical elements, and acess requirements required for ongoing structural inspections.

2.1 *Hierarchy of controls and control philosophy*

Control measures are generally required to further reduce the level of risk, and the hierarchy of controls is used as a guide on the most suitable types of controls to use. ERIC (Eliminate, Reduce, Inform | Control) or the standard hierarchy of controls (Eliminate, Substitute, Isolate, Engineering, Administration PPE) are good starting points. The OMAT [EMERST, 2012] hierarchy of controls (Eliminate, Substitute/Minimize, Passive Engineering, Active Engineering, Alarms and Warning Systems, Procedural, Awareness/Competency) was derived for large earth moving equipment and is useful for items with mechanical equipment and interaction. The overall resilience of the controls for major hazards can be appreciated by mapping the type and functionality of the controls against the PFEEER [HSE, 1997] hierarchy (Elimination, Minimize hazards/energies, Separate people from consequences, Prevention – reduction of likelihood, Detection of event, Control – limitation of scale, intensity, duration & recovery to normal operations, Mitigation of consequences, Evacuation, escape and rescue). This presentation is best suited using a bow-tie assessment.

Care is required for structures where the structural integrity for particular design loads/scenarios is dependent on safety devices, even though "fail to safety" principles may be adopted. Good practice is generally to implement multiple, independent safety devices (preferably passive/without human action required) which do not have common failure modes. Critical safety devices should be identified during the design phase, their accuracy, effectiveness and consequences of failure understood, and communication to the user in place to ensure their continued safe operation through a traceable audit system.

There can be considerable differences between structural design standards relating to this issue. The Australian standards for bulk material handling machines (AS4324.1) and cranes (AS1418) require scenarios to be considered where the control system has been ineffective, or alternatively requires specific

requirements to mitigate and limit the effects of failure of critical components.

The bow-tie risk assessment methodology is a useful tool for these scenarios as it can enable the full spectrum of scenarios from a safety and enterprise viewpoint to be developed. In general, most of the systems used to limit the probability of an event occurring, or to limit the consequences of an event are dependent on humans for correct installation, maintenance, and in extreme conditions, not to remove or bypass the system.

2.2 *Risk tolerability*

The tolerability criteria for the risk management is critical, the criteria is often referenced as being ALARP – As Low As Reasonably Practicable. One of the key issues in practice is defining this criteria. Reviews of general risk management practices, which are applicable for engineering design, have identified issues with the application of the ALARP criteria such as not applying good practice, reverse ALARP, salami slicing, and inappropriate controls amongst others.

The legislative definition of the ALARP is also a challenge in terms of structural engineering in general and in particular Safety in Design. Various legislative guides generally define ALARP by weighing up several factors which involve: the likelihood of a hazard or risk occurring; the degree of harm that may result from the hazard or risk; what a person concerned knows or ought reasonably to know about the hazard or risk and the ways of eliminating the risk, including knowledge available at the time, understanding the impact of failure of risk controls measures, human error and interaction between multiple hazards; the availability and suitability of ways to eliminate or reduce the hazard or risk; and the cost of eliminating or reducing the risk and whether this cost is "grossly disproportionate" to the risk. This criteria is very difficult to apply to a design engineering perspective. UK's HSE and IStructE and Institutions of Civil Engineers have a discussion document on this issue [Institution of Civil Engineers, 2010] which highlights the further work required in this particular issue.

Extreme care needs to be taken using risk prioritizing matrices to determine if a risk is tolerable.

2.3 *Transfer of information*

A key requirement of Safety in Design is the transfer of information from the designer to other parties. Lessons from the UK, which are being adopted in parts of Australia, indicate that particular attention should be placed on exceptional/significant hazards. These hazards are defined [Department of Mines and Petroleum, 2010], [Safe Work Australia, 2010] as being (a) not likely to be obvious to a competent contractor or designer; (b) unusual in they occur in unusual circumstances or because of the nature of the site or (c) are difficult to manage. This method avoids extensive tick and flick sheets where these hazards are mixed with obvious hazards. The design basis for structures for mining and industry should be communicated as part of this to enable the structure to be operated within its design basis.

Ideally this information should be transferred in a suitable formation for other parties, such as drawing mark-ups or the creation of a health and safety file. These records are then maintained and used by downstream parties.

3 DISCUSSION OF ISSUES AND EXAMPLES

Safety in Design will be a key component in further reducing the accident and fatality rate in the mining and resource industries, however it is not without its challenges.

A balanced Safety in Design approach is required for structures in the mining and resources industries. Construction preferences to reduce working at heights and other construction risks (and perhaps even construction and initial project costs) may introduce vulnerabilities to the structural integrity of the structure over its life span. Management of this residual risk may require ongoing monitoring over the life of the structure. This may introduce additional hazards to inspection personnel, in addition to the structural integrity risks which depend on the effectiveness of the inspections to detect the presence of structural distress or other issues. One key element of Safety in Design involves assessing the relative risks during the initial construction of a facility vs the relative residual risks over the life of the facility. This is quite challenging where hazards relating to low probability, high consequence events are involved.

Challenges may be encountered on cost issues related to safety in design. Adopting Safety in Design principles will lead to reduced costs due to fewer incidents, longer life, reduced maintenance, higher maintenance etc. from a global, whole of life perspective. However, on an elemental level, initial capital costs may be higher, even though the total costs may be reduced and/or have a lower risk residual profile, more appropriate maintenance profile etc. A significant portion of these decisions are based on personal experience of decision makers, which can vary significantly.

Structural designs generally consider pre-service scenarios to an extent that the construction methodology and other pre-service actions are known. One key challenge is the interface at and the determination of the construction sequence for the works and other pre-service actions. It is not unusual for the pre-service scenarios to govern certain components and joints, particularly lifting of sub-assemblies at ground level fully fitted out. Further checks are generally required to validate the assumptions as part of standard construction practices.

The following examples discuss several projects where Safety in Design challenges were encountered and how the Safety in Design approach was adopted.

Figure 3. Large door for confined space entry into a tank.

3.1 *Design basis for a structure to load large trucks*

A new bin structure was being designed and constructed to load large trucks. A key issue was the interaction between the vehicles and the structure. Significant work was undertaken to minimize the probability of a collision between the vehicles and the structure with considerations for alignment, space, protection walls at local points in place to minimize the probability of a vehicle impacting the structure. The design basis for the support structure was determined in conjunction with the client and other stakeholders. The support structure was designed to withstand a collision load calculated from the Australian standard. However, the design basis for the support structure was required to go further and include the requirement that the structure not collapse should a support leg be ineffective as the result of a vehicular collision.

This example shows how there may be a considerable difference of opinion with the definition of ALARP and the tolerance of risk between various stakeholders. The explicit considerations for the post-vehicle collision integrity of the structure had significant implications on the fundamental nature of the framing system. These requirements were in additional to the various controls to reduce the probability and severity of a truck collision.

3.2 *Considerations for tanks*

Significant long term advantages can be achieved by adopting Safety in Design approaches with tanks, particularly relating to confined space entry. Requirements relating to confined space entry typically require entry into the confined space to be minimized, and then access into the tanks be of sufficient size to allow for evacuation of the confined space if necessary. The size of the openings into the tank should be as large as possible from a maintenance perspective. This may enable protected vehicles to enter the tank to minimize safety risks or to minimize down time of the tank.

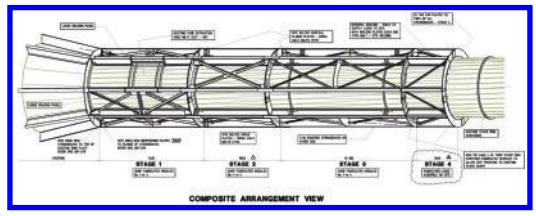

Figure 4. Module strengthening methodology for a stack.

These options however may increase the initial fabrication and erection cost of the tank. The optimum size of the entry points into the tank may be beyond the limits in simplified standards for tanks and higher order analysis such as FEA may be required to design the tank in these instances. These up-front increases in costs need to be balanced against increase in tank life and reduced down time of the tank and associated process equipment.

3.3 *Stack life extension and risk reduction works*

A modular strengthening arrangement was adopted for the temporary life extension of a stack. The stack at an industrial facility had undergone corrosion to the extent that its structural integrity was in doubt by the relevant stakeholders. From a constructability viewpoint, the use of an external modular skeleton structure minimized working at height issues and minimized the extent of work on site which could be influenced by process conditions at the construction area.

Safety in Design considerations were also considered for the demolition of the stack at the end of the life extension work and for the design of the new stack. Temporary structures to assist with the removal of the corroded stack were designed in collaboration with the contractors. The new stack was designed with splice connections to minimize the on-site work, construction materials were selected for superior corrosion resistance, the stack configuration incorporated aspects to enable further works, for process reasons, at a later stage with minimal down time.

3.4 *Duct life extension*

Safety was a key consideration in the design of life extension and risk reduction works for an existing large diameter duct. The duct had undergone an earlier process event which resulted in significant distortion. Risk reduction works were judged to be necessary based on the operational criticality of the duct, the findings of a condition assessment and other items.

A key Safety in Design criteria was the structural integrity of the duct and other structures during the erection of the new works. There were numerous structures placing constraints on the construction methodology, along with the preference for minimum disruption to operations. A staged approach was chosen to temporarily support the duct on new supports, install temporary works for positioning the new

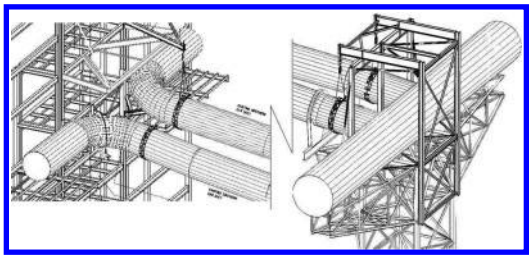

Figure 5. Temporary works for duct life extension.

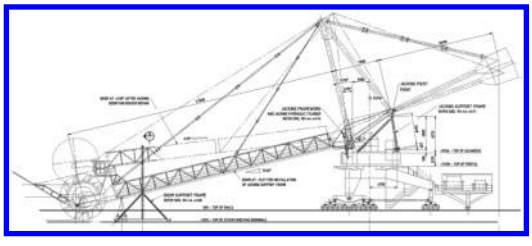

Figure 6. Temporary works for reclaimer remediation.

support truss, and then to lift in the new support truss in a very congested area. The new support truss was lifted onto the temporary steelwork, rolled under the ducts and other permanent steelwork and connections completed. One of the key lessons learnt from this project was that in this situation developing the most appropriate methodology for the works was the key to the project success, far more so than the analysis tools for the works.

3.5 *Reclaimer remediation works*

Stability considerations played key considerations for the return to service works for a bucket wheel reclaimer. Reclaimers are balanced machines and overturning of the machine about the rails or slew bearing failure has occurred previously. The machine balance and the stability of the machine was a significant hazard that needed to be proactively managed throughout the works from a Safety in Design perspective.

The balance and stability of the machine was a key criteria in the design of the work packages for the refurbishment works. The balance of the machine was baselined prior to the works commencing. Calculations on the balance were undertaken on almost a daily basis depending on the mass distribution on the reclaimer. Measurements of the mass of items removed from the reclaimer were undertaken as well as ongoing measurements of the luff cylinder pressures to determine the safety of the machine from a overturning stability and slew bearing loading perspective.

4 CONCLUDING COMMENTS

Safety in Design is an essential component of the continuing effort to reduce and eliminate fatalities and injuries in the mining and resources industries. Structures for these industries have inherent risks associated with the construction, operation, maintenance, disposal and ongoing management of their structural integrity. It is at the planning and design stages that these hazards are best identified, designed out where practicable or appropriate controls integrated into the works by knowledgeable and safety focused staff who are part of an overall team committed to safe, planned, predictable, professional project outcomes. This approach is essential for the development of long life, low operating cost, "Tier One" mining and resource industry facilities.

Risk-based design in mining structures

M. Mmusi
Worley Parsons TWP (Department of Civil/Structural Engineering), Worley Parsons Group, South Africa

A. Masarira
Anglo American Technical Solutions (Structural Engineering), Anglo Operations Limited, South Africa

ABSTRACT: The structural infrastructure in mining is exposed to excessive and even extreme loading conditions due to the nature and environment of mining operations. The structures in most mining plants often support mechanical equipment for material processing and the loads applied to these structures are often dynamic in nature and could vary in magnitude and intensity. Most loading conditions in mining are unique especially underground mining. Therefore a clear understanding of these conditions is important. The critical aspect is ensuring that proper assumptions are made. It is therefore imperative that a risk based approach be adopted in dealing with these structures. The risk based approach would consider the fact that mining operations rarely follow processes that are easily predictable. During all the stages of the design the structural engineer needs to ask the following questions: what are the possible risks the structure will be exposed to, what are the possible unwanted events (accidental loading) that could occur during the life of the structure, what could go wrong during the life of the structure. This paper proposes a risk based design approach for mining structures. It considers the operating and environmental conditions to which mining structures are exposed to.

Keywords: Risk-based design, mining structures, extreme loading

1 INTRODUCTION

As the pressures of production continue to increase in the mining industry, the soundness and integrity of the associated structures is also continually tested. Failure investigation and analysis more than often reveals cases where only vendor supplied loads were applied and not much thought was put into other possible loading conditions. This is generally as a result of over-reliance on vendor supplied drawings (i.e not exploring other loading possibilities), and what are the risks of not exploring other loading possibilities, lack of understanding of the production conditions and project time constraints. As such risk based design is imperative.

Risk based design is centred on the risk needs of a specific structure. The probability of failure will allow certain uncertainties to be captured such as unknown loading conditions especially in dynamically loaded structures. The major benefits of this method is firstly safety as this is paramount in any mining activity, and secondly economical as the client would reduce costs over the long term through unnecessary and often expensive re-engineering, repair, strengthening and in the extreme cases replacement structures which results in disruption of production. The author proposes that the risk based design approach be applied only to "critical/complex" structures as per the agreement of the structural engineer and the client. This will save the client cost and time and focus on areas of necessity.

This paper will provide an overview of the basic concepts and benefits of risk-based design as applied to the mining and minerals industry. A framework will be proposed on how to apply risk-based design. A case study will also be presented on a complex mining structure on how specific aspects of risk-based design could have been applied.

2 RISK BASED DESIGN: PHILOSOPHY AND PRINCIPLES AS APPLIED IN MINING

Risk can be defined as the potential losses resulting from exposure to hazard. Ayyub et al. (1998) define risk as a method used to asses and evaluate uncertainties associated with an event. Therefore risk should be based on an identifiable failure scenario, its occurrence probability or likelihood, its consequences, consequence significance, and population at risk.

3 UNCERTAINTY

The analysis of a structural engineering problem frequently involves the development of a computational model. In some cases it is the model of the entire structure or a particular aspect of interest of the structure. Therefore the engineer decides which aspects of the structure to include and which to leave out.

Depending on the information about the structure and the background of the analyst, other characteristics of the system might end up unknown consequently increasing the overall uncertainty of the structure. Therefore, based on the level of accuracy of the model three categories surface; Abstracted, non-abstracted and unknown aspects of the structure. Some of these uncertainty types can be dealt with probabilistically (what is the likely hood of a particular loading type occurring), statistically (depending on past events there is a likely hood of a particular event/loading condition occurring) and reliability (based on experience a particular method is suitable in solving an event/loading condition). Reliability also takes into account the limitations of the codes of practice and experience has an important role to perform. For example at the preliminary stage of design it is well known that span/300 as per design codes is insufficient for sizing dynamically loaded structures and from experience span/80 works well as a thumb-suck value on what to expect. Uncertainty can be viewed as a subset of ignorance in the context of human knowledge.

The three main types of uncertainty in risk assessment that are commonly identified are (i) parameter uncertainty, (ii) model uncertainty, (iii) and completeness uncertainty. Parameter uncertainties are as a result of the estimation of parameters, contained in the model either through limited data or lack of experience. Model uncertainty fundamentally addresses the ability of the model to represent reality this will involve accuracies of applied boundary conditions. Completeness uncertainty addresses the uncertainty of the model in representing all possible risk scenarios. It is imperative that the differences of these uncertainties are understood, because a complete consideration of one type of uncertainty may still lead to insufficient understanding of the model. Parameter uncertainty can easily be addressed since a series of possible loading conditions can be established from experience and from the full knowledge of the operating conditions this allows the analyst to focus on critical loading conditions which are not only confined to vendor supplied information.

4 SAFETY

Safety can be defined as the judgement of risk acceptability for the structure (Ayyub et al 1998). Safety and safety requirements are relative since the decision of risk acceptance may vary depending on the individual making the judgement, the sensitivity of the industry towards risk, transportation of structural components to site which in turn is governed by the construction sequence. Safety standards also differ from client to client.

5 PERFORMANCE

The performance of a structure is its ability to meet functional requirements during the expected design life of the structure. The performance of a structure can be described by various elements such as reliability, capability, efficiency, and maintainability (Modarres 1993). Under operational conditions the performance of a structure is influenced and therefore lifecycle and structural health monitoring (SMH) of the structure is necessary to ensure continued performance at optimal levels.

6 HUMAN ERROR

The human contribution of risk can be estimated from an understanding of behavioural sciences. Hardware failure and human error should be addressed in the risk assessment since they both contribute to risk associated with the system. Therefore once human error probabilities are determined, human error/failures are treated in the same manner as hardware failures in performing risk assessment quantification.

Human reliability analysis is generally considered to be composed of three stages, namely (i) error identification, (ii) modelling and (iii) quantification. With use of FEA or any other tools one of the techniques that can be used to mitigate human risk is model verification. This simply allows the design engineer to verify that the applied loads are indeed as per design requirements (Mmusi, 2012).

7 RISK BASED DESIGN FRAMEWORK AND RISK MANAGEMENT

A framework has been developed which follows a step by step procedure which will assist the design engineer in mitigating risk. It would not be feasible to apply the proposed framework to each and every structure in a plant, as such risk based design would only be confined to critical structures. The initial step is to identify what a critical structure is. A critical structure can be defined as and to only confined to (i) a complex structure by nature of its design (ii) a structure supporting complex mechanical equipment that is in some instances on the critical path, (ii) a complex dynamical loaded structure with either one or more vibrating equipment. The above categories can be expanded as deemed satisfactory by the design engineer in agreement with the client.

The structure should firstly be designed as per the relevant design codes and in the case of supported mechanical equipment the loads should be applied as per vendor drawings, this will provide for all legal requirements and otherwise. It is the responsibility of the designer to identifying the potential failure modes, and to look beyond the scope vendor supplied loading. In the process of brainstorming possible loading and failure scenarios some structures will require unreasonable member sizes. The design engineer's judgement in consideration with cost restraints should be applied. It is fundamentally impossible to cover all possible risks however, a level of confidence should be

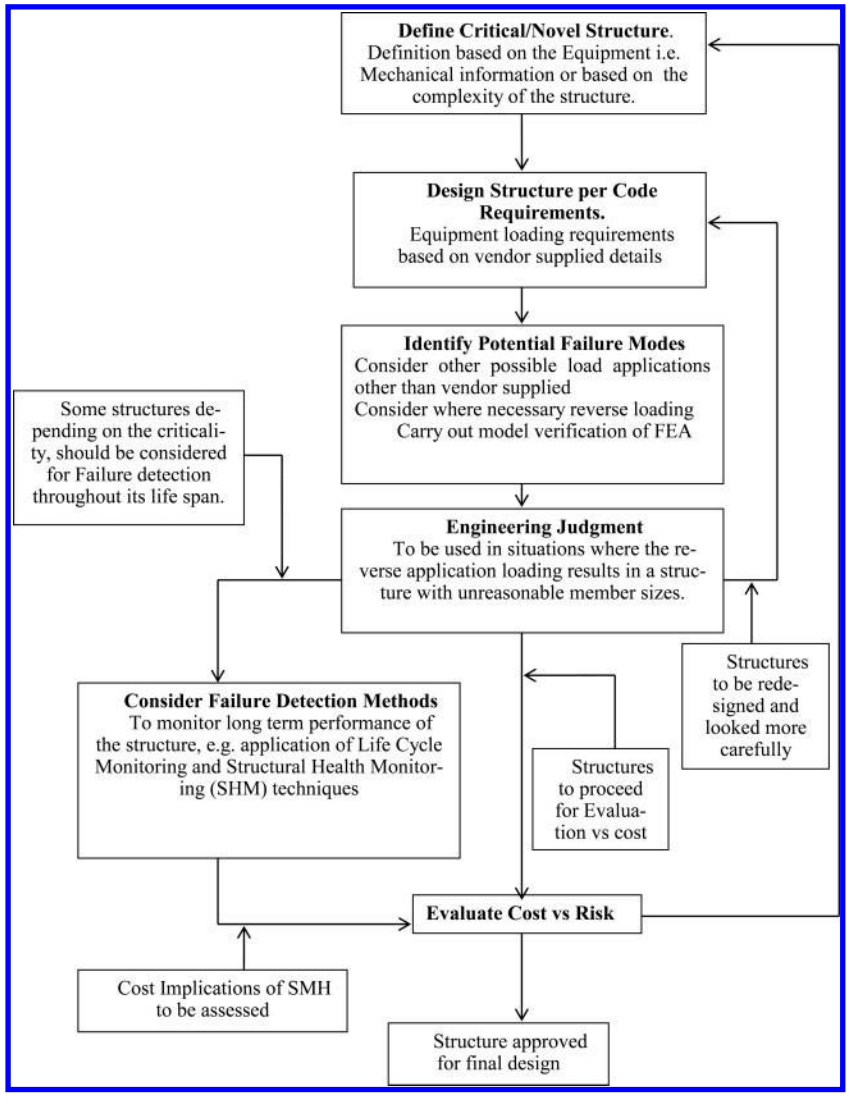

Figure 1. Risk Based Design Framework.

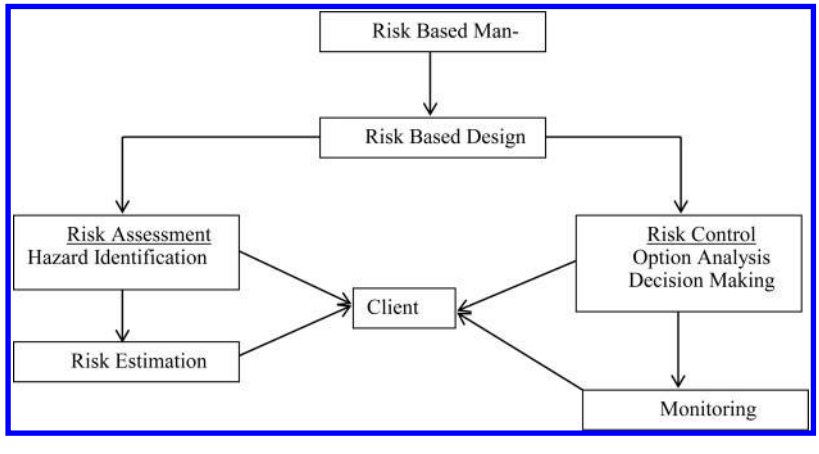

Figure 2. Risk Based Methodology/Management.

attained by the design engineer that sufficient work has been carried out and this will form part of the design calculations. The final stage is to ensure that the structure would last the intended design life. Various tools are available and the application of life cycle monitoring and structural health monitoring is essential. For dynamically loaded structures sensors and accelerometers can be used to monitor the performance of a structure over time. This stage will assist in detecting possible damage due to operational effects or loading conditions that could not have been established or were missed due to the complexity of structure.

8 RISK BASED METHODOLOGY AND MANAGEMENT

In order to close the loop on Risk based design, a methodology on management is required. The engineering consultants (for example Engineering Procurement and Contracting Management (EPCM)) are primarily responsible for identifying and implementing risk. However this should be communicated with client at all stages as this will have cost implications.

9 CONCLUSION

A systematic approach allows an engineer to evaluate expediently and easily complex engineering systems for safety and risk under different operational and extreme conditions. The ability to quantitatively evaluate these systems helps reduce cost. Risk based design can be used as a management tool that assists the structural engineer and project manager to foresee possible risk items, failure prevention, and consequence mitigation and finally risk communication with client.

Simulated virtual portfolio for masonry buildings

A. Mühlhausen, U.E. Dorka & F. Obón Santacana
University of Kassel, Germany

A. Smolka & M. Stupazzini
Munich Re, Munich, Germany

ABSTRACT: Assessment of damage costs due to an earthquake currently lacks the level of detail that is required for realistic pricing of individual insurance risks. Sophisticated numerical tools, which are widely used to assess structural behavior in great detail (like FEM), have been developed to a level where they may be used with confidence in seismic risk assessment and as such, enable the insurance industry to perform more realistic assessments.

In order to produce a virtual damage database, the "Simulated Building Portfolio"-Tool (SBP-Tool) was developed at the University of Kassel in cooperation with Munich Re. For using this tool several input parameters are needed in order to simulate a whole portfolio consisting of 3-D Finite Element models.

Thus validated virtual portfolios can be created now in regions with similar masonry buildings in order to assess damage costs where no or little event data are available.

1 INTRODUCTION

The assessment of damage losses due to an earthquake is an important issue for the insurance and reinsurance industry, but currently lacks the level of detail that is required for realistic pricing of individual risks.

Once a again, recent earthquakes that stroke Chile (Maule, Mw 8.8, February 6, 2010), New Zealand (Darfield, Mw 7.0, September 3, 2010 and Lyttelton, Mw 6.1, February 21, 2011) and Japan (Honshu, Mw 9.0, March 11, 2011) in the last three years proved the strategic importance of this kind of industry and renewed the crucial question of how to develop a resilient concept for society.

Any further advancement in that respect is strictly related to the capabilities of creating reliable models to predict seismic risk. This process implies a better understanding of the hazard, of the vulnerability and of the exposure that is involved.

Even if important on-going projects, like the Global Earthquake Model (GEM), are aiming at sharing and improving our knowledge, the "state-of-the-art" of the empirical data-set regarding earthquake's economic losses presents a severe non-uniformity. The worldwide information available is extremely different from both the quality and the geographical points of view.

Since earthquakes are rare events, the situation will not likely change significantly in the foreseeable future. It is therefore necessary to further investigate the development of innovative concepts based on consolidated numerical simulation techniques.

2 A NEED FOR COMBINING SOPHISTICATED SEISMOLOGICAL AND STRUCTURAL MODELS IN RISK SIMULATION

Guidotti (2012) shows how to describe a spatial variability of strong-ground motions through large-scale 3D simulations of wave propagation in near-surface soils. He developed complex 3D FE-models for a region of 1 km × 1 km and a depth of 50 m. More than 1.000.000 Finite Elements are typically required to simulated the wave propagation in a particular soil system.

Using these complex soil models, Guidotti assessed the response of buildings due to the simulated wave propagation by modeling them as rigid bodies (Fig. 1). This neglects the dynamic characteristics and the nonlinear structural behavior of buildings despite being the controlling factors for the response of buildings under seismic actions. Furthermore, the seismic damage to a particular building cannot be estimated with such over-simplified models; a combination of such detailed wave propagation models with sophisticated structural models for the buildings in question is required if reliable data for seismic risk analysis is to be provided.

3 THE SBP-TOOL FOR GENERATING A VIRTURAL PORTFOLIO

To create this kind of building models, the so-called "Simulated Building Portfolio-Tool" (SBP-Tool) was

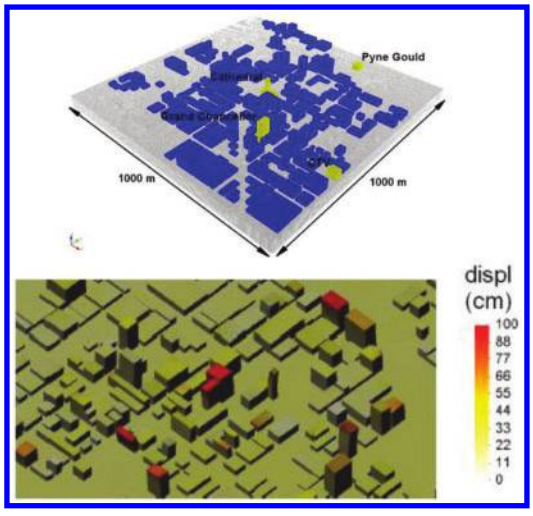

Figure 1. Top: Sophisticated 3D FE model of sub-soil with rigid blocks on top representing buildings in Christchurch. Down: A snapshot of the simulated displacement of the rigid block buildings. Guidotti (2012).

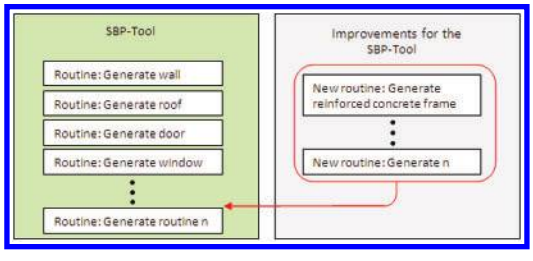

Figure 2. Import new routines to generic SBP-Tool, Mühlhausen (2012b).

developed at the University of Kassel in cooperation with the Munich Re, Mühlhausen (2010, 2011a, 2011b, 2012a). It provides a virtual portfolio of realistic buildings by using a set of global building criteria provided by the user in a configuration file. A statistical process automatically generates each individual building for the portfolio using the given range for each criterion.

The program is written in ISO C99 and features a modular design (Fig. 2). This allows for easy adaptation to different structures (steel frames, rc-frames with masonry infill, etc.) and inclusion of additional building features, like stairs or penthouses. Currently, the SBP-Tool is used to generate 3D linear FE-models of masonry buildings (Fig 3).

Using the configuration file, the SBP-Tool creates two ASCII files. The first contains the geometric and material data necessary for a FE-software to create a complex numerical model. It contains all the information regarding the nodes, elements, restraints and constraints, material properties for the roof, outer and inner walls, and the degrees of freedom (DOFs) subjected to loads. The second ASCII file contains the commands required for assembling the stiffness and mass matrices in the FE Software Slang (2004).

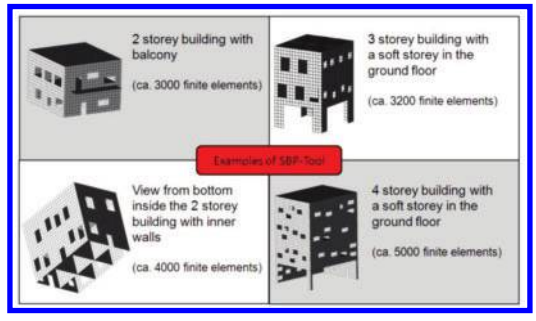

Figure 3. 3D linear FE-models for masonry buildings created by the SBP-Tool, Mühlhausen (2012b).

Figure 4. A regional portfolio of 3D FE-models for masonry buildings simulated with the SBP-Tool. This can be combined with any seismic input, e.g. wave propagation models, Mühlhausen (2012b).

Whereas the first file does not depend on any particular FE-software, the second one must be adapted to its specific commands. This allows the use of other FE-software (Ansys, Open Quake etc.) without interfering with the initial generation process of the buildings.

SLang imports the ASCII files and, by executing the commands, it creates the mass and stiffness matrices. They are exported as two additional output files. Furthermore, Slang creates a file with all the information associated with each DOF. Thus, a set of 4 files is created for each building generated containing all the necessary information to perform a dynamic in particular a time history analysis.

In general (e.g. non-linear structures) around 500 power spectra are required to determine the standard deviation of a local variable with an accuracy of greater than 99% according to the central limit theorem.

That means for a given portfolio like the one in figure 4 with 65 buildings and approximately 1.700.000 DOFs, 8.500.000 time histories analyses are required. To compute 8.500.000 time histories in a short period of time, the use of an efficient algorithm in combination with parallel computing (see chapter 4) is necessary.

In the case of linear structures, the use of power spectra provides an efficient way to calculate the required statistical values of local variables, which can be obtained by multiplying the transfer function of the local variable with the power spectrum of the input process (ground motion).

This transfer function describes the relationship between the output, a local variable (e.g. stresses),

and a normalized input, the loading (e.g. excitation at the foundation – earthquakes). They are a property of an individual structure, and they can be determined without the knowledge of the loading event. Only the location where the load is applied must be known. For linear models, these functions are constant over time and therefore, they only have to be computed once.

They can be obtained by evaluating a single time history.

4 THE PORTFOLIO SIMULATION

To perform the time history analysis with the required efficiency and speed a parallel implementation of Dorka's substructure algorithm Roik (1989), Dorka (1991, 1998, 2002), Bayer (2005) and Dorka (2006, 2007) is needed. This algorithm is a discrete formulation of the dynamic equilibrium equation (1):

$$M\frac{d^2u}{dt}+C\frac{du}{dt}+Ku=p(t)+f_r+f_s \qquad (1)$$

Its integration constants γ and β are variables. With $\gamma=0.5$ and $\beta=0.25$, it becomes the well-known Newmark scheme. It also accommodates experimental and non-linear numerical restoring forces f_r+f_s through a parallel sub-stepping process within each time step, thus avoiding time-consuming matrix inversions and iterations. Therefore, this algorithm can take advantage of multi-core and multi-processor computers using parallel libraries and other optimisations, resulting in solving 10000 DOFs in 43,94 ms per time step on a regular laptop computer Obón Santacana (2011a, 2011b, 2012). In other words: the simulation of one of the buildings in Figure 3 with 10000 to 12000 DOFs subjected to an earthquake of 40 seconds (4000 time steps) needs app. 3 minutes regardless of non-linearities, because the sub-stepping within each time step does not cause any significant reduction in performance due to its parallel implementation if the adequate number of cores or processors is available.

The time histories will be stored in a HDF5 format with all necessary information for the time parameters (date, duration, number of DOF, number of time steps and duration of time step) and for the time integration (acceleration, velocity, displacement and stresses) for further processing, e.g. Matlab.

Thus, several thousand realistic 3D FE building models are created and simulated under earthquake loading using only a few hours on a regular desktop. Figure 4 shows a small simulated portfolio of 65 buildings using around 500.000 finite elements (1.700.000 DOFs). Approximately 30% of the buildings have a balcony and 20% of the buildings have a soft storey.

5 DEFINING A VIRTUAL PORTFOLIO

The global building stock is highly heterogeneous in terms of design, construction practices and vulnerability to natural hazards.

GEM, the Global Earthquake Model Foundation, delivers in this respect powerful tool to get a better understanding of how to simulate a virtual portfolio in a particular region in the world. On one hand there is the open source Inventory Data Capture Tool (IDCT) and on the other hand the GEM Earthquake Consequences Database (GEMECD). Both applications deliver information regarding the earthquake event itself and a first idea of the building stock. The development of a third tool, and from the point of view of this paper the most interesting one, was launched in December 2010, namely "GEM Building Taxonomy". This tool intends to provide a classification of building characteristics in an ordered system.

The newest version of the GEM Building Taxonomy V2.0 should be available in March 2013 and will require 13 attributes to describe a building. These are: material of the lateral load-resisting system; types of lateral load-resisting system, roof and floors; height; date of construction; structural irregularity; occupancy; direction (to describe the orientation of the building with different lateral load-resisting systems in two principal horizontal directions); building position within a block, shape of building plan; exterior walls; and foundation, Brzev (2012).

The vision of the GEM Building Taxonomy team is to create a unique description (code) for a building or a building typology.

Although developed independently, both tools use similar or even the same attributes (Table 1) to identify a building or define a portfolio.

The SBP-Tool is written in a generic way that allows adding new attributes from the GEM Building Taxonomy or to modify the currently used SBP-Tool's parameters. This allows the direct use of the GEM Building taxonomy in the SBP-Tool. It also allows further development of the GEM taxonomy with respect to additional criteria needed for risk simulation.

6 INSURANCE LOSS ESTIMATION FOR VIRTUAL MASONRY BUILDINGS

Loss curves are an important tool for the insurance industry to estimate the potential risk and damage to a building (single risk) or portfolio and can be described by the relationship between renovation costs and return period.

The loss curves in figure 5 and 7 were determined with a sophisticated statistical process that has already been published in Mühlhausen (2010, 2011a and 2011b).

As a first approximation for a crack criterion for masonry, a threshold for the principal tension stress was chosen and also, a linear relationship between costs and damaged area was assumed. These assumptions allow estimating loss curves for a typical building (single risk), using the linear simulation method based on power spectra, as described in chapter 3.

By looking at four seemingly similar buildings (figure 6) from this study, it is apparent that, the simulated

Table 1. The 13 attributes of "GEM Building Taxonomy" and the required input parameters of the SBP-Tool.

Attribute or SBP-Input Parameter	GEM Building Taxonomy	SBP-Tool

** % of the whole portfolio has this input parameter

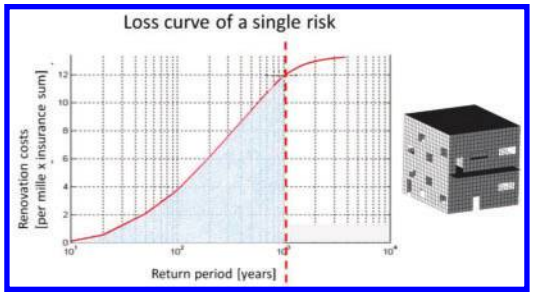

Figure 5. Typical loss curve for one building (right) with the expected linear threshold for masonry buildings, Mühlhausen (2012b).

loss curves (figure 7) may be grouped according to certain attributes.

In this case, there is a first indication, that the ratio of wall openings may be an important criterion.

Currently, studies are under way to clarify the role of such attributes in insurance loss estimation. Once clarified, such attributes should be made available through GEM's building taxonomy.

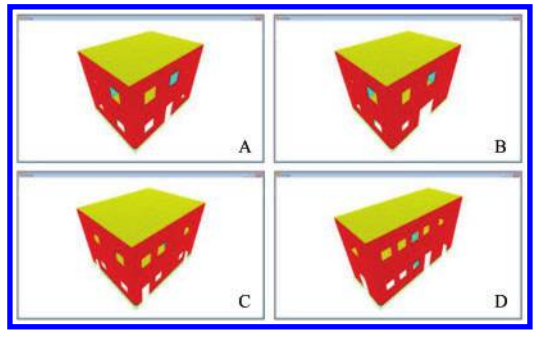

Figure 6. Typical masonry buildings (variant A to D) with sligthly different dimension and openings, Mühlhausen (2010).

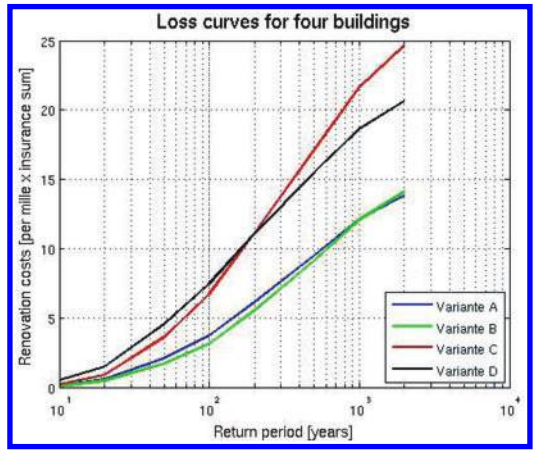

Figure 7. Loss curves for the four buildings from figure 6. Building A, B and C, D may be placed in different loss groups based on their ratio of wall openings, Mühlhausen (2010).

7 CONCLUSION AND OUTLOOK

Reliable seismic damage and loss simulation not only requires sophisticated seismological ground models, but foremost detailed structural models, since damage and repair needs depend on the dynamic characteristics and local non-linear structural behavior. Virtual building portfolio consisting thousands of FE models can now be generated with the SBP-Tool developed at the University of Kassel. Their seismic risk can be within a reasonable time frame by using an efficient algorithm in combination with parallel computing.

Although developed independently, GEM's building taxonomy and the SBP-Tool use similar or even the same attributes to identify a building or to define a portfolio. It allows further development of the GEM taxonomy with respect to additional criteria needed for risk simulation.

In this respect, the SBP-Tool can only generate masonry buildings but an extension for other building types (e.g. steel-concrete composite structures) is already under development.

Effective lightweight design of a rocket interstage ring through mixed-integer optimization

H. Köke, L. Weiß & C. Hühne
Institute of Composite Structures and Adaptive Systems,
DLR German Aerospace Center, Braunschweig Germany

ABSTRACT: The full lightweight potential of carbon fiber reinforced plastics in complex structures can only be exploited using an adequate combination of material and design. Potential combinations can be found, using an optimization routine integrated into the design process. This paper presents a detailed comparison of the optimization results for distinctive rocket interstage design concepts. The complex cylindrical grid structure has to withstand the mission loads while being as light as possible. For the efficient use of the superior material properties, carbon fiber reinforced plastics are combined with a foam core to form a sandwich configuration. To minimize the total mass, parametric finite element models are used within a constrained, mixed-integer optimization. The structure is modeled using a bottom up strategy. An optimization framework, incorporating the CAE software Ansys into the multi-purpose optimization package pyOpt, is presented. The augmented lagrangian particle swarm algorithm is used to find the configurations having minimal weight. As manufacturability is an important design requirement, a winding process is represented by constraints in the parameter set of the geometry. The stiffnesses of the structure, as well as strength criteria of the laminate are used as inequality constraints for the optimization. Further on, a lower bound of the first natural eigenfrequency using additional constraints, is investigated. Finally, the impact of the governing geometry, material parameters and hence their influences on the optimization problem are carefully reviewed. It is shown that appropriate design – material combinations can significantly reduce the structural mass.

1 INTRODUCTION

Within this paper, the interstage ring of a two stage rocket will be optimized (fig. 1). For the purpose of the start of engine number 2, the ring must be constructed in a way that the hot gases can leave, while still maintaining a target stiffness. Therefore a grid concept was established, consisting of axial bars wich are interconnected with wounded helix like sandwich structures. This concept provides enough open sectional area for the gas to exhaust.

In order to save weight, the interstage was designed to be constructed out of carbonfiber reinforced plastic (CFRP). The high specific stiffness and strength characteristics of uni-directional CFRP can be used to adjust the structure to achieve the required targets for stiffness, buckling constraints and different strength criteria for each loadcase.

The main configuration consists of axial CFRP bars and wounded sandwich helixes. Whereat the wounded helix structures consists of a foam core, which is interrupted by the axial bars, and two CFRP cover skins which are applied in a following manufacturing step. Thereby covering also the axial bars and acting like a further stiffener.

Thus, the needed parameters for setting up the finite element (FE) model are continuous and discret valued. Usually such problem would be simplified by relaxing the integer parameters to continuous ones and a concluding rounding to possible steps. In this case, it is not possible to relax the optimization problem by making the integer division of the axial and helix bars continuous. The manufacuring constraints for a wounded grid structure demand an equal distribution of knot points across the structure. Therefore the optimization model in combination with the optimization algorithm has to be chosen carefully.

In previous studies the augmented lagrangian particle swarm algorithm has proven reliable in finding an optimium under challenging contitions, as shown by Jansen and Perez (2011).

2 INTERSTAGE RING

The structural modelling of the interstage ring is done in Ansys Classic. The internal script language APDL is used for the pre- and post-processing and also for solving the different loadcases. This offers an easy way for enabling the optimization algorithm to retrieve the structural response of each probed parameter set.

The fundamental parameters of the model are shown in tab. 1. The height and the diameter of the interstage ring are not variable, as they are the assembly

constraints for integrating the ring in the rocket. The loads are generated in a preliminary, analytical process and are covering the main acting forces.

The optimization of the model is a step in the preliminary design, therfore 4-node shell elements are used, to keep calculation time as low as possible.

The constraints are modeled by two multi-point-constraints (MPC) as shown in fig. 2. MPC # 2 forms a displacement constraint on the lower end of the ring, with all degrees of freedom being zero. This overestimates the stiffness of the assembly point, as it would appear rigid.

This optimization is, as mentioned before, part of an early preliminary design, Therefore the stiffness can be adjusted in a following step. MPC # 1 transmits

the loads in the ring. An overview of all considered loads is given in tab. 1. In addition, MPC # 1 constrains a radial widening of the structure. This, like MPC #2, acts like an infinitelly stiff adjacent component.

Every loadcase was calculated individually followed by a linear buckling and modal analysis. Each response for the load case specific stiffness, the linear buckling load and the first eigenfrequency was saved. The CFRP failure criteria for maximum strain in each bar was also calculated, using the given allowables in tab. 3.

To avoid an overestimation of the calculated failure criteria due to high element strain in the boundary areas, the only elements for failure criteria evaluation are between 30%–70% of the ring's height. But, as will be shown, the strength criterias are not the driving factor behind the optimization.

3 UNIT CELL

In order to keep the amount of optimization parameters to a minimum and to reduce the time for the pre-processing of the FE model, a unit cell approach is used to implement all necessary data. Thus, to build the whole model, copying the unit cell in a specific manor is sufficient. Fig. 3 shows the geometry of the unit cell and the used element sections. The optimization model builds upon this specific topology. This is the same in every model.

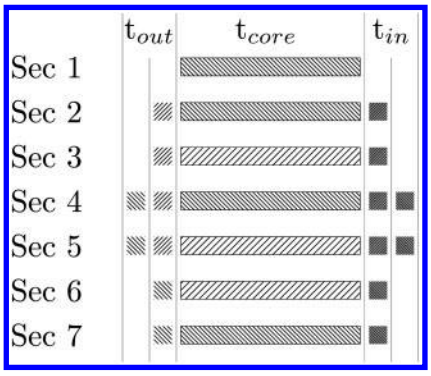

Figure 4. Composition of element sections.

The unit cell contains all used optimization parameters, tab. 2 gives an overview. As mentioned above, the parameter set includes continuous and integer parameters. As can be seen, parameter x_3 is a continuous factor for the width of the helix bars. This is required to maintain the topology of the unit cell constant.

In order to reduce the assemblage points at the boundaries, it was defined to begin and end the structure at the knot points. This requirement together with an integer amount of axial bars, defines the angle between the helixes and the axial bars. The helixes were then modeled in a cylindrical coordinate system, using the diameter of the interstage and the helix angles. As buckling is an important constraint for the optimization, the curved geometry of the helix is supposed to be a key factor for a correct calculation of the load factor.

Using boolean operations, the overlapping areas are sliced to build the specific topology and are then linked to the defined element sections. For each section a material composition representing the manufacturing process is imposed fig. 4. The model is build upon the thickness of the core (t_{core}) and width of the axial bars (w_{bars}), since they represent the stiffest part of the interstage. The thickness of the bars is coded in element section Sec 1. Together with the width of this specific area and the used CFRP material, as shown in tab. 3, the cross-section of the axial bar ist defined. Based on parameter t_{core}, the thickness of the foam core is set equal to this of the axial bar, otherwise there would be a gap in the winding process. This element section modelling approach was used for every other definition. The counterclockwise wound sandwich skin is always on top of the clockwise wound ones. Thus, making the whole structure an unsymmetric. But the overall impact is, as will be shown, negligible.

4 OPTIMIZATION PROCEDURE

The overall goal was to reduce the weight of the interstage ring. Therefore the optimization objective is to minimize the total mass of the interstage ring.

The framework for the optimization was programmed in Python. Ansys Classic is used for calculating all needed structural responses and saving them in text files. The optimization was carried out by pyOpt, Ruben E. Perez (2012). This optimization framework provides the implementation of the augmented lagrangian particle swarm algorithm (ALPSO).

The ALPSO algorithm is a heuristic and derivative-free global optimization method. It enforces the constraints by a Lagrangian formulation, while maintaining the Karush-Kuhn-Tucker conditions. None the less, the results must be carefully investigated, since the explicit constraint equations are not known.

The optimization constraints include material (max strain), stability (buckling of the bars), and stiffness (of the interstage concerning LC 1 and eigenfrequency re) specific values, see tab. 4. Regarding the structural requirements of the interstage, a minimum axial stiffness was demanded, to trim the eigenfrequency of the rocket. Also, buckling should not occur until 1.5 times the load of each load case.

5 OPTIMIZATION RESULTS

The displayed results of the optimization are only one sixth of all calculations. The optimization was done with 6 workers, using the mpi implementation in pyOpt. Only the results of worker 1 are shown.

CFRP		9	1

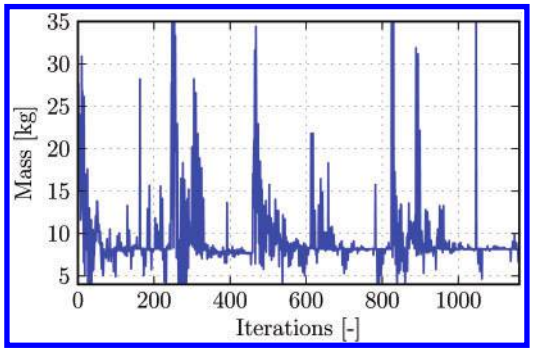

Figure 5. Convergence of total mass.

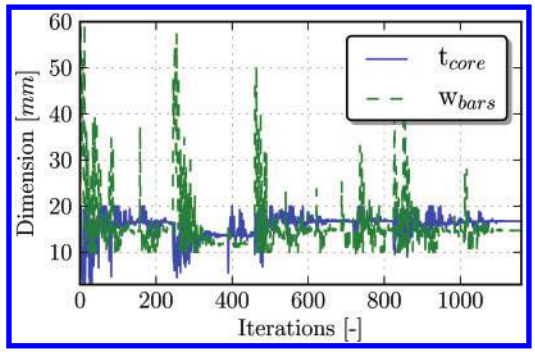

Figure 6. Width and height of the axial bars.

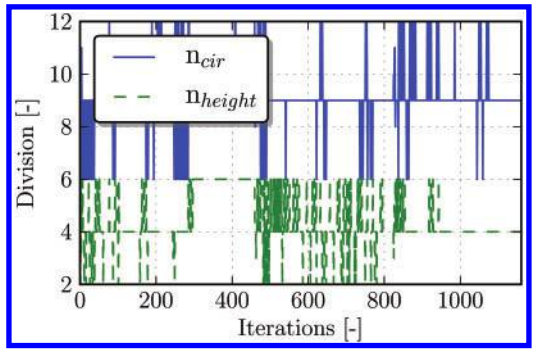

Figure 7. Divison of height and circumference.

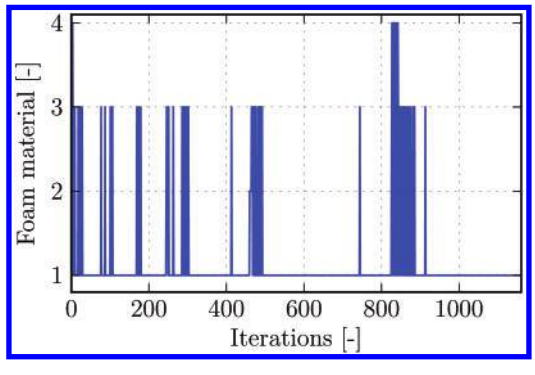

Figure 8. Foam material.

Fig. 5 shows the convergence history of the total mass of the interstage ring. The optimization algorithm is able to probe parameter sets within a total mass range from 4.5 kg to over 35. It can be seen that after 1000 iterations the total mass converges to around 8kg. It must be noted, that with 6 workers, the total amount of iterations must be multiplied with 6. Therefore, the total number of iterations is around 7500.

The driving factors of the total mass are n_{cir}, n_{height} and the cross section of the axial CFRP bars. Fig. 6 shows the convergence of the cross sectional parameters of the bars. The two parameters converge after 1050 iterations.

As described earlier, the integer parameters in this optimization are the division in axial and helix bars. The convergence history of this two parameters are shown in fig. 7. The division in height converges in under 980 iterations to a value of 4, while the algorithm still tries minor variations to optimize the total mass. Similarily, the division in circumference needs around 1100 iterations to achieve the final value of 9.

The used foam material ranges between 1 to 4, as can be seen in tab. 3. From 4 being the weakest but lightest to 1 being 4.6 times stiffer, but also 3.4 heavier. The optimization algorithm converges after 900 iteration to the Rohacell 110IG.

The convergence between the two CFRP materials can be seen in fig. 9. The buckling constraints are the most demanding, therefore the stiffer CFRP material is preferred by the optimization algorithm. Since failure

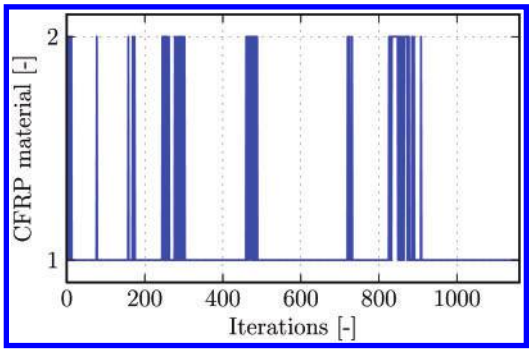

Figure 9. CFRP material.

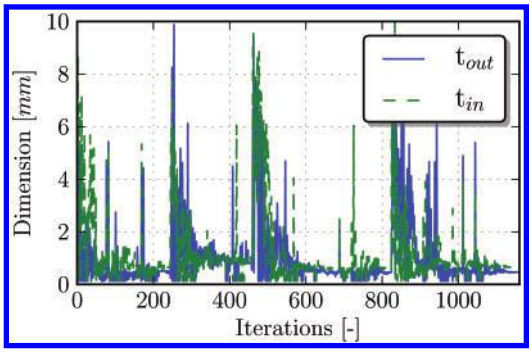

Figure 10. Thicknesses of the inside and outside CFRP plies.

is not the main driving constraint, the lower allowables of the UMS3536/UMS45 are acceptable.

The converged thicknesses of the wounded CFRP skins of the helix bars are shown in fig.10. The algorithm tends to make the inner plys thicker then the outside ones. This can be explained with the overall tendency of the wounded helixes to deform radial to the interstage, thus, making bending the dominating load. As the compression allowables of the CFRP materials are lower then the tensile ones, the laminate thickness must be greater on the compression side.

Fig. 11 shows the maximum strain failure index, for tension or compression, for each load case. As mentioned before, the evaluation of the maximum strain criteria takes place between 30%–70% of the interstage height. It can be shown that LC2 is the most demanding load case, although the one with the least force. The evaluation of the results indicates that at the knots, the helix bars are highly stressed due to an alternating orientation of the deformation.

Fig. 12 shows the maximum strain failure index for LC 1 of the optimized interstage ring. The achieved values are acceptable, since the failure constraints are not the driving parameter behind the optimization.

Another constraint is the axial stiffness of the interstage. Since there are accelerated masses during launch above the interstage, a required minimal stiffness must be achieved. The axial stiffness is directly linked to eigenmode of the whole rocket and must

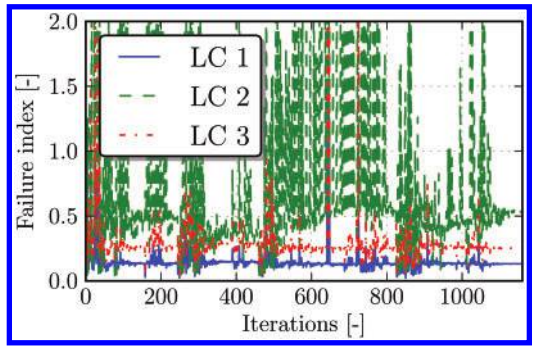

Figure 11. Convergence of load case specific maximum strain failure.

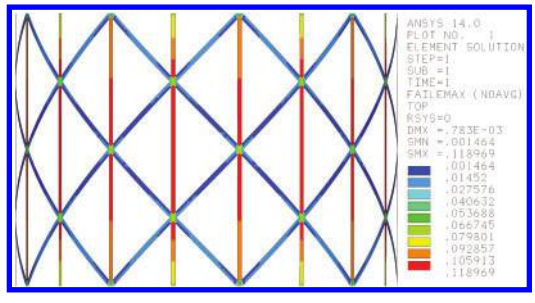

Figure 12. Maximum strain failure index for the best configuration with LC_1.

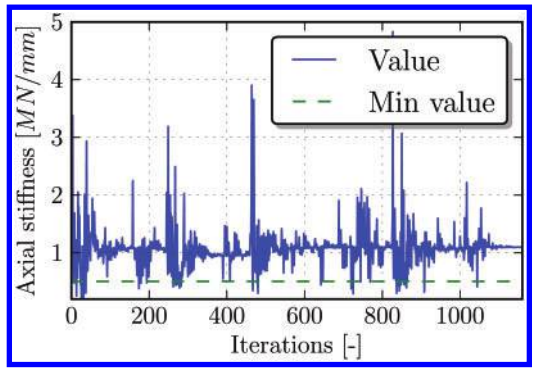

Figure 13. Convergence of the axial stiffness.

therefore be achieved. As shown in fig. 13 the required stiffness is over accomplished. To infer from that, the axial stiffness is not the restricting parameter in this optimization. Nearly every parameter set results in an axial stiffness over 1 MN/mm.

The convergence history of the load case specific buckling constraint is shown in fig. 14. They were extracted from the prestressed structural model and imply the multiple of the load before buckling might occur. The first buckling mode, along with the multiple load factor, was calculated using lanczos algorithm. Load case 3 is the most demanding. The applied moment compresses a small part of the interstage ring, containing just one or two axial bars. This immense

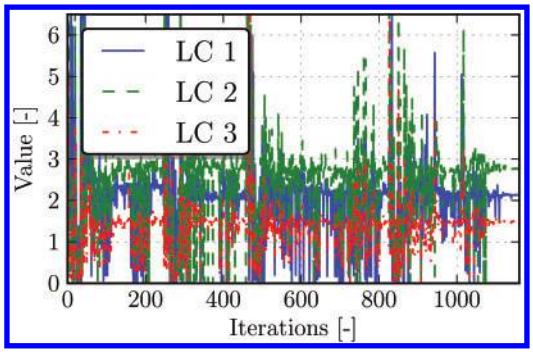

Figure 14. Load case specific buckling constraint.

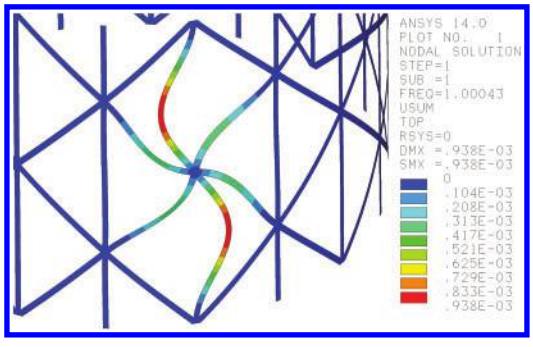

Figure 15. Exaggerated nodal displacement for critical buckling mode in LC 3.

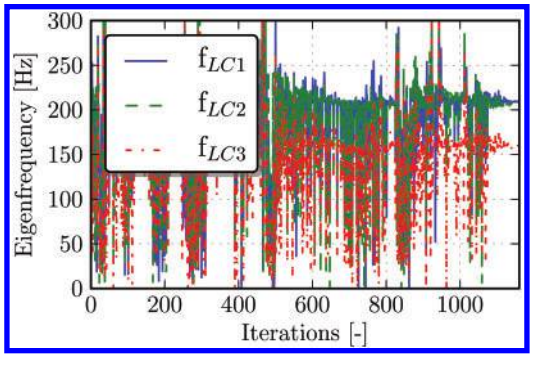

Figure 16. Eigenfrequency of the prestressed interstage.

load, results from the first eigenmode of the rocket and must be endured at all times, without stability failure. One can see that this is the only constraint nearby the specific boundary, hence the most driving parameter behind the optimization. In fig. 15 the buckling eigenform is shown. Since the thickness of the bar is greater then the width, an s-like mode lying in the tangential plane of the interstage ring occurs.

The convergence history for the first eigenfrequency for each load case specific pre-stressed model is shown in fig. 16. It can be seen that the majority of all probed parameter sets are above the required 8 Hz.

6 CONCLUSION

The presented optimization of a grid interstage structure, shows the capability of the used unit cell approach combined with the augmented lagrangian particle swarm algorithm to solve mixed-integer constrained optimization problems.

The investigation of the results gives insight to the system response. The optimization of the grid structure tends to be only constrained by stability. Local buckling of bars is the most critical factor. This constraint is governed by the acting bending moment. The buckling mode for this load can be in the tangential plane of the interstage, or normal to it. Depending on the chosen second area moment. The optimization algorithm tends to make the bars thicker then wider, maximizing the bending stiffness of the sandwich-helix bars. The originating mode depends therefore upon the usage of a sandwich helix.

In a continuative investigation, the stiffening effect of the sandwich should be investigated. It is most likely that a monolithic helix and their implementation in the unit cell would steer the stability criteria, because of the changing moment of inertia for the axial bars.

Topology optimization with local stress constraints in a simultaneous analysis and design setting

Dirk. P. Munro & Albert. A. Groenwold
Department of Mechanical and Mechatronic Engineering, University of Stellenbosch, South Africa

ABSTRACT: We present a simultaneous analysis and design (SAND) formulation for the topology optimization of continuum structures with local stress constraints. We argue that the SAND formulation significantly decreases the burden on computational resources, compared to the traditional nested analysis and design (NAND) approach, especially for very large scale problems. The topology optimization problem is solved in a sequential approximate optimization (SAO) setting in which the availability of the exact analytical form of the constraint equations allow for the inclusion of exact second-order information in the Hessian of the sub-problem. The combination of the SAND formulation and a new form of stress-constraint allow for a zero lower bound on the design variables. Results are presented for the two-bar truss topology optimization problem.

1 INTRODUCTION

Topology optimization of continuum structures is a branch of structural optimization that sets out the achieve the optimal distribution of material in a design space subject to a set of boundary conditions, applied loads and constraints. It is sought that minimal human creative input be required to arrive at an optimal design. The definition of optimality and the design constraints might take on a wide variety of forms depending on the requirements on the design. Bendsøe & Sigmund (2003) present an extensive review of the numerous problem formulations in topology optimization.

Topology optimization of continuum structures requires the union of structural analysis and numerical optimization. This is achieved, in part, via the material distribution method, which requires the discretization of the entire design domain; the spatial area where material may or may not be present. The discretization of the design domain give rise to a system of equations that describe the physical responses of the structure, also referred to as the equilibrium equations. The solution of which form the structural analysis component of the optimization procedure. Finding the solution of the set of equilibrium equations adds significantly to the storage requirements and computational effort required to solve the optimization problem. Especially as the size of the elements are reduced (and number of elements increased) to obtain more accurate solutions.

Traditionally, the union of structural analysis and numerical optimization is achieved via the nested analysis and design (NAND) approach. The NAND approach is an iterative procedure that requires alternate phases of structural analysis (finite element analysis being the most popular) and numerical optimization. The large system of equilibrium equations is solved exactly in each iteration to obtain the structural responses for a given design. In this paper we explore an alternative to the NAND approach, namely simultaneous analysis and design (SAND). See Arora & Wang (2005) for an extensive review of the NAND and SAND formulations. In the SAND approach the equilibrium equations enter the optimization problem as a set of equality constraints. Although the optimization problem increases in complexity, no computational effort is spent on solving the equilibrium equations in each iteration. What is more, the equilibrium equations need not be satisfied exactly in each iteration; only the final solution should be feasible.

The size of problem considered in the NAND formulation is limited by the computational storage requirements of the structural analysis phase as well as the information required by the optimization phase. Currently sequential approximate optimization (SAO) is the dominant solution methodology. It is considered more efficient to solve a series of approximations to the problem, especially as each evaluation of the constraint functions requires a structural analysis to be carried out. We argue the SAND formulation is even more suited to the efficient implementation of sequential approximate optimization due to the sparsity of the equilibrium equations and the availability of the exact analytical form, which reduce computational storage requirements substantially. This formulation, we believe, lends itself to the solution of very large scale problems in a reasonable amount of time.

In section 2 we review the general statement of the topology optimization problem. Section 3 is a brief overview of SAO. Section 4 is a description of the SAND problem formulation. Finally, in section 5,

results are presented for the optimization of the two-bar truss test problem. Please note at this stage the work presented should be considered as a work in progress. The solution procedure is a proof of concept and by no means optimal.

2 THE TOPOLOGY OPTIMIZATION PROBLEM

We consider the problem of determining the optimal distribution of an isotropic material subject to a set of boundary conditions and applied loads. Bendsøe & Sigmund (2003) present the material distribution method as the predominant approach to determining the optimal *lay-out* of material.

Let f_0 denote the structural objective, defined as a function to be minimized, and f_j the constraints on the design. The material distribution method sets out to identify the optimal distribution of material $x(s)$ in the known, pre-defined design domain Ω. The boundary conditions and applied loads are defined in terms of Ω. The general form of the problem, where $x(s)$ denotes the presence or absence of material at the spatial position s, is defined as:

$$\begin{aligned} \min_{x} \quad & f_0(x) \\ \text{subject to} \quad & f_j(x) \leq 0 \qquad j = 1,2,...,m, \\ \text{with} \quad & x(\boldsymbol{s}) \in [0,1] \quad \forall \ \boldsymbol{s} \in \Omega. \end{aligned} \tag{1}$$

where m is the number of constraints. However, the discrete programming problem is NP-complete. In the light of the this and the desire to implement efficient continuous non-linear programming algorithms the binary requirements on the material variables are relaxed to $0 \leq x(s) \leq 1$. Variables at intermediate values are then penalised to encourage purely binary or 'black-white' designs. The most popular being the 'simple isotropic material with penalization' (SIMP) approach, suggested, amongst others by Bendsøe (1989). Form here on we will refer to the material variables as the design variables of the problem.

The topology problem (1) is discretised using the finite element method. The most popular discretised model involves the parametrization of the elasticity matrix for element i as (with SIMP parameter p)

$$\boldsymbol{C}_i(x_i) = x_i^p \boldsymbol{C_0} \tag{2}$$

where C_0 is the elasticity matrix of the solid isotropic material. In the case where stress constraints are considered the material strength is also parametrized to ensure a realistic model (Duysinx & Bendsøe 1998). Although attempts have been made to provide physical interpretation of the design variables at intermediate densities in terms of specific types of composite structures (Bendsøe & Sigmund 1999), questions still exist around the general interpretation and comparison of designs with material at intermediate values. Therefore, we consider a simplified approach where the material thickness is parametrized. The thickness, h, is expressed as $h_i = x_i^p h_0 = x_i^p$ with h_0 defined with value 1. Hence, the optimization problem is viewed as a sizing problem. It is important to note that this distinction is only conceptual. Mathematically the two models are exactly equivalent. Both yield exactly the same discretised equilibrium and stress equations. The elemental stiffness matrices are expressed as

$$\boldsymbol{K}_i = x_i^p \int_{v_i} \boldsymbol{B}_i^T \boldsymbol{C}_0 \boldsymbol{B}_i dv_i \tag{3}$$

Then the general topology optimization problem is stated as

$$\begin{aligned} \min_{x} \quad & f_0(\boldsymbol{x}, \boldsymbol{q}) \\ \text{subject to} \quad & f_j(\boldsymbol{x}, \boldsymbol{q}) \leq 0 \qquad j = 1,2,...,m, \\ & \boldsymbol{K}(\boldsymbol{x})\boldsymbol{q} = \boldsymbol{w}, \\ & 0 \leq \boldsymbol{x}_i \leq 1 \qquad i = 1,2,...,n \end{aligned} \tag{4}$$

where $x \in \mathbb{R}^n$, q and $w \in \mathbb{R}^u$, $f_0 : \mathbb{R}^{n+u} \rightarrow \mathbb{R}$ and $f_j : \mathbb{R}^{n+u} \rightarrow \mathbb{R}, j = 1,2,...,m$. Respectively, m and n are the number of constraints and the number of finite elements in the mesh. The vector q denotes the vector of nodal displacements and w the vector of nodal forces (assumed to be design independent), the dimension of which, u, depend on the method of discretization. We restrict ourself to the use of Q8 elements.

3 SEQUENTIAL APPROXIMATE OPTIMIZATION

Sequential approximate optimization (SAO) is a branch of optimization algorithms in which successive approximate sub-problems are solved to arrive at a final solution. The sub-problems, which approximate the local behaviour of the actual problem, are deemed easier to solve in each successive iteration.

A sub-problem is constructed by approximating the objective and constraint functions around the current iteration point. Usually analytical functions, which are inexpensive to evaluate, are used as surrogate functions. An approximate sub-problem in iteration k has the form

$$\begin{aligned} \min \quad & \tilde{f}_0(\boldsymbol{x}^{\{k\}}) \\ \text{subject to} \quad & \tilde{f}_i(\boldsymbol{x}^{\{k\}}) \leq 0, \quad i = 1,2,...,m \end{aligned} \tag{5}$$

where the optimization variable in iteration k is $x^{\{k\}} \in \mathbb{R}^n$ and $\tilde{f}_i : \mathbb{R}^n \rightarrow \mathbb{R}, i = 0,1,2,...,m$ are approximated (analytical) constraint functions. The solution to the sub-problem in iteration k forms the starting point for the subsequent sub-problem, $x^{k+1} = x^{k*}$.

We consider sub-problems with quadratic objective functions and linear constraints. These approximations are based on second- and first-order Taylor-series expansions respectively. However, second-order information of the constraints are incorporated in the sub-problem by considering the Hessian of the Lagrangian

in the quadratic objective function. We consider the Lagrangian

$$L^k = \tilde{f}_0(\boldsymbol{x}^{\{k\}}) + \sum_{j=1}^{m} \lambda_j^{\{k-1\}} \tilde{f}_j(\boldsymbol{x}^{\{k\}}) \tag{6}$$

with, λ_j^{k-1}, the Lagrange multiplier of constraint j at the previous iteration. To limit storage requirements only the diagonal terms of the Hessian matrix are incorporated. Also, to ensure convex approximations, only the combination of positive second-order terms and Lagrange multipliers are added to the Hessian of the Lagrangian. Refer to Etman, Groenwold, & Rooda (2011) for an extensive view on sequential convex programming using approximate diagonal QP sub-problems.

For topology optimization in a SAND setting the analytical form of the constraint equations are readily available. This allows the exact second-order derivatives of the constraint functions to be included in the diagonal part of the Hessian of the Lagrangian.

4 SIMULTANEOUS ANALYSIS AND DESIGN

4.1 *Problem formulation*

The most popular approach to structural approximation has been one where a clear distinction exist between the structural analysis and numerical optimization phases. In this view only the the design variables are treated as optimization variables. All other response variables such as displacements, stresses and strains being implicit functions of the design variables. Hence the nodal displacements and design variables are not independent, but related by the equilibrium equations:

$$\boldsymbol{K}(\boldsymbol{x})\boldsymbol{q} = \boldsymbol{w} \tag{7}$$

Therefore the system of equilibrium equations need to be solved exactly in each iteration. An analysis code is used to calculate q given x in each iteration of the optimization procedure.

In gradient based optimization first order sensitivities of the objective and constraint functions are also required. Consider function $f(x, q)$, either denoting the objective function or a constraint function in (4). The first-derivative of which, to the design variables, is

$$\left.\frac{df(\boldsymbol{x},\boldsymbol{q}(\boldsymbol{x}))}{d\boldsymbol{x}}\right|_{n\times 1} = \left.\frac{\partial f(\boldsymbol{x},\boldsymbol{q}(\boldsymbol{x}))}{\partial \boldsymbol{x}}\right|_{n\times 1} + \left.\frac{d\boldsymbol{q}(\boldsymbol{x})}{d\boldsymbol{x}}\right|_{n\times u} \left.\frac{\partial f(\boldsymbol{x},\boldsymbol{q}(\boldsymbol{x}))}{\partial \boldsymbol{q}}\right|_{u\times 1} \tag{8}$$

The partial derivatives in (8) present no particular difficulty. However the calculation of dq/dx requires further analysis. Two methods to determine the sensitivity derivatives are the direct and adjoint methods, see Haftka & Gurdal (1992).

In contrast, the SAND formulation requires both the design variables and the nodal displacements to be treated as design variables in the optimization problem. In this distinction lies the main difference between SAND and NAND formulations. The variables x and q are now independent and no sensitivity derivatives need to be calculated. However the equilibrium equations are imposed on the optimization problem as a set of equality constraints relating x and q. Problem 4 is redefined as

$$\begin{aligned} \min_{x} \quad & f_0(\boldsymbol{x},\boldsymbol{q}) \\ \text{subject to} \quad & f_j(\boldsymbol{x},\boldsymbol{q}) \le 0, \\ & h_l(\boldsymbol{x},\boldsymbol{q}) = \boldsymbol{K}_l(\boldsymbol{x})\boldsymbol{q} - \boldsymbol{w} = 0, \\ & 0 \le \boldsymbol{x}_i \le 1 \end{aligned} \tag{9}$$

where $i = 1, 2, ..., n$, $j = 1, 2, ..., m$ and $l = 1, 2, ..., u$. The equality constraints (and/or inequality constraints), denoted by the vector $h(x, q) \in \mathbb{R}^u$, need not be satisfied in each iteration of the optimization procedure. Only at the final solution point should $h_l(x^*, q^*) = 0$.

Further, in the NAND formulation elements may not assume values of zero due to the ill-conditioning of the stiffness matrix, K. Zero lower bounds on the design variables pose no particular problem in a SAND setting. The system of equilibrium equations are defined as equality constraints and not solved *per se*. We speculate that this characteristic allow continuation strategies to be implemented on the SIMP parameter p to improve designs towards purely 'black-white' solutions.

4.2 *Sparsity and storage requirements*

Due to the decoupling of x and q in the SAND formulation the Jacobian and Hessian matrices of f_j and h_l are extremely sparse. For large problems sparsity in the order of 99% can be expected. This lends itself to an efficient sparse implementation in a SAO setting. Figure 1 depicts the number of non-zero elements in the constraint Jacobian and Hessian matrices for a given number of Q8 finite elements with local stress constraints. The number of elements is denoted by n_e and a arbitrary 3×1 proportioned design domain is considered. We consider the separable approximate sub-problem where only diagonal Hessian terms are stored. The storage requirements of which, as seen from figure 1, is negligible compared to the constraint Jacobian. Note that the storage requirements scale linearly relative problem size. In comparison the NAND formulation has less design variables than an equivalently sized SAND formulation. However, due to the calculation and storage of the sensitivity derivatives (dq/dx) in each iteration, the storage requirements do not scale linearly. Also, the solution of the equilibrium equations requires forward reduction and back substitution for n_e pseudo-load vectors to solve for the vector q and matrix dq/dx. This procedure becomes very

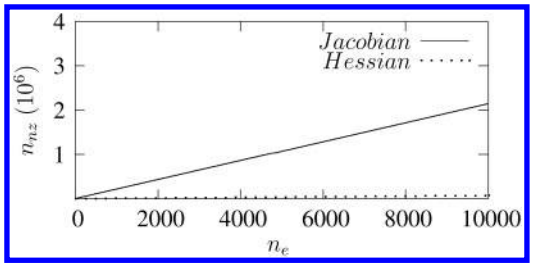

Figure 1. Storage requirements of the SAND formulation.

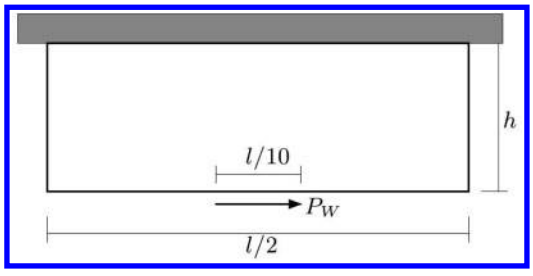

Figure 2. The two-bar truss ($P_W = 6N$, $l = 6$m, $h_0 = 1$m, $S_y = 20N/\text{m}^2$, $E = 1N/\text{m}^2$, $\nu = 0.3$)

expensive in terms of computation time as problem size grows.

5 WEIGHT MINIMIZATION OF THE TWO-BAR TRUSS WITH LOCAL STRESS CONSTRAINTS

5.1 *Problem description*

We here present some results obtained when applying a SAO procedure to a SAND formulation of the topology optimization of a continuum structure. The test problem is the well-known two-bar truss problem with ground structure as shown in figure 2. The structure is modelled under the assumption of plain stress, with P_W the load and S_y the yield stress of the material. E and ν denote the Young's modulus and Poisson ratio of the material respectively. The discretisation of the problem is denoted by mesh multiplier m_e; with the height and width of the ground structure divided into $5m_e$ and $15m_e$ elements respectively.

We consider the problem of weight minimization, defined by the objective function

$$f_0(\boldsymbol{x}) = \sum_{i=1}^{n} x_i \tag{10}$$

We assume values of unity for the density and volume of the material elements.

5.2 *Local stress constraints*

Stress constraints, which are by their nature local restrictions, place a limiting value on some stress-related failure measure anywhere in the structure. We consider the von Mises stress failure measure. Defined, for planar problems, as

$$\sqrt{\sigma_x^2 - \sigma_x\sigma_y + \sigma_y^2 + 3\tau_{xy}^2} \leq \bar{\sigma} \tag{11}$$

where the maximum stress value, $\bar{\sigma}$, is defined as the yield stress of the material. The stress components are calculated with equations derived with the finite element method.

Stress constraints may enter the optimization problem in a wide variety of forms to either ease the use approximations or to improve physical representation of the problem (See Bendsøe & Sigmund (2003, 83)). The well documented stress-singularity problem also plays a major role in the formulation of the stress constraints. Briefly, the stress-singularity problem is described as the degeneracy of the feasible design domain caused by the stress measure tending to infinity as the density or thickness of the material tends to zero. These degenerate domains protrude from the feasible domain as infinitely thin slivers into the infeasible region. The global optimum of the problem might be located in one of these degenerate domains which is virtually inaccessible by the optimizer. Refer to Cheng & Wang (2000) for a complete description of the stress-singularity problem. Currently, the dominant procedure is to make the feasible domain more accessible with so called ϵ-relaxation (Cheng & Guo 1997).

Note that the von Mises stress measure is only a function of the nodal displacements, q. However, as stated by Bendsøe & Sigmund (2003, 82),, the stress constraints should *only* be imposed if material is present. Therefore a dependency on x_i is enforced to facilitate a mechanism to remove stress constraints from the optimization problem as elements tend to zero thickness.

We depart with the form of stress constraints devised by Wood (2012, 180)

$$\frac{\sigma_i^m}{\bar{\sigma}}(1+\epsilon) - \frac{\epsilon}{x_i} - 1 \leq 0 \tag{12}$$

Where a continuation strategy is applied such that $\epsilon \to 0$. This formulation is preferred due to the more conservative limit imposed on the allowable stress of an element at intermediate thickness (Wood 2012, 180). Note that the function is concave in x_i. Therefore to improve the convexity of the constraint and to allow $x_i \to 0$ we consider the slightly altered form

$$f_j(\boldsymbol{x}, \boldsymbol{q}) = x_j \left[\frac{(\sigma_j^m)^2}{\bar{\sigma}^2}(1+\epsilon) - 1 \right] - \epsilon \leq 0 \tag{13}$$

Where the entire constraint is simply multiplied with x_i, note $x_i \geq 0$. The notion that the dependency on x_i effectively removes the constraint from the problem for elements at zero thickness is clear from this formulation. The von Mises stress and yield stress are both squared to simplify the analytical form of the equations and derivatives.

5.3 *Numerical considerations and standard settings*

A continuation strategy is employed whereby ϵ is reduced with $\epsilon/1.1$ whenever the maximum constraint violation is less than 1×10^{-6}. This is done until $\epsilon = 1 \times 10^{-4}$ at which point ϵ is set to zero[1]. This, along with $\check{x} = 0$ (see section 4.1), leads to the solution of a unrelaxed problem with zero lower bounds on the design variables.

Bendsøe & Sigmund (1999) argue that a SIMP parameter of value $p \geq 3$ is required to realistically interpret design variables at intermediate values in terms of certain configurations of composite structures. However since we view the thickness of each element as the design variables we are not confined to this requirement in a conceptual sense. We chose $p = 2$ such that the equilibrium equations are quadratic in x_i. Thus the second-order Taylor-series expansion approximates the separable part of the equilibrium equations exactly. It should be noted that the severity of intermediate design variable penalization is indeed sacrificed. Therefore we expect designs with more variables at intermediate thickness. That is more 'gray' areas. For now we accept this with a greater focus on the solution procedure as opposed to the interpretation of the final design.

The design variables, x, are initialised at 1 and the nodal displacements, q, at 0. Also, a filter is applied to the constraint Jacobian such that all terms with a magnitude of less than 1×10^{-6} are set to zero. This not only reduces computation time, as shown by Wood (2012, 193), but also prevents numerical difficulties in solving the sub-problems. The algorithm is deemed to have converged once ϵ acquires a value of zero and the infinity norm of all the design and displacement variables is less than 1×10^{-2}.

The optimization code used to determine the optimal topologies is SAOi (Groenwold, Etman & Tosserams 2009), a FORTRAN-based sequential approximate optimization algorithm developed by Groenwold and Etman[2] for the solution of large-scale non-linear constrained optimization problems. The IBM ILOG CPLEX optimizer is employed as sub-problem solver. All optimization runs were done on a machine with the following configuration:

Processor:	Intel(R) Xcon(TM) 8 core CPU 3.73GHz
Memory:	Total memory (RAM), 31.5 GiB
Operating System:	Linux 2.6.34-12-desktop x86-64, openSUSE 11.3 (x86-64)

[1] This departs slightly from the commonly accepted continuation strategy, proposed by Cheng & Guo (1997), whereby the lower bound of the design variables and ϵ are related by $\check{x} = \epsilon^2$. Also, ϵ and thus $\check{x}$ are only reduced to some, small, non-zero value.

[2] Freely available for academic use from the originator, Albert A. Groenwold, via e-mail.

Table 1. Results

m_e	n_e	f_v	$\phi_{B\&W}$	N_{iter}	T_{avg}
4	1200	0,228	0,807	502	1,46
6	2700	0,223	0,833	743	4,86
10	7500	0,221	0,865	831	13,14

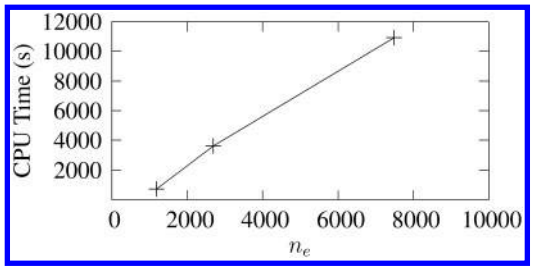

Figure 3. Computation Time.

5.4 *Results*

Table 1 is a summary of the results obtained for three mesh sizes. The volume fraction, f_v, is defined as the objection function value at final design normalised to the amount of elements, n_e, in the mesh. The 'black-white' fractions of the final designs are denoted by

$$\phi_{B\&W} = \frac{n_{e[0]} + n_{e[1]}}{n_e} \tag{14}$$

with $n_{e[0]}$ and $n_{e[1]}$ the number of elements on their lower bounds and upper bounds respectively. N_{iter} is the number of iterations required for convergence and T_{avg} the average time per iteration in seconds. Figure 3 depicts the overall computation time for the three problem sizes. From this we deduce, although only three data points are considered, that the computation time scales linearly relative to problem size. Figure 4 shows the representative optimal topologies for the three meshes considered. Note the design denoted by mesh multiplier $m_e = 6$ converges to some local minimum resulting in a different overall shape to the solution. This characteristic is related to the fact that the equilibrium equations are not solved exactly in each iteration. Highlighting one of the main challenges of the topology optimization problem in a SAND setting.

6 CONCLUSION

This paper reflects a work in progress. Topology optimization with local stress constraints is computationally extremely expensive and the size of problem that can currently be solved in a reasonable amount of time, with a reasonable amount of computational resources, is disappointingly small. In the light of this we pursue the SAND formulation in a SAO setting of

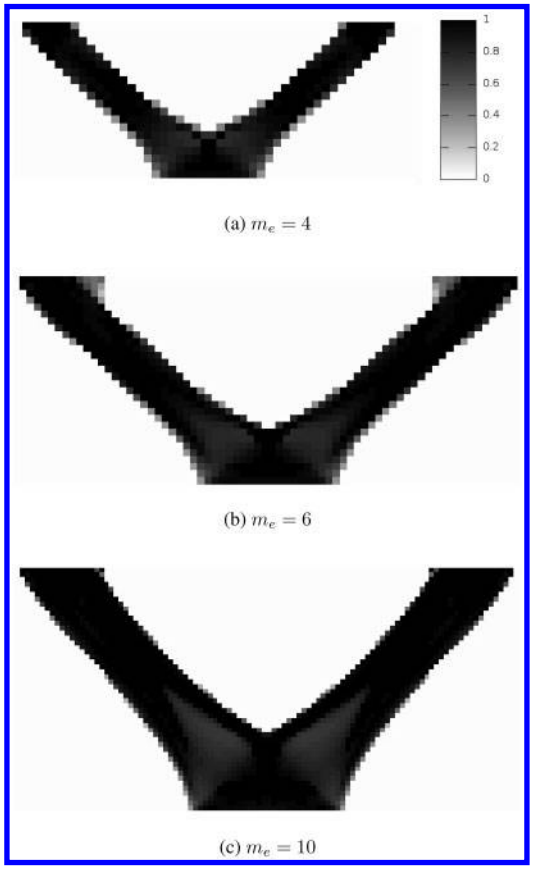

Figure 4. Optimum topologies generated by weight minimization of the two-bar truss structure.

the topology optimization problem with local stress constraints.

We show the storage and computation requirements of the SAND formulation scale linearly with problem size. Hence, although our solution procedure is not currently optimal, we suspect the SAND formulation can be exploited to drastically reduce time to solution, especially for very large problems.

The system of equilibrium equations, solved exactly in the NAND formulation, is incorporated in the optimization problem as a set of equality constraints. Thus the system of equations is not solved *per se*, allowing the design variables to obtain values of exactly zero, completely removing elements deemed to be void for an optimal design. This aspect is not only physically more representative, but also facilitates the removal of constraints that no longer influence the optimization problem, speeding up the solution procedure.

Future work will include the solving of the subproblems as a quadratically constrained quadratic problems (QCQP). Further, with the equilibrium equations formulated as equality constraints, continuation strategies on the SIMP parameter, p, become possible. Ill-conditioning of the stiffness matrix in the SAND formulation having no effect on the solution procedure. Such strategies may be used to improve 'black-white' fractions of final designs.

Finally, although we consider relaxed stress constraints, we speculate the SAND formulation may yield a different view of stress-relaxation altogether. The equilibrium equations, defined as equality constraints, need not be satisfied in each iteration. Hence iterations to final design are allowed to be infeasible, possibly making stress relaxation redundant.

Reliability-based robust optimization using variance based methods

G. Karaki
Civil Engineering Department, Faculty of Engineering, Birzeit University, West Bank

ABSTRACT: Numerical models are built for structural systems to obtain response predictions. The system input parameters are uncertain due to the lack of information in one hand and to their inherent variability on the other hand. Thus, under uncertain conditions, the field of reliability-based optimization provides a realistic tool for structural optimization. This paper is concerned with exploring an approach based on variance methods of sensitivity analysis to ensure the robustness of the optimized design. The suggested procedure is performed on an engineering problem.

1 INTRODUCTION

The models of the engineering systems are not of deterministic nature as variability and uncertainty in the input parameters defining the model exist. Hence, in design tasks finding an optimum solution that cope with these uncertainties is a current goal for researchers in engineering practice. Therefore, researchers have proposed different methods for reliability analysis and reliability-based optimization algorithms where the input parameters are considered as random variables. Furthermore, the robustness of the optimum solution is of high importance. As a probabilistic analysis is performed, assumptions are made for the characteristics of the probability density functions of input parameters. However, there is uncertainty in these characteristics of the distribution functions; mean value, variance and distribution type. The influence of the uncertainty mentioned need to be checked and a procedure for this to be proposed.

A record of some of the recent work on reliability-based optimization methods can be found in numerous references, e.g (Frangopol, 1985, Tu et al., 1999 & Dubourgh et al., 2011). The different studies are concerned in deriving methods and algorithms for the optimization problem, deterministic- or reliability-based. The topic of robust design when using reliability-based optimization is often performed by simplifying the problem for which a weighted average of the sensitivity factors can be used as an objective function for the optimization problem (Wang et al., 2001 & Kim, 2010). This limits the application of such procedures to the possibility to formulate the relations, in other words, the gradients, of the responses of engineering problem to the input parameters studied. Furthermore, the interaction between the inputs and their effect on the responses studied are ignored. Thus, an exact statement regarding the robustness of the optimized design cannot be made.

This paper suggests a procedure to find the best design parameters of the engineering system using a global optimization algorithm. The randomness of the input parameters and the uncertainty in their definition using reliability and sensitivity analysis measures are used to check the reliability and robustness of the optimized design solution.

2 RELIABILITY OPTIMIZATION

2.1 *Reliability based design optimization*

In a deterministic design optimization, the designs are often driven to the limit of the design constraints, neglecting the uncertainties in the input parameters and the modeling process. These uncertainties in simulation based designs are to be considered in the design optimization process, as these uncertainties may lead to large variations in the performance of the designed system and lead to failures in that are not accounted for. Reliability based design aims to obtain optimal designs characterized by a low probability of failure when considering the different uncertainties of the system studied. The uncertain input parameters are considered as random variables following a probability distribution function with deterministic mean and standard variation. The probability of failure considering a design limit state is used a measure for the reliability of the designed system. Then an optimization algorithm is performed to find an optimum design by minimizing the probability of failure. A mathematical optimization problem has the form

Minimize $f_0(x)$
Subject to $f_i(x) \leq 0,\ i = 1 \ldots n$

Where x is the optimization (design) variables, f_0 is the objective function, and f_i are the constraints function with n is the number of constraints

2.2 *Optimization algorithm*

The particle swarm optimization (PSO) is a parallel evolutionary computation techniques developed by Kennedy and Eberhart (Kennedy & Eberhart, 1995). The optimization is based on the social behavior of bird flocks or fish schools. The core idea behind PSO is the fact that social information is shared among a population. Each particle is assigned with a random speed and is relatively moved through the problem space. It is attracted towards the location of the best fitness achieved by the particle itself and by the location of the best fitness achieved by the whole population. This search and movement makes this algorithm of a global nature

PSO is chosen for its global nature, direct and simple implementation, and its independence of gradient information of the objective function considered. PSO is an effective and robust optimization algorithm. However, these algorithms need the appropriate setting for their control parameters, which often are chosen depending on a form of trial-and-error for each particular optimization problem at hand (Eberhart & Shi, 1998).

The general steps of the algorithms as the following:

1. Initialization where the speed and position of all particles are randomly set to pre-defined ranges
2. Speed updating where at each iteration the speeds of all particles are updated according to

$$\vec{s}_i = w\vec{s}_i + b_1 R_1(\vec{x}_{i,best} - \vec{x}_i) + b_2 R_2(\vec{g}_{i,best} - \vec{x}_i)$$

   Where x_i and s_i are the position and speed of particle i, $x_{i,best}$ and $g_{i,best}$ are the position with the best objective value found by particle i and the entire population, w is a weighting parameter, R_1 and R_2 are random variables between [0,1], and b_1 and b_2 are controlling factors of the algorithm
3. Position updating by assuming a unit time interval between successive iterations, the location of all particles are updated according to

$$\vec{x} = \vec{x}_i + \vec{s}_i$$

4. Memory updating at which $x_{i,best}$ and $g_{i,best}$ are updated when the following condition is met

$$\begin{aligned} \vec{x}_{i,best} &= \vec{x}_i \quad if\ f(\vec{x}_i) > f(\vec{x}_{i,best}) \\ \vec{g}_{i,best} &= \vec{g}_i \quad if\ f(\vec{g}_i) > f(\vec{g}_{i,best}) \end{aligned}$$

   where $f(x)$ is the objective function
5. Termination criterion at which the algorithms repeat steps 2 through 4 until a certain termination conditions are met

3 ROBUST DESIGN

3.1 *Robustness*

Not only the reliability of the optimized design of importance, but also its robustness. Robust designs are the designs at which the variation in the objective function or optimized solution is minimal against the uncertainties in the inputs of the system. For this purpose, a sensitivity analysis is suggested to check the assumptions regarding the uncertainties of the system's inputs, e.g. mean value, standard deviation and distribution type.

3.2 *Variance based sensitivity indices*

Sensitivity analysis is the study of how uncertainties in the output of a model are apportioned to the uncertainties of the inputs. The use of sensitivity analysis in this study is to apportion the variance of the optimized solution to the assumed characteristics used in the reliability study. It is employed as a means of robustness for the design solution using reliability based optimization.

Variance-based methods have been chosen as they are independent from the engineering problem investigated and the interactions between input parameters. Moreover, such sensitivity analysis provides the importance ranking of the input parameters, and quantifies their contribution to the variance of optimization solution.

The main idea of variance-based methods is to estimate the amount of variance that would disappear if the true value of the input parameter X_i is known. This can be described by the conditional variance of an objective function $f(x)$ fixing at its true value $V(f|X_i)$, and is obtained by varying over all parameters, except X_i. Since the true value of X_i in complex engineering problems is unknown, the average of the conditional variance for all possible values of X_i is used, i.e. $E(V(f|X_i))$. Having the unconditional variance of the output $V(f)$ and the expectation of the conditional variance $E(V(f|X_i))$, the following relation holds:

$$V(f) = V\big(E(f|X_i)\big) + E(V(f|X_i))$$

The variance of the conditional expectation $V(E(f|X_i))$ is determined. This term is often referred to as the main effect, as it estimates the main effect contribution of the X_i to the variance of the objective function. Normalizing the main effect by the unconditional variance $V(f)$ results in the first order sensitivity index:

$$S_i = V\big(E(f|X_i)\big)/V(f)$$

Interaction between input parameters that affect the variance of the objective function can also be detected, which are known as higher order effects. The total effect index S_{Ti} is used to represent the total contribution of the input parameter X_i to the output, i.e. the first order effects, in addition to all higher order effects. A total effect index is defined as:

$$S_{Ti} = 1 - V\big(E(f|X_{\sim i})\big)/V(f)$$

Sampling based methods are used to evaluate the sensitivity indices (Saltelli et al., 2008).

3.3 *General procedure of robust reliability-based design*

1. The uncertainty in the inputs of the engineering system is considered using the probability theory
2. The probability of failure for a required design limit state using Monte Carlo simulation is determined

$$PF = 1/m \sum_{k=1}^{m} I_f(x^k)$$

   where m is the number of run samples of input parameter, $I_g(x^k)$ is an indicator function, where its value is 0 for a based sample output and 1 for a failed sample
3. The Optimization process is performed to obtain the design variables that minimize the probability of failure when considering the uncertainty of the systems input.
4. A variance based sensitivity analysis is run for the variability of the definition of the uncertainty of system's input
5. The sensitivity indices indicates which of the input parameters that need further study to ensure a higher robustness of the optimized design solution

The procedure is independent of the field of engineering problem or the type of its developed models. The optimization algorithm used is an effective and robust algorithm. Furthermore, the sensitivity analysis detect the first order and higher order effects which is of importance to complex engineering problems.

4 NUMERICAL EXAMPLE

A Test engineering problem is used for the illustration of the application of the suggested procedure. This engineering problem is concerned with the drift of a single story frame due to lateral loading applied at floor level. The force may represent the static equivalent lateral loading of a seismic action on a building, which is considered as a random variable described using a probability distribution function with specific characteristics. The design objective is to limit the drift of the upmost corner of the frame to an acceptable limit. The objective function for the optimization problem is the probability of failure which is related to the possibility that frame's drift exceeds a chosen design limit. However, the specific probabilistic characteristics that define the uncertainty of the lateral force, which is of main importance to the drift values, are themselves uncertain. Therefore, the sensitivity analysis is used to examine the performance of the output of the reliability-based optimization process against the uncertainty of the probabilistic characteristics of the input parameter (force). This is performed using variance based methods as mentioned before.

Table 1. Particle Swarm Optimization (PSO) characteristics.

Parameter			
No. of Particles	200	Control parameter (b1)	0.2
No. of iterations	100	Control parameter (b1)	0.2
Weight (w)	0.7		
LB Height	2.0 m	LB EI ($\times 10^6$)	0.5 kNm^2
UB Height	4.0 m	UB EI ($\times 10^6$)	2.0 kNm^2

Table 2. Input parameters used for the sensitivity analysis.

Parameter		
Distribution type	Uniform distribution	$0 \leq$ xdis$<1/3$ 'Normal' $1/3 \leq$xdis$\leq 2/3$ 'Lognormal' $2/3 <$ xdis < 1 'Gumbel'
Mean value	normal distribution	mean = 120 kN
COV		COV = 0.10
	lognormal distribution	mean = 0.25 COV = 0.10

A single span, single bay frame loaded with lateral loading is chosen as mentioned before. The failure condition is described as:

$$\mathcal{F} = \{(F, H, EI): \Delta > FH^3/(24EI)\} = \{(F, H, EI): 0 > FH^3/(24EI) - \Delta\}$$

where Δ is the limiting drift of the upper most corner of the frame. The optimization process is executed to find the height of the frame (H) and its flexural stiffness (EI). The objective of the optimization problem is to minimize the probability of failure (PF) conditioning on upper and lower bounds for the design variables. PF is estimated using Monte Carlo estimation where 1000 samples are used.

It is important to ensure that the optimized solution is only dependent on the variability of the considered inputs and not on the performance of the optimization process. A check is done on the PF of the frame for every optimized design parameters to ensure the negligible effect of PSO algorithm on the variability of the output. The following are the main characteristics of the optimization process obtained from trial-and-error-procedure.

The sensitivity analysis is used to apportion the variability of the optimized solution to the assumptions made regarding the force input description. For each sample, a type for the distribution is chosen randomly with a random assignment of a mean value and a standard deviation as presented in Table 2 is run using the reliability-based optimization algorithm. Figure 1 and 2 present the optimized design parameters histograms for 1000 samples.

The sensitivity analysis is performed for the input parameters presented in Table 2.

The sensitivity analysis is performed using sampling-based methods where 1000 samples are run

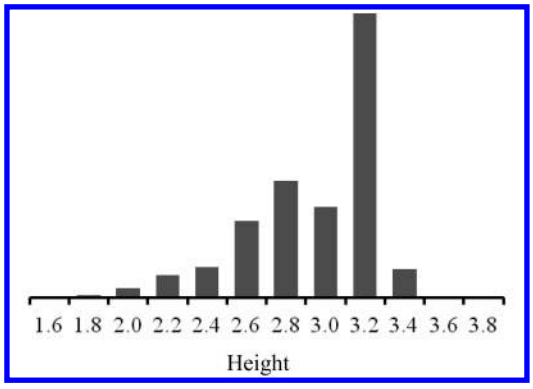

Figure 1. Histogram of optimized design variable of Height, mean value of 2.85 m. and standard deviation 0.31 m.

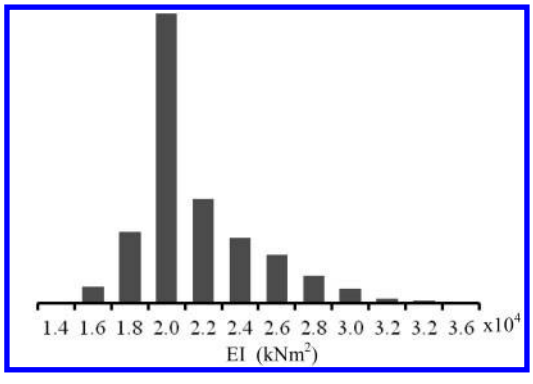

Figure 2. Histogram of optimized design variable of flexural stiffness, mean value of 2.07 m^4 and standard deviation 0.30 m^4.

Table 3. Sensitivity indices for characteristics of probabilistic definition.

Parameter	Opti. Height		Opti. EI	
	S_i(%)	S_{Ti}(%)	S_i(%)	S_{Ti}(%)
Mean Value	2	24	1	45
Standard Deviation	51	73	43	83
Distribution type	22	58	12	66

for every input parameter considered. The estimated sensitivity indices are presented in Table 3.

From Table 3, it can be seen that the main contributor to the variance of the optimized solution of the suggested problem is the assumed coefficient of variation followed by the assumed type of distribution. The higher the uncertainty in these assumptions, the lower is the robustness of the optimized solution. It can also be noticed that high interactions exist between the input parameters considered in the sensitivity analysis (S_{Ti}-S_i). This is expected as the inputs are inter-related in defining the probabilistic descriptions of a random variable. It also means that when controlling one of these inputs by increasing the degree of certainty in its value would significantly decrease the variability of the performance of the reliability based optimization and consequently increase the robustness of the procedure. This procedure of using variance based methods shed light on the variables where attention should be given to ensure the robustness of the reliability-based optimization design.

5 CONCLUSIONS

The design and analysis of engineering systems require creating numerical models that are exercised to obtain the desired outputs. However, these models are data dependent, e.g. geometric information or/and physical parameters. These data have uncertainties in their value and description. This paper is concerned with reliability-based optimization for which the uncertainty of the system inputs are considered in the design. Furthermore, the effect of the definition of this uncertainty is tested using variance based sensitivity analysis. This is performed to highlight the main sources of the variance for the optimized output in order to comment on the robustness of the reliability-based design. This procedure is applied and illustrated for a simple example; however the algorithm is generic and problem/model independent. It is to be applied to a large-scale engineering problem for which local meta-models are used to over-come the computational cost of such a procedure.

ABSTRACT: Designing structures with minimal environmental impact is emerging as a serious concern in the construction sector. Conventional structural design practice involves designing first for strength, followed by secondary checks on deflections and other serviceability limits states. If these limits are exceeded, the conventional solution has been to add material to increase stiffness. When the design is governed by unpredictable events such as fluctuating loads, strong wind storms or earthquakes, the structure is effectively overdesigned for most of its working life. This paper presents a methodology to design adaptive structures that minimize the whole life energy consumption. The methodology is illustrated on plane pin-jointed trusses, both determinate and indeterminate. Strategically placing actuators allow the internal flow of forces to be homogenized and displacements to be controlled. The actuators only start working when the loads reach a certain threshold. Below this threshold, the structure resists loads mainly passively thereby limiting significantly the operational energy used. It was found that both indeterminate and determinate topologies bring substantial energy savings up to 70% of the total energy.

1 INTRODUCTION

1.1 *Background and conceptual framework*

Active control has been used in civil engineering structures for a variety of purposes. The most widespread application so far has been in vibration control (Soong, 1988). Shape morphing has also been studied (Ramrakhyani, et al., 2005). The potential of using adaption to save material has been investigated by a few (Teuffel, 2004) but whether the energy saved by using less material makes up the energy consumed through control and actuation is a question that has so far received little attention. The methodology presented in this paper aims to address this. A design process is proposed that produces an optimum adaptive structure that minimizes the total energy spent throughout the whole life of the structure (embodied in the materials + operational).

The process is illustrated diagrammatically in the conceptual graph shown in Fig. 1. This graph shows the total energy as a function of some notional degree of active control of the structure. The whole life energy is made of two components: operational energy and the embodied energy. For a completely passive design the embodied energy (mass of material) dominates the whole life energy: members are designed to bear 100% of the maximum expected load to meet strength and serviceability requirements. By contrast for a highly adaptive design, the embodied energy will be small but the operational energy necessary to control and actuate throughout the life of the structure will be high. The methodology proposed here seeks the minimum in whole life energy that lies between these two extremes.

In a conventional design, members are sized based on a worst case scenario i.e. the maximum expected load combination. If embodied energy is to be saved, clearly, member sizing should not be governed directly by this worst load combination but by some fraction of it. As the loads approach their worst values, conventional members will reach their capacity. Then strategically located active elements provide controlled output energy (actuators) in order to manipulate actively the internal flow of forces and stresses. In this way stresses can be homogenized and deflections kept

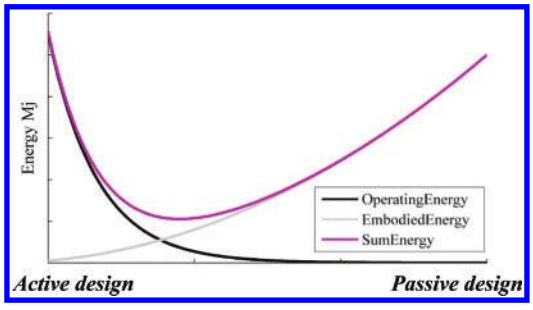

Figure 1. Whole-life energy vs. degree of adaptation.

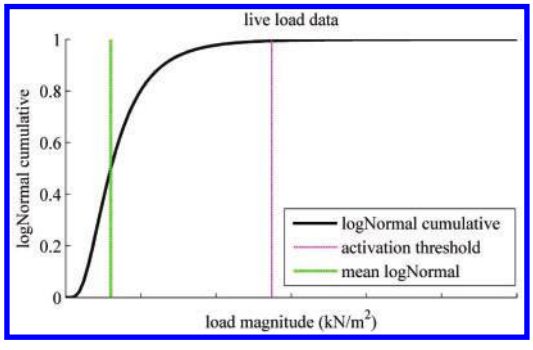

Figure 2. Load activation threshold.

within desired limits. The active elements (actuators) are only activated for compensation of the displacements and internal forces when the loads reach a certain threshold. Therefore operational energy is only used when necessary.

It is intuitively clear that this design process will be particularly beneficial when the design is governed by large loading events that have a small probability of occurrence (storms, earthquakes, unusual crowds but also transient rolling loads such as trains). To illustrate this, Fig. 2 shows the cumulative frequencies of occurrence for a generic stochastic load. The pink line represents the activation threshold which demarcates two zones in the load range. On the left hand side are the more probable low levels of load that the passive load-bearing capacity of the structure will be able to withstand without actuation. On the right are rarer loads with higher magnitude which the structure will only be able to withstand using both passive and active load-bearing capacity.

1.2 *Case study*

The design process is illustrated on a roof made of simple indeterminate cantilever planar trusses supporting 10 meters of cover each (out of plane). Fig. 3 shows the truss constrained at one end and subjected to both dead load and live load.

To test the effectiveness, the ratio of the cantilever's span to depth is deliberately set high at 25 (depth = 1.2 m). The dead load on the roof panels is set to 3 kN/mˆ2 which means each truss supports a

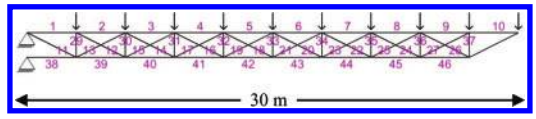

Figure 3. Cantilever pin-jointed truss.

uniformly distributed load (UDL) of 30kN/m. The live load is modeled as a log-normal distribution with 0.5 standard deviation and mean at 20% of the max expected load. The load distribution acts on the structures for the 10% of structure's life-cycle assumed to be 50 years. For the purpose of this case study, the type of distribution can be considered representative of the majority of loading scenarios such as earthquake, strong winds, snow, rolling loads or even occupancy patterns in building. In terms of magnitude the maximum expected live load is set equal to the dead load.

2 DESIGN METHODOLOGY

2.1 *Load path optimization*

The first stage of the design process consists in minimizing the set of member cross-section areas A_i and the bar forces F_{ik} subjected to satisfying equilibrium constraints as well as a set of inequality constraints expressing that the member' forces are limited by material yield in tension and buckling in compression. At this stage, geometric compatibility is not yet respected. This initial phase of the methodology is inspired from Teuffel (Teuffel, 2004) but unlike Teuffel, the self-weight and buckling constraints are introduced making the problem nonlinear. The problem was solved using a nonlinear sequential quadratic solver (SQP) (Nocedal & Wright, 2006). The problem can be formulated as follows:

$$\min\ V = \sum_{i=1}^{n} \mathrm{A}_i * l_i \tag{1}$$

s.t.:

$$\boldsymbol{B} \cdot \boldsymbol{F}_k - \boldsymbol{P}_k = 0 \tag{2}$$

$$a)\ \frac{F_{ik}}{A_i} \leq \sigma_T \cdot MUT; \quad b)\ -\frac{F_{ik}}{A_i} \leq \sigma_C \cdot MUT \tag{3}$$

$$\frac{F_{ik}}{A_i} \leq \sigma_{crit} \tag{4}$$

where V is the total volume, l_i is the length of the i^{th} element and $n$is the total number of elements. Eq.2 is a set of equality constraints which represents the equilibrium equations: **B** is the cosine direction matrix and k numbers the load cases. These constraints are nonlinear because the self-weight of the structure changes iteratively and so does the vector of external loads **P**. Ultimate limit states (ULS) are represented by the set of linear inequalities in eq. 3

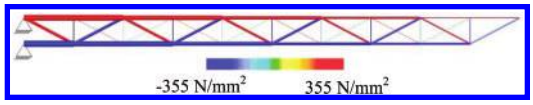

Figure 4. Optimal (non-compatible) forces distribution.

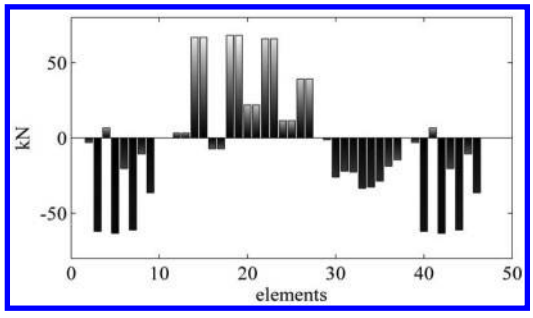

Figure 5. Difference between compatible and non-compatible axial force for each element.

where σ_T and σ_C are material yield stress in tension and compression respectively. Setting the material utilization factor (MUT) to 1, gives absolute minimum weight structures. The nonlinear stability constraints are represented in eq. 4 where critical loads (σ_{crit}) are computed iteratively using the Euler buckling formulation. Eq. 3b and eq. 4 are mutually exclusive for each element.

Fig. 4 shows the optimal (non-compatible) distribution of axial forces and cross sectional areas obtained for the cantilever case study.

The set of section areas is found by optimizing against the maximum expected load. Then a minimum set of bar forces must be found for any other instance of the load distribution. The problem can be formulated as:

$$\begin{cases} a)\ \min\left(norm\left(\boldsymbol{F}_{\boldsymbol{k}}^{\boldsymbol{eq}}\right)^2\right) \\ s.t. \\ b)\ \boldsymbol{C}^{\boldsymbol{ULS+buckling}} \cdot \boldsymbol{F}_{\boldsymbol{k}}^{\boldsymbol{eq}} - \boldsymbol{A}_{\boldsymbol{k}}^{\boldsymbol{optimal}} \leq 0 \\ c)\ \boldsymbol{B} \cdot \boldsymbol{F}_{\boldsymbol{k}}^{\boldsymbol{eq}} = P_{jk} \end{cases} \quad (5)$$

where F_k^{eq} is the optimal equilibrium pattern of forces for lower levels of loads than the maximum expected load; $C^{ULS+buckling}$ is the matrix of the constraints from eqs(3–4) and P_{jk} is j^{th} component of load case k. If a determinate topology had been chosen for the truss, the actuator length changes would have only affected the geometry but not the state of stress of the structure (small displacements), i.e. F_k^{eq} is obtained by eq.5(c) directly.

Fig.5 shows the difference $\Delta\mathbf{F}_k$ between the optimal (non-compatible) forces and the compatible axial forces of the structure without active control. The x-axis shows the element numbers as labeled in Fig. 3 while vertical axis shows the force difference in kN.

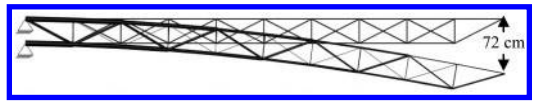

Figure 6. Compatible displacements without active control.

As can be seen from Fig. 6, the maximum displacement is well beyond serviceability limits (span/180 = 16 cm)

For these reasons, active work in the form of actuator length change is needed for both forces and displacements correction.

2.2 *Active element topology*

The next stage in the design process involves finding the best location for the actuators. The optimum actuator positioning is found by first choosing a set of nodes whose displacement must be controlled (CDofs). For the truss studied here, the vertical displacements of all the nodes of the top chord are selected and constrained so that the cantilever tip moves within span/180 (i.e. 16cm). The difference between compatible and optimal forces $\Delta\mathbf{F}_k$, and between the desired and compatible displacements $\Delta\mathbf{u}_k$, are the inputs to find the most efficient (minimum operational energy) topology for the actuators.

The minimum desirable number of actuators is equal to the indeterminacy of the system plus the number of controlled DOFs which in this case is $8 + 9 = 17$. This is the minimum number of actuators necessary to turn the structure into a controlled mechanism. The most efficient positions for the actuators are those where the active elements have the largest effect on both axial forces and controlled displacements. This problem can be formulated as a least square optimization routine starting with the computation of the sensitivity matrices S^U and S^N for displacements and axial forces. These matrices store the effect of a unit length change for each element on nodal displacements (SU) and axial forces (SF) on the other elements. Each element length is increased by one unit length at a time. The resulting axial forces and nodal displacements are obtained using a flexibility approach (Patnaik, et al., 1991).

It is then possible to find the active element length changes ΔL that satisfy the desired controlled DOFs (Δu) eq.6 and compatibility conditions eq.7:

$$\min\left\|\boldsymbol{S}^{\boldsymbol{U}} \cdot \Delta\boldsymbol{L}^{\boldsymbol{all}} - \Delta\boldsymbol{u}\right\|^2 \quad (6)$$

$$\boldsymbol{S}^{\boldsymbol{F}} \cdot \Delta\boldsymbol{L}^{\boldsymbol{all}} = \Delta\boldsymbol{F} \quad (7)$$

At this stage $\Delta\mathbf{L}_{\text{all}}$ is obtained considering all elements as active. In order to derive the set of most efficient elements the contribution towards the desired control displacement is evaluated as efficiency (8) of each member as:

$$eff_{ik} = \frac{\sum_i^{nCDofs} \frac{\boldsymbol{S}^{\boldsymbol{U}} \cdot \Delta\widetilde{\boldsymbol{L}_{ik}}}{\Delta\boldsymbol{u}_k}}{nCDofs} \quad (8)$$

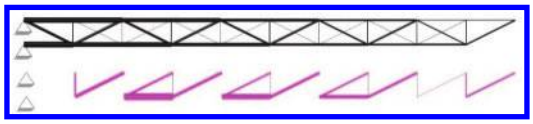

Figure 7. Optimal actuators topology.

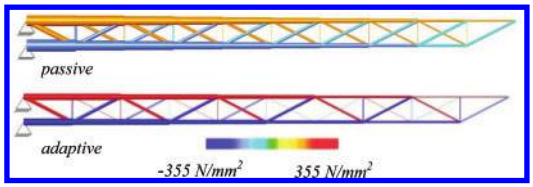

Figure 8. Optimal stress distribution passive vs. adaptive.

$$Eff_i = \frac{\sum_{k=1}^{nloadCases} \boldsymbol{eff}_k}{nloadCases} \quad (9)$$

where $\Delta\tilde{L}_{ik}$ is the vector composed of the length change of element i for the load case k having all the others components set to 0 and nCDofs is the number of controlled Dofs. The global efficiency Eff_i of each member is obtained from eq. (9). Fig. 7 shows the optimum positioning of the actuators for our cantilever truss structure, given a free choice of their number and location.

Once the position of the actuators is known, their required length changes is computed to bring the controlled nodes as close as possible to their required limits while enforcing the compatibility conditions eq.(11) as constraints:

$$\min \left\| \mathbf{S}_{\boldsymbol{red}}^{\boldsymbol{U}} \cdot \Delta\mathbf{L} - \Delta\mathbf{u}_{\boldsymbol{red}} \right\|^2 \quad (10)$$

$$\mathbf{S}_{\boldsymbol{red}}^{\boldsymbol{F}} \cdot \Delta\mathbf{L} = \Delta\mathbf{F} \quad (11)$$

$\mathbf{S}_{red}^{U}$ and $\mathbf{S}_{red}^{F}$ are reduced versions of $\mathbf{S}^{u}$ and $\mathbf{S}^{F}$ obtained by only keeping the columns corresponding to the chosen active elements. Finally, the length changes (ΔL_i for each actuator as initial deformation) are imposed together with external loads to check that the displacements of the controlled DOFs are within the desired limits. Fig. 8 shows the comparison between the adaptive truss and the corresponding passive optimized version.

2.3 *Embodied-operational energy optimization*

The work done by the actuators can be expressed as:

$$W_k = \sum_{actThr}^{size(P_k)} \sum_{i}^{na} \frac{\left(F_{ik}^{comp} + {}^1\!/_2 \cdot \Delta F_{ik}\right) \cdot \Delta L_{\,ik} \cdot fq \cdot t_k}{actMechEff} \quad (12)$$

In eq. (12) it is assumed that an actuator exerts a total force sum of F_{ik}^{comp}, the passive element contribution with no active control (compatible), and additional force contribution ΔF_{ik} performing a length change ΔL_{ik}. The operational frequency is kept constant for

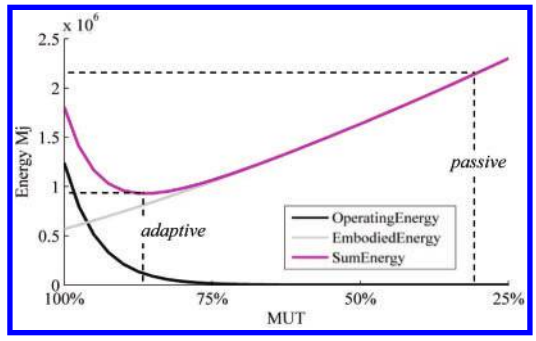

Figure 9. Embodied & operational energy curves.

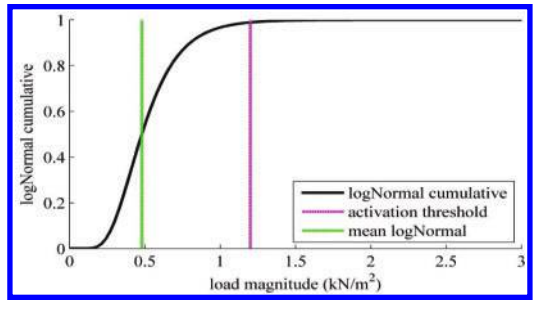

Figure 10. Load activation threshold (LAT).

any occurrence $time_k$ of each load case P_k (hours of occurrence). Working frequency and working efficiency of the actuators are set as 5 Hz and 50% respectively as conservative assumptions. The total operational energy is the sum of the energy needed for compensation of forces and displacements for all the loads above the activation threshold (actThre) and for all the actuators (na).

In order to take into account the minimization of the operational energy, the design process described in eqs.(1–10) is repeated iteratively within an outer loop. The main variable of the outer loop is the parameter MUT (material utilization factor). The active-passive system that corresponds to the minimum of the sum of embodied and operational energy is the optimum sought (fig.9).

Fig. 10 shows the activation threshold that corresponds to the optimal MUT value. Comparison between the adaptive and an analogous structure optimized using the same formulation of eqs.(1–4) with additional compatibility constraints $\mathbf{K} \cdot \mathbf{u}_k = \mathbf{P}$ shows that total energy savings remain substantial (55% in this case) even when considering the operational energy (fig. 11).

In both cases, embodied energy savings represent the major benefit when taken over the whole life of the structure, with other significant benefits in size reduction and construction transport and erection weight demands. The embodied energy is computed using the Bath Inventory of carbon and energy (Hammond & Jones, 2008).

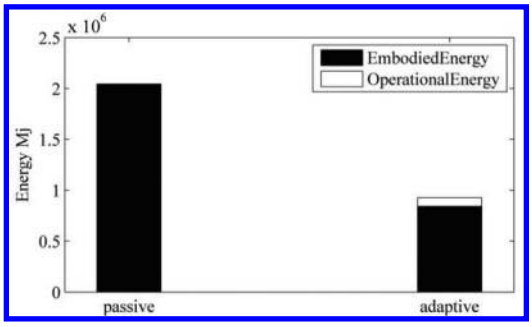

Figure 11. Energy savings comparison.

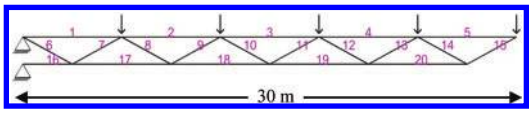

Figure 12. Determinate cantilever truss.

Figure 13. Optimal actuators topology determinate.

2.4 *Modifying the method for determinate cases*

This section studies the behavior of the determinate version of the cantilever truss described in the previous section (Fig. 12).

The only difference in the mathematical formulation is in the computation of the actuators topology. For the determinate case the actuators length change does not change the state of stress of the structure thus eq. (7) and eq. (11) are not necessary. The problems in eq. (6) and eq. (10) can be solved directly by computing the pseudo-inverse of the sensitivity matrix for displacements:

$$\Delta \boldsymbol{L} = \boldsymbol{S}^{U+} \cdot \Delta \boldsymbol{u} \tag{13}$$

which gives the actuators length change that compensate for displacements. Applying eqs.(8–11) gives the optimum actuator configuration for the displacements compensation. This is shown in Fig. 13.

Displacement correction can be dealt with in several ways. The simplest consists in setting the desired nodal displacement so as to stay within serviceability limits. A better way is to assign the desired displacement by taking into account the rate of change of the curvature between consecutive bays to avoid the formation of kinks in the deflection. Fig.14 shows the difference of the controlled shape with and without curvature constraints.

Comparison with an equivalent optimised passive truss gives energy savings of 60%. Optimal forces at maximum expected load for the adaptive and passive configuration are shown in Fig. 15.

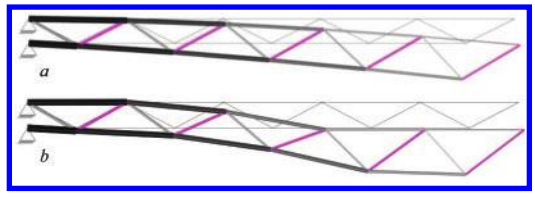

Figure 14. (a) curvature constr. (b) no curvature constr.

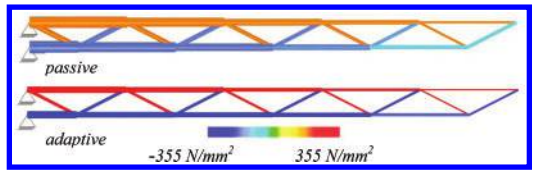

Figure 15. optimal stress distribution passive vs. adaptive.

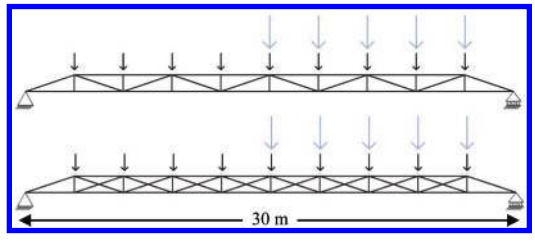

Figure 16. Determinate & indeterminate simply supported.

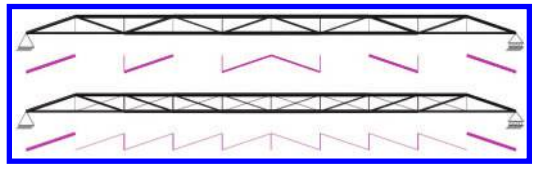

Figure 17. Adaptive trusses with actuators positions.

3 DETERMINATE VS INDETERMIANTE

In this section determinate and indeterminate trusses are compared in order to assess the effect of the load path redirection by the actuators for the control of internal forces and displacements. The next case study focuses on a simply supported truss beam supported by a pin at the bottom left corner and a roller at the bottom right node (Fig.16). The dead load is again 3 kN/m^2 supporting 10 m of roof out of plane. Two cases of live load are considered: in the first, a UDL is applied over the whole top cord whereas for the second only on the right half of the truss. The magnitude of the first UDL is set to dead load for the first load case and to twice the dead load for the second. The same load probability distribution as previously is taken for both the load cases.

The result of the optimization routine in terms of sections and actuators topology, only taking into account the first load case, are shown in Fig.17.

The optimal forces for both determinate and indeterminate adaptive/passive designs are shown in Fig. 18.

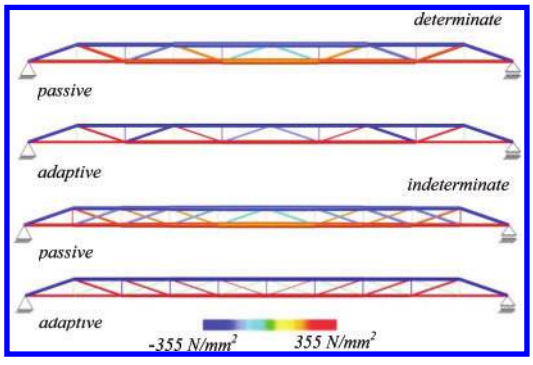

Figure 18. Comparison force distributions determinate vs. indeterminate case.

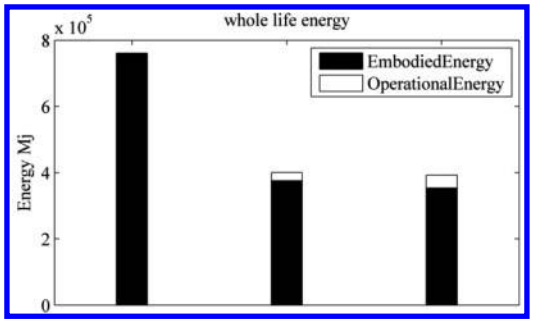

Figure 19. Comparison passive vs det. & indet. trusses.

For the determinate case the axial forces in the adaptive and passive structures are simply scaled version of each other. The material is more efficiently utilized and stresses tend to reach the maximum allowable values in the active structure.

By contrast, in the indeterminate case the axial forces in the passive and active truss are different. In the passive truss, the vertical elements work very little whereas the cross bracings are quite heavily used both in tension and in compression. The active indeterminate structure has all its vertical members in compression and in the cross bracing, the tension members have become dominant. Actuation has effectively turned the truss structure into a Pratt truss which is the best topology for the type of load acting on it.

In terms of total energy savings, both determinate and indeterminate designs achieve 50% with respect to the passive structures. Breaking down the total energy into embodied and operational shows that the adaptive indeterminate achieves 10% reduction for the former but a 40% increase for the latter compared to the adaptive determinate (Fig.19). The increase in operational energy is due to the load path redirection and the bigger number of actuators (Fig. 19).

Similar results are obtained when the two load cases are applied as combination case (fig. 20).

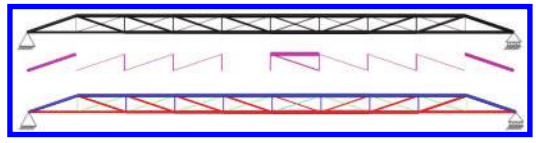

Figure 20. Force-sections distribution and actuators positions found for the load combination case.

4 CONCLUSIONS

A design procedure was presented that allows the design of structures that minimize whole life energy by introducing actuations at optimum placement in pin-jointed truss structures. Maximum energy savings are achieved by embedding the actuators with optimum placement and by finding the load threshold at which active control becomes necessary. Results from two planar structure case studies were presented. First for a determinate cantilever it was shown that the optimal active design allowed 50% of the total energy to be saved compared to an optimized passive design with the same topology. The second structure studied was a simply truss beam. Both a determinate and an indeterminate topology were tested. Similar savings around 50% were achieved for both. The indeterminate truss allows load path redirection. This in principle could allow a better homogenization of the stresses inside the truss. However, the whole life energy costing showed that the extra actuation needed in the indeterminate truss allows only minor further substantial energy savings with respect to the determinate case.

ACKNOWLEDGEMENTS

The authors would like to thanks the EPSRC and Expedition Engineering for funding this research project.

Softening some effects of the no free lunch (NFL) theorems in optimization via parallel computing

S. van Huyssteen & A. Groenwold
Department of Mechanical and Mechatronic Engineering, University of Stellenbosch, Matieland, South Africa

ABSTRACT: The no free lunch (NFL) theorems, aptly named by Wolpert and Macready, imply that no search or optimization (SO) algorithm will always outperform all other SO algorithms. Not only may an algorithm fare very different when applied to different classes of problems, but different implementations of a given algorithmic paradigm may result in the same. In this paper, parallel computing is used to soften this effect of the NFL theorem which is very well known in practice.

In this parallel paradigm different optimization solvers compete in parallel to solve a nonlinear optimization subproblem. The first successful iterate is then accepted. This approach allows us to solve SO problems far more efficiently than is possible with a single solver. Our numerical experiments show that the most suitable solver, usually selected a priori, may change as the iterations progress, contrary to intuition.

1 INTRODUCTION

In search and optimization the famous no free lunch (NFL) theorems of Wolpert and Macready (Wolpert & Macready 2005) imply that "any two algorithms are equivalent when their performance is averaged across all possible problems", although some authors have argued for an *(almost) no free lunch*[1] theorem. Nevertheless the theorems are still applicable in practice, see Droste (Droste, Jansen, & Wegener 2002). In an attempt to soften some of the implications of the NFL theorems we discuss a strategy in which we let different optimization solvers compete in parallel, to solve a nonlinear optimization subproblem. The first valid iterate obtained is accepted which lets the program follow the most efficient search path while ignoring the slow or erroneous subsolvers.

We are equipped with three solvers, one dual solver `l-BFGS-b` (Byrd, Lu, Nocedal, & Zhu 1995, Zhu, Byrd, Lu, & Nocedal 1994) and two QP solvers `E04NQF` (NAG Library Manual, Mark 22 2009) and `LSQP` (Gould, Orban, & Toint 2004). Two asynchronous parallel algorithms were developed in a sequential approximate optimization (SAO) framework. The first algorithm relies on thread cancellation by setting signal flags written with OpenMP, while the second algorithm forces cancellation of threads using POSIX libraries, also know as Pthreads.

We concentrate on the solution of inequality constrained nonlinear optimization problems. Since there exists many different methods for solving such problems we only give the general form of the problems here. Consider the inequality constrained nonlinear optimization problem $\mathcal{P}$ of the form

$$\begin{aligned} &\min_{\boldsymbol{x}} \; f_0(\boldsymbol{x}) \\ &\text{subject to} \;\; g_j(\boldsymbol{x}) \leq 0, \qquad j = 1,2,\ldots,m, \\ &\qquad\qquad \check{x}_i \leq x_i \leq \hat{x}_i, \qquad i = 1,2,\ldots,n, \end{aligned} \tag{1}$$

where $f_0(\boldsymbol{x})$ is the real valued scalar objective function, and the $g_j(\boldsymbol{x}), j = 1,2,\ldots,m$ are m inequality constraint functions. $f_0(\boldsymbol{x})$ and $g_j(\boldsymbol{x})$ depend on the n real (design) variables $\boldsymbol{x} = [x_1, x_2, \ldots, x_n]^T$. $\check{x}_i$ and $\hat{x}_i$ represent lower and upper bounds on the primal variable x_i respectively. Additionally, functions $f_0(\boldsymbol{x})$ and $g_j(\boldsymbol{x}), j = 1,2,\ldots,m$ are assumed to be (at least once) continuously differentiable.

To solve the general nonlinear optimization problem above most state of the art methods construct successive approximate subproblems $\tilde{\mathcal{P}}[k], k = 1,2,3,\ldots$ at successive approximations $x^{\{k\}}$ to the solution x^*. The solution of subproblem $\tilde{\mathcal{P}}[k]$ is $\boldsymbol{x}^{\{k*\}}$, which may be obtained by using any suitable continuous

[1] An *(almost) no free lunch* (ANFL) theorem shows that for any problem that can be optimized efficiently by a search heuristic/solver there can be constructed many related functions where the same heuristic is bad. As a consequence, search heuristics use some idea how to look for good points and can be successful only for functions when given the correct information.

programming method. Then $\boldsymbol{x}^{\{k+1\}} = \boldsymbol{x}^{\{k*\}}$ is the minimizer of subproblem $\tilde{\mathcal{P}}[k]$.

To solve the subproblem $\tilde{\mathcal{P}}[k]$ multiple optimization solvers are started in parallel. This results in a highly irregular parallel algorithm, because it contains subcomputations whose amount of work is not known in advance. Irregular parallel algorithms are complex from a parallel programming standpoint since the workload can only be distributed at runtime. Important subclasses of irregular algorithms include algorithms using *taskpools* and *speculative algorithms* (Guerraoui 2010). Our focus is on speculative algorithms[2]. Like any parallel algorithm, a speculative algorithm A is supposed to solve a problem P assuming a set of executions (or traces) M. By the characteristics of speculative algorithms the complexity of the path in A is supposed to be lower than its complexity in M, a serial component in A, Guerraoui (Guerraoui 2010). There are several possibilities to consider when writing a speculative algorithm of this kind of which we discuss only two.

Since the OpenMP 3.0 standard (OpenMP Architecture Review Board 2008) does not support forced thread cancellation, flagged thread cancellation is used in our first parallel algorithm, an approach proposed by Leopold (Süß & Leopold 2006). However, the lack of proper thread cancellation has a negative effect on the performance of the algorithm. Therefore we developed a second algorithm using Pthreads. Pthreads allows *forceful cancellation*, where a thread has the ability to cancel another thread from the outside. This type of cancellation runs the risk of memory leaks due to the fact that the canceled thread may not get the opportunity to clean up after itself. We will ignore this warning because there exists several ways to overcome this as will be elaborated on later.

This paper is arranged as follows. We depart with a description of thread parallelism and highlight the pitfalls of flagged and forced cancellation. The algorithms are then applied to a well-known design optimization problem; other problems were also considered, but are not provided in this paper. Finally the benefits that these methods have over existing sequential equivalents are summarized in the conclusion.

2 THREAD CANCELLATION ALGORITHMS

This section discusses the two parallel algorithms that are used in this paper. The first is the flagged thread cancellation algorithm and second is a forced thread cancellation algorithm.

2.1 *Thread cancellation using flags*

Tasks are called from within a parallel region, where the number of threads must be assigned before the start of the parallel region. This may be done anywhere in the serial code before the parallel region. In OpenMP parallel tasks are started using the SECTIONS directive. Each task nested within the SECTIONS directive is then executed once by each thread in the team.

Contained within each parallel task is an iterative check. Once any one of the solvers have completed, a flag is set with the appropriate task number. The iterative check will pick up that the value of the task number has changed and will immediately return from the task. If there has been no change in the flag value, the task continues until it itself returns. Since OpenMP does not include forceful thread cancellation, one must wait until all threads have attained the changed flag state and have exited successfully. This becomes a big problem when the size of each task iteration is highly irregular, as is often the case with different QP solvers.

Great care needs to be taken by the programmer to ensure that all flags are checked correctly. Human error could be encountered when using flags to indicate that the parallel region should be aborted. Problem-specific values that must be updated are flushed for each solver. However, this is important to ensure data conformity. If flags are not appropriately flushed, the program will most likely exhibit deadlock[3]. In OpenMP the sequence of barrier constructs must be the same for every thread in the team in order to exit correctly.

Since it is not possible to use language-level thread cancellation in OpenMP, flags are used to indicate when execution of a thread must halt. If flags are iteratively checked in competing threads and one of the competing threads is having difficulty during an iteration, the remaining set of threads must wait for a checkpoint to be reached in that thread. Even if all the other competing threads have completed, this thread may be detrimental to the overall performance of the algorithm. The information in this troublesome thread is not needed for further execution in our case, making forceful thread cancellation more effective.

2.2 *Forced thread cancellation*

POSIX is an acronym for Portable Operating System Interface. Although the acronym originated to refer to the original IEEE Standard 1003.1–1988, which was required after code portability became a concern for software developers. Thus, a standardized C language thread programming interface was specified for UNIX systems, namely the IEEE POSIX 1003.1c standard. Implementations that adhere to this standard are often also referred to as Pthreads. The POSIX standard has

[2] Speculation is the idea that the design of an algorithm follows an *if-then-else* control structure. The speculative path is the specific (expected) path of the algorithm which is executed. If the conditions are not met, a backup path is executed instead.

[3] A *deadlock* is a runtime situation that occurs when a thread is waiting for a resource that is never going to be available (Chapman, Jost, & Pas 2008. It is sometimes referred to as *software lock* or *soft lock*.

continued to evolve and undergo revisions. The latest version is known as IEEE Std 1003.1 (POSIX 2004).

Other than using on-node task communication via shared memory, such as MPI, the threads of a Pthreads process share the same address space, eliminating intermediate memory copy operations. Therefore, most memory operations are cache-to-CPU, or memory-to-CPU in the worst case scenario. This type of multithreading proves to be very effective when asynchronous requests need to be handled (Dongarra, Foster, Fox, Gropp, Kennedy, Torczon, & White 2003) on large server systems. For this reason Pthreads includes a thread cancellation library. However, Pthreads is highly platform dependent and is mostly aimed at codes written in C and C++, see (Barney 2008). We have therefore written wrapper functions for the needed C library functions in order to use them in our program which is written in FORTRAN.

Unfortunately, because we use wrapper functions for the use in our FORTRAN program, the cleanup functions that free the memory in canceled threads could not be implemented. These cleanup functions need to be called within the same lexical context (within the same brackets) as the parallel function and ensure memory conformity. This is an obvious problem for (official) modules. For our investigation we use these non-thread safe functions only to demonstrate the advantages. If the source codes were to be modified (rewritten in C) this would not be a problem.

In this implementation the competing processes are canceled, instead of setting flags, with a call to `thread_cancel(tid)` where supplying the appropriate thread-ID will cancel that thread no matter where the thread is in its execution process. This following section presents detailed results on solving a subproblem with both of the above mentioned methods.

3 RESULTS

The cam design problem (Dolan, More, & Munson 2004) is used to illustrate how solving the subproblems in parallel compares with solving the problems with the respective solvers in a serial application. The cam design problem has $3n+4$ constraints, where n is the number of design variables. Therefore, since the number of design variables and constraints are high, it is expected that the QP solvers will perform better for this problem.

Non-fatal errors are allowed for the subsolvers; for more information the reader is referred to the respective Warnings and Errors sections in the manuals. For the `l-BFGS-b` routine, only the error-(`msg`) value of 0 is allowed, for `E04NQF` `msg` $= 0, 5$ and for `LSQP` `msg` $= 0, -5$. The 5 and -5 errors are non-fatal, but indicate the presence of some numerical difficulties and 0 indicates that no errors were encountered. It is possible to restrict all warnings and errors, but for some problems this increases the execution time with little gain in accuracy. The capability to suppress errors is something that cannot be done during serial execution without aborting the routine.

3.1 *Cam design problem*

The cam design problem (Dolan, More, & Munson 2004) aims to maximize the area of a valve opening for one rotation of a convex cam, with constraints on the curvature and on the radius of the cam. Refer to Appendix A.1 for problem specific information and some tables showing the performance of the solvers in serial and the two parallel algorithms.

Below we show the iteration history of the cam design problem for one of the parallel algorithms, the problem size is $n = 2000$. Here we wish to illustrate the algorithm's ability to filter errors during execution. This can be seen in the last column of the iteration history where the first couple of iterations return with error state 5. Figure 1 shows the execution times for the respective solvers and parallel algorithms on a log-scale graph. Here we see that our parallel algorithm with forced thread cancellation executes faster than the slowest solvers, but never faster than the fastest solvers. This may be attributed to the overheads of spawning and cancelling new threads or waiting for flags to be set. We left the serial-`l-BFGS-b` solver out of the plot as it fails for problem sizes within the range where we are testing. The flagged thread cancellation algorithm does well but suffers from long wait times because flags cannot be checked.

Another desirable quality of using solvers in parallel is that the algorithms follow the shortest execution path. Please refer to tables 1 through 5. After inspecting k^* and l^* in the tables, which indicate the amount of outer and inner iterations respectively, one can clearly see the dominance of the parallel algorithms. The parallel algorithms tend to converge faster and with much less computational effort. The presence of inner iterations indicate that the solver is struggling to reach the required accuracy in the solution.

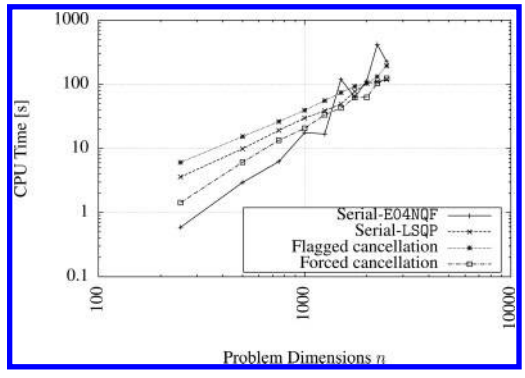

Figure 1. Maximization problem for the area of a valve opening for one rotation of a convex cam and solved using dual and QP solvers in both serial and parallel.

For some solvers the execution times vary abruptly when problem size is increased as the serial-E04NQF routine in Figure 1 depicts. This behaviour is not reflected in the parallel algorithms, when threads are forcefully canceled or when flags are checked in regular intervals.

4 CONCLUSION

A parallel SAO method was created to show that it is beneficial to solve subproblems with multiple solvers in parallel. The source code for some of these solvers were not available, therefore, flags could not be checked regularly using the flagged thread cancellation routine. Without the ability of flagged thread cancellation to check the flags at sufficiently short intervals the algorithm waits unnecessarily for slow routines to check the required flags. To overcome this deficiency, a similar parallel algorithm was written to forcefully cancel these slow threads. This method is not thread safe, and is only used to show how the parallel algorithms would perform, if flags could be checked regularly.

These parallel algorithms present several desirable properties. The first is the ability of the parallel algorithms to filter out selected errors. If one solver does not return a good enough answer, it is likely that one of the others will. There is no way to do this with a serial program.

Secondly, the parallel algorithms follow the most efficient search path, resulting in the number of iterations needed by the parallel algorithms to complete being generally less than those of the serial algorithms. This property is very desirable in FEM and/or CFD programs, as many function evaluations are done between these iterations. Therefore, when the number of iteration steps is reduced, the performance of these FEM and CFD models will increase substantially.

Thirdly, the parallel algorithms tend to be almost as fast as the most effective serial routines for a greater range of problems, accounting for overheads and provided that flags are checked regularly. There is therefore no need for the user to tune a specific algorithm to his problem to get a result in as short a time as possible, which eliminates the re-running of programs.

Finally, parallel algorithms are more stable than serial algorithms because solvers that suffer from numerical errors are simply ignored. The results therefore tend to be more accurate than those of individual serial routines.

In conclusion, the proposed parallel methods are very promising alternatives when the problem types to be solved are not known in advance. Thus, by performing two (or more) evaluations in parallel and terminating the competing thread whenever a viable solution is returned, we ensured that the most effective solver is used for the solution of the subproblem at each approximation of an SO algorithm. This softens the implications of the classic NFL theorem by eliminating the need for user interaction in tuning or selecting the best solver for any problem.

4.1 *Future work*

These parallel algorithms present the opportunity for further investigation. The first would be to create stable thread-safe solvers which allow flags to be checked regularly, or the development of thread cancellation libraries for different programming languages.

Single precision solvers which are on average two times faster than double precision routines now become a viable method for solving nonlinear optimization subproblems. By adjusting the desired precision of the solution, single precision solvers may be used during the initial iterations and only updated to double precision during the final iterations. If any of the single precision routines fail to return a viable solution, the double precision routines take over.

The inclusion of single precision routines lend the ability to use single precision arithmetic on GPUs. This should show considerable speedups.

Finally, several different solvers may be added in parallel which might produce interesting results.

A PROBLEMS AND TABLES

A.1 *Cam design problem*

The cam design problem (Dolan, More, & Munson 2004) aims to maximize the area of a valve opening for one rotation of a convex cam, with constraints on the curvature and on the radius of the cam. The cam design problem has $3n + 4$ constraints, where n is the number of design variables. Since the optimal cam shape is symmetric, one considers only half of the design angle. The tables of results for this problem are listed below. The tables start with the serial solvers and end with the routines where the solvers are used in parallel.

In the tables, n indicates the number of design variables, m the number of constraints, k^* indicates the number of outer iterations, and l^* the number of inner iterations. The optimal function values are indicated with f^*, where h^* and r^* respectively indicate the maximum constraint violation and KKT-condition of the result. CPU is the real execution time.

ABSTRACT: A new design methodology for adaptive structures was presented in a companion paper. In it, it was shown that active control can lead to significant whole life energy savings when the design is governed by rare but strong loading events. In this paper a systematic exploration is presented of the domain in which adaptive two-dimensional pin-jointed cantilever and simply supported trusses are beneficial in terms of whole life energy savings and monetary costs. This exploration took three directions. First, the influence of the ratio of live load over dead load was investigated for various spans. Second the aspect ratio of the truss (span to depth) was varied. It is shown that that the biggest percentage energy savings remain substantial for the whole solution domain reaching maxima from small/medium span structures. However, considering the outcome of monetary cost analysis it reveals that adaptive structures only become cost effective for medium/high span structures. Third the results from both studies are combined and an optimal region where adaptive structures are both energy and cost effective is identified.

1 INTRODUCTION

1.1 *Understanding the domain of applications for adaptive structures*

The potential of active control for structures to be more energy efficient has received little attention (Korkmaz, 2011). Actuation itself consumes energy therefore any investigation into using active control to save material in structures must account for the total energy spent throughout the life of the structure: the embodied energy as well as the operational energy necessary for actuation. In a companion paper (Senatore, et al., 2013) a design methodology for adaptive structures was presented and it was shown how active control can be used to bring significant total energy savings in discrete structural assemblies (pin-jointed trusses). In this methodology, the structures were subjected to a dead as well as a randomly fluctuating live load.

The procedure consists of two nested optimization processes. The inner optimization starts by designing a minimum weight structure by first ignoring compatibility. Compatibility is then satisfied by strategically replacing some members by actuators whose length changes can manipulate actively the internal flow of internal forces and deflection. The hybrid passive-active structural system is designed so that in normal loading conditions it can take the load using its passive capacity and actuators locked into position. If a change in the loads causes a state of stress that violate an ultimate limit state (ULS) constraints, internal load path redirection is performed by the active system. Also in the event of very high level of loads above the activation threshold, it can rely on the full active load-bearing capacity to provide for displacement correction. In this way passive resistance (through material and form) is replaced with operational energy. By looping over different values of the material utilization factors, the load activation threshold can be adjusted. Figure 1 show how the total energy, made up of embodied and operational energy reaches a minimum as the MUT is changed from 100% (fully active) to 25% (passive design). This process allows a design that minimizes the total energy to be found. It is implemented as multi-objective optimization routine using non-linear programming and variational analysis. The methodology applied to simply supported and cantilever trusses

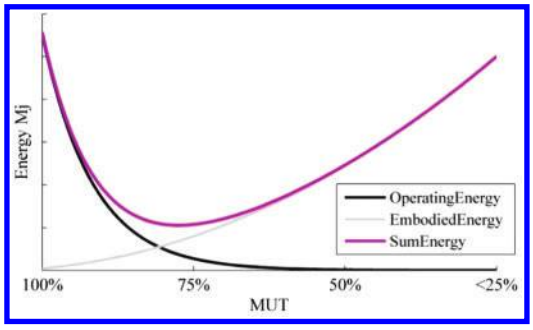

Figure 1. Whole-life energy vs. degree of adaptation.

achieves whole life energy savings (considering 50 years life time) of 55% and 70% respectively (Senatore et al., 2013). However those conclusions were reached by making a number of assumptions. The purpose of this paper is to find out how robust the energy savings achieved are as some of the assumptions made are examined critically and the input parameters used are varied systematically.

1.2 *Built-in assumptions and performance metrics*

First it is necessary to list those assumptions. It is assumed throughout that idealized linear motors are used with a mechanical efficiency set to a low level (50%). This is a conservative value as the mechanical efficiency of such motors is usually around 80% (Sclater et al., 2011). The maximal operational frequency is set at 5 Hz. This is the upper natural frequency that will dominate the response of most structures excited by wind, earthquakes or pedestrians. A higher frequency means higher operational energy so assuming a high value does not favors active technology.

The operational energy needed to power the sensors and control system is considered negligible compared to the work done by the active elements. Sensors generally need low power inputs (usually around 1 W) to operate (Culshaw, 1996) and many strain sensors do not need any power at all. This means that the whole control system can stay in "hibernate" mode consuming very little for most of the life of the structure. When the sensors detect higher internal stresses or strains then the control system is activated. Generally the occurrence of severe loads is expected to be less than the 5% of the life-cycle of a building (Culshaw, 1996). Assuming a value of 100 W for the power needed by the control system (similar to the power needed by a modern 4-core PC) in operational mode (5% of the total time), the energy consumption due to the control system would equal 200–300 kg of steel (conversion obtained using the Inventory of carbon and energy (Hammond & Jones, 2008)) over the design life of the structures (50 years). This additional penalty can be neglected for most cases except for very small structures (for instance span lower than 8 meters) where the absolute savings in terms of mass becomes comparable with the loss of energy due to power the control system.

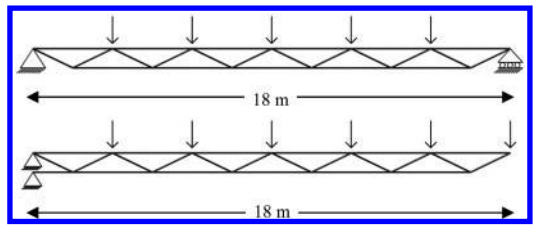

Figure 2. Sample for simply supported and cantilever case.

1.3 *Parametric exploration*

The parametric study presented in this paper will three main directions:

1. It studies the influence of the ratio of the live load over the dead load vs. the length of the span.
2. A simplified cost analysis will be carried out to check to which extent the energy saving made translate into monetary savings.
3. The main geometrical features such as span and span to depth ratio of the trusses are varied to study the importance of the shape of the structure.

Results from the three strands will be combined in order to identify an optimal region where adaptive structures are most effective in terms of both energy and monetary savings.

2 LIVE TO DEAD LOAD V. SPAN

2.1 *Settings*

In this section the performances of a cantilever and a simply supported pin-jointed determinate truss beam are studied when the ratio of live to dead load is varied from 0 to 2. The performances in terms of energy savings will in general depend on the particular type of topology chosen. However, in the companion paper it was shown that when two comparable trusses, one determinate and the other indeterminate are optimized through the proposed methodology, the total energy savings achieved through optimum actuation in both structures are in fact very similar. Therefore the sensitivity study to the live to dead load ratio is limited to determinate topologies.

The span of the trusses is varied from 18 m to 126 m for the simply supported truss and from 9 m to 63 m for the cantilever. The ratio between the span and the depth (height) of the trusses is kept constant at 30. The dead load is set to 3 kN/m^2 on the roof panel and each truss supports a 10 m wide span of roof resulting in a UDL of 30 kN/m for each truss. Fig. 2 shows one example from the range of structures tested for both the simply supported and cantilever case.

The live load is modeled using parameterized log normal distributions. Their mean is set to 10% percent of the maximum expected load. In this way, the higher

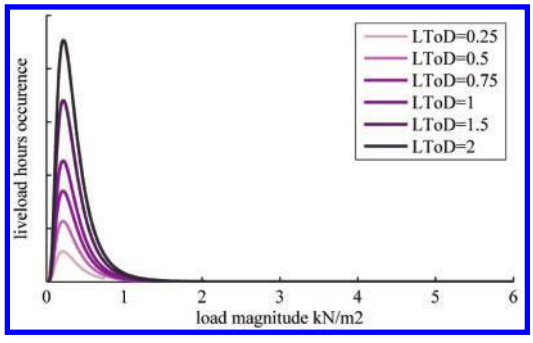

Figure 3. Live load distributions.

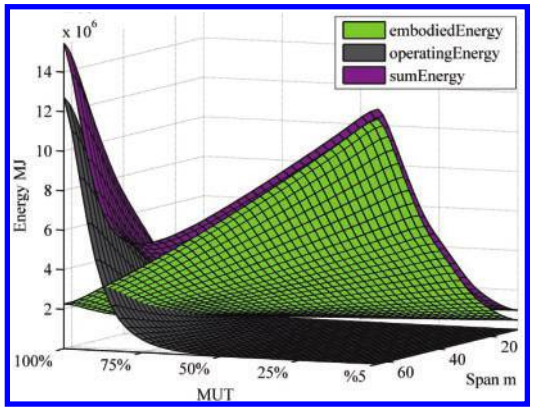

Figure 4. Embodied-Operational energy | liveToDead = 0.75.

the live to dead load ratio, the stronger and rarer the max expected load while the lower level of loads have higher occurrence. Fig. 3 shows the log-normal distribution for a live to dead ration ratio varying from 0.25 to 2.

All the adaptive trusses are compared with their passive version which is optimized using the non-linear technique described in the companion paper.

2.2 *Energy analysis*

The first set of simulations focuses on the simply supported case. Fig. 4 is a 3D plot showing the total energy (embodied + operational) against varying MUT (material utilization factor) and span. For the particular simulation shown here the live to dead load ratio was set to 0.75. For each span at different live to dead load ratios, a global optimum of the total energy can found. This plot is a straightforward three dimensional extension of the graph shown in Fig. 1.

For clarity, the same data is shown again in fig 5 as a colored contour map. The almost horizontal black line shows the locus of the optimal MUT for each span.

Generally, the performances of adaptive structures in terms of energy savings are at their highest when the passive design is stiffness-governed i.e. when the size of the members is controlled by deflection limits rather than strength. In fact, as the live to dead load increases

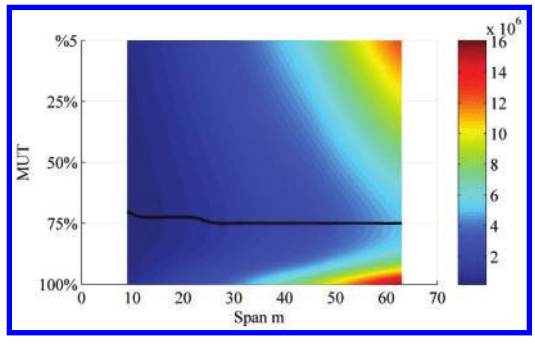

Figure 5. Total energy | live to dead ratio = 0.75.

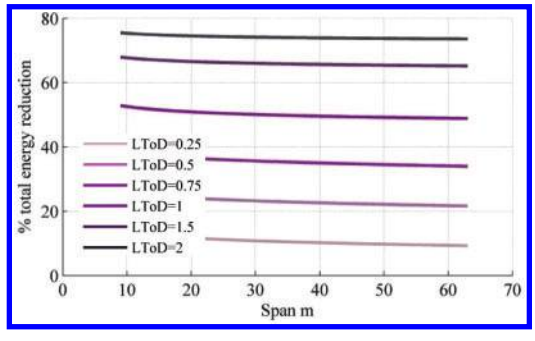

Figure 6. Percentage energy savings cantilever.

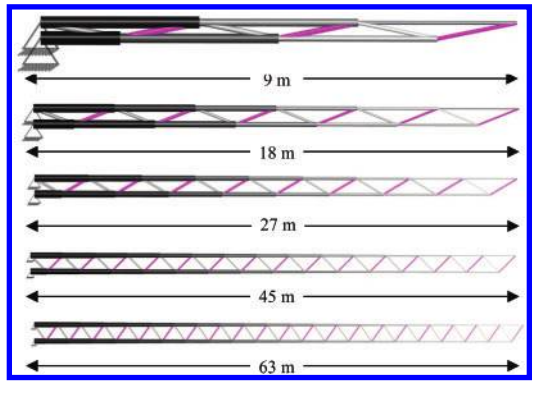

Figure 7.

so do the energy savings (Fig. 6). While the span and live to dead load ratio are varied, the ratio between span and depth is kept constant. For this reason the energy savings in percentage in terms are very similar for different spans which are at the same live to dead load ratio. However there is a slight decrease in energy saving as the span increases (Fig. 6).

This decrease is due to the fact that the width of each bay is kept constant at 3 m thus becoming deeper (more structurally efficient) as the span increases. There is therefore less to be saved from the passive structures as the span increases. Fig. 7 shows the optimized adaptive trusses at different spans at live to dead load ratio equals to 1.

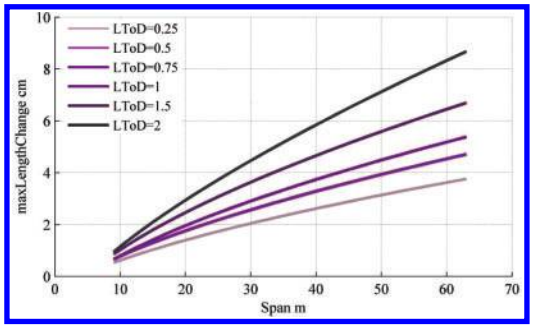

Figure 8. Max actuators' length change.

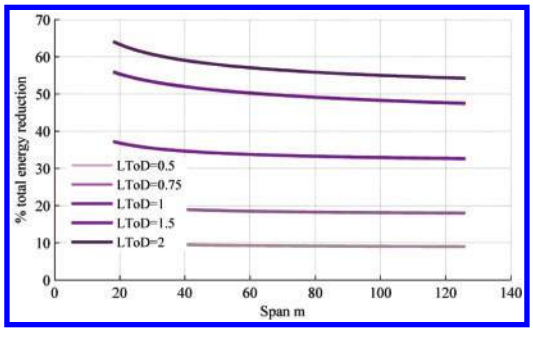

Figure 9. Energy percentage savings simply supported.

Fig. 8 shows that the actuator length changes remain small (always less than 10 cm) even for very long spans (up to 63 m) which experience large tip deflections and high live to dead load ratios.

This is possible as the coordinated small length changes of the actuators manage to achieve an effective control of the structures.

Fig. 9 shows the percentage energy savings for the simply supported case. Note that, although similar percentage energy savings are achieved, the span of the trusses has doubled.

2.3 *Monetary costs analysis*

An adaptive truss structure is made of sensors (strain gauges), structural steel, actuators and the control system. The cost of sensors (strain gauges) actuators and the control system are mainly dependent on the type of technology adopted. Electric linear motors and hydraulic are the most commonly used technologies for actuation. The most important characteristics affecting the cost of an actuator are the stroke length, the max static and dynamic force and the duty cycle. Strain gauges are cheap; their cost is therefore neglected from the model. The cost of construction material (structural steel for this case) depends on the type of building. The assumptions made in this study are:

- The actuator cost is set to £2000/unit. This is the average cost of a hydraulic cylinder with a push/pull load of 100 tons (Rexoth, 2013) (Hydrover, 2013).

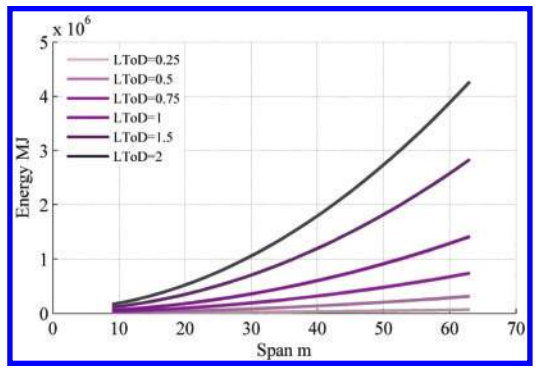

Figure 10. Embodied energy difference (passive-adaptive).

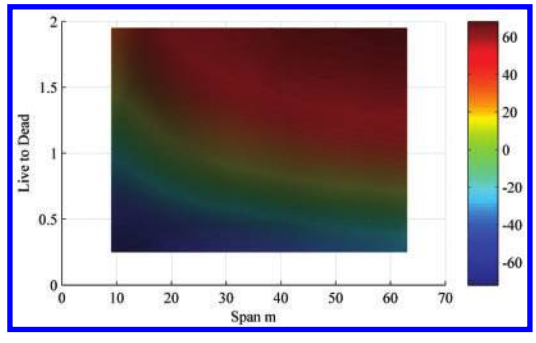

Figure 11. Cost savings adaptive vs. passive cantilever.

The latter is an average value for the internal forces considered for the both the cantilever and simply supported trusses;

- The cost of the control system mainly depends on the number of channels necessary to gather data from the sensors and input signals to the actuators. The average cost for both a single dual channel strain gauge amplifier and actuator control board is £200 respectively (Fylde, 2013); (RobotEq, 2013);
- the cost of steel per tonnage is set to £ 3000/tonnage (TATA Steel, 2012);
- The maintenance for the actuators is assumed to happen once per year involving a technician taking a full-day to inspect 5 actuators. The cost of one inspector is 500£ per day;

Unlike the percentage of energy savings (Fig. 6), the energy difference in absolute terms increases with the span. This means that the gap between the embodied energy (or mass) of the passive and the adaptive structure become very large for longer span (Fig. 10).

For long spans, the large difference in mass between the adaptive and the passive structure outweighs the additional expenditure for sensors, actuators and control systems as shown in fig 11 which compares the percentage monetary cost savings for the adaptive and the passive designs. Note that below a live to dead load ratio of 0.75, cost savings are negative even for long spans (from green to blue).

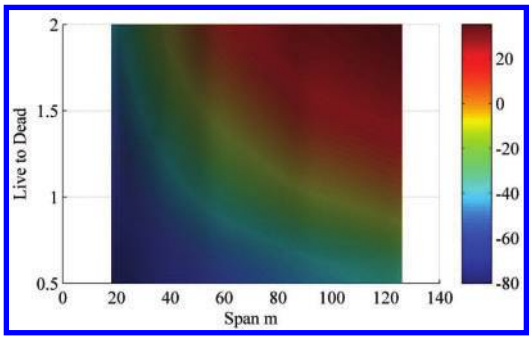

Figure 12. Percentage cost savings simply supported.

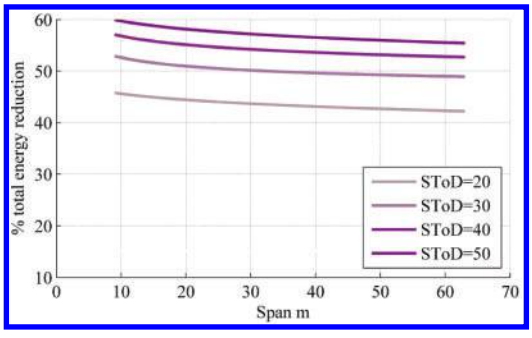

Figure 13. Energy percentage savings cantilever case.

Similar results are obtained for the simply supported case (fig. 12). However in that case the area where the adaptive trusses are cost effective compared to the passive ones is reduced (green to red area).

3 SPAN TO DEPTH VS. SPAN

3.1 *Energy analysis*

In the next set of simulations, the influence of the span to depth ratio on the performances of adaptive structures is investigated. The setting described in section 2 holds except that this time the live to dead load ratio is kept constant and equals to 1. The span to depth ratio is varied from 20 to 50 going from deep to very slender configurations.

The performances of the adaptive structures in terms of energy savings against span and span to depth ratio are plotted in fig. 13 for the cantilever case.

As observed in section 2, the percentage savings remain very similar along the span axis while the increase substantially as the span to depth ratio increases. Similar results are obtained for the simply supported case. Fig. 14 shows simply supported adaptive trusses with identical spans but different span to depth ratio.

Because the ratio of live to dead load is constant, in this case it is possible to show the variation of the activation threshold which goes from being very close to the maximum expected load for deep trusses to much lower value for slenderer configurations.

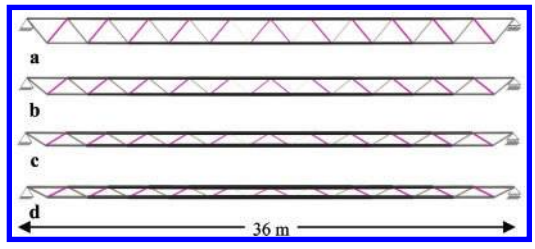

Figure 14. a) StoD = 20; b) StoD = 30; c) StoD = 40; d) StoD = 50.

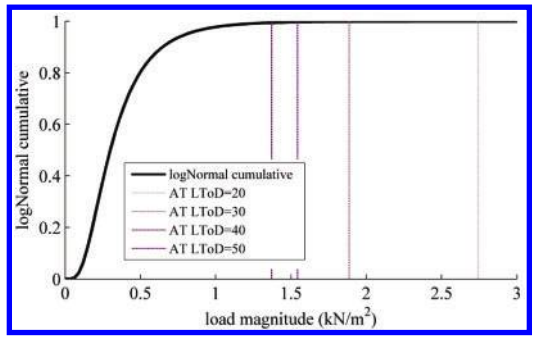

Figure 15. Load activation threshold variation for different span to depth ratios.

As seen previously, the maximum length change of the actuators does not exceed 20 cm even for very slender trusses (span to depth of 50).

3.2 *Monetary costs analysis*

A similar cost analysis to that done for live to dead load variation was carried out for the span to depth ratio variation. The conclusions are similar to both for the cantilever and simply supported beam.

4 CONCLUSIONS: OPTIMAL REGION OF THE SOLUTION DOMAIN

In order to determine the boundaries of the region where adaptive structures of the type studied here bring the most benefit, the results obtained so far must be combined. To do this, the percentage energy savings are first filtered through cost savings test. If the active design costs more than the passive one, the active design is assigned a score of 0 (i.e. no energy savings are considered). Then positive costs savings and energy savings are averaged thus forming a unique value for each span and live to dead load ratio for the cantilever (fig. 16) and simply supported case (fig. 17). In this way it is possible to identify an optimal region where adaptive structures are effective in terms of both energy and monetary cost savings.

The curves in the graphs show how the fronts of these optimal regions change for different span to depth ratio. The optimal region tends so to cover larger

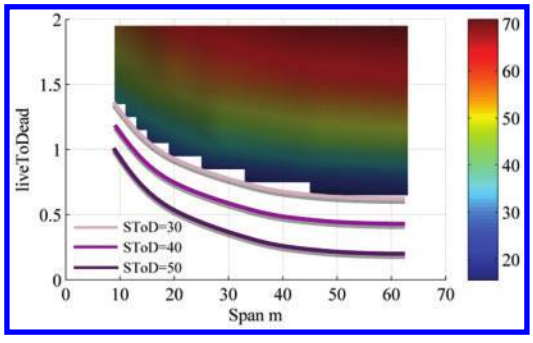

Figure 16. Optimal region cantilevers.

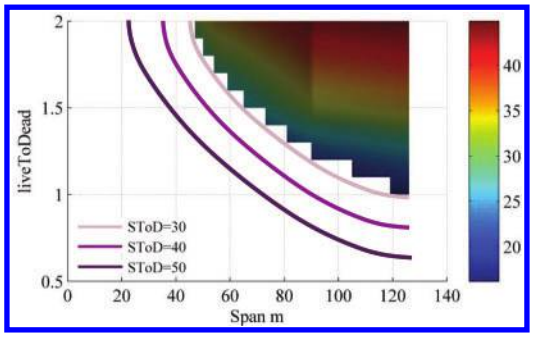

Figure 17. Optimal region simply supported.

area of the solution domain as the span to depth ratio increases.

Fig 16 and 17 are consistent. This means that for the two classes of structures studies in this paper, the conclusion is similar: adaptive structures are most beneficial both in energetic and monetary terms for long span structures where the live load is larger than the dead load. However, as the slenderness of the structure increases, adaptive structures become both energy and cost effective even at medium/small spans. This is broadly the type of structures that are stiffness governed.

ACKNOWLEDGEMENT

This work could not have been carried out without funding from the UK Engineering and Physical Sciences Research Council (EPSRC) as well as financial and technical support from Expedition Engineering. Their help is greatly appreciated.

ABSTRACT: The design of hot-rolled steel portal frames can be sensitive to serviceability deflections. In such cases, in order to reduce frame deflections, practitioners can increase the size of the haunch and/or the sizes of the steel standard sections used for the column and rafter members of the frame. This paper investigates the effect of such serviceability deflection on the optimal design of steel portal frames, using evolutionary algorithms that optimizes frame weight, taking into account both ultimate as well as serviceability limit states. The results show that heuristic search methods, namely, real-coded and real-coded niching genetic algorithms are efficient and reliable. The niching strategy results in a 66.7% reduction in the computational time. It is shown that serviceability deflections, as recommended by the Steel Construction Institute, govern the design of a 30 m span portal frame, where material cost increases by 27% compared to an ultimate limit state design only.

1 INTRODUCTION

It is estimated that 50% of all constructional steelwork in the UK is used for the primary framework of single-storey buildings. Within this major market sector, the hot-rolled steel portal frame has become the most common structural form in pitched roof buildings (see Figure 1), because of its economy and versatility for a wide range of spans (Lim and Nethercot 2003, Salter *et al.* 2004, Phan *et al.* 2011, and Wrzesien *et al.* 2012).

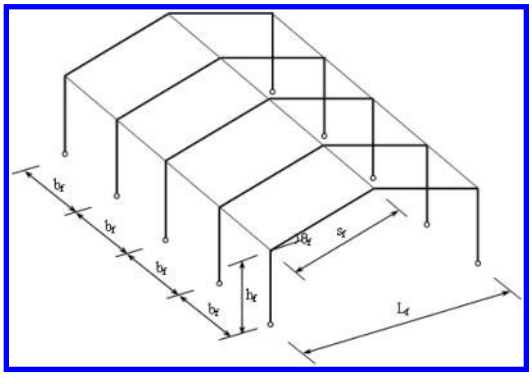

Figure 1. Parameters used to define portal framing system.

In this paper, the serviceability limit state requirements for steel portal frames, as recommended by the Steel Construction Institute (SCI), are used for the frame design; these limits are proposed in order to avoid problems of tearing in cladding fixings, due to differential deflections in between adjacent frames (SCI Advisory Desk AD-90 2010). In addition, less stringent deflection limits, as recommended by practitioners in industry, are also considered. These deflection limits are shown in Table 1. This paper investigates the effect of such deflection limits on the optimal design of hot-rolled steel portal frames using heuristic search techniques, namely, real-coded genetic algorithm (RC-GA) and real-coded niching genetic algorithm (RC-NGA).

Using the proposed optimal algorithms, the frame weight per unit area on plan of the building is minimized through selecting the most appropriate steel standard cross-section (i.e. Universal Beam Section) for the columns and rafters of frame, as well as the size of eaves haunch, by designing the frame to both ultimate and serviceability limit states (Phan *et al.* 2013a).

In this paper, the frame is designed to the ultimate limit state with two design procedures, either rigid-plastic or elastic design methods. It is shown that serviceability deflections, as recommended by the

Table 1. Deflection limit for steel portal frames

	SCI recommendations		Industry suggestions	
	Absolute deflection	Differential deflection	Absolute deflection	Differential deflection
Lateral deflection at eaves	$\leq \frac{h_f}{100}$	$\leq \frac{b_f}{200}$	$\leq \frac{h_f}{100}$	$\leq \frac{h_f}{150}$
Vertical deflection at apex	–	$\leq \frac{b_f}{100}$ and $\sqrt{b_f^2 + s_f^2}/125$	–	$\leq \frac{L_f}{200}$

Steel Construction Institute, govern the design of a 30 m span portal frame, with material cost increasing by 27% compared to an ultimate limit state design alone.

2 OPTIMIZATION PROBLEM FORMULATION

2.1 *Frame description*

Details of the frame used for the benchmark design example are shown in Figure 2; the geometry of the frame and section sizes for the column and rafter are taken from a worked example in an SCI guide on steel portal frame design (Salter *et al.* 2004).

As can be seen in Figure 2, Benchmark Frame has a span of 30 m, height-to-eaves of 7 m, and pitch of 6°; other parameter for the building topology is the distance between adjacent frames (b_f) of 6 m. In the design of the Benchmark Frame, it can be seen that the eaves haunch length is taken as 10% of the frame span and uses the same section size as the rafter section. It is assumed in this paper that side rails and purlins are placed close enough on the columns and rafters to prevent lateral torsional buckling.

2.2 *Frame loads*

The dead load (DL) and live load (LL) acting on the Benchmark Frame are 0.66 kN/m^2 and 0.6 kN/m^2, respectively. Under such loads, the frame should be checked under the following ultimate load and serviceability load combinations as follows:

$$\begin{aligned} &\text{ULC1} = 1.4\text{DL}+1.6\text{LL} \\ &\text{SLC1} = 1.0\text{DL}+1.0\text{LL} \\ &\text{SLC2} = 1.0\text{LL} \end{aligned} \tag{1}$$

It is worth noting that SLC1 is applied to determine the absolute deflection, whilst SLC2 is for differential deflections (see Table 1).

2.3 *Frame analysis and design*

In this paper, the Benchmark Frame is designed to the ultimate limit state using either rigid-plastic or elastic design methods. The internal forces, namely, axial forces, shear forces, and bending moments at the critical sections are determined in order to carry out the member checks. For instance, the columns, rafters and eaves haunches are checked for local capacity under shear, axial, or moment capacity, and combined

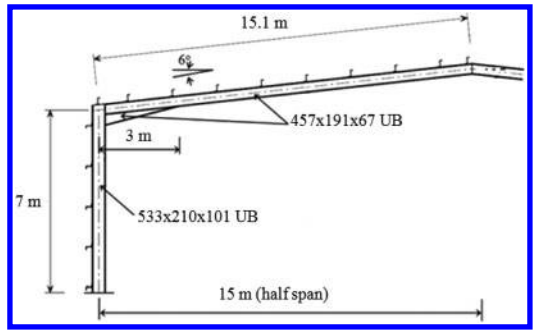

Figure 2. Details of Benchmark Frame (Salter *et al.* 2004).

moment and axial force. Frame deflections at the eaves and apex are determined from elastic frame analysis.

Comparing the two serviceability requirements to the Benchmark Frame, the vertical deflection at the apex of the SCI recommendations is 60% more stringent than that from industry suggestions.

2.4 *Weight function and design constraints*

The objective of the overall design optimization is to determine the portal frame having the minimum steel material weight, whilst satisfying the design requirements. The objective function can be expressed in terms of the weight of the primary members per square meter of the plan as follows:

$$\text{Minimize W} = \frac{1}{L_f b_f}\left(\sum_{i=1}^{m} w_i l_i + \sum_{j=1}^{n} w_{hj}\right) \tag{2}$$

where W = weight of frame; w_i = weight per unit length of standard steel section used for members; l_i = length of members; m = number of members; w_h = weight of a single haunch; and n = number of haunches.

The objective function (Eq. 2) is minimized, subjected to the following normalized constraints for plastic design, in accordance with BS 5950-1 (2000):

$$\begin{aligned} g_1 &= \frac{F_v}{0.6 p_y A_v} - 1 \leq 0 \\ g_2 &= \frac{F_c}{p_y A_g} - 1 \leq 0 \\ g_3 &= \frac{M_x}{M_{cx}} - 1 \leq 0 \\ g_{4P} &= \frac{M_x}{M_{rx}} - 1 \leq 0 \\ g_5 &= \frac{1}{\lambda_p} - 1 \leq 0 \\ g_6 &= \frac{\delta_e}{\delta_e^u} - 1 \leq 0 \\ g_7 &= \frac{\delta_a}{\delta_a^u} - 1 \leq 0 \end{aligned} \tag{3}$$

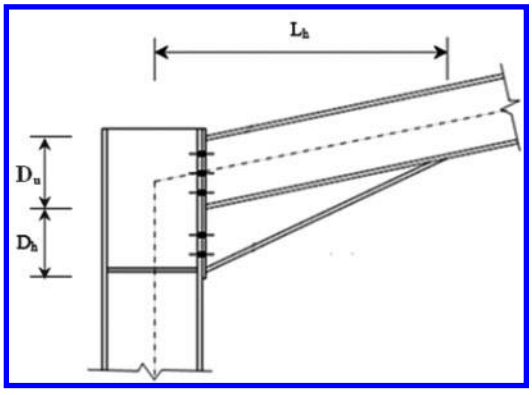

Figure 3. Details of eaves haunch.

For elastic design, the constraint g_5 is excluded and the design constraint g_{4P} is replaced by the constraint g_{4E} below:

$$g_{4E} = \frac{F_c}{A_g p_y} + \frac{M_x}{M_{cx}} - 1 \le 0 \qquad (3')$$

where g_1 = shear capacity; g_2 = axial capacity; g_3 = bending capacity; g_{4P} = reduced moment capacity for plastic design; g_{4E} = combined axial force and bending moment for elastic design; g_5 = constraint for plastic load factor; g_6 and g_7 = horizontal and vertical deflection limits, respectively (see Table 1); F_v = shear force; p_y = yield stress; A_v = shear area; F_c = axial force; A_g = gross area of cross-section; M_x = applied moment; M_{cx} = moment capacity of cross-section; M_{rx} = reduced moment capacity of cross-section; λ_P = collapse load factor for plastic design; δ_e and δ_a = deflections at eaves and apex, respectively; and superscript u indicates the maximum permissible deflection.

2.5 *Design variables*

The weight of frame is minimized by selecting the most appropriate cross-section for columns and rafters from the list of 72 Universal Beam cross-sections, S275 steel grade, along with optimizing the size of eaves haunch. It is assumed that the eaves haunch flange is the same as rafter flange and its web thickness is also the same as the web of rafter cross-section. The section properties of such haunches are calculated based on equations by Saka (2003).

In this paper, the haunch length (L_h) is varied in the range from [5%, 25%] of the frame span; haunch depth (D_h) varied from range of [$0.05D_u$, $4D_u$], with D_u being the depth of rafter cross-section inclined with the relevant pitch (see Figure 3). The cross-section of columns and rafters are processed as discrete variables, whilst the size of the eaves haunch, *i.e.*, haunch length and haunch depth is processed as continuous variables, using the optimal algorithms as described in the next section.

3 EVOLUTIONARY ALGORITHMS

3.1 *Real-coded genetic algorithm*

Real-coded genetic algorithm (RC-GA) is an evolutionary computation technique involving the principle of natural selection, such as survival of the fittest. The characteristic of RC-GA is that genetic operators are directly applied to the design variables without coding and decoding as with binary GAs. Solving optimization problems using RC-GA is therefore less cumbersome when compared to the binary-coded GAs (Deb 2001). The algorithm used in this paper randomly generates a set of solutions known as an initial population. From this population, the next generation of solutions is evolved by conducting three genetic operations: selection, crossover and mutation.

The steps for carrying out RC-GA are summarized as follows:

Step 1: Initial population of individual designs is constructed randomly. In the optimal design of the Benchmark Frame, the size of initial population (*Pop-size*) is selected, which is approximately larger than ten times the design variables. The probability for conducting crossover and mutation is set as 0.9 and 0.1, respectively (Deb and Gulati 2001, Phan et al. 2013b). The evolutionary process is terminated after 240 generations.

Step 2: Each candidate in the population is evaluated by calculating its fitness function that is applied to transform an optimization problem having design constraints to an unconstrained problem using penalty method. In this paper, penalty values are imposed empirically, in proportion to the severity of design constraint violation, which are checked through either plastic design or elastic design methods, as mentioned in Eq. 3.

Step 3: Elite strategy is applied to preserve the candidates having lowest/lightest fitness values for the next generation without being destroyed by random crossover and mutation operators. In this paper, two of best candidate is kept as offspring for the population in the next generation.

Step 4: Using the tournament selection randomly comparing the fitness values of two candidates, individuals are copied into the mating pool for crossing over and mutating, so that the better candidates may be created as in the natural selection. The SBX crossover and polynomial mutation is applied (Deb 2001). The individual that satisfies the design constraints and has the minimum weight is recorded.

Step 5: The initial population is replaced by the new population and steps 1–4 are repeated until a predefined number of generations is reached. This individual with the minimum weight of all generations is assumed to represent the fittest/best design.

3.2 *Real-coded niching genetic algorithm*

The real-coded niching genetic algorithm (RC-NGA) also uses five steps, as described in the RC-GA, to search for the optimum solution. However, the

difference with RC-GA is that two individuals are randomly selected and their fitness values compared if their distance is smaller than a critical one; this distance is empirically predefined, known as niching radius (Deb 2001). For the convenience of applying the niching strategy, the normalized distance, d_{ij}, between two individuals is calculated as follows:

$$d_{ij} = \sqrt{\frac{1}{n}\sum_{k=1}^{n}\left(\frac{x_k^{(i)} - x_k^{(j)}}{x_k^u - x_k^l}\right)^2} \quad ; \; 1 \le i, j \le Pop\text{-}size \qquad (4)$$

where n = number of design variables; $x_k^{(i)}$ and $x_k^{(j)}$ = corresponding kth decision variable in two vectors $x^{(i)}$ and $x^{(j)}$; x_k^u and x_k^l = respective upper and lower bounds of the kth decision variable.

If after a certain number of checks, no solution $x^{(j)}$ is found to satisfy the critical distance, $x^{(i)}$ is selected for the crossover operation. By this way, only solutions in same region (or niche) compete against each other for crossover. The application of niching strategy to crossover is referred to as mating restriction. The effect of niching technique is to maintain the diversity of the population by the preferential retention of candidate solutions from regions that are under-represented whilst simultaneously eliminating some of the candidate solutions from regions that are overcrowded based on the presumption that candidate solutions in the same neighborhood would tend to be similar.

4 DESIGN EXAMPLES

4.1 *Plastic design of Benchmark Frame*

In this section, the Benchmark Frame is designed plastically, using the plastic collapse mechanism (see Figure 4) under symmetric line load, w, obtained from the ultimate load combination (Davies and Brown 1996).

As can be seen in Figure 4, the frame collapses with the first plastic hinge forming at the underside of the haunch of the column, and the second plastic hinge forming along the rafter near to the apex; the sections between the hinges are assumed to remain rigid. It is worth noting that second-order effect is not considered in this paper since the frame geometry satisfies the sway check requirements (BS 5950-1 2000, and Lim *et al.* 2005).

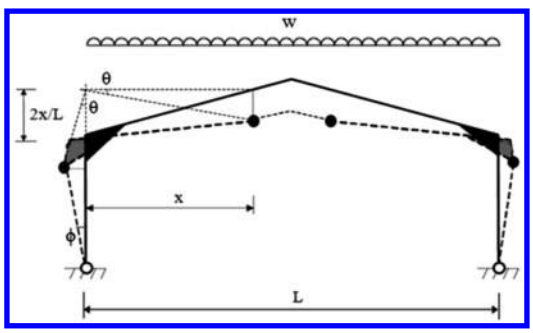

Figure 4. Plastic collapse mechanism under symmetric load.

The horizontal position of the second hinge (x), measured relative to the centerline of the left hand side column, can be determined from the following virtual work expression as follows (Davies and Brown 1996):

$$M_{cx_c}(\phi+\theta) + M_{cx_r}\theta = wx\frac{x\theta}{2} + w\left(\frac{L}{2} - x\right)x\theta \qquad (5)$$

where M_{cx_c} = moment capacity of column cross-section; and M_{cx_r} = moment capacity of rafter cross-section.

Based on such a collapse mechanism, the internal forces, namely, bending moment, shear and axial forces are determined for the ultimate limit state design, whilst elastic analysis is used to determine the deflections at the eaves and apex of the frame, under the serviceability load combinations. Industry deflection limits are used for serviceability limit state design (Phan *et al.* 2013a).

For the optimization of Benchmark Frame using RC-GA, three population sizes of 40, 80 and 120 are used to investigate its capacity of convergence to the optimum solution. RC-GA was run 10 times to check for the consistency of the result. Table 2 shows the best solution obtained after number of trials.

It can be seen from Table 2 that the best design obtained from the RC-GA is improved when the population size increases. The population size of 40 does not generate the design as good as the design obtained from these population sizes of 80 and 120. The RC-GA shows the best performance with the population size of 120.

The minimum unit weight obtained is 19.21 kg/m^2. It is also observed in Table 2 that the population in the last generation from the evolutionary process is dominated by the best solution, in which the diversity of population in later generations has been significantly reduced, as compared to the initial population.

Details of the best design obtained from the RC-GA are shown in Table 3.

As can be seen, the optimum haunch length accounts for 13% of frame span, which leads to a lighter cross-section assigned to the rafter, as compared to the frame design in SCI example. The design obtained from RC-GA is 5% lighter than the SCI frame design. It is observed that the ultimate design constraint governs the optimal design with plastic collapse load factor achieving the unity, *i.e.*, $g_5 = 0$, whilst the

Table 2. Effect of population size on RC-GA.

Pop-size	Minimum weight (kg/m^2)	Average weight (kg/m^2)	Maximum (kg/m^2)	Function evaluations
40	22.80	22.80	22.80	96000
80	19.21	19.21	19.21	32000
120	19.21	19.21	19.21	28800

constraints of such factor for the SCI frame is not active, *i.e.*, $g_5 = -0.04$.

For the optimization using RC-NGA, three population sizes of 40, 80 and 120 are also used to investigate its capacity of convergence to the optimum solution. The critical distance of niching radius is found 0.25 when the proposed algorithm shows the best performance. The results obtained after 10 trials from the optimization with each population are shown in Table 4.

As expected, RC-NGA generates the same minimum weight as the best design obtained from the RC-GA, with details of frame as shown in Table 3. It is interesting to see in Table 4 that the distribution of population in the last generation still shows the diversity of individuals and RC-NGA can effectively search for the optimum solution with small population size of 40 individuals. The computational time is therefore reduced by 66.7%.

4.2 *Elastic design of Benchmark Frame*

In this section, the Benchmark Frame is designed with elastic method for both ultimate and serviceability limit state. A first-order elastic analysis using the general purpose finite element package ANSYS (ANSYS Inc. 2009) is used to analyze the portal frame. The frame is optimized based on the steps as described in Section 3. For serviceability limit requirements, either industry or SCI deflection limits are applied to the optimization.

Based on the appropriate population size observed in the plastic design, the RC-GA with population size of 120 is used to optimize the Benchmark Frame. The consistency of optimal result is considered through 10 times of trials.

It is observed that RC-GA converges to the optimum solution within the predefined number of generations. The minimum weight of the Benchmark Frame with industry deflection limits is 21.12 kg/m^2 and that with the SCI deflection limits is 24.34 kg/m^2. As can be seen, the Benchmark Frame with using SCI deflection limits is 27% heavier than the same frame with plastic design using industry deflection limits. Details of the best design obtained after running 10 times of trials are shown in Table 5.

As can be seen in Table 5, the optimum haunch length of the Benchmark Frame using industry deflection limits accounts for 14% of frame span. With the stringent requirement of the SCI deflection limits, the haunch length accounted for 17% of frame span.

The ultimate design constraint governs the optimal design of Benchmark Frame with industry deflection limits; the critical constraint of strength at the shallow end of the eaves haunch nearly achieved the unity, *i.e.*, $g_{4E} = -0.01$. However, using the SCI deflection limits, it is observed that the constraint of vertical deflection at the apex of Benchmark Frame governs the optimal elastic design, *i.e.*, $g_7 = 0$.

For the optimization using RC-NGA, it is found that the population size of 40 candidates is suitable to search for the optimum solution. The critical niching distance is also 0.25. It was observed that 10 runs converged to the same optimum solution with same design as shown in Table 5, for either industry or SCI deflection limits.

Figure 5 shows the progress of RC-NGA converging to the optimum solution for the Benchmark Frame under industry serviceability requirements. As can be seen, RC-NGA converged to the best solution after 230 generations. The diversity of the population can be observed in Figure 5 through the distribution of minimum, mean, and maximum values, whilst these values become the same in the RC-GA after around 75 generations. This fact demonstrates the limit of RC-GA, as compared to RC-NGA.

The computational time for solving the optimization problem, with the population of 40, was 8.0 hours, for a laptop machine having a processor speed of 2.0 GHz and memory of 2.0 GB RAM.

5 CONCLUSIONS

The effect of serviceability limit state on the optimal design of steel portal frame with haunch rafter is considered with a frame span of 30 m, under the action of gravity loads. When the cladding system does not require stringent deflection limits, industry suggestions for deflection limits can be used; the constraint for ultimate limit state governs the design. If the concern of cladding damage, owing to frame deflection, is considered, more stringent deflection limits from the SCI can be applied. The optimal design of the benchmark frame using SCI deflection limits is 27% heavier than optimal plastic design of such frames using industry deflection limits and 15% heavier than optimal elastic design of such frame, also using industry deflection limits.

The evolutionary algorithms, namely, RC-GA and RC-NGA have demonstrated the robustness and efficiency in searching for the best solution in design space. The mixture of design variables, *i.e.*, discrete and continuous variables is effectively processed by the proposed optimal algorithm using real parameters. The effect of niching method in maintaining the diversity of the population is also investigated and it is found that a small population size can be applied, as described in the RC-NGA. The computational time is therefore reduced by 66.7%, as compared against the RC-GA.

Optimization of the injection molding processes using the Moldflow simulation program on the example of electrical connectors

M. Szostak & R. Staniek
Poznan University of Technology, Poznan, Poland

ABSTRACT: The paper presents the optimization process of two prototype injection molds for the production of electrical connectors. Simulation using the Moldflow2012 program shows the filling processes of injection molds in terms of manufactured products quality. The simulation showed only the minor hazards (during the filling and packing phases) that can occur during the manufacturing of these two parts. After finishing the computer simulation, on the selected injection molding machines the optimization of the production parameters were carried out for both molds. As a result of the optimization carried out, it was possible to shorten the cycle time for manufacture of the products, respectively: from 10.1 s to 9.1 s for the first product and from 9.5 s for 8.5 s for the second one. As a result of the work it was possible to increase the efficiency of the manufacturing process and reduce the manufacturing costs of those parts.

1 INTRODUCTION

The task of the work was to prepare the initial 3D models of injection molds selected for the production and carried out simulation studies of the filling process in terms of shortening the cycle time and reduce internal stress and improve the quality of chosen products. These include the analysis of the polymer filling of the molds, determining of the injection pressure value, the pressure drop during the process, temperature of the front of flowing material, the orientation of the surface and the average temperature of the products, the time to obtain a temperature which allowed to remove the products from injection mold, areas of rapid solidification, shrinkage of the products, air traps, weld lines, differences of products temperature and cooling time, distortions associated with the differentiation of molding cooling, shrinkage and orientation of the products. In this paper filling simulations of two selected prototype injection molds has been presenting, allowing determining the parameters such as the time of filling the mold material and the potential closure of the gas. The results of the analysis are used to design optimal cooling channels, optimal points for ejectors and venting points.

2 MOLDS AND MATERIALS

Two molds with number 7344 and 7405 has been selected for the analysis and it was assumes that in both cases the products are made from PA 6.6. type FRIANYL A63 RVO. The two products obtained on the chosen molds are shown at the figure 1 and 2.

Figure 1. The view of product no 7344.

Figure 2. The view of product no 7405.

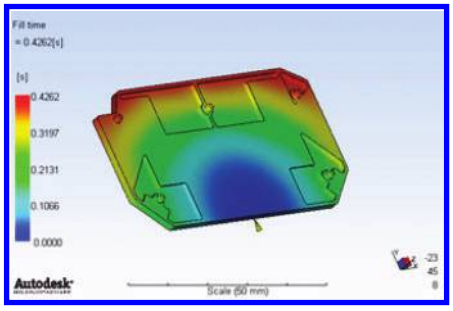

Figure 3. Study for the mold 7344: Fill time.

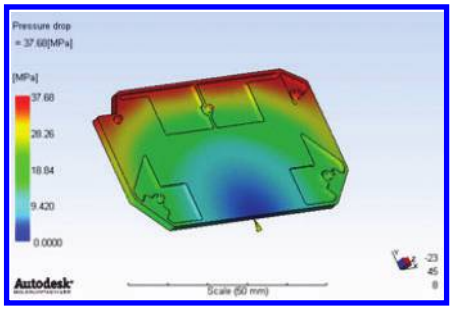

Figure 4. Study for the mold 7344: Pressure drop.

3 MOLDFLOW SIMULATION

3.1 *Results for the mold 7344*

On the figures 3–9 the results of a few selected analyzes made ??by the program are presented. Autodesk Moldflow is showing all phases of the process, and indicating the potential hazards of the process and its possible impact on the quality of the manufactured part. These include the analysis of the filling time of the mold, the injection pressure, the pressure drop during the process, the temperature of the front of flowing material, the orientation of the surface of the molding, the average temperature of the molding, the time to obtain a molding temperature allowing the product for removal from the injection mold cavity, areas of rapid solidification, shrinkage of molding, air traps, weld lines, locations of possible subsidence, differences in molding temperature, cooling time and its spread, distortions associated with the molding cooling temperature differences and molding contraction. On the drawings 3–9 selected seven important parameters describing the process of injection molding products has been shown.

Summarizing the simulation results for the mold 7344 it can be concluded that the Moldflow program pointed out that the main problem in the molding process is associated with scattering of the cooling time of individual areas of the molding which is caused by non-uniform wall thickness of the product. In addition, the program pointed out the possibility of quality problems of the molds associated with filling and holding pressure phases. Simulation showed no problems

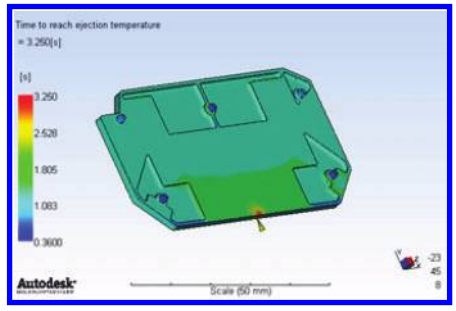

Figure 5. Study for the mold 7344: Time to reach ejection temperature.

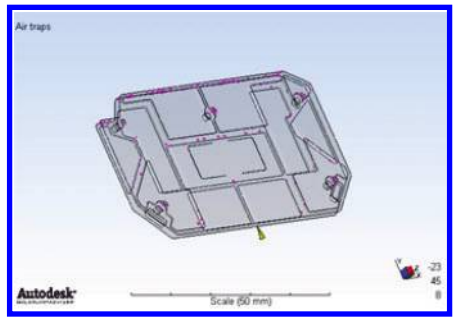

Figure 6. Study for the mold 7344: Air traps.

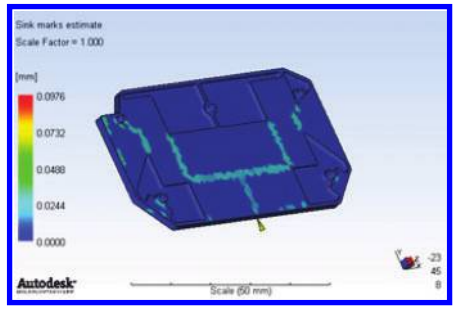

Figure 7. Study for the mold 7344: Sink marks.

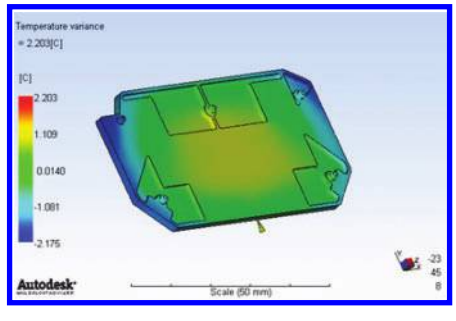

Figure 8. Study for the mold 7344: Temperature variance.

related to sink mark on the molding surface or its deformation. Calculated process times were: filling time 0.41 s, holding pressure time 1.5 s, cooling time 3.5 s, the time to open the mold 5.44 s and the total cycle time 10.85 s (see Figure 10).

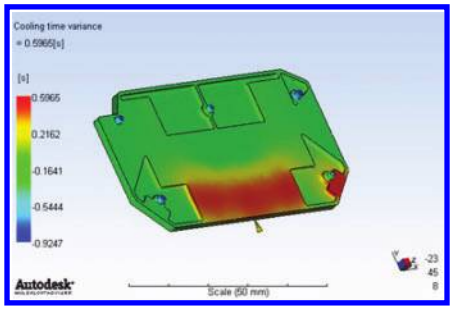

Figure 9. Study for the mold 7344: Cooling time variance.

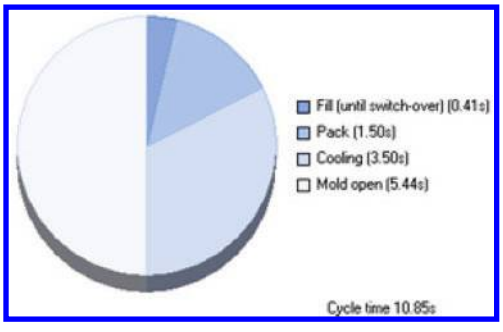

Figure 10. Graphic presentation of the total cycle time for the mold 7344.

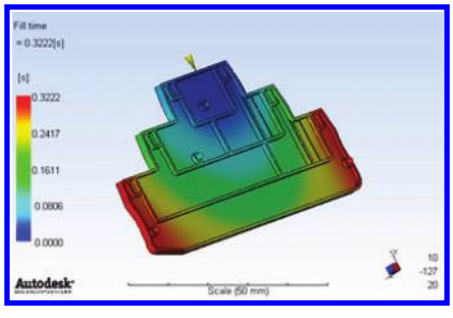

Figure 11. Study for the mold 7405: Fill time.

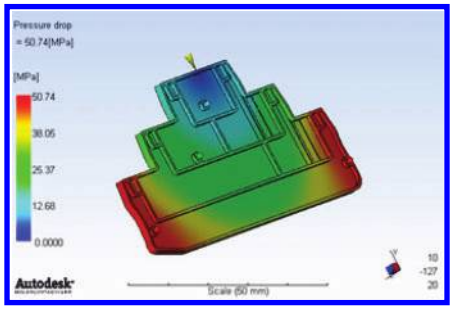

Figure 12. Study for the mold 7405: Pressure drop.

3.2 *Results for the mold 7405*

Below, similar like for the mold no.7344 on figures 11–18 has been shown the results of analysis performed by the Moldflow program showing all phases of the process and indicating the potential hazards of the process and its possible impact on the quality of the manufactured part.

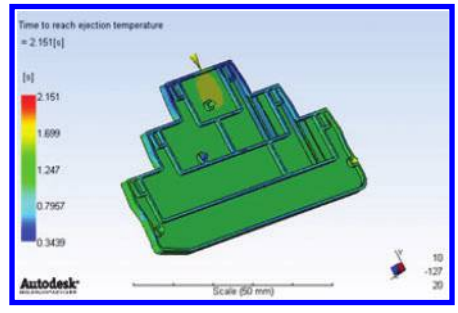

Figure 13. Study for the mold 7405: Time to reach ejection temperature.

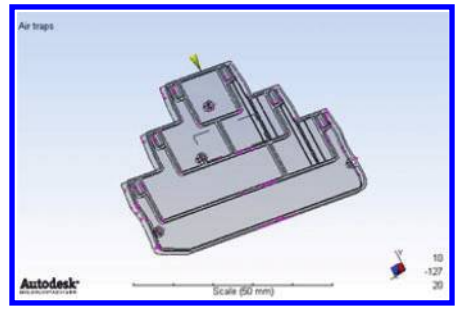

Figure 14. Study for the mold 7405: Air traps.

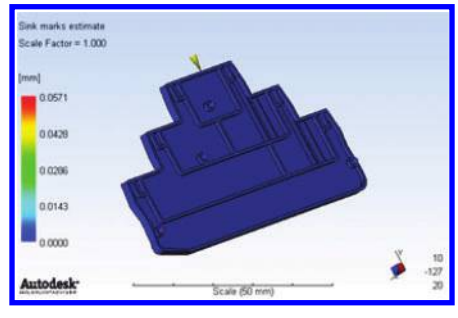

Figure 15. Study for the mold 7405: Sink marks.

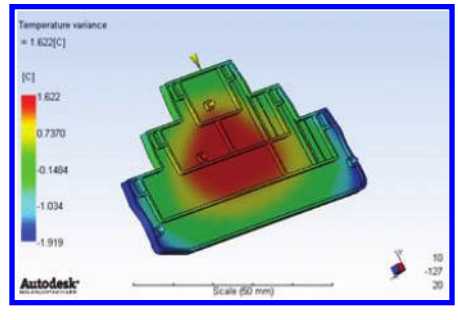

Figure 16. Study for the mold 7405: Temperature variance.

Summarizing the simulation results for the mold 7405 it can be concluded that the program Moldflow indicated a possibility of molding quality problems associated with filling and holding pressure phases. Simulation has not revealed any problems with the

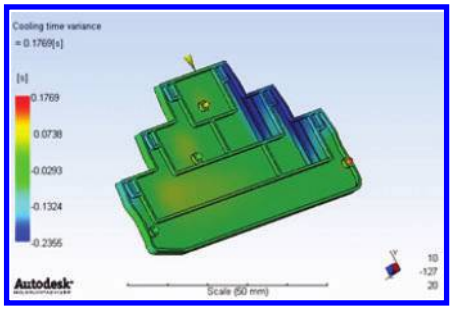

Figure 17. Study for the mold 7405: Cooling time variance.

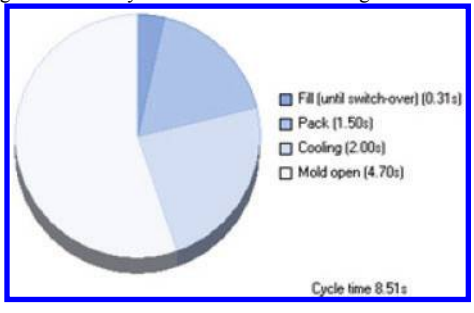

Figure 18. Graphic presentation of the total cycle time for the mold 7405.

molding and cooling. As in the previous mold any problems related to the sink mark on the molding surface or its deformation has been observed. Calculated process times were, respectively: filling time 0.31 s; holding pressure time 1.5 s; cooling time 2.0 s; the time to open the mold of 4.70 s and the total cycle time of 8.51 s (see Figure 18).

4 PROCESS OPTIMIZATION ON THE INJECTION MOLDING MACHINES

After testing the mold filling process of prototypes mold using the simulation software in terms of the quality of the molded parts, as well as the efficiency of the injection molding process, the optimization process of the injection parameters, for these two molds, on selected production machines has been carried out. For the optimization of the injection molding process the two DEMAG injection molding machines, D-50 for the 7344 mold and D-35 for the 7405 molds, has been chosen.

Three attempts were made to optimize the injection molding process for each of these molds (7344 and 7405). Within the framework of the optimization process mainly the following settings: temperatures in plasticizing cylinder, injection pressure, injection speed, dosing time, cooling time, holding pressure time, has been changed.

As a result of the optimization process, without degrading the mechanical properties and surface moldings quality, we have managed to reduce the cycle times by 10.5% for the mold 7405 and 12.4% for the 7344 mold. Visualization of reducing cycle times for all the forms are shown in figures 19 and 20.

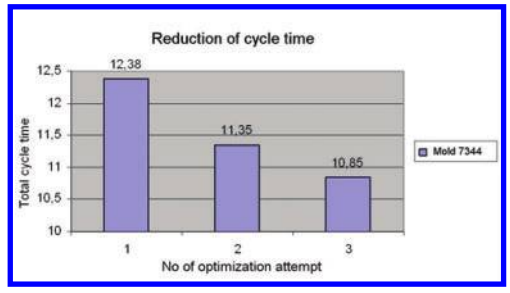

Figure 19. Cycle times after optimizing the injection molding process on the mold 7344.

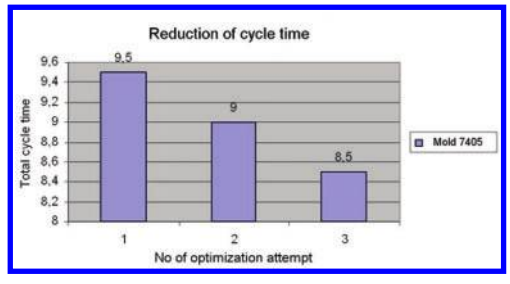

Figure 20. Cycle times after optimizing the injection molding process on the mold 7405.

Optimization of the production process for a 7344 mold enabled the cycle reduction of the 1.53 seconds which is about 12.4% of the total cycle time.

Optimization of the production process for a 7405 mold enabled the cycle reduction of the 1.0 seconds which is about 10.5% of the total cycle time.

5 CONCLUSIONS

Conducted simulations of the injection molding process for the two prototype injection molds showed only minor hazards that can occur during a production process.

Larger risks arising from the diversity of molding wall thickness can occur for the mold 7344.

The simulation for 7405 mold shows only a small possibility of molding quality problems associated with the filling and packing phases.

Practical tests on the injection molding machines made with use of the technological parameters identified in the simulation showed no technological problems and quality of products manufactured on that two molds.

The studies have shown that design of the molds is correct and guarantees a good quality product at a high injection efficiency of the described products.

Comparison of simulation results of injection molding process obtained by MoldFlow and Moldex3D programs

M. Szostak & R. Staniek
Poznan University of Technology, Poznan, Poland

ABSTRACT: The paper describes the problem of difference in computer simulation's results of injection molding process. In this paper the results from Autodesk Moldflow Insight and CoreTech Moldex3D are compared. In both programs obtained parts were free from quality defects, however their output properties were different. Analyzed simulation systems showed compliance in the calculation of cycle time and injection volume. The calculated clamping pressure was similar to that shown in the experimental test. For the calculation of air bubbles, the programs showed only the qualitatively similar results. Areas of occurrence of defects were similar, but their number varies. Proper preparation of the model and parameters of the simulation depends on the user and his knowledge of the injection molding process. This, how the simulation will be carried out, has an impact on the output results of the simulation, which in the face of a real process may sometimes mislead the users.

1 INTRODUCTION

The aim of the study is a comparative analysis of the results of computer simulations of the injection molding process made in Autodesk Moldflow and Moldex3D CoreTech programs on the example of molding used in the electrical industry. The study shows also the differences in the obtained results from simulations and an attempt to determine their origin.

For the purposes of the simulation the geometry of the connector used in the electrical industry, made of PA 6.6 has been prepared. Model details in both programs are presented in Figure 1 (MoldFlow) and Figure 2 (Molde3D). In the table 1 the actual parameters of the injection molding process used in the manufacturing plant for the production of this piece are shown.

Computer simulation of injection molding process must be preceded by the preparation of a model part. Depending on the type of software, the process is carried out in separate modules of the package or with the main program. In the case of the "Moldflow" program: import geometry, FEA mesh application, the choice of material, the definition of injection points, selection the type of simulation and the cooling system is possible without the use of additional modules. In the case of the "Moldex3D", the above processes except to choice of material and the type of simulation are defined in the subprogram "Moldex Designer".

Table 1. Injection molding parameters set on the machine.

Parameter	Value
Temperature zone 1 [°C]	268
Temperature zone 2 [°C]	265
Temperature zone 3 [°C]	265
Nozzle temperature [°C]	270
Screw moving [ccm]	28
Switch point [ccm]	8
Residual pillow [ccm]	6.6
Decompression [ccm]	3
Backpressure [MPa]	7
Injection speed [ccm/s]	28
Injection pressure [MPa]	64
Holding pressure [MPa]	25
Clamping force [kN]	500
Injection time [s]	0.96
Holding time [s]	2.0
Dosing time [s]	1.38
Cooling time [s]	5.0
Cycle time [s]	13.0

Table 2. Processing parameters introduced to the "Moldflow" program .

Parameter	Value
Mold temperature [°C]	70
Injection temperature [°C]	270
Mold opening time [s]	5
Cycle time [s]	8
Polymer speed [ccm/s]	5
Switch point [s]	0.96

2 MOLDFLOW SIMULATION RESULTS

Based on the entered injection molding parameters (Table 2) the molded part without quality defect was obtained. Complete filling of the mold cavity will take place earlier than switching into holding pressure phase. This is related to the high speed of material flow set on 5 cm/s. If we will use a lower value, filling time would be longer, but there is risks that switch to the packing process will appear before the end of the injection phase. Simulation result did not show a significant numbers of voids. These sites are the result of retention of air or gas bubbles due to plastic flow fronts. They are present in the space between the two injection points and at the edges of the geometry. We can prevent to avoid them by changing the distribution of injection points and using the ejectors in the places their appear.

Analyzing the pressure distribution at the end of the injection phase, we will find a significant drop in pressure on the molding side with a single point of injection and the even distribution of pressure on the molding side with two injection points. The minimum pressure is visible in the farthest part of the molding on the side with a single point of injection. In this section,

Table 3. Processing parameters introduced to the "Moldex3D" program.

Parameter	Value
Mold temperature [°C]	80
Injection temperature [°C]	285
Mold opening time [s]	5
Injection time [s]	0.96
Polymer speed [ccm/s]	15
Switch point [%]	98
Holding pressure time [s]	2

the temperature at the front of plastic is also the lowest. This results in the greatest deformation in that part of the connector of nearly 0,5 mm.

3 MOLDEX3D SIMULATION RESULTS

With the assumed parameters of the injection molding process, the simulation shows the obtained molding without quality defects. Injection time was set at 0.96 sec and the pressure switch point at 98% of filling the cavity volume.

The simulation showed the possibility of appearing the number of air bubbles, especially in the areas of the pivots, and on the geometry surfaces. The largest number of voids is located on the inner side of the part.

In the case of pressure distribution at the end of the injection phase, it can be observed a significant decrease of pressure on the molding side with a single point of injection. The polymer in this part of the geometry flows more slowly, so the time to fill a cavity is longer, as is confirmed by the measurements of the injection time.

The temperature at the front of the flowing polymer is uniform and is about 285°C, being close to the set point of injection temperature. This is indicated by a uniform color throughout the entire volume of the mold. The characteristic distribution of the results allows obtaining similar properties in the cross-section geometry of the product. The only decrease of the temperature at the front of flowing polymer was recorded on the surface of the hinge connecting of the two parts of the product.

The thickness of the hinge is much lower than the wall thickness of the part. The analysis showed no overcooling or overheating points on the part. Distribution of volume contraction, which contributes to the deformation of the product, is also uniform. In the areas most distance from the injection points, is about 10%.

4 COMPARIZON OF THE SIMULATION RESULTS

In table 4 the results of the simulation are comapred with the data obtained in the experiments on the

Table 4. Comparison of the computer simulations results with machine parameters.

Processing parameters	Moldflow	Moldex 3D	Injection test
Injection time, [s]	0.54	0.96	0.96
Injection temperature, [°C]	270	285	270
Mold temperature, [°C]	70	80	70
Real injection pressure, [MPa]	97.6	28	64
Injection volume, [ccm]	2.42	2.43	
Holding time, [s]	2.0	2.0	2.0
Holding pressure, [MPa]	29.3	17.75	25
Switch point	0.96 s	98.00%	8 ccm
Mold opening time, [s]	5.0	5.0	5.0
Cycle time, [s]	13.00	12.96	13.00
Total weight, [g]	2.6001	2.485	2.6
Polymer flow speed [ccm/s]	5,0	2.53	5
Clamping force, [T]	2.2	11.87	50
Calculation time (for injection and holding phase)	1 h 26 min	2 h 24 min	–

injection molding machine. We can notice a difference in the definition of the switching point. For "Moldflow" program it is given in seconds – 0,96 s, for "Moldex3D" in percentage of the volume of the cavity – 98% and for real machine parameters in ccm – 8 ccm. The greatest difference in the results was observed for the injection pressure which was the result of different speed of the polymer flow.

5 CONCLUSIONS

Received results of injection molding process in Autodesk Moldflow Insight and CoreTech Moldex3D programs have shown that the obtained parts were free from quality defects, however their output properties were different. Analyzed simulation systems showed compliance in the calculation of cycle time and injection volume. The calculated clamping pressure was similar to that shown in the experimental test. For the calculation of air bubbles, the programs showed only the qualitatively similar results. Areas of occurrence of defects were similar, but their number varies. Due to the time-consuming process connected with preparation of model of the produced part, very important become the computation time. In the case of "Moldflow" program, this time was much shorter, the calculation last for 1 h 26 min, while for the "Moldex3D" – 2 h 24 min. Proper preparation of the model and define the parameters of the simulation depends on the user and his knowledge of the injection molding process. This, how the simulation will be carried out, has an impact on the output results of the simulation, which in the face of a real process may mislead the users. In the case of the purchase cost, it is significantly higher for the "Moldflow" program. However, the price is justified, because the program is obtained with a highly developed data base of polymer material, with a user-friendly interface and with relatively fast computational processes. Engineering support programs help users to reduce the number of experimental trials carried out. These decrease the start up time of the new product, as well as reduce the cost of its implementation. However, some knowledge of the injection process and training of the program user is required to obtain the intended benefit after purchasing the simulation program.

ABSTRACT: Severe Plastic Deformation (SPD) such as Equal Channel Angular Extrusion (ECAE) and three-Axis forging are now standard methods employed to strengthen structural metals. Here, we assess the viability of a modified three axes forging method (an SPD technique) for pre-processing of high purity Niobium, used for Superconducting Radio Frequency Cavities (SRFC) fabrication. Starting with a Nb of hardness and grain size of HVN 52.4 ± 2.5 and $139 \pm 118\,\mu$m, respectively the processing resulted in a significant increase in hardness to HVN 100.2 ± 5.2 ($D = 97.52 \pm 41.15$), and an average HAGB of 10%, after only one cycle of deformation. Although additional cycles of deformation produced modest increase in hardness, the microstructure underwent substantial refinement and homogenization to the extent that the grain size was about $1.41 \pm 0.46\,\mu$m (HAGB of 61%), after 16 cycles. Comprehensive analysis of the microstructure and hardness using Orientation Imaging Microscopy and Vickers microhardness techniques, respectively clearly indicated that two processing regimes existed during the use of modified three axis forging: at low strain ($\varepsilon \leq 2.6$), in which grains segment into deformation bands or cell blocks (or subgrains), the percentage of High angle boundaries is low (HAGB $\leq 10\%$). At high strain ($\varepsilon \geq 2.6$), orientation splitting occurs leading to significant grain refinement and increase in the HAB%. It can be concluded that the 3-axis forging of Nb using reshaping die resulted in the production of billet with microstructure and microtexture suitable for the manufacture of superconducting radio frequency cavities.

1 INTRODUCTION

1.1 *Superconducting radio frequency cavities*

Superconducting radio frequency (SRF) technology involves the application of electrical superconductors to radio frequency devices. The material of choice for Superconducting Radio Frequency Cavities (SRFC) is pure Niobium. The cavities are traditionally made of Niobium sheets, which are deep drawn or spun into half cells and then e-beam welded together to form multi-cell accelerator cavities as shown in Figures 1a&1b.

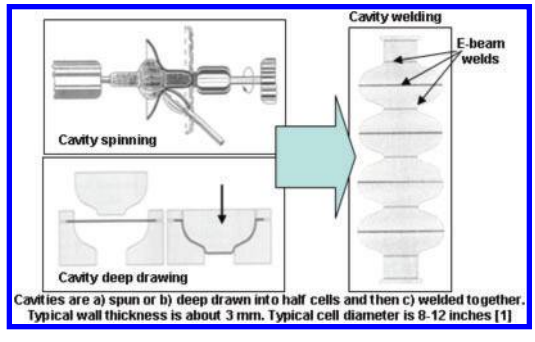

Figure 1. Schematic showing how superconducting radio frequency cavities are spun or deep drawn into their required geometry and e-beam welded together. Typical cell wall thickness is about 3 mm. (Padamsee, 2008).

Deep draw-ability of the sheets used for manufacturing SRFCs depends heavily on the microstructure and texture of the niobium sheet. Unsuitable microstructure or texture can lead to a variety of issues during cavity manufacturing. Of paramount importance is the electrical resistivity, which needs to be ultra-low in order to allow the Radio Frequency resonator to obtain an extremely high quality factor, Q. Production of bulk quantities of Nb with favorably refined microstructure and texture through the use of innovative severe plastic deformation methods is currently being explored to facilitate easier manufacture and improved function of SRFCs. This study examines the suitability of a modified three axes forging method as an SPD technique for producing the

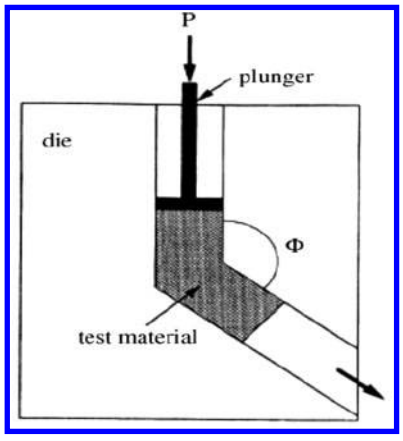

Figure 2. Schematic diagram showing equal channel angular pressing process (Cherukuri, 2005).

requisite microstructure and texture in Nb for the production of SRFCs. The requisite microstructure and texture for niobium for SRFC manufacture include: uniform, equiaxed (grain shape aspect ratio ≤ 2), fine grain ($\leq$50 μm) microstructure required to avoid tearing/surface roughness during deep drawing or spinning; sufficiently high percentage of high angle grain boundaries ($\geq$60%) for complete and continuous recrystallization during annealing.

1.2 *Severe plastic deformation (SPD)*

Severe plastic deformation process is any metal forming operation in which a very high level of plastic strain is imposed on a material (Azushima, 2008). Although there are different definitions of what is considered to be severe plastic strain, a convenient convention was laid out by Prangnell, 2007:

- low strains : $\varepsilon < 2$
- low medium strains $\varepsilon = 2 - 4$
- medium to high strains $\varepsilon = 4 - 6$
- ultra/very high strains $\varepsilon > 6$

Significant reduction in cross-sectional area results when conventional methods such as rolling, wire drawing or swaging are used to achieve severe plastic deformation. However, with Equal Channel Angular Extrusion (ECAE) method there is little or no reduction in the cross sectional area of the deformed piece. The technique of Equal Channel Angular Extrusion entails pressing a billet through a die made of two intersecting channels of equal cross section as shown in Figure 2 (Cherukuri, 2005).

Shearing deformation is imposed on the material at the bend region. Deformation is achieved through a combination of shear strain and redundant deformation (Prangnell, 2007). This results in the material being plastically strained while the cross sectional dimensions of the work piece are maintained

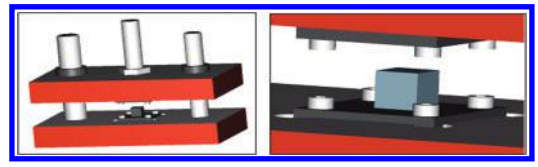

Figure 3. Three axis forging apparatus and the position of billet (the MTS hydraulic press not shown).

(Azushima, 2008). The work pieces must be either square bars or round rods. Recently, research has been undertaken to scale the method up for refining sufficiently large ingots of niobium for SRFC manufacture (Hartwig, 2007). ECAE processing is limited by the billet geometry. Therefore, there are efforts to use another form of severe plastic deformation process, known as the three-axis deformation method as an alternate method of processing the microstructure (see Fig. 3). In this case, the work piece, usually of cube dimension, is compressed in the 3-Orthogonal axis to complete a cycle. This method of processing has been shown to be capable to refine microstructure of copper (Belyakov, 2003) and other materials (Azushima, 2008).

Most severe plastic deformation methods have not yet been fully developed for industrial scale production of SPD material, and there is a great deal of continuing research into the development of SPD technology.

1.3 *Applications of severely plastically deformed materials*

There are a number of applications and potential applications that can capitalize on the ultra fine-grained materials resulting from severe plastic deformation. The applications range from military (lighter and more durable armor plates and more effective armor penetrators), medical (UFG titanium for joint implants), electronics (nano-scale grained sputtering targets), to aerospace (airframe weight reduction through the usage of lightweight UFG components). A comprehensive review of most of the applications of severe plastic deformation can be found in a 2008 study on SPD technology (Azushima, 2008), which illustrates the current state of SPD processes for engineering metals and alloys. It is noted that grain refinement through SPD can serve as an alternative to alloying as a means of material strengthening. This is forecasted to lead to greater simplicity, cost reduction and easier recycling of waste metals (Azushima, 2008) and (Han, 2008). In the study reported here, we assess the viability of a modified three axes forging method (an SPD technique) for pre-processing of high purity Niobium, used for Superconducting Radio Frequency Cavities (SRFC) fabrication. It is our believe that the manufacture of niobium RF cavities stands to benefit substantially from advances in SPD technology.

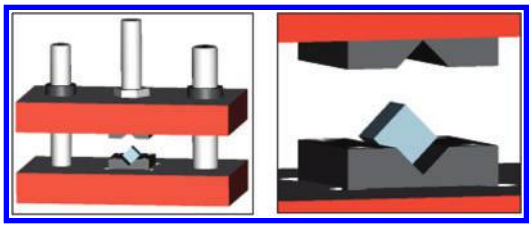

Figure 4. Re-shaping die and the position of the billet (MTS hydraulic machine not shown).

Table 1. A list of three axis forged niobium samples.

Three axial forging strain	# of Cycles	Mean strain per cycle
$\varepsilon = 0.65$	1	0.65
$\varepsilon = 1.33$	2	0.68
$\varepsilon = 2.60$	4	0.65
$\varepsilon = 5.20$	8	0.65
$\varepsilon = 10.0$	16	0.63

2 MATERIALS AND EXPERIMENTAL

2.1 *Material*

High purity grade of niobium (purity 99.99%) known as Residual Resistively Ratio grade was used in this study. The material was supplied by Ati-Wah Chang Allegheny Technologies. This type of niobium is used in the manufacture of superconducting radio frequency cavities for particle accelerators. Niobium purity is of importance as inclusion atoms can severely degrade cavity performance. In order to be of this grade, it was manufactured using the electron beam melting technique, which causes impurities to outgas prior to ingot solidification.

2.2 *Three axis forging*

The three axis forging apparatus used for this work comprised of a two post Danly die set fitted with hardened D2 tool steel forging surfaces which were set in and bolted to the die as shown in Figure 4. Die surfaces were finely ground using 3 μm diamond solution. The billets for forging were in the form of 15 mm cubes cut to size by electron discharge milling (EDM) and finely polished on all sides with P4000 silicon carbide paper. The tool steel forging platens were cleaned with alcohol and inspected for surface flaws or visible scratches. Damaged forging platens were removed and re-polished with a silicon carbide paper followed by 3 μm diamond solution. Platens then were lubricated with several coats of colloidal graphite lubricant prior to each forging. The strain per pass (i.e. 1 uniaxial compression) was approximately $\varepsilon = 0.2$ for a total of $\varepsilon = 0.6$ per cycle (i.e. 3 compressions). The imposed true strain for each compression pass was determined by the formula:

$$\varepsilon = \ln(h_0/h) \tag{2.1}$$

Where h_0 is the initial height and h is the height after the billet has been compressed. The total strain was the summation of the strain imparted during each compression pass. Dimensions of the billet were taken in between compression passes. The actuator on the hydraulic press was set to move at a standard compression rate of 0.015 mm/s for both forging and reshaping and for both materials, which provided an average strain rate of 0.001/s. The load cell was set to record stroke height and load data at a sampling rate of 1 Hz. A list of the samples and their forging strains are listed in Table 1.

2.3 *Re-shaping apparatus*

The reshaping dies (also made of hardened D2 tool steel) could also be fitted to the same die set (Figure 4) and used to undo undesired warping of the billet. The platens were a pair of thick plates with 90 degree grooves that combined together formed a square channel matching the exact geometry of the work piece. The reshaping dies were used as needed in between cycles to re-shape the billet, thereby returning it to its original cube shape before any subsequent three axis forging would be done.

2.4 *Vickers hardness testing*

Vickers hardness testing is a common and fairly simple non destructive test for mechanical properties. It is widely employed in studies on SPD of niobium and other materials (Mathaudhu 2006). The Vickers hardness testing machine imparts a specified load for a set amount of time to a surface using diamond indenter of a distinct geometry. It produces a Vickers Hardness Number, which is a measure of material hardness. The size of the indent was measured and used in conjunction with the load on the Vickers hardness equation to give a Vickers hardness number. By indenting the entire surface, it was possible to produce a hardness map, which can be used to assess the level of homogeneity of the hardness in a material following processing. In each case a matrix of indents (totaling 576 in the form of a 24×24 square array) was done over the sectioned face to generate a hardness map.

2.5 *Orientation imaging microscopy*

Orientation Imaging Microscopy (OIM) is a fully automated Electron Back-Scattered Diffraction (EBSD) technique. Electron Back Scatter Diffraction (EBSD) is a scanning electron microscopy (SEM) based technique widely employed as a material characterization technique used to determine localized crystallographic orientation and microtexture (or preferred crystallographic orientation). EBSD has been used to routinely determine grain boundary character distribution, grain

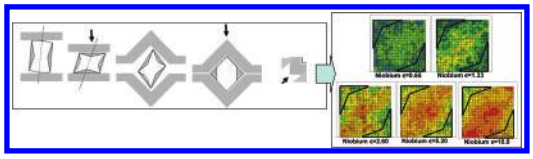

Figure 5. Diagrammatic representation of how reshaping leads to the formation of dead corners (indicated by gray cross hatchings) where there is less strain than the bulk material.

diameter, grain shape, microtexture in studies of niobium (Hartwig, 2007 and Mathaudhu 2006) and copper (Zhao, 2008), subjected to SPD. Investigation of microstructure and microtexture of the SPD materials is often carried out using automated EBSD.

3 RESULTS AND DISCUSSION

3.1 *Vickers hardness*

The Vickers hardness data is provided as a hardness map (a matrix of indents totaling 576 in the form of a 24×24 square array) over the entire sectioned face of the sample. With the exception of the increasing contour level with strain, the hardness profiles of all the samples were similar (see Figure 5). The variation and the shape of the hardness profile can be traced back to the use the reshaping die, which subjected the samples to additional compression along one diagonal in order to return it to cube shape. Because of the inhomogeneity in hardness, three main regions can be identified, and they are: dead corner, core region and compressed corner.

During uniaxial compression the areas of a deformed billet that are near to the forging surface are restricted by friction from free outward expansion. Within these areas, cone shaped regions called dead zones form, which experience less deformation (Figure 5) than the bulk material. Lubrication and polishing of forging surfaces can reduce the size of the dead zones however they are unavoidable. However, during reshaping, samples are subjected to an additional compression along one diagonal to return it to cube shape. This results in additional strain within the region aligned with compressed diagonal. The area that sees this additional straining consists of the core and deformed corners. Conversely, dead corner areas form in the off-diagonal billet corners where there is no additional strain during reshaping (Figure 5).

The Vickers hardness of the processed samples, ranging from cycle 1 to cycle 16 are presented in the form of contour plots, which are superimposed on the plot of hardness versus strain (number of cycles) in Figure 6. It is evident that Niobium strain-hardened very fast at the early stages ($\epsilon = 0.65$) of the processing. Strain hardening was gradual in the intermediate stage ($0.65 \leq \epsilon \leq 2.6$) and then taper off

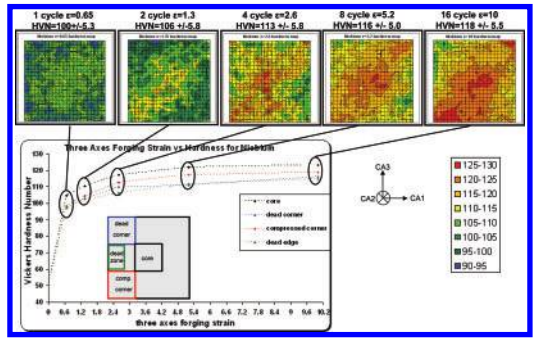

Figure 6. Plot of Vickers hardness as a function of strain for various regions of billets of three axes forged niobium.

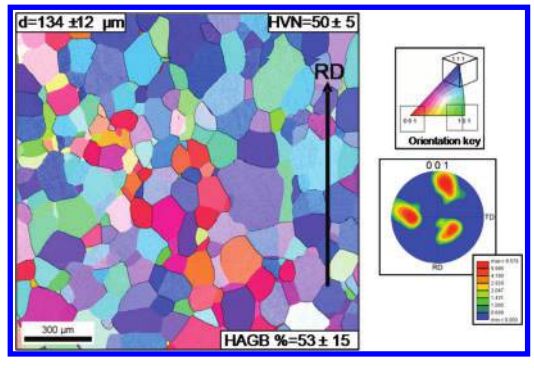

Figure 7. OIM Micrograph, inverse pole figure map and its corresponding pole figure along with a GBCD plot for the niobium in the as-received condition.

with increasing strain. One may argue that the material had not been fully hardened after 16 cycles and strain of $\epsilon = 10$.

The precipitous increase in hardness at the early stages of processing may be attributed to either the build up of dislocations or substantial refinement in grain size of the material or both. By applying a comprehensive OIM analysis, it will be possible to resolve which of these are responsible for the increase in hardness that was noticed at the early stages of processing.

3.2 *Evolution of microstructure with strain*

The OIM micrograph of the as-received microstructure is presented in Figure 7. The microstructure was characterized by equiaxed grain structure suggestive of a fully recrystallized material. This is more so, because individual grains maintained a near uniform coloration, indicating that there are no remnants of deformation or recovered regions within the grains. Analysis of the OIM data revealed that the grain size was large ($d = 134 \pm 12\,\mu m$) and a high percentage of high angle grain boundaries ($53 \pm 15\%$).

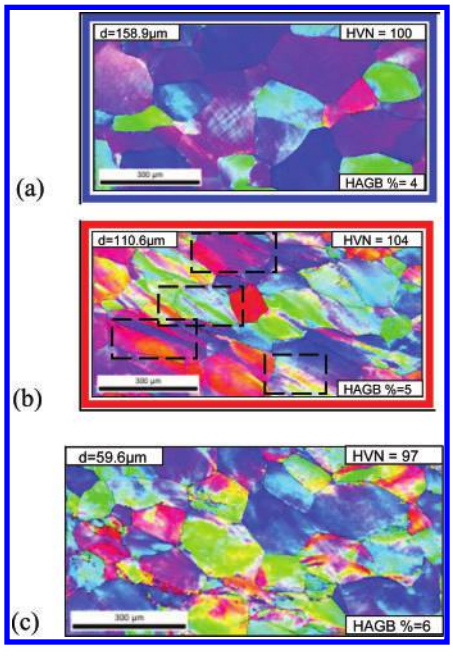

Figure 8. OIM maps for Nb subjected to 1 cycle ($\epsilon = 0.65$). The variation in colors within the grains is an indication of deformation.

The hardness profile of section 3.1 revealed that the hardness of the material upon processing was heterogeneous and led to the classification of three distinct regions, namely, the dead corner, core region and compressed/deformed corner. It is noteworthy that the OIM analysis of the processed material showed similar characteristics. Henceforth, the microstructure results for each strain will be presented for these three regions.

The OIM micrographs of the dead corner, core region and the compressed corner are presented in Figures 8a, b and c, respectively for material processed to 1 cycle ($\varepsilon = 0.65$). The grains in the dead corner region (Fig. 8a) are characterized by near uniform coloration, similar to the as-received material. This suggests that the dead region had seen little or no deformation. However, the microstructure of the deformed corner and the core region shown in Figs 8b and c, respectively displayed grains with varied colors. The diagonal nature of some of the deformed regions within the grains is indicative of shear banding. The percentage of high angle grain boundaries (HAGB) in the dead corner, deformed corner and core region was 4%, 5% and 6%, respectively. Additional processing of the material up to the strain, $\varepsilon \sim 1.33$, resulted in the intensification of the shear bands, which resulted in inhomogeneous microstructure. Even the dead corner started showing deformation bands. Furthermore, there was reduction in grain width, with little or no change in the percentage of HAGB. Processing of the material at strains, $\varepsilon \geq 2.66$ resulted in substantial refinement of the microstructure and an abrupt increase in the percentage of HAGB.

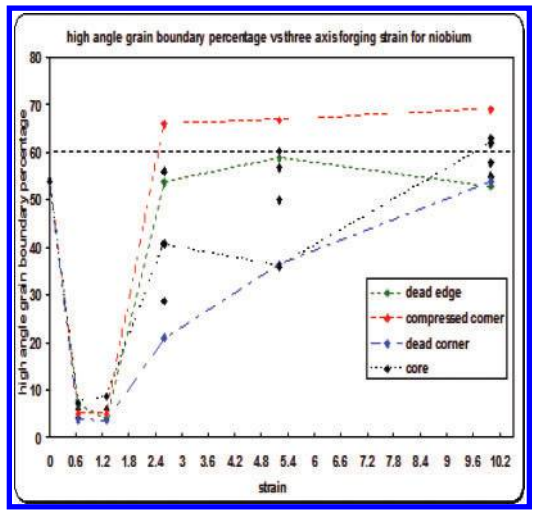

Figure 9. Plots of high angle grain boundary percentage as a function of the three axes forging strain.

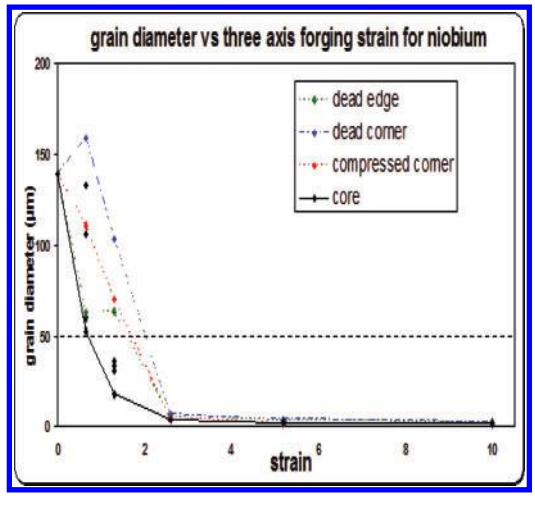

Figure 10. Plots of grain diameter as a function of the three axes forging strain.

Figures 9 and 10 present the evolution of HAGB as a function of strain and grain diameter as a function of strain, respectively for all the processing strains. The predominance of low angle boundaries (percentage of HAGB ~5%) in the microstructure at the early stages of processing indicates that the microstructure was characterized by subgrains and deformation bands. Therefore, the plot of Figure 10 is essentially of cell diameter refinement, which were subgrains at low strains ($\varepsilon \leq 2.66$) and grains at high strains. At strain, $\varepsilon = 10$, the microstructure of the deformed corner was very much similar to that of the core region as can be seen in Figure 11.

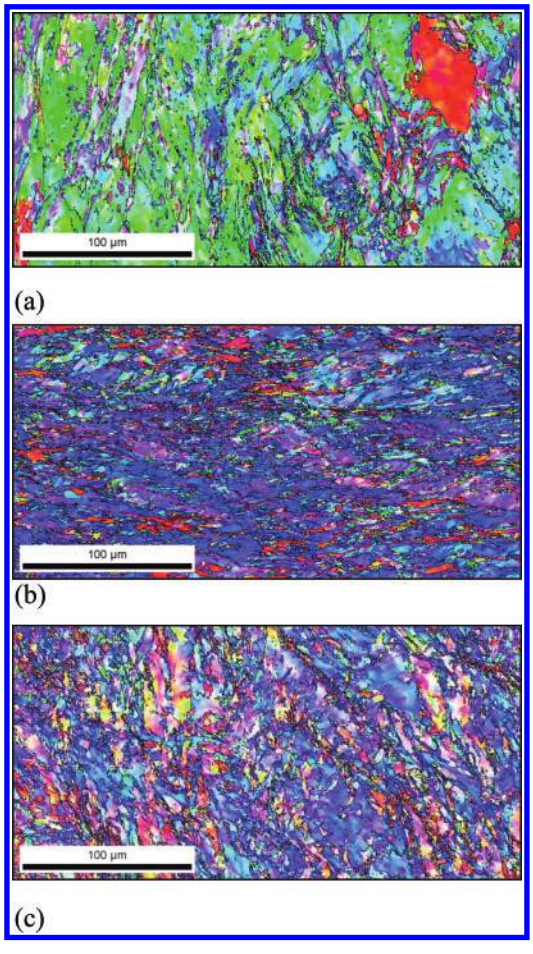

Figure 11. OIM maps for Nb subjected to 16 cycles ($\epsilon = 10$). There was little or no difference between the deformed corner (b) and core region (c) microstructure.

4 CONCLUSIONS

The microstructure produced via three axes forging with reshaping die can be characterized as non-homogeneous and consisting of three main regions, namely, the dead corner, core region and compressed/deformed corner. The core of the billet underwent more intense straining while the dead corner was the least heavily deformed. The most important result is that the forging procedure was able to produce microstructure suitable for the manufacture of SRFCs. The microstructure after a strain of $\epsilon = 10$ was characterized by equiaxed (GSAR ≤ 2) fine grain ($d = 1.4 \pm 0.5\,\mu m$), with sufficiently high percentage of HAB ($59 \pm 6\%$). These properties are necessary to promote formability and cavity wall strength in addition to ensuring continuous recrystallization during pre-production annealing.

ABSTRACT: Steel is widely used in all types of structures, due to its relatively low cost, high strength to weight ratio and speed of construction. When used in most automobile applications, steel may require case-hardening processing. Conventional case-hardening of steel have major drawbacks in being very expensive and hazardous to perform. In this study, an alternative method, which involves the use of cassava leaves and peels is being explored. Cassava contains varying degrees of cyanogenic glucoside (15-1000 mg of HCN per kg of cassava). These cyanogenic glucosides, when hydrolyzed by enzymes, form Hydrogen Cyanide (HCN) in the form of triple bond of Carbon and Nitrogen, which is responsible for the case-hardening process. The actual processing involves pack-cyaniding of the cassava leaves with $BaCl_2$ as energizer. Because the process relies on diffusion, our study has focused on grain boundary diffusion and the effect of grain size on the case-hardening of mild steel. Grain refinement of the mild steel was carried out via a severe plastic deformation technique known as three-axis forging. The microstructure analysis results via Orientation Imaging Microscopy (OIM) were correlated with the hardness data for case-hardening using cassava leaves.

1 INTRODUCTION

Most developing countries have an acute shortage of spare parts and components for maintenance work, especially in the automobile industry. With the high local exchange rates, the importation of such spare parts in these countries has become virtually impossible (Adetunji et al, 2009).

Gear teeth, camshaft, and other automobile components, need considerable toughness to withstand impact and good surface hardness to resist wear or abrasion. These components are generally made from mild steel and can be produced by surface or case hardening. The result of Case Hardening is an outer case that is wear-resistant with a ductile inner core. A major drawback with conventional case hardening methods is that they are expensive and involve handling extremely poisonous and toxic substances in the form of gas or liquid.

This research utilizes a novel technique in which cassava leaves are pack-cyanided to case harden various types of steel (Ibironke, 2004).

1.1 *Case Hardening*

Case hardening utilizes the diffusion of Carbon (C) and/or Nitrogen (N) as interstitial atoms into the surface of a material. The result is an outer case that is wear resistant with an inner core that is ductile and able to absorb impact.

Case hardening can be done by at least four methods: carburizing, nitriding, cyaniding, or carbonitriding. With the cyaniding method in particular, a major drawback is that the process is expensive and involves the handling of extremely poisonous and toxic substances in the form of gas or liquid. Therefore, cassava leaf pack-cyaniding has been developed as an alternative method for case hardening.

1.2 *Cassava*

Cassava is an important source of carbohydrate for millions of people due to its large tuberous and starchy roots. It is grown in tropical and subtropical regions.

Cassava, as well as more than 2500 plant species, contains cyanogenic glucosides (Zagrobelny, 2003). Cyanogenic glucosides act as a defense mechanism against herbivore attack for plants. They are stored in plant vacuoles and when the tissue is disturbed (i.e. chewing), cyanogenic glucosides are brought into contact with lyases that hydrolyze the cyanogenic glucosides causing the release of toxic hydrogen cyanide (HCN).

This HCN can breakdown into Carbon (C) and Nitrogen (N) atoms, which can be made to diffuse interstitially into the surface of steel, thereby serving as case hardening source during the pack cyaniding. The HCN distribution in cassava is within the range of 15-1000 mg of HCN per kg of cassava. This level of toxicity in within the optimal range for pack cyaniding applications.

1.3 *Grain Size and Diffusion*

Pack-cyaniding utilizes C and N as diffusing agents into interstitial sites of the steel work piece. This is due to the fact that the difference in atomic diameters of C/N and Fe is greater than 15% as can be seen in Table 1. For interstitial diffusion, the activation energy is substantially lower than that of substitutional diffusion (Table 2).

Much research has established that the mean jump frequency of atoms at dislocations, grain boundaries, and surfaces is much higher than that of the same atom within the lattice (Shewman, 1989). This means that grain size can affect the rate of diffusion. Therefore, it is important to investigate the effect of starting grain size on pack cyaniding, especially since this may influence the final case and core microstructure. In this study, grain refinement was accomplished by 3-Axis Forging, a form of Severe Plastic Deformation (SPD).

Table 1. Atomic radii of C, N, and Fe.

Element	Atomic Radius **(nm)**
C	0.077
N	0.071
Fe (BCC)	0.124

Table 2. Diffusion coefficients and activation energies for substitutional (Fe in Fe) versus interstitial (C or N in Fe) atoms.

Diffusion Process	D_0**(10**$^{-4}$ m^2s^{-1}**)**	Q(kJmol^{-1})
Fe in Fe (α)	118	281
N in Fe (α)	0.005	76
C in Fe (α)	0.008	83
C in Fe (γ)	0.7	157

2 EXPERIMENTAL

2.1 *Materials*

Two types of steel, namely Low-Carbon Steel and Nitridable-Grade Steel were used for this investigation. The chemical components of these alloys are presented in Table 3.

It is expected that 1018 Steel will be involved in high temperature processing where C will be diffused into interstitial vacancies. However, there is limited solubility of C in Fe at low temperatures. In fact, maximum solubility is 0.022 wt% C in Ferrite. Therefore, C cannot be used as a diffusion element in case hardening at low temperatures. Steel containing Aluminum and Molybdenum (Nitralloy 135 M) are preferable for they can form Nitrides at low temperatures.

With the formation of both carbides and nitrides during pack cyaniding, varied results are expected for Steel with dependence on chemical composition and temperature.

2.2 *Three-Axis Forging*

Severe plastic deformation (SPD) via Three-Axis Forging is performed on cube-shaped billets of approximately 12mm, using both grades of steel, to achieve an ultra-fine microstructure. It is expected that steel with initial fine grains will need less processing to achieve a fine, hard case with a fine, ductile core.

Table 3. Chemical composition of low-carbon steel (1018) and nitridable steel (Nitralloy 135 M).

1018 Steel **Component**	**Wt %**
Carbon	0.15-0.20
Manganese	0.60-0.90
Silicon	0.15-0.30
Phosphorus	0-0.04
Sulfur	0-0.05
Nitralloy 135M	
Carbon	0.38-0.43
Chromium	1.6
Molybdenum	0.35
Aluminum	1.1

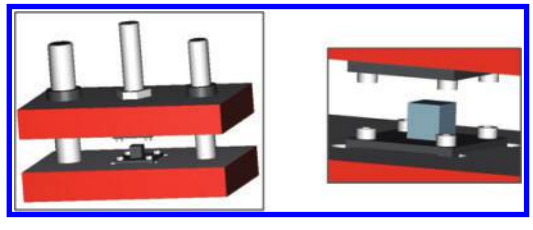

Figure 1. Three-axis forging apparatus. Forging die is actuated by a hydraulic press. A cube-shaped billet of 12 mm is compressed in an open die along 3 axes. The initial dimensions of the cube are retained.

2.3 *Experimental Procedure*

This work consists of two sub-tasks: (1) pre-processing of the steel and (2) pack-cyaniding processing. The effect of pre-processing on the cassava pack cyaniding method will be analyzed.

The pre-processing (1) consists of using Three-Axis Forging to refine the microstructure of Steel. Preliminary work in our laboratory has shown that Three-Axis Forging can substantially refine grain structure (Bembridge, 2011). The Three-Axis Forging technique was. adopted for grain refinement. It is expected that steel with initial fine grains will require less pack-cyaniding processing to achieve a fine, hard case with a fine, ductile core.

The pack-cyaniding processing stage (2) involves converting the cassava peels and leaves to the appropriate condition from which C and N are extracted from it. Different energizers, including $BaCO_3$ and $BaCl_2$, are then packed in pouch with the cassava leaves and mild steel. These were heated at various temperatures (400°C – 950°C) at a series of time periods (1hr-5hr). Average powder particle size ranged from 0.125–1.0 mm. All samples were then analyzed with Orientation Imaging Microscopy (OIM) and Vickers hardness testing.

3 RESULTS

3.1 *Initial Microstructure*

Scanning Electron Microscope (SEM) micrographs of 1018 Steel and the Nitralloy 135 M are presented in Fig. 2a and 2b, respectively. It is evident that the 1018 microstructure consists mainly of proeutectoid Ferrite (α) and Pearlite. On the contrary, the microstructure of Nitralloy consists of a mixture of Bainite and Martensite.

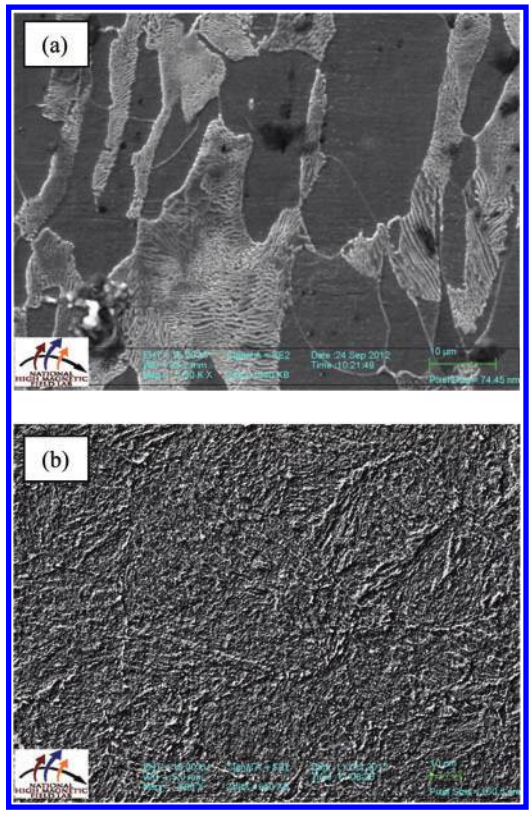

Figure 2. SEM micrographs of as received (a) 1018 Steel and (b) Nitralloy 135 M.

3.2 *Preliminary Results*

3.2.1 *Cassava Pack Cyaniding at 800°C*

Preliminary work was conducted to investigate the effect of cassava pack-cyaniding on the as-received 1018 Steel. Figure 3 presents the hardness profile of the material when processed at 800°C. It is evident that the hardness of the surface region (known as the case region) was about 35% higher than the core region. Furthermore, the case region extended to about 0.25 mm from the surface of the work piece.

Figures 4(a) and (b) are the Orientation Imaging Micrographs of the work pieces processed at 800°C for 1 hr and 3 hrs, respectively. In each case, the grain structures of the case regions were finer than that of the core regions. One hour processing time resulted in a smaller case region and larger core grain size when compared to the 3 hr processed material. The presence of very fine grain size in the case region can suggest that in addition to the diffusion of Carbon there was multiple nucleation of recrystallization in this region.

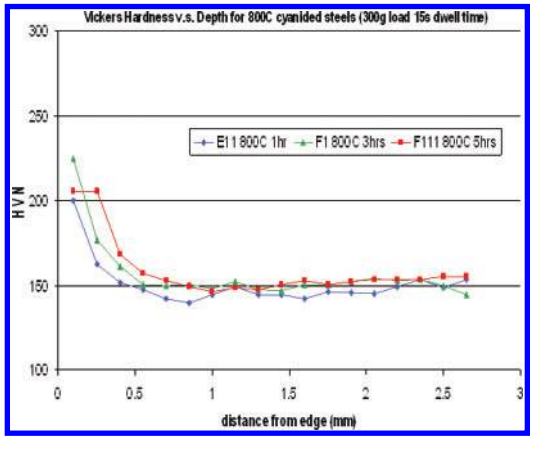

Figure 3. Vickers hardness profiles of Cyanided Steel at 800°C (from 1 hr to 5 hrs) plotted as a function of distance from outer edge (case).

3.2.2 *Grain Size Refinement in Niobium*

As stated in section 1.2, part of the study was directed at understanding the effect of grain size on diffusion rate. Therefore, there was need to refine the grain size of the work piece. Previous work in our laboratory has utilized Three-Axis Forging to refine the

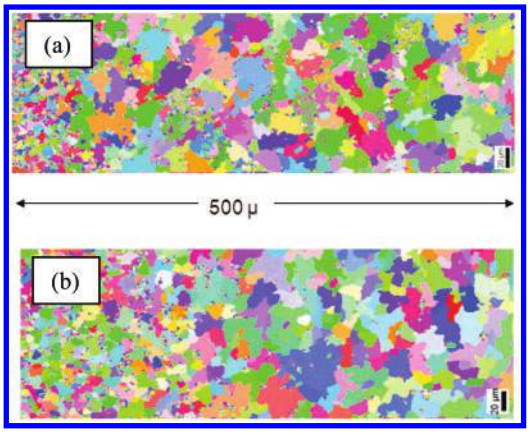

Figure 4. OIM micrographs of Mild Steel reveal variation from case to core (left to right) through the depth of Steel at 800°C for (a) 1 hr and (b) 3 hrs.

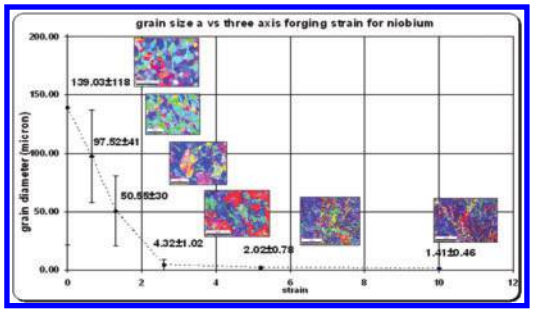

Figure 5. Average grain diameter as a function of true strain for Niobium that has undergone SPD via 3-Axis Forging.

grain size of Niobium at room temperature (Bembridge, 2011). Starting with an average grain diameter of $\sim 139\,\mu$m, this procedure was able to refine the grain size to $\sim 1.41\mu$m, as can be seen in Figure 5. Clearly, the average grain diameter decreased by one order of magnitude at the completion of processing.

Figure 6 shows Vickers microhardness testing data performed on Niobium as a function of strain, ranging from $\epsilon = 0$ up to $\epsilon = 10$. The data shows a noticeable strain hardening response at low strain ($\epsilon = 0.65$). The hardness continued to increase gradually up until $\epsilon = 2.6$, then very slowly beyond that point (Bembridge, 2011).

3.3 *Grain Size Refinement in Steel*

Using the Three-Axis Forging procedure, the 1018 steel was deformed to strains up to 3. Figures 7(a) to (d) present the OIM micrographs of the as-received, $\varepsilon = 1$, $\varepsilon = 2$ and $\varepsilon = 3$, respectively. The as-received microstructure (Fig. 7a) was characterized with large discernible grain structure. However, upon processing, the microstructure was fibrous in nature, showing that grain refinement had commenced in the material.

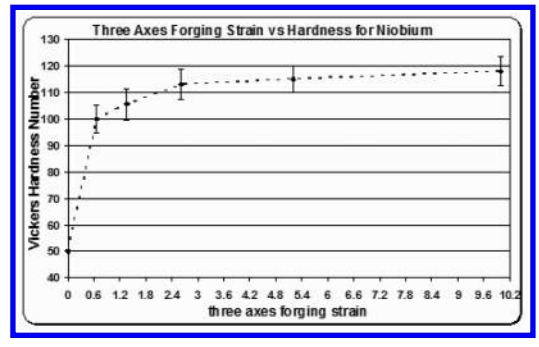

Figure 6. Plot of average Vickers hardness as a function of true strain for Niobium.

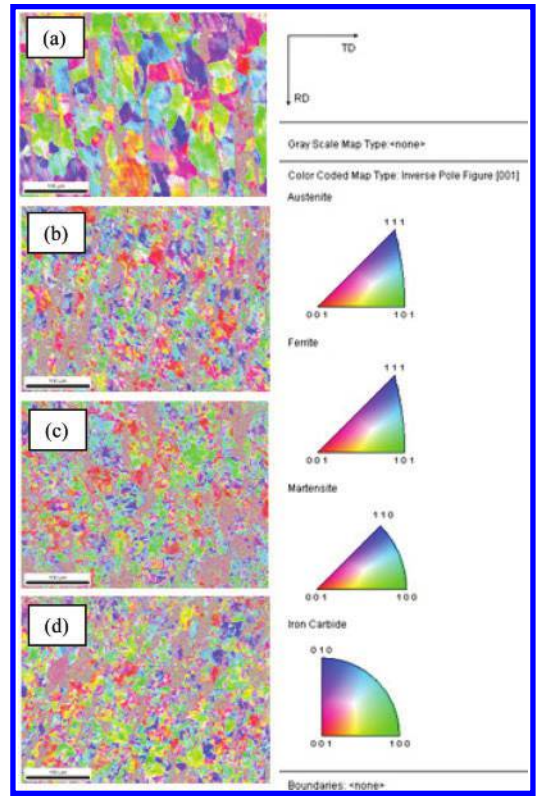

Figure 7. OIM micrographs of 1018 Steel at (a) $\epsilon = 0$, (b) $\epsilon = 1$, (c) $\epsilon = 2$, and (d) $\epsilon = 3$.

There are indications that the shear bands may have cut across several grains. Additional analysis will be carried out to determine the average misorientations in the material.

Automatic Vickers hardness testing was conducted on the samples for strains of $\epsilon = 0$ to 2. Average hardness was plotted as a function of the true strain (Fig. 8). The strain hardening response was very pronounced at low strain ($\epsilon = 1$). This is due to the buildup of deformation bands at low strains in Steel.

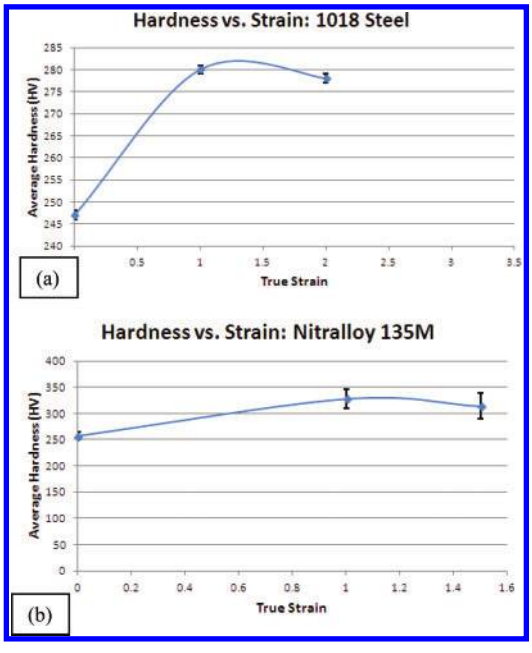

Figure 8. Average Vickers Hardness (HV) as a function of true strain for (a) 1018 Steel at $\epsilon = 0,1,2$ and (b) Nitralloy 135M at $\epsilon = 0,1,\ 1.5$.

4 CONCLUSIONS

An alternative case-hardening method utilizing cassava leaves as the source for pack-cyaniding was developed. Low-Carbon Steel and Nitridable-Grade Steel were subjected to severe plastic deformation by three-axis forging for the purpose of grain refinement. Because the pack-cyaniding process relies on diffusion, this work was conducted to analyze grain boundary diffusion and the effect of grain size on the case-hardening of mild steel.

1. Using cassava leaf pack-cyaniding, mild steel was processed at 800°C at 1 hr, 3 hrs, and 5 hrs. Vickers microhardness values for mild steel revealed an increase in hardness to a depth of approximately 0.25 mm within the case. The finer microstructure within the processed case region of mild steel is associated with the higher Vickers hardness values. This validates the cassava leaf pack-cyaniding produces case depths comparable to conventional cyaniding methods.
2. Three-axis forging of Steel at low strain ($\epsilon \leq 3$) resulted in grain refinement with microstructural features similar to deformation bands which cut across several grains.

Non-destructive evaluation (NDE) practice for concrete bridges in USA

A. Ghorbanpoor
University of Wisconsin-Milwaukee, Milwaukee, Wisconsin, USA

S. Boone
Federal Highway Administration, US DOT, McLean., USA

ABSTRACT: A large number of concrete bridges in the United States have reached or exceeded their initial design life. Over the last several years, frequent deterioration of these bridges has occurred. Also, some of the relatively new bridge structures have experienced pre-matured degradation due to poor construction practices or use of inferior materials. Bridge owners in the US are beginning to more frequently include non-destructive evaluation (NDE) techniques to assess the conditions of in-service and new bridge structures. This facilitates more informed and cost-effective decisions to be made on repair, rehabilitation, or replacement of such structures.

Over the last several years, the US Department of Transportation (US DOT), the Federal Highway Administration (FHWA), and other research agencies within the US, have supported research efforts of various investigators to develop state-of-the-art NDE capabilities to overcome the long existing problem of bridge condition assessment. As a result, numerous NDE capabilities have been developed that can address the needs of bridge owners for bridge condition assessment.

This paper will present a discussion on the state of concrete bridge condition in the US as well as the state-of-the-art NDE practice for condition assessment of these structures. Concrete bridges rely on conventional, prestressing, or post-tensioning steel reinforcement to resist all relevant applied tensile loads while they are in service. Unfortunately, many of these bridge structures experience exposure to harsh environments and loading conditions during their service lives. This has lead to various modes of concrete deterioration and most importantly to severe corrosion of reinforcing steel within concrete. While research and development related to NDE techniques and instrumentation have advanced over the last few decades, it has been recognized that more need to be accomplished in areas such as education, standardization, data integration and interpretation.

1 INTRODUCTION

According to the US National Bridge Inventory (NBI) data, there are just over 600,000 bridges in the United States. Among these structures, concrete bridges constitute more than 65 percent. While concrete bridge structures are inherently durable, many in the US are now more than 50 years old. Many of these bridges have shown signs of distress and deterioration due to age and exposure to aggressive environments. In most cases, concrete deterioration in bridges develops over time and the bridge owners have sufficient time to perform necessary repairs. Examples include spalling of concrete in bridge decks, thermal and creep cracks, minor corrosion of non-structural and structural steel, etc. However, under some circumstances, bridge deterioration can lead to structural collapse. Examples include major corrosion of prestressing or post-tensioning steel, and major chemical concrete degradation leading to material softening. To keep bridge structures in service, bridge owners have invested significantly to repair and maintain them. In the US, bridge owners include states, cities, counties and other municipalities. The US Department of Transportation (US DOT) and Federal Highway Administration (FHWA)provide guidelines and resources for bridge safety evaluation program throughout the US. The FHWA has established the National Bridge Inspection Standard (NBIS) that mandates a minimum of a biannual safety bridge inspections for all bridges in the United States. It has long been recognized that effective and economical repairs in bridges can be possible only when structural and material conditions are understood first. This understanding can be achieved through the use of practical and effective inspection techniques including visual and other non-destructive evaluation (NDE). Effective and successful bridge evaluation is required in order to meet one of the five strategic goals of the US DOT which is to maintain a "State of Good Repair." This is defined as ensuring the United States proactively maintains its critical transportation infrastructure in a state of good repair. To enhance the effectiveness and more successful application of various NDE techniques to bridge

structures, more research, validation, standardization and education will need to be done. Recent efforts from the FHWA has focused on identifying such NDE needs for application to bridge structures. In Fall 2012, the FHWA coordinated the work of experts from the United States during a workshop to identify critical NDE needs for the US infrastructure (Boone 2013). These critical needs, as listed below, are not unique only to the United States as many nations face similar needs.

i Provide NDE education and training/certification.
ii Develop a NDE validation center for material and real bridge level specimens.
iii Standardize NDE procedures and protocols.
iv Create bridge condition and reference baseline data for quality assurance.
v Overcome the limitations of existing NDE and identify methods to address these limitations.
vi Determine cost benefit analysis of NDE.
vii Develop decision making/risk-based analysis framework to help put NDE in the design, maintenance, inspection, and repair process (incentives for States).
viii Determine the probability of detection for different NDE techniques.
ix Incorporate maintenance and inspection into the design process.
x Create improved methods for data visualization and presentation.
xi Implement a data/technology repository.
xii Create improved methods for data fusion and combination of techniques.
xiii Identify mature technologies and develop an applicability and deployability matrix.
xiv Identify limitations of visual inspection and identify easier methods to determine when NDE is required.

Meeting the above stated needs can significantly enhance the use of NDE in highway bridge structures.

In spite of the expressed concerns for the successful use of NDE techniques for bridge applications, the use of certain NDE methods have proven to be valuable in condition assessment of bridges.

Concrete bridge deterioration primarily results from material degradation and corrosion of reinforcing or prestressing steel. Corrosion of steel in concrete causes cracking and eventual failure of the structure if it is not detected early and repaired in a timely fashion. The most common method of bridge evaluation in the US has been based on performing visual inspection. While visual inspection, if performed by a qualified inspector, is often informative and useful, it cannot produce all the necessary information regarding the condition of the structure due to its inherent limitations. Specifically, visual inspection cannot reveal information on defects and signs of deterioration that are internal or invisible to the inspector. Accordingly, bridge owners are relying more on the use of currently available conventional NDE tools as well as more advanced methods.

Bridge decks represent the largest volume of materials and structural members in bridges. Since bridge deck failures and steel corrosion in concrete bridges are the most common and significant deterioration types, they will be the primary focus of discussion in this paper.

2 BRIDGE DECK DEFECTS AND INSPECTION

Beside corrosion of steel inside concrete, bridge deck deterioration includes delamination, honeycombing due to poor construction practice, concrete cracking due to temperature and load, and material degradation. At the initial stages, most defects in bridge decks are small and below the deck surface. They gradually advance to become larger defects with time, thus adding exposure to aggressive environments and the service load to which they are subject. When bridge deck defects reach the deck surface, they are usually at a critical state of deterioration where major repair and retrofit will be required. Concrete deck defects at early stages are more difficult to detect since they are usually located under the deck surface. These defects are not visible and visual inspections cannot detect them. Special NDE techniques have been developed that can help detect such defects in bridge decks. There is no single NDE technique that can be used to detect all defects caused from various deterioration mechanisms. Accordingly, one will need to utilize one or more appropriate NDE techniques to detect defects caused by specific deterioration mechanisms. A comprehensive research study sponsored by the Wisconsin Department of Transportation and the FHWA has identified various deterioration mechanisms for bridge decks as well as relevant NDE techniques that have shown promise for bridge deck defect detection (Ghorbanpoor & Benish 2003). The research has also identified advantages and limitations for these techniques. The identified techniques include chain drag and hammer sounding, ultrasonic pulse velocity, ultrasonic pulse echo, spectral analysis of surface waves, infrared thermography, impulse response, radiography, impact-echo, ground penetrating radar, and petrographic analysis.

A more recent study supported by the Transportation Research Board, SHRP2 program, has determined the effectiveness of a series of relevant NDE techniques for bridge decks through performing a series of validation tests in both laboratory and field (Gucunski et al. 2013). The research examined the performance of the techniques based on five measures of accuracy, precision or repeatability, ease of use, speed of test and data interpretation, and cost. The study placed its focus on non-destructive test evaluations for four types of deterioration in bridge decks. They included delamination, corrosion, vertical cracking, and concrete degradation. These deterioration types were selected due to their frequency of occurrence and the level of priority bridge owners place on them routinely. The NDE methods that were evaluated

under this study included chain dragging and hammer sounding (CDHS), impact echo (IE), ultrasonic pulse echo (UPE), ultrasonic surface waves (USW), impulse response (IR), ground-penetrating radar (GPR), half-cell potential (HCP), galvanostatic pulse measurement (GVP), electrical resistivity (ER), and infrared thermography (IR). For detecting delamination, only four of the selected methods (IE, CDHS, GPR, and IR) showed fair to good ability, based on the five criteria of accuracy, precision, ease of use, speed and cost, for detection of delamination in bridge decks. Among the four methods, the impact echo was more effective with a score of 2.8 in a scale of 1 to 5, with 1 representing poor and 5 excellent. The IR and GPR methods were ranked next but with the limitations of sensitivity to the time of the test during the day and the amount of moisture on the surface, in the material, and in the void. The CDHS method was only effective when the defect size was relatively large and when it was close to the surface. With respect to corrosion of steel in bridge decks, no method included in the study has the capability for accurate and direct measurement of corrosion due to their inherent physical characteristics. However, three techniques (HCP, GVP, and ER) were identified as having fair to good ability to provide information regarding the characterization of the corrosive environment. Only one method, ultrasonic surface wave, was found to have a fair to good ability to detect vertical cracks with known crack depth and to provide quantitative assessment of concrete material degradation.

The study by Gucunski et al. (2013) concluded that there is no single method of NDE that is able to successfully detect all types of defects in bridge decks and that the ultimate choice for the method and equipment depends on the type of deterioration that is a primary concern. The results of this study confirmed the same finding by others, including Ghorbanpoor & Benish (2003).

3 CORROSION INSPECTION IN BRIDGES AND CABLES

According to an estimate by the Strategic Highway Research Program (SHRP) of the U.S. National Research Council, the total cost of corrosion damage in United State bridges is approximately $20 billion and it is increasing at $500 million per year (NACE International 2011). If corrosion damage plus prevention and mitigation are considered for the US bridges, the total direct annual cost is about $8.3 billion (Koch et al. 2002). The expressed staggering cost of corrosion damage and mitigation is primarily due to the aging of the US bridge structures (Ghorbanpoor 2000, Ciolko & Tabatabai 1999).

Corrosion in bridges occur in all members including those in the substructures and superstructures. Over the last several decades, various methods of NDE have been utilized to determine the extent of corrosion and mixed levels of success have been achieved. Many NDE methods that sometimes have been claimed to yield success for detection of corrosion in bridges do not have such capability due to their inherent physical characteristics. At best, some of these techniques can only be effective in assessing the corrosive condition of the environment under test. Several of the more advanced NDE methods have been studied by different researchers to determine their effectiveness for detection of steel section loss due to corrosion in bridge structures. They included ultrasonic, ground penetration radar, radiography, acoustic emission (Ciolko & Tabatabai 1999), magnetic flux leakage or MFL (Ghorbanpoor et al. 2000), and remnant magnetic field or RMF (Scheel & Hillemeier 1997, Scheel & Hillemeier 2003, Hillemeier & Scheel 1998). These studies have concluded that the magnetic-based NDE methods have the most potential for success in detection of steel section loss due to corrosion in bridges. A more recent corrosion detection study at Lehigh University included a validation program for various NDE methods to detect corrosion and steel section loss due to the corrosion as well as defects in prestressing steel for concrete box girder bridges as well as laboratory concrete slabs with known defects in their embedded reinforcing and prestressing steels (Jones et al. 2010, Naito & Jones 2010). The NDE methods that were included in the Lehigh study included ground penetrating radar, line scanning thermography, galvanostatic pulse corrosion, ultrasonic shear wave, magnetic flux leakage, remnant magnetic field, and electromagnetic corrosion detection. Non-destructive testing experts with expertise in the above stated methods participated in the "blind testing" study. The concrete box girder test samples were removed from a Pennsylvania bridge that was being replaced due to excessive corrosion in the prestressing strands within the lower flanges of its girders. After the conclusion of the validation test program, the concrete box girders were sectioned and the strands were exposed to measure and record the amount of section loss at various locations along the length of each strand. The laboratory concrete slabs included reinforcing and prestressing steel that were placed in different depths within the slabs. Each reinforcing bar or prestressing strand had one or more manufactured areas of section loss of varying amounts at different locations along its length. The information about the amounts and locations of the manufactured section loss were not made available to the participants before the testing program was concluded at Lehigh University and before the final test reports were submitted by all participants. The results of the study indicated that only the magnetic flux leakage and remnant magnetic field were able to detect, with good accuracy, section loss in prestressing and reinforcing steel due to corrosion and manufactured defects.

Other studies have shown that the MFL method is a field worthy nondestructive evaluation technique that offers a very good capability for detection of corrosion or section loss in the tendons of post-tensioned (P-T)

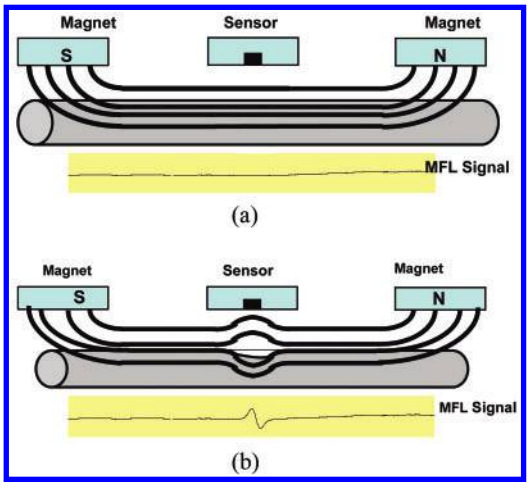

Figure 1. Concept of magnetic flux leakage (MFL). (a) MFL signal from a tendon without flaws, (b) MFL signal from a tendon with a flaw (Ghorbanpoor & Abdelsalam 2012).

concrete segmental box girder bridges (Ghorbanpoor 2000 & 2008, Christen et al. 2003, Ghorbanpoor & Abdelsalam 2012). The successful corrosion detection capability of the MFL technique in P-T tendons leads to the conclusion that there is a good potential for the method to be used effectively for corrosion detection also in cables of cable stay bridges. Corrosion of steel in external P-T tendons has been recognized by bridge owners and engineers as being a serious concern. The tendon corrosion has sometimes led to severe section loss that results in a major reduction of the load carrying capacity, or full fracture of such tendons. The problem arises from various design and construction shortcomings that lead to grouting voids and penetration of aggressive materials inside the tendons. Major degradation of prestressing steel may be avoided through the use of an effective NDE method, such as MFL, when tendon corrosion can be detected at an early stage of deterioration.

The basic operating principle of the magnetic flux leakage (MFL) is based on introducing a DC magnetic field to the reinforcement or P-T tendon and measuring the changes in the magnetic field caused by the presence of corrosion or loss of section. Any loss of section in the steel will result in the leakage of the magnetic flux to the neighboring areas where they can be detected by magnetic sensors. Figure 1 demonstrates a magnetic field change resulting in a MFL signal that is due to a loss of section in the bar as an assembly of a set of magnets and a sensing device are moved along the length of the bar.

Through laboratory tests and calibration exercises as well as mathematical modeling, specific data can be obtained to assist with the correlation of results in terms of flaw sizes and locations in steel bars and prestressing strands during MFL tests in real structures. The extent of the leakage of the magnetic field is proportioned to the level of loss of section in the steel from corrosion or fracture. It is also a function of the magnetic properties of the steel and surrounding media, and the distance between the sensing element and the location of the defect (Ghorbanpoor et al. 1991). Mathematical relations to determine the peak-to-peak variations, or the amplitude, of the magnetic flux leakage for subsurface flaws may be used for the purpose of calibrating the MFL test results (Brady & Stanley 1997). Equations 1 & 2 provide estimates of the MFL signal peak-to-peak values for cylindrical and spherical inclusions, respectively, in a steel structure.

$$\Delta H_y \approx 2.6 H_a \left(\frac{a}{d}\right)^2 \quad (1)$$

$$\Delta H_y = \frac{1.717(\mu-\mu_o)}{(2\mu+\mu_o)} H \left(\frac{a}{d}\right)^3 \quad (2)$$

In Equations 1 & 2, ΔH_y is the amplitude variation in the magnetic field in a direction vertical to the test surface, H is the magnetic field strength, μ and μ_0 are magnetic permeability for the medium and the flaw, respectively, a is the flaw radius, and d is the distance between the flaw and the position of interest or the location of the sensing element.

Several demonstrations of the successful application of the MFL method for detection of corrosion in bridge structures have been cited in this paper. Additional successful applications of the MFL technique for corrosion detection in concrete and cable stay bridges may be found in the available literature (Bertrand et al. 2012 & 2012).

4 CONCLUSION

Concrete bridges in the United States constitute a large portion of all bridges and they face deterioration problems due to aging, exposure to harsh environments, and loading. Efforts by the US Department of Transportation, Federal Highway Administration, State DOT offices and various researchers have led to the development of a series of NDE techniques and methods of testing to address early detection of defects and remediation for bridge structures. While several NDE techniques have already been developed and are being used in highway bridges, it has been found that no one method has the ability to detect all defect types that are encountered in various bridge members. For detection of bridge deck delamination, it has been found that IE and to some extent IR and GPR are effective. For measuring the corrosion activity in an environment, HCP, GVP, and ER may be used with the consideration of their inherent limitations. For detection of vertical cracks in concrete, USW may be used successfully. It has been found that the MFL technique is the most effective NDE technique for detection of steel section loss in prestressed and post-tensiond structures. Generally, it is more effective to use more than one suitable technique to make an assessment of the structural condition of bridge structures. It has also been concluded that more needs to be done in terms of

NDE related education, standardized procedures, overcoming current limitations, probabilistic and decision support approaches, data visualization, and data fusion and interpretation from multiple techniques.

H. Ghasemi & F.S. Ibrahim
Federal Highway Administration, McLean, Virginia, USA

ABSTRACT: Federal Highway Administration (FHWA) have invested into the development of an automated system for condition assessment of concrete bridge decks using nondestructive evaluation (NDE) technologies. The primary objective of the system development is to enable rapid and economical assessment and monitoring of a large number of bridges as a part of the Long Term Bridge Performance (LTBP) Program. The automated system is a robotic platform equipped with multiple NDE sensor and imaging technologies. In particular, the system carries ground penetrating radar (GPR) and acoustic arrays, four electrical resistivity (ER) probes, and three cameras for deck surface and panoramic bridge imaging. The NDE sensors and applied NDE methods enable assessment of corrosion, delamination and concrete quality. The data collected by multiple technologies are wirelessly transferred and analyzed in a "command van", and in most case presented in a near real time. The condition assessment of decks using a robotic system enables data collection at far higher rates than by the manual collection by a group of NDE technicians.

1 INTRODUCTION

Bridge decks, due to their high exposure to the environmental conditions and direct application of traffic loading, deteriorate faster than other bridge components. Providing bridge deck maintenance or rehabilitation of roughly 600,000 bridges in the United States is a formidable task. It is especially so considering the fact that their average age is 44 years. The Federal Highway Administration's (FHWA's) Long Term Bridge Performance (LTBP) Program research team interviewed a number of state Departments of Transportation (DOTs) regarding the expenditure levels for maintenance, rehabilitation, and replacement of bridge decks. The conclusion of the interviews was that bridge decks constitute between 50 and 80 percent of the overall expenditures for bridges.

Good bridge management requires periodical inspections and evaluations using the means that can provide objective information about the condition of the bridge and its components. The predominant practice of condition assessment of concrete bridge decks in the States is by visual inspection and the use of simple nondestructive evaluation (NDE) tools like chain drag and hammer sounding (Figure 1). While such approaches have its merits, they also have limitations in terms of the early problem detection and characterization of deterioration or defects with respect to their state of progression. More advanced NDE technologies have shown promise in condition assessment of concrete bridge decks and have been implemented in the FHWA's LTBP Program.

While many advanced NDE technologies can accurately detect and characterize problems in bridge decks and other structures, there is a need to improve their application in a number of ways. Firstly, the speed of data collection should be increased. Secondly, both the data collection and data analysis and interpretation need to be automated. Thirdly, the condition assessment should be as close as possible to real time. Finally, the presentation of the results of the evaluation needs to be more comprehensive and data presentation more intuitive. With all these goals in mind, the FHWA initiated development of a robotic system for condition assessment of concrete bridge decks. A strong argument for this investment was the need to evaluate and monitor performance of hundreds of bridge decks throughout the States in the next phase of the Program.

2 LTBPP BRIDGE DECK PERFORMANCE STUDY

Interviews with state DOTs and the LTBPP's expert task group indicated the performance of bridge decks as the key bridge performance issue. For that purpose the LTBPP initiated in 2009 a program of comprehensive condition assessment of concrete decks using multiple NDE technologies (Gucunski et al., 2012 and 2013). The assessment of bridge

Figure 1. Assessment of bridge deck delamination using chain drag.

Figure 2. Assessment of delamination using IE method.

decks within the LTBPP concentrates on the detection, characterization and progression monitoring of corrosion, delamination and concrete degradation. A multi-faceted program of performance evaluation was developed for that purpose, which relies on NDE, visual inspection and physical sampling and testing. Five NDE technologies are implemented for the characterization of the three deterioration types: ground penetrating radar (GPR), electrical resistivity (ER), half-cell potential (HCP), impact echo (IE), and ultrasonic surface waves (USW) method. The GPR is used to identify bridge deck areas with likely deterioration and highly corrosive environment, to map all metallic objects and to measure the concrete cover. The ER is used to assess the potential for corrosive environment, while the HCP is used to measure corrosion activity. The primary goal of IE is to detect and characterize delamination. A device called Stepper that carries three IE probes is used for that purpose (Figure 2). Finally, the USW method is deployed to obtain information about the concrete quality through a measurement of concrete elastic modulus.

As an illustration a typical result of the NDE based condition assessment, delamination maps from 2009 and 2011 surveys of a bridge in Virginia are presented in Figure 3. The condition maps demonstrate the ability of IE to detect and define the boundaries of delamination, to describe the severity of delamination, and to monitor delamination progression with time. In addition, the quantitative nature of the results of NDE surveys enable a quantitative description of deterioration and more objective assessment of condition rating. As it is illustrated in Table 1, percentages of the deck at various stages of delamination can be easily calculated, and the progression of delamination well monitored. Combined with bridge deck segmentation, percentages can be calculated also for different sections of the deck. This can be utilized to identify the areas of faster deterioration progression and or the ones that should have priority in maintenance or rehabilitation. Finally, condition indices are calculated using a weighted area approach. According to the formula used, on a scale 0 to 100, where 100 is the best condition, this bridge received a condition rating with respect to delamination of 70 in 2009, and 57.2 in 2011.

Table 1. Assessment of deck delamination of a bridge in Virginia for 2009 and 2011.

	Severe Delamination		Incipient Delamination	
	2009	2011	2009	2011
Shoulder	24%	33%	20%	26%
Slow Lane	12%	21%	32%	40%
Fast Lane	12%	23%	36%	40%
Entire Deck	15%	25%	30%	36%

The NDE data collection, analysis, interpretation and presentation for surveys using multiple technologies represents a significant effort. Typically, a team of five to six NDE experts and technicians are involved conduct evaluations using the described five NDE technologies. The condition assessment using a further described robotic system significantly reduces that effort and is also expected to significantly reduce costs of evaluation and monitoring.

3 AUTOMATED DATA COLLECTION AND ANALYSIS

3.1 *Description of the robotic platform*

The robotic system with its components is shown in Figures 4 and 6. The robot itself is approximately 1.25 m wide and 1.5 m long. It has four omnidirectional wheels, which enable the robot to move in any direction or turn in place. The robot carries multiple NDE sensors, digital cameras, positioning devices and devices for obstacle avoidance.

The front side of the robotic platform is shown in Figure 4. Two acoustic arrays and four electrical resistivity probes are attached. Each of the acoustic arrays has multiple sources (impactors) and receivers (Figure 5). Different combinations of those are utilized to conduct multiple IE and USW tests. As a result, both IE

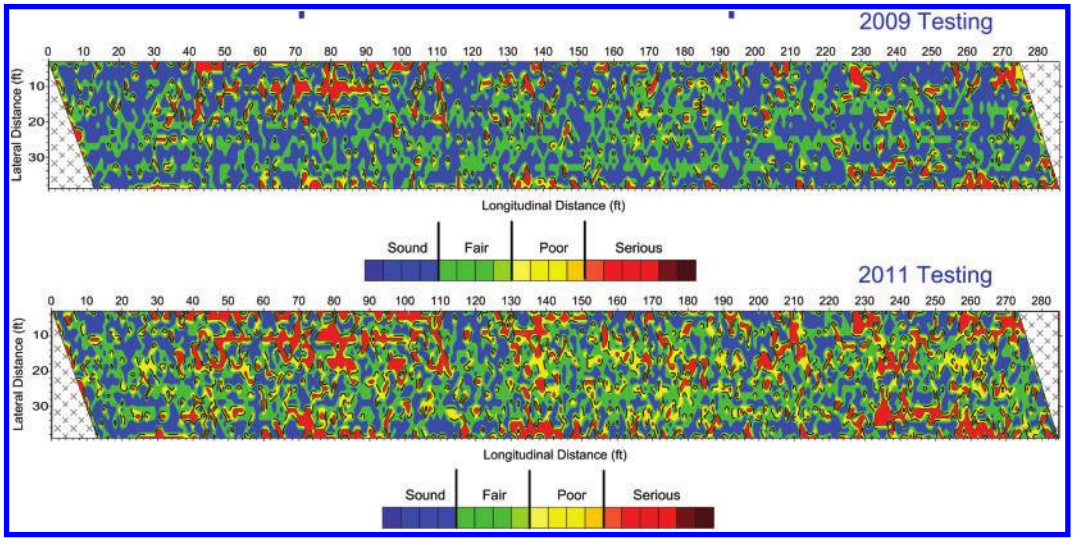

Figure 3. Delamination maps from impact echo testing for a bridge in Virginia.

Figure 4. The front view of the robotic platform and the attached components.

and USW data are collected at a resolution three to five times higher than typical data collection within the LTBPP, which is on a 0.6 m by 0.6 m grid. The two acoustic arrays are 1.8 m wide enabling surveys over a half of the width of a typical lane in a single robot run. The four resistivity probes are the Wenner probes (Figure 5) spaced 45 cm apart. There is a spraying system that keeps the probe electrodes moist at all times to ensure electrical coupling between the probes and concrete deck.

There are also two digital cameras positioned approximately 90 cm above ground that are used for imaging of the surface of the bridge deck. Each of the cameras covers approximately a 0.9 by 0.6 m deck area. The images collected are being automatically stitched into a single high resolution image of the deck surface. Also on the robot's front end is a laser scanner, which is used for obstacle avoidance. Two additional laser scanners on the sides (not visible in the figures) are used primarily for collision avoidance with curbs and barriers.

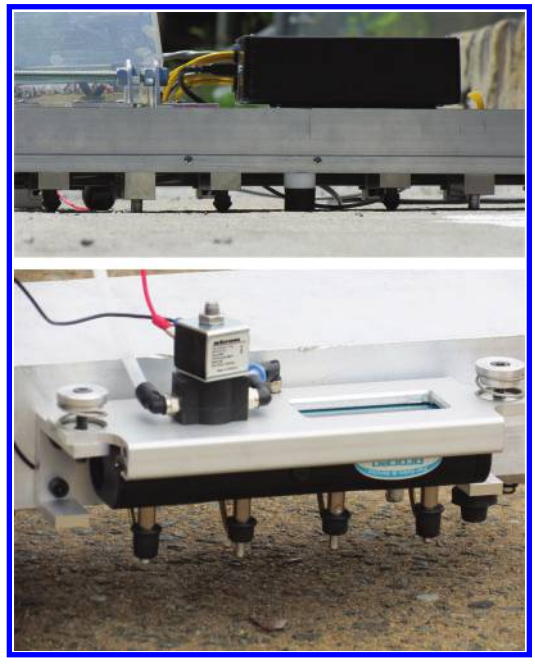

Figure 5. Impactors and sensors of the acoustic array (top) and a Wenner type electrical resistivity probe (bottom).

Two IDS Hi-Bright GPR arrays are mounted on the rear side of the robotic platform. Each of the arrays has sixteen antenna, or eight pairs of antennas of dual polarization. Similar to the acoustic arrays, the GPR arrays cover a strip of the deck 1.8 m wide. Finally, there is the third digital camera mounted on a mast in the middle of the robotic platform. The mast can lift pneumatically the camera to a 4.5 m height to take 360 degree panoramic images of the bridge deck.

Figure 6. The rear view of the robotic platform with GPR arrays.

The robot utilizes three systems for path planning and maneuvering. Those include a differential global positioning system (GPS), a wheel encoder and an inertial measurement unit (IMU). As shown in Figures 4 and 6, the robot carries two Novatel GPS antennas on the front and rear ends of the robot. The third GPS antenna, "the base station", can be placed at any point of the bridge deck. The data from the three positioning systems are fused using Kalman filter to secure the movement of the robotic system with the accuracy of several cm. It is necessary to take only three GPS coordinates on the bridge deck to fully define the robot's path. The robot moves fully autonomously, i.e. when the robot completes one survey strip it turns 180 degrees and slides laterally to a position for scanning of the next strip. The robot can also be operated manually using a joystick, Iphone or android type devices.

3.2 *Data analysis and presentation*

As stated in the introduction, the objectives of the robotic platform development included an automated and near real time data analysis, an improved data interpretation through a multi NDE complementary approach, and advanced and more intuitive data visualization. The data analysis, interpretation and visualization are conducted in the "command van" (Figure 7). The van is also used to transport the robot. The robot is unloaded and loaded using a pair of light ramps. During the transportation the sensor arrays are folded, as shown in the figure.

The data are wirelessly transmitted from the robot to the command van as they are collected. The data are analyzed as received. For example, the impact echo records are analyzed to create a delamination map, the deck surface images are stitched and analyzed to create a cracking map, etc. The robot operator can control and monitor data collection and analysis on four main monitors in the van. As an illustration, a screen describing the GPR data collection and analysis is shown in Figure 8. The top of the figure shows a GPR B-scan with the "picked" rebars (tips of hyperbolas). Below the scan are the diagrams of the amplitudes of reflections of the rebars, and the evaluated depth of the rebars

Figure 7. The command van with the robot in position for transportation.

(concrete cover). The information is used to map the reinforcement, plot the concrete cover map, describe the corrosive environment of the deck, and to identify zones of possible deterioration. In addition, condition indices are calculated and compared to the ones from the previous testing, if that one was conducted. A complete list of the functions that can be displayed on the four monitors is presented in Table 2. In addition, the operator has two additional monitors that allow monitoring of the robot movement and position on the deck. The monitoring of the movement is done by a camera on the roof of the van, as shown in Figure 7.

The results of all the evaluations listed in Table 2 can be reviewed using the condition maps, similar to the ones shown in Figure 2. In addition to the described data presentation, a 3D data visualization platform enables a very intuitive review of all the main deterioration types in the deck. In the 3D view, zones of low modulus, poor quality concrete are described as clouds of different levels of translucency and color. Similarly, delaminations are presented as predominantly horizontal surfaces, where the degree of translucency, and color type and intensity define the extent and severity of delamination. Finally, the corrosive environment is described through coloring of rebars, where hot colors indicate a highly corrosive environment. The 3D body of the deck can be overlaid by the image of the

4 CONCLUSIONS

The robotic system with integrated multiple NDE technologies enables condition monitoring of concrete bridge decks on a regular basis. The system overcomes deficiencies of the manual and single NDE technology data collection approaches in several ways: 1) the data collection is rapid and fully autonomous, 2) the application of the robotic system significantly reduces exposure of the bridge inspection crews to the passing traffic, 3) the complementary use of multiple NDE technologies enables detection of different deterioration type and enhances the certainty of detection, and 4) the associated platform for data visualization facilitates a more complete and more intuitive presentation of the deterioration and defects in the deck. While the initial objectives of the development were to address the needs of the LTBP Program, it is expected that the robotic platform will also in longer term be of benefit to state DOTs and other bridge owners. The benefits will stem from getting the information that will allow better planning, better selection of intervention procedures, and from reduced frequency and duration of traffic interruptions during inspections.

ABSTRACT: This paper presents a vision for the future monitoring systems which will become normal requirements for management of bridges as key objects of national infrastructure in the UK and elsewhere. Rather than being pushed by authorities and legislation, we expect that bridge managers will recognize the clear business cases for investing in well-designed targeted monitoring. To support this proposition, the paper presents two case studied where state-of-the-art bridge monitoring technology was used or potentially could be used to:

- Decide when to inspect and change bridge bearings, and
- Decide when to close various traffic lanes to reduce probability of overstressing bridge structural components.

1 INTRODUCTION

The UK Government's 2011 National Infrastructure Plan [1] signalled the need for investments of up to £250bn over 10 years to return UK infrastructure (transport, power, communications, water, and waste) to world class levels of performance. Only about a third of this can be provided from a public purse in the UK. The rest must come from private funding - most likely overseas sovereign investment funds. The key problem is clearly how to attract such funding and how to convince private finance that the investment in the UK infrastructure is sound. Having hard data about past and future physical performance of such infrastructure is a way forward to justify investment and attract private funding. In fact, it could well be the *only* way forward.

Focusing on bridges as key elements of any national infrastructure, the American Society of Civil Engineers (ASCE) reports a cost of $140bn to repair all deficient bridges in the United States [2]. Similar to the UK, whilst taxpayers in the USA can be expected to fund a small proportion of such enormous investment, as for the general infrastructure mentioned above, the remainder must come from private sources. The primary requirements for attracting both private and public investment in an infrastructure asset are managed risk and reliability of performance in continuous operation with ever increasing service and safety demands. Maximising return on investment requires minimisation of costs necessary to achieve that performance – put simply *getting more from less*. These requirements highlight the process of the whole-life performance management of civil infrastructure, a process involving decisions about design, construction, operation, maintenance, repair, decommissioning and demolition. Ensuring that such decisions are informed, correct and cost effective is the most important unsolved challenge in civil infrastructure management, attracting hundreds of researchers and multi-£M global research investment. These people and this investment are all trying to solve one of the most challenging problems in civil structural engineering nowadays: how to convert testing and monitoring data from objects of infrastructure, into knowledge and decision making when managing infrastructure as public assets? The problem is particularly acute for bridges, considering their importance, and is really about how to make sense of bridge testing and monitoring data. This research has yet to deliver significant benefits in the real world due to incoherent engagement with stakeholders, misdirected emphasis in the past focusing on hardware rather than data interpretation, tendency to view infrastructure assets in isolation and the lack of a systematic approach to link experiences between different structures. This is a recognised problem in the USA and Federal Highway Administration (FHWA) are still "working the problem" [4].

Focusing on bridges, the above stated problem is obviously not new. A paradigm shift is needed across the board and with all stakeholders in the way how bridges are managed from their conception to their decommissioning. Considerable cultural changes are needed and these will follow changes in the business models used for managing bridges including the legal

and economical framework within which public assets like bridges operate. This applies not only to the USA, but also to the UK, Europe and rest of the world. The prolonged crisis which has been shaking the foundations of the world economy for several years now may well become a badly needed catalyst for the required paradigm shift.

The continued drive for better and more enduring performance from bridges is crippled by the lack of technically sound, reliable, harmonised and economic means for monitoring asset condition. Hence, informed decision making by bridge managers is severely impaired. There is potential nowadays to transform monitoring into an *enabling technology* that will revolutionise the decision making process at all stages of an infrastructure's life-cycle: from design to demolition. This will yield extraordinary reduction of the currently very high direct and indirect cost of bridge performance management. The enabling technology will also foster growth of the infrastructure monitoring and decision support systems as a new technology sector which key role would be to resolve the £multi-trillion global challenge of managing deteriorating and failing infrastructure.

The aim of this invited paper is therefore to present a case and vision for this paradigm shift, making use of existing examples not only in civil engineering, but also in other engineering disciplines where such paradigm shifts happened and changed forever the ways how industries operated.

2 FUNDAMENTAL CAUSES OF PROBLEM

In essence, the problem lies in the nature of civil structural engineering design and disproportionately low level and certainty of information on which it is based relative to the huge importance of such structures. Because of this, in civil engineering the acceptable level of risk of structural failure or lack of its serviceability is at least an order of magnitude lower than for more technologically advanced structures employed in mechanical and aerospace engineering. There are three key reasons for this low risk approach:

1. Civil infrastructure, in particular major long-span bridges, underpin human society and supports not only traffic but the daily lives of hundreds of thousands of people and economies of linked regions.
2. Unlike aircraft, automobiles, trains and other mass produced machinery, which are extensively tested as prototypes during their design, objects of civil infrastructure including bridges are unique one-off designs with no opportunity for extensive prototype testing during design and before going into service. As such, they are designed with considerably reduced knowledge base and their structural performance is poorly understood making prediction of future behaviour difficult if not impossible.
3. The ambiguity and degree of uncertainty related to the actual operation of the structure, and potential increases in load and usage in the future, force the use of an extremely conservative design embedded in design guidelines which are used instead of prototype testing.

Notwithstanding the low-risk design methodology, critical infrastructure items such bridges deteriorate with time to such a point that, if no action is taken, they become unserviceable requiring closure and repairs, or may even collapse. To guard against this, operating authorities prescribe methods of routine, typically visual, inspection, which are slow, costly, and subjective, hence potentially quite unreliable.

The prime example of the dubious reliability of the current bridge inspection regime was generated in the UK during winter 2011/2012. A sudden and totally unexpected decision to completely close the Hammersmith flyover in London was made on 23 December 2011 after many nights of closure of the flyover for maintenance and visual inspection throughout 2011. This structure takes 90,000 vehicles per day on a strategically vital A4 route making it the prime gateway to London, not just for the West of the country, but also for one of the world's largest and busiest airports at Heathrow. This prime route remained completely closed until 13 January 2012, causing traffic chaos in West London for a period of three weeks, covering the Christmas and New Year holidays before partial reopening slightly reduced the chaos. This situation lasted for months. Apparently, an exceptional overloading event worsened the state of corroded tensioning cables of the 50-year old structure so that they started snapping at a rate fast enough for the authorities to close the flyover. This is speculation, since the structure had not been monitored over a long enough period of time. Hence, there is no information about 'normal loading' and no evidence that that the dramatic closure was actually necessary.

If anybody thought this was a chance the identification of a *new crack* on the already damaged Boston Manor viaduct forced a dramatic closure of the M4 between London and Heathrow airport – a key section along the Olympic Route Network. This lasted for five days in early July 2012. The new crack had been identified in a "sensitive location" following the final stages of the complex repairs to 15 mm long hairline cracks discovered *by chance* [5] in April in welds on the viaduct just west of junction 2 near Hounslow. A 7.5t weight restriction on the damaged stretch had been imposed immediately, diverting coaches and lorries onto busy local roads. The latest news is that Boston Manor viaduct is beyond further repairs and will be replaced.

How many similar cases and surprise total closures are lurking within the UK fleet of key bridges on the national transportation network?

3 THE WAY FORWARD

Interestingly, if a sudden event happened to a Roll Royce aero-engine high above the Pacific, such as a

lightning strike causing the engine to cough, monitoring sensors within the engine would automatically record all relevant responses. This data would be transmitted immediately from the aeroplane to the Rolls Royce 24/7 operations room in Derby, UK which continuously assesses on-line the performance of thousands of working jet engines around the world. Based on the instantaneous information from the aircraft and the expected performance, a decision would be made while the plane is still in the air if the engine requires additional inspection after landing, causing delays and financial losses. In the past and without the benefit of permanent monitoring and data streaming and analysis, this would almost certainly be the case as – similar to bridges – safety is paramount. However, it is not anymore due to this *service based* business model of manufacturing jet engines which is based on the on-line condition monitoring technology and instantaneous decision making process which Rolls Royce mastered and commercialised around the world. The data constantly collected from engines is invaluable to airlines as the information enables Rolls Royce to predict when engines are more likely to fail, letting the airlines schedule engine changes efficiently. Embracing such technology and innovation transformed Rolls Royce from a failing company in 1971 into a currently most successful manufacturer of jet engines in the world.

Why can't the same business model be employed in the management of bridges? Over many years in the UK there has been fragmentation of construction industry and infrastructure management characterised by significant shift towards the use of subcontracting, overly complex procurement approaches and uncertainty of future work on key infrastructure due to lack of vision and leadership. This has increased transaction costs, encouraged shortermism and deterred industry from a more strategic approach to investment in skills, technology and innovation [6]. There are, however, clear signs that this approach is changing offering great opportunities to the sector, one of them being use of permanent monitoring for effective decision making in managing key objects of infrastructure, including bridges.

4 MOTIVATION

Wenzel [7] noted that construction sector is conservative needing strong push to motivate it to implement new technologies, such as converting monitoring data into decision making. He outlined the following motivation drivers:

1. Responsibility-driven motivation, stemming from design standards, codes and guidelines which make mandatory requirements to instrument, monitor and interpret before deciding what to do with a particular structure, such as bridge in operation. This is particularly so when covering events such as emergencies or accidents whereby monitoring data before the event can describe what is 'normal' and data after the event can be used to establish if the structure still behaves as 'normal'. Conventional assessment in such situations tend to be overly conservative, usually to compensate for the lack of reliability.
2. Economy-driven motivation, stemming from, say, the need to reduce unnecessary maintenance costs, such as expensive and not particularly reliable regular inspections, or from the need to prioritise repairs within limited budgets which make use of more reliable information about the remaining life prediction of the structure. Another emerging motivation within this category is the need for an informed transfer of ownership from public to private hands, whereby hard data from the structure provides a more reliable information of the value and longevity of the structure which is an asset for the new owner, including their finance and insurance organisations.
3. Curiosity-driven motivation whereby forward-looking owners, operators and – in general – clients, understand limitations of the current civil engineering design practise and want to learn about the actual behaviour to help them plan future designs.

The following example will demonstrate usefulness of monitoring in decision making about their operation.

5 ASSESSMENT OF BRIDGE BEARINGS

The Humber Bridge was opened in 1981. Spanning 1410 m, it held the record of the world's longest single spans suspension bridge until 1997. The Bridge spans the Humber Estuary between Hessle (North) and Barton-on-Humber (South). The Hessle side span is 280m and the Barton side span is 530 m (Figure 9).

The aerodynamically shaped bridge box girder is discontinuous at the towers. At each end there is a pair of 'A-frames' which are approximately 3.8 m tall and 3.4 m wide (Figure 10). These bearings primarily accommodate axial movement of the span ends, but also permit rotation of the deck in the horizontal plane and in the vertical plane of bridge axis and towers as the bridge deforms under a combination of traffic, wind and temperature effects. In total there are 12 of these bearings, four on each span.

Figure 1. Humber Bridge instrumentation.

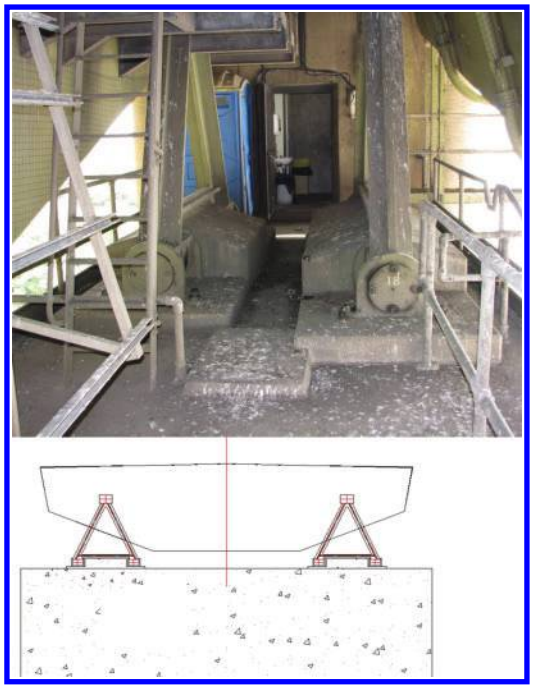

Figure 2. Top: Photo showing a pair of A-frames, one for the main and one for the side span. Bottom: The sketch shows a pair of A-frames connected to the main span box girder.

A pair of Hilti PD4 extensometers on each end of the main span was used to monitor the longitudinal deck movement at the positions of the two A-frames in Figure 10 (bottom). Hence, these two sets of data provided information to measure both longitudinal extension and horizontal plane rotation of the bridge at its end.

The end rotation is strongly dependent on wind speeds, as shown in Figure 11.

Ambient acceleration response of the deck is continuously recorded at midspan and used to estimate (in real time) the natural frequencies and damping ratios of the lowest frequency vibration modes. For the first (lateral) mode of vibration, Figure 12 shows the estimated natural frequencies as a function of the RMS of the corresponding block(s) of acceleration data. It can be seen that at about 0.2 m/s^2 RMS the frequency generally reduces and stabilises at about 0.054 Hz for higher levels of response. This indicates the likely non-linear 'stick-slip' behaviour somewhere in the structure, as confirmed by damping estimates whereby a similar 'unsticking' effect is observed roughly at the same RMS acceleration levels (Figure 13). The damping, however, is amplitude-dependent with lower damping corresponding to higher responses.

Figure 14 (top) shows diurnal variation of the four horizontal displacements measured extensiometers.

Figure 14 (bottom) cumulative quasi-static horizontal displacements of the four points on the two ends of the main span which indicate that their total travel is between 2 m and 3 m over the 10 day analysed. This means that each bearing travelled at least

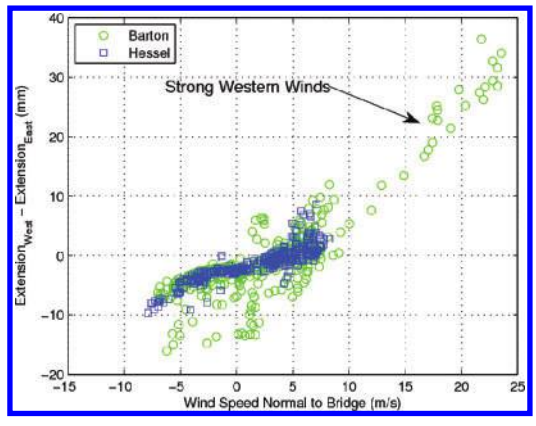

Figure 3. Hessle end rotates less than the Barton end under strong Western winds.

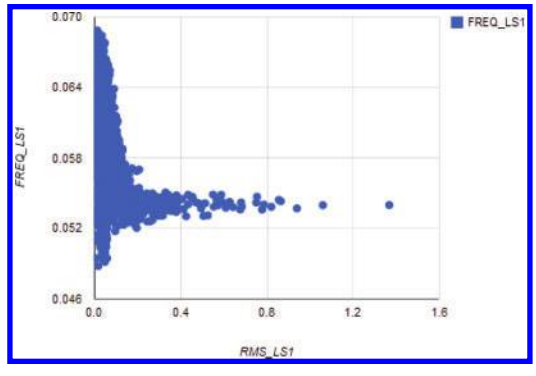

Figure 4. Amplitude-dependent natural frequency.

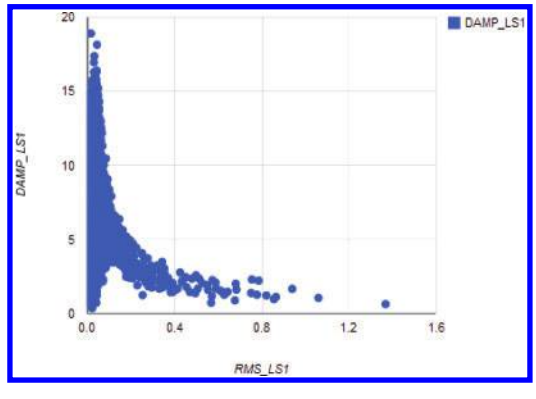

Figure 5. Amplitude-dependent damping.

3km since the opening in 1981. Not surprisingly, this has been linked with excessive wear at the A-frames and the likely stick-slip effect previously mentioned. Closer inspection indicated that one of the bearings visibly dropped and is resting on the concrete plinth underneath due to wear of the bottom of the pin-bush arrangement. Hence, in recent years the adequacy of capacity and performance of the main span A-frames

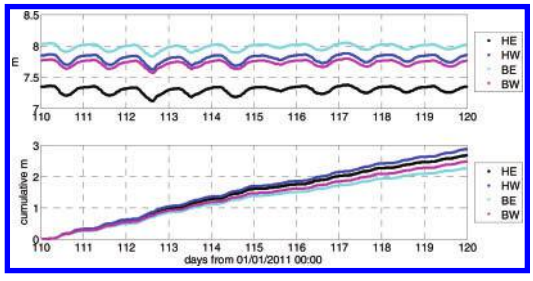

Figure 6. Diurnal variation of horizontal displacement at the bridge ends (top). Cumulative displacement of bridge decks over 10 days.

Figure 7.

has been questioned, based on the monitoring results which highlighted potential issue in the structure.

6 BRIDGE DAY-TO-DAY TRAFFIC MANAGEMENT

Modern bridge monitoring technology enables on-line access to continuous data streams, including video data, which can be used to see live performance of the bridge. Such systems may be used to control day-to-day bridge usage to avoid potential overstressing of structural elements.

Figure 15 shows a situation on a major partly loaded suspension bridge where one half of the bridge cross section is empty and the other is fully loaded due to a morning rush-hour accident.

As a consequence, the on-line monitoring system immediately registered that the stay cable tensions suddenly peaked whereas the natural frequency of the system dropped suddenly (Figure 16).

Figure 17 shows a major 6-lane road bridge in Continental Europe. The steel structural system with inclined supports acts as a 'shallow' frame with end columns rigidly connected to the structure that are 'sensitive' to temperature effects.

Figure 18 shows bending moment diagrams due to partial traffic load and temperature effects of +35°C. A potential problem for this bridge structure is that

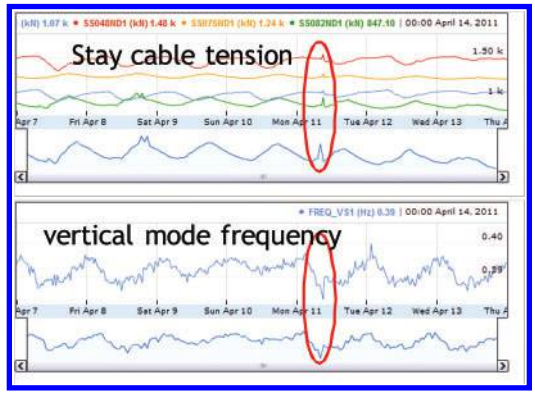

Figure 8. On line monitoring system picked up sudden tensions in stay cables and drop in the natural frequency of the bridge structure, which could be set up to trigger alert when managing traffic in cases of frequent bridge congestions.

Figure 9. Major road steel bridge.

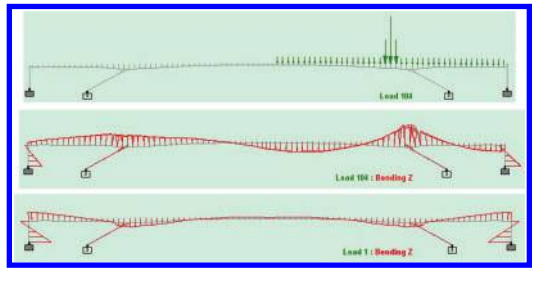

Figure 10. Critical load case – partial traffic loading combined with extreme temperature effects.

the combination of live load as shown in Figure 18 (top) with winter temperature of −35°C will make sure that the two bending moments arithmetically add at the bottom of the vertical end column which is fixed.

This is potentially unsafe situation which can be managed by a permanent monitoring system which would monitor temperature and strain/stresses at the bottoms of the end columns. In case of low temperatures and if the strain readings require, the traffic over this vital bridge can be reduced, reducing the

risk of a potentially unsafe situation that would otherwise require prevention by disruptive and expensive remedial work on the end columns.

7 CONCLUSIONS

This paper presents a vision for the future monitoring systems which will become normal requirements for management of bridges as key objects of national infrastructure in the UK and elsewhere. Rather than being pushed by authorities and legislation, we expect that bridge managers will recognize the clear business cases for investing in well-designed targeted monitoring.

To support this proposition, the paper presents three case studies where state-of-the-art bridge monitoring technology was used or potentially could be used to manage the following key aspects of bridge operation and maintenance:

- Deciding when to inspect and change bridge bearings, and
- Deciding when to close various traffic lanes to reduce probability of overstressing bridge structural components.

ABSTRACT: In Structural Health Monitoring (SHM), structural model updating plays an important role in maintaining integrity and safety of structures. This paper presents a model updating method using the measured global mode and local primary frequency. First the global test is experimented to obtain the low order modes which reflect the global information of the structure. Then the mass is added on the member of structure to increase the local dynamic characteristic and to make the member have local primary frequency. When a local excitation is applied on a member, if the caused vibration mainly consists of only one single modal which represents most of the local distortion, then the corresponding frequency is defined as the local primary frequency. Local primary frequency reflects more local information of the member and hence is more sensitivity to the local damage. Therefore, both low mode and local primary frequencies are combined and used for model updating. The effectiveness and accuracy of the proposed method is verified by the experiment.

1 INTRODUCTION

Structural health monitoring is a hot research in civil engineering, thereinto model updating is one of its important theoretical base, and provides reliable evidence for structural monitoring, forecasting and its safety assessment. However in civil engineering with the structures more and more huge and complexity, the accurate modal updating has becoming more and more difficult, which requires the proper dynamic measurements, as well as the efficient exploitation of the measurements.

Structural modal represents the structural basic dynamic information which is easy to be obtained or identified, and so modal-based damage identification or model updating methods are applied widely in civil engineering. In 2010 Zhao etc. identified the damage location and extents via the difference of the frequencies and mode shapes before and after damage occurred. In 2012, Shi etc. via the perturbation of the modes, damages of a bridge structure is identified considering variation of its boundary condition. However in practice, usually only a few low order modals can be identified, and are not sensitivity to local damages. Therefore it is hard to identify accurately all the parameters of the whole structure only via those data.

Recently substructure methods are popular on model updating of important local members via the local responses which avoid the difficulties of the whole structural model updating. Yang used continuous nonlinear least squares methods to estimate the substructure acceleration, velocity and displacement as well as parameters of its stiffness and damping etc.; meanwhile, the interface forces of the substructure are estimated. This method can effectively trace the variance of the structural damage. Xing and Mita identified structural damages of a shear model via ARMAX methods by staggered substructure, where degree freedom of each substructure is limited. Ou etc. proposed the Isolated Substructure Method which isolated the substructure virtually from the global structure into an virtual independent structure via local responses, and thus the classical methods aiming at the global structure can be used for substructure model updating. Substructure methods are usually used for identifying the local structure, and often required to monitor or identify the substructure boundary. The application becomes difficult on the substructures with complex boundary.

Above all, for the global structure test, it is not easy to capture the local modification, while local test can't accurately reflect the information of global

structure, especially structures like truss. Truss usually consists of hundreds of thousands of bars, and the change or damage of each bar has little influence on the global structure. In order to simultaneously update the global structure and local modification, this paper combines the global and local dynamic information, and performs a fine model updating of the truss structure.

2 MODAL UADATING

In structural model updating, the measured dynamic information is taken as known, and proper physical parameters are selected as optimization parameters, which are often optimized by minimizing the errors between the tested modal and the theoretical finite element model. The precision and the amount of the measured data are the key factors in structural model updating. Aiming at the characteristic of space truss, this paper respectively uses modal test on global structure and amounts of tests on local bars. The dynamic information which is sensitivity tothe local damage is digged for the updating.. The objective function is built via combing the information of both global structure and local structure, which is shown in Equation 1.

$$f(\mu)=\sum_i \alpha_{g,i}\left\|\frac{\omega_{g,i}(\mu)-\bar{\omega}_{g,i}}{\bar{\omega}_{g,i}}\right\|+\sum_j \alpha_{s,j}\left\|\frac{\omega_{s,j}(\mu)-\bar{\omega}_{s,j}}{\bar{\omega}_{s,j}}\right\| \quad (1)$$

where μ is the modification factor to be updated; $\bar{\omega}_{g,i}$ is the identified ith low order frequency of the global structure, while $\omega_{g,i}(\mu)$ is the corresponding frequency of the theoretical FEM model, $\alpha_{g,i}$ is the weight of error of the corresponding measured global information; $\bar{\omega}_{s,j}$ is the jth measured frequency which reflects the local information, while $\omega_{s,j}(\mu)$ is the corresponding frequency of the theoretical FEM model, $\alpha_{s,j}$ is the weight of error of the measured local information.

3 TRUSS EXPERIMENT

An experiment of a space truss model is performed here to introduce the proposed model updating method by combing the global and local information, and the efficiency of the method is verified.

3.1 *Truss model*

A supported steel 20-span space truss is shown in Figure 1, which is an experimental rail-cum-road bridge model. It is 8 m long with the height of 0.9 m, width of 0.56 m, and consists of 312 bars, with the nodes of 108. The young's modulus is 2.06 Gpa, and the density is 7850 Kg/m^3. The bars, steel tubes, are connected by bolted spherical joint (bottom right in Figure 1), of which the diameter is 80mm. The bars are classified into three types according to its radius, see Table 1.

Figure 1. A truss experimental model.

Table 1. Three types of bars in truss structure.

Types		Bar A	Bar B	Bar C
Number		80	198	34
Tubes	Outside diameter(mm)	30	20	14
	Thick(mm)	8	3	3
Bolt	Types	M20	M16	M10
	Length(mm)	100	90	60

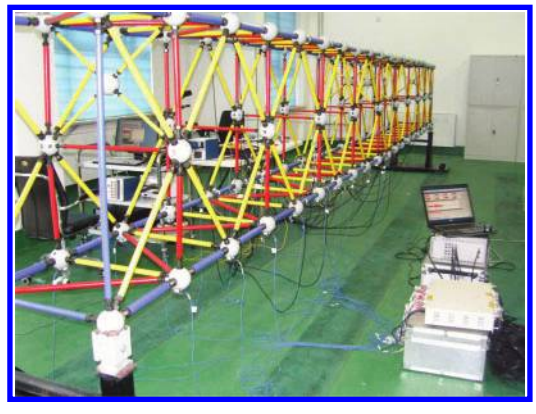

Figure 2. Accelerations placement.

3.2 *Model test of the global truss*

Accelerometers are located on the bottom nodes of the truss, shown in Figure 2. Ambient excitation is applied on the structure, and the modal shapes and frequencies are identified via the caused random responses, shown in Figure 3 and Table 2.

First the theoretical finite element model (FEM) is built, where each bar is defined as an element. The model has 312 elements with 108 nodes and 638 degree of freedoms. The element cross sections

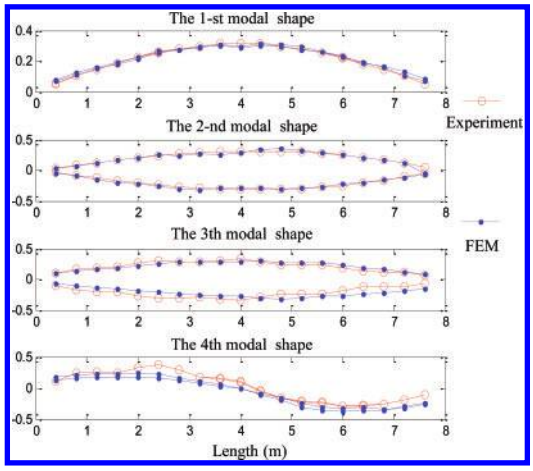

Figure 3. The comparison of modes of global structure.

Table 2. The errors of lower order natural frequencies of global structure.

Order	Experimental	Theoretical	Error
1	18.4	23.27	26.47%
2	27.6	34.41	24.67%
3	36.8	52.58	42.89%
4	53.3	76.97	44.41%

and initial moment are calculated from the geometric dimensioning. The nodes are rigid and set as mass points to consider the weight of the spherical joints and bolts. The mass is evaluated as 2.83kg. Figure 3 and Table 2 respectively compares the modal shapes and frequencies which are obtained from the experimental model and FEM model. It shows that the errors between them are rather obvious, around 30%, which tells that the built theoretical FEM model is very coarse.

3.3 *Local dynamic test*

The members of bar B in Table 1 are classified into four kinds according to their lengths and positions (Figure 4). Local dynamic tests are performed on the four kinds of bars. In order to increase the local dynamic characteristic, masses are added in the middle of the bars. Due to that the weight of one accelerometers and its connector is 340g, so in the experiment location of the accelerometer plays the role of the additional masses, and the value of added mass is adjusted by the number of the located sensors. For long bar, its local stiffness is relatively small, and one additional mass is enough, that is, one accelerometer is located. For short bar, its local stiffness is rather big, and more sensors are needed. The location of the sensors or additional masses is shown in Figure 5.

A straight bar in horizontal plane is taken as an example to illustrate and experimentally verify that

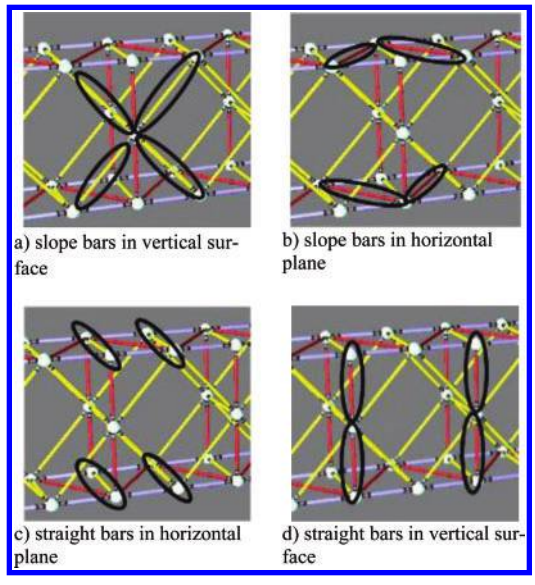

Figure 4. Four kinds of elements.

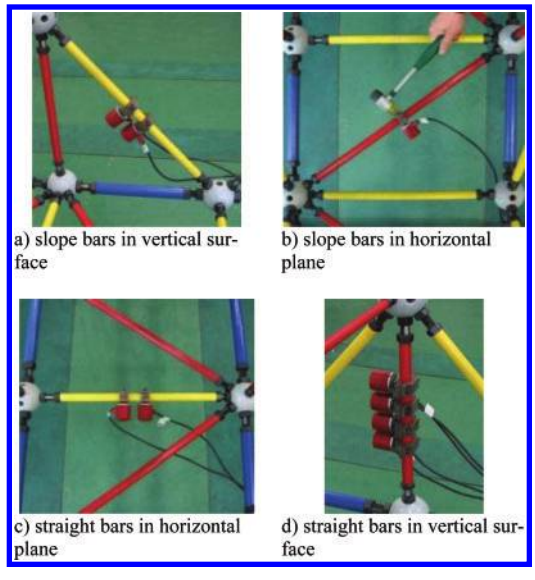

Figure 5. The placements of additional masses.

local characteristic can be increased via adding mass on the corresponding bar. Three cases are discussed, that is, two, three and four masses (sensors) are respectively added on the bar. In each case, a hammer excitation is applied on the middle of the bar, and the corresponding responses are measured, then the spectrum analysis is performed. The obtained power spectrums in the three cases are shown in Figure 6. Because the excitation is applied on the local bar, so the local model is certain to be excited. The bigger the additional mass value is, the more obvious the caused local characteristic will be. In the cases of two or three additional masses, the power spectrum

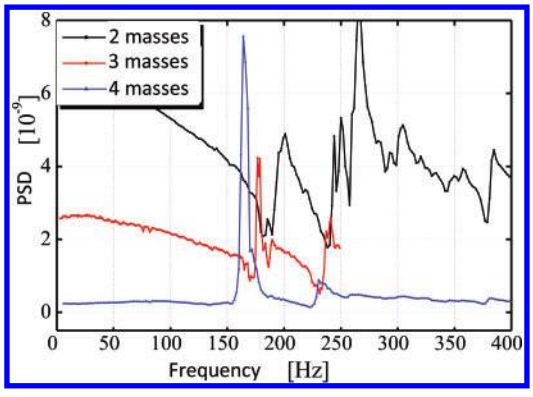

Figure 6. The power spectrum.

of the global structure has multiple peaks. It is hard to judge which frequency belongs to the local bar, and which frequencies reflect the model of the global structure, that is to say, the local characteristic is not obvious. While in the case of four additional masses, the power spectrum only has one peak, it shows that the action of the local excitation is mostly absorbed by the local bar itself and the additional masses. In this case, the caused vibration mainly is the distortion of the local bar, so the frequency corresponding to the peak in the power spectrum belongs to the local bar and is defined as the local primary frequency primary frequency. Certainly the local primary frequency is mainly determined by the stiffness of the bar. In order to compare the measured local primary frequency and that of the theoretical model, 58 bars are picked up to perform an test, which are respectively 14 bars from the slope bars in vertical surface, 16 bars from slope bars in horizontal plane, 20 bars from straight bars in horizontal plane and 8 bars from straight bars in vertical surface. Sensors(masses) are located on these bars respectively according to the way shown in Figure 5, and the hammer excitation is applied. The identified local primary frequencies are shown in Figure 7. Table 3 compares the measured local primary frequency and that of the theoretical model, where respectively one bar is chosen from each kind of bars. It shows that the identified value from the experiment has obvious difference from the theoretical value, which tells that the theoretical model has significant error compared to the actual model, and needs to be updated.

3.4 *The selection of updating parameters*

In practice, the actual Young's modulus of the steel, physical dimension and the density have little error from the theoretical values. Then the factor which causes the errors of FEM model is mainly due to the node model, and so node model is updated in the model updating.

First the fine model of the bolted spherical joint, bolt and the steel pipe are built considering their actual way of connection, shown in Figure 8. It considers the local reinforcement of the spherical joint($r = 4$ cm) to the

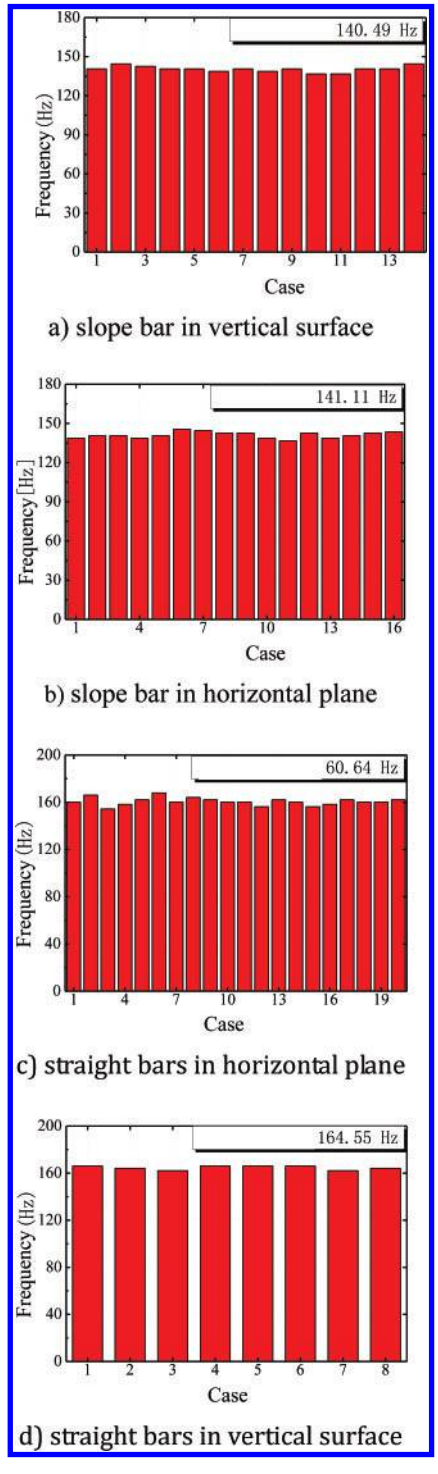

Figure 7. The identified local primary frequencies.

ends of the pipe by a reinforcement parameter k which is the ratio of the spherical joint stiffness to the pipe stiffness. The definite value of k needs to be optimized. In addition, it considers the local weakening caused by

Table 3. The errors of local primary frequencies of 4 kinds of elements

Types	Identified	Theoretical	Error
Slope bar in vertical surface	138.67	151.24	9.06%
Slope bar in horizontal plane	140.63	155.57	10.62%
Straight bars in horizontal plane	166.02	176.28	6.18%
Straight bars in vertical surface	164.06	186.52	13.69%

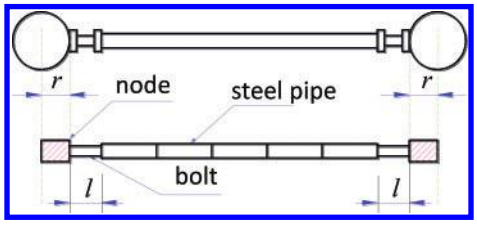

Figure 8. Fine modeling of the element.

bolt. Denote l the weakening length, which needs to be optimized. The stiffness in the weakening range takes the value of the bolt. Because there are holes in the spherical joint and it is connected with bolts and nuts, so it is hard to determine the joint weight, which needs to be updated. Above all, reinforcement parameter k, weakening length l and the joint weight m are taken as the model updating parameters.

According to the model in Figure 8, a bar is divided into 9 elements including 2 spherical joint elements, 2 bolt elements, and 5 pipe elements. Then the fine model will have 2606 nodes with 2918 bar and 15614 degree of freedoms(Dofs). Certainly the model is complicated and the computational work will be huge. Therefore, model reduction is considered.

For each bar, the fine model has 9 elements and 60 Dofs. Through Guyan reduction, the 60 Dofs are condensed into 12 Dofs on the two ends of the bar, and thus the dimension for the condensed substructure stiffness and mass matrix is 12. Then the condensed stiffness and mass matrix are used to assemble the parameter matrix of the whole structure model, except the bar with additional mass, i.e. the bar to be updated, of which its fine model with 60 Dofs is directly used without reduction. In this way, it balances the considerations on the computational work, the relative accurate connection and the accuracy of the local bar analysis.

3.5 *Model updating*

After building the fine FEM, the identified 4 models (Figure 3) and 58 local primary frequencies (Figure 7) are used to optimize the joint mass m, reinforcement parameter k_i, and weakening length l_i of the four kinds of bars via the objective function (Equation 1). The optimized joint mass m equals to 3.33kg, and the parameters k_i, l_i are shown in Table 4. Substitute the modified parameters into the FEM, the frequencies and modes of the model are estimate and compared with the values identified from the measurements, respectively shown in Table 5 and Figure 9. The comparison of the local primary frequencies here only lists some typical cases, shown in Table 6. In all the comparisons, the biggest error is 5.55%, which shows that the updated space truss model reflects the actual truss structure on both global dynamic behavior and local characteristic and the model is updated effectively and accurately.

Table 4. The model updating of the node parameters

Type	l(cm)	k
Straight bars in vertical surface	4.5	3.2
Slope bars in vertical surface	2.9	4
Straight bars in horizontal surface	6.7	1.6
Slope bars in horizontal surface	2.7	8

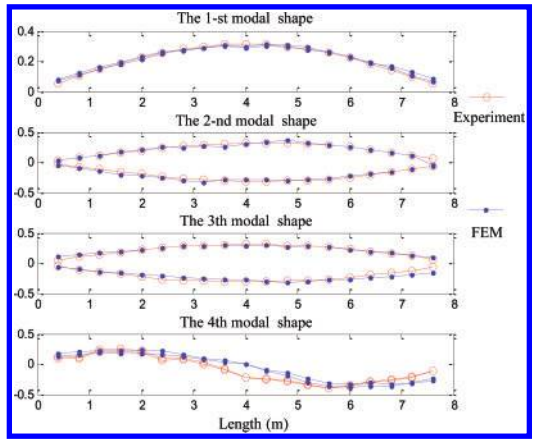

Figure 9. The comparison of modes of global structure.

Table 5. The errors of lower order natural frequencies of global structure

Order	Identified	Theoretical	Error
1	18.4	18.82	2.28%
2	27.6	27.25	−1.25%
3	36.8	38.63	4.97%
4	53.3	50.34	−5.55%

4 CONCLUSION

This paper effectively combines the dynamic information of the global structure and the local structure, and performs the model updating of a space truss structure

Table 6. The errors of local primary frequencies.

Types	Identified	Estimated	Error
Straight bars in vertical surface	166.02	162.81	−1.93%
Slope bars in vertical surface	140.63	138.99	−1.17%
Slope bars in horizontal surface	138.67	138.24	−0.31%
Straight bars in horizontal surface	164.06	167.55	2.13%

experimentally. The obtained main conclusions are as follows:

(1) According to the characteristic of the space truss, masses are added on the local bars to enlarge their local characteristic. In this way, under local excitation the vibrates mainly represented by the local bar.
(2) Local primary frequencies mainly reflect the characteristic of the local bar, while the easily identified low order models mainly reflect the global structural characteristic. So their combination can adequately use the measured data and effectively performs the structural model updating.
(3) Fine model of the local bar is built; meanwhile model reduction is used to reduce to the number of Dofs. This improves the optimization efficiency and on the other hand also assures the built FEM reflect the structural real information as much as possible.

ABSTRACT: The acquisition of pertinent modal data in good quality and sufficient quantity is fundamental to the success of a structural identification/damage detection process using a global dynamics based approach. A series of studies have been conducted recently to explore the potential use of the so-called artificial boundary condition (ABC) frequencies for structural identification. The ABC frequencies correspond to the natural frequencies of the structure as if additional pin supports (artificial boundary) were inserted at certain locations, but they are derived from the frequency response measurements on the original structure without the actual need of inserting the additional pins. This paper introduces and discusses the studies investigating into the effectiveness of using such frequencies in a FE modal updating procedure and the practicality of extracting such frequencies from a typical modal testing survey.

1 INTRODUCTION

Structural identification and damage detection have attracted considerable attention in the civil engineering research community over the last three decades. In the context of global structural assessment, a lot of researches have been devoted to develop techniques for evaluating the condition of an existing structure based on the assumption of availability of the required modal data, particularly natural frequencies and mode shapes. In real applications, however, measurement errors and environmental noises dictate that only a limited amount of such data as acquired from a physical test may be truly useful in a parameter identification or damage detection procedure.

It is well recognised that modal frequencies may be measured with generally much higher accuracy as compared to mode shapes. Typically the errors in the measured natural frequencies may be controlled within 1%, whereas the errors in elements of a measured mode shape vector could be as much as 20% (Mottershead & Friswell 1993). However, the limitation in relying on the frequency information is also obvious; the total number of such frequencies that may be measured from a structure is limited; and moreover, lower order natural frequencies are generally insensitive to local damages. In this respect, seeking additional modal frequency data becomes a subject of much research interest.

The use of the zeros (anti-resonances) in the frequency response function (FRF) curves for damage detection of structures has been explored by many researchers. Since the zeros occur generally at different frequencies for different measurement points, there exist many more zeros than resonances, and thus it provides a plentiful resource for the enlargement of the frequency dataset (Lallement & Cogen 1992). Studies on the use of anti-resonances for finite element model updating (e.g. Ambrogio & Fregolent 2000, Jones & Turcotte 2002) tend to suggest that the anti-resonances from the driving-point FRFs are more suitable for model updating. As a matter of fact, the anti-resonances in a driving-point FRF are effectively the natural frequencies of a modified system by adding a pin (restraint) to the respective DOF.

A more general approach to generating additional modal frequency would be altering the boundary condition so as to derive the perturbed natural frequencies of a structure (Li et al. 1995). However, such an idea can hardly be implemented in practice due to the obvious impracticality of physically changing the boundary condition of a real structure for a measurement purpose.

The possibility of obtaining a diverse range of "perturbed" natural frequencies without the need to actually impose the additional supports has been theoretically established through the introduction of the concept of artificial boundary condition (ABC) frequencies (Gordis 1996, 1999). Using this approach, the natural frequencies of a structure with "artificially" added pin supports at certain locations may be derived from the incomplete frequency response function (FRF) matrix measured from the original structure. The term of "artificial boundary condition"

reflects the fact that, although the frequencies thus derived are equivalent to the natural frequencies of the perturbed system, the perturbed boundary conditions need not be actually imposed. In the case of ABC frequencies with a single ABC pin, it degenerates to the driving-point anti-resonances.

With the incorporation of the ABC frequencies, the modal frequency dataset can potentially be expanded dramatically. Three key questions then naturally arise, namely,

a) how effective the ABC frequencies could be in a structural parameter identification or finite element (FE) model updating process,
b) given the large number of possible ABC configurations, even for a limited number of ABC pins, how should a selection be enforced so that the chosen ABC frequency information would only improve the general condition of the identification, and
c) how accurate the ABC frequencies may be extracted from physical measurements.

A series of investigations have thus been organised to comprehensively address the above questions (see for example Tu & Lu 2008, Lu et al. 2008, Mao & Lu, in prep.). In this paper, an overview of the above investigations will be provided, along with brief descriptions of the relevant techniques and discussion on some key measurement and data processing considerations.

2 BACKGROUND THEORY

The concept of the ABC frequencies is somewhat analogous to the driving point anti-resonances, in which case the singularities in the frequency response function (FRF) correspond to the natural frequencies of the structure as if a single artificial pin was added at the respective DOF. It is conceivable that if multiple pins could be involved, the resonant frequencies will generally become more sensitive to structural parameter changes. The way of deriving such ABC frequencies (with multiple pins) was first proposed in the works by Gordis (1996, 1999). For a linear system and considering the partition between the measured and unmeasured coordinate (DOF) sets, the steady-state equation of motion of the forced vibration at a forcing frequency (rad/s) may be written as:

$$\left(\begin{bmatrix} \mathbf{k}_{mm} & \mathbf{k}_{mo} \\ \mathbf{k}_{om} & \mathbf{k}_{oo} \end{bmatrix} - \omega^2 \begin{bmatrix} \mathbf{m}_{mm} & \mathbf{m}_{mo} \\ \mathbf{m}_{om} & \mathbf{m}_{oo} \end{bmatrix} \right) \begin{Bmatrix} \mathbf{x}_m \\ \mathbf{x}_o \end{Bmatrix} = \begin{Bmatrix} \mathbf{f}_m \\ \mathbf{f}_o \end{Bmatrix} \quad (1)$$

where $\mathbf{k}$ and $\mathbf{m}$ are stiffness and mass matrices, $\mathbf{x}$ and $\mathbf{f}$ are vectors of generalized response and excitation amplitudes, respectively. Subscript *'m'* and '*o*' represent the measured coordinates (or DOFs) and unmeasured DOFs ('omitted coordinate set' or OCS), respectively. The OCS is effectively a reduced system, in which all the measured DOFs are restrained or pinned to the ground. Introducing the impedance matrix, $\mathbf{Z} = \mathbf{k} - \omega^2\mathbf{m}$, Eq. (1) can be re-written as:

$$\begin{bmatrix} \mathbf{Z}_{mm} & \mathbf{Z}_{mo} \\ \mathbf{Z}_{om} & \mathbf{Z}_{oo} \end{bmatrix} \begin{Bmatrix} \mathbf{x}_m \\ \mathbf{x}_o \end{Bmatrix} = \begin{Bmatrix} \mathbf{f}_m \\ \mathbf{f}_o \end{Bmatrix} \quad (2)$$

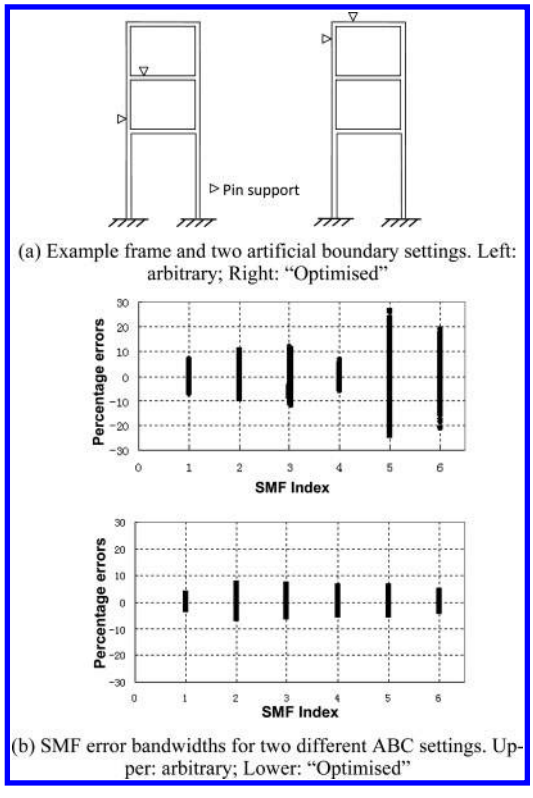
Assuming no excitations are imposed on the omitted coordinates, i.e., $\mathbf{f}o = \mathbf{0}$, it follows:

$$(\mathbf{f}_m) = \left(\mathbf{Z}_{mm} - \mathbf{Z}_{mo}\mathbf{Z}_{oo}^{-1}\mathbf{Z}_{om}\right)(\mathbf{x}_m) \quad (3)$$

or

$$\frac{\mathbf{f}_m}{\mathbf{x}_m} = \mathbf{H}_{mm}^{-1} = \left(\mathbf{Z}_{mm} - \mathbf{Z}_{mo}\mathbf{Z}_{oo}^{-1}\mathbf{Z}_{om}\right) \quad (4)$$

where $\mathbf{H}_{mm} = \mathbf{x}_m/\mathbf{f}_m$ is the incomplete frequency response function (FRF) matrix measured from the structure.



Eq. (4) expresses the inherent relationship between the inverse of $\mathbf{H}_{mm}$ and the dynamic characteristics of the OCS as represented by $\mathbf{Z}_{oo}$, such that at the natural frequencies of the OCS, $\mathbf{Z}_{oo}^{-1}$ is singular, so $\mathbf{H}_{mm}^{-1}$ is also singular, and vice versa. Consequently, by identifying the singularities (resonance frequencies) from the elements of $\mathbf{H}_{mm}^{-1}$, one can determine the natural frequencies of the OCS, i.e., the frequencies of the structure as if it was physically pinned at the measured DOFs. Thus, from a theoretical point of view the determination of the perturbed natural frequencies (called ABC frequencies herein) of the structure with additional pin constraints would become a matter of measuring and processing the relevant FRFs from the existing structure.

3 EFFECTIVENESS OF INCORPORATING ABC FREQUENCIES IN STRUCTURAL IDENTIFICATION

Prior to embarking on the investigation of the extraction of ABC frequencies from physical tests, it was considered necessary to establish a comprehensive understanding with regard to the potential effectiveness of incorporating ABC frequencies in a parameter identification process. For this purpose, a numerical simulation study has been conducted in a FE model updating framework. To assist in the selection of more effective ABC frequencies, a Genetic Algorithm (GA) based optimisation approach has also been developed (Tu and Lu 2008).

3.1 *General effectiveness of ABC frequencies in FE model updating*

A 3-storey 1-bay frame from a set of cases being studied is used here as an illustration, see Fig. 1(a). The frame is simplified to have 6 flexural rigidity parameters to be determined, one for each individual beam and

(a) Example frame and two artificial boundary settings. Left: arbitrary; Right: "Optimised"

(b) SMF error bandwidths for two different ABC settings. Upper: arbitrary; Lower: "Optimised"

Figure 1. Illustration of effect of incorporating ABC frequencies in FE model updating (Tu and Lu 2008).

one for all columns in an individual storey. A dimensionless stiffness modification factor (SMF), which is defined as the ratio between the actual flexural rigidity and that of the reference (intact) beam or column, is considered in the updating process.

For a comparison, three different sets of frequency information are used respectively, namely i) the first 6 natural frequencies, ii) the first six natural frequencies plus six ABC frequencies with two artificial pins at randomly selected locations (see Fig. 1(a)), and iii) similar combination as above but with the ABC frequencies selected via an optimization procedure, which will be described in 3.2.

Fig. 1(b) depicts the projected update results of the 6 SMFs in terms of the variation (error) range for a fixed level of 1% perturbation (uniformly distributed error) in the frequency data for the above mentioned dataset ii) and iii), respectively, from a sensitivity analysis. For dataset-i) the results are worse than case ii) and so they are not shown. It becomes clear that the incorporation of a reasonable number of ABC frequencies generally improves the model updating conditions. Furthermore, through a rigorous selection procedure the incorporation of the same number of ABC frequencies could yield considerably more accurate results; in the present illustrative example the maximum error in the updating result reduces from 30% to around 8%.

Similar analysis was also performed on different combinations of the two pin locations, as well as on other frame configurations, and the trends are generally consistent. Two general observations are thus established, namely, a) with the addition of a reasonable number of ABC frequencies, the condition of the parameter identification is generally improved; and b) the effectiveness of using a certain set of ABC frequencies, e.g., with two artificial pins, is dependent upon the locations of these pins. For this reason, a systematic selection of the ABC patterns is deemed to be necessary.

3.2 *A GA-based algorithm for optimisation of the ABC configurations*

For the optimal configuration of possible artificial boundaries, a novel method using binary GA has been developed (Tu and Lu 2008). The essential consideration in this approach is to code the ABC pin positions, normally being a sub-set of the DOFs where measurements are considered possible. This DOF library is then arranged in the form of a row vector, which consists of the numbers of the candidate DOFs in the search domain. The phenotype variables in GA are integer numbers which identify the DOFs in the DOF library, herein using a sequential number. In principle, all combinations of the ABC pins may be incorporated. For practicality and simplicity, a pre-defined fixed number (e.g. two) of ABC pins will usually suffice. Subsequently the optimisation reduces to determining the optimal locations of these pins.

In the proposed procedure, the integer variables identifying the DOFs are coded using binary bits in the GA chromosome. The single point crossover is used and mutation is implemented by bit flip (binary mutation). Once the evolution process is completed, the binary chromosomes are converted back to the corresponding DOFs, thus the "optimal" artificial boundary is obtained.

The fitness of a chromosome, which represents the adequacy of a particular ABC pin arrangement, may be evaluated in different ways. The present approach uses a sensitivity analysis concerning the variation in the updated parameters $\{\delta p\}$ for a given margin of variation in the measurements $\{\delta R\}$, i.e., $\{\delta R\} = \mathbf{S}\{\delta p\}$. In a numerical analysis, the sensitivity matrix $\mathbf{S}$ may be evaluated as the percentage changes of the response components due to one percent change of the structural parameters from a reference state. The sensitivity of the ABC frequencies is calculated by extending the sensitivity of the natural frequencies (Friswell and Mottershead, 1995), as:

$$\frac{\partial f_i}{\partial p_j} = \frac{\{\phi_i\}^T \left(\frac{\partial \mathbf{K}}{\partial p_j} - 4\pi^2 f_i^2 \frac{\partial \mathbf{M}}{\partial p_j} \right) \{\phi_i\}}{8\pi^2 f_i \{\phi_i\}^T \mathbf{M} \{\phi_i\}} \tag{5}$$

where f_i and $\{\phi_i\}$ here become the ith "natural frequency" and the associated mode shape of the ABC

system, and the matrices **K** and **M** represent the stiffness and mass matrix of a structural system incorporating the ABC as well. By an inversion procedure, the parameter change vector can be related through a gain matrix G to the response change vector as:

$$\{\delta p\} = \left(\mathbf{S}^T\mathbf{S}\right)^{-1}\mathbf{S}^T\delta\{R\} = \mathbf{G}\{\delta R\} \tag{6}$$

After obtaining the vector of $\{\delta p\}$ for a randomly sampled response dataset within a pre-defined perturbation (error) bound (1% herein), the overall variation of $\{\delta p\}$ is taken to represent the fitness of the chromosome using the following formula:

$$\text{Fitness} = -\left(\mu_{\text{SD}} + \sigma_{\text{SD}}/\mu_{\text{SD}}\right) \tag{7}$$

where μ_{SD} denotes the mean of the standard deviation (SD) in each element of $\{\delta p\}$, and σ_{SD} is the standard deviation of SD.

The example case given in 3.1 (Fig. 1(b)) is clearly illustrative of the effectiveness of the above GA-based ABC selection procedure.

4 EXTRACTING ABC FREQUENCIES FROM PHYSICAL TESTS

The next and even more crucial question is how practical and reliable the ABC frequencies may be extracted from real measured responses. From the experimental investigations conducted so far on a laboratory scale, the results are generally encouraging. A comprehensive coverage of the experimental study is reported elsewhere (Mao and Lu, in prep.). In this section a brief overview of representative experiments and the main observations are provided and discussed.

4.1 *Test programme and sampling requirement*

The test specimens included a steel model beam and an aluminum slab, with fixed end supports. Fig. 2 shows the basic set-up on the model slab. A measurement grid was arranged such that a variety of combinations of input-output locations could be accommodated. The beam was actually divided into 30 segments along its length, whilst the slab had a 10 × 5 measurement grid points, denoted as A1 through J5.

For this exploration, the excitation was generated by hammer impact. The responses were recorded with small-size modal testing accelerometers. Confining to one and two artificial pin supports, which already allows for the examination of a large number of ABC configurations, only two accelerometers were needed, one fixed at the impact point, and another being moved from point to point for different tests. After measurements from all tests were collected, FRFs were calculated.

As high quality FRF curves is key to the derivation of the ABC frequencies, an accurate record of the impact force becomes important, and this necessitates

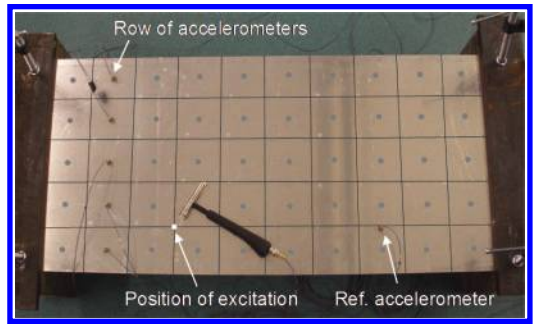


Figure 2. Test set-up for the model slab.

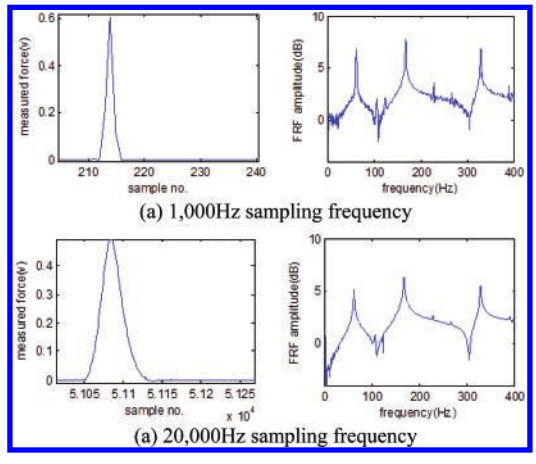

Figure 3. Measured impulse forces (left) and corresponding FRF curves (right) using different sampling frequencies.

a sampling rate which could be orders of magnitude higher than what may be appropriate for sampling the structural responses. Figure 3 gives a comparison of a FRF curve resulting from the tests where the impact force was sampled using a sampling rate of 1000 and 20000 per second, respectively. The improvement with the increased sampling rate is apparent. In different applications, a sufficient sampling rate for the impact force will depend on the pulse duration which in turn depends upon the type (hardness) of the impactor tip. A trial measurement would help determine an appropriate sampling rate satisfying both the recording accuracy and the efficiency in terms of processing and computational costs.

4.2 *Processing of FRFs for improved quality*

Standard signal processing techniques, such as windowing, averaging and filtering were implemented in the calculation of the FRFs.

A procedure based on the Single Value Decomposition (SVD) is also employed to further improve the quality of the measured FRFs. In the procedure adopted, the impulse response function (IRF) is firstly obtained from FRF data using inverse Fourier transform, and these IRF data are then used to form a Hankel

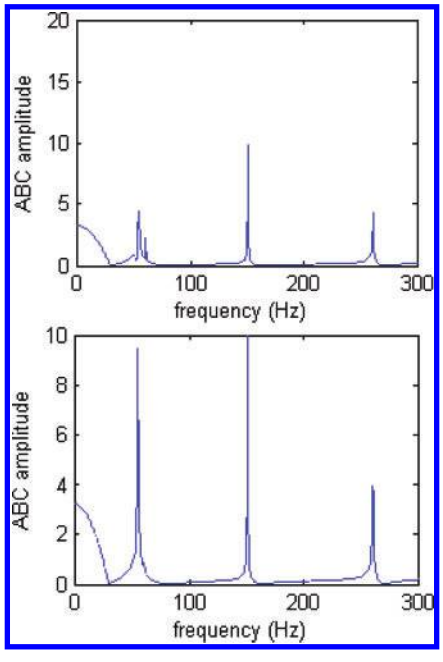

Figure 4. Typical one-pin ABC curves from the test beam. Upper: before applying SVD; Lower: after SVD.

Table 1. Beam's one-pin ABC frequencies: experimental vs. and FE predicted results.

Scenario	Frequencies (Hz): measured / FE		
(Pin location)	1st	2nd	3rd
"6"	39.9 / 38.8	105.2 / 104.8	210.3 / 206.4
"22"	54.2 / 53.7	152 / 150	261 / 262.7

matrix following the recommendation in Sanliturk and Cakar (2005). The rank of the Hankel matrix is then determined from the singular value distribution curve, and higher singular numbers are eliminated. Finally, the modified Hankel matrix is reinstated, and with an inverse Fourier transform a noise-removed FRF is obtained.

4.3 *Extraction of ABC frequencies*

Combining the impact and response measurement positions yields various ABC configurations. With the processing described above, the required FRFs are made available to compute the $\mathbf{H}_{mm}^{-1}$, from which the ABC frequencies for the respective ABC pin arrangements can be identified. For verification, the test beam and slab were also analysed using FE models to predict the respective modal properties.

Figure 4 illustrates some typical one-pin ABC curves for the test beam. The first few peaks can be firmly identified as the corresponding one-pin ABC frequencies, and this is confirmed by comparing to the FE predicted natural frequencies of the beam where

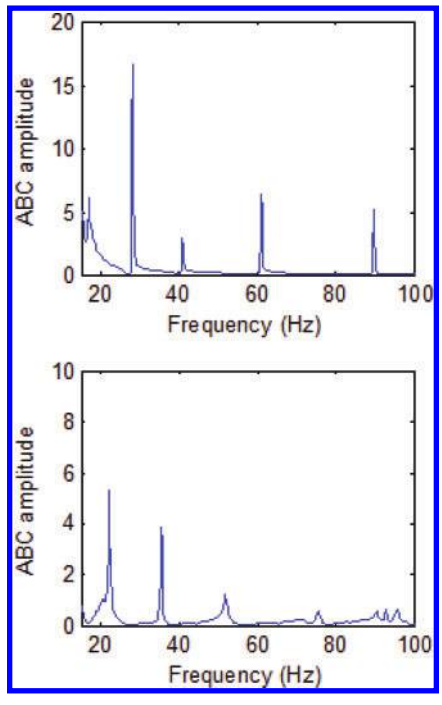

Figure 5. Typical one-pin ABC curves from the test slab (Pin at locations of A1 and D2, respectively).

a real pin is inserted at the respective location, see Table 1. From the results shown in Figure 5, it can also be observed that the ABC curves resulting from SVD-processed FRFs are smoother and the (ABC) frequencies are more clearly identifiable.

Figure 5 presents some typical one-pin ABC curves from the test slab. The extracted first three ABC frequencies also compare well with the FE predicted results (not shown).

For the two-pin ABC frequencies, there are a large number of permutations of possible two-pin configurations. For a general observation, two typical scenarios may be of interest, namely i) two pins at nearby locations, and ii) two pins at well-separated locations. Typical two-pin ABC curves obtained for cases falling into the above two scenarios, respectively, are given in Figure 6. Comparison of the extracted ABC frequencies with those predicted by the respective FE model shows a reasonable agreement.

Summarising the above results and observations, it may be concluded that effectively all one-pin and two-pin ABC frequencies may be extracted for a beam or slab having similar dynamic characteristics as the test specimens. The adopted data processing procedure pertaining to an impact testing approach appears to work well in improving the quality of the measured FRF functions, and subsequently improves the quality of extracted ABC frequencies. The extracted one-pin and two-pin ABC frequencies tend to exhibit similar accuracy as the natural frequencies, thus these data may be employed for the general structural identification purpose.

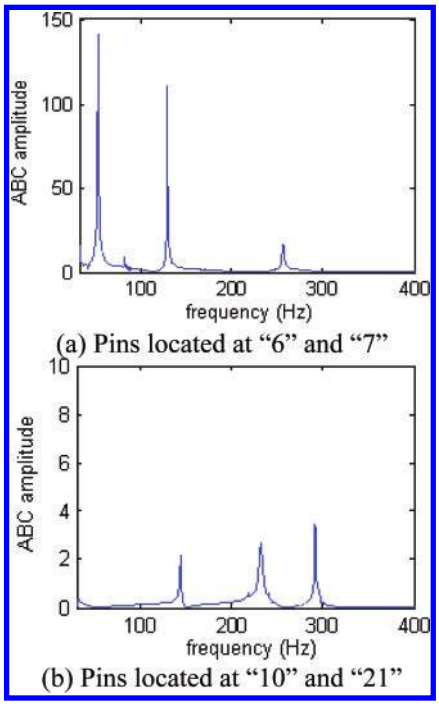

Figure 6. Typical two-pin ABC curves for different 2-pin configurations.

5 CONCLUSIONS

The availability of ABC frequencies provides a seemingly promising opportunity to expand the modal frequency dataset, and consequently enhance the overall sensitivity of the dataset to global as well as local structural changes. A series of studies have been conducted in an attempt to address several pertinent questions towards the potential use of such novel frequencies information in practice. Results so far tend to support the following conclusions:

1) the effectiveness of incorporating ABC frequencies in structural parameter identification; this has generally been established through a systematic numerical simulation study;
2) the scope for optimisation of the ABC configurations so as to assist in the selection of more effective ABC frequencies. A binary GA-based methodology has been developed and the approach proves to work out satisfactorily, and
3) obtaining the ABC frequencies in a real measurement environment; the results from the laboratory experiments are clearly encouraging.

The experimental investigations thus far have demonstrated that, with a careful implementation of testing, data acquisition and processing procedures as outlined in this paper, effectively all one-pin and two-pin ABC frequencies in the first few ABC modes can be obtained with quality and accuracy matching the comparable orders of natural frequencies. Considering the availability of abundant one- and two-pin ABC configurations, the scope for selecting the more effective ABC frequencies for a particular parameter identification task is promising.

Further investigations are ongoing to look into the workability of extracting the ABC frequencies in more realistic and ultimately real-life structures.

A novel two-step method for localization and assessment of cracks in beams

G.R. Gillich & Z.I. Praisach
Universitatea "Eftimie Murgu" Resita, Resita, Romania

ABSTRACT: This paper proposes a new approach for damage assessment in beams, based on a relation contrived by the authors describing the frequency changes for bending vibration modes in respect to damage location and depth. It involves one term controlled by damage location, proportional with the mode shape curvature squares, and one influenced by damage depth alone. This permits decoupling the location issue with that of damage severity estimation. To find the damage location the relative frequency shift for several bending vibration modes are determined by measurements and compared with the corresponding mode shape curvature squares calculated for numerous locations; the location is found when the calculated series fit the measured one. The second step is to find the depth of damage placed on the identified location, producing the measured frequency change. The method is simple and reliable, is not affected by noise and is applicable to all types of beams.

1 INTRODUCTION

Regular inspection of engineering structures is crucial to detect damages in real time and assess their safety and reliability. Early damage identification permits properly programmed maintenance in order to extend the service life of structures, or the putting out of operation and replacement to avoid accidents. Dynamic nondestructive evaluation methods, due to their global perspective, are able to indicate the occurrence of damages even in large structures, locate the damaged area and estimate their severity. Intensive researches in this domain where performed last decades in order to develop reliable damage detection methods, focused on the use of various features identified from measured response time-histories or spectra of these time-histories.

A comprehensive review regarding damage identification in structures from changes in their vibration characteristics is provided by Doebling et al. (1998). Some authors use natural frequency shifts for damage detection (Cawley & Adams 1979, Salawu 1997). Due to low sensitivity of frequency shift to damage, precise models on one side and measurements on the other are required. Because discrete models are mainly used, the similitude between the real structure and the model is often inadequate, so that changes in frequency caused by damage can be smaller than those observed between the undamaged structure and the mathematical model. This makes almost impossible to discern between inadequate modeling and changes due to damage, consequently the use of models is difficult to be used (Friswell 2007). Other problems in using natural frequency shifts to detect damages reside in the fact that natural frequencies are sensitive to changes in temperature and loads applied on the structure.

Methods based on mode shape changes compare differences between the measured modal shapes before and after damage. A single-number measure of mode shape changes to assess damage in beams is proposed by West (1984), namely the Modal Assurance Criterion (MAC); it compares a mode shape in the undamaged and damaged state respectively. The Coordinate Modal Assurance Criterion (COMAC) combines information from different vibration modes and is able to indicate the probable location of damage (i.e. Maia et al. 1997, Heylen et al. 1997). Mode shape curvatures are more sensitive to damage and can also be used (Pandey et al. 1991). The decrease in modal strain energy caused by damage is used by Cornwell et al. (1999) to identify structural damage. In all cases the mode shape vectors must be one-to-one associated to the measurement points coordinates, difficult to achieve while a large number of measurement locations is required to accurately characterize mode shape vectors and to provide enough resolution for determining the damage location. Additionally, because the methods use discrete models with multiple degrees of freedom, the sensor locations must be carefully matched to the finite elements associated to these degrees of freedom.

Methods based on flexibility of the structure constitute another class of damage identification methods. They make use of dynamically measured flexibility matrix, written as a mode superposition, to estimate changes in the static behavior of a structure, in most cases completed with static measurements. Several variants of this method are known, like the change in flexibility method, the change in uniform flexibility

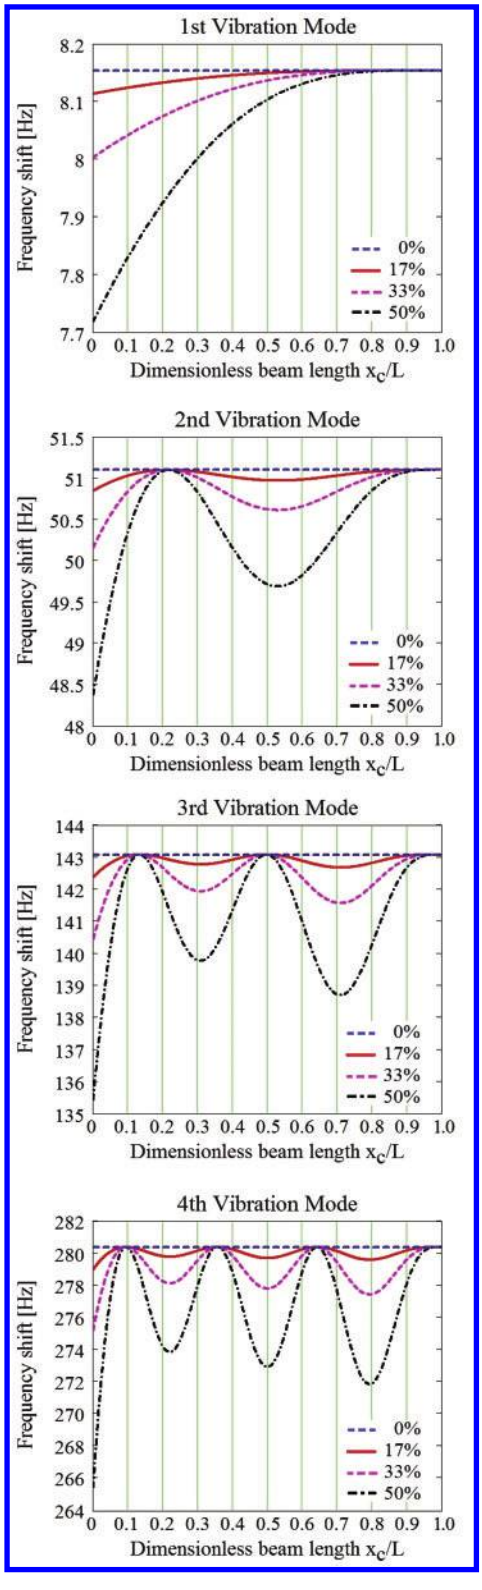

Figure 1. Frequency shift curves for the first four bending vibration modes of the cantilever beam.

curvature method and other similar methods, largely described by Pandey & Biswas (1994).

Even if Rytter (1993) present the damage location and quantification problems on different levels, suggesting the possibility to separate the two attempts, most methods presented in literature are focused on directly linking changes of modal parameters to a given damage, without decupling the localization and assessment problem (Gillich & Praisach 2012). Furthermore, no simple relation between damage location and depth on one side and frequency changes due to damage for bending beams on the other are presented in literature. Approaches like that presented by Chondros et al. (1998) offer solutions, but imply to solve an 8×8 matrix for all possible damage scenarios.

Previous researches performed by the authors, focused on natural frequency changes since they are the most easy to acquire data characterizing the beam dynamics. As result we have find a relation providing the exact solution for frequency changes of all bending vibration modes, for any damage scenario and irrespective of the beam support type. It allowed to trace, for damaged beams, frequency shift curves and to better understand the phenomenon occurring by the appearance of damage. This paper presents a simple, reliable method to detect, locate and evaluate damages in beam-like structures, developed basing on this relation.

2 FREQUENCY SHIFT CURVES

Detailed investigations using the finite element method were performed on a beam in four support type cases: fixed-free, fixed-fixed, fixed-pinned and pinned-pinned. While researches reported in literature present numerical and experimental analyses considering few vibration modes (mainly three or less) and a low number of damage scenarios, it is impossible to get a global picture about how a damage affect the dynamic behavior of beams. To overcome this, we analyzed the effect of damages in form of closed cracks in 200 locations along the beam, for 9 levels of depth. For all 1800 scenarios we found, by means of the finite element method (FEM), the first ten natural frequencies of the damaged beams. The results allow to accurate represent the frequency shift curves for all analyzed cases; Figure 1 shows these curves for the first four vibration modes of the cantilever beam.

One observes in Figure 1 that, for each vibration mode, there are particular locations in which damage does not affect the natural frequency. These locations are identical with the inflection points of the mode shape curvature; Figure 2 presents them for the fourth bending vibration mode of the cantilever beam. In these locations the beam dose not curve, maintaining its linearity, consequently no bending stress is present. Obviously, these locations, expressed in terms of dimensionless distance x_C/L, are different for the different vibration modes of a beam.

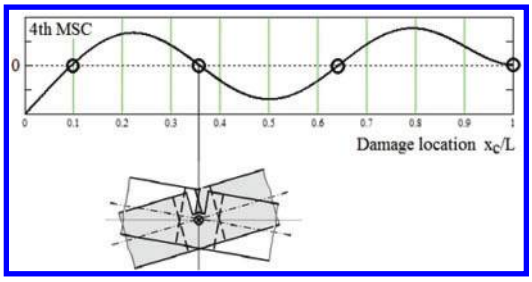

Figure 2. Fourth mode shape curvature with highlighted inflection points and slice behavior; one observe just rotation.

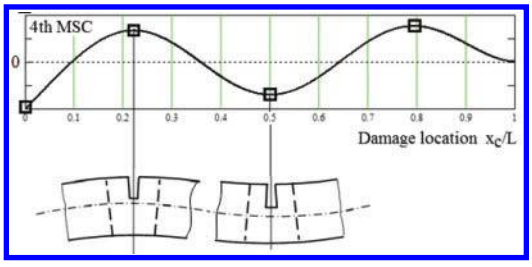

Figure 3. Fourth mode shape curvature with highlighted extreme points and slice behavior; one observe strong bending.

On the other hand, the locations x_C/L in which no frequency changes due to damage occurs in a given mode are similar for all beams identically supported.

On other particular locations natural frequency changes attend local maxima; these points fit the points of extreme of the respective mode shape curvatures (Fig. 3). In these locations the slices suffer the most important bending and consequently the slices placed on these locations store important strain energy. Thus, a damage placed here reduces dramatically the strain energy stored in the slice, and therefore the total stored energy in the beam, so that a significant effect upon the dynamic behavior of the beam in terms of natural frequency decrease takes place. These locations, expressed in terms of dimensionless distance x_C/L, are also different for the different vibration modes of a beam, but similar for a given mode for identically supported beams.

The location of these two classes of points is dependent of the mode shape $\phi_i(x)$ and its second derivative, the mode shape curvature, thus specific for different boundary conditions. The good concordance between particular points of the mode shape curvature and the frequency shifts is found analyzing the strain energy distribution along the beam. For a slice, the strain energy is expressed as:

$$\mathrm{d}U_i(x) = \frac{1}{2} EI\left(\phi_i''(x)\right)^2 \mathrm{d}x \tag{1}$$

where E = Young's modulus, I = moment of inertia of the transversal cross-section of the healthy beam and dx = slice length. For a slice affected by damage, e.g. with reduced moment of inertia I_D, the stored strain energy is:

$$\mathrm{d}U_{i-D}(x) = \frac{1}{2} EI_D\left(\phi_i''(x)\right)^2 \mathrm{d}x \tag{2}$$

and consequently the strain energy decrease

$$\begin{aligned}\Delta\mathrm{d}U_i(x) &= \mathrm{d}U_i(x) - \mathrm{d}U_{i-D}(x) \\ &= \frac{1}{2} EI\left(\phi_i''(x)\right)^2 \mathrm{d}x - \frac{1}{2} EI_D\left(\phi_i''(x)\right)^2 \mathrm{d}x \\ &= \frac{1}{2}(EI - EI_D)\left(\phi_i''(x)\right)^2 \mathrm{d}x\end{aligned} \tag{3}$$

Equation 3 reveals that the effect of a damage occurring on a slice reduces the total strain energy of the beam proportional with the decrease of the slice rigidity $\Delta EI = EI - EI_D$ and the value of the mode shape curvature square at that location. It can be assumed that the frequency decrease due to damage is proportional with the strain energy reduction in the beam caused by that damage.

This hypothesis is confirmed by results obtained by Chondros et al. (1998), who consider a rotational spring placed at the damage location, linking the two halve segments and reducing the transferred energy; the spring stiffness must be adjusted every time in concordance to its location. Opposite to their approach, we consider the effect of damage (i.e. stiffness reduction) at the location where the mode shape curvature square and implicit the bending moment attends the global maximum. Afterwards, we adjust it for different locations by the value of the mode shape curvature square at that location. A study comparing results obtained by the two methods lead to similar results (Gillich et al. 2012).

Based on this theory, we contrived a relation expressing the natural frequencies f_{i-D} for a beam with a transversal closed crack of depth a placed at distance x_C from the beam end, as:

$$f_{i-D}(x_C, a) = f_{i-U}\left[1 - \gamma(0,a)\cdot\left(\bar{\phi}_i''(x_C)\right)^2\right] \tag{4}$$

where $\gamma(0,a)$ = coefficient representing the stiffness reduction and f_{i-U} = frequency of the undamaged beam.

The undamaged beam's natural frequencies for the i-th bending vibration mode can be calculated using the well-known relation:

$$f_{i-U} = \frac{\lambda_i^2}{2\pi}\sqrt{\frac{EI}{\rho A L^4}} \tag{5}$$

where λ_i = mode number value, ρ = beam's mass density, A = cross-section area and L = beam length.

Normalizing the frequency of the damaged beam given in Equation 4 by the frequency of the undamaged beam, one obtains

$$\bar{f}_{i-D}(x_C, a) = 1 - \gamma(0,a)\cdot\left(\bar{\phi}_i''(x_C)\right)^2 \tag{6}$$

with the maximum 1 if no damage occur. This relation is important when qualitative analyses are performed.

One remark that in Equations 4, 6 the normalized mode shapes curvature square is used, taking values between 0 and 1. Its can be expressed as:

$$\bar{\phi}_i''(x_C) = \left| \frac{\phi_i''(x_C)}{\max(\phi_i''(x))} \right| \tag{7}$$

The coefficient $\gamma(0,a)$ has, for a given damage and beam geometry but irrespective to the support type, the same value for all bending vibration modes. It can be determined using the stress intensity factor from fracture mechanics, for mode I - opening crack. Functions for the stiffness reduction in respect to damage depth are reported by Liebowitz & Claus (1968), Ostachowicz & Krawczuk (1991), Chondros et al. (1998). Highlighting the stiffness decrease, Gillich et al. (2012) proposed a simpler relation to determine the value of $\gamma(0,a)$ as:

$$\gamma(0,a) = 1 - \sqrt{\frac{\delta_{U\max}}{\delta_{D\max}}} \tag{8}$$

where $\delta_{U\max}$ = maximum static deflection of the healthy beam under own load and $\delta_{D\max}$ = maximum deflection of the damaged beam when the discontinuity is placed in the location where the bending moment have the biggest value. These deflections are determined using the FEM for various damage depths, so that the function $\gamma(0,a)$ can be determined.

The relation providing the frequency value of the damaged beam, presented in Equation 4, permit plotting relative frequency shift curves, for beams with any support type, just using the adequate mode shape curvature. Results obtained analytically are in good concordance to them obtained by means of the finite element method.

Equation 4 is valid for open cracks too, but obviously the values of coefficient $\gamma(0,a)$ for the same damage depth a increase, consequently the natural frequency of beams with closed cracks are lower than that of identical beams with open cracks, if placed on the same location.

Attention should be paid to the fact that, for open cracks associated with mass loss, the natural frequency of the undamaged beam cannot be used as a base-line, while the frequency due to mass loss increase.

3 DAMAGE LOCATION COEFFICIENTS

The frequency shift curves presented in Figure 1 show that any location along the beam can be characterized by a series of n values representing the frequency change of n bending vibration modes. These series are unique for asymmetric structures, or characterize mirrored pairs of locations for symmetric structures. The natural frequency shifts for any damage location and vibration mode can be found from the modified form of Equation (4), as:

$$\begin{aligned} \Delta f_i(x_C,a) &= f_{i-U} - f_{i-D}(x_C,a) \\ &= f_{i-U}\left[\gamma(0,a)\cdot(\bar{\phi}_i''(x_C))^2\right] \end{aligned} \tag{9}$$

Dividing Equation 9 by f_{i-U} result the relative frequency shift as the product of two terms, of which the first is proportional to the severity and the second depends solely on the location of the damage:

$$\Delta f_i^*(x_C,a) = \gamma(0,a)\cdot(\bar{\phi}_i''(x_C))^2 \tag{10}$$

Normalizing the n values of the relative frequency shift for a location x_C by the biggest value of the series, the effect of damage depth is isolated, and a series defined by the location alone is obtained. We denoted the individual values

$$\frac{\Delta f_i^*(x_C,a)}{\max(\Delta f_{1\ldots n}^*(x_C,a))} = \Phi_i(x_C) = \frac{(\bar{\phi}_i''(x_C))^2}{\max((\bar{\phi}_{1\ldots n}''(x_C))^2)} \tag{11}$$

damage location coefficients (DLC), and the whole series, containing n coefficients

$$\Phi : \{\Phi_1(x_C), \ldots \Phi_i(x_C), \ldots \Phi_n(x_C)\} \tag{12}$$

damage location index (DLI).

Obviously, the biggest value of a DLC in a damage location index is the unit, all other DLC being smaller (possible also zero). In very particular cases two DLCs can have the unit value or can be very close to it. Figure 4 depict the normalized frequency shift curves for a cantilever beam, presenting the normalized frequency shifts for damages placed at $x_C/L = 0.15$, 0.3, 0.45 and 0.6 respectively. Figure 5 show the values of the corresponding damage location indexes for the analyzed cases, the DLCs being calculated using Equation 11.

One observes that sets of these values constitute patterns for all damage locations. While they are determined exclusively using data obtained from the undamaged beam, being used as reference values, the damage localization procedure is not based on models, so that modeling errors are avoided.

The damage localization procedure is therefore reduced to comparing measured data with a priori known patterns. Suppose that by starting monitoring a beam, the measured frequencies for n vibration modes are:

$$F_U^m : \{f_{1-U}^m, \ldots f_{i-U}^m, \ldots f_{n-U}^m\} \tag{13}$$

Afterwards, the frequencies are measured either continuously or periodic. Samples extracted from time in time provide new results:

$$F_D^m : \{f_{1-D}^m, \ldots f_{i-D}^m, \ldots f_{n-D}^m\} \tag{14}$$

If differences between the two series are observed, the appearance of a structural damage is presumed

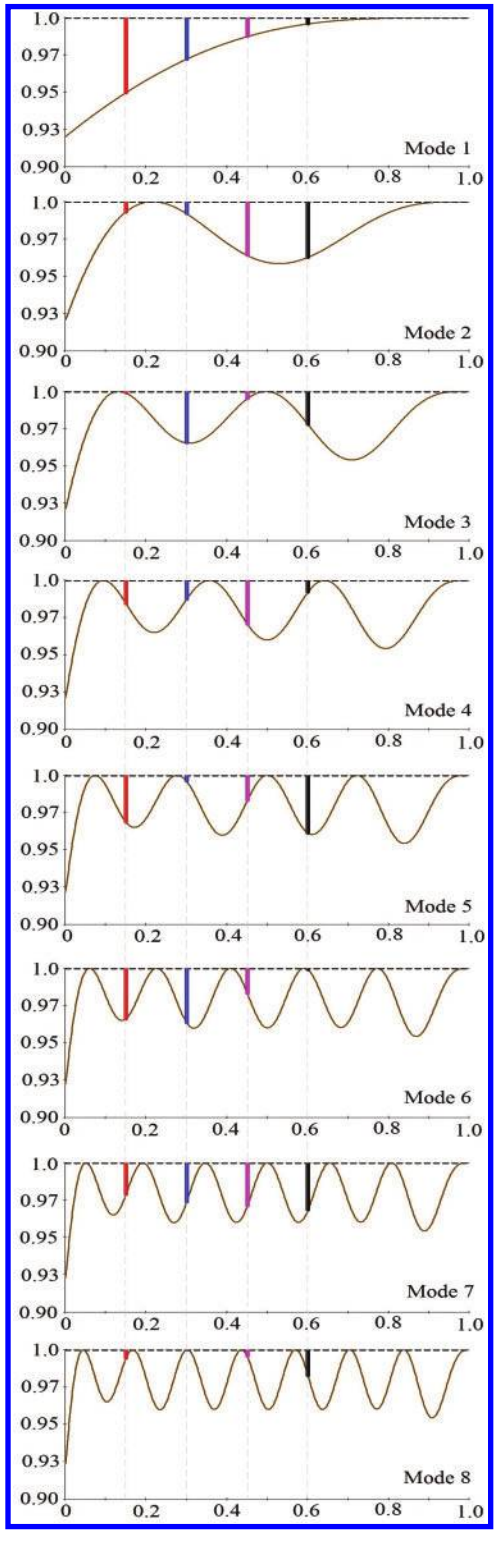

Figure 4. Normalized frequency shift curves for a cantilever with four damage scenarios: S1 ($x_C/L = 0.15$); S2 ($x_C/L = 0.3$); S3 ($x_C/L = 0.45$) and S4 ($x_C/L = 0.6$).

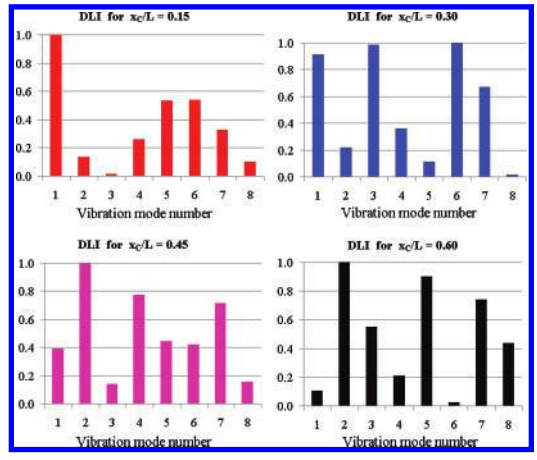

Figure 5. Damage location indexes for the four analyzed damage scenarios.

and the measured data is processed in order to find its location. First the frequency shifts are calculated inserting in Equation 10 the measured series presented in Equations 13 and 14. The relative frequency shift

$$F^{*m} : \{\Delta f_1^{*m}, ... \Delta f_i^{*m}, ... \Delta f_n^{*m}\} \tag{15}$$

for the n analyzed modes are obtained. These values are than normalized by dividing each of them to the biggest value of the series, how it is presented below:

$$\Psi_i = \frac{\Delta f_i^{*m}}{\max(\Delta f_{1...n}^{*m})} \tag{16}$$

obtaining the values:

$$\Psi : \{\Psi_1(x_C), ... \Psi_i(x_C), ... \Psi_n(x_C)\} \tag{17}$$

Comparing the series Ψ given by Equation (17) with series Φ obtained from Equation (11) for numerous locations x along the beam, one can find the location x_C where the terms of the two series match together; so the crack location is identified.

The recognition process, finalizing the first step in damage assessment, can be done by visual methods, where the values are replaced by segments, or it can make use of statistical methods. The authors have developed a program to automatically indicate crack location when frequencies of the healthy and damaged beam are known.

4 DAMAGE SEVERITY EVALUATION

Once the crack location identified, the normalized mode shape curvature' square of mode one for that location can be calculated from Equation 7. Knowing the relative frequency shift for mode one Δf_1^{*m} from measurements, the coefficient $\gamma(0,a)$ indicating

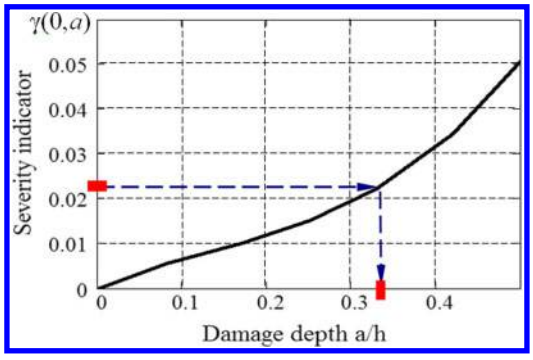

Figure 6. Damage severity vs. dimensionless damage depth.

damage severity can be computed using Equation 9. While the relation $\gamma(0,a)$ in respect to depth a is given by Equation 8, it can be graphically represented, like shown in Figure 6. For the determined value of $\gamma(0,a)$ the dimensionless damage depth a/h is identified.

This second step is simple and offers an image about damage depth, without being highly accurate. For precise geometrical damage characterization local methods are needed.

5 CONCLUSIONS

This paper presented a two-step damage detection method able to assess damages in beams from changes in their natural frequencies. For these kind of structures the rule how frequencies change due to damage in respect to their location and beam support type was establish for all bending vibration modes. The manner how these changes take place characterizes a location along the beam, consequently constitutes a pattern proper to be used for damage localization. In this paper patterns where derived from mode shape curvatures, as indicators of stored energy; for short beams the strain energy has to be directly involved. The method implies the use of a single accelerometer and is not affected by noise, while solely the frequency has to be identified. The method is applicable to all kind of beam-like structures with initial constant bending stiffness EI, or to structures with initially known damage.

Model updating of strategic building structures under real earthquake loading

R. Ceravolo, A. De Stefano, E. Matta, A. Quattrone & L. Zanotti Fragonara
Department of Structural, Geotechnical and Building Engineering, Politecnico di Torino
Torino, Italy

ABSTRACT: Public buildings such as hospitals, schools, churches and city halls constitute an asset of strategic importance into the life of a community. The assessment of the safety conditions and the vulnerability to natural catastrophic events must be checked, also resorting to experimental techniques. The adoption of vibration monitoring procedures represents a particularly appealing perspective for existing structures. The growing use of permanent monitoring systems allows collecting data of the structural response during earthquakes. An invaluable tool for structural health monitoring and damage detection, parametric system identification through model-updating is an inverse problem, affected by several kinds of modelling assumptions and measurement errors. By minimizing the discrepancy between the measured data and the simulated response, traditional model-updating techniques identify one single optimal model that behaves similarly to the real structure.

1 INTRODUCTION

In the event of an earthquake, dynamic monitoring systems can supply precious information on the actual behaviour of existing buildings, allowing for the calibration of numerical models, which can be used for assessing the structural seismic safety as well as for designing possible rehabilitation interventions. In the latter connection, FE models are updated on an experimental basis from data supplied by the permanent monitoring system.

This concept has recently inspired the foundation, within the Italian Department of Civil Protection (DPC), of the Structures Seismic Observatory (OSS), a national-wide network for the permanent monitoring of the seismic response of more than one hundred strategic public buildings in Italy. This network allows a rapid evaluation of the damage induced by seismic actions on monitored structures and on neighbouring similar buildings, helping DPC in planning and managing emergency activities in the earthquake's aftermaths. The OSS network includes: (i) the primary sub-network, comprising 105 strategic public buildings (schools, hospitals and city halls), 10 bridges and a few dams, all intensely instrumented with a dynamic permanent monitoring system (16–32 accelerometers each), and (ii) the secondary sub-network, comprising 300 buildings, all equipped with a simplified monitoring system (7 accelerometers each).

Four of the buildings included in the main sub-network, monitored during the Lunigiana/Garfagnana event (January 27th, 2012), have been selected as case studies in the framework of the inter-university Italian DPC-ReLUIS 2010–2013 Project, and commended to the Department of Structural, Geotechnical and Building Engineering at Politecnico di Torino, as a partner Unit, to the aim of dynamic characterization. This paper briefly introduces these four case studies and exemplifies the modal identification and model-updating procedure on one of them, namely the city hall of San Romano in Garfagnana.

2 THE FOUR SELECTED CASE STUDIES

The four case studies are listed in Table 1 and depicted in Figure 1. They have all been monitored

Table 1. The four selected case-study buildings (buildings description provided in Figure 1).

	Building (a)	Building (b)	Building (c)	Building (d)
Structural typology	Masonry	RC frames	RC shear walls	Masonry
Year of construction	1930	1972	1972	1359 (rebuilt 1761)
Volume (m^3)	2990	1687	7726	1764
Height (m)	14.8	15.8	16.3	9.5 (bell tower 23)
Number of sensors	20	16	22	26
PGA X (g)	0.023	0.024	0.035	0.035
PGA Y (g)	0.018	0.031	0.020	0.053

Depth: 60 km	14:53:14	

by DPC during the seismic event which has stroked the Lunigiana/Garfagnana area on the 27th of January, 2012, whose synthetic properties are summarized in Table 2. For each of the four buildings, a dynamic identification has been performed using the acceleration data recorded during the said seismic event and a finite element (FE) model has been accordingly constructed and updated. For the sake of brevity, the identification and calibration procedure is exemplified in what follows for the first building only, i.e. the city hall of San Romano in Garfagnana.

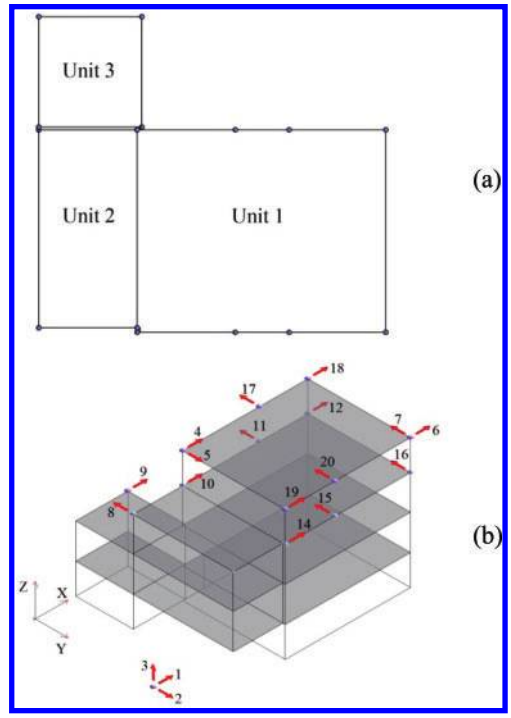

Figure 2. City Hall of San Romano in Garfagnana: (a) planar view; (b) sensors position and orientation.

3 THE CITY HALL OF SAN ROMANO IN GARFAGNANA

Particular attention will be given in this paper to the case study of the city hall of San Romano in Garfagnana whilst the principal results will be listed for all the four buildings.

3.1 *The building*

San Romano in Garfagnana is located in a medium-to-high seismicity area (seismic zone 2 according to the OPCM 3274 Seismic Code, 2003). The city hall consists of a main building and two adjacent smaller units constructed at a later time (Figure 2a). The main building is a 4-storey masonry structure built on reinforced concrete foundations, having a 19.2 × 11.4 m^2 rectangular plan and a 14.8 m height. Built in the '30s, it was seismically and statically retrofitted in 1998. Foundations were sandwiched between new r.c. curbs, in order to achieve a more uniform distribution of soil pressures. Main masonry walls were plated with reinforced cement mortar, in order to increase shear strength. The original masonry walls distribution was recovered through reconstructing those elements which had been removed through the years. Floors were stiffened and strengthened, and their connection with masonry improved. In order to enhance structural regularity, a structural joint was realized between units 2 and 3, while units 1 and 2 were connected through steel bars' reinforcements inserted in adjacent walls. A survey on

the mechanical properties of the constituent materials indicates a characteristic compressive strength of 115 MPa for the stone blocks and of 7.2 MPa for the masonry panels.

3.2 *The monitoring system*

OSS permanent monitoring system consists of 20 force-balance uniaxial accelerometers. 17 accelerometers are installed along the building height and the remaining 3 accelerometers, constituting the ground reference channels, are placed inside an underground inspection hole. The position and orientation of the sensors are shown in Figure 2b. Among the 17 accelerometers deployed along the elevation, 16 are installed in units 2 and 3 (attached to the floors at the first and second levels) and only one is deployed in unit 3 (along the X direction). The acquisition system incorporates an AD converter and is connected with a GPS receiver for synchronization with the international UTC time.

4 THE NUMERICAL MODEL

For each building analyzed, based on original archive documentation a preliminary model has been constructed in order to highlight possible critical issues in the structural dynamic response and help interpreting processed signals. The structural members have been modeled using mono and bi-dimensional finite elements and adopting linear, elastic and isotropic material properties.

In details, the model of the city hall of San Romano in Garfagnana model consists of bi-dimensional plate- and shell-type finite elements grouped in macro-elements. The wooden roof has been modeled only in terms of its inertial contribution, as a uniformly distributed mass on the beams which crown the masonry walls.

Masonry properties have been deduced partly from destructive and non-destructive tests and partly from typical values suggested by the literature and by current Italian codes, depending on the outcome of visual inspections. In order to simply account for soil-structure interaction, the structural nodes are clamped at the foundation level and the stiffness of the underground wall elements is initially increased.

The efficacy of the structural joint located between units 1 and 3 is highly uncertain because of the lack of documental information and because of the presence of only one sensor in unit 3. The joint is therefore modeled as a stripe of shell elements with reduced equivalent stiffness.

5 DATA ACQUISITION AND MODELLING

Dynamic identification from signals recorded during the seismic event requires that the input spectral components be distinguished from structural frequencies. In the assumption that the three ground reference signals reflect the input load into the dynamic system, the dominant earthquake components can be easily identified, helping with the estimated transfer functions and coherence functions.

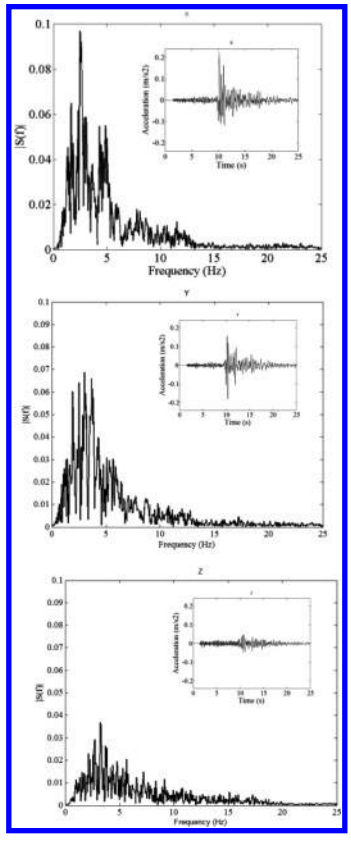

Figure 3. Acceleration spectra (and time-histories) of the three input components.

5.1 *Data acquisition and pre-processing*

The analyzed experimental data are represented by the 20 acceleration signals recorded during the Lunigiana/Garfagnana earthquake. Figure 3 reports the time history and the acceleration spectra of the three input components, as recorded by the three ground reference sensors, respectively along the X, Y and Z directions. The seismic energy content appears to be mostly concentrated in the 2–7 Hz frequency band. Dynamic identification from signals recorded during the seismic event requires that the input spectral components be distinguished from structural frequencies. In the assumption that the three ground reference signals reflect the input load into the dynamic system, the dominant earthquake components can be easily identified.

5.2 *Experimental modal analysis*

Structural modal identification has been conducted through applying an algorithm belonging to the family

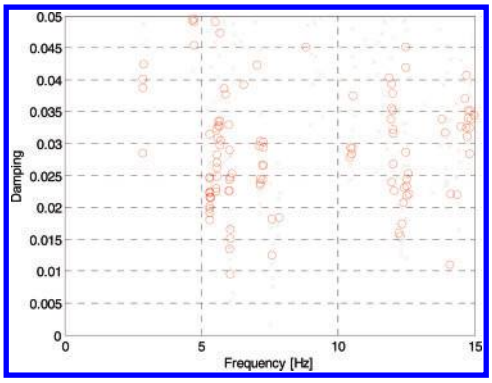

Figure 4. Example of Frequency-damping clustering diagram for the City Hall of San Romano.

5	4.40	1.6	2nd flex. Y, global

of SSI (Stochastic Subspace Identification) (Peeters & DeRoeck, 1999; Larimore 1990), implemented in the SDIT3 code (Ceravolo & Abbiati, 2013).

5.3 *Dynamic identification procedure*

The identification algorithm has been applied to the output signals through progressively increasing the system order. In order to discriminate between real structural modes and spurious numerical modes the following stabilization criteria have been applied: (i) frequency variation <2%; (ii) damping variation <15%; (iii) damping ratio values comprised between 0% and 10%; (iv) MAC (Modal Assurance Criterion) >95% (Allemang 2002). Stabilization and frequency-damping clustering diagrams are reported in Figure 4. The seismic dominant frequency components, apparent in the stabilization diagram, have been subsequently identified and excluded from the model-updating procedure. The resulting identified frequencies and damping ratios for all the four buildings are reported in Table 3.

Identified mode-shapes 1 to 4 of the city hall of San Romano are represented in Figure 5. It is worth noting that unit 3 seems not significantly involved in

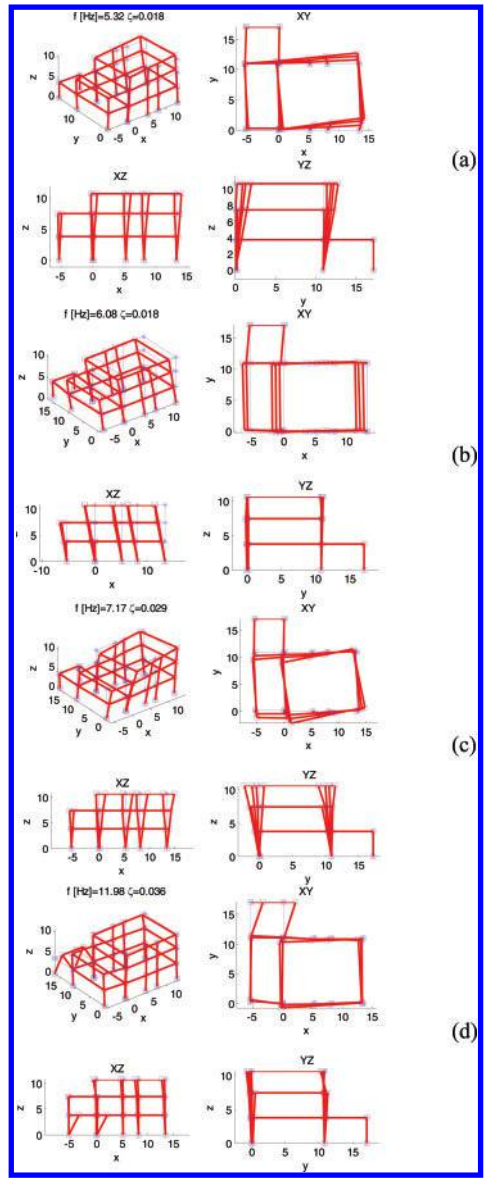

Figure 5. Identified mode-shapes: (a) mode 1 - 1st flexural along Y; (b) mode 2 - 1st flexural along X; (c) mode 3 - 1st torsional; (d) mode 4 - local mode.

the first global modes but provides the largest displacement component in the fourth mode, which is therefore labeled as a local mode. This suggests a very limited participation of this unit to the overall dynamics of the building, and consequently a substantial efficacy of the uncertain structural joint between units 1 and 3.

6 MODEL UPDATING

The updating procedure adopted consists in three main steps:

1. Discretization of the FE model in homogeneous zones, to reduce the numbers of updating variables;
2. Sensitivity analysis, to choose the most influencing parameters involved in the overall dynamic behavior;
3. Minimization of error function, updating the parameters so that the analytical modal model would match the experimental modal model.

6.1 *Discretization of the FE model*

Depending on the different age and type of the main parts of the three units, a total of 17 materials (linear elastic and isotropic) are preliminary identified in the baseline model. In order to reduce the number of updating variables, parameters which are likely to be less uncertain and less influential on the global dynamic behavior are excluded from updating. The model is therefore parted in the 6 homogeneous zones represented in Figure 6a. The structural joint between units 1 and 3 is one of them, its nominal value having been manually calibrated to 0.10 GPa in order for the analytical modes' sequence to match the experimental one.

6.2 *Objective function and sensitivity analysis*

The objective (or error) function selected for updating, and therefore used for the sensitivity analysis as well, is defined as (Friswell & Mottershead 1995):

$$\varepsilon(\mathbf{x}) = \sum_{i=1}^{m}\left[\alpha_i\left(\frac{f_{ai}-f_{ei}}{f_{ei}}\right)^2 + \beta\left(\frac{1-\sqrt{MAC_i}}{MAC_i}\right)\right] \quad (1)$$

where $\mathbf{x}$ is the updating parameter vector, f_{ai} and f_{ei} are the analytical and experimental i-th natural frequencies, MAC_i is the Modal Assurance Criterion between the i-th identified mode-shape and the corresponding i-th analytical mode-shape, αi and βi are the weight factors for the frequency and the mode-shape errors, respectively.

The sensitivity analysis is based on the local sensitivity index defined by Saltelli et al. (2000) as:

$$\hat{S}_i = \frac{\ln(\varepsilon)-\ln(\varepsilon_0)}{\ln(x_i)-\ln(x_{i0})} \quad (2)$$

where x_{i0} and $x_i = x_{i0}\cdot(1+d)$ are, respectively, the initial nominal value of the i-th updating parameter and its value incremented of a given percentage δ (here assumed equal to 5%), ε_0 is the error corresponding to the nominal model, and ε is the error corresponding to equaling all parameters to their nominal value while setting the i-th parameter to x_i.

Expressed in terms of percentage values, the relative sensitivity index is reported in Figure 6b. The elastic modulus of the lower stories appears clearly predominant.

Based on the sensitivity analysis, the four most significant parameters have been chosen as the updating parameters. For the city hall of San Romano, these parameters are summarized in Table 4, with their initial nominal values reported in the second column.

In this case, the model-updating procedure has consisted in the numerical minimization of the objective function e in Eq. (1) by means of a genetic algorithm,

1	2.00	1.5%	98%
2	2.49	−5.6%	95%
3	3.61	5.5%	88%

using 15 generations and a population of 300 individuals. Weights α_i and β_i are taken as 0.8 and 0.2, as suggested by Merce et al. (2007). The updated values of the five selected parameters are reported in the third column of Table 4.

The optimal solution is reported in Table 5, which is referred to the four monitored building. A satisfactory agreement between the analytical and the experimental modal models can be appreciated. MAC values between analytical and identified modes, in particular, are always greater than 80%. The first mode-shapes of the updated model are reported in Figure 7 for the building in San Romano. Figure 8 reports the first three vibration modes resulting from the updated model of the hospital monitored in Castelnuovo.

7 CONCLUSIONS

The experimental dynamic identification of four strategic building belonging to the OSS permanent seismic monitoring network is here reported as an example of a larger pilot study including a total of four public buildings monitored during a recent earthquake. The study provides useful indications on how to design monitoring actions and experimentally updated numerical model which can be of help in assessing the current structural seismic safety and in planning future interventions.

ABSTRACT: A continuous monitoring of aeronautical structures is essential to guarantee the safety of both airplanes and passengers. Impacts are one of the most important causes of damage in aeronautical structures. The possibility to reconstruct the energy and the forcehistory of an impact on a structure can be a useful technique to determine if possible damage is present. In this paper a frequency domain method is applied to a composite plate in order to reconstruct the force caused by an impact. In the first step the position of the load is considered known its force history is identified.In the second step the impact is applied at hypothetical unknown position and both its location and force history are identified. Analyses considering the influence of noise are also conducted. The influence of energy of the impact, relative location between impact and sensors, and position of sensors is also investigated.

1 INTRODUCTION

Damage detection in aeronautical structures is a key factor for the economy of aeronautical industries as well as for the safety of passengers. The increasing use of composite materials in aircraft applications requires real time monitoring of the performances of critical structural elements. This monitoring cannot be accomplished by standard Non Destructive Techniques (NDTs), which can perform only a local analysis when the airplane is not in flight. Furthermore, NDTs can be long and expensive, while a real time analysis would provide data on the structure as the plane is airborne. This type of analysis is the essential step to go from NDTs to Structural Health Monitoring (SHM). Two main approaches can be used in order to detect the presence of damage in a structure: a passive one, which requires only the acquisition of data, and an active one, which needs also a known external stimulus.

One of the main sources of damage in aeronautical structures is the impact caused by e.g. debris or birds. The reconstruction of the impact energy and location is very important in SHM. It is a passive technique, as the analysis is performed only from data collected by sensors. The main advantage of this approach is that the mathematical background is simple, as a linear relationship can be established between the force applied by the impact and the signal collected by the sensors. The impact force and location can be obtained from sensors' response by applying an inverse transform. The main disadvantage of this approach is that it can be difficult to calculate the exact relationship G between force and signal, especially for complicated structures. Previous papers evaluated this relationship analytically, using a Finite Element Method (FEM) approach or from experiments. They were able to calculate G only for few impact cases. Previous papers (Martin and Doyle 1996) and (Doyle 1997) applied this inverse technique to simple beams and plates, knowing a priori the position of the load. However in real cases the position of the load is unknown so a straight forward method cannot be applied. In (Meo et al. 2005)a method for locating an impact and reconstructing its history based on the estimation of the wave propagation speed was provided; however it is difficult to apply this method to composite panels due to the direction dependence of the wave propagation speed. Other authors(Hu et al. 2007), proposed a method based on a minimization problem to simultaneously reconstruct the force history and find its location. Another research (Park et al. 2009), proposed a technique based on an initial estimation of the impact location, which was then updated with an error minimization method. However the accuracy of the technique was based on the resolution of the grid points used to evaluate the relationship G. Other examples of force reconstruction and calculation of response at different locations can be found in (Wu et al. 1994; Ribeiro et al. 2000; Jacquelin et al. 2003; Liu and Shepard 2006; Chen and Yuan 2010; Law et al. 2011).

In this research a FEM based analysis is conducted in order to calculate G for specific cases. A frequency domain analysis is then performed in order to reconstruct the force. A novel interpolation approach is then applied to extend the validity of the analysis to unknown impact locations. In the first part of the paper

the mathematical background is presented. Then, the numerical model is described. Results of impact simulations and force reconstruction are shown, first for the case in which the position of the impact was known and then for different unknown impact positions. The influence of noise in data on the predictions is investigated in the final part of this paper.

2 METHODOLOGY

The relationship between a dynamic load and the response of the plate at a certain point, assuming that the system is linear time-invariant, is given by a convolution integral:

$$u(t) = \int_0^t g(t-\tau)p(\tau)d\tau \tag{1}$$

In this equation p is the load, u is the response (e.g. displacement, acceleration,…) and g is a transfer function which represents the structure. According to the Convolution theorem, a convolution in the time domain analysis corresponds to a product in the frequency domain analysis. So taking the Fast Fourier Transform (FFT) of the signals leads to:

$$U(f) = G(f)P(f) \tag{2}$$

This is a direct problem; the response is obtained from the force exerted on the structure. However, for SHM application the key point is to reconstruct the force history and possibly its location from the response. This is called an inverse problem. Before continuing with the inverse problem formulation, it is useful to give the definition of Fourier transform. A discrete signal *s(t)* is usually available inside a timewindow$T$. At a fixed time interval ΔT, N samples are obtained. The Discrete Fourier Transform (DFT) provides *S(f)*, a representation of the time domain signal *s(t)* in the frequency domain. The number of frequency components depends both on the number of samples N and time window T, being $T=N\cdot\Delta T$. The frequencies at which frequency components are available are given by the following equation:

$$f_0 = 0, f_1 = \frac{1}{N\cdot\Delta T}, f_2 = \frac{2}{N\cdot\Delta T}, \ldots \\ \ldots, f_{N-1} = \frac{N-1}{N\cdot\Delta T} \tag{3}$$

Each component is given by a summation of the contribution of each sample:

$$S_k = \frac{1}{N}\sum_{n=0}^{N-1} s(n\cdot\Delta T)\cdot e^{-i\frac{2\pi kn}{N}} \tag{4}$$

The frequency representation of a signal is a complex discrete spectrum. Each component refers to a defined frequency, which depends on the window and sampling time. The resolution of the spectrum depends on the window, while the number of components depends on the samples. The FFT is a variation of DFT in which the calculation is done with less time consumption. From equation (4) it is clear that the number of frequency components k can vary, with a maximum value of N. This aspect can be very useful in certain situations when data are corrupted by noise.

A simple inversion of equation (2) is however not always possible, especially when data are obtained experimentally. This is due to the fact that G is a function which can have zeros; in such cases there is no information on the force at certain frequencies. Usually the presence of boundary conditions in the structure amplifies this problem (Martin and Doyle 1996). To overcome this problem, a small amount of random noise can be added to the matrix. Hence, equation (2) is rearranged as:

$$G_k^* \cdot U_k = [G_k^{\,2} + R_k]\cdot P_k \tag{5}$$

Where * indicates the complex conjugate and k indicates the frequency domain component. If two sensors are available, the equation can be written as:

$$P_k = \left[\frac{G_1^* \cdot U_1 + G_2^* \cdot U_2}{G_1^{\,2} + G_2^{\,2} + R}\right]_k \tag{6}$$

The problem consists on finding the correct representation of the function G. This can be evaluated using different techniques such as the impulse response function (IRF) (Jacquelin, Bennani et al. 2003), wavelet deconvolution (Doyle 1997) or frequency response function (FRF) (Martin and Doyle 1996). In this paper the last technique is applied. It is important to underline that the function G depends not only on the mechanical properties of the system or on its boundary conditions, but also on the relative position between the load and the sensor. This is a very important issue because in many real situations it is not possible to know a priori the location of an impact, so the matrix G is not available in that case. In such a situation, it is important to know the matrix at some points in the structure. With this information it can be possible to obtain the required matrix, i.e. the one at the impact location, with an interpolation. Another important issue is then to locate the impactcorrectly.

In this paper the following approach is developed:

1. First a preliminary estimation of the impact position is made using an energy criterion. The inputs to the energy criterion are the sensor signals (out of plane displacements).
2. With this position, G is calculated with a third order interpolation, based on known responses at given locations.
3. Then the force is reconstructed with equation (6).
4. The corresponding displacement is calculated with the direct problem provided by equation (1).

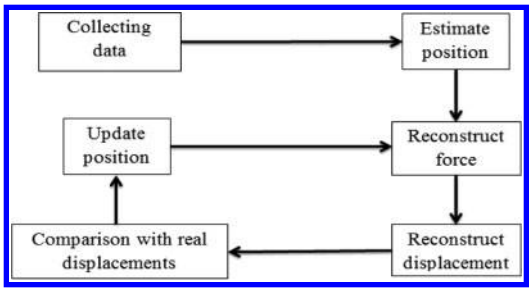

Figure 1. Localization procedure.

5. The calculated displacements are compared to the real ones. If the error is larger than a tolerance,these steps are repeated using new displacements.

The energy criterion is based on the calculation of the integral of the displacements:

$$E_i = \frac{1}{t_f - t_o}\int_{t_0}^{t_f} |u_i(t)|^2\, dt \tag{7}$$

$$\bar{x}_c = \frac{\sum E_i x_i}{\sum E_i} \quad \bar{y}_c = \frac{\sum E_i y_i}{\sum E_i} \tag{8}$$

In the above equations *i=1,2,..., number of sensors*.After each displacement has been reconstructed in step 4, equation (7) is applied and each calculated $E_i$is compared to the real E_i. Based on the maximum difference, the estimated position of the load is updated, defining a Δx or Δy which is added to the previous predicted position in step 1 and the procedure starts again. A schematic representation of this procedure is given in the Figure 1.

3 MODEL OF THE PLATE

The model under investigation is a composite plate, with all the four edges simply supported. All the properties of the plate can be found in table 1. The plate is modeled with 9652 s4r elements provided by Abaqus 6.10. The explicit package was used as the integration method, with duration of *5e-3s* and step of *1e-7s*. This system was selected because an analytical solution, which provides accurate results, is available in literature(Pierson and Vaziri 1996). The finite element solution obtained with the presented model is compared to the analytical one in order to validate the impact model. The Hertzian contact approach is used to model a nonlinear spring, with one end attached to the plate and with the other end attached to a mass of *6.28 kg* with an initial velocity of 1.76 m/s. The value of $k = 0.610^9 \mathrm{N/m}^{0.5}$ used in equation (9) was provided in (Pierson and Vaziri 1996); x is the compression of the spring.

$$F = k \cdot x^{0.5} \tag{9}$$

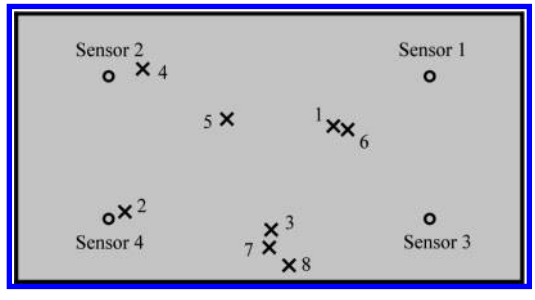

Figure 2. Schematic representation of the plate with sensors (circles) and impact positions (crosses).

Table 2. Positions of impacts and of sensors.

Position	X [m]	Y [m]
1	0,016	0,006
2	−0,036	−0,018
3	0	−0,028
4	−0,0315	0,022
5	−0,0105	0,008
6	0,0195	0,005
7	0,0005	−0,023
8	0,005	−0,033
Sensor1	0.04	0.02
Sensor2	−0.04	0.02
Sensor3	0.04	−0.02
Sensor4	−0.04	0.02

In the first simulation, the position of the impact is known, so the matrix G is available at the correct location. This simulation is useful to derive some important considerations on the capabilities of the method, as well as some limitations. The velocity of the mass was reduced to 1 m/s in the following simulations; the reason will be explained in the results section. In order to obtain the required information to reconstruct the force, the FRF of the system was calculated at four chosen locations, highlighted in Figure 2. These points also represent the output locations at which displacements were obtained during the analysis.

In the second case the position of the load was moved on the plate, but the FRF corresponding to a

load in that position was not calculated. In this case the four points denominated as "sensors" represent both the positions of the output and the position of the load in the FRF calculation. In this way 16 matrices G are available for the analysis: 4 matrices for each load case. This step can be considered a training of the system. This is the first step needed to reconstruct the force applied at an unknown position.

Eight different positions of the impact were chosen, with the same mass and velocity described before. For each impact, the procedure described in the previous section was applied and the force reconstructed. As it is possible to see from Figure 2, these positions lay both inside the rectangle formed by the sensors and outside. This is an important aspect, which will be underlined in the following section.

In order to determine the convergence of the method, as the real force is considered unknown, the convergence is checked on the calculated displacements. They are compared to the real one and, according to the sensors which suffers the greatest error, a Δx or Δy is defined in order to update the position. Their values decrease as the error decreases.

Both for the displacements and for the position of the impact, the error is calculated with equation (10). In the displacement case the *value* is the energy of the displacement, evaluated with equation (7), while in the position case, it is the distance between the point and the center of the plate.

$$error = \left| \frac{value_{calculated} - value_{true}}{value_{true}} \right| \qquad (10)$$

4 RESULTS AND DISCUSSION

4.1 *Known position of the impact*

As described previously the first simulation was done knowing the position of the impact, hence being able to calculate previously the FRF at that location. In this way equation (4), rearranged in order to consider 4 sensors, can be applied straightforward without any interpolation approach. From Figure 3 it is possible to see the analytical, FEM and reconstructed solution for the impact. Comparing the analytical and FEM solutions,it is clear that the FEM model accurately predicts the real impact force.

What is interesting to highlight is the difference between the FEM and reconstructed force. The overall shapes of the loads are very similar but the maximum amplitudes are significantly different. The reason behind this mismatch lies on the large deflection (nonlinear response) of the plate under the impact force. A demonstration of this can be done by running the analysis without considering the nonlinear geometrical effect and then reconstructing the force. The result is given in Figure 4. As it is possible to notice, the two loads considered in this case match completely. The reason behind this different behavior relies on equation (1). As this equation is only applicable to linear

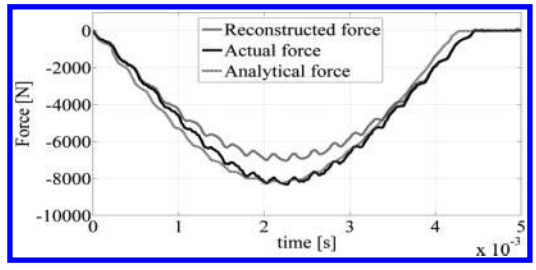

Figure 3. Comparison between analytical, FEM and reconstructed force for an impact at 1.76 m/s.

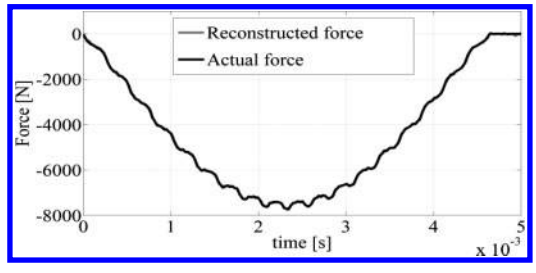

Figure 4. Comparison between FEM and reconstructed force for an impact at 1.76 m/s, linear analysis.

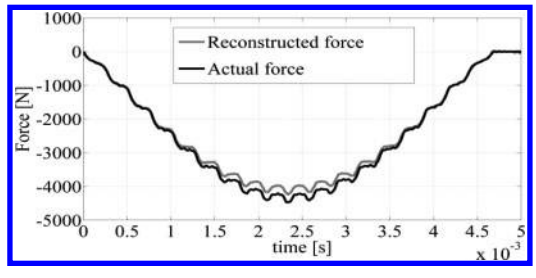

Figure 5. Comparison between FEM and reconstructed force for an impact at 1,m/s.

systems, any large deflection of the plate under a certain force cannot be reconstructed correctly. In order to reduce the amount of nonlinearity in the process, the analysis was conducted with a reduced impact, 1 m/s. The result for this case is given in Figure 5. In this case a small mismatch is still present but the level is much lower than in the previous case. In the following analysis this velocity is considered for the impact.

4.2 *Unknown position of the impact*

This part of the analysis is certainly the most challenging as it represents most of the real cases. The analysis results showed that the presented approach is suitable for the purpose of both localizing and reconstructing the impact under certain circumstances. In particular, it was found that the relative position between the impact and the sensors can influence the final results. In some cases the position of the load was wrongly calculated and so the interpolation of the transfer matrix was incorrect. However, for certain cases, the results

were accurate in terms of both force and displacement reconstruction.

The convergence of the method is very good in the first 100 iterations while a plateau in the error appears after those. This probably means that the parameters used in the position updating procedure are suitable at the beginning of the analysis but they need to be updated when the error is small. In Figure 6,one result is presented. It is clear that the force is reconstructed correctly. The convergence of the reconstructed displacement at one sensor to the real one is also shown in Figure 7.

In Figure 8 one case in which the approach fails to reconstruct the force is presented. When the impact was located outside the rectangle formed by the sensors, the interpolation approach gave incorrect results. This was due to an error in the position calculation, which was much different than the real one. An explanation is given in Figure 9 in which the error in position calculation of all the cases under exam is presented. While for most of the cases this error is low, for three impact cases it is really high. In order to investigate the method also when the load was applied at those positions, the output locations were changed and the area of that rectangle increased. However the results were not satisfactory, probably because of the proximity of the boundary condition which affected the FRF. Analyses on plates with bigger dimensions are under development in order to better understand the effect of relative position of sensors, boundaries and impacts on estimating the impact location.

4.3 *Influence of noise*

One of the greatest difficulties in the application of the inverse problem is that, during experiment, data can be corrupted by noise. If the level of disturbances is too high, the possibility to reconstruct correctly the force history can be greatly affected. In this section the proposed method is applied to one of the cases shown previously, after a certain amount of white noise was added to data with the command *'awgn'* of Matlab. This is also the opportunity to underline an important aspect of this approach. Recalling equation (4), the inverse problem involves calculating the value of the FFT of the force at each frequency component. The number of these components depends on the number of frequency components of the displacements, so on the sampling frequency. However not all of them must be used. In certain cases it can be useful to apply the analysis using only the low frequency content of the data. In this way the values at the highest frequencies, which can often be corrupted by noise, are not taken into account. In the following figures an example of the reconstruction at position 5 is given using all the frequency components and by using only first 20 components. Data were corrupted with a signal to noise ratio (SNR) of 20. The results are compared in Figures 10 and 11. These figures suggest that by using a few frequency components of the response, noise can be filtered and the impact force can be reconstructed accurately.

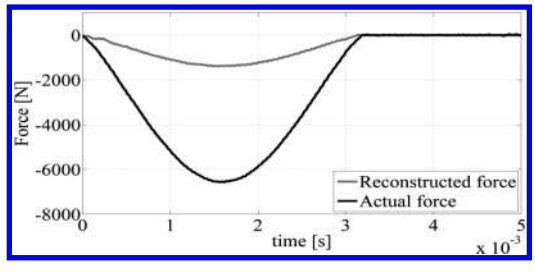

Figure 8. Result obtained for an impact at position 8.

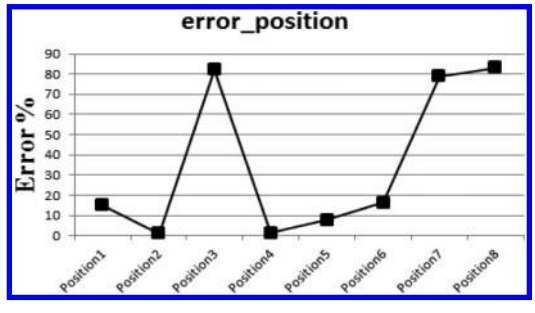

Figure 9. Error in the position calculation.

5 CONCLUSIONS

This paper presents a frequency domain approach to the inverse problem of force reconstruction. The application of the method to a case in which the position of the impact was known indicated that this technique is suitable to reconstruct the impact forcehistory.

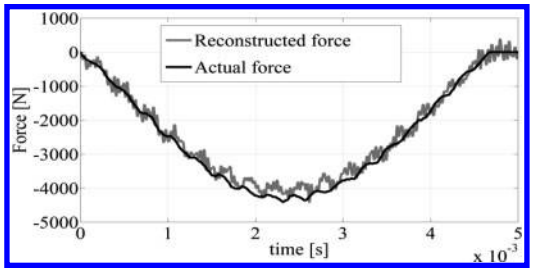

Figure 10. Reconstruction of force after the addition of noise using all frequency components.

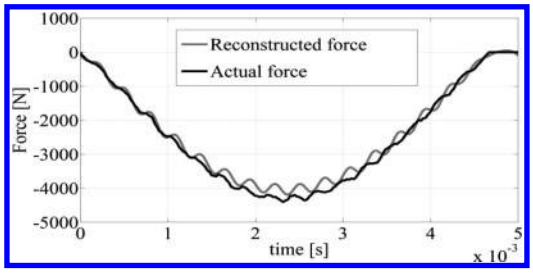

Figure 11. Reconstruction of force after the addition of noise using all frequency components.

However it also revealed that the method fails in reconstructing the correct amplitude of the load when its intensity leads to large deflection of the structure. The application to a case in which the position of the load was unknown provided useful information about the optimal mutual position between sensors and impact. In particular it highlighted how the proposed method fails to reconstruct correctly the force if the load is applied outside the sensors' grid area. However increasing this area did not provide better results, probably because of the proximity of the boundaries of the plate.The influence of noise was also investigated; the use of a few frequency components revealed that this noise can be filtered in order to obtain a better result.Further analyses are being conducted on a plate with wider dimensions in order to perform a deeper analysis on the position of the impact.

Influence of multiple cracks upon the dynamic behavior of beams

Z.I. Praisach & G.R. Gillich
Universitatea "Eftimie Murgu" Resita, Resita, Romania

ABSTRACT: This paper presents the way how multiple damages influence the dynamic behavior of beam-like structures, in terms of natural frequencies, mode shapes and stiffness. The analyzed cases include asymmetric supported beams with rectangular cross-section. The undamaged beams are considered with constant cross-section; damages are in form of open, transversal cracks. The analyses permitted to clearly define the relation between damage depth and location, respective frequency changes. As a significant result, we succeed to find a single mathematical relation describing the frequency changes for all bending vibration modes, involving one term defining damage's location and one defining its depth. While the first term changes for different modes, being defined by the mode shape curvature, the second maintain its value for all modes, being affected just by damage depth. Afterwards, scenarios for multiple cracks were analyzed and compared with the results obtained for these cracks considered one-by-one.

1 INTRODUCTION

Since the early 1980s the subject of damage detection using vibration data has received attention from the engineering and research communities.

In the context of Structural Health Monitoring (SHM) it can distinguish two methods for damage identification: local and global methods. Local methods inspect the structure in a relatively small area by using classical methods of Non-Destructive Testing (NDT), for example the ultrasonic methods, magnetic field methods, radiography, eddy-current methods, thermal field methods. All of these experimental techniques require that the vicinity of the damages known *a priori* and the portion of the structure being inspected is readily accessible (Doebling, et al. 1998). The inspection procedure can be very expensive and time consuming, especially when it involves components at inaccessible locations.

The global model-based damage identification is considered as a special application of system identification methodology. The damage causes characteristic local changes in stiffness, damping and/or mass, and, as a consequence of these changes, shifts of the dynamic characteristics, such as eigenfrequencies, modal damping and mode shapes, occur. The deviations between the actual dynamic properties and the undamaged state it used to detect the damage and diagnose its location and extent (Balageas et al. 2006).

The dynamic behavior of cracked structures has been investigated by many researches. Dimaragonas presented a review on the researches have been done on the issue of vibration of cracked structures until 1996 (Dimaragonas 1996). Doebling et al. provided an overview of methods to detect, locate and characterize damage in the structural and mechanical systems by examining changes in measured vibration responses (Doebling et al. 1998).

There are two approaches in using natural frequencies for damage detection: numerical and analytical. The numerical approaches by using Finite Element Analysis (FEA) is performed on a numerical model with the stiffness of the elements in the model changed systematically until the natural frequencies of the numerical model matches those measured on the real structure. The disadvantage is that an accurate numerical model of the structure is needed, which is not always easy to generate. In the analytical approach, the damage is modeled as a spring when formulating the vibration theory, assuming that it produces a discontinuity in stiffness (Rizos et al. 1990).

This paper presents the way how multiple damages influence the dynamic behavior of beam-like structures, in terms of natural frequencies, mode shapes and stiffness. The method considers a large series of weak-axis bending vibration modes for the damaged and undamaged beam. The natural frequency shifts of these modes for each crack constituting a unique signature (Gillich & Praisach 2012).

2 THE ANALYTICAL APPROACH

The research was conducted to find how the natural frequencies of several weak-axis bending vibration modes changes by occurrence of a crack. In the prior authors researches, it was demonstrated that for any vibration modes there are particular locations in which a damage do not affect the natural frequency of the respective vibration mode. These locations are identical with the inflection points of the mode shape

curvature (Fig. 1b). These locations x are different for the different vibration modes. The locations x, in which no frequency changes due damage occur, are similar for all beams identically supported. At these locations no bending occurs and consequently no strain energy is stored in the beam. There are also locations in which main frequency changes occur (Fig. 1c). These locations are identical with the points of extreme of the mode shape curvatures. These locations, x are also different for the different vibration modes, but similar for a given vibration mode for identically supported beams. The location of these points is dependent of the mode shape and its second derivative and is specific for different boundary conditions (Gillich et al. 2012a).

Comparing the frequency changes for various positions along the beam with the strain energy of slices placed on those locations:

$$dU_i(x) = \frac{1}{2} EI\left(\phi_i''(x)\right)^2 dx \tag{1}$$

where $U_i(x)$ = the strain energy of a slice dx located at distance x from the origin axis (Fig. 1a) for the vibration mode i and $\Phi_i''(x)$ = the mode shape curvature for mode i at that location.

Taking in consideration the above remarks and considering that between frequency changes of a certain vibration mode i and the corresponding mode shape curvature there is a direct relation:

$$f_{i_D}(x,a) = f_{i_U}\left[1-\gamma(0,a)\cdot\left(\overline{\phi}_i''(x)\right)^2\right] \tag{2}$$

where $f_{i_D}(x,a)$ = the frequency of the damaged beam with damage located at distance x and having a = the depth value and f_{i_U} = the frequencies of the undamaged beam for the i-th bending vibration mode. $\gamma(0,a)$ is a term depending on the damage severity and $\Phi_i''(x)$ = the mode shape curvature of the i-th mode. In Equation (2) we used the normalized mode shape curvature. The term $\gamma(0,a)$ = the stiffness loss at the location where the curvature achieves maxima and has the same value for all bending vibration modes for a given beam. It has the expression (Gillich et al. 2012b):

$$\gamma(0,a) = 1-\sqrt{\frac{v_{U\max}}{v_{D\max}}} \tag{3}$$

where v_{Umax} = the maximum deflection of the undamaged beam and v_{Dmax} = the maximum deflection of the damaged beam under own load, the damage being located at the place where the bending moment has the maximum value. Damages are in form of open transversal cracks. It is also possible to use, in stand of Equation (3), one derived from the fracture mechanics theory (i.e. that presented by Ostachowicz & Krawczuk 1991)

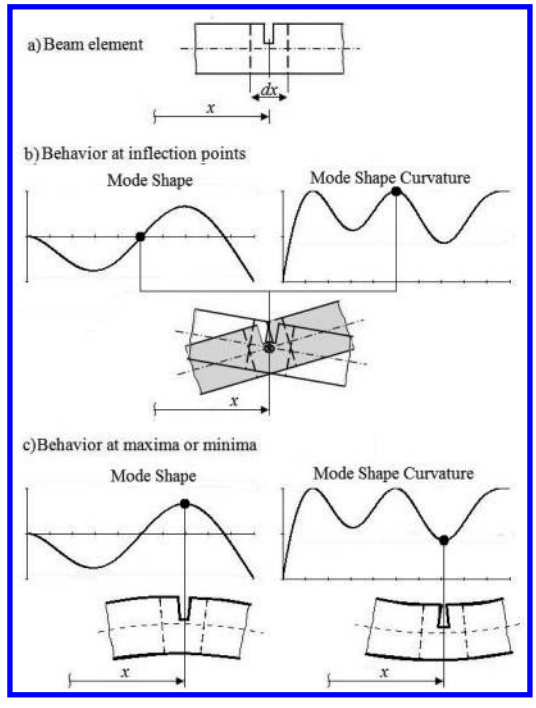

Figure 1. Behavior of the mode shape curvature points at the inflection point (b) and at the maximum or minimum points (c).

The natural frequency shifts for any damage location can be found from the modified form of Equation (2):

$$\Delta f_i(x,a) = f_{i_U} - f_{i_D}(x,a) = f_{i_U}\left[\gamma(0,a)\cdot\left(\overline{\phi}_i''(x)\right)^2\right] \tag{4}$$

or, dividing by f_{i-U} result the *relative frequency shift*, as:

$$\Delta f_i^*(x,a) = \frac{f_{i_U} - f_{i_D}(x,a)}{f_{i_U}} = \gamma(0,a)\cdot\left(\overline{\phi}_i''(x)\right)^2 \tag{5}$$

The relative frequency shift represent a single line matrix with i terms and uniquely characterize a crack in terms of depth a and location x for asymmetric structures.

3 THE NUMERICAL APPROACH

3.1 *Dynamic behavior of beam with one crack*

The chosen type of beam is a steel beam having: mass density $\rho = 7850\,\text{kg/m}^3$; Young's modulus $E = 2.0 \cdot 10^{11}\,\text{N/m}^2$; Poisson's ratio $\nu = 0.3$.

The geometrical characteristics of the beam: wide $b = 0.05$ m; height $h = 0.005$ m and consequently, for the undamaged state the cross-section $A = 250 \cdot 10^{-6}\,\text{m}^2$, moment of inertia $I = 520.833 \cdot 10^{-12}\,\text{m}^4$.

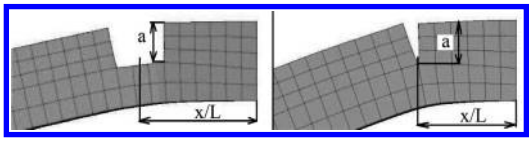

Figure 2. Left side – damage width of 3 mm and right side – damage width of 0 mm.

Were considered two dimensions of beam length 0.6 m, respectively 1 m and four type of supporting ends: clamped – free, clamped – clamped, hinged – sliding and clamped – hinged.

The medium dimension of the mesh element was 1 mm and the first ten natural frequencies of the weak-axis bending modes for the undamaged beams were determined. Afterwards, a series of damages placed separately one after the other on 200 locations along the whole length of the beam were modeled with 9 (nine) levels of depth, reducing the cross-section by: 8%, 17%, 25%, 33%, 42%, 50%, 58%, 67% and 75%, respectively. The first ten natural frequencies of the weak-axis bending modes for each case of the damaged beam were determined. Damages are in form of open transversal cracks with 3 (three) cases: 3 mm damage width, 2 mm damage width and 0 mm (Fig. 2).

The Equation (5) was verified and validated. For the first ten natural frequencies, at each location of the damage and each depth of the damage, are calculated the relative frequency shift and the results are represented in diagrams (Fig. 3). The curves formed by segments unifying this pair of values just indicate the tendency of the shift in frequency and are used to make easier comparison with the shift of natural frequencies obtained by measurements. These diagrams, for each location of damage and each level of depth have a unique signature, or pattern, in the natural frequency shift spectrum for asymmetric supported beams. For symmetric supported beams, due to the effect of symmetry, there are always two location providing one pattern.

Example, a steel cantilever beam with geometrical dimensions 50 × 5 × 600 mm. Analytical results for the first ten natural frequencies for undamaged and damaged beam are presented in Table 1 and the numerical results are presented in Table 2. The damage is located at $x / L = 0.2$ from clamped end with $a = 0.25h$ damage depth and 2mm damage width.

Figure 3 presents the relative frequency shift using the results from Table 1 and Table 2.

Analyzing Figure 3 it can observe a good correlation between analytic approach and numeric approach.

3.2 *Dynamic behavior of beam with multiple cracks*

In physics and systems theory, the superposition principle, also known in the literature as the superposition property, states that, for all linear systems, the net response at a given place and time caused by two or more stimuli is the sum of the responses which would have been caused by each stimulus individually (Valerie Illingworth (ed), 1991). Mathematically, for a linear system F, defined by $F(x) = y$, where x stay for input and y for output or response, the superposition (i.e., sum) of inputs yields a superposition of the respective responses:

$$F(x_1 + x_2 + \cdots) = F(x_1) + F(x_2) + \cdots \tag{6}$$

This principle applies to any linear system, including algebraic equations, linear differential equations, and systems of equations of those forms.

6	347.452	346.337	0.321
7	485.458	485.444	0.003
8	646.562	644.093	0.382
9	830.783	828.739	0.246
10	1038.109	1037.831	0.027

By using the Equation (5) of relative frequency shift definition, the superposition principle for a damaged beam with multiple cracks can be applied.

In the first case it is considered a steel cantilever beam with geometrical characteristics 50 × 5 × 1000 mm heaving three open cracks of 2 mm width located from clamped end at $x_1/L = 0.077, x_2/L = 0.351$ and $x_3/L = 0.5$. First and third crack have $a_1 = a_3 = 0.5h$ damage depth, the second crack is of $a_2 = 0.25h$ damage depth.

The natural frequencies for the first ten vibration mode were determined for the undamaged beam and for the damaged beam one by one. In other words, the right terms of Equation (6) will be determined. The results are presented in Table 3 for damage located at $x_1/L = 0.077$ and $a_1 = 0.5h$ damage depth, in Table 4 for damage located at $x_2/L = 0.351$ and $a_1 = 0.25h$ damage depth and in Table 5 for damage located at $x_3/L = 0.5$ and $a_3 = 0.5h$ damage depth.

The relative frequency shift for each location of the damage are presented in Table 3, 4 and 5 and the relative frequency shift tendency is illustrated in Figure 4.

Table 5. Numerical results. Damage location $x_3/L = 0.5$ and $a_3 = 0.5h$ damage depth

Vibration Mode i	Natural frequency f_{i_U} [Hz]	Natural frequency f_{i_D} [Hz]	Relative frequency shift [%]
1	4.090	4.067	0.564
2	25.627	25.017	2.378
3	71.754	71.755	−0.001
4	140.627	137.479	2.239
5	232.520	232.520	0.000
6	347.452	339.973	2.152
7	485.458	485.446	0.002
8	646.562	633.123	2.079
9	830.783	830.730	0.006
10	1038.109	1016.669	2.065

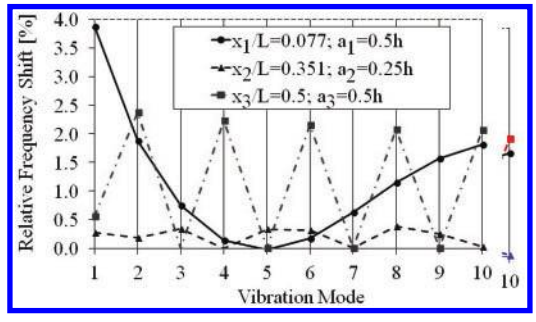

Figure 4. Relative Frequency Shift for three locations of damage.

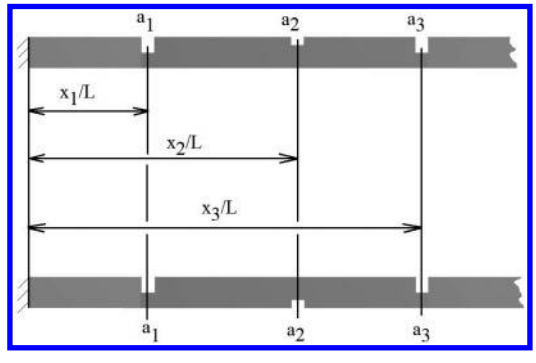

Figure 5. Damaged beam with three open cracks: top – the cracks are located on the upper side of the beam; down – the second crack is located on the lower side of the beam.

Now, we consider the damaged beam with three open cracks located at: $x_1/L = 0.077$ with $a_1 = 0.5h$ damage depth, $x_2/L = 0.351$ with $a_1 = 0.25h$ damage depth and $x_3/\mathrm{L} = 0.5$ with $a_3 = 0.5h$ damage depth.

Are considered two situations: first – all three open cracks are located on the upper side of the beam, second – first and third open cracks located on the upper side of the beam and the second crack is located on the lower side of the beam.

Table 6. Numerical results. Three damages location: $x_1/L = 0.077$ with $a_1 = 0.5h$ damage depth; $x_2/L = 0.351$ with $a_2 = 0.25h$; $x_3/L = 0.5$ with $a_3 = 0.5h$ damage depth, damages located on upper side of the beam

Vibration Mode i	Natural frequency f_{i_U} [Hz]	Natural frequency f_{i_D} [Hz]	Relative frequency shift [%]
1	4.090	3.901	4.619
2	25.627	24.493	4.425
3	71.754	70.969	1.095
4	140.627	137.257	2.396
5	232.520	231.787	0.315
6	347.452	338.252	2.648
7	485.458	482.364	0.637
8	646.562	624.018	3.487
9	830.783	815.786	1.805
10	1038.109	996.885	3.971

Table 7. Numerical results. Three damages location: $x_1/L = 0.077$ with $a_1 = 0.5h$ damage depth; $x_2/L = 0.351$ with $a_2 = 0.25h$; $x_3/L = 0.5$ with $a_3 = 0.5h$ damage depth, second damage located on lower side of the beam

Vibration Mode i	Natural frequency f_{i_U} [Hz]	Natural frequency f_{i_D} [Hz]	Relative frequency shift [%]
1	4.090	3.900	4.647
2	25.627	24.475	4.492
3	71.754	70.968	1.097
4	140.627	137.178	2.453
5	232.520	231.790	0.314
6	347.452	338.059	2.703
7	485.458	482.350	0.640
8	646.562	623.701	3.536
9	830.783	815.901	1.791
10	1038.109	995.865	4.069

The natural frequencies for the first ten vibration mode for the damaged beam with three open cracks located on the upper side of the beam are presented in the Table 6 and natural frequencies for the first ten vibration mode for the damaged beam with three open cracks with second crack located on lower side of the beam are presented in Table 7.

The superposition principle is shown in Figure 7 by using relative frequency shift. The three curves represents: the values of relative frequencies shift presented in Table 6, the values of relative frequencies shift presented in Table 7 and sum of the relative frequencies shift from Tables 3, 4 and 5. It can be observed that the results are very close.

In the second case it is considered a steel cantilever beam with geometrical characteristics 50 × 5 × 600 mm heaving two closed cracks (Fig. 7) located from clamped end at $x_1/L = 0.0055$, $x_2/L = 0.01$ with $a = 0.5h$ damage depth.

The relative frequency shift for: damaged beam with damage located at $x_1/L = 0.0055$ and $a = 0.5h$ damage depth, damaged beam with damage located at $x_2/L = 0.01$ and $a = 0.5h$ damage depth and damaged beam with two damages located at $x_1/L = 0.0055$ and $x_2/L = 0.01$ having $a = 0.5h$ damage depth are presented in Table 8 and the relative frequency shift tendency is illustrated in Figure 8.

Analyzing the Figure 8 it can be observed that for the vibration modes 1 and 2 there is a small deviation between sum of the relative frequency shift and relative frequency shift obtained for damage beam with two closed cracks. Anyhow, the superposition principle can be applied for damaged beams with multiple closed cracks.

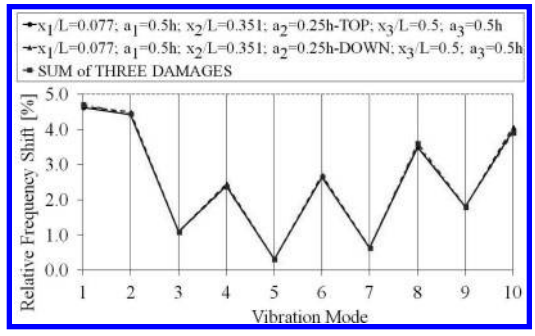

Figure 6. Superposition principle. Beam with three open cracks.

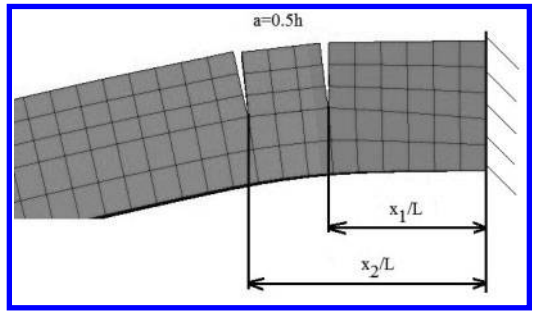

Figure 7. Beam with two closed cracks, first crack located at $x_1/L = 0.0055$ and second crack located at $x_2/L = 0.01$, both having $a = 0.5h$ damage depth.

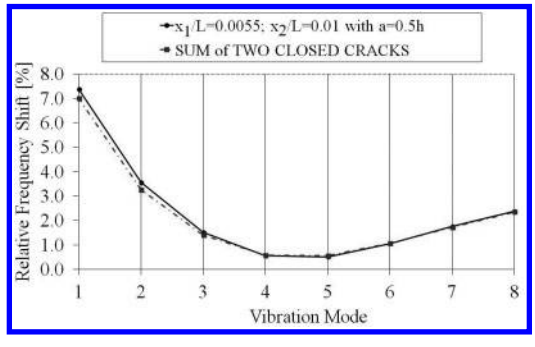

Figure 8. Superposition principle. Beam with two closed cracks.

Table 8. Numerical results. Relative frequency shift: $x_1/L = 0.0055$, $x_2/L = 0.01$ with $a = 0.5h$ damage depth

Vibration Mode i	Natural frequency f_{i_U} [Hz]	Natural frequency f_{i_D} [Hz]	Relative frequency shift [%]
1	3.907	3.473	7.008
2	2.288	1.271	3.263
3	1.259	0.260	1.407

8	0.398	1.981	2.350

4 CONCLUSIONS

The superposition principle presented in this paper, applicable to beams with open cracks or closed cracks, is based on certain phenomena characteristic to the dynamic behavior of beams, highlighted as a result of several numerical and experimental studies developed by the authors.

This property can be used to detect and assess damages in beams, even for complex cases.

Researches performed this direction revealed that it is a clear dependency between deflection and frequency changes, what makes deflection an important feature of beam behavior, usable in damage assessment.

To verify the applying the superposition principle were analyzed many locations of the damages on the beam. For open cracks, the small differences between sum of the relative frequencies shift and the values obtained for damaged beams with multiple cracks are insignificant. There are some small deviations for closed cracks, especially for first, second and third vibration modes between sum of relative frequencies shift for each closed crack and relative frequencies shift for damaged beam with multiple closed cracks.

Structural health monitoring of continuously welded underground pipelines based on quasi-distributed wireless inclinometers

Suzhen Li, Ming Zhao & Naihui Gao
College of Civil Engineering and the State Key Laboratory of Disaster Research in Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: For the convenience of distribution and construction, most pipelines are buried underground. Besides corrosion, crack and material flaw, failures occurring in buried pipelines are particularly associated to structural damages externally induced by surface loading or permanent ground deformation. In the framework of structural health monitoring (SHM), this paper presents a real-time technique for safety evaluation of continuously welded underground pipelines subjected to external interference by using quasi-distributed wireless inclinometers. Based on the multiple inclination measurements, the location of abnormal surface loading and permanent ground deformation can be identified. Structural deflections are then derived based on the infinite beam model on elastic foundation and cubic spline interpolation for the estimation of pipeline behavior. Numerical simulations are conducted to investigate the effectiveness of the proposed method for detection and localization of external intrusive events as well as the influence of sensor placement and measurement error.

1 INTRODUCTION

With the rapid development of economic and industry, it is of great significance to monitor and maintain the integrity and reliability of the increasingly extensive pipeline network to ensure the smooth transportation of oil, gas and other energy sources over long distances. For the convenience of distribution and construction, most pipelines are buried underground. Besides corrosion, crack and material flaw, failures occurring in buried pipelines are particularly associated to structural damages externally induced by surface loading or permanent ground deformation (PGD), which is sometimes unavoidable in the case of nearby superstructure construction or foundation pit excavation.

A distinct consequence that either surface loading or PGD brings to the pipeline is the supervention of longitudinal bending. The flexural deflection is an important parameter for pipeline health monitoring and safety evaluation. Different from the case of other beam structures like bridges, the measurement and estimation of pipeline flexural deflection faces some specific challenges: (1) LVDT (Linear variable differential transformer) is inconvenient to be installed onto a underground pipeline; (2) The traditional leveling process is high labor cost and low measuring precision; (3) The unexpected external interference makes the load pattern unknown, and so as the deflection pattern. The number and the placement of sensors should be carefully designed.

In the framework of structural health monitoring (SHM), this paper presents a real-time technique for safety evaluation of continuously welded underground pipelines subjected to external interference by using quasi-distributed wireless inclinometers. Based on the multiple inclination measurements, the location of abnormal surface loading and permanent ground deformation can be identified. Structural deflections are then derived based on the infinite beam model on elastic foundation and cubic spline interpolation for the estimation of pipeline behavior. Numerical simulations are conducted to investigate the effectiveness of the proposed method for detection and localization of external intrusive events as well as the influence of sensor placement and measurement error.

2 A PIPELINE SHM SYSTEM USING WIRELESS INCLINOMETERS

2.1 *System architecture*

The overview of an integrated SHM system for underground pipeline using wireless inclinometers is given in Figure 1. To identify the pipeline deflection due to surface loading or construction excavation, dual axis inclinometers are attached onto the top surface of the pipe in series along the longitudinal length. A few sensors consist of a set in charge of a certain area (e.g. Zone-1) and via cables are connected to a local RTU (Remote Terminal Unit). Based on wireless transmission techniques (GPRS, Zigbee or 3G), the on-site data can be sent to the management center for pipeline health monitoring and safety evaluation. This system is expected to work as a subsystem integrating to gas or water SCADA (Supervisory Control and Data Acquisition System).

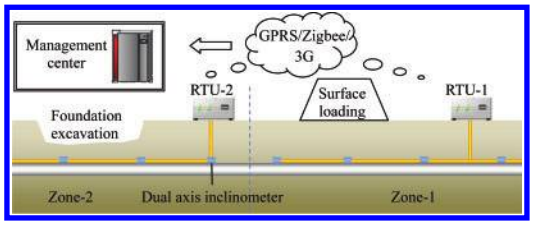

Figure 1. A pipeline SHM system using wireless inclinometers.

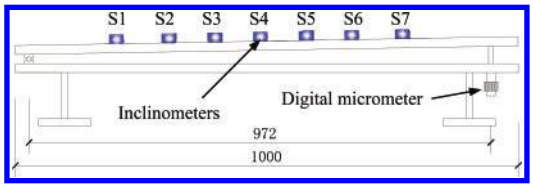

Figure 2. Calibration table for wireless inclinometers.

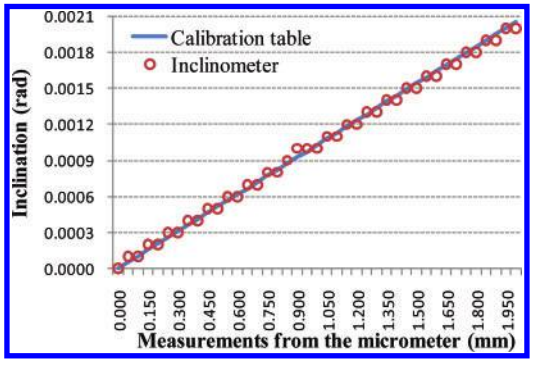

Figure 3. Characterization of the developed inclinometer.

2.2 *Wireless inclinometers*

A wireless inclinometer is recently developed in our laboratory by using MEMS (Micro Electro Mechanical systems) technique. To characterize the performance of the developed sensor, a calibration table is designed as shown in Figure 2. The total length of the table is 1m with a hinge at one hand and a digital micrometer at the other. Since the precision of the micrometer is 0.001 mm, the precision of the table is higher than 0.0001 degree, which is good enough for sensor characterization.

Seven inclinometers are selected as testing samples. The calibration result of a sensor (S3) is illustrated in Figure 3. It can be found the measurements from the developed sensor agree well with the data set by the calibration table.

Taking the set data from calibration as a reference, the errors of the measured inclinations at different measuring range can be calculated. The maximum error in the all testing cases is defined as the precision of the sensor. It can be seen from Table 1 that all the seven sensors achieve a high measuring precision. The largest error is 0.005 degree for S5. Most of the sensors achieve the precision of 0.003 degree. For the following analysis, the measuring precision of the developed inclinometer is conservatively determined as 0.005 degree.

Table 1. Sensor precision (unit: degree)

3 DEFLECTION ESTIMATION OF A BEAM BASED ON MULTIPLE INCLINATION MEASUREMENTS

3.1 *Basic idea*

Consider a typical gas pipe with abutting ends welding together large quantities of pipe segments. It is reasonable to simplify the pipe as a beam model of homogeneous material and geometric properties. According to mechanics of materials, the deflection (y) and rotation (θ) of a beam over the length (x) have the relation as:

$$y = \int \theta dx + C \tag{1}$$

Here, C is integration constant determined by boundary conditions.

If load pattern and boundary conditions are given in advance, which means the deflection and rotation pattern of the beam model is known as well, the rotation measured at a few locations can determine the deflection distribution. This method is widely used in the case of periodic inspection on simply supported beam bridge. The maximum deflection of the bridge under the concentrated stack loading at the mid-span can be identified by one-point rotation measurement, based on which the structural performance of the bridge can be further evaluated.

The significant difference of pipeline structural health monitoring from the above case lies in the fact that the load pattern is unpredictable and so as the deflection pattern. Numerical interpolation is a good solution to the reconstruction of rotation and deflection distribution using multiple inclination measurements. The number and the placement of sensors should be carefully designed.

3.2 *Deflection estimation method based on cubic spline interpolation*

Since the rotation function in terms of x for a beam under various load patterns is normally cubic or less, it is applicable to use cubic spline interpolation to construct rotational function θ(x).

For a given table

x	x_0	x_1	…	x_n
$S(x)$	θ_0	θ_1	…	θ_n

with $a = x_0 < x_1 < \ldots < x_n = b$, if the function $S(x)$ holds:

(1) $S_i(x)$ for each sub-range $[x_{i-1}, x_i]$ $(i = 1,2,\ldots,n)$ can be written as a cubic polynomial;
(2) $S(x)$,$S\prime(x)$,$S\prime\prime(x)$ are all continuous at $[a, b]$;
(3) $S(x_i) = \theta_i (i = 1, 2, \ldots, n)$, i.e., inclination measurements ; $S(x)$ is the cubic spline interpolation function regarding the knots $x_0, x_1, \ldots, x_n$.

A key issue to determine the polynomial coefficients is the adoption of boundary conditions. Regarding the actual mechanic behavior of a pipeline, the following equations are included in this work:

$$\begin{cases} S'''(x_1 - 0) = S'''(x_1 + 0) \\ S'''(x_{n-1} - 0) = S'''(x_{n-1} + 0) \end{cases} \tag{2}$$

Its physical meaning is that the first two sub-ranges are subjected to the exactly same external load and so as the last two, which is a reasonable assumption for buried pipelines since the external inference is usually localized.

For the efficient numerical computation, a standard procedure is followed. Suppose it holds:

$$S''(x_i) = M_i (i = 0,1,2,\cdots,n) \tag{3}$$

As $S_i(x)$ for the sub-range $[x_{i-1}, x_i]$ is a cubic polynomial, $S\prime_i(x)$ is linear and can be written as:

$$S_i''(x) = M_{i-1}\frac{x_i - x}{h_i} + M_i\frac{x - x_{i-1}}{h_i}, x \in [x_{i-1}, x_i] \tag{4}$$

with

$$h_i = x_i - x_{i-1} \tag{5}$$

The double integrals of Eq.(4) lead to:

$$S_i(x) = M_{i-1}\frac{(x_i - x)^3}{6h_i} + M_i\frac{(x - x_{i-1})^3}{6h_i} + A_i(x - x_{i-1}) + B_i \tag{6}$$

Here, A_i, B_i is the integral constant, which can be determined based on $S(x_{i-1}) = \theta_{i-1}$ and $S(x_i) = \theta_i$ as:

$$\begin{cases} A_i = \dfrac{\theta_i - \theta_{i-1}}{h_i} - \dfrac{1}{6}(M_i - M_{i-1})h_i \\ B_i = \theta_{i-1} - \dfrac{1}{6}M_{i-1}h_i^2 \end{cases} \tag{7}$$

Substitute Eq.(7) to Eq.(6):

$$S_i(x) = M_{i-1}\frac{(x_i - x)^3}{6h_i} + M_i\frac{(x - x_{i-1})^3}{6h_i} + \left(\theta_{i-1} - \frac{1}{6}M_{i-1}h_i^2\right)\frac{x_i - x}{h_i} + \left(\theta_i - \frac{1}{6}M_i h_i^2\right)\frac{x - x_i}{h_i} \tag{8}$$

Regarding $S\prime_i(x_i - 0) = S\prime_{i+1}(x_i + 0)$, it is established

$$\mu_i M_{i-1} + 2M_i + \lambda_i M_{i+1} = g_i \qquad (i = 1,2,\ldots,n-1) \tag{9}$$

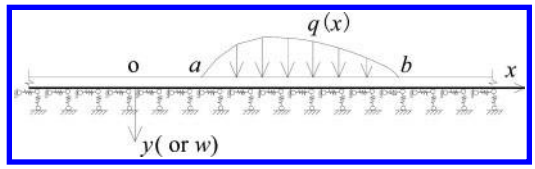

Figure 4. Infinite beam model on elastic foundation

Here,

$$\begin{cases} \mu_i = \dfrac{h_i}{h_i + h_{i+1}} \\ \lambda_i = \dfrac{h_{i+1}}{h_i + h_{i+1}} = 1 - \mu_i \\ g_i = \dfrac{6}{h_i + h_{i+1}}\left(\dfrac{\theta_{i+1} - \theta_i}{h_{i+1}} - \dfrac{\theta_i - \theta_{i-1}}{h_i}\right) \end{cases} \tag{10}$$

Two more equations can be included according to the boundary conditions given in Eq.(2)

$$\begin{cases} \lambda_1 M_0 - M_1 + \mu_1 M_2 = 0 \\ \lambda_{n-1} M_{n-2} - M_{n-1} + \mu_{n-1} M_n = 0 \end{cases} \tag{11}$$

The combination of Eq.(9) and Eq.(11) yields

$$\begin{bmatrix} \lambda_1 & -1 & \mu_1 & & & & \\ \mu_1 & 2 & \lambda_1 & & & & \\ & \ddots & & \ddots & & \ddots & \\ & & & \mu_{n-1} & 2 & \lambda_{n-1} & \\ & & & \lambda_{n-1} & -1 & \mu_{n-1} & \end{bmatrix} \begin{bmatrix} M_0 \\ M_1 \\ \vdots \\ M_{n-1} \\ M_n \end{bmatrix} = \begin{bmatrix} 0 \\ g_1 \\ \vdots \\ g_{n-1} \\ 0 \end{bmatrix} \tag{12}$$

Based on Eq.(12), the solution of $M_0, M_1, M_2, \cdots, M_n$ can be achieved. The rotation function $S(x)$ and the deflection function y(x) can be finally calculated regarding Eq.(8) and Eq.(1).

4 STRUCTURAL HEALTH MONITORING OF BURIED PIPELINE SUBJECTED TO EXTERNAL INTERFERENCE

4.1 *Analytical model for buried pipeline*

The infinite beam model for a continuously welded underground pipeline on elastic foundation can be found in Figure 4. It is simplified as a 2-D problem within the vertical plane. The methodology is exactly same to detect the vertical and lateral interference on the pipeline by using the measurements from dual axis inclinometers. The elastic foundation is considered by applying a series of springs vertically supported to the beam model.

4.2 *Numerical simulations*

Regarding external interference, structural health monitoring of underground pipeline is supposed to

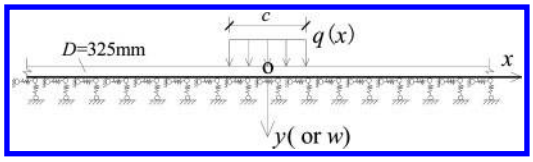

Figure 5. The pipeline model for numerical simulations.

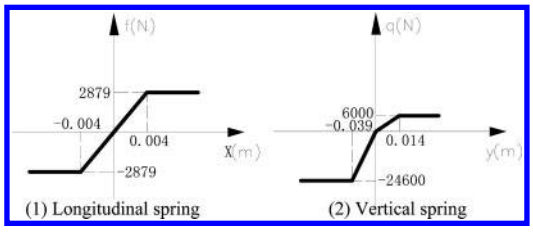

Figure 6. Stiffness of the springs for elastic foundation.

achieve three-level targets: (1) detection of interference; (2) localization of interference; (3) to evaluate the effect on pipelines. In this work, the three targets can be integrated to detect and assess the abnormal deflection. Based on the model for buried pipeline, numerical simulations are conducted to investigate the effectiveness of the proposed method in Section 3.2 for detection and localization of external interference as well as the influence of sensor placement and measurement error.

Consider a buried pipe with the outside diameter of 325 mm and the wall thickness of 10 mm. Since most of the external interferences on the buried pipe act in the form of additional soil pressure, the load can be approximately simplified as the uniformly distributed load (see Figure 5), which has no essential influence on the verification of the effectiveness of the proposed method. As the external interference is usually localized, the vertical displacement of the pipe can be assumed to be zero as long as the distance from the interference is far away enough.

According the guidelines for the seismic design of pipeline system from ASCE, the stiffness of the longitudinal and vertical spring given in Figure 6 is adopted. Suppose the volume weight of the backfill soil is 19 kN/m^3; the internal friction angle is 30deg; the pipe-soil friction coefficient is 0.55; the buried depth is 1.2 m.

Numerical studies are conducted based on the commercial software ANSYS. The pipe is modeled by PIPE16 with the element size of 0.2m. The longitudinal and vertical springs are applied to each node by using the element COMBIN39.

4.3 *Sensor placement*

For the given model in Figure 5, the identified results may be affected by two parameters including the distance (d) of sensors and the distributed length (c) of loads.

Consider the case of $c = 1$ m and the maximum deflection of 20 mm. The deflection and rotation of the pipe structure can be calculated based on the forward analysis using ANSYS. Suppose the sensors are installed on the pipeline at different distances ($d = 1$ m, 2 m, 3 m, 4 m, 5 m). The rotations at the corresponding positions can be then used as the measurements for deflection identification.

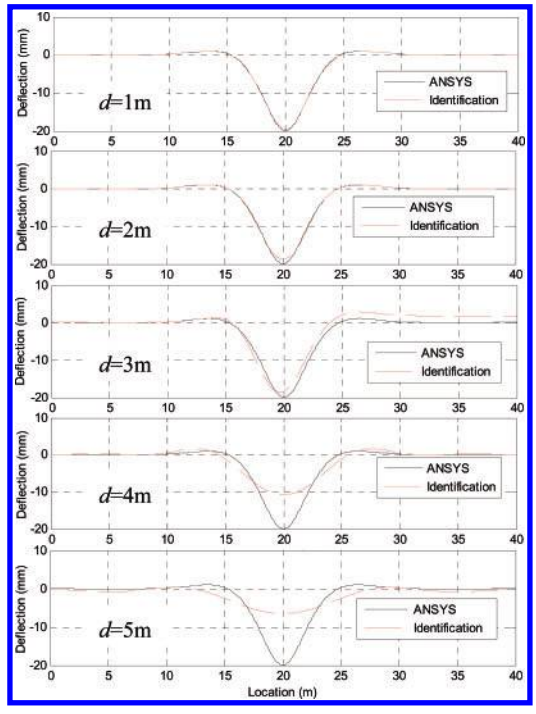

Figure 7. Identified deflections ($c = 1$ m).

According to the method proposed in Section 3.2, the pipeline deflection can be estimated using the multiple inclination measurements. The identified results are illustrated in Figure 7, by comparing with the set deflections based on forward analysis. It can be seen that the deflection is almost exactly recovered when $c = d$=1m. With the increase of the sensor distance, the identification precision is getting worse. It is indicated that the abnormal deflection due to external inference can be detected and located even when the sensor distance is five times the distributed length of loads.

Consider the case of $d = 3$ m and still the maximum deflection of 20 mm. Assuming the distributed length (c) of loads is 1 m, 3 m, 6 m, 9 m respectively, the pipeline deflections are identified and compared with the deflection calculated by ANSYS. As shown in Figure 8, the identified results achieve very good accuracy when $c \geq d$. If the external interference is more localized than sensor distribution, the identified accuracy is degraded but still good enough to locate the abnormal event. It also verifies the effectiveness of the method to identify permanent ground deformation and the potential application in early-warning of nearby foundation pit excavation.

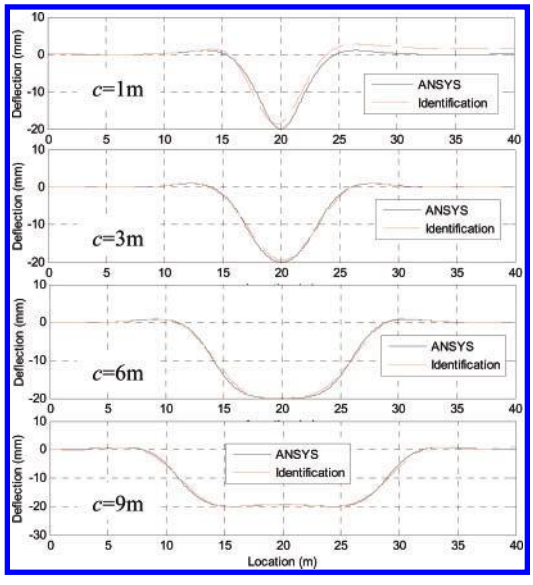

Figure 8. Identified deflections ($d = 3$ m).

4.4 *Measurement error*

In a general way, the measurement error has a significant influence on the inverse analysis for parametric identification. It is always important to investigate the feasibility of the method using the noise contaminated signals.

Suppose $d = 3$ m and $c \geq d$. Totally 200 simulation cases are conducted with the maximum deflection increasing to 20 mm. As characterized in Section 2.2, the precision of the developed inclinometer is 0.005 degree. The measurement error here is simulated as a random number of absolute value less than 0.005, which is artificially introduced to the rotation calculated by ANSYS.

Based on the inclination measurements including random noise, the pipeline deflections are identified for the all 200 cases. The absolute error can be obtained from the difference of the identified deflection and the calculated one. For each case, the largest error is taken and plotted in Figure 9. It is indicated from this statistical chart that the identified accuracy of deflection can get to 1 mm, 0.8 mm, 0.6 mm to ensure a probability of guarantee of not lower than 98%, 95%, 90%. It is a very good precision in comparison with most of current techniques for deflection measurement.

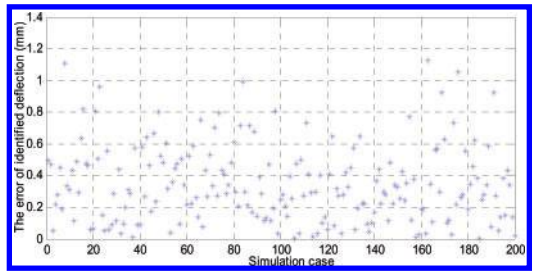

Figure 9. The statistical chart of the absolute errors of identified deflections.

5 CONCLUSIONS

Failures occurring in buried pipelines are particularly associated to structural damages externally induced by surface loading or permanent ground deformation. The flexural deflection is an important parameter for pipeline health monitoring and safety evaluation. This paper presents a safety monitoring technique for continuously welded underground pipelines subjected to external interference by using quasi-distributed wireless inclinometers. Some conclusions are summarized as follows: (1) Based on the infinite beam model on elastic foundation and cubic spline interpolation, pipeline deflection can be determined by multiple inclination measurements regardless of load pattern; (2) The developed wireless inclinometer has been testified and characterized as the measuring precision of 0.005 degree; (3) Numerical studies verify that the identified deflection can achieve very good accuracy if the sensor distribution is more localized than external interference. The identified accuracy of deflection can get to 1mm, 0.8mm, 0.6mm to ensure a probability of guarantee of not lower than 98%,95%,90%.

Cable break detection in pre-stressed bridges, parking decks and girders

B. Hillemeier
Technische Universität Berlin, Germany

S. Knapp
IFDB, Berlin

ABSTRACT: The Remanent Magnetism Method (RM-method) is a non-destructive method to identify potentially unsafe conditions in pre-tensioned and post-tensioned concrete structures. The RM-method identifiesfractures in single pre-stressing wires, even when they are bundled with intact wires. Fractures produce characteristic magnetic leakage fields, which are measured with Hall-Effect sensors. The magnetic field of the tendons is measured at the concrete surface, once they have been pre-magnetized with an electromagnet.The parameters associated with fractured wires are the intensity of the magnetic poles, the distance between tendon and concrete surface and the crack width.The knowledge of these parameters allows drawing conclusions about the reduction of the cross-sectional area or the number of fractured wires in a tendon.The method has been evaluated by the German Federal Highway Research Institute (BundesanstaltfürStraßenwesen, BASt) and is going to be described in a DGZfP directive (German Association for non-Destructive Testing).The test results are indicated just in time in a gray-scaled magnetic laptop picture.

1 DEVELOPMENT OF BRIDGE EXAMINATION IN GERMANY

88 percent of the about 120.000 bridges in Germany are reinforced or pre-stressed concrete bridges. Probably in all countries as well as in Germany traffic infrastructure is chronically underfunded. 46% of the bridge decks in Germany are only sufficient or worse weighted according to the condition notes of the German Federal Highway Research Institute (BASt). Estimates assume that about 7 billion € are needed for examination and repair within the next ten years (Naumann 2011).

Within the years 2008/2009 the German BASt-Institute has carried out a nationwide evaluation of the stock. The condition data have been evaluated after a list of criteria. For each structure an object-related priority number has been determined. Relevant features are rated using grades between 1 (very good) and 4 (unsatisfactory) for structural stability, traffic safety and durability.

Pre-stressed concrete bridges, built between 1960 and 1985 and bridges with the condition note less than 3.0 have urgently to be examined.

1.1 *Pre-stressed concrete damages*

The reasons for corroded pre-stressing wires very often are poorly injected sheathings, the diffusion of chlorides by deicing salts, or chemical components in former grouting systems promoting corrosion. Pre-stressing wires in Germany were frequently made from tempered steel of strength class St 1420/1570, beeing technically approved until the mid 1960s. Damage analysis showed characteristic features of fracture mechanisms. Steel strengthening methods could lead to residual stresses dependingon an unsuitable hardening process leading to a retarded crack propagation. Other probable causes for defects of pre-stressing steel are hydrogeneembrittlement, untightwaterproofingwithchloride penetration, fatigue and overloading of structures, e.g. bridges.

1.2 *The magnetic detection of fractures in pre-stressing wires*

A magnetized pre-stressing wire is comparable to a bar magnet. At the positions where the magnetization starts and ends intense magnetic end-poles are generated and remanently memorized in the pre-stressed steel. At the location of a fracture, a dipole is formed, a magnetic north pole and south pole are generated (Fig. 1). The stray field of the dipole is measured at the concrete surface. The intensity of the signal is directly proportional to the reduction in cross-section of the pre-stressing strand. The signal level is also influenced by the concrete cover, the arrangement of mild reinforcement or embedded steel fittings (Hillemeier 1993, 1995; Hillemeier & Scheel 1998; Scheel & Hillemeier 1997).

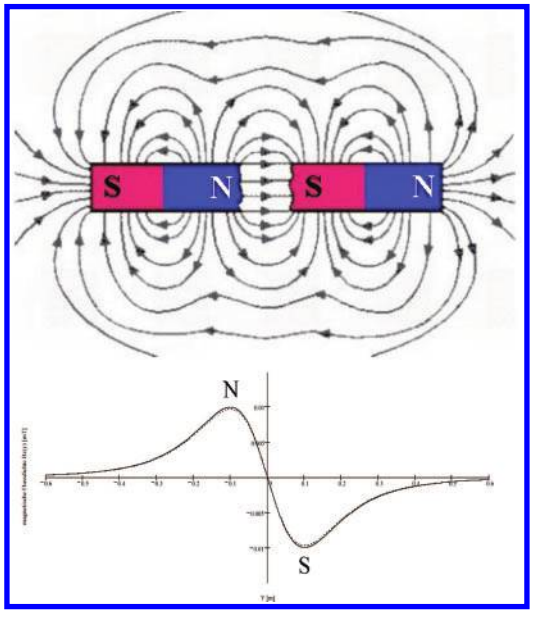

Figure 1. Locating fractures in pre-stressing wires. The curve of the measuring signal shows a characteristic graph. The inflection point of the curve is located exactly between the two magnetic poles (extreme values) and precisely defines the center location of the fracture.

1.3 *The working steps*

The following steps are involved during inspection of pre-stressed concrete components for possible fractures in pre-stressing wires:

- Accessibility to the building
- Locating the pre-stressing wires, e.g. by radar
- Installation of a mechanical guidance system to run the magnet and sensor along the member, Fig. 2
- Magnetization of the pre-stressing wires
- Measuring the magnetic field of the remanently magnetized pre-stressing wires
- Signal processing
- Interpretation of data

1.4 *The magnetization*

The pre-stressing steel should get best possible magnetized up to its magnetic saturation. Prestressing wires could have been exposed to magnetic fields prior to their installation. Such magnetic contaminations are eliminated by full saturation. Full saturation will be accomplished by using a 30 kg electromagnet (Fig. 2) within depths of up to 30 cm concrete cover. In the case of a tendon with a sufficiently large cross-section ($A \geq 50\,\text{mm}^2$) and with distances between the installed mild reinforcement bars which vary not too much, fractures can be detected up to a concrete cover of 30 cm. In the case where a tendon consists of 40 single wires with a small cross-section each (about $20\,\text{mm}^2$) mounted behind a dense mild reinforcement, the detectability of single steel fractures (one fracture

Figure 2. Measurement devices fixed under a girder for inspection. Bridge beams, factories and indoor pools, post-tensioned bridge slabs, pre-stressed parking decks and circumferential tendons of oil tanks have been inspected.

in a cross-section) might be restricted to a concrete cover of 10 cm only. The detectability always depends on the concentration and the local arrangement of the reinforcement. In a seven-wire-strand one fractured wire leads to a cross-section reduction of about 13% which is representing a good distinguishability.

1.5 *The equipment*

The pre-stressing wires are magnetized using specially developed electromagnets which are operated by a power supply unit that runs on continuous and alternating current.

The magnetic flux density is measured using Hall-Effect sensors. This type of sensors shows a fairly high sensitivity and robustness and is easily manageable in the field. The measured magnetic flux signals are stored in a computer in order to get evaluated attentively later. Immediate data evaluation also takes place by visualizing the magnetic pole situation in a gray scaled picture. (Fig. 3).

To guide the equipment precisely along the path of the pre-stressing wire, auxiliary fixtures are available for inspecting the upper, lower, and sideway surfaces of a concrete structure. A standard power supply with conventional connection specifications of 230 Volts and 16 Amps is sufficient.

2 TESTING OF PRE-STRESSED CONCRETE BRIDGE DECKS AND PARKINGSTRUCTURES

Location of pre-stressing steel fractures in bridge decks and parking structures involves the following processes:

– For bridge investigations under traffic, minimum two lanes must be blocked for traffic for each measurement line
– The works on bridges have to be prepared meticulously. Positioning of small magnets supported by conveying are prerequisites for a required exact

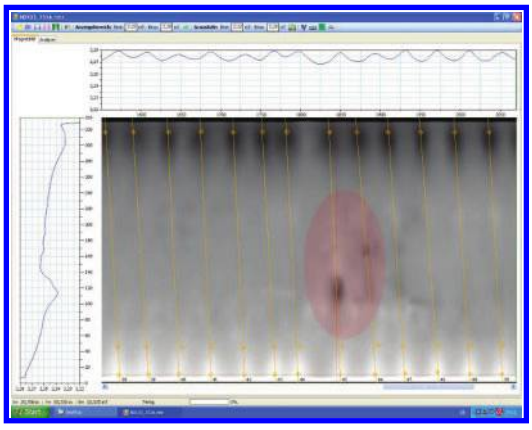

Figure 3. Fast data evaluation during the measurement. The result gets visualized in a gray scaled picture mathematically produced by a computer software. The black poles (north) are connected virtually with the white poles (south). Changing of polarity on an intersection line indicates a fracture, here to be seen inside the pink ellipse.

position indication of fractures within a millimeter range
- It is beneficial to classify the measurement tracks in 50 m to 100 m sections in order ensure data security due to the high amount of data
- Magnetization of the pre-stressing steel and scanning of the magnetic flux density according to the pre-mentioned modifications can increase the measurement speed on bridge decks up to 600 m/h
- Data acquisition and processing
- Data interpretation

The position of the tendon has to be known along the entire magnetized length within a tolerance of about 10 cm. Consequently, it is often necessary to locate the tendons using ground penetration radar before the magnetization may start.

The disadvantage of using small electro-magnets is the time consuming magnetization procedure, because the magnets have to be moved several times along the tendons until a satisfactory magnetization for evaluation is achieved.

2.1 *Single-step-magnetization*

In cases where measurements can be performed from the top surface of the concrete component, the use of larger magnets is feasible.

As a consequence a big electromagnetic unit of 3,50 m length has been developed (Fig. 4). The legs of the electromagnetic yoke have a height of about 1 m and consist of iron cores and coils with an inner diameter of 35 cm. The magnetic yoke with a mass of approximately 3,0 t is operated with a controllable DC power supply with a maximum power output of approximately 16 kW. With this magnet, whose length corresponds to the width of one traffic lane (3,75 m), it is possible to magnetize a 3 m long section of a tendon in one step.

Figure 4. The big line scanner driven by the big magnet on a highway-bridge in Germany.

With this, a fast procedure for locating pre-stressing steel fractures in transverse tendons of bridge decks or tendons in large plane structures, such as parking decks, has become available. The measuring speed has been increased by magnitudes. As a result, structural testing of the pre-stressing steel, required to maintain structural safety, could be performed without severe disruption of traffic.

An array of 335 Hall-effect sensors in a straight line of 3.35 m would be the most obvious solution to this task. Coping with the difficulties for calibration a 3 m long big line scanner has been developed in 2011. 120 Hall-sensors are mounted in six 50 cm long single elements driven extremely near to the testing surface. The robustness of measurement, the resolution of the signal and the speed could be enhanced significantly compared to the previously used rotating system since 2006 (Szielasko et al. 2006). Fig. 4 shows a photograph of the new equipment on a highway-bridge in Germany.

3 MATHEMATICAL EVALUATION OF FRACTURES

Innovations with the MFL-technique can be expected by mathematical simulation of reinforcement arrangements and their magnetic responses. Fractures in a steel bar can be visualized with their specific magnetic flux density. The PhD-thesis of Chol-I Pak delivered advantages in this respect (Pak 2009). The pre-stressing tendon got magnetized up to its magnetic saturation and though to its full remanence. Equivalent magnetic charges are introduced into the reinforcing bar in accordance with Fig. 5.

The magnetic flux density at point P(x,y,z), where e_1, e_2 and S in Fig. 5 meet, can be investigated according to the following formula (1), with B=magnetic field, P=position point P, Q=charge, r=distance of P from charge Q, m_0= 4p x 10^{-7} Tm/A, m = magnetization, A=area, d=diameter of the bar, z=depth of

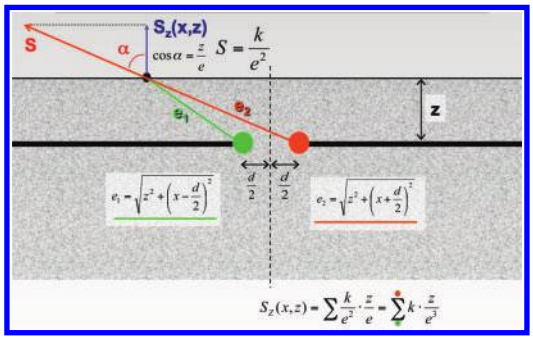

Figure 5. Magnetic charges +Q(green) and –Q(red) are implemented at the positions –d/2and +d/2distance of the fracture of the bar. The bar is oriented along the y-axis, the concrete cover is z.

the bar (vertical distance of measurement), x=position (x=0 over the bar), y=position along the bar.

$$\boldsymbol{B}(\mathrm{P}) = -\frac{\mu_0}{4\pi}\sum_{i=1}^{2}\frac{Q_i}{r_i^2}\cdot\boldsymbol{e}_{r_i}$$

$$Q = \int_A \boldsymbol{m}\,dA = \frac{B_{R,S}}{\mu_0}\cdot\frac{\pi d^2}{4}$$

$$B_z(x,y,z) = -\frac{\mu_0 Q}{4\pi}\left(\frac{z}{\left[x^2+(y-y_1)^2+z^2\right]^{3/2}} + \frac{z}{\left[x^2+(y-y_2)^2+z^2\right]^{3/2}} - \frac{z}{\left[x^2+(y-y_3)^2+z^2\right]^{3/2}} - \frac{z}{\left[x^2+(y-y_4)^2+z^2\right]^{3/2}}\right), \quad (1)$$

Mathematical derivations (Hillemeier & Pak 2012) show that the distance in y-direction between the two extreme values is identical with the depth z(at x = 0) of the bar representing the concrete cover.

$$\frac{\partial \Delta B_{Bruch}}{\partial y} = 0$$

$$-\frac{3B_{R,S}\cdot d^2\cdot z\cdot l_B\cdot(x^2-4y^2+z^2)}{16\left(x^2+y^2+z^2\right)^{7/2}} = 0$$

$$y_{Peak} = \pm\frac{1}{2}\sqrt{x^2+z^2} \quad (2)$$

The distance between the two peaks at x=0 (projection line of the axis of the bar onto the concrete surface) equals z, the concrete cover of the bar. Figure 6 visualizes the fact which is important concerning the evaluation of fractures in reinforcing bars.

4 GIRDER EXAMINATION

The following example shows the investigation of a roof construction of a sports hall in Bavaria, Germany, with a combined measurement unit by magnet and sensors, the so called “small” line-scanner. The roof construction consisted of eight roof girders with the shape of hyperboloid shells (HP-shells). The hall has been built in the years 1970/71 and was prestressed

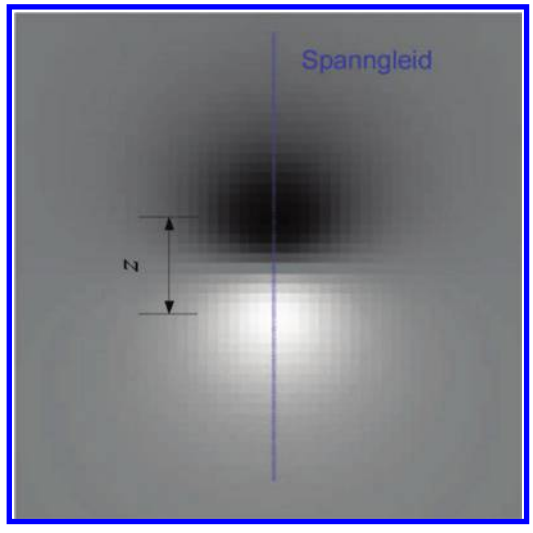

Figure 6. Typical fracture signal measured two-dimensionally. The distance of maxima equals the depth of the bar. See formula (2) with explanations.

Figure 7. Magnet-Sensor-Unit, adapted by a substructure in order to follow along straight lines the curvature of the double curved HP-shells

with prestressing steel St 1500/1700. The span of the girders is 18 m, the width 2.70 m and the thicknesses 10 cm at the ends and 6 cm in the center. Altogether 30 prestressing wires are arranged crosswise in two prestressing ribbons with 15 wires each. The prestressing wires have a diameter of 7.5 mm and a distance to each other of 30 mm.

Worrying deformations of the roof let the assumption arise that these damages resulted of broken prestressing wires. The accessibility to the structure was the most difficult task, to lead the magnet-sensor-unit along the bent ceiling girders. The special construction is shown in Fig. 7 and the pictorial representation of the magnetic stray flux in Fig. 8. The change of the magnetic north pole to the magnetic south pole at a fracture is seen in a sharp black-and-white transition.

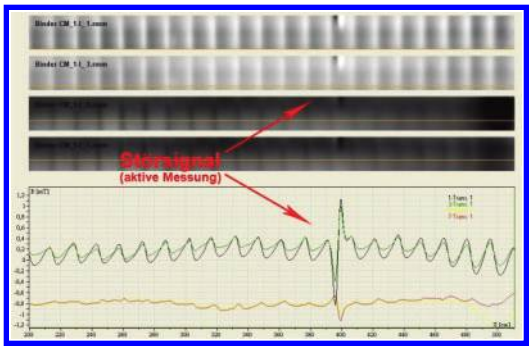

Figure 8. The upper curves are generated by an active field. The lower curves represent the effect of a de- and re-magnetization, suppressing signals from transversal reinforcement. The peak-signal does not show the characteristics of a fracture signal, it represents the signal of a specific steel item.

5 OUTLOOK

The MFL-testing method will show continuous improvement by the development of the magnetization device, the sensor equipment and the mathematical analysis of the complex arrangements of the reinforcement in real structures. Learning by doing is getting a deeper sense also in this challenging field of checking safety and durability of existing pre-stressed structures.

Detection of damage due to salt crystallization through the Scaling Subtraction Method

P. Antonaci, P.G. Bocca, A.S. Gliozzi & M. Scalerandi
Politecnico di Torino, Turin, Italy

ABSTRACT: A laboratory procedure aimed at generating a progressive deterioration of the interface between brick and mortar layers in controlled experimental conditions was developed at the Non Destructive Testing Laboratory of the Politecnico di Torino. It was carried out to explore the role of salt crystallization due to water infiltration and is intended as a preliminary stage in the design of a pre-qualification procedure to be applied to repair mortars for restoration of historical masonry buildings. The evolutionary phenomenon of mortar de-bonding generated in the lab was analyzed through a non destructive technique denoted as Scaling Subtraction Method (SSM), which is based on the detection and post-processing of the nonlinear response of the system to prescribed ultrasonic excitations. The results obtained are able to describe the experimental evidence correctly, thus allowing to characterize the mechanical behavior of the interface. Further than providing a better understanding of the mechanical degradation process under consideration, they highlight the effectiveness and potentialities of the non destructive technique used and therefore substantiate the use of the SSM to predict de-bonding phenomena also in problems characterized by different boundary conditions or damage mechanisms.

1 INTRODUCTION

Some of the most important problems affecting masonry structures are related to rising damp and to the presence of soluble salts into capillary water (Rirsch & Zhang 2010, Lubelli *et al.* 2004, Fassina *et al.* 2002): due to repeated wet-dry cycles, some salts tend to crystallize in the form of expansive compounds, causing progressive cracking and de-bonding phenomena, especially at the interfaces between different material layers, where such compounds tend to collect. An early diagnosis of the onset of such damage phenomena would make it possible to perform corrective actions promptly, thus optimizing repair costs and structural performances during service life. For this reason, it is crucial to have effective and reliable diagnostic tools, offering high resolution in detection, so as to properly identify early symptoms. A full non-destructive character is additionally required in order to keep the building functionality during inspection and monitoring.

Among these tools, ultrasonic inspection techniques (such as those based on attenuation or pulse velocity measurements) are currently widely used for damage characterization in the Building Engineering field (McCann & Forde 2001, Kim & Kim 2009), because of the close interaction between the ultrasonic wave propagation properties and the material mechanical/elastic properties.

Recent studies have revealed that the elastic excitation of cracks at the micro- or meso-scale can induce the generation of nonlinear terms in the ultrasonic wave propagating through the damaged element (Guyer & Johnson 1999, Guyer *et al*. 1999). Such terms are specifically related to damage, since they cannot be ascribed to heterogeneity or geometrical flaws of the element tested, and for this reason nonlinear ultrasounds can be significantly more sensitive to the degradation of the material mechanical properties than traditional linear ultrasonic techniques, yet in the early stages of damage (Van den Abeele *et al.* 2001, Solodov & Busse 2007, Antonaci *et al.* 2010). Therefore, improving experimental methods to properly excite a structural element and extract the full nonlinear signature in the resulting ultrasonic output signals can lead to more effective diagnostic tools to test its integrity.

Based on the above considerations, the present work aimed to check the effectiveness of a nonlinear ultrasonic technique recently developed by the authors and denoted as Scaling Subtraction Method (SSM) (Scalerandi et al. 2008, Bruno et al. 2009), when applied to the characterization of damage induced by the crystallization of expansive salts in masonry systems.

A damage protocol consisting in performing repeated cycles of imbibition in a salt solution followed by a drying phase was carried out to produce salt crystallization in coupled brick-mortar specimens. SSM measurements were made at the end of each cycle, so as to follow the evolution of damage with progressive crystallization. Mass measurements were also performed in order to produce a control indicator to be used as a reference to evaluate the SSM outcome.

2 MATERIALS AND METHODS

2.1 *Specimens*

Two masonry systems, each one constituted of an assembly of a clay brick with two external layers of restoration mortar, were considered in this study. Their final geometry is reported in fig. 1.

The bricks were selected among those commercially available in order to be representative of most common building products. Similarly, the mortar chosen was a typical example of de-humidifying mortar, as commonly used in restoration works. In particular, it was a cement-free prepacked mortar, with a base of hydrated lime and hydraulic lime, natural fine sand, polyacrylonitrile fibers and additives.

The external layers of repair mortar were not applied in complete adhesion to the brick support, on the contrary they were applied in symmetrical and regular discontinuity, created in the casting phase through the interposition of a thin steel leaf. These discontinuities behave as notches which are able to trigger multiple crack propagations.

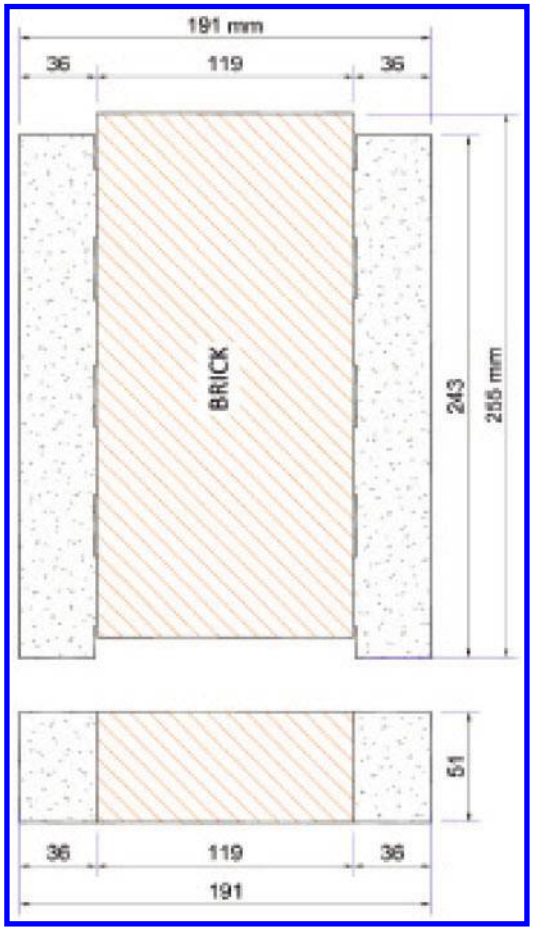

Figure 1. Geometry of specimens.

The samples thus produced were water-cured for 28 days and subsequently air-cured in indoor environment up to the time of testing.

2.2 *Salt crystallization protocol*

In accordance with Standard UNI EN 12370, after verification of mass stability, the specimens were subjected to a damage protocol consisting in immersion in a solution of Sodium Sulfate Decahydrate in deionized water for 2 hours at a temperature of 20°C, subsequent oven-heating at 85°C for approx. 14 hours, further oven-heating at 105°C for additional 4 hours, final cooling down at room temperature for a duration of approx. 2 hours. This process of imbibition followed by a drying phase tends to make the salt crystallize, with consequent alteration of the stress state due to the salt expansive action.

At the end of the cooling phase, the specimens were subjected to mass measurements to assess the amount of salt crystallization, and to SSM measurements, as described in the following. Then the damage protocol was repeated in successive steps, each one always followed by mass measurements and ultrasonic tests, until final rupture occurred due to complete de-bonding of either one or both the external mortar layers.

2.3 *SSM measurements and data processing*

As mentioned before, at the end of each step of the salt crystallization protocol described above, ultrasonic characterization tests were performed. They were carried out with the aid of two identical narrowband piezoelectric transducers with working frequency of 55.5 kHz, placed at the center of two opposite longitudinal faces of the specimen and used one as an emitter and the other as a receiver. An arbitrary waveform generator forced the emitter to vibrate according to a prescribed sine burst law, while a high voltage linear amplifier properly amplified the excitation signals. Finally, a digitizing oscilloscope was used for data visualization and acquisition. The entire setup is schematically shown in fig. 2.

Figure 2. Setup for nonlinear ultrasonic tests.

The linearity of the testing apparatus was preliminarily verified in the proper range of strain amplitudes and frequency using a reference steel sample. Salol was used as a coupling agent.

Ultrasonic measurements were performed injecting sets of sinusoidal bursts with varying amplitudes as input signals, and recording the related response of the system, in terms of received waveforms. Each input burst was composed of 10 sine cycles with the same amplitude and frequency of 55.5 kHz; then the excitation amplitude was progressively increased for successive bursts: for each damage step, 15 input amplitudes (in the range $[1 \div 20]$ V, before amplification) were used to excite the system. A time window of 200 μs was used for the acquisition of the received waveforms, even though, as described below, only first arrivals were considered in the analysis.

For the generic step i, the weight of the sample was monitored before ultrasonic measurements and the mass value was indicated as m^i. Recorded ultrasonic output signals representing the response of the system to the input excitation of amplitude A_k were denoted as $u_k^i(t)$, with i damage step index and k input amplitude index.

A post-processing of the recorded data was required to characterize the progression of damage due to salt crystallization in terms of nonlinearity evolution of the system. To do so, the established Scaling Subtraction Method (SSM) was used (see Bruno 2009 as a reference). Such a method is based on the detection of the loss of proportionality between input and output signals caused by nonlinear elastic effects in the ultrasonic waves propagation. In consolidated granular media, as well as in similar media such as brick, mortar, concrete and most building materials, these nonlinear elastic effects are highly amplified in the presence of cracks at the micro- and meso-scale and consequently tend to become more and more marked with increasing damage. Considering a generic damage step i and an excitation amplitude A_k, if the system was linear the response to that excitation amplitude would be expected to be $u_{ref}^i(t) = A_k/A_1 \cdot u_1^i(t)$, where A_1 is the lowest excitation amplitude and $u_1^i(t)$ is the corresponding response, that can be measured experimentally.

Since nonlinear effects tend to be negligible for low excitation amplitudes, it can be argued that the nonlinear signature contained in the output signal at the amplitude k is entirely expressed through the SSM signal defined as $w_k^i = u_k^i - u_{ref}^i$. Considering a small time window of the recorded signal around the first arrivals ($\Delta t = 60$ μs), the nonlinear effect can be quantified as:

$$\theta_k = \max_{\Delta t} \left| w_k^i \right| \tag{1}$$

Such a nonlinear effect must always be related to the amount of energy used to excite the specimen, which can be expressed as:

$$\eta_k = \max_{\Delta t} \left| u_k^i \right| \tag{2}$$

When plotting the experimental data for varying excitation amplitudes in terms of θ vs. η plots, a power-law dependence of θ on η is observed:

$$\theta = a\eta^b \tag{3}$$

where the parameters a and b can be estimated by best fitting of the experimental data. Finally, a proper nonlinearity indicator can be defined as the value of θ corresponding to a given amount of excitation energy η_0, as obtained from eq. 3. In this analysis, a nonlinearity indicator related to each damage step i was obtained as $\Theta^i = a\eta_0^b$, with $\eta_0 = 2$ V and a and b best fitting parameters.

3 RESULTS

As a first consideration, it is interesting to analyze the mechanism of damage caused by salt crystallization and its evolution with increasing imbibition/drying cycles, as resulting from mass measurements. Considering the percent mass variation with respect to the corresponding initial value for the elements tested (see fig. 3), it can be seen that both specimens underwent final rupture due to complete de-bonding of the external mortar layers when their mass increased by approx. 5%. Actually, in both cases visual inspection revealed that significant decay occurred even before the ultimate rupture, involving prevalently the brick component of the specimens, with surface exfoliation and partial material disintegration. The consequent mass loss related to these phenomena could not be measured during the experiments: this aspect should be taken into account when evaluating the actual mass increase due to salt crystallization, which is expected to be eventually slightly larger than the measured one.

The two specimens differ somehow from each other in terms of mass variation rate with increasing damage steps, especially at the beginning of the damage procedure: they could be ascribed to possible casual

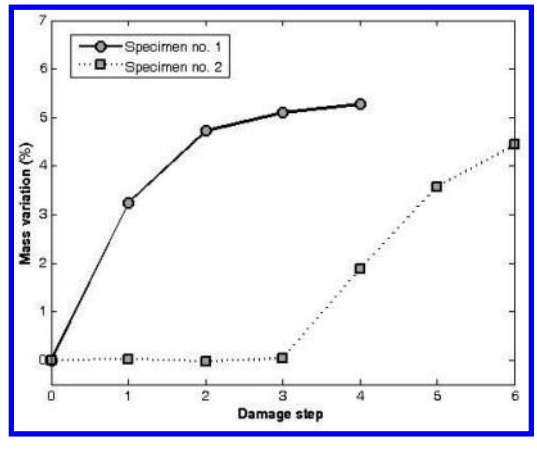

Figure 3. Percent mass variation with increasing damage steps.

discrepancies in manufacturing, resulting in a better brick-mortar adherence for specimen no. 2. This is probably the cause for a delay in the onset of the mass increase due to salt crystallization, which is perfectly reflected by the SSM data analysis, as it will be shown in the following. Nonetheless, as soon as the crystallization process takes place, the mass increase rate is almost the same for both specimens, leading to rupture in about 4 cycles.

It must be noticed that there is no evidence of any precursory trend in the percent mass variation with approaching failure: indeed, the mass increase due to progressive salt crystallization is probably balanced by the mass loss caused by partial material disintegration with increasing damage steps. As a consequence, the mass variation trend globally assumes a quite flat profile, which cannot provide any useful indication about the onset of de-bonding phenomena occurring in the element under investigation.

A clearer view of damage evolution can be obtained considering the results of the ultrasonic tests as a function of increasing salt crystallization. Based on the SSM analysis illustrated in Section 2, the evolution of decay can be described in terms of Θ curves as a function of damage steps, and accordingly in fig. 4 the variation of the Θ indicator with respect to the intact state is reported for both specimens in a logarithmic scale. When considering the behavior of specimen no. 1, it can be noticed that the nonlinear content of the output response increases with increasing damage, in agreement with the mass variation trend.

The same goes for specimen no. 2: here again the nonlinear effects caused by damage accumulation make the Θ curve rise as a function of damage steps, except for steps no. $1 \div 3$, where it tends to be roughly constant. On the other hand, it can be observed that during the same damage steps almost no mass variation occurred, meaning that the brick-mortar adherence for this specimen was strong enough to ensure a very good resistance to damage growth during the initial imbibition-drying cycles. Therefore, the SSM analysis turned out to be reliable in describing the evolution of the system, in agreement with the mass variation measurements.

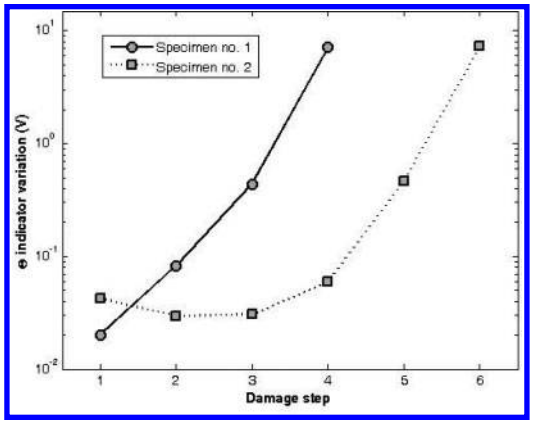

Figure 4. Variation of the nonlinearity indicator Θ as a function of increasing damage steps.

As a whole, the nonlinearity trend is similar for the two elements analyzed, but the most important feature to be observed is that in both cases the Θ variation curves show a faster growth when approaching rupture. This is a very interesting characteristics because, unlike mass variation curves, it potentially allows to make a prediction about the residual lifetime of the bond between the mortar layers and the underlying brick support under the effects of expansive salt crystallization, or at least to provide an early warning in the framework of a monitoring system. This makes nonlinear ultrasonic characterization methods, and particularly the SSM data analysis, very attractive in view of the development of highly efficient monitoring methodologies.

4 CONCLUSIONS

A lab-scale masonry system constituted by a traditional hand-made brick coupled with external layers of dehumidifying mortar was subjected to repeated imbibition-drying cycles inducing progressive crystallization of an expansive salt at the interface between brick and mortar, eventually leading to complete debonding. Such a damage protocol was set up in order to simulate the detrimental effects of rising damp in masonry buildings, in the presence of soluble salts into capillary water.

The evolution of damage was described by means of a mass variation indicator and a nonlinearity indicator experimentally derived from nonlinear ultrasonic tests based on the Scaling Subtraction Method. The experimental evidence revealed that the type of damage here investigated causes an increase in the nonlinear response of the system to an ultrasonic excitation, in a similar way as already attested in the scientific literature for several other forms of degradation. The use of a nonlinearity indicator such as the one here proposed proved to be very useful for the purposes of damage monitoring, since it showed a high sensitivity to the appearance of decay and was able to provide precursory indications with approaching failure.

A damage evaluation method for bridge substructures using longitudinal impact dynamic responses

J.W. Zhan, H. Xia & N. Zhang
School of Civil Engineering, Beijing Jiaotong University, Beijing, China

ABSTRACT: A two-stage damage evaluation method for bridge substructures is proposed. The damage indices based on frequency response functions of the longitudinal dynamic responses under impact loads are used to determine whether damage exists in bridge substructures. The damage extents are determined by finite element model updating method with the longitudinal modal parameters as inputs. The damage evaluation criteria for bridge substructures are suggested based on the limit values of damage indices. The proposed damage evaluation method is verified by an engineering case.

1 INTRODUCTION

Substructures are very important members to support the superstructures in bridges. Most researches, however, focused on the damage evaluation of superstructure, but very little attention paid to the substructures. Various damage identification methods have been proposed utilizing either static parameters or dynamic responses. Damage in bridges can result in changes of their mechanical properties such as mass, stiffness, damping and boundary conditions, which can be reflected by changes in their dynamic characteristics. Damage identification based on the dynamic characteristics of structures has become currently an active research topic in civil engineering (Pandey 1991, Salawu 1997, Hassiotis 2000, Palacz 2002, Wang 2001, Ren 2001). Among the vibration properties, the dynamic responses and natural frequencies are the most sensitive indicators of damage and can be used for the condition evaluation of substructures.

In many countries, the vibration amplitudes and the natural frequencies of bridge substructures are restricted to the allowable ranges. If they are beyond the limit values, then the substructures are judged unsafe (China 2004). According to some studies, however, it is not easy to use the measured amplitudes to evaluate the damage because they are related to the type, weight, length and running speed of vehicles. It is often difficult to consider all these factors in processing the measured amplitudes (Nishimura 1992, 2001). Due to the complexity of vehicle excitation, it is also difficult to obtain the natural frequencies of substructures by train-induced dynamic responses.

In this paper, the vibration of the substructure body, bearing stiffness and subsoil stiffness are used as condition parameters. The sensitivities of longitudinal responses under impact forces to damage are analyzed. The frequency response functions (FRF) based damage index signature assurance criterion (SAC) is used to judge whether damage exist and to determine the global damage extent. With the tested longitudinal impact responses and modal parameters as objectives, the bearing parameters, stiffness parameters and the subsoil parameters are obtained by the finite element model updating method. Thus, the working states of the bridge substructures can be evaluated.

2 SUBSTRUCTURE DAMAGE EVALUATION USING DYNAMIC RESPONSES

The damage of bridge substructures includes structural false, bearing deterioration and subsoil degradation, which usually result in the change of lateral or longitudinal dynamic responses. For most highway bridges, the lateral deformation is main shearing. On the other hand, the constraints of superstructure and bearings are very strong due to the integrity of superstructure, so the lateral modal parameters and dynamic responses are not very sensitive to damage. In contrast, the longitudinal stiffness of substructures is small and the vibration in the longitudinal direction is bending, so it is very easy to excite their local vibration by impact forces. Under the strong constraints of the superstructure in the longitudinal direction, the longitudinal responses under impact forces are transient and local, and the substructures can be simplified as cantilever models with subsoil and bearing constraints (see Fig. 1).

Different from the complicated vehicle excitations, the impact forces executed by the weight hammers and the frequency response functions can be measured simultaneously. The impact forces can be applied on the columns or the bent caps in the longitudinal or lateral direction.

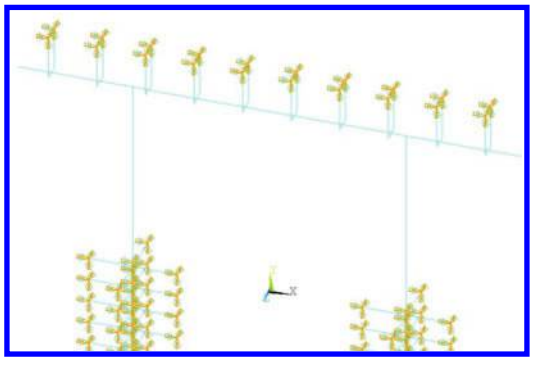

Figure 1. Simplified model in the longitudinal direction.

The soundness index (SI) of the substructure is defined as:

$$\mathrm{SI} = \frac{\text{measured frequencies}}{\text{benchmark values}} \tag{1}$$

In this formula, the benchmark frequency of the tested substructure is computed by the benchmark frequency formula or adopted as its initial test value in the healthy condition. For the symmetrical double-column highway bridge substructures, if the bearings, column body and subsoil are intact, the longitudinal natural frequencies and dynamic responses of the two columns should be the same. When SI is below 0.90, it indicates that damage exists in the structure (Zhan 2005).

Under the impact forces, the motion equation of the substructure can be expressed as:

$$\mathbf{M}\ddot{\mathbf{X}} + \mathbf{C}\dot{\mathbf{X}} + \mathbf{K}\mathbf{X} = \mathbf{P} \tag{2}$$

where: **M**, **K** and **C** are, respectively, the mass, stiffness and damping matrices of the structure; **P** is the impact force vector acted on the substructure.

When the impact force is a unit one, the frequency response function is:

$$H_{pl}(\omega) = \sum_{r=1}^{n} \frac{\phi_{lr}\phi_{pr}}{(\omega_r^2 - \omega^2 + 2j\zeta_r\omega_r\omega)M_r} \tag{3}$$

where: p and l denote the force point and the response point, respectively; M_r is the r-order modal mass.

The signature assurance criterion (SAC) is usually used to describe the similarity of the FRFs of different points:

$$\mathrm{SAC}_{pij} = \frac{(|\{u\}^{\mathrm{T}}\{v\}|)^2}{(\{u\}^{\mathrm{T}}\{u\})(\{v\}^{\mathrm{T}}\{v\})} \tag{4}$$

where: nf is the total number of frequency point; $\{u\}^T = \{H_{pi}(\omega_1), H_{pi}(\omega_2), ..., H_{pi}\omega_{nf})\}$ is the FRF vector of point i; $\{v\}^T = \{H_{pj}(\omega_1), H_{pj}(\omega_2), ..., H_{pj}(\omega_{nf})\}$ is the FRF vector of point j.

If SAC = 1.0, the FRFs of two points are fully linearly related and no structural damage exists, and if SAC = 0.0, the two points are totally unrelated and severe damage emerged in the structure. SAC is not related to the amplitude, but the shape of FRF, so the error induced by the incorrectness of modal shapes can be overcome. Damage Index (DI) based on SAC value is defined as:

$$\mathrm{DI} = 1 - \mathrm{SAC} \tag{5}$$

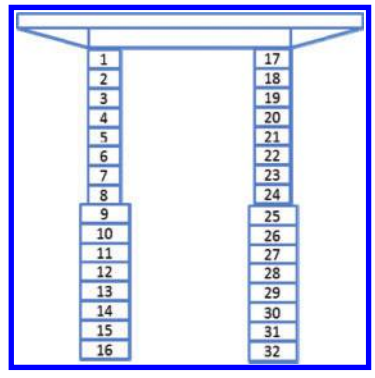

Figure 2. Finite element model of the substructure.

Table 1. DI in different damage scenarios.

Damage element	DI at different damage extents			
	20%	50%	65%	80%
1	0.06	0.25	0.40	0.56
2	0.04	0.14	0.24	0.41
3	0.03	0.07	0.13	0.26
4	0.03	0.05	0.07	0.15
5	0.03	0.05	0.07	0.15
6	0.03	0.06	0.11	0.22
7	0.03	0.09	0.16	0.31
8	0.04	0.11	0.21	0.40
9	0.03	0.08	0.15	0.33
10	0.03	0.08	0.16	0.33

A symmetrical highway bridge substructure shown in Fig. 2 is used to analyze the influence of damage on DI. The subsoil surface is near point 9. The lateral responses of symmetrical points on the two columns, for example 1 and 17, are compared and DI is obtained. Different elements are damaged with different extents in turn. The damage scenarios shown in Table 1 are investigated.

It can be seen that DI of the substructure increases with the damage extents and that the damage near the subsoil has more influence on DI than the others. According to Table 1, the following evaluation criteria for bridge substructures are suggested.

3 QUANTITATIVE DAMAGE EVALUATION OF BRIDGE SUBSTRUCTURES

For bridge management, soundness index SI is an indicator of damage, which can point out the integral damage extents of substructures. However, it is

Table 2. Suggested damage evaluation criteria.

DI range	Measures	Judgment rank
$0 \le DI < 0.05$	sound	1
$0.05 \le DI < 0.10$	damage exists but does not influence the serviceability	2
$0.10 \le DI < 0.20$	condition monitoring should be conducted	3
$0.20 \le DI < 0.40$	reinforcement should be done	4
$0.40 \le DI$	severe damage exist, detailed inspection and reinforcement should be conducted	5

more important to know the location of damage and determine the damage extent.

In recent years, the finite element (FE) model updating technique has become a powerful tool to identify the real parameters of structures and evaluate the damage extents. Many researches have focused on this area (Teughels 2002).

The procedure of updating a finite element model uses measurement data as reference. The estimated natural frequencies and mode shapes are usually considered and the modeling parameters are updated to minimize the differences between experimental and numerically calculated modal parameters. In essence, this is an optimization problem.

The optimization parameters of bridge substructures are chosen as elastic modulus E of substructure body, m value of subsoil and bearing coefficient K. The objective function F comprises two terms, one related to the natural frequencies of global and local modes, and another related to the MAC values of global and local modes:

$$F = \sum_{i=1}^{nmode} w_{fi}\left[\frac{(2\pi f_{ti}^2 - 2\pi f_{ai}^2)}{(2\pi f_{ti}^2)}\right]^2 + \sum_{i=1}^{nmode} w_{\phi i}[1 - \mathrm{MAC}(\phi_{ai}, \phi_{ti})]^2 \quad (6)$$

where: w_{fi} and $w_{\varphi i}$ are, respectively the weighing factors of natural frequencies and mode shapes; f_{ti} and f_{ai} are the i-order experimental and analytical frequencies; ϕ_{ti} and ϕ_{ai} are the vectors containing the experimental and numerical modal information regarding the mode i; $nmode$ is the number of used modes.

The constrained optimization problem can be expressed as:

$$\min : F = F(x) \quad (7)$$

The constrained conditions are:

$$F_k(P) \le \xi \quad \text{and} \quad |F_{k+1} - F_k| / F_k \le \varepsilon \,\&\, k \le N \quad (8)$$

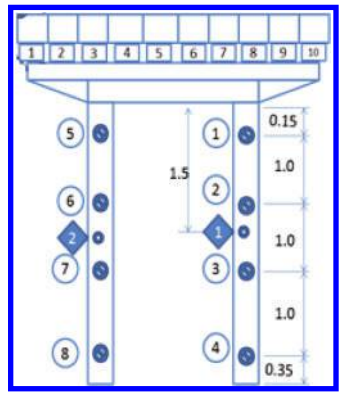

Figure 3. Longitudinal elevation of test substructure.

where: ξ is the allowable error of objective function, ε is the convergence coefficient, N is the designated iteration number.

4 ENGINEERING CASE OF SUBSTRUCTURE DAMAGE EVALUATION

4.1 *Sketch of the test bridge*

The bridge shown in Fig. 3 is a substructure of a two-way bridge with 10 spans of simply-supported box-girders. Two impact points are arranged in the middle of the left column and right column, respectively. The sensors on the columns and the impact points are shown in Fig. 4. The columns were impacted in the longitudinal direction.

4.2 *Damage evaluation*

The time-domain dynamic response and frequency spectrum of point ⑤ are shown in Fig. 5. According to the principle of impact vibration test method

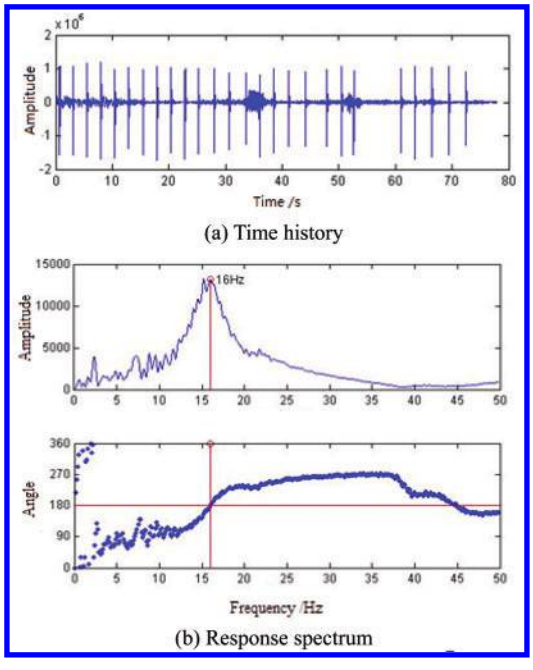

Figure 5. Dynamic response and spectrum of point ⑤.

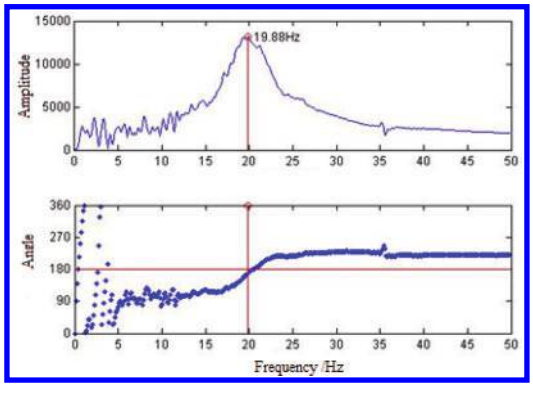

Figure 6. Response spectrum of point ①.

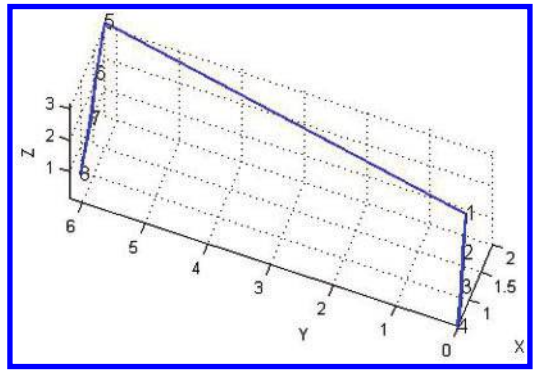

Figure 7. Left column dominating mode (16.0 Hz).

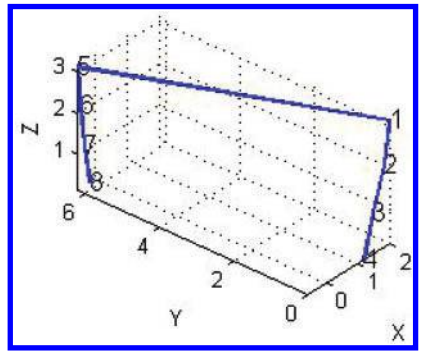

Figure 8. Right column dominating mode (19.88 Hz).

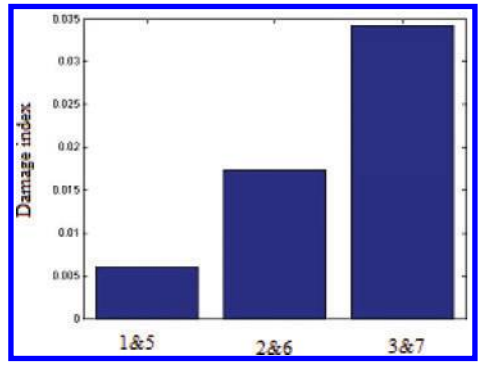

Figure 9. Damage index of the substructure.

(IVTM), the natural frequency of left column is determined as 16.0 Hz (Zhan 2005). Similarly, the natural frequency of right column is 19.88 Hz (Fig. 6). The mode shapes corresponding to the two frequencies are shown in Figs. 7 and 8, respectively.

According to the design, the two columns have the same height, same material and same bearing constraints. Therefore, if the two columns are sound, they should have similar frequency and mode shape, otherwise, damage must exist in the substructure.

If the condition of the right column is assumed good and its natural frequency is used as benchmark value, the soundness index of the left column is SI=16/19.88=0.8. It is blow the safety limit value 0.90, so it can be estimated that the damage happens in the left-column side. To find out the damage type, the bent cap is impacted by a 30 kg hammer in the lateral direction and the damage index DI is analyzed. The DI of three-group points in Fig. 9 is all near zero. According to the evaluation criterion in Table 2, a conclusion is drawn that the substructure belongs to rank 1 and no structural damage in the columns.

Because there is no structural damage in column, possible damage is bearing deterioration or subsoil degradation. The finite element model updating method is used to evaluate the damage. In the analysis, three natural frequencies and mode shapes in the longitudinal direction are used as objective data. The ten bearing of

girders are classified into two groups, i.e. the left five bearing and the right five bearings, whose stiffness are k_1 and k_2, respectively. The m value of the subsoil,k_1,k_2 and the elastic modulus E of the column body are used as variables in the updating analysis.

After the system identification, the true values of the designed variables are obtained and following conclusions can be drawn:

(1) The elastic modulus E of the column body is 3.50×10^4 MPa, which is bigger than the design value of 3.25×10^4 MPa, so the column body is sound.
(2) According to the design and the corresponding code, the m value of the subsoil is 5000 kN/m^4. The identified value is 5921 kN/m^4 The safety coefficient is 1.19 so it can be seen that the subsoil can satisfy the service requirements
(3) The identified horizontal and vertical stiffness for the left 5 bearings are 26989.2 kN/m and 13154736.0 kN/m, which are far smaller than the identification values (60102.0 kN/m and 29294160.0 kN/m) of right 5 bearings. A possible explanation is that different settlements of the two columns cause uneven forces of the bearings. The site investigation proved the substructure inclined to the left side and the left column settles down more than the right one.

5 CONCLUSIONS

In this paper, a damage evaluation method for bridge substructures is proposed. Compared with the lateral responses, longitudinal responses of substructures are easier to measure and sensitive to damage, so the responses and modal parameters in the longitudinal direction are used to evaluate the working state of substructures. The method uses the stiffness of substructure body, the stiffness of bearing and the m value of the subsoil as variables. The signature assurance criterion (SAC) that describes the similarity of FRFs of points is used to quantify the integral damage. The whole identification procedure is divided into two stages: (1) Use the damage indexes based on SAC to determine whether damage exists. (2) Identify the damage extents by finite element model updating method with the longitudinal modal parameters as inputs. A highway bridge substructure engineering case indicates that the proposed damage evaluation method using the longitudinal dynamic responses can effectively judge the damage type and quantify the damage.

Structural damage identification in small scale models of bridge decks

R. Carrazedo & T. M. Juliani
University of São Paulo, São Carlos School of Engineering, São Carlos, Brazil

ABSTRACT: As a nondestructive technique, experimental dynamic analysis offers many advantages on structural integrity evaluation than conventional destructive methods. No damage with the extraction of samples is necessary and the test can be repeated as many times as needed. Natural frequencies and modal shapes are important information on the global response of a structure that can be obtained by experimental dynamic analysis. Once a localized damage affects this global response, its detection is possible. In this paper vibration measurements were carried out on small scale models of a bridge deck to obtain their fundamental dynamic properties. The measurements were carried out through accelerometers placed in strategic positions to obtain the relevant modal data of both slabs and beams of the deck. Unknown excitation forces were applied, simulating operational conditions. Post processing of experimental data was carried out using specialized routines in order to precisely obtain the experimental natural frequencies and mode shapes. On the other hand, theoretical models were developed with the Finite Element Method (FEM) to establish the ideal conditions of the undamaged structure. Comparison between theoretical and experimental models allowed damage identification based on Modal Assurance Criterion (MAC) and Coordinate Modal Assurance Criterion (COMAC).

1 INTRODUCTION

Experimental dynamic analysis has been extensively used as a tool for integrity evaluation of existing structures. For many types of structures the measurements can be implemented with ambient vibrations, simplifying test procedures.

This is the case of bridges, where the traffic induced vibrations can be measured and experimental modal analysis can be performed to identify natural frequencies and mode shapes.

However, many questions regarding measurement procedures, post-processing of the results and comparison to theoretical models are still interesting subjects of research, especially the use of modal data to structural assessment.

In this paper an experimental / numerical dynamic analysis of small scale bridge decks is described as well as the results obtained in structural damage identification through modal data.

A reinforced concrete beam bridge with a central span of 16.8 m and two cantilever spans of 3.7 m was selected for this analysis. Fig. 1 shows the geometry of this bridge, a common structural configuration in Brazilian roads. It is a simple geometry with two longitudinal beams (0.4 m x 1.2 m), five transverse beams (0.2 m x 1.2 m) and a 0.18 m slab.

Instead of dealing with measurements in a real scale bridge subjected to traffic induced vibrations the authors preferred in this initial phase of the research to develop a study with small scale models of the bridge deck under laboratory conditions. With this approach the operations related to the measurements are extremely simplified and the number of situations to be tested can be increased. Every effort was tried to simulate the field conditions in the laboratory with a reasonable agreement.

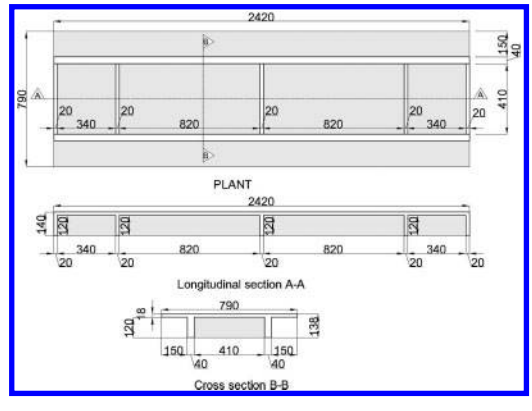

Figure 1. Dimensions of the real scale bridge (in cm).

2 METHODOLOGY

2.1 *Small scale specimens*

A 1/20 scale was selected for the models. With this scale, the models were light enough to allow easy handling (18 kg) and large enough to allow pouring a cement mortar into the forms.

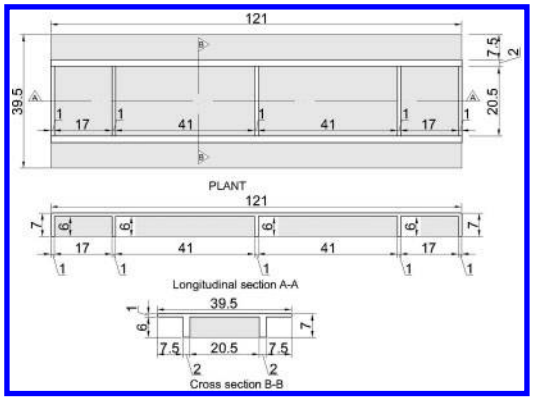

Figure 2. Dimensions of the small scale specimens (in cm).

Figure 3. View of small scale specimens.

Besides this, Harris and Sabnis (1999) mentioned previous studies showing accurate estimates of natural frequencies and mode shapes in 1/3 scale models, although inaccuracies on determination of viscous damping were reported. Successful research works on dynamic behavior of small scale models of bridges (1/30 and 1/33.3 scale) were also described.

Considering these facts and the nature of the present analysis (based only on modal shapes and frequencies) the use of the 1/20 scale was considered an adequate approach. The dimensions of the small scale model are shown in Fig. 2.

The small scale specimens were produced so that model 1 would be an undamaged model and model 2 had structural defects in the form of cracks shown in Fig. 3 (one at the mid section and other near to the corner). These cracks were filled with epoxy resin to simulate a retrofitting process (less than 1 mm of epoxy thickness was used).

A cement mortar with 323 kg/m^3 of Type III - Portland Cement (according to ASTM C150), 1615 kg/m^3 of natural sand and 300 kg/m^3 of water was used. This mortar had a density of 2065 kg/m^3.

The dynamic modulus of elasticity was obtained through resonant acoustic tests with the equipment Sonelastic and in accordance with ASTM C215-08. An impact was applied in one face of the cylinder and

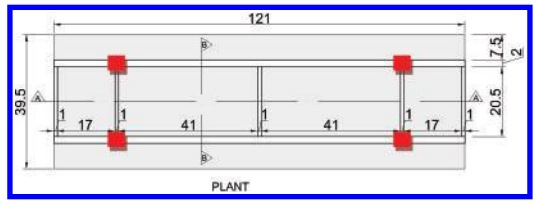

Figure 4. Bottom view of small scale specimens with the polymer pads.

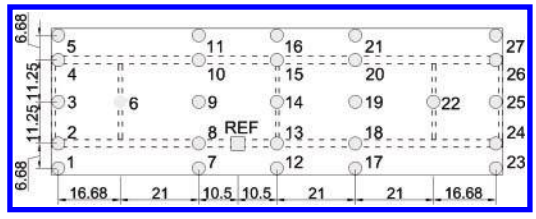

Figure 5. Reference and measuring positions.

the sound was measured by a microphone in the opposite face. Analysis of the sound spectrum allowed clear identification of the frequencies associated to the first longitudinal and first flexional modes of the cylinder. The dynamic elastic modulus was of 23120 MPa, as average of 3 cylinders. Only one batch was used to produce concrete for the two models and control cylinders.

Polymer pads with dimensions of 6 mm x 26 mm and 52 mm were used as supports of the deck in four positions shown in Fig.4. The dynamic stiffness of these pads were also obtained through resonant acoustic tests, based on rigid body motion of a steel disk supported by these pads. The steel disk had 190 mm of diameter and 98 mm of thickness. The total mass of this disk was similar to the bridge model mass. As a consequence the dynamic stiffness of the pads was determined under the same level of stress of the bridge models. The vertical stiffness was of 174571 N/m and the horizontal stiffness was of 300000 N/m.

2.2 *Experimental program*

Bruel Kjaer accelerometers model 8344 were used connected to an acquisition/conditioning system from Vishay Measurements Group – System 6000.

During all tests one accelerometer was fixed at the reference position while the other was positioned at one of the several measurement positions described in Fig. 5

Excitation was applied by impacts of a hammer with a rubber point. The impacts were applied in several locations along the axis where the traffic lanes would be in a real situation. The excitation force was not measured and no exact control of the applied force was possible.

The acceleration x time history was recorded by the acquisition system with a sampling frequency of 2000 Hz. A low pass filter of 800 Hz was applied to reduce noise.

2.3 *Post processing of the measured data*

Post processing of the acquired data was developed with special routines developed with the open source software Scilab.

Power spectral densities were estimated through the pspec function, which is based on the Welch's averaging modified periodogram. A rectangular window with 1000 points of length and 100 points of offset was used. Auto and cross spectra were calculated (PSD and CPSD).

Phase, coherence and transmissibility between the signals in the reference (i) and measurement (j) positions were determined with spectral densities based on the equations of Felber (1993).

The phase angle was calculated as:

$$\theta_{ij} = \arctan\left(\frac{imag(CPSD_{ij})}{real(CPSD_{ij})}\right) \quad (1)$$

while the coherence function was evaluated as:

$$coherence_{ij} = \frac{CPSD_{ij}^2}{PSD_i \cdot PSD_j} \quad (2)$$

and the transmissibility ratio as:

$$TR_{ij} = \frac{real(CPSD_{ij})}{real(PSD_i)} \quad (3)$$

Some of these values were used to check the quality of the acquired data. The phase angle should assume values near to 0^o or 180^o while the coherence should be close to 1 for the natural frequencies. The transmissibility ratio was used to construct the experimental mode shapes.

2.4 *Numerical simulations*

A Finite Element Model (FEM) was created with the software Abaqus version 6.12 to evaluate the properties of an ideal undamaged structure with the properties described in the item 2.1. Solid elements with quadratic interpolation and reduced integration were used (C3D20R). The used mesh is shown in Fig. 6.

A modal analysis was performed identifying all eigenvalues and eigenvectors in the frequency range of interest.

2.5 *Damage identification*

Damage identification was possible through comparison between numerical and experimental frequencies and mode shapes, using MAC (see Allemang and Brown, 1982) and COMAC (see Lieven and Ewins, 1988) coefficients.

The Modal Assurance Criterion (MAC) was used to verify the correspondence between the analytical (i) and experimental (j) mode shapes. The comparison

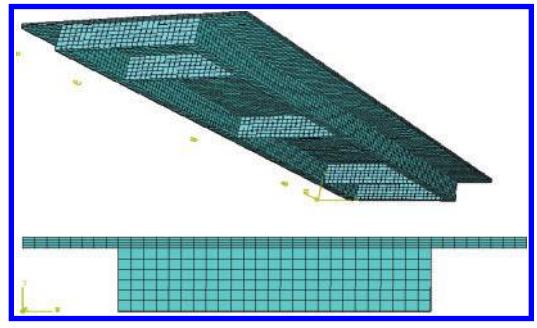

Figure 6. Mesh of the Finite Element Model.

for the same mode should give a MAC close to 1. On the other hand the MAC coefficient between different modes should be close to 0. The MAC coefficients were calculated as:

$$MAC_{ij} = \frac{\left|\{\Phi_i^a\}^T \{\Phi_j^e\}\right|^2}{\left(\{\Phi_i^a\}^T \{\Phi_i^a\}\right)\left(\{\Phi_j^e\}^T \{\Phi_j^e\}\right)} \quad (4)$$

where Φ_i^a is the vector of analytical modal coordinates of mode i and Φ_j^e is the vector of experimental modal coordinates of mode j.

The Coordinate Modal Assurance Criterion (COMAC) was used to identify for each modal coordinate (j) the match between the analytical and experimental data for the n identified modes.

$$COMAC_j = \frac{\left(\sum_{i=1}^{n} \Phi_i^a(j)\Phi_i^e(j)\right)^2}{\left(\sum_{i=1}^{n} \Phi_i^a(j)\Phi_i^a(j)\right)\left(\sum_{i=1}^{n} \Phi_i^e(j)\Phi_i^e(j)\right)} \quad (5)$$

where Φ_i^a and Φ_j^e are the analytical and experimental vectors of modal coordinates of mode i.

3 RESULTS AND DISCUSSION

3.1 *Numerical results – undamaged model*

In Fig. 7 the numerical mode shapes are shown together with the natural frequencies. Rigid body modes were not considered.

Contour plots of the deformed shapes however were more valuable for comparisons of these modes with the experimental counterparts. Some of the contour plots are shown in Fig. 8.

3.2 *Experimental Results*

3.2.1 *Time domain*

Figure 9 shows an acceleration x time curve where the results of several impacts are shown. It is possible to notice a good resolution of the signal compared to the noise floor.

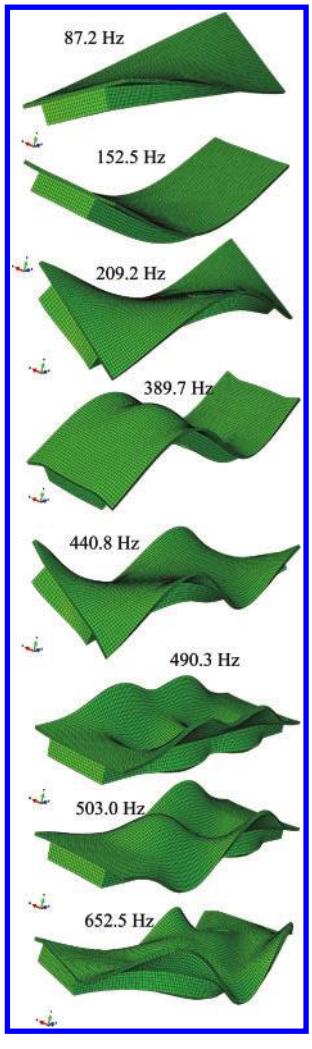

Figure 7. Mode shapes and natural frequencies obtained with the numerical model

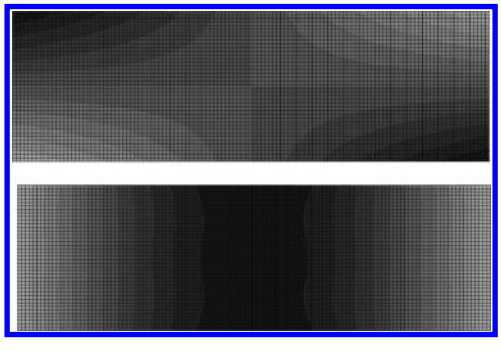

Figure 8. Contour plot of numerical mode shapes – model 2.

3.2.2 *Vibration spectra, phase and coherence*

Typical vibration spectra obtained for the reference position and one measuring position are shown in

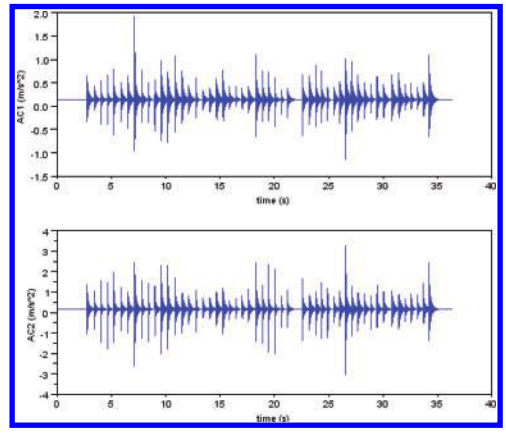

Figure 9. Acceleration × time curves.

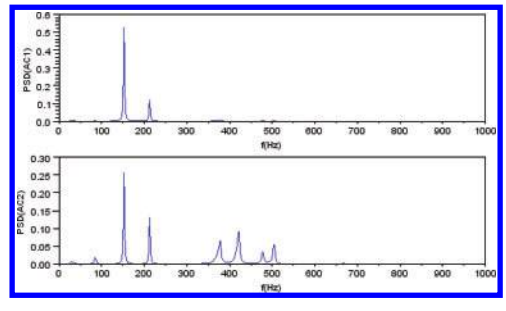

Figure 10. Power Spectral Density (PSD) × frequency curves.

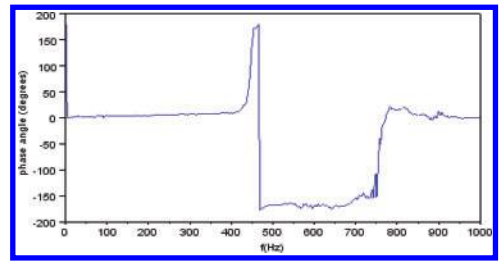

Figure 11. Phase angle × frequency curve.

Fig. 9. As shown several peaks were clearly identified for the measuring positions PSD(AC2). The same peaks were not so clear, but could also be identified in the reference position PSD(AC1).

Plots of phase and coherence functions are also shown in Fig. 10 and 11. The phase angle assumed values close to 0^o or $\pm\ 180^o$, as expected. The coherence was close to unity for most of the frequencies of interest.

3.2.3 *Natural frequencies*

The frequency peaks identified in spectral analysis are shown in Table 1. Only modes with coherence close to unity and experimental modal shapes in reasonable agreement with the numerical ones are shown. It is important to notice that the experimental frequency

Table 1. Natural frequencies – numerical x experimental.

		Experimental	
Mode	Numerical	Model 1	Model 2
1	87.2	84	84
2	152.5	136*	150
3	209.2	208	210
4	389.7	-	376
5	440.8	-	426

of the second mode in model 1 (marked with *) was significantly lower than the numerical. This may be caused by structural damage.

3.2.4 *Mode shapes*

Experimental mode shapes were evaluated through contour plots such as the shown in Fig. 12, which were compared to their numerical counterparts such as Fig. 8. In this case a reasonable representation of the theoretical mode shape was observed.

3.2.5 *MAC coeficients*

Tables 1 and 2 show the MAC coefficients calculated for model 1 and 2. It is possible to notice that the first three experimental mode shapes were in good agreement with the numerical ones in both models.

3.2.6 *COMAC coeficients*

The COMAC coefficients were calculated based on the first three modes of both models. A contour plot of

389.7	0.000	0.000	0.001	**0.865**	0.030
440.8	0.223	0.001	0.002	0.065	**0.616**

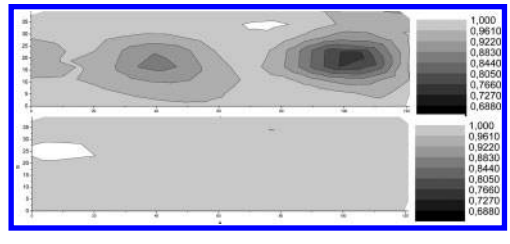

Figure 14. COMAC values calculated for model 1 and 2, respectively.

COMAC values in Fig. 13, showed: possible damaged zones on model 1 (COMAC ranging from 0.688 to 0.999) and almost no damaged zones in model 2 (COMAC ranging from 0.965 to 0.999).

4 CONCLUSIONS

The comparison between experimental and numerical frequencies indicated a possible damage in model 1 (the experimental frequency of mode 2 was significantly lower than the numerical). Besides, the COMAC plot of model 1 showed probable damage zones. As no damage was imposed to model 1 a possible explanation was a significantly higher local water/cement ratio in the slabs due to bleeding. High water content (300 kg/m^3) was used and excessive vibration may have occurred in model 1.

On the other hand, model 2, which initially had cracks, was then retrofitted with epoxy resin and behaved as an undamaged model during the tests. A

close agreement between experimental and numerical frequencies was observed and also for MAC and COMAC coefficients.

The final conclusion was that the dynamic experimental analysis was capable of identifying structural damages in model 1 although these damages were not intentionally imposed to the specimens. At the same time the technique showed that the retrofitting process in model 2 reestablished totally the flexural stiffness of the deck.

5 FUTURE IMPLEMENTATIONS

The results shown here are part of an ongoing research project. Several tests with small scale models will be carried out in a near future simulating different types of structural damages in bridge decks.

Based on these partial results some necessary improvements were identified in the experimental procedures and will be implemented in the remaining tests:

- A more careful control of mortar mix proportions (lower water content), filling and vibration is necessary to avoid bleeding or undesired lack of homogeneity;
- A higher sample frequency and longer acquisition times will be adopted to improve frequency resolution and the accuracy of the results;
- The location of the reference and measuring positions will be further analyzed to improve the number and the quality of experimental mode shapes.

ACKNOWLEDGEMENTS

The authors express their sincere gratitude to FAPESP (São Paulo State Foundation for Research) for the financial support.

ABSTRACT: Vibration-based damage detection methods try to apply structural features extracted from vibration signals to perform damage diagnosis. The local flexibility method (LFM), which can determine local stiffness variations of beam structures using measured modal parameters, is one of the promising approaches. The LFM method is founded on virtual forces that cause nonzero stresses within a local part of the structure. In this study, non-local virtual forces which cause concentrated stresses in a local part and nonzero stresses in the other parts of a structure are employed. The theoretical basis of the proposed pseudo local flexibility method (PLFM) which uses the non-local virtual forces is derived. The effects of the number of modes on damage detection results of three damage scenarios of a numerical hyperstatic beam are studied. The results show that much fewer modes are required for the PLFM to estimate the damage locations and extents with acceptable accuracy. Therefore, the feasibility of the PLFM is higher due to limited number of high quality modes can be identified in real world application, especially for ambient vibration measurement.

1 INTRODUCTION

Many vibration-based structural damage detection techniques which perform damage diagnosis of a structure based on structural dynamic characteristic parameters have been proposed in the last two decades. Toksoy and Aktan (1994) first tried to detect damage locations based on structural flexibility matrices of a beam structure. However, the damage detection algorithms based on flexibility matrices lack a solid theoretical background until the damage location vector method which can locate damage was developed by Bernal (2002). Reynders and De Roeck (2010) further developed the local flexibility method (LFM) with a robust theoretical background to not only detect damage locations but also damage extents.

The LFM utilizes flexibility matrices of a beam structure constructed by lateral displacement mode shapes. Combined with corresponding load configurations which cause stress fields within a local region of the beam structure, the damage extent of the local region can be estimated. The LFM does not require a finite element model of the beam structure. The structural modal parameters identified from the ambient vibration signals both before and after damage are the key information for the LFM. The number of modes necessary for the LFM is usually quite small, especially for a simply supported beam where only the first mode could be sufficient. However, for a hyperstatic beam, the number of modes required for estimation of the damage could be much higher. This makes the feasibility of the LFM much lower because in practice only the first few modes could be identified with high quality using ambient vibration signals. Therefore, in this study, non-local virtual forces which cause concentrated stresses in a local part and nonzero stresses in the other parts of a structure are employed. The theoretical basis of the proposed method which uses non-local virtual forces is derived. The effects of the number of modes on damage detection results of three damage scenarios of a numerical hyperstatic beam are studied. The proposed method is named as the pseudo local flexibility method (PLFM) and is explained and validated in the following sections.

2 PSEUDO LOCAL FLEXIBILITY METHOD

The local flexibility method (Reynders & De Roeck, 2010) considers a structure with volume $\boldsymbol{\Omega}$ and boundary $\boldsymbol{\Gamma}$ which is subjected to the Dirichlet boundary conditions along part of the boundary. A first load system $\boldsymbol{f}^1$ is applied at a limited number of r DOFs where response can be measured. The first load system for the PLFM is chosen such that the induced stress field $\boldsymbol{\sigma}^1$: (1) can be calculated from the loading without knowledge of the structure's stiffness; and (2) consists of

concentrated stresses in a small volume $\boldsymbol{\Omega}_p$ and also stress outside $\boldsymbol{\Omega}_p$. Note that $\boldsymbol{f}^1$ is assumed only causes non-zero stress within $\boldsymbol{\Omega}_p$ for the LFM. Based on the virtual work principle with the body force neglected:

$$\int_{\Gamma} \boldsymbol{t}^T \delta \boldsymbol{x} d\Gamma = \int_{\Omega} \boldsymbol{\sigma}^T \delta \boldsymbol{\varepsilon} d\boldsymbol{\Omega} \tag{1}$$

where $\boldsymbol{t}$ is the vector with applied tractions, $\boldsymbol{\sigma}$ is the corresponding stress vector, $\delta \boldsymbol{x}$ is a virtual displacement field that obeys the Dirichlet boundary conditions and $\boldsymbol{\varepsilon}$ is the corresponding virtual strain vector. If the virtual displacement field is chosen as the one that is induced by the first load system $\boldsymbol{f}^1$ while the forces and the stresses are due to the second load system $\boldsymbol{f}^2$ which obeys the boundary condition of the system, one has that:

$$\sum_{j=1}^{r} f_j^2 x_j^1 = \int_{\Omega_p} (\boldsymbol{\sigma}_p{}^2)^T \boldsymbol{\varepsilon}_p{}^1 d\boldsymbol{\Omega}_p + \int_{\Omega_q} (\boldsymbol{\sigma}_q{}^2)^T \boldsymbol{\varepsilon}_q{}^1 d\boldsymbol{\Omega}_q \tag{2}$$

where x_j^1 is the displacement at DOF j corresponding to the first load system. Assume that the structure is linear elastic and that $\boldsymbol{\sigma}^1$ is proportional to $\boldsymbol{\varepsilon}^1$ with stiffness constant K. If the virtual work is calculated before and after damage has occurred, one has that:

$$\frac{\sum_{j=1}^{r} f_j^2 x_j^1}{\sum_{j=1}^{r} f_j^2 x_{jd}^1} = \frac{\frac{1}{K_p}\int_{\Omega_p} (\boldsymbol{\sigma}_p{}^2)^T \boldsymbol{\sigma}_p{}^1 d\boldsymbol{\Omega}_p + \frac{1}{K_q}\int_{\Omega_q} (\boldsymbol{\sigma}_q{}^2)^T \boldsymbol{\sigma}_q{}^1 d\boldsymbol{\Omega}_q}{\frac{1}{K_p+\Delta K_p}\int_{\Omega_p} (\boldsymbol{\sigma}_p{}^2)^T \boldsymbol{\sigma}_p{}^1 d\boldsymbol{\Omega}_p + \frac{1}{K_q+\Delta K_q}\int_{\Omega_q} (\boldsymbol{\sigma}_q{}^2)^T \boldsymbol{\sigma}_q{}^1 d\boldsymbol{\Omega}_q} \tag{3}$$

If the energy within $\boldsymbol{\Omega}_p$, denoted as $\boldsymbol{E}_p$ or $\boldsymbol{E}_{pd}$, is much smaller than the energy within $\boldsymbol{\Omega}_q$, denoted as $\boldsymbol{E}_q$ or $\boldsymbol{E}_{qd}$, Equation (2) can be derived as:

$$\frac{\sum_{j=1}^{r} f_j^2 x_j^1}{\sum_{j=1}^{r} f_j^2 x_{jd}^1} = \frac{E_p + E_q}{E_{pd} + E_{qd}} \cong \frac{E_p}{E_{pd}} = \frac{K_p + \Delta K_p}{K_p} \tag{4}$$

where $\Delta \boldsymbol{K}_p$ is the change in the stiffness parameter in $\boldsymbol{\sigma}_p$ due to damage. It is assumed that $\boldsymbol{K}_p$ and $\Delta \boldsymbol{K}_p$ are constant within $\boldsymbol{\Omega}_p$, while $\boldsymbol{K}_q$ and $\Delta \boldsymbol{K}_q$ are not necessary to be constant within $\boldsymbol{\Omega}_q$.

For a beam structure, suppose the shear deformation can be neglected, Equation (2) can be modified as:

$$\frac{\sum_{j=1}^{r} f_j^2 x_j^1}{\sum_{j=1}^{r} f_j^2 x_{jd}^1} = \frac{\frac{1}{(EI)_p}\int_0^{\ell_p} M_p^2 d\ell + \frac{1}{(EI)_q}\int_0^{\ell_q} M_q^2 d\ell}{\frac{1}{(EI)_p+(\Delta EI)_p}\int_0^{\ell_p} M_p^2 d\ell + \frac{1}{(EI)_q+(\Delta EI)_q}\int_0^{\ell_q} M_q^2 d\ell} \tag{5}$$

where EI is the bending rigidity, M is the bending moment and l is the length of a beam. Similarly, if the strain energy within $\boldsymbol{\Omega}_q$ is neglected, Equation (4) can be derived as:

$$\frac{\sum_{j=1}^{r} f_j^2 x_j^1}{\sum_{j=1}^{r} f_j^2 x_{jd}^1} \cong \frac{EI_p + \Delta EI_p}{EI_p} \tag{6}$$

The virtual displacement vector $\boldsymbol{x}^1$ under the first load system $\boldsymbol{f}^1$ can be obtained using the following equation:

$$\boldsymbol{x}^1 = \boldsymbol{H}\boldsymbol{f}^1 \tag{7}$$

where $\boldsymbol{H}$ is the flexibility matrix. With the assumption of lumped and approximately equally distributed mass, the flexibility matrix can be estimated using the identified unscaled modal parameters as (Reynders & De Roeck, 2010)

$$\boldsymbol{H} \cong \boldsymbol{H}^n = -\boldsymbol{\Phi}\boldsymbol{\Lambda}_c^{-1}(\boldsymbol{\Lambda}_c{}^H \boldsymbol{\Phi}^H \boldsymbol{\Phi}\boldsymbol{\Lambda}_c + \boldsymbol{\Phi}^H\boldsymbol{\Phi})^{-1}\boldsymbol{\Lambda}_c{}^H\boldsymbol{\Phi}^H \tag{8}$$

where $\boldsymbol{\Phi}$ is the matrix of mode shapes, $\boldsymbol{\Lambda}_c$ is the diagonal matrix of system poles and ^{H} is the Hermitian transpose. If only the first n modes are available, then the flexibility matrix is truncated, denoted as $\boldsymbol{H}^n$. Note that the contribution of the modes in the flexibility matrix is proportional to the inverse of square of the system poles. The influence of the higher modes is much smaller than the one of lower modes. As a result, the number of truncated modes needed to approximate a non-truncated flexibility matrix is much smaller than the ones needed to approximate a non-truncated stiffness matrix. This benefits the practical cases where only limited number of lower modes can be identified with acceptable accuracy, especially using ambient vibration signals.

The calculation of both the LFM and PLFM includes: (1) using the identified modal parameters to construct the truncated flexibility matrix; and then (2) multiply the truncated flexibility matrix and the virtual forces together. The truncated flexibility matrix and the second load system $\boldsymbol{f}^2$ for LFM and PLFM are identical. The only difference of the calculation between LFM and PLFM is the first load system $\boldsymbol{f}^1$.

Based on the theory above, the two main sources of error when estimating rigidity reduction using PLFM are: (1) the truncation error of flexibility matrix due to limited number of modes, denoted as ER_E; and (2) the neglect of virtual strain energy within $\boldsymbol{\Omega}_q$ in Equation (3), denoted as ER_E. Note that for the LFM only exists, while for the PLFM both ER_H and ER_E exist. The key point of the PLFM is that if the non-local first load system $\boldsymbol{f}^1$ can reduce ER_H for a large amount and at the same time induce ER_E which is much smaller than ER_H, the chosen of the non-local first load system should benefit the damage detection results.

3 NUMERICAL STUDIES

We use the same numerical beam model in (Reynder and De Roeck's 2010) to illustrate the feasibility of the proposed PLFM. A hyperstatic IPE100 of 6m length is modeled by 48 beam elements of equal length. It is assumed that only the vertical accelerations at the 25 equidistant points are measured (Figure 1). Totally three damage scenarios are considered. The first two damage scenarios are: (1) a bending rigidity reduction

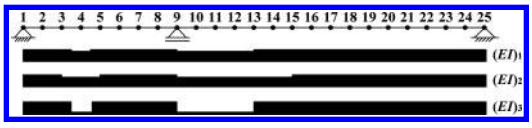

Figure 1. Measurement points and EI distribution of the three damage scenarios of a hyperstatic beam.

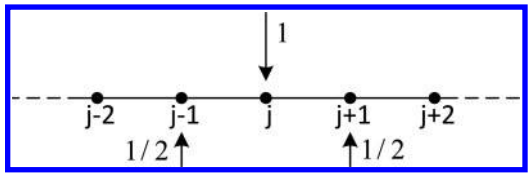

Figure 2. A load configuration of a beam structure that causes concentrated virtual stresses within the region between node j−1 to node j+1.

of 5% at the 2 elements adjacent to measurement point 4 and the elements between points 9 and 13; and (2) a bending rigidity reduction of 10% between elements 3 and 5 and between points 9 and 15. The last damage scenario is the same as the first damage scenario but the stiffness reduction ratio increases to 90%.

At each measurement point, the force configuration in Figure 2 and Figure 3 is applied as $\boldsymbol{f}^1$ for the PLFM and LFM, respectively. The corresponding displacements at the measured DOFs are calculated using the truncated flexibility matrices constructed by different number of modes. For both methods, the force configuration in Figure 2 is applied as $\boldsymbol{f}^2$. Figure 4 shows the estimated relative bending rigidity, denoted as R, estimated with the first 2 unscaled modes using the PLFM and LFM, as well as the reference value which can be calculated using the exact flexibility matrix and the virtual forces. It is evident that the estimated relative bending rigidity using the LFM is quite close to the reference value only at measurement points 6, 7, 9, 11, 13 and between 15 and 23. The estimated relative bending rigidity using the LFM at the other points is far from the reference value. These points are at the measurement points where nonzero stresses exist at both damaged and undamaged locations. On the other hand, the estimated relative bending rigidity using the PLFM is quite close to the reference value at any locations. The relative bending rigidity estimated using the LFM becomes acceptable if the first 12 unscaled modes are used, as shown in Figure 5. Note that the relative bending rigidity estimated using the PLFM is even more accurate than the one estimated using the LFM at most of the points. Similar phenomenon can be observed from the second damage scenario as shown in Figure 6 and 7. In Figure 6, the estimated rigidity reduction ratio using the LFM at point 4, 6, 8, 10, 14 and 16 is far from the reference value. Again, these points are also at the measurement points where nonzero stresses exist at both damage and undamaged locations. The estimated rigidity reduction ratio at point 16 is 4.2, which is outside the limit of the vertical-axis. In the damage scenario 3, the damaged beam becomes more complex

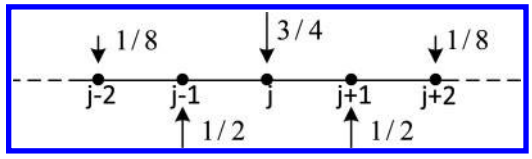

Figure 3. A load configuration of a beam structure that causes non-zero virtual stresses only within the region between node j−2 to node j+2.

because the bending rigidity reduction ratio increases to 90%. As a result, in order to estimate the relative bending rigidity, the required number of modes for the PLFM increases to 9 as shown in Figure 8, while the required number of modes for the LFM increases to 16 as shown in Figure 9.

Obviously, based on the numerical results above, the PLFM can estimate the relative bending rigidity much closer to the reference value if the same number of modes are used. Much fewer modes are required for the PLFM to estimate the rigidity reduction ratios. The merit of PLFM can be explained via the following two reasons.

The first reason is that the error caused by the neglect of strain energy within $\boldsymbol{\Omega}_q$ in Equation (3), i.e. ER_E, is quite small comparing to ER_H. For instance, when the load configuration in Figure 2 is applied at the measurement point 9 of the intact beam as the first load system $\boldsymbol{f}^1$, the strain energy within $\boldsymbol{\Omega}_q$ is 20.6% of the strain energy within $\boldsymbol{\Omega}_p$. When the same load is applied at the same point of the beam with damage scenario 1, the strain energy within $\boldsymbol{\Omega}_q$ becomes 21.2% of the strain energy within $\boldsymbol{\Omega}_p$. The error ER_E caused by neglect of the strain energy within $\boldsymbol{\Omega}_q$ is only 2.8%, which is the largest for damage scenario 1. The smallest ER_E for damage scenario 1 is 0.0% when the load configuration in Figure 2 is applied at the measurement point 2. As long as the ratio between the strain energy within $\boldsymbol{\Omega}_p$ and $\boldsymbol{\Omega}_q$ do not change too much, the error ER_E caused by the neglect of strain energy within $\boldsymbol{\Omega}_q$ in Equation (2) is quite small. It is evident that this ratio could change more if larger rigidity reduction is induced. Taking the damage scenario 3 for example, the maximum ER_E is at point 10 whose error increases to 18.5%. Even though, the rigidity reduction ratio estimated using the PLFM is still much better than the LFM using the same number of modes, as shown in Figure 8.

The second reason is that the accuracy of flexibility matrix required by the first virtual load system $\boldsymbol{f}^1$ for the LFM is much higher than the one for the PLFM. For the PLFM, the first virtual load system $\boldsymbol{f}^1$ is much simpler. As a result, the exact virtual displacement caused by the $\boldsymbol{f}^1$ can be estimated using a truncated flexibility matrix constructed with fewer modes. On the contrary, for the LFM, the first virtual load system $\boldsymbol{f}^1$ is more complex, which causes the exact virtual displacement also more complex. Therefore, the exact virtual displacement could not be estimated with acceptable accuracy using a rough flexibility matrix constructed with fewer modes.

4 CONCLUSIONS

In this paper, a pseudo local flexibility method (PLFM) to localize and quantify the damage of a hyperstatic beam structure is proposed.The PLFM breaks the constraint of the LFM that only virtual forces which cause

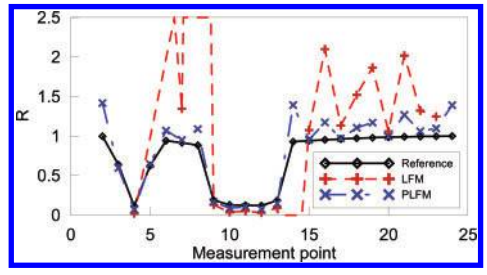

Figure 8. Estimated rigidity reduction ratio for damage scenario 3 using the first 9 unscaled modes.

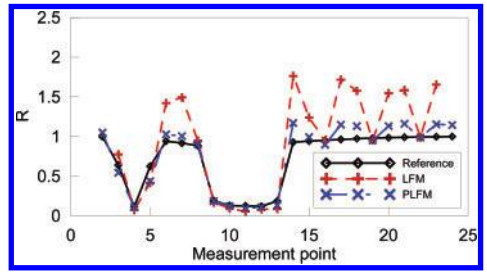

Figure 9. Estimated rigidity reduction ratio for damage scenario 3 using the first 16 unscaled modes.

nonzero local stress within a small part of a structure can be applied. That is, non-local virtual forces which cause a global but concentrated stress filed of a structure is valid for the PLFM. The release of the constraint on the virtual forces makes a simple force configuration possible. The results of numerical studies of a hyperstatic beam show that much fewer modes are required for the PLFM to estimate the damage location and extent with acceptable accuracy. Therefore, the feasibility of the PLFM is higher due to limited number of high quality modes can be identified in real world application, especially for ambient vibration measurement.

ABSTRACT: This study is intended to investigate how damage in a steel truss member results in load redistribution and the fault detection from the traffic-induced vibration data of the bridge. A damage experiment is carried out on a real nine-span-continuous steel-truss bridge. Stress redistribution of truss members due to cut in a diagonal member was observed under live load as well as dead load. Frequencies and damping constants led to a low fault-detection performance. Nonetheless there exists a possibility to detect a fault utilizing changes in frequencies and damping constants, of which success substantially varies amongmodes. On the other handan improved performance in fault detection was observed by the damage-sensitive feature derived from linear system parameters of an AR model.

1 INTRODUCTION

The collapse of the I-35W Mississippi River bridge in Minneapolis, Minnesota, USA on August 1, 2007, was an unprecedented shock to the civil engineering community. (National Transportation Safety Board 2008) After the event bridge inspections in Japan also observed damages at members of steel truss bridges. The importance and need for bridge inspection and monitoring has increasingly become more apparent aftermath of these events. Among the inspection and monitoring, bridge owners have been captivated by the vibration-based bridge health monitoring (BHM) since the vibration-based BHM is expected to provide more efficient way of BHM comparing to visual inspections. (*e.g.*Salawu 1997, Doebling et al. 1998)

In the vibration-based BHM of truss bridges, an important point that must be clarified is how the possible load redistribution of the bridge due to damage on a truss member affects the success of fault detection in terms of the vibration-based BHM. How to excite the bridge economically, reliably and rapidly is another technical issue in the vibration-based BHM with short to medium span. For small to medium span bridges moving vehicles on the bridge are dominant external sources for vibrations of the bridges. The bridge vibration induced by moving vehicles is called as traffic-induced vibration of bridges which is a kind of non-stationary vibration. (e.g. Kim & Kawatani 2008, Chang et al. 2013) Despite of the non-stationary property of the traffic-induced vibration, the idea of using the traffic-induced vibration data in the BHM is that parameters identified repeatedly under moving vehicles may provide a pattern and give useful information about fault detection. (Kim et al. 2013)

This study investigates how damage in a steel truss member results in load redistribution, and also to examine how the load redistribution affects fault detection utilizing the traffic-induced vibration data of anine-span continuous steel truss bridge. This study deemsthe Mahalanobis distances (MD) of frequency, damping constant and damage indicator derived from linear system parameters of a time series model as damage-sensitive features. Potential changes in the damage-sensitive features due to damage are emphasized by the Mahalanobis-Taguchi system (MTS) (Taguchi & Jugulum 2000).

2 ON-SITE DAMAGE EXPERIMENT

On-site damage experiments were conducted on a real nine-span-continuous steel-truss bridge shown in Figure 1. The observation span was the sixth span from the A1 abutment. The roadway roughness condition was poor for the bridge has not been maintained for quite a long time. Figure 2 shows the experiment-setup and a diagonal member before and after severing the member. Acceleration responses of the bridge were measured and utilized in fault detection. Strain gages were also deployed to measure stress changes before and after severing the member. Accelerometers

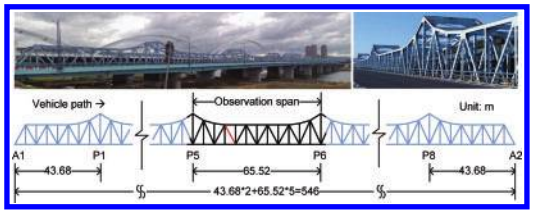

Figure 1. Elevation view of the bridge.

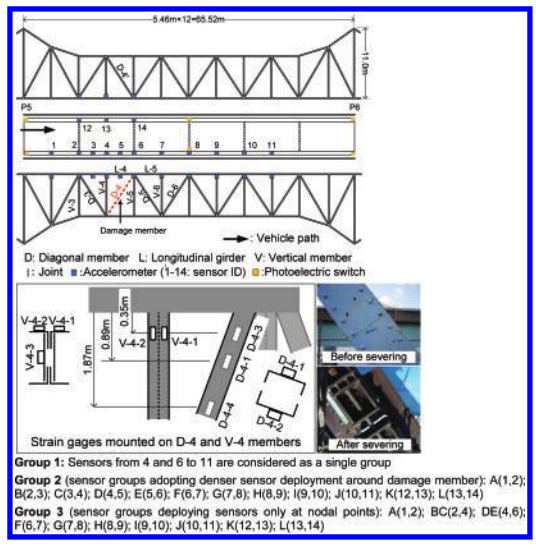

Figure 2. Sensor deploying map.

aremore densely installed around the damage member. It is noteworthy that an excessive displacement of the damage member was controlled by wrapping a safety member around the damage member and installingtension bars in the safety member to prevent abrupt release of tensile force of the damage member and any possible bridge collapse during the damage experiment.

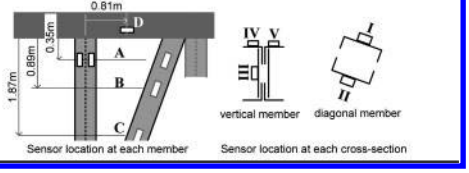
The MTS requires larger number of observations than the number of variables/sensors. However only a limited number of runs were carried out in the field experiment in order to reduce time and cost. Therefore this study utilizes data from sensor groups to reduce the number of sensors which is considered as the number of variables in MTS since reducing the number of variables in MTS results in a similar effect of increasing the number of observations relatively. Three different sensor groups which is also depicted in Figure 2 are considered in fault detection by means of MTS: Group 1 utilizes all the observation data from the 7 observation points, 4 and from 6 to 11, for the damage detection; Group 2 utilizes the data from two adjacent observation points for detecting even the damage location; Group 3 utilizes the observation points except the two observation points, 3 and 5, near the damage member to examine the feasibility of damage-location detection without using data of the sensors which are densely installed near the damage member.

The same vehicle was used in the campaign of experiments in two days, even though vehicle weights were slightly altered from 253 kN to 258 kN. However effects of the small difference of the vehicle's axle load to the bridge response were negligible. Photoelectric switches mounted on the entrance, center and end of the span were used to estimate location and average speed of the passing vehicle. The vehicle-drop test showed that natural frequencies of the vehicle were 3.0 Hz and 3.5 Hz for bounce motions of the front axle and rear axle respectively. Those for hop motions appeared around 12 Hz for the front axle and 14 Hz for the rear axle.

Vehicle-induced vibrations of the bridges before and after severing the member were measured and utilized in fault detection of the bridge.During the experiment, 18 runs were carried out for the intact bridge which comprises 4 runs under vehicle speed of 10 km/h, 7 runs under vehicle speed of 20 km/h and 7 runs under vehicle speed of 40 km/hr. For the damage bridge, 15 runs were carried out for intact bridge which comprises 3 runs under vehicle speed of 10 km/h, 6 runs under vehicle speed of 20 km/h and 6 runs under vehicle speed of 40 km/h.

3 LOAD REDISTRIBUTION

Load redistribution due to severing the diagonal member is examined utilizing the stress redistribution estimated from strain measurements. Table 1 shows change of stresses of observed members due to damage under dead load: tensile stress of the D-4 member was released to 60Mpa in average; on the other hand, the average tensile stress increased to 56Mpa at the V-4 member; for other members such as D-3, D-5, and V-5 increase of compressive stress was observed. An interesting point is that increase of both compressive and tensile stresses were observed at D-4', L-4 and L-5 members as the out-of-plane behavior led to bending moments at the members.



Static and dynamic responses of the truss members, D-4 and V-4, under vehicle load are shown in Figures 3 and 4. Figure 3 shows the static and dynamic strain responses measured at the diagonal member (D-4 in Figure 2) which was cut after the experiment on the healthy bridge. The horizontal axis indicates the position of the front axle of the vehicle from the P5 pier. Applying the damage on the member reduced strains of the member down to half of the strain of the intact member. One reason for strains of the damaged member do not converge to zero after severing the member may be that usually truss members are distorted by out-of-the-plane behavior of the bridge due to damage of the member, but nonetheless the safety member prevents the out-of-the-plane behavior and raises a bending stress in the severed member.

Those strain responses on the vertical member (V-4 in Figure 2) which is adjacent to the damaged

member are shown in Figure 4. Differently from the damaged member no obvious change of peak strains was observed. However, strain responses following the peak response showed larger strains than those strains before applying the damage, which demonstrates stress redistribution under vehicle load. It implies that vehicle-induced vibrations of the bridge hold an indication of some sort of change.

4 CHANGE OF DYNAMIC PARAMETERS

4.1 *Fault detection using MTS*

The MTS is one of the pattern recognition methods, which is used in diagnostic applications to make

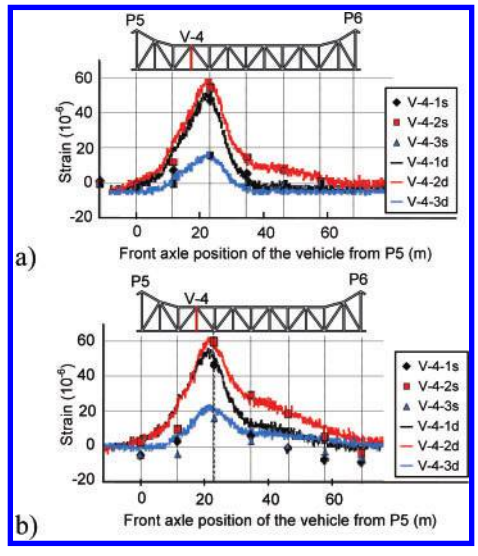

Figure 4. Strain responses of the vertical member (V-4): a) Intact; and b) Damage. (s: static response; d: dynamic response).

quantitative decisions by constructing the multivariate measurement scale MD. (Taguchi & Jugulum 2000) In the MTS, the Mahalanobis space (MS) is obtained using the standardized variables of normal data. The MS can be used to discriminate between normal and abnormal data.

In applying MTS, firstly a measurement scale with MS needs to be constructed as a reference: this is done using the data from a normal group and calculating their MDs, whose value should be close to 1. The standardized normal data are obtained using Equation 1.

$$z_i^p = \frac{x_i^p - \mu_i}{\sigma_i} \tag{1}$$

where z_i^p indicates the standardized p-th tuple of normal data for j-th variable; z_i^p, the p-th tuple of normal data for i-th variable; μ_i, mean value of the i-th variable; and, σ_i, the standard deviation of i-th variable. Those mean and standard deviation values are estimated from Equations 2 and 3 respectively.

$$\mu_i = \frac{1}{n}\sum_{p=1}^{n} x_i^p \tag{2}$$

$$\sigma_i = \frac{1}{n}\sqrt{\sum_{p=1}^{n}\left(x_i^p - \mu_i\right)^2} \tag{3}$$

If $\mathbf{Z} = (z_1^p, z_2^p, \ldots)z_k^p$, and denotes $\mathbf{C} \in \mathbb{R}^{k\times k}$ correlation matrix for k standardized variables, then MD calculated for the p-th tuple of normal data in a sample size n with k variable is given by

$$MD_p = D_p^2 = \frac{1}{k}\mathbf{Z}_p^T\mathbf{C}^{-1}\mathbf{Z}_p \tag{4}$$

Next, the signal space is obtained from abnormal data or newly observed data. Abnormal data are also standardized utilizing mean and standard deviation values of the normal data as

$$y_i^p = \frac{w_i^p - \mu_i}{\sigma_i} \tag{5}$$

The $\overline{MD_p}$ of the normalized abnormal data, $\mathbf{Y}_p = (y_1^p, y_2^p, \ldots, y_k^p)$, in the signal space can be defined by Equation 6 from the normalized abnormal data and $\mathbf{C}$, which is obtained from known data.

$$\overline{MD}_p = \overline{D^2}_p = \frac{1}{k}\mathbf{Y}_p^T \mathbf{C}^{-1}\mathbf{Y}_p \tag{6}$$

If newly monitored data is abnormal $\overline{MD_p}$ should be considerably greater than one.

The required conditions to utilize the MTS are as follows: the number of variables k of normal data is equivalent to that of abnormal data; the number of observation data n is larger than that of variable k; and the standard deviation of normal data σ_i is not zero.

4.2 *Fault detection using dynamic characteristics*

The linear dynamic system can be modeled by the AR model (autoregressive model) (*e.g.* Ljung 1999, Kim et al. 2012) as

$$y(k) + \sum_{i=1}^{p} a_i y(k-i) = e(k) \tag{7}$$

where $y(k)$ denotes the output of the system, a_i is the i-th order AR coefficient and $e(k)$ indicates the error term.

This study also adopts the AR model to model vibrations of the bridge and to identify dynamic characteristics of the bridge. The stabilization diagram combined with the singular value spectrum taken from the frequency domain decomposition (FDD) (Brincker et al. 2000) is also used to choose dynamic parameters to be monitored. The MDs of frequencies and damping constant corresponding to the 1.96Hz and 7.64Hz were considered as damage-sensitivity features. The mode shapes corresponding to the mode near 1.96Hz and 7.64Hz were also considered to detect damage location.

Results of applying the frequency and damping of the Group 1 into the MTS are shown in Figure 5, in which the red horizontal line denotes the threshold. In deciding the threshold, the largest and smallest values of MD taken from the cross-validation were removed, and the trimmed mean value was adopted as the threshold using (n-2) MD distances to reduce the effect of outliers on the MDs.The n-fold cross-validation was also adopted for assessing how the results of a statistic analysis will generalize to an independent data set. (Bishop 2006) Figure 5 demonstrated difficulty of

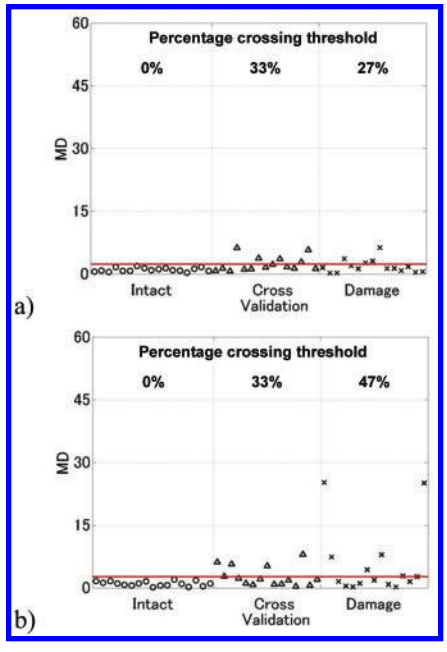

Figure 5. MDs of frequencyof Group1: a) 1.96 Hz; b) 7.64 Hz.

detecting anomalous event from the MDs of 1.96Hz, while MDs of 7.64Hz led to a little higher probability to detect an anomalous event compared to that of 1.96Hz. As shown in Figure 6, for those of damping constants corresponding to 1.96Hz, the MDs led to a higher possibility than those corresponding to of 7.64Hz differently from tendency of the frequency.

The COMAC (Coordinate Modal Assurance Criterion) (Lieven & Ewins1988)value is estimated to identify the damage location. Figure 7 shows the plot of COMAC value at each observation point of the Group 3 and clearly provides the suspected damage location. Two modes associated with 1.96Hz and 7.64Hz were considered.For those COMAC values taken from considering all the 14 observation points (Group 2), no clear difference were observed compared to the result from the 12 observation points shown in Figure 7, and omitted for brevity.

The modal assurance criterion (MAC) values (Ewins 1984)of Group 3 were changed from 0.9913 to 0.9905 for the mode corresponding to 1.96Hz, and from 0.938 to 0.865 for the mode corresponding to 7.64Hz.The MAC values considering all the 14 observation points (Group 2) led to changes from 0.991 to 0.990 for the mode corresponding to 1.96Hz, and from 0.934 to 0.861 for the mode corresponding to 7.64Hz, but no obvious difference with the MAC values from Group 3 was observed.

4.3 *Fault detection using damage indicator*

The coefficient a_p of the AR model shown in Equation 7 is related to the pole of the system since the

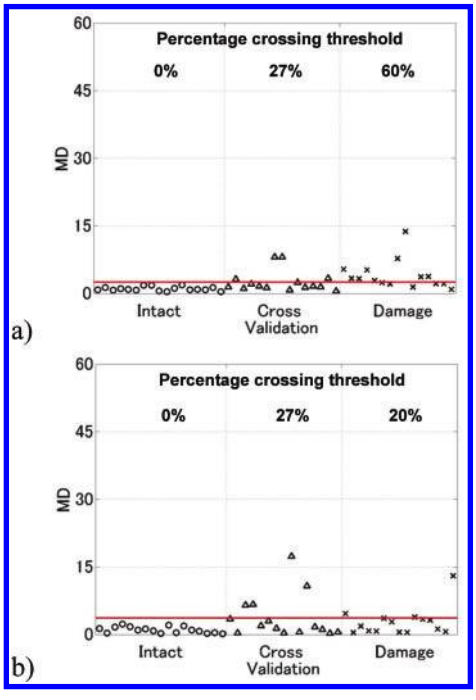

Figure 6. MDs of damping constant of Group1: a) 1.96 Hz; b) 7.64 Hz.

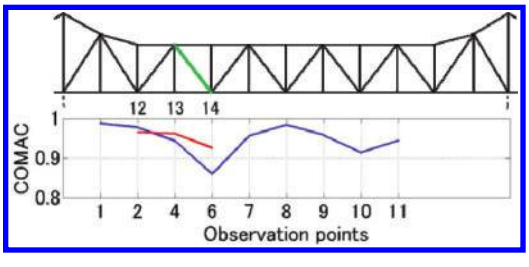

Figure 7. COMAC from modes corresponding to two dominant frequencies 1.96Hz and 7.64Hz.

z-transformation of Equation 7 can be written as (*e.g.* Oppenheim et al. 1996)

$$Y(z) = H(z)E(z) = \frac{1}{1+\sum_{i=1}^{p} a_i z^{-i}} E(z) \quad (8)$$

where $Y(z)$ and $E(z)$ are z-transformations of $y(k)$ and $e(k)$, $H(z)$ is the transfer function of the system in the discrete-time complex domain, and z^{-i} denotes the forward shift operator.

Values of z in which the elements of the transfer function matrix show infinite values are the poles. This means that the denominator of the transfer function is the characteristic equation of the dynamic system, given as

$$z^p + a_1 z^{p-1} + a_2 z^{p-2} + \cdots + a_{p-1} z + a_p = 0 \quad (9)$$

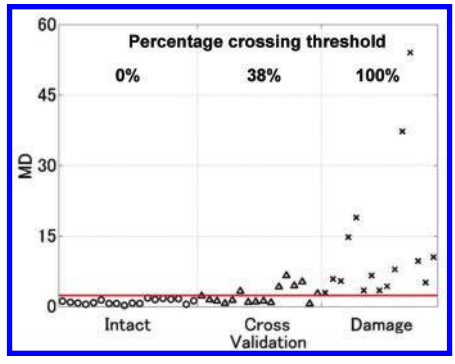

Figure 8. MDs of DI from Group1.

The poles on the complex plane are associated with the frequency and damping constant of the dynamic system of structures. The poles z_k of Equation 9 are obtained by finding the roots of the AR coefficient polynomial in the denominator of $H(z)$. The number of poles in the z -plane equals the AR model order. It should be noted that AR coefficients can be defined by sums and products of its roots z_k according to Vieta's formula. (*e.g.* Bold 1982) In other words, AR coefficients are directly associated with the modal parameters, and AR coefficients are also affected by damage (Kim et al. 2013). Therefore the MD of the parameter which is obtained from AR coefficients as shown in Equation 10 (Nair et al. 2006) is adopted as a damage-sensitive feature.

$$\mathrm{DI} = \frac{|a_1|}{\sqrt{\sum_{i=2}^{3} a_i^2}} \quad (10)$$

where a_i denotes the i-th AR coefficient and DI is the damage indicator that considers up to the third AR coefficient.

The fault detection of the bridge is also carried out by means of the MTS. Figure 8 shows that all of MDs of the DI crossing the threshold, and indicates high possibility of detecting anomalous events of the bridge. It is obvious that the DI acts more sensitively against potential faults compared to the result derived utilizing frequency and damping constants shown in Figures 5 and 6.

Detecting the damage location is carried out using the Group 2, and the results are summarized in Figure 9a). Apparently the probability of crossing the threshold was higher at the sensor group which contains the observation points near the damaged member. The success of detecting the damage location is natural since the stress drastically decreased only at the damaged member as shown in Figures 3 and 4 and two additional sensors installed near the damage member store more information about the damage.

However, it is a rather unrealistic idea to predict the damage suspected member and install sensors around the damage suspected member for monitoring. A remaining question, thus, to be answered would be

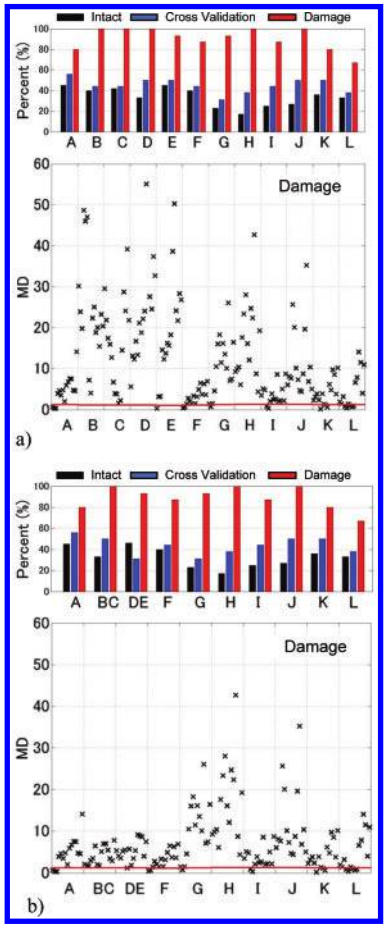

Figure 9. MDs of DI and percentage of MDs crossing the threshold: a) Group 2; and b) Group 3.

the feasibility to detect damage location when sensors are installed at the panel points. Therefore, this study examines the feasibility of detecting damage location utilizing Group 3 in which the two observation points near damage member, points 3 and 5, are not considered. The results are summarized in Figure 9b), and it shows difficulty of detecting the damage location without considering sensors near the damage. However, it is still obvious from the percentage of MDs crossing the threshold that the DI can provide an effective damage-sensitive feature for fault detection.

5 CONCLUDING REMARKS

This study investigates feasibility of a vibration-based bridge health monitoring of a real steel truss bridge utilizing traffic-induced vibrations of the bridge.This study uses the MDs of damage indicator (DI) from linear system parameters of an AR model,frequencies and damping constants as damage-sensitive features. The MTS is applied to emphasize potential change of the damage-sensitive feature due to damage.

Obvious load redistribution was observed even under live load as well as dead load. The most obvious stress change was observed at the damaged member as expected. Load redistribution to other members due to the damage even under live load implies that vehicle-induced vibrations of the bridge have an indication of some sort of change and moreover signals measured at a location away from the damage member also have an indication of change in the bridge.

Frequencies and damping constants led to a low fault-detection performance. Nonetheless there exists a possibility to detect a fault utilizing changes in frequencies and damping constants, of which success substantially varies among modes. On the other handan improved performance in fault detection was observed by DI.

Denser sensor deployment near the damage member led to success of detecting damage location by means of MTS. On the other hand damage location detection was unsuccessful after excluding the sensors near the damage member in the damage detection procedure.

More comprehensive investigations are needed to clarify the reason of failure to detect damage location after removing the sensors near the damage member in consideration.Deciding the optimal number of sensors is another future research. However the proposed fault detection approach is nonetheless applicable to BHM of real truss bridges.

A system model for lifecycle monitoring of bridges

M. Wild & O. Fischer
Chair of Concrete and Masonry Structures, Technische Universität München, Germany

G. Dori & A. Borrmann
Chair of Computational Modeling and Simulation, Technische Universität München, Germany

ABSTRACT: In current bridge maintenance practice, condition grades are assigned to individual bridges, based on regularly performed inspections. The main limitations to this approach are the time-discrete and also subjective nature of grade assignment. To overcome this issue, major bridge authorities are developing new methods for condition assessment, based on collecting and evaluating sensor data in real time. In this research, a system model-based approach has been developed to accurately model the correlations between the deterioration mechanisms and the measurement values indicating the progress of the deterioration. A major challenge in this context is to correctly model the impact of local deterioration on the condition of the bridge as a whole. The actual state propagation mechanism is achieved by means of logical connection elements. The resulting impact tree can be used for propagating the condition assignments from the leaf nodes (the sensors) to the top (the entire bridge).

1 INTRODUCTION

In most industrialized countries, large parts of the infrastructure were erected during the 1960's and 1970's. As a result they are now facing an increasing aging stock of infrastructure buildings. To maintain the infrastructure safe and at the same time to keep the impact on public budget at a tolerable level, an elaborate management scheme for these buildings, including inspections, maintenance and repairs is necessary.

In current bridge maintenance practice, condition grades are assigned to individual bridges, based on regularly performed inspections. Some of the main limitations of this approach are the time-discrete and also subjective nature of grade assignment, resulting in significantly diverging grades for bridges in the same condition. To address this issue, major bridge authorities are developing new methods for condition assessment, based on collecting and evaluating sensor data in real time. In this context it is essential to correctly model the impact of local deterioration on the state of the entire bridge.

In this paper we introduce a system-model based approach which is used to precisely model (1) the correlations between the deterioration mechanisms and the measurement values indicating the progress of the deterioration and (2) the impact of the condition of individual bridge components on the condition of the overall bridge system. The resulting impact tree can be used for simulating deterioration mechanisms as well as for determining the actual condition of bridge, based on sensor measurements. To this end, condition assignments are propagated from the leaf nodes (the sensor measurements) to the top node (the entire bridge). A major function of this propagation mechanism is provided by the logical connection elements which are located between the different layers of the impact tree and model rules for state propagation. These rules can either be based on empirical models or probabilistic or deterministic approaches.

2 COMMON MODELING APPROACHES

Some system modeling methods are already used to describe real bridge structures (Sianipar & Adams 1997, LeBeau & Wadia-Fascetti 2000). These approaches have in common that the investigated bridge is subdivided into single structural components, which are linked by logical conjunctions to obtain the entire bridge system model. The level of detail for a structural component depends on the relevance of the element for the structure. Commonly used modeling approaches in the context of reliability analyses are reliability block diagrams, fault tree analysis and event tree analysis (Klinzmann 2008).

In the abovementioned modeling approaches, structural elements can be set to the states "in service" or "default". This binary description is based on Boolean operators. The relevance of each element depends on the particular problem (stability, durability etc.) and the system structure. The individual elements have to be placed in their position in the system model and linked to each other, according to their task in the real bridge system. Complex systems can be modeled in this way as serial or parallel system or as combination

of the two. The systems structure function can be set up using state variables of individual elements and, based on this function, the failure probability of the system can be evaluated.

The reduction of complex interrelationships to a binary notation leads to a significant limitation in system modeling of bridge structures. It is not possible to capture partially deteriorated or damaged structural elements in this model. In addition, time dependent modeling of damage processes (e.g. corrosion of reinforcement) are not taken into consideration by the abovementioned approaches.

3 IMPACT TREE

3.1 *The system model approach*

The key idea of the new approach is to generate a system model which takes into account dependencies of structural components as well as interactions between damage mechanisms. It is important to avoid "black-box" systems in order to obtain a better understanding of deterioration processes and their interactions (Neumann &Haardt 2012). The developed system model is able to identify causes of damage and to determine the criticality of damage as well as their impact on individual bridge components and on the bridge itself.

The newly introduced impact tree model enables the analysis of condition and damage potential for both single structural components and complete systems. Implemented in software the impact tree can be used for condition assessment of structures in real time. Also it is possible to simulate certain deterioration processes by variation of input parameters to identify critical damage hot-spots at the planning stage of a bridge.

The impact tree is an improvement of the above mentioned fault tree. It uses a new rating system and more flexible connection elements than those used in the binary description of the fault tree (Reay & Andrews 2002).

The impact tree is composed of three hierarchical ordered levels: (1) the structure level, (2) the damage level and (3) the parameter level (Fig. 1).The elements can be grouped to modules to simplify the process of modeling an impact tree. All elements of each level can show their actual condition as output value. So the cause of a condition change of the whole bridge can be determined exactly.

3.2 *Structure level*

The structure level of the new modeling approach comprises all aspects of the bridge regarding the static system, relevant structural components and, at the lowest level, the building materials.

In the course of structure level preparation the bridge is fragmented into functionally smaller and smaller structural elements and ordered into a hierarchical way according to their role in the system of the bridge.These components are named structure elements of the system model. The bridge itself is represented by the top element of the impact tree.

As shown in the example below structure elements of particular interest, e.g. the bridge superstructure can be subdivided in several uniform elements. This will facilitate the allocation of condition changes in significant parts of the system model.

3.3 *Damage level*

The next level, which extends the structure level, is the damage level. Here, possible damage mechanisms which could occur on a structural component are allocated as damage elements to the corresponding (lowest) elements of the structure level. A damage element could be e.g. failure of reinforcement. The connection of a damage element to a structural element defines the exact allocation of the specific damage. This enables a functional system analysis. Using sophisticated building information modeling approaches the connection of damage elements to structure elements could be done by using a 3D model of the structure (Borrmann et al. 2012 & Lukas et al. 2012).

Damage elements which may have more than one cause will be hierarchically divided into sub-elements. As an example corrosion of reinforcement can be subdivided into elements regarding to the cause of corrosion: chloride respectively carbonation inducement. Damage elements are visualized by dash-dotted boxes within the impact tree model.

3.4 *Parameter level*

A further subdivision of the damage elements leads to the finest level of the impact tree: the parameter level. Parameters, which constitute an indication of beginning or further propagation of damage, will be allocated to the corresponding lowest element of the damage level. They can be a precondition or a cause of damage. Also parameters which indicate the propagation of damage are located in the parameter level.For reinforcement corrosion one precondition parameter is humidity. In contrast, the spalling of the concrete surface can already indicate onset or progression of reinforcement corrosion. All these parameters provide input values for the system analysis.

Wherever possible, all necessary parameters should be a part of a suitable monitoring concept that can feed the system model real time data to determine the condition of the bridge. Another approach to fill the system model with input data is to manually define the necessary or missing parameters. Although the parameters within the system model are linked to a damage element and thus bounded to a structure element, there is no need to locate them on the corresponding component of the bridge. For example the settlement of a pier can provide information about the condition of superstructure elements. Therefore, the measuring process actually takes place on the pier,

but the impact is considered at the superstructure element. Parameter elements are depicted as dotted boxes within the impact tree model.

3.5 *Connection elements*

A difficulty in creating an impact tree is the limited number of reliable described damage mechanisms. There are some damage mechanisms and correlations which have been investigated in detail (e.g. Sudret 2008), but the broad scope cannot be described by available realistic models.

For the newly introduced system model, interconnections between elements can be described by freely definable calculation rules. The main difference between the impact tree and the fault tree are these interconnections called logical connection elements (logic). In contrast to connections by Boolean operators of a fault tree,the logic element of the impact tree can describe different relationships between elements in a very flexible manner. These relationships are defined as a combination of equations and rules that describe the propagation of damage from one element to another.

There is the possibility to apply the following models and approaches:

- physicalmodels with deterministic approaches
- chemicalmodels with deterministic approaches
- probabilistic approaches
- empirical approaches
- etc.

As an example for a physical model, the description of fatigue behavior of reinforcing steel by a Wöhler curve can be mentioned. In this case parameter elements contain stress range and number of load cycles. This input values enable us to draw conclusions on the condition of the structure element (reinforcing steel) by the use of the hypothesis of damage accumulation according to (Palmgren 1924 & Miner 1945). The calculation rule is implemented in the connection element.

A probabilistic deterioration model for the description of reinforcement corrosion applied for life cycle management can be seen in (Gehlen 2000).

On basis of empirical values or statistical analysis decision-matrices can be set up without any detailed background knowledge about the damage process itself. In this type of matrix input parameters were correlated to each other in consideration of their consequences on the condition of the connected structure element. The defined relationships determine the output values of the logic elements - the grade of damage of a structure element.

When no calculation models or applicable descriptions of damage propagation are available, logic elements can be defined according to the currently used - inspection based - grade assignment methodology. Thus, a stepwise transition from the current approach to a full reliability based procedure can be realized in practice.

4 CONDITION EVALUATION BY THE IMPACT TREE

4.1 *Evaluation process*

The condition of individual elements can be represented on a rating scale. For example a ten-stage scale or a scale of warning colors similar to traffic lights (green: insignificant, yellow: warning, red: critical) can be implemented to elements of an impact tree. The condition, indicated by the scale, depends on stepwise predefined lower or upper limit values, e.g. maximum chloride content. The classification of the condition on a scale is independent of the calculation rule implemented in the logic element. Thus a consistent format can be used to show the condition of all elements.

The process using an impact tree for condition evaluation goes from bottom to top. The input values of parameter elements are checked and updated constantly during the evaluation. In the connected superordinate logic operation, these values are evaluated by predefined calculation rules. The easiest calculation rule is a comparison to limit values. If the values are below the limit, the rating scale shows an insignificant state (green light). Exceeding predetermined limit values leads to a warning or critical state based on the exaggeration of the limit by measuring values. The damage element will be activated if a signal of the subordinate parametric element shows a warning or critical value. The rating scale of the structure element gives notice of its condition which is calculated by the connected logical element. The condition evaluation process continues in loops until the parameter values change and an uncritical state is reached or until the top element in the structure level (which symbolizes the bridge itself) is reached.

4.2 *Sample application of the impact tree*

Using the example of a single span reinforced concrete bridge the application of the impact tree approach is explained in the following.

4.2.1 *Deterioration mechanisms*

As a representative deterioration mechanism corrosion of longitudinal reinforcement is chosen in this example. In the damage level of the impact tree (Fig. 1) are shown the subelements “chloride induced corrosion” and “carbonation induced corrosion” according to the cause of damage.

In this example an approach by (Novak et al. 2002) was selected to model the deterioration mechanisms. This approach is implemented in the connection elements “logic 6a” and “logic 6b” of the impact tree in form of a decision matrix. The incorporated input values are carbonation, concrete cover and chloride content (Tab. 1 & 2).

4.2.2 *Structure of the impact tree*

The top element of an impact tree is always the structure as a whole – in our example the bridge. In the next division the bridge is subdivided according to its

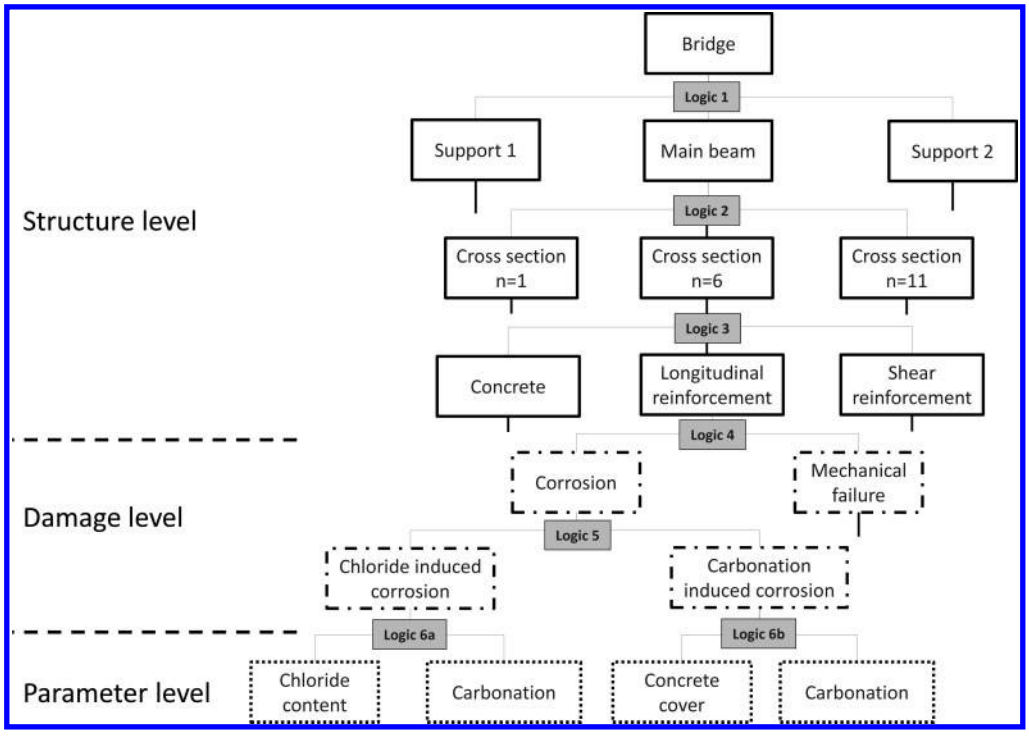

Figure 1. Example: condition evaluation by the impact tree.

Table 1. Corrosion rate due chloride induced corrosion (Novak et al. 2002)

Carbonation	Chloride content M%	Corrosion rate μm/a
yes	0,5	100
	2,0	150
no	0,5	10
	2,0	50

Table 2. Corrosion rate due carbonation induced corrosion (Novak et al. 2002)

Carbonation	Concrete cover d cm	Corrosion rate μm/a
yes	$d \leq 2$	60
	$2 < d \leq 4$	20
	$d > 4$	30
no	-	0

static system in the supports and the main beam. In this example the focus is on the main beam. Hence the beam is modeled as combination of several cross sections. At each of them the lowest partition of structure level is built of the used materials.

By the element "logic 4" structure and damage level are connected. In this case study corrosion processes of longitudinal reinforcement are discussed. The remaining branches of the impact tree are neglected. According to the used approach of the corrosion process, subordinated damage elements with their appropriate parameter elements are modeled.

The elements of the impact tree are linked by connection elements (logic 1-6) as shown in Figure 1. The resulting impact tree can be used for propagating the condition from the parameter level to the top element. In the following the main logical connection elements are specified. The logic elements 6a and 6b have two input parameters each. Based on the decision matrices of Table 1 & 2 the appropriate corrosion rate is defined as output value for further considerations. Also the logic calculates the criticality of the damage element. In the next step, in "logic 5", the interaction of both damage mechanisms is determined. In the current example the processes are assumed as accumulative. The remaining cross section of reinforcement is calculated in "logic 4" in consideration of the determined corrosion rate and a certain time period. In "logic 3" the statically required reinforcement is calculated and compared to the remaining cross section of reinforcement. Depending on this comparison the condition of the structure element (cross section *n*) is shown on the connected rating scale. Due to the fact that the system is statically determined, the condition of the cross section is identical to the condition of the main beam and the entire structure.

4.2.3 *Analysis by the impact tree*

The impact tree system model facilitates the analysis of deterioration processes and causes in the examined structure. There are different aspects on which we will focus further on.The first step of an impact tree analysis in the given example is to determine structural

hot-spots. For this parameter elements are kept constant at a certain default value, while the structural element under investigation (main beam) is subdivided in a certain number of cross sections. To get a continuous significant curve in the result diagram, we introduce a variable longitudinal coordinate x. The corrosion rate is independent of the longitudinal coordinate x, because the input values of all connection elements of parameter and damage level are equal. So the critical cross section depends only on the load applied on the main beam. Assuming a uniformly distributed load, the bending moment in the middle is at its maximum. A comparison of the required to the remaining reinforcement by the implemented calculation rule leads to the result that the middle part of the beam is identified as most critical. This method easily can be transferred to more complex structures.

The prediction of future condition states is another possible application of an impact tree. A precondition is here a time dependent definition of deterioration processes. In the example the corrosion process is time dependent due to the corrosion rate in micrometer per year. The variation of the input parameter time leads as a result to time-condition diagrams of all elements. By means of this result the critical moment of structure elements or the bridge as a whole can be determined.

The influence of different damage mechanisms or some measuring values can also be investigated by the impact tree. For this application parameter elements of interest can be varied. The consequences of parameter variation can be seen on the rating scale of the appropriate element. In the given example variation of chloride content with or without present carbonation is a suitable parameter to determine the influence of measuring values (parameter level) on the deterioration process.

The determination of the actual condition of the structure is one of the most important applications of the impact tree. In combination with an appropriate monitoring system condition assessment can be executed in real time. Measuring devices applied at identified hot-spot areas deliver the input values for the system analysis by the impact tree. But also further locations have to be taken into account by planning a monitoring concept. Due to the fact that each element of the impact tree, whether structure element, damage element or parameter element, is connected to a rating scale which is representing its condition, it is not only possible to determine the condition of the bridge itself; moreover causes of damage (parameter level) and the propagation of damage can be recognized.

5 CONCLUSION

In this paper is introduced a system model based approach for determining the condition of bridges, based on sensor measurements. The impact tree model consists of three different levels (structure level, damage level and parameter level). The modeling approach considers correlations between the deterioration mechanisms and the measurement values indicating the progress of the deterioration and also the impact of the condition of individual bridge components on the condition of the overall bridge system.

There are different possible applications of the impact tree. It can be used to simulate deterioration mechanisms by variation of parameter elements as input values during the planning phase of a bridge to detect critical damage mechanisms or structural components – so called hot-spots. Also it is possible to determine the actual condition of a bridge, based on sensor measurements in real time. On the basis of this information the impact tree model can be used as well to propagate future condition states by varying significant input values. For all applications, condition assignments are propagated from the leaf nodes (the sensor measurements) to the top node (the entire bridge).The most important function in this propagation mechanism is provided by the logical connection elements which are introduced between the different layers of the impact tree and model rules for state propagation. These logic elements are able, in contrast to Boolean interconnections of the fault tree, to describe different and flexible relationships between elements using a combination of equations and rules that describe the propagation of damage from one element to another. Thus, the impact tree can represent the next generation of modeling approaches for bridge maintenance problems.

New investigations of damage mechanisms can be implemented easily in the logic connection elements of an impact tree.Future work will concentrate on developing logical connection elements for a broad range of deterioration mechanisms and different approaches to condition assessment (deterministic/probabilistic).

The opportunities of blind source separation techniques in the automation of modal identification for vibration based SHM

C. Rainieri & G. Fabbrocino
Structural and Geotechnical Dynamics Laboratory StreGa, DiBT Dept., University of Molise, Termoli, Italy

ABSTRACT: Accurate and effective methods for estimation of modal properties of civil structures in operational conditions play a relevant role in a number of applications ranging from validation of numerical models to Structural Health Monitoring (SHM). Several Operational Modal Analysis (OMA) methods are available and several successful applications are reported in the literature. Beside the classical time domain and frequency domain techniques, the use of Blind Source Separation techniques for output-only modal analysis is rapidly spreading. In the present paper their theoretical background is reviewed and attention is focused on the Second Order Blind Identification (SOBI) and the effect of analysis parameters on response time and accuracy of modal identification results. These aspects are of interest in view of the automation of the method and its integration within vibration-based SHM systems. The herein discussed results have suggested criteria for setting of the analysis parameters able to reduce the computational efforts and provide accurate estimates. The latter topic is of interest also when single modal identification tests are carried out. The proposed rule of thumbs has also been validated against some experimental case studies. They are representative of the different levels of complexity usually encountered during real modal tests. Comparisons with modal estimates provided by well-established OMA techniques have confirmed the potentialities of SOBI in this field.

1 INTRODUCTION

Several algorithms for automated identification (Rainieri & Fabbrocino 2010) and tracking (Rainieri et al. 2011) of modal parameters based on Operational Modal Analysis (OMA) methods have been developed in recent years. As a consequence, modal based damage detection techniques (Doebling et al. 1996) are again gaining in popularity, even if they suffer limitations in terms of damage localization and, above all, quantification, as well as drawbacks related to sensitivity to measurement quality and environmental and operational factors. Nevertheless, continuous monitoring of modal parameters has a large potential in performance and health assessment of civil engineering structures (Rainieri et al. 2010). Applications range from prompt detection of damage and degradation phenomena to post-earthquake health assessment and emergency management.

In this framework, the encouraging results obtained from the application of Blind Source Separation (BSS) techniques (Ans et al. 1985), and in particular Second Order Blind Identification (SOBI) (Belouchrani et al. 1997), as innovative tools for OMA has led to an increasing attention on their modal identification performance and on the opportunities of automation provided by these new data processing techniques.

In the present paper, after a review of the basics of BSS and, in particular, SOBI, attention is focused on this last method and on the results of some sensitivity analyses aimed at the assessment of the effect of analysis parameters on computational time and accuracy of modal identification estimates. The results of sensitivity analyses will lead to the formulation of basic guidelines for application of SOBI to output-only modal identification. In particular, a rule of thumbs for the setting of the analysis parameters aimed at an accurate estimation of the modal parameters and a control of the computational efforts is suggested. It allows for an automatic setting of the analysis parameters and, as a consequence, it points the way towards the automation of the modal identification process, for instance in combination with the strategy proposed in Poncelet et al. (2008). On the other hand, the separation of the modal contributions makes the analysis easier and can support the development of hybrid strategies for the automation of OMA (Rainieri & Fabbrocino 2013, Rainieri & Fabbrocino 2011).

The proposed criterion for parameter setting is herein applied to a number of experimental case studies. They are selected in order to provide examples of the different levels of complexity, which can be encountered during real modal tests. The comparison with the modal parameter estimates provided by well-established OMA procedures will lead to the identification of potentialities and limitations of SOBI in the field of dynamic identification on a rational basis.

2 BSS FOR MODAL IDENTIFICATION

BSS techniques allow for the extraction of a set of signals, the sources, from observations of their mixtures (Ans et al. 1985). In the last decade an increasing number of applications to structural dynamics have appeared in the literature. However, their use in this field is still a challenge (Antoni 2005). Nevertheless, different BSS algorithms have shown a potential in the field of output-only modal analysis, and a physical interpretation and prove of their applicability are given in (Kerschen et al. 2007).

In the context of modal identification, BSS techniques can be referred to as time domain methods. Moreover, since no model is fitted to data, they can be classified as non-parametric. The absence of stabilization charts to be interpreted or model parameters to be set makes BSS techniques an interesting alternative to classical time domain modal identification methods, such as Stochastic Subspace Identification (SSI) (Van Overschee & De Moor 1996). Thus, a performance assessment of BSS techniques for OMA of civil structures is of interest. However, some limits in the use of BSS for modal identification can be traced back to the basic assumptions of the different techniques. In fact, they may have different degree of compatibility with the dynamic systems of interest.

BSS techniques can be classified as linear (Belouchrani et al. 1997) or non-linear (Storck & Deco 1997), depending on the type of combination of the sources. Moreover, linear simultaneous (static) mixing (Belouchrani et al. 1997) and convolutive mixing (Thi & Jutten 1995) can be considered. The dynamic response of a system is given by the convolution product of the impulse response function and the external forcing vector but the problem of a convolutive mixture of sources is not completely solved yet. However, the response of a dynamic system can be also interpreted as a static mixture of sources (Kerschen et al. 2007). Assuming linear and static mixtures, the noisy model can be expressed in matrix form (Poncelet et al. 2007):

$$\{x(t)\} = [A]\{s(t)\} + \{\sigma(t)\} \tag{1}$$

where {x(t)} represents the recorded data, {s(t)} are the source signals, {σ(t)} is the noise corrupting the data and [A] is referred to as the mixing matrix. BSS has the goal of recovering the sources {s(t)} from their observed mixtures {x(t)}, based on a poor knowledge of the mixing matrix [A] and general assumptions about the sources. Applicability of BSS to vibration data is demonstrated by the comparison of Eq. (1) with the relation between physical response {x(t)} and modal response {q(t)} via the modal matrix [Φ]:

$$\{x(t)\} = [\Phi]\{q(t)\} \tag{2}$$

Thus, under given assumptions, the modal coordinates may act as virtual sources (Poncelet et al. 2007). No mathematical model is assumed to describe the process that produced the measured data. The mixing model is the only assumption, confirming that BSS techniques can be referred to as non-parametric procedures for modal identification.

In the case of static mixing, two approaches can be identified: the first is based on higher-order statistics, if sources are statistically independent and no more than one source is Gaussian (Comon 1994); the second relies upon second-order statistics, if sources are uncorrelated (Belouchrani et al. 1997). In both cases separation is affected by some indeterminacies related to the order of the sources (any permutation of the sources is also a solution of the blind identification problem) and their amplitude.

The first application of BSS to modal identification (Feeny & Kappagantu 1998) was based on Principal Component Analysis (PCA). However, the required knowledge of the mass matrix limited its applicability (Kerschen et al. 2007). Independent Component Analysis (ICA), instead, seems to be more promising in this field. The main assumptions in ICA are the mutual independence and non-Gaussianity of the sources. Under this assumptions, source separation is obtained by maximizing the non-Gaussianity of the sources through the solution of an optimization problem based on a given cost function. The main drawbacks of ICA are related to the use of high-order statistics, whose computation is computational demanding and difficult in the presence of a scarcity of data, and to some limitations strictly related to modal identification. In fact, ICA works well only in the case of weakly damped systems, characterized by damping ratios lower than 1% (Kerschen et al. 2007). These reasons make ICA unattractive for modal identification purposes.

Methods based on second-order statistics of the observed signals assume that sources are uncorrelated for all delays and have different spectra. Among these, the Algorithm for Multiple Unknown Signal Extraction (AMUSE) (Tong et al. 1991) and SOBI are based on a similar theoretical background. In fact, they exploit the information contained in covariance matrices. However, while SOBI jointly diagonalizes several time-shifted covariance matrices, AMUSE relies upon eigenvalue decomposition of the covariance matrix evaluated at one time lag. Thus, SOBI overcomes the shortcoming of AMUSE related to an eventual inappropriate choice of the time lag. This can result in two similar eigenvalues and makes unfeasible the identification of the sources. It has been shown that SOBI is also much more robust to noise than AMUSE (Zhou & Chelidze 2007). When SOBI is applied to vibration data, the real valued mixing matrix implies real valued mode shape estimates. This can be a drawback of the method in the presence of complex modes. An evolution of SOBI able to deal with complex modes is the Blind Modal Identification (BMID) algorithm (McNeill & Zimmerman 2008).

Taking into account the superior potential of SOBI for dynamic identification with respect to other BSS

techniques (PCA, ICA, AMUSE...) and that civil structures often show real modes, attention is herein focused on SOBI and its performance for output-only modal analysis of civil structures. In the context of output-only modal identification, SOBI can be classified as a non-parametric, low order time domain method. As a consequence, a number of sensors larger than or equal to the number of active modes is required for their identification. This is a common limitation of BSS techniques when applied to OMA. Moreover, unlike other two-step modal identification methods, SOBI provides mode shape estimates at the first step, while natural frequencies and damping ratios are recovered in a second step through post-processing of the obtained sources.

From a practical viewpoint, SOBI is based on a pre-processing step aiming at centering and whitening of data, and on the Joint Approximate Diagonalization (JAD) (Belouchrani et al. 1997, Cardoso & Souloumiac 1996) of a number of time-shifted covariance matrices. Once the measured data are centralized by removal of the mean value, whitening is obtained by the eigenvalue decomposition of the covariance matrix at $\tau = 0$:

$$[R_x(0)] = [E][D][E]^T \tag{3}$$

where [E] is the orthogonal matrix of eigenvectors and [D] is the diagonal matrix of eigenvalues; the whitened data vector is obtained as follows:

$$\{z(t)\} = [D]^{-1/2}[E]^T\{x(t)\} = [W]\{x(t)\} \tag{4}$$

The mixing matrix [A], providing the mode shape estimates for the structure under test (as pointed out by the comparison between Equation 1 and Equation 2), is obtained by JAD of p time-shifted covariance matrices. It looks for a matrix [Ψ] that approximately diagonalizes the time-shifted covariance matrices through the solution of an optimization problem. The matrix [Ψ] is iteratively identified by minimizing the sum of all off-diagonal terms of $[\Psi]^T[R_z(\tau_i)][\Psi]$, i=1,…,p, for the p time-shifted covariance matrices:

$$\min_{[\psi]} \sum_{i=1}^{p} off\left([\psi]^T[R_z(\tau_i)][\psi]\right) \tag{5}$$

A numerical algorithm based on Jacobi rotation technique (Cardoso & Souloumiac 1996) is adopted to this aim. Under the assumption that [Ψ] is orthogonal, the JAD of the p time-shifted covariance matrices allows for the identification of the de-mixing matrix [U] and the mixing matrix [A]:

$$[U] = [\Psi]^T[W] \tag{6}$$

$$[A] = [W]^{-1}[\Psi] \tag{7}$$

The natural frequency and damping ratio of the modes are finally extracted from the resulting sources after demixing. This can be done according to different procedures (single-degree-of-freedom curve fit, spectral analysis, and so on). In this study the natural frequency of the i-th mode is estimated by a linear regression on the zero crossing times of the associated source, while damping ratio is calculated through the logarithmic decrement technique, in agreement with another well-established OMA technique, the Enhanced Frequency Domain Decomposition (EFDD) (Gade et al. 2005).

Table 1. Modal properties of the simulated 6-DOF system.

Mode #	Natural frequency [Hz]	Damping ratio [%]
I	1.509	1.00
II	2.823	0.80
III	3.810	0.81
IV	4.737	0.87
V	5.593	0.95
VI	6.167	1.00

3 JAD PARAMETERS AND MODE ESTIMATES

In this section the results of some sensitivity analyses are summarized. They are aimed at the assessment of the effect of the parameters governing the JAD on response time and accuracy of modal estimates provided by SOBI. A rule of thumbs is proposed for the automation of SOBI when it is applied for OMA and vibration based SHM of civil structures. It is also applied to a number of experimental case studies related to civil structures and characterized by increasing degree of complexity. Comparisons with the modal estimates provided by well-established OMA methods are reported to further validate the rule.

The problem of the definition of mechanisms for noise rejection and, therefore, for the prior identification of the expected number of sources associated to structural modes is out of the scope of the present paper. Here a number of sources equal to the number of measurement channels are extracted, in agreement with similar OMA applications reported in the literature (Poncelet et al. 2007). Noise sources are eliminated in the second step of analysis aimed at the estimation of natural frequencies and damping ratios from the sources. The effect of the parameters governing the JAD (the number p of time-shifted covariance matrices to be jointly diagonalized, and the threshold t used to stop JAD) on accuracy of modal estimates and response time has been quantified by sensitivity analyses. The benchmark is represented by a simulated 6-DOF system (whose modal properties are reported in Table 1) subjected to a Gaussian white noise. Rayleigh damping is adopted.

The response of the system has been simulated at all the six DOFs and it has been sampled at 20 Hz. White noise has also been added to the time series in order to simulate measurement noise. A signal-to-noise ratio of 5 dB has been considered. The adopted

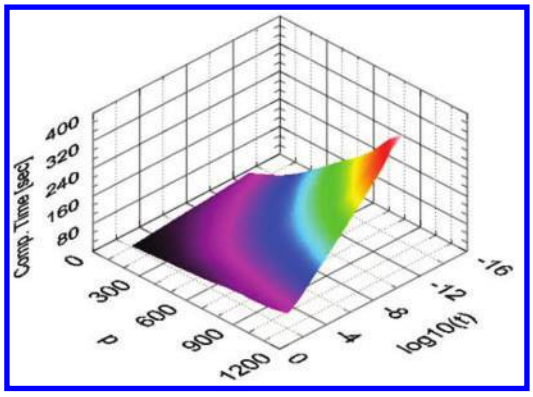

Figure 1. Sensitivity of response time to t and p (sample plot).

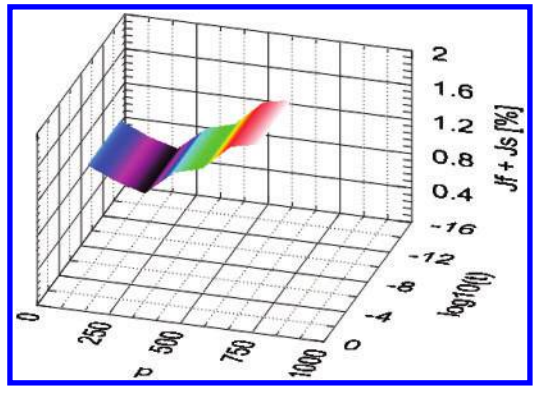

Figure 2. Sensitivity of overall accuracy to t and p.

sampling frequency leads to the extraction of four modal responses and two noise sources.

About parameter settings, a careful literature review has provided a suggested value for t. In particular, Cardoso & Souloumiac (1996) stated that very small values for t have no sense because the diagonality criterion is approximate itself. Thus, it is usually unnecessary to push the accuracy of the rotation matrix to the machine precision, but a value equal to its square root is suggested. However, this value has been determined according to a theoretical framework and not in view of OMA. Even if the response time might not be a problem for single modal identification tests, its control can be of interest for continuous, automated monitoring. The response time can range from fractions of seconds to several minutes or hours depending on the settings of t and p and the number of measurement channels. Figure 1 shows the dependence of the response time from p and t for a real dataset consisting of 12 measurement channels. As expected, it increases when p becomes larger and t decreases. Moreover, the larger the number of measurement channels, the higher the response time. Thus, the assessment of the influence of t and p on the modal parameter estimates can provide effective hints to ensure their accuracy or reduce the response time with little or no accuracy losses. To this aim, the simulated dataset has been processed by SOBI, the four modes in the range 0-10 Hz have been identified and compared with the theoretical values for different settings of t and p. The overall accuracy of the modal identification results in terms of natural frequencies and mode shapes has been quantified by the cumulative frequency scatter J_f and the cumulative discrepancy between corresponding mode shapes J_s:

$$J_f = \sum_{i=1}^{N_m} \left| \frac{f_i^{SOBI} - f_i^{ref}}{f_i^{ref}} \right| \cdot 100 \qquad (8)$$

$$J_s = \sum_{i=1}^{N_m} \left[1 - MAC\left(\{\psi_i^{SOBI}\}, \{\psi_i^{ref}\} \right) \right] \cdot 100 \qquad (9)$$

and their combination. N_m is the number of identified modes, while the MAC (Allemang & Brown 1982) between theoretical and estimated mode shapes is given by:

$$MAC\left(\{\phi_i^{SOBI}\}, \{\phi_i^{ref}\} \right) = \frac{\left| \{\phi_i^{SOBI}\}^T \{\phi_i^{ref}\} \right|^2}{\left(\{\phi_i^{SOBI}\}^T \{\phi_i^{SOBI}\} \right)\left(\{\phi_i^{ref}\}^T \{\phi_i^{ref}\} \right)} \qquad (10)$$

The plot of J_f+J_s vs. p and t for the simulated dataset is shown in Figure 2. It is possible to recognize that accuracy is mainly influenced by p, while a weak variation with t can be observed. Moreover, for t not larger than 1E-8, results do not change anymore. This limit value for t is expected to be data dependent. However, similar sensitivity analyses carried out on real datasets have provided the same results. Even if it is impossible to extrapolate a general rule, the obtained results seem to confirm that this value can be assumed as reference to obtain very stable results. Moreover, the little effect of t on the accuracy of estimates allows to set a threshold larger than 1E-8 in order to reduce the response time. In particular, it can be increased up to 1E-4 with negligible effects on the estimates but relevant reduction of response time, in particular when the number of measurement channels is larger. Above that value the approximations start inducing major effects on the estimates.

About the effect of p on accuracy, the analysis of the individual contributions J_f and J_s has pointed out that the trend in J_f+J_s depends on the trend of J_f vs. p, since J_s monotonically and slowly decreases with increasing values of p (even if for the single mode the 1-MAC vs. p plot can be not monotonic). This is consistent with the higher robustness of SOBI to noise with respect, for instance, to AMUSE, as a consequence of the joint diagonalization of several time-shifted covariance matrices. On the other hand, the trend of J_f can be probably addressed to the larger effect of disturbance beyond a certain decay level. As a final result, an optimal setting for p able to maximize the overall accuracy of modal estimates can be obtained from the minimum of the J_f+J_s function. Repeating the sensitivity analysis

Table 2. Test cases, modal identification results and comparisons.

Case study	Characteristics	Channels	(f_s [H_z], p)	Mode #	f_{SOBI} [H_z]	f_{ref} [H_z]	MAC
6-DOF system	Simulated data	6	(10, 400)	I	1.51	1.51	0.998
				II	2.82	2.82	0.999
				III	3.81	3.81	0.999
				IV	4.73	4.74	0.998
Tower of the Nations (Naples)	Well separated modes	8	(5, 360)	I	1.81	1.81	=1
				II	1.38	1.38	=1
				III	1.66	1.66	=1
Carmine's Bell Tower (Naples)	Close modes, noisy data	12	(5, 300)	I	0.70	0.70	=1
				II	0.76	0.76	=1
School of Engi-neering (Naples)	Close and coupled modes	12	(10, 400)	I	0.92	0.92	=1
				II	0.99	0.99	0.999
				III	1.30	1.30	=1

for different values of the sampling frequency, in order to change the number of modes in the frequency range of interest, the trend of the J_f+J_s function is kept, but the value of p corresponding to its minimum changes, as expected. However, when the sampling frequency changes by a factor of x with respect to that of the original dataset, the optimal setting for p changes by the same factor. Focusing the attention on the fundamental mode, which is obviously present in all the analyses, and on the decay level associated to this value of p, this was found to be the same for different values of the sampling frequency. Thus, the time to observe a certain amplitude decay more than the number of samples plays a major role in determining the accuracy of estimates. This is consistent with the change of the optimal setting of p with the adopted sampling frequency and with the increasing effect of noise when p is set much too large. The analysis of the decay level associated to the optimal setting for p seems to suggest the following rule for its evaluation. Taking into account the results of sensitivity analyses and that all the sources always start from a value of the amplitude equal to 1, the optimal setting of p has been associated to a ratio between the maximum amplitude of the i-th cycle and that of the first cycle (occurring at t>0) in the order of 10% for the fundamental mode (Fig. 3). As a consequence, the optimal value of p can be determined in a couple of iterations starting from a trial value and changing it in a way able to fulfil the suggested rule.

The rule has been validated against four real datasets. Reference modal parameters have been extracted according to well-established techniques, such as FDD (Brincker et al. 2000) and SSI, which provided very consistent estimates in terms of both natural frequencies and mode shapes. Even if SOBI and its variants have already been applied to the modal identification of real civil structures (Hazra 2010), to the best of the authors' knowledge this study represents its first systematic application to modal identification problems typically encountered in civil engineering and characterized by different degree of difficulty. Relevant information and details for each case study are reported in Table 2.

More details can be found elsewhere (Rainieri & Fabbrocino 2010). Taking into account how the value

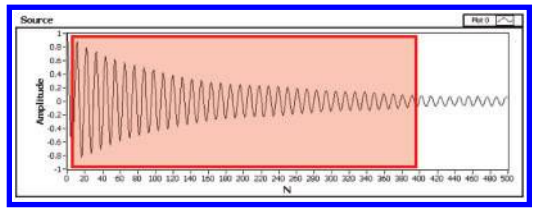

Figure 3. Illustration of the rule of thumbs to set p.

of t influences the accuracy, a value of 1E-8 has been adopted in the analysis of the real measurements. For each dataset, the optimal value of p has been determined according to the above mentioned rule of thumbs. The obtained modal identification results are reported in Table 2 in comparison with reference estimates provided by other, well-established OMA methods. A very good agreement can be observed, confirming that SOBI can be effectively applied for output-only modal identification of civil structures.

In order to validate the proposed rule for the setting of p, the real datasets have been analyzed also for different values of p. The function J_f+J_s vs. p has been evaluated around the estimated optimal value of p and considering as reference values of the natural frequencies and mode shapes those provided by the SSI (however, the same results are obtained considering the modal estimates provided by FDD as references, since they are very consistent with the corresponding estimates by SSI). Its plot (Fig. 4) shows that the proposed rule has been able to properly evaluate the optimal setting of p even in the case of real datasets.

4 CONCLUSIONS

In the present paper OMA by BSS has been reviewed, focusing the attention on SOBI. The moderate complexity and computational demand of the algorithm and the separation of modal contributions make it suitable for automation and integration into SHM systems. In this perspective the influence of JAD parameters on accuracy of modal estimates and response time

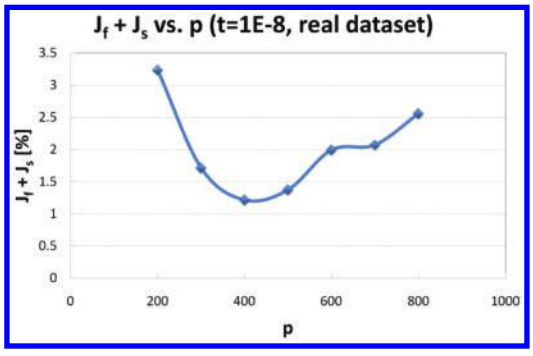

Figure 4. Validation of the proposed rule for setting of p.

has been analyzed. Rules of thumbs for their setting have been identified and validated. The good agreement of SOBI estimates with those of well-established OMA techniques, such as FDD and SSI, confirms the effectiveness of SOBI for OMA of civil structures. However, the typical limit of low order methods in the presence of a reduced number of sensors has to be taken into account.

Transducers frequency influence on ultrasonic velocity measurements in concrete specimens

G. Concu, B. De Nicolo, N. Trulli & M. Valdés
Department of Civil Engineering, Environmental and Architecture, University of Cagliari, Italy

ABSTRACT: Ultrasonic testing is a non invasive surveying technique suggested for concrete quality control. European standards concerning the determination of ultrasonic velocity in concrete take into account measurements stability, repeatability and reproducibility, and address the main factors influencing velocity measurements, but no exhaustive suggestion is given about the frequency characteristics of the transducers to be used in the test. Commercial measurements systems offer several types of transducers with different frequency characteristics, the choice of which is left with the operator, who has to decide without clear standards or guidelines. This work reports the preliminary results of an experimental campaign aimed at establishing the influence of transducers natural frequency on ultrasonic velocity measurements in concrete. Several concrete specimens have been made and tested by using transducers with different natural frequency. The correlation between transducers frequency and ultrasonic velocity has been exploited and discussed, also with relation to curing stage and concrete compressive strength.

1 INTRODUCTION

Non-destructive techniques based on ultrasonic wave propagation are generally used in structural diagnosis and also suggested for concrete quality control. They are applied directly in the field for investigations of a wide range of structures and infrastructures, and in laboratory for materials characterization.

Traditional application of UT is based on measurements of the velocity V of acoustic waves propagating through the material. UT is preferentially carried out applying the Direct Transmission Technique, in which the wave is transmitted by an emitter transducer through the test object and received by a receiver transducer on the opposite side. This allows to measure the time T the wave needs to travel through the object's thickness, from the emitter to the receiver, along a path of length L; the average velocity of the wave is then obtained from the ratio L/T. The wave velocity is directly related to structures elastic parameters, e.g. dynamic modulus of elasticity, Poisson's ratio and density, so that its analysis provides information on physical and mechanical properties of the material, crucial for materials quality control and on site structural performance assessment (Camplani, 2008; Cannas, 2008; Concu, 2006; De Nicolo, 2005).

Standards concerning the determination of ultrasonic velocity in concrete, e.g. European EN 12504-4, take into account the problems of measurements stability, repeatability and reproducibility, and address the main factors influencing velocity measurements. Nevertheless, no exhaustive suggestion is given about the natural frequency of the transducers to be used in the test. The only given information is that transducers natural frequency should normally be within the range 20 kHz to 150 kHz, and that it is preferable to use high frequency transducers (60 kHz to 200 kHz) for short path lengths (down to 50mm) and low frequency transducers (10 kHz to 40 kHz) for long path lengths (up to a maximum of 15m). However, commercial measurements systems often offer several types of transducers with different frequency characteristics, the choice of which is left with the operator, who have to decide without clear standards or guidelines. This paper reports the preliminary results of an experimental campaign aimed at establishing the influence of transducers frequency characteristics on ultrasonic velocity measurements in concrete.

Several concrete cubic specimens have been prepared and tested by using transducers with different natural frequency. Correlations between transducers frequency and ultrasonic velocity have been analyzed also taking into account both curing stage and concrete compressive strength.

2 EXPERIMENTAL CAMPAIGN

The experimental campaign has been carried out on 27 cubic specimens 150mm sized, casted by using a C 40/50 strength class concrete (NTC, 2008).

Ultrasonic measurements have been performed using the ultrasonic test equipment Pundit Lab+, developed by Proceq. This testing equipment includes:

- four pairs of standard transducers with natural frequency respectively of 24 kHz, 54 kHz, 150 kHz and 250 kHz for emitting and receiving signals;

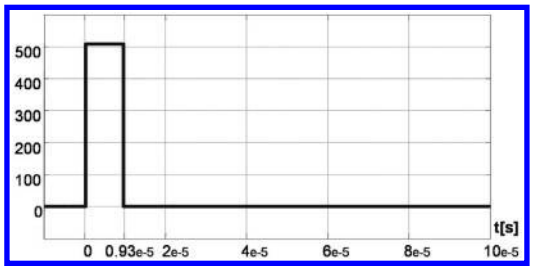

Figure 1. The energizing signal. Amplitude is measured in Volts.

– a unit for signals generation, acquisition and preliminary analysis;
– a PC for data storage and further signal processing;
– a dedicated software Pundit Link which unlocks the full capabilities of the ultrasonic test system.

The energizing signal is a square wave with high input voltage of 500 V (Fig. 1), which allowed signals to be detected even if strongly attenuated.

UT has been carried out on specimens during the curing stage at 7, 14 and 28 days. For each specimen, three measures of velocity have been performed for each couple of opposite sides. The velocity value associate with a specimen is the average of all the value measured on that specimen.

After 28 days of curing compressive tests have been carried out according to UNI EN 12390-3.

3 RESULTS

Table 1 shows a summary of velocity values measured at the selected different curing times by using 24 kHz, 54 kHz, 150 kHz and 250 kHz natural frequency transducers. Figures 2-5 show how ultrasonic velocity varies with curing time and with transducers natural frequency.

From Table 1 and figures 2–5 it can be inferred that ultrasonic velocity increases with curing time independently on the resonant frequency of the applied transducers. The increase is of about 150 m/s after 28 days of curing. Average and standard deviation values are quite similar for the various resonant frequencies.

Table 2 reports specimens compressive strength and density determined at 28 days of curing.

3.1 *Regression analysis*

A regression analysis has been performed in order to evaluate the reliability of ultrasonic velocity measured at 28 days of curing with the different resonant frequency transducers in predicting compressive strength. Figures 6-9 show the correlation between velocity and compressive strength for the different natural frequencies. Table 3 reports regressions parameters.

Table 1. Ultrasonic signal velocity.

Transducer	V*[m/s]	SD*[m/s]	COV* [%]
7 DAYS OF CURING			
24 kHz	4472	26.48	0.59
54 kHz	4499	29.38	0.65
150 kHz	4464	31.38	0.70
250 kHz	4474	35.74	0.80
14 DAYS OF CURING			
24 kHz	4578	73.91	1.61
54 kHz	4546	42.00	0.92
150 kHz	4544	37.59	0.83
250 kHz	4532	36.08	0.80
28 DAYS OF CURING			
24 kHz	4618	29.93	0.65
54 kHz	4638	31.37	0.68
150 kHz	4636	29.42	0.63
250 kHz	4650	28.89	0.62

*V = Average of all samples, SD = Standard deviation, COV = coefficient of variation.

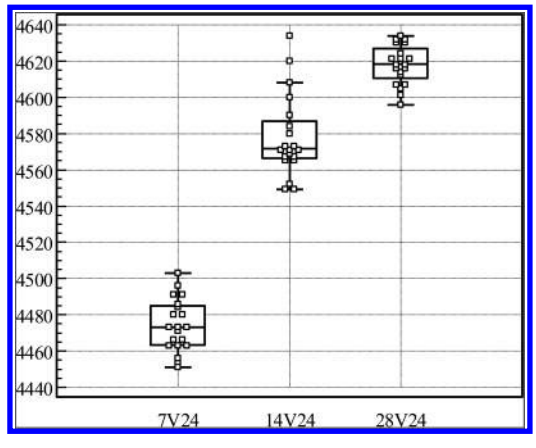

Figure 2. Average velocity V at 7, 14 and 28 days of curing. Measures performed with 24 kHz natural frequency transducers.

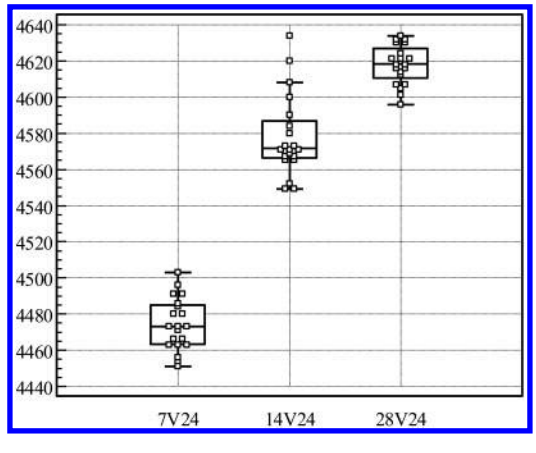

Figure 3. Average velocity V at 7, 14 and 28 days of curing. Measures performed with 54 kHz natural frequency transducers.

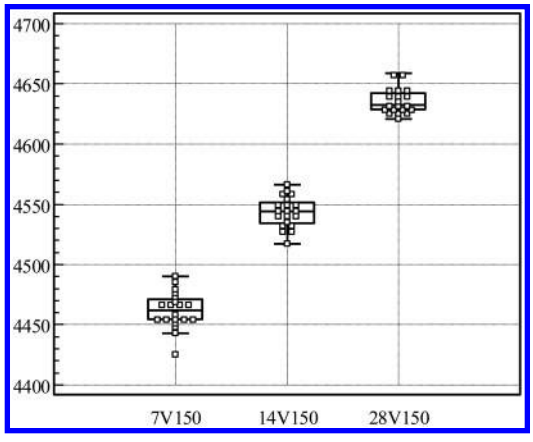

Figure 4. Average velocity V at 7, 14 and 28 days of curing. Measures performed with 150 kHz natural frequency transducers.

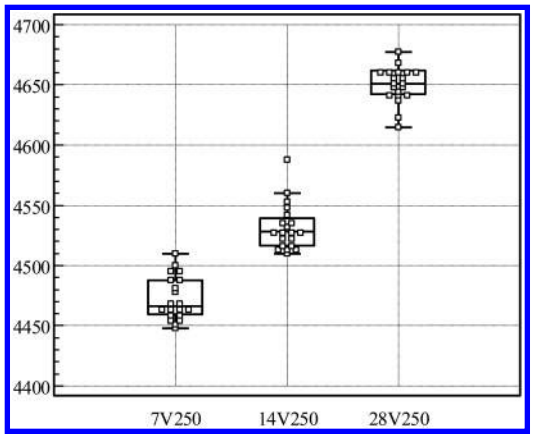

Figure 5. Average velocity V at 7, 14 and 28 days of curing. Measures performed with 250 kHz natural frequency transducers.

Table 2. Specimens compressive strength and density.

28 days of curing	
Compressive Strength	
Average [N/mm^2]	56.23
SD* [N/mm^2]	1.84
COV* [%]	3.27
Density	
Average [kg/mm^3]	2323
SD* [kg/mm^3]	10.89
COV* [%]	0.47

*SD = Standard deviation, COV = Coefficient of variation.

Correlations between average velocity and compressive strength are represented by quadratic polynomial curves with a coefficient of determination R^2 ranging from 0.4453 to 0.9010. The best correlation is provided by ultrasonic tests in which the 250 kHz resonant frequency transducers have been used.

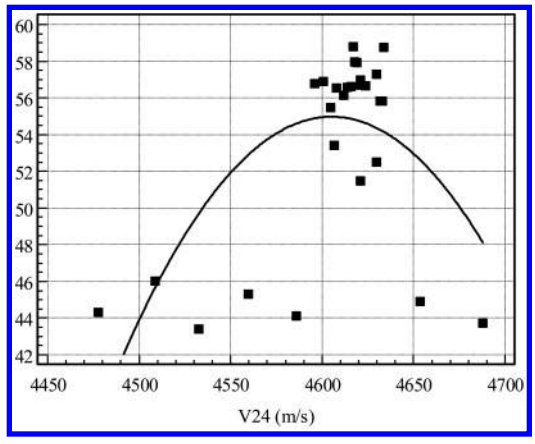

Figure 6. Correlation between 28 days average velocity and compressive strength. Measures performed with 24 kHz natural frequency transducers.

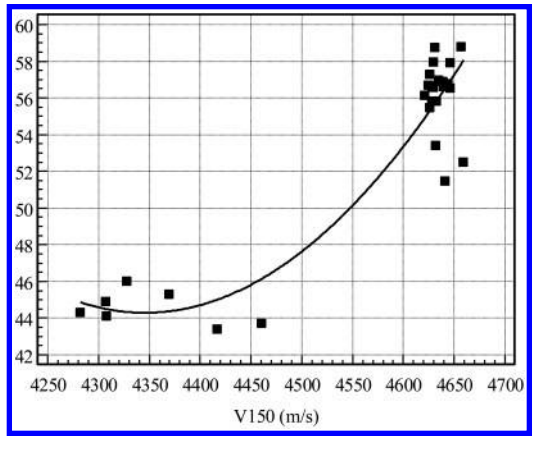

Figure 8. Correlation between 28 days average velocity and compressive strength. Measures performed with 150 kHz natural frequency transducers.

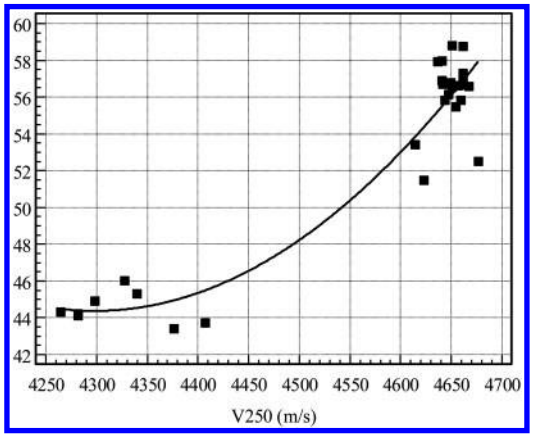

Figure 9. Correlation between 28 days average velocity and compressive strength. Measures performed with 250 kHz natural frequency transducers.

Table 3. Regressions parameters.

Freq.	Equation	R^2
24 kHz	$y = -21192{,}6353 + 9{,}2282x - 0{,}0010 \times^2$	0,4453
54 kHz	$y = 5317{,}6823 - 2{,}3864x + 0{,}0003 \times^2$	0,7237
150 kHz	$y = 2688{,}6725 - 1{,}2171x + 0{,}0001 \times^2$	0,8685
250 kHz	$y = 1800{,}5781 - 0{,}8172x + 0{,}0001 \times^2$	0,9010

4 CONCLUSION

An experimental campaign has been started with the aim of establishing the influence of transducers natural frequency on ultrasonic velocity measurements in concrete.

Several concrete specimens have been prepared and tested by using couple of transducers with resonant frequency of 24 kHz, 54 kHz, 150 kHz and 250 kHz respectively.

The correlation between transducers natural frequency and ultrasonic velocity has been exploited and discussed, also with relation to curing stage and concrete compressive strength.

Results achieved since now highlighted that ultrasonic velocity increases with curing time independently on the resonant frequency of the applied transducers. This increase is of about 150 m/s after 28 days of curing. Average velocity and standard deviation values are quite similar for measurements performed by using the different resonant frequencies.

A simple statistical elaboration of the acquired data pointed out the reliability of ultrasonic velocity measured at 28 days of curing in predicting compressive strength. With the exception of the 24 kHz transducers, in the other cases (54 kHz, 150 kHz and 250 kHz transducers) the coefficient of determination R^2 for the regression equation correlating ultrasonic velocity and compressive strength is significantly high, the best correlation being provided by the 250 kHz resonant frequency transducers. This outcome is not in unison with the European standard UNI EN 12504-4, which states that it is preferable to use high frequency transducers (60 kHz to 200 kHz) for short path lengths (down to 50 mm) because high frequency pulses become attenuated more rapidly than pulses of lower frequency.

Application of SHM system based on modal filtration to the truss structure

K. Mendrok, T. Uhl & W. Maj
AGH University of Science and Technology, Department of Robotics and Mechatronics, Krakow, Poland

ABSTRACT: The paper presents the application of damage detection technique based on modal filtration to the monitoring of the truss structure model. Test object was a scaled down version of typical element of a roof structure. It was mounted in the specially built hydraulic test stand. During the tests the structure was loaded with increasing force until the damage occurred. In the paper the method and developed SHM system are briefly presented together with the results of the tests for civil engineering-like structure.

1 INTRODUCTION

1.1 *Vibration based damage detection*

One of the groups of damage detection algorithms used in nondestructive testing and structural health monitoring is the group of the so-called vibration methods, i.e. methods that use data in the form of accelerations of vibrations in time or frequency domains. They are based on the observation of changes in the system's vibration responses, which result from damage occurrence. The methods' main idea is model-based diagnostics defined in the following way: the model of a particular system in an undamaged state is given, and this model is compared to the model identified from the data measured on the object in the current state. Differences between these two models indicate the object modification (e.g. stiffness or mass decrease), which may be caused by damage. A detailed description of some of the methods mentioned above, together with its verification can be found in Mendrok & Uhl (2004), Doebling et al. (1998) and Carden & Fanning (2004). The most convenient model, which can be applied in the described approach, is a modal model. It is relatively easy to identify and, by means of operational modal analysis, may be identified only from response data; it is, therefore, very useful in diagnostics. Apart from its advantages, application of modal model-based diagnostics within damage detection has several limitations and faults. First of all, there is a serious problem distinguishing between the changes in parameters resulting from damage and those caused by environmental changes e.g. temperature or humidity. That is especially visible in civil engineering structures monitoring. A further limitation of modal model-based diagnostics involves difficulties with the automation of procedures. Despite the current development of autonomous modal analysis procedures in many scientific centers, the total independence of an engineer's interference is still problematic in practice. Additionally, diagnostic symptoms in the form of natural frequencies, modal damping coefficients and modal vectors are estimated periodically, and depend on the subjective assessment of a testing team. Also the computational cost required by the modal parameters estimation algorithms is rather high, and makes problematic its implementation on the embedded diagnostic systems.

There is however a method which uses vibration data as well as a modal model of the object and, in addition, overcomes all mentioned above limitations. This is the advantage of modal filtering applied to the data recorded on the object.

1.2 *Modal filtration*

A modal filter is a tool used to extract the modal coordinates of each individual mode from a system's output (Meirovitch & Baruh 1982, Zhang et al. 1990). It decomposes the system's responses into modal coordinates, and thus, on the output of the filter, the frequency response with only one peak, corresponding to the natural frequency to which the filter was tuned, can be obtained. The modal filter was used for the first time for damage detection and structural health monitoring by Slater & Shelley (1993). Later on also Gawronski & Sawicki (2000) and El-Ouafi Bahlous et al. (2007) applied it in this field. One more way of using modal filtering for structural health monitoring is presented by Deremeker & Preumont (2006) and later by Mendrok & Uhl (2010a). The frequency response function of an object filtered with a modal filter has only one peak corresponding to the natural frequency to which the filter is tuned. When a local change occurs in the object – in stiffness or in mass (this mainly happens when damage in the object arises), the filter stops working and, on the output characteristic, other peaks start to appear, corresponding to other imperfectly filtered natural frequencies. On the other hand, a global change in entire stiffness or mass matrix

(due to changes in ambient temperature or humidity) does not corrupt the filter and the filtered characteristic still has one peak, although it is slightly moved in the frequency domain. Such an approach has also been applied in this paper due to its advantages over the classical modal model based methods: robustness for environmental changes, low computational cost, autonomous operation.

2 SHM SYSTEM BASED ON THE MODAL FILTRATION

2.1 *General assumptions*

The authors decided to implement modal filtration as a practical measuring – diagnostic system. Its main assumption was that it should be completely independent. It means that the user should be able to perform full diagnostic procedure without necessity of usage of any additional measuring device or software. To fulfill above requirement the original 16-teen channel measuring – diagnostic unit was designed and the dedicated modal analysis and modal filtration software was developed. Generally the system composed of both hardware and software is supposed to work in one of the three modes: operation in dynamic signal analyzer mode for the purposes of the modal testing, operation in diagnostic mode (acceleration of vibration measurements, frequency characteristics estimation modal filtration of the characteristics, damage index calculation) operation in monitoring mode (the same activities as in diagnostic mode but performed periodically).

2.2 *Measuring unit and modal analysis software*

In order to develop the SHM system, dedicated measuring device has been designed and built. The device's logic structure contains CPU and FPGA modules connected with each other and with some additional peripheral devices. CPU module is included mainly for control purposes – it implements user interface together with some peripheral devices like keyboard, LCD display and communication units. FPGA module on the other hand, contains all logic modules necessary for implementation of desired method. The device structure contains also 16 A/D converters which moves analog input signal delivered from vibration sensors into digital domain, and two high speed synchronous RAM modules needed for data buffering and data processing needs. FPGA goal is to provide synchronous signal acquisition from all 16 channels and maintain all functionality necessary for measurement process like triggering, configuration, over condition detection and many others. The FPGA also contains data processing module, so it is also responsible for desired algorithm implementation. Thanks to that, CPU task is limited mainly to maintain control and auxiliary functions only. This is very important from power consumption point of view, because CPU device does not need to be fast (and complicated), and therefore it consumes much less power. Of course FPGA device also consumes power, but it's power consumption can be precisely controlled during operation. Thanks to that the whole device can work fully independently in diagnostic mode (without any PC connected to it), and it can be battery powered, which is very important especially in portable applications.

The main goal of the software written for the described SHM system is the estimation of the modal filter coefficients. For this purpose, the application provides the following functionalities:

- Geometrical model definition of the tested object.
- Measurement points definition, namely the assignment of specific points of a geometric model to the sensors placed on an object.
- Execution of measurement and presentation of the results (time histories, PSD, FRF and coherence), and data archiving.
- Execution of modal analysis by:
  - calculation of stabilization diagram,
  - estimation and visualization of mode shapes for selected poles,
  - estimation of modal filter coefficients and visualization of filtration results.

The application was created in the .Net Framework 3.5 environment with use of additional external libraries.

3 PERFORMED TESTS

3.1 *Test stand description*

The measurements could be successfully accomplished thanks to courtesy of interested staff members of the Faculty of Automotive and Construction Machinery Engineering at Warsaw University of Technology. The object of the test was a single truss shown in Figure 1 mounted on a specially built test stand in the laboratories of the Faculty of Automotive and Construction Machinery Engineering at Warsaw University of Technology (Galezia et al. 2012, Szulim et al. 2012). It is a typical element usually found in roof constructions, and it's damage may directly lead to roof crash. During the experiment a force was applied to the truss as shown in the figure.

The main goal of the test was to proof that modal filtration and designed system can be successfully used for damage detection for such objects. The photo of measuring stand is presented below in Figure 2.

A set of sensors was installed on the bottom beam of the truss. A significant advantage of this approach

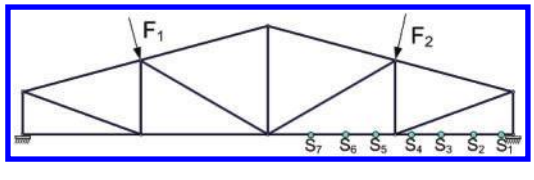

Figure 1. Object of tests.

Figure 2. Photo of the laboratory test stand.

is that it is not necessary to place a large number of sensors on examined object even if it is large. The user can place only a few sensors evenly distributed on the object. The result in damage detection efficiency would be very similar. However a bit of experience is needed from the user to choose a proper area and sensors number. What is more, position of each sensor cannot be changed during measurements, as it would affect damage detection quality (Mendrok & Uhl 2010b). As a matter of fact this method can be successfully used in applications where the measures are performed periodically. In this case sensors doesn't need to be installed permanently, however user have to ensure that every sensor is mounted exactly in the same point of the object as it was during reference measure. This can be achieved by using dedicated spacers (between object and sensors) mounted permanently on tested object.

3.2 *Preliminary tests*

At the very beginning measuring unit was connected to PC (with dedicated analytic software installed) in order to calculate modal filter coefficients for object in reference state. The reference state is defined as a state of object without damage in it's typical working conditions. In this case it was assumed a state of truss mounted on test stand with no force applied to it. The photo of hardware unit connected to the PC with installed software is presented in Figure 3.

To obtain the modal model and from it the modal filter coefficients, the impulse test was performed. The 0.1 kg modal hammer with force sensor was used to excite the structure. The responses were measured in the 7 points shown in Figure 1 by one-axis accelerometers. The following parameters were used

Figure 3. Hardware unit connected to the PC.

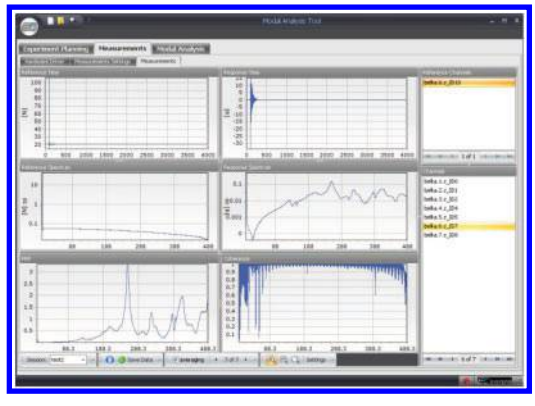

Figure 4. Exemplary results of modal testing.

during the measurements: bandwidth – 500 Hz, spectral resolution – 0.25 Hz. The frequency response functions together with power spectral densities averaged 9 times in frequency domain were recorded. The exemplary view of graphical user interface during measurements is placed in Figure 4. In the last step the results of measurements were verified for their correctness. The ordinary coherence function and repeatability of the driving point frequency response function were the quality criteria.

In the next step the modal parameters were estimated with use of the LSFD algorithm, which is implemented in the software. The results obtained during the identification process are presented in Figure 5.

The last step of the reference data preparation consists in modal filter coefficients estimation. After model extraction user is able to verify quality of designed filter (which is shown below in Figure 6).

As the result, three modal filters had been calculated, each for different natural frequency and corresponding mode shape. Coefficients of these filters were then transferred to MDU, which enabled it to work independently and calculate damage index values for each defined filter.

3.3 *Damage measurements*

During the experiment, load was slowly increased in several steps. The reference measurements were

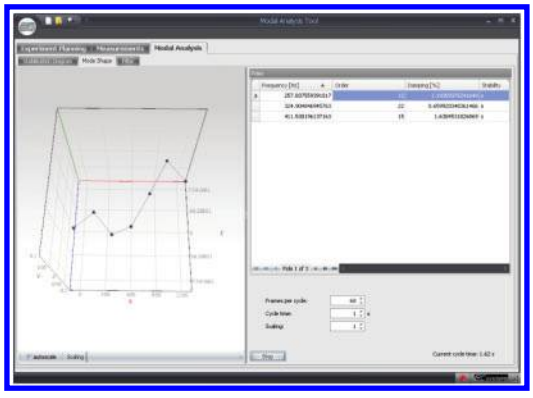

Figure 5. View of the software GUI for the mode shape visualization.

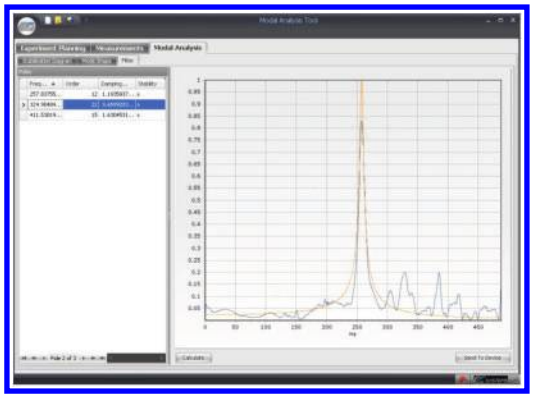

Figure 6. View of the software GUI for the filter quality verification.

performed without load and next load was applied with use of hydraulic drives. The load was increased up to 35 kN. Every 5 kN the diagnostic procedure was launched and damage index was calculated. The 35 kN load caused serious deformation of the tested truss. To see if the deformation is in the elastic range the load was released and increased again. At the level of 35 kN the damage occurred. One of the clamps was broken and that ended the experiment. In Figure 7 deformed frame with 35 kN load in first load cycle is shown. In Figure 8 the broken clamp after second load cycle is presented.

As it was stated above, every 5 kN the damage index values were calculated. They are gathered together in Table 1.

For better visualization of the results are presented as plot in Figure 9.

Both Table 1 and Figure 9 exhibits very clear trend of the damage index value. It grows together with load increase. Especially the modal filter tuned to Mode shape 3 presents linear dependency. It indicates that the method and SHM system based on it can detect not only damage but also the load change. This is very useful information for the roof monitoring system because it can give the information about too big snow layer.

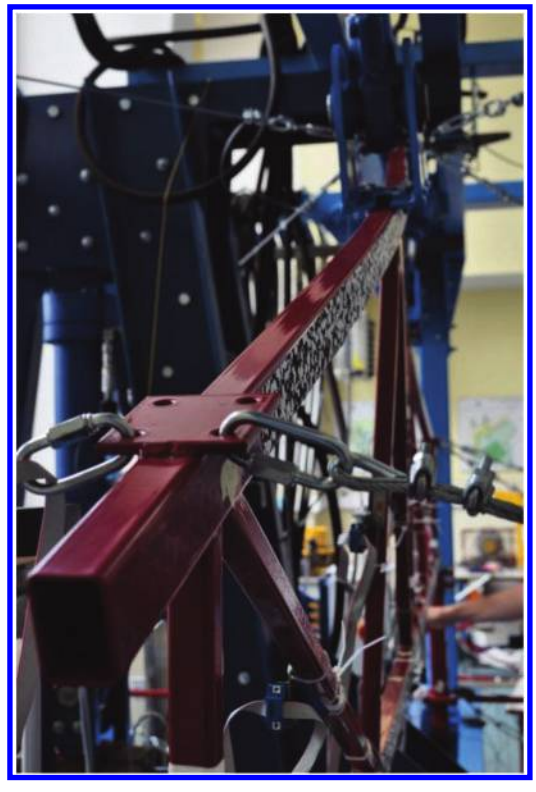

Figure 7. Deformed frame after first load cycle.

Figure 8. The broken clamp after second load cycle.

Another interesting information is that after complete load release the damage index did not returned to the 0 value. It means that the 35 kN load introduced some structural changes to the structure. This results were confirmed by the camera-based measurements of the structure deflection. After the load release the truss did not returned to its original shape.

Table 1. Values of damage index (DI) calculated for modal filter (MF) tuned to consecutive mode shapes

	Measurement Results			
No	DI(MF 1)	DI(MF 1)	DI(MF 1)	Load
1	1.46E−02	4.53E-02	2.82E-02	F = 0 kN
2	8.07E−01	8.17E−01	4.00E−01	F = 5 kN
3	8.83E−01	7.59E−01	4.80E−01	F = 10 kN
4	9.60E−01	9.24E−01	6.98E−01	F = 20 kN
5	1.03E+00	1.11E+00	7.52E−01	F = 25 kN
6	1.11E+00	1.30E+00	8.31E−01	F = 30 kN
7	1.44E+00	1.31E+00	1.34E+00	F = 35 kN
8	8.54E−01	8.71E−01	7.10E−01	F = 15 kN
9	2.07E−01	4.39E−01	3.50E−01	F = 0 kN
10	1.35E+00	1.16E+00	1.13E+00	F = 35 kN

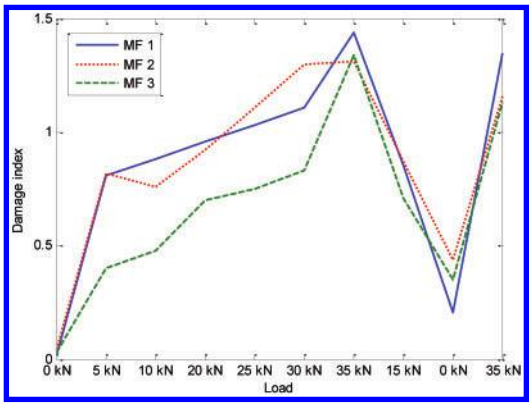

Figure 9. Values of damage index in function of load.

4 CONCLUSIONS

The paper presents the results of laboratory tests for a damage detection procedure and monitoring system based on modal filtration. The object of test was a single truss mounted on specially build laboratory test stand, which imitate real working conditions for this object.

A general conclusion is that the developed SHM system detects damage with good sensitivity and it is suitable for the truss like structures. Apart from detection of damage it also provides information on load changes, which can be very useful in roof structure monitoring. It can detect not only the cracks or other damages but also the excessive load, e.g. due to the snow layer.

In the further development of the SHM system based on modal filtration, authors plan to install it on other type of real structures such as bridge to verify its monitoring ability.

ACKNOWLEDGEMENTS

Research funding from the Polish research project MONIT (No. POIG.01.01.02-00-013/08-00) is acknowledged by the authors

Authors would like to also express their special thanks to Professor Stanislaw Radkowski, dr Jedrzej Maczak and Adam Galezia for the possibility and help in measurements on the stand in Warsaw University of Technology.

System identification of masonry buildings in Vienna

F. Kopf, D. Schäfer, M. Pietsch & H. Wenzel
VCE – Vienna Consulting Engineers, Vienna, Austria

ABSTRACT: Intensive scientifical works in the field of earthquake research caused the classification of new earthquake zones in wide areas of Europe, also in Austria. The introduction of the compulsory Eurocode 8 changed the estimation of earthquake risk for buildings in Austria's cities significantly. The endangerment by earthquakes for buildings in the Vienna Basin became a deciding factor, not only in planning, but also financially. In order to eliminate this problem for the real estate economy, the research project SEISMID was launched and thanks to financial contribution of the "Technologieagentur der Stadt Wien (ZIT)" it could be finished successfully on 31.12.2010. This project was the first step to compensate the lack of knowledge and experience in this sector in Austria. Historical masonry buildings are very complex structures. Their global dynamic behavior is affected by many components (foundings, walls…), that consist of many sub-components themselves (bricks, joints, etc.). There are many constraints for the dynamic system identification of the micro- and macro-behavior while taking measurements. This article describes the technical aspects of the measurements, which was acquired within SEISMID and could be tested successfully.

1 INTRODUCTION

Proofing the stability of collapse of buildings under seismical loads is mostly performed with numerical methods because of increasing non-linear effects of material response, which also causes nonlinearity regarding the stiffness and damping of structures.

Any attempt to analyze the stability of buildings under conditions similar to real earthquakes would require enormous loading devices and yield undesirable damages of the buildings which then would have to be assessed. For these reasons the dynamical response of buildings is analyzed with numerical models. This is usually possible for modern buildings with a known geometry and controlled material properties. Problems emerge with old masonry buildings which have a great dispersion of material properties, accomplishments, joins etc. In this case it is mostly impossible to make sufficiently accurate assumptions, required for numerical models. For such cases it turned out, that measurements done with small amplitudes in the linear elastic range can be used for the calibration of numerical models. The calibration with this kind of data improves the accuracy of numerical models significantly even in the non- linear-elastic range.

2 MEASUREMENT METHODS

For analyzing the spectrum of single measurement points it would be sufficient to make measurements completely independent from each other. For analyzing the behavior of entire buildings it is not sufficient to focus on single measurement points. The signals have to be observed together, it is necessary to analyze their relation in space and time. For this kind of analysis the signals have to be absolutely synchronized. A possible workaround would be to work with one reference-sensor remaining on one place, whereas the other sensors can be re-positioned. With synchronized measurement devices (Brimos Wireless Recorder) it is possible to use many sensors and recording units on different places; the quality of synchronization is comparable to an assembly made with only one central recording device. The main advantage of the Brimos Wireless Recorder system is its flexibility and the lack of long cables that would be difficult to handle.

Figure 1. Acceleration sensor (left) and geophone (right).

3 SIGNAL COMBINATION IN TIME DOMAIN ANALYSIS IN FREQUENCY DOMAIN

3.1 *Signal combination in time domain*

The used sensors usually take measures in three spatial directions. In this way, the translatory movement of the

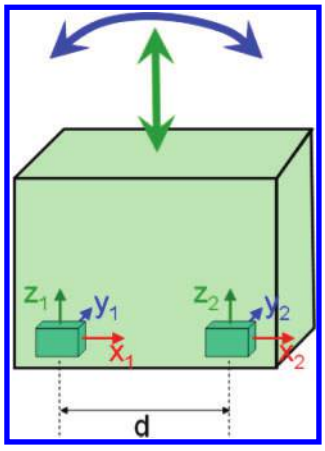

Figure 2. Translatory and rotatory movement of a structure.

measured building point is documented, but in order to find out the composition of the various building movements for each single measurement point it is useful to analyze the relations between discrete sensors synchronized in time.

If we assume a translatory movement, superposed with a rotatory movement around the y-axis, these movements will be recorded by the sensors drafted on figure 2, but they cannot be interpreted immediately. If we are only interested in the vertical movement, then we can calculate the mean value of the vertical signals.

$$z_translation = \frac{z_1 + z_2}{2} \quad (1)$$

The rotatory movement would be equalized, if the center of rotation is exactly between both sensors. In this case, the vertical movement of the structure can be interpreted from the two combined signals. The rotatory oscillation around the y-axis causes diametrically opposed vertical oscillations (z-direction). The linearized angle of rotation (in radiant) can be calculated from the given signal-combination within a defined time interval in the following way:

$$y_rotation = \frac{z_1 - z_2}{d} \quad (2)$$

This formula can be applied to measure rotatory oscillations around any axis that is perpendicular to the plane mounted by the line between the sensors and the vertical z-axis. These combined signals can now be treated as one signal, recorded by an imaginary sensor that would be placed exactly between the sensors and could measure vertical and rotatory movements around the y-axis.

3.2 *Analysis in the frequency domain*

If Fourier Transformation is applied to those previously combined signals, it is possible to determine the frequencies of the vertical and rotatory movements separately. Of course, these frequencies are also visible as peaks in the FFT-diagram of the original sensors, but with signal-combination they can be assigned to the separate oscillation-components. In the following, some useful signal combinations for building-measurements and its applications will be discussed.

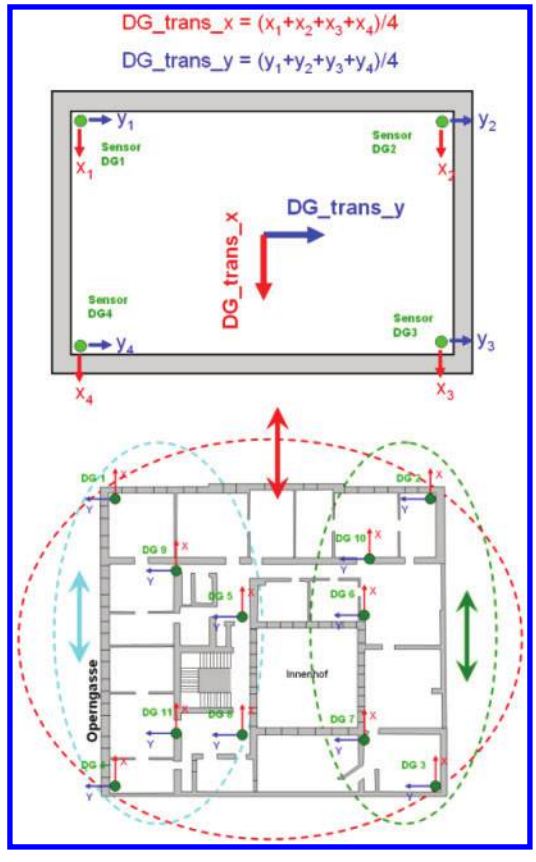

Figure 3. Translatory building movement in plan view.

4 SIGNAL COMBINATIONS

4.1 *Translatory movements*

Normally the roof-layer of wilhelminian style buildings is the place where measurements should be made. If the roof level is in an original state (no additional flats built on top), it is mostly easy to have access. Besides, the displacements caused by oscillations are strongest in the roof level which yields very significant signals.

Figure 3 shows a simplified ground sketch of a roof level. In all four corners of the building a sensor that measures the accelerations in three directions was placed. If a mean value of the signals of these four sensors for all three directions in space is built, then this combined signal equals the translatory movements of the roof level in its center. The combined signals can be seen as a virtual sensor placed exactly between the four

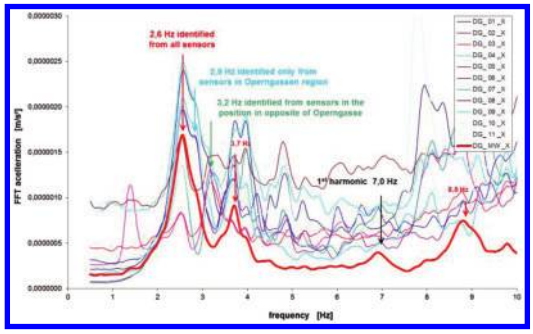

Figure 4. Translatory building movement in x-direction in frequency domain.

real sensors. Thus, this is only the case, if the entire roof level behaves like a rigid structural element. In buildings built during the Wilhelminian era, this will never be the case, thus the mean vertical signals are mostly useless. In horizontal direction, the assessability is dependent on the shear rigidity of the slabs. In many cases, the shear rigidity of the slabs can be assessed by comparing the discrete signals with the mean values. In the following example, a big number of sensors were placed in the roof level of a wilhelminian style building and the mean value in horizontal direction was compared with each single signal (ground sketch is given in figure 3).

Figure 4 shows the analysis of the signals in x-direction of all sensors after FFT-analysis in frequency domain. The mean value of these signals was computed in the time domain and after that FFT – analysis was applied. In figure 4 one can see it in bold. A basic oscillation of 2.6 Hz in x-direction of the building is obvious in the mean value and can also be identified from each single measurement positions. But to assume, that a building from the Wilhelminian era would accomplish a rigid movement is not appropriate. Therefore the shear rigidity of the roof level is too weak. Very often, parts of a building have a „dynamic life of its own". It is recognizable, that the part of the building along the Operngasse is oscillating at about 2.9 Hz, whereas in the part averted from the Operngasse, this 2.9 Hz oscillation is not recorded but one with 3.2 Hz. It is interesting to see that almost every sensor captures a peak at 4.8 Hz, but the mean signal does not. In this part of the building a very significant oscillation around 4.8 Hz was recorded, but the mean value does not show a peak in this frequency range. This indicates, that the oscillation is not translatory, the sensors obviously oscillate in an opposed way and equalize in the mean value. Below we want to introduce these kinds of oscillations.

4.2 *Rotatory movements in rooftop level*

Also for regarding the rotatory movement we have to assume a shear resistant plate in the roof top level. A center of rotation is being assumed (in the case of a rectangular form it's middle point), the connecting lines to the sensor positions are drawn (in a case of a rectangular form the diagonals). Now, the two horizontal components of the sensor's signals are vectorially composed in a way that the direction is perpendicular to the connecting line and clockwise around the center. The components obtained for each sensor are averaged to an "entire rotational signal", which shows the rotatory wave forms around the vertical axis by FFT-analysis. In the case of a rectangular ground form, the position of the center of rotation is easy to find, and the sensors placed in the corners of the building are placed nearly in the same distance from the rotational center. If additional sensors are used and if they have different distances to the assumed center of rotation, the single components of the rotational signal have to be divided by the sensor's distance to the rotational center in order to describe the kinematics in a correct way. But in this case it might be a problem, that the effect of the components of those sensors are overestimated, which are close to the rotational center. In their signals there will be hardly significant components of the rotational oscillation. For this reason it is better to take only components of those sensors into consideration, whose distance to the rotational center is big and more or less equal. Then it's not necessary to regard the distance to the rotational center, because all components get the same weight. Also the dependency of the accurate position of the assumed rotational center is neglectable in this case.

For the building shown in figure 5, two kinds of rotatory movements were investigated. Once, four sensors placed in the corners of the buildings were used (outer corners), another time the corners close to the court in the middle (inner corners). Both rotatory signals were investigated and are shown in bold (figure 6). The frequency domain analysis shows some peaks that do not coincide with peaks of other types of oscillation. The rotation at the outer corners coincides very well with the rotation at the inner corner. This can be seen as an acknowledgement of the method.

4.3 *Deviatory movements in the roof level*

Different from translatory and rotatory wave forms; in case of deviatory movement, rigid movement caused by shear resistance of the slabs, does not have to be assumed. In opposite, in this case dynamic shear movements are made measurable. According to figure 7, those horizontal signal components are determined, that either point to each other or point to opposite directions at the other diagonal line. By combining these components, it is possible to show a waveform that is significant for the dynamic shear movements of the entire roof floor (black dashed line in the sketch). If there is only rigid movement, this waveform must not exist and the deviation signal must theoretically equal zero. The example for this waveform is from a house from the Wilhelminian era, which was first measured in its original state. Afterwards, the shear resistance of the existing wooden slab was improved by assembling a composite slab, that was connected to the outer

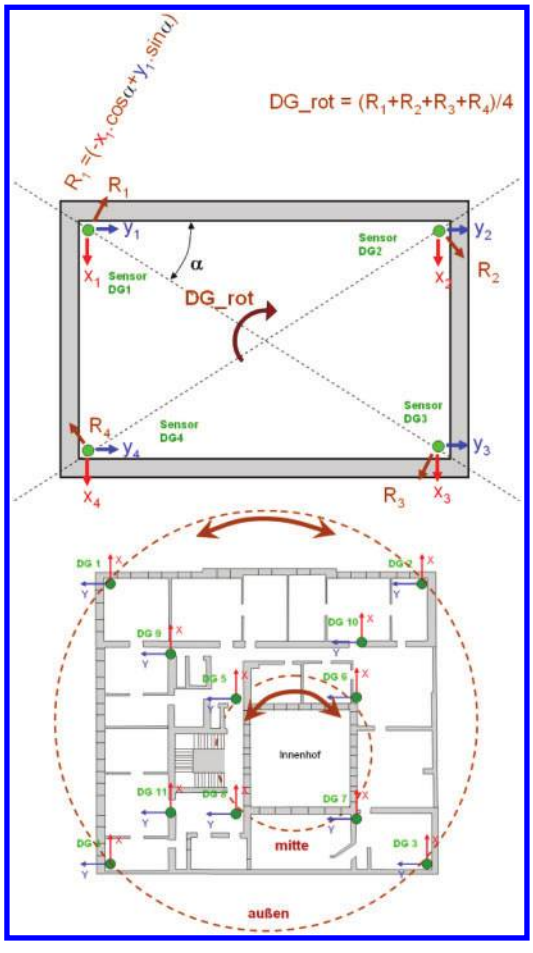

Figure 5. Rotatory building movement in ground view.

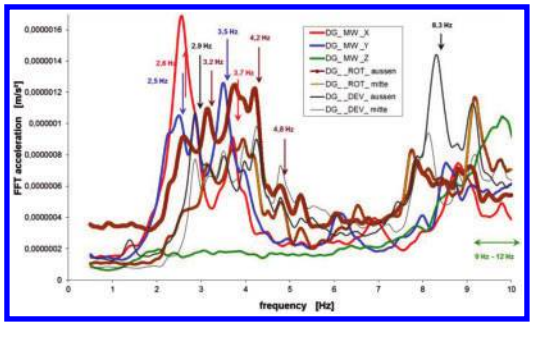

Figure 6. Rotatory building movement around the vertical axis in frequency domain

walls. This didn't change the mass of the structure, but improved the shear resistance. The following figures show the change of the wave forms by assembling a composite slab.

The interpretations of changes caused by the assembly of a shear resistant slab are shown in figure 7. They show the waveform analysis with combined signals in an effective way. If there were used single sensors

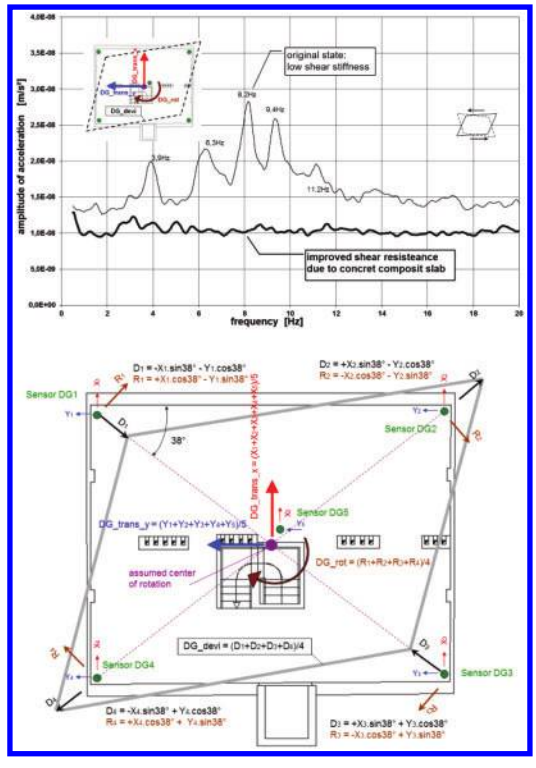

Figure 7. Deviatory building movement.

only, the interpretation would have been much more difficult and far more speculative.

4.4 *Determination of the first harmonic in the building cross section*

If the frequency of the first harmonic can be easily determined by applying a spectral analysis (FFT) from the first obvious peak in the low frequency range, this does not mean, that the following peaks are the following harmonics. The first harmonic in the building's cross section is shown in figure 8 and characterized by the fact that the horizontal oscillation of the 2nd story and the roof level occur in a reverse phase. This "opposite oscillation" of the two stories can be useful for the analysis.

Figure 8 shows the horizontal acceleration of each floor of building in frequency domain. The basic harmonic at 2.6 Hz is easily recognizable. The amplitudes of the upper stories are higher than those of the lower stories. For determination of the first harmonic, we focus on the "opposite oscillation" of the stories OG_02 (blue line) and OG_05 (red line). Instead of comparing the phases via FFT and getting a confusing image, a more stable algorithm was developed. The opposite oscillation is characterized by the difference between the signals (OG_5 - OG_2). This difference has a maximum (thin black line L1 in diagram). If the two stories oscillate in the same phase and have a different amplitude in the basic oscillation, then the FFT

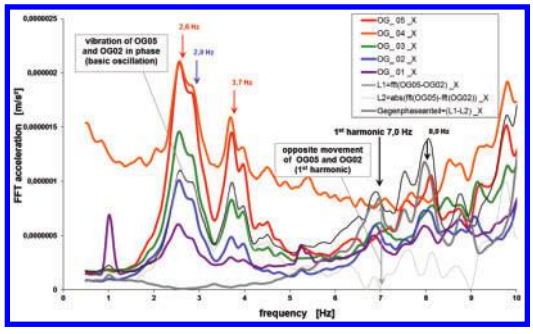

Figure 8. Basic oscillation and first harmonic in a building's cross section.

of the difference-signal shows a peak, that is equal to the difference of the FFT analyses of both signals (L2 = abs(FFT(OG_5) FFT(OG_2)), thin grey line in diagram). The conclusion is, that the difference of those lines (L1-L2) is an appropriate indicator for phase reverse oscillation of both stories. This line is shown in the diagram with a thick grey line. It's first significant maximum is at 7 Hz. This is the frequency of the first harmonic.

5 DYNAMIC MEASUREMENTS FOR THE DETERMINATION OF PROPOERTIES OF WALL STRUCTURES

5.1 *Wave dispersion in elastic media*

In an elastic and isotropic medium, the compression- and shear waves propagate with different but constant velocities that are independent of the frequency of the wave and also from the structure's geometry. They depend only on the material properties. The velocity of compression waves v_p can be determined with the following formula, where E_s is the elastic modulus (with prevented lateral strain) and ρ is the density of the material.

$$v_p = \sqrt{\frac{E_s}{\rho}} \tag{3}$$

The shear wave velocity v_s can be calculated via the modulus of elasticity in shear G and the material density ρ in the following way.

$$v_s = \sqrt{\frac{G}{\rho}} \tag{4}$$

With the following formulas, we can transform the values into such for isotropic linear-elastic material, whereas υ is the radial strain coefficient, E is the Youngs Modulus and G is the modulus of elasticity in shear.

$$E = \frac{(1+\upsilon)(1-2\upsilon)}{1-\upsilon} \cdot E_s = 2(1-\upsilon) \cdot G \tag{5}$$

$$G = \frac{1-2\upsilon}{2(1-\upsilon)} \cdot E_s = \frac{1}{2(1+\upsilon)} \cdot E \tag{6}$$

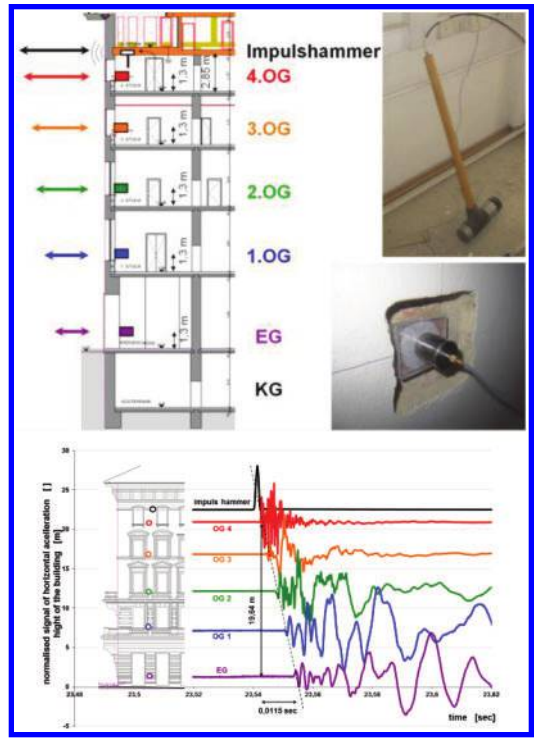

Figure 9. Experiment for wave dispersion in masonry wall.

5.2 *Measurement of wave dispersion in masonry walls*

The idea to measure the wave dispersion in masonry walls was to determine its properties in its undisturbed entity. Laboratory tests with bore cores and samples of mortar and bricks can only selectively assess the different components of masonry walls. Goal of this experiment was to capture the in situ properties of masonry walls in today's conditions after decades of loading. In order to measure the wave dispersion in masonry walls, sensors were placed along a masonry pillar in every story. The dynamic impact was realized in the top story with an impulse hammer. Hoping to be able to differentiate the shear wave from the compression wave, the sensor were placed horizontally, also the dynamic stroke was done in the horizontal direction.

Figure 9 shows the progression of the recorded measurement signals (horizontal acceleration) according to the vertical position of the sensors in the measured masonry pillar. The dispersion velocity can be recognized by the time delay between the sensors.

$$v = \frac{19{,}64\ m}{0{,}0115\ s} = 1708\ m/s \tag{7}$$

Before the arrival of the wave, the signal is completely homogenous and shows no agitation. This means, that the wavefront can be assigned to the compression wave. This compression wave causes also

Table 1. Different wave-velocities because of non-linear and amplitude-dependent material properties.

	Medium impact	Strong impact	Difference
Pillar 1	1363 m/s	1315 m/s	−3,5%
Pillar 2	1546 m/s	1502 m/s	−2,9%
Pillar 3	1650 m/s	1583 m/s	−4,1%
Average	1519 m/s	1466 m/s	−3,5%

vertical oscillations, but obviously the horizontal component is dominant. Therefor it is not possible to recognize the following shear wave. Using formulas for linear elastic, isotropic materials it is possible to estimate the material properties.

$$v_p = \sqrt{\frac{E_s}{\rho}} \tag{8}$$

In dependency of the radial strain coefficient, the other material parameters can be determined. Table 1 shows the result from measurements at different pillars in the same building. Various light strokes and various strong strokes with the impulse hammer were accomplished. The nonlinearity of the material parameters is obvious. The greater the amplitudes, the lower the stiffness of the material, which yields smaller wave velocities.

As we have seen, it is relatively easy to measure the compression wave in a masonry pillar. The shear wave can be slightly recognized in the top story, but it is strongly damped. Because of the anisotropy of the masonry wall it would be good to be able to measure the compression wave going vertically through the pillar, as well as the shear wave, which is propagating with horizontal oscillations through the pillar in vertical direction. In this case it would be possible to determine the relevant parameters directly. No assumption for the radial strain coefficient would have to been taken. A comparison with this dynamic method for determination of material properties with conventional methods has not yet been undertaken.

Shear wave travel times in multi-story buildings for system identification and damage detection

E. Şafak, E. Çaktı & E. Zengin
Boğaziçi University, Kandilli Observatory and Earthquake Research Institute, Istanbul, Turkey

ABSTRACT: Seismic response of multi-story buildings can be formulated as a one-dimensional wave propagation problem in terms of wave velocities and frictional damping values at each story, and the wave reflection and transmission coefficients at each floor. When compared to commonly used modal analysis and its parameters (i.e., modal frequencies, damping values, and mode shapes), the wave propagation approach provides a better insight into the response and its parameters are more sensitive to damage. A critical parameter of the wave propagation approach is the wave velocities (or, wave travel times) in the building. The commonly used approaches to calculate wave travel times from vibration records have been to use the phase shift of a characteristic peak in the records, or the delay time for the peak of the cross-correlation function of the records. These two approaches do not give accurate wave velocities, because the damping in the building also alters the phase of the records. This paper presents a methodology to calculate the velocity of seismic waves in multi-story buildings more accurately than the current procedures. The methodology involves utilization of the envelopes of the impulse response functions with respect to roof, and can separate the phase shifts due to damping and the wave travel time. As an example, seismic wave velocities in three instrumented multi-story buildings are calculated by using their earthquake records and the methodology presented.

1 INTRODUCTION

Although common approach has been modal analysis, seismic response of multi-story buildings can also be formulated as a one-dimensional wave propagation problem in terms of wave velocities and fricitonal damping values at each story, and the wave reflection and transmission coefficients at floor levels (Safak, 1999). Recorded responses from instrumented buildings clearly show the propagation characteristics of seismic response in buildings.

As an example, Figure 1 shows the recorded E-W accelerations of a 17-story steel frame building in Los Angeles during the M = 4.7 Yorba Linda earthquake of 3 September 2002. The building, known as the Factor Building, is located at the University of California campus in Los Angeles (UCLA), and instrumented with 72 acceleration sensors. With four channels at every floor, the building is one of the most densely instrumented buildings anywhere in the world, providing continuous data at 500 Hz (Kohler et al., 2007). Although the propagation of waves is not clear from the full time histories of the response shown in the figure, it becomes very clear if one takes a closer look to a short time interval. To see the waves, we consider a one-second long segment of the records, as depicted with a pink band in Figure 1, and deconvolve the records with the basement and roof records. The deconvolution gives the impulse-response functions for a basement and roof impulse. The reason for looking at the impulse-response functions is that they are independent of soil-structure interaction effects and provide a much clearer view of the wave propagation (Safak, 1995). Figures 2a and 2b show the impulse-response functions with respect to the basement and the roof in 3D view. Horizontal axes are the time and the floor number, and the vertical axis is the impulse response. The figures clearly show the propagation of waves in the building. It takes about 0.4 second for the waves to reach from the ground to the roof.

It can be shown that the deconvolution by the roof record eliminates the upgoing wave components in the signals, resulting in a simple downgoing wave (Snieder and Safak, 2006; Safak and Cakti, 2009b). In comparison, the signals deconvolved by the foundation-level records include both upgoing and downgoing waves, resulting in more complex impulse-response functions. This is clearly seen in the figures. The roof record is simply twice the upgoing wave at the top story (i.e., the free-surface reflection because of the air above), whereas the records at other floors are a sum of upgoing and downgoing waves (Safak, 1999). Thus, deconvolution by the roof record eliminates all upgoing waves in the signals.

When analysing vibration records from instrumented structures, it has been shown that, for system

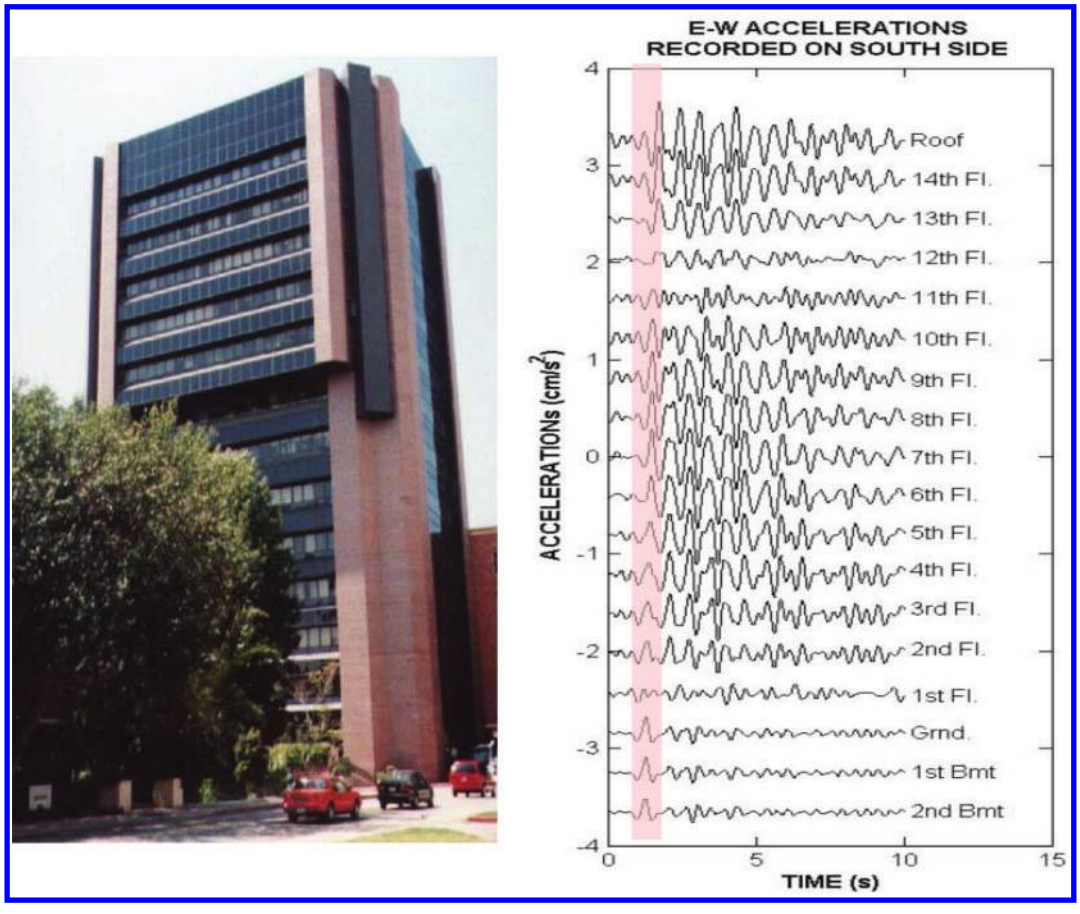

Figure 1. Factor Building and recorded acceleration from the M = 4.7 Yorba Linda earthquake.

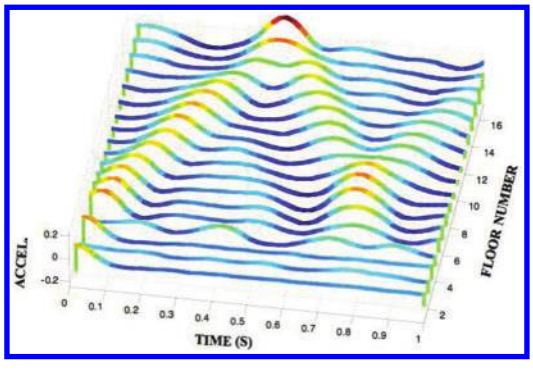

Figure 2a. Propagation of seismic waves, after deconvolution by the basement record, during a one-second interval in Factor Building.

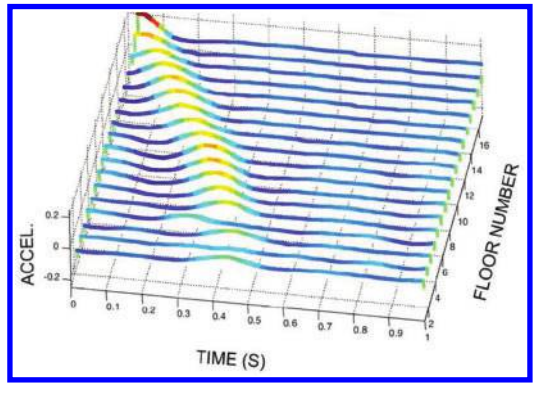

Figure 2b. Propagation of seismic waves, after deconvolution by the roof record, during a one-second interval in Factor Building.

identification and damage detection, the wave propagation parameters are more reliable and robust than modal parameters, and also more sensitive to damage (Safak, 1998). This is particularly true for older, historical structures because these structures do not meet the requirements of the classical modal analysis, such as elasticity, linearity, mass and/or stiffness proportional damping (Safak and Cakti, 2009a).

In this paper, first a new methodology is introduced to calculate the wave velocities in multi-story buildings. The methodology provides a more accurate estimation of wave velocities than the commonly

used other methods, for it eliminates the phase shifts introduced by damping. Next, the velocities of seismic waves in three instrumented multi-story buildings are calculated by using their vibration records during earthquakes.

2 CALCULATION OF WAVE VELOCITIES

A critical step in using wave travel times for identification and damage detection is the accurate calculation of wave travel times. This first requires a high-quality and high-sample-rate recording. For multi-story buildings, the sampling interval in the records should be at least 1/10th of the shortest travel time between any two successive floors. Wave travel times cannot be calculated accurately from the raw data, because the noise in the signals alters the peak amplitudes and phases. The two processing steps that help to increase the accuracy in wave travel time calculations are band-pass filtering and deconvolution. Band-pass filters should be selected such that the filtered signal has a much higher signal-to-noise ratio than the original signal. This is accomplished by selecting the pass-band to keep only the resonant frequencies of the building. The band-pass filters should be either a zero-phase filter, or the filter should be applied twice, first forward and then backward, so that the phase content of the signal is not altered. As discussed above, the deconvolution of the records by the roof record eliminates the upgoing components in the signals, resulting in a simple downgoing wave. This process gives a much cleaner signal for calculating wave velocities.

The standard approach to calculate the wave travel times between two recording points have been either to use the time difference for a characteristic peak in the signal, or to determine the time lag where the cross-correlation of the signals has a maximum. These methods are acceptable for non-dispersive, non-attenuating media, where the waveforms do not change their shape as they travel. In structures, the waves attenuate due to damping. The attenuation changes the shape (i.e., the phase) of the waves. In other words, the phase shifts in two records are caused by the combined effects of wave travel times, plus the phase distortions due to damping (Safak and Cakti, 2009a). A rigorous theoretical analysis of wave dispersion in an attenuating medium can be found in Aki and Richards (1980).

It is possible to eliminate the phase shifts introduced by damping on the calculated wave travel times. This can be accomplished by calculating the time shifts from the envelopes of the signals, rather than the original signals. The envelope functions are determined by taking the Hilbert transforms of the signal, and then calculating the corresponding analytic function. It can be shown that for narrow-band signals that are propagating in a frequency-dispersive medium, the envelope functions are not affected by the dispersive properties of the medium (Safak and Cakti, 2009a).

Table 1. Seismic wave velocities at Factor Building.

Dominant Direction	Frequency (Hz)	Travel time (s) for h = 74.77 m	Velocity (m/s)
East-West	0.40	0.52	145
North-South	0.50	0.42	180
Torsion	1.70	0.23	330

3 EXAMPLES

Using the methodology presented above, seismic wave velocities in three buildings are calculated from their earthquake-induced vibration records. The first building is the UCLA's Factor Building, which is described above. From the inspection of the Fourier amplitude spectra of the EW and NS accelerations, it was concluded that the building has three dominant frequencies, and the corresponding mode shapes are three-directional (i.e., modes include two translations and a rotation. In order to determine the dominant directions of the modes, we band-pass filtered the roof records around the resonant frequencies and plotted the corresponding particle displacements of the roof. Next, we calculated the envelopes of roof impulse-response functions and the wave velocities for each direction. The identified wave velocities are summarized in Table 1 below.

The second building is the 10-story, reinforced-concrete Millikan Library at the Caltech's campus in Pasadena, California, as shown in Figure 3 (Snieder and Safak, 2006; Clinton et al., 2006). The building has three accelerometers at every floor and continuous recording. By using the records from the same Yorba Linda earthquake, the dominant frequencies of the building are identified from the Fourier amplitude spectra of the EW and NS accelerations. The roof particle displacements, calculated by band-pass filtering the records around the resonant frequencies, show that the modes are mainly uni-directional with not much torsional component. Thus, from the envelopes of roof impulse-response functions for each direction, the wave velocities are calculated as shown in Table 2 below.

The third building is the 62-story, reinforced-concrete Sapphire Building in Istanbul (Figure 4). With a height of 261 meters, it is currently the tallest building in the city. The building is being monitored continuously with 30 accelerometers, placed as shown in Figure 4. The wave travel times are calculated by using the data from the M = 6.2, Aegean Sea earthquake of 8 January 2013. The dominant modes of the building are determined from the Fourier amplitude spectra and the corresponding particle displacements of the roof. The particle motions have shown that the building's motions are dominated by torsion. This is probably due to the fact that the building is much wider in the NS direction. For each horizontal direction and rotation, the wave velocities are calculated from the envelopes of roof impulse-response functions. The results are summarized in Table 3 below.

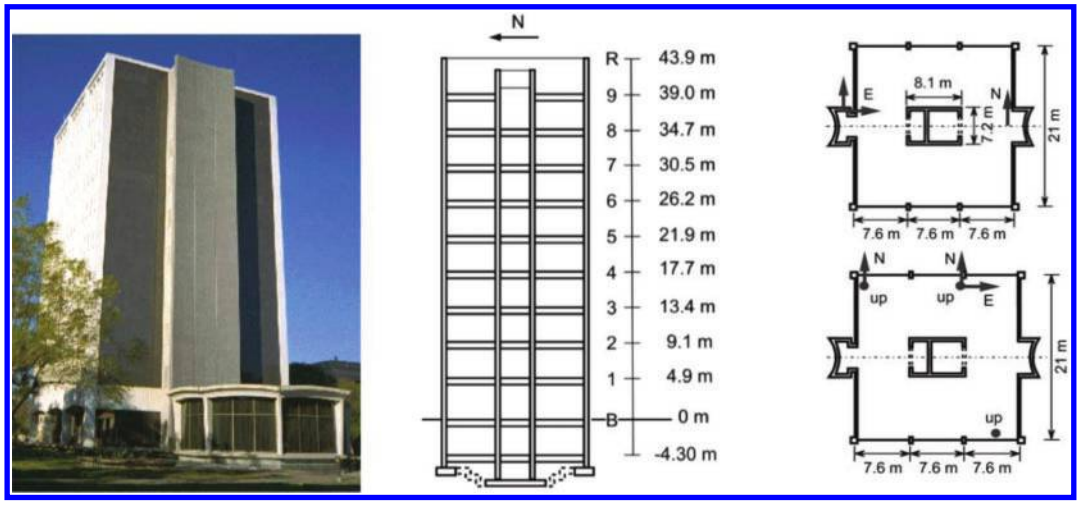

Figure 3. Millikan Library, vertical cross-section, and typical floor and basement sensor locations.

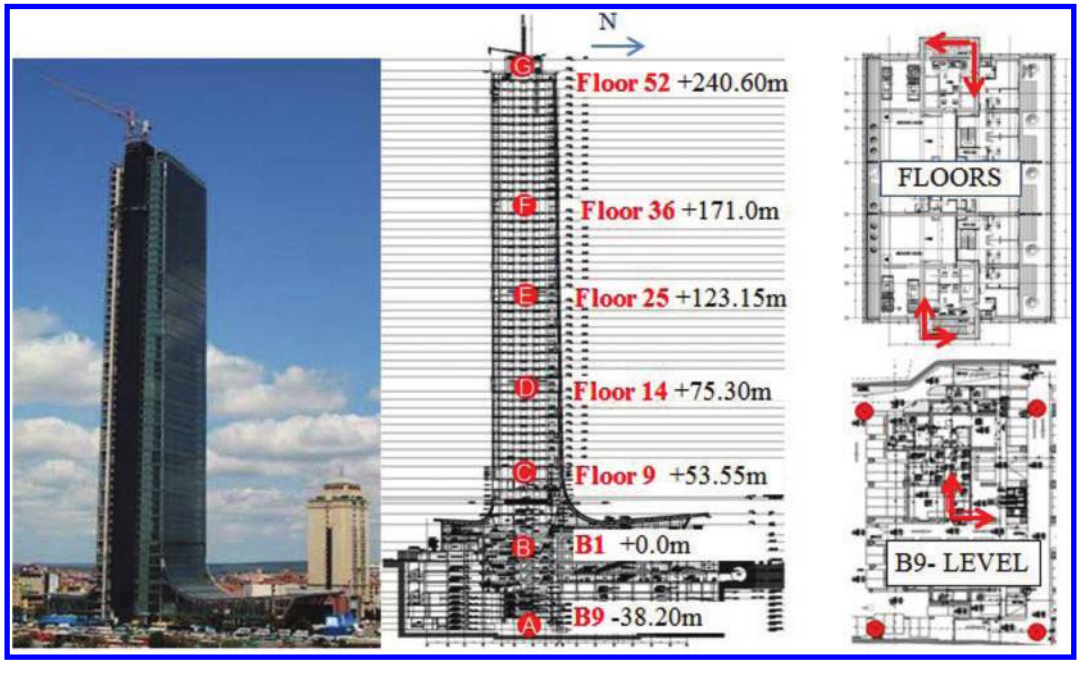

Figure 4. Sapphire Building, vertical cross-section, and typical floor and basement sensor locations.

Dominant Direction	Frequency (Hz)	Travel time (s) for h = 39 m	Velocity (m/s)
East-West	1.00	0.25	156
North-South	1.70	0.16	243

Table 3. Seismic wave velocities at Sapphire Bldg.

Dominant Direction	Frequency (Hz)	Travel time (s) for h = 187 m	Velocity (m/s)
East-West	1.90	0.52	145
North-South	0.40	0.42	197
Torsion	0.80	0.23	1247

4 CONCLUSIONS

The wave travel times in multi-story buildings give a critical insight into the behaviour of multi-story buildings, as well as superior tools for system identification and damage detection. Impulse-response functions provide much clearer signals than the original records for the calculation of wave travel times.

The roof impulse-response functions are better than the commonly used foundation impulse-response functions, because the former one leads to a simple downgoing wave in multi-story buildings. The story damping alters the phase characteristics of the waves as they propagate up and down the building. This may create an error in the calculation of wave travel times. To eliminate the phase shifts due to damping, the wave travel times should be calculated from the envelope functions of the impulse response functions.

The calculated wave velocities from the earthquake records of three buildings indicate that the wave velocities are around 150 to 250 m/sec. for translational motions, and higher for torsional motions.

Application and developments of the infrared thermography in the building construction sector

S. Knapp
IFDB – Professor Hillemeier & Knapp GmbH, Berlin, Germany

B. Hillemeier
Technische Universität Berlin, Germany

ABSTRACT: This paper gives an overview of active thermography methods for investigation of building structures. It briefly describes the theory of thermography and discusses the development and optimization of pulse-thermography concerning the detection of reinforcement, voids and inhomogeneities in concrete and brickwork components. The following examples illustrate the development and application of this method.

1 INTRODUCTION

Infrared thermography is an image producing technique that measures the infrared radiation from the surface of a body and associates the distribution of radiation or temperature in a false-color image. Thermography differs in passive and active methods. In passive thermography the temperature differences develop in a natural way, as the temperature distribution by the sun or the cooling process during the night (Hillemeier 2012). To obtain more significant results, temperature differences can also be forced artificially. Thereby unsteady temperature profiles are produced by artificial decrease or supplying heat. This is known as active thermography methods. With the aid of a thermography camera, the normal or generated temperature profile is observed and recorded digitally over a period of time.

Thermography is used primarily in the construction physics sector as a passive process. Snap-shots of outdoor and indoor areas from building elements are produced to illustrate the surface temperature and the surface distribution (Fouad & Richter 2008). These recordings give conclusions on thermotechnical construction defects or irregularities, like thermal bridges, different air flows and moisture contents, which can be evaluated in terms of energysaving thermal insulation and possibly eliminated.

However, thermography can be also used for the localization of inhomogeneities or defects in components. In this case, active thermography techniques are used, in which the surfaces to be examined are heated with an appropriate heat source and the temperature profile and the temperature change is detected with a thermography camera. Depending on the respective heat sources, the following different methods are used (Maierhofer at al. 2002).

At the impulse thermography structural components are irradiated with a heat source and subsequently, the cooling behavior observed on the surface with a thermography camera. In this case the pulse duration of the heat source can vary between seconds to several hours. The thermal conductivity, heat capacity and density of the respective component could be influenced by subsurface inhomogeneities; thus, it could be localized by the temporal behavior of the cooling surface.

At the lock-in-thermography, the surface temperature would be taken after a periodic heating of the structural component with a camera. With the help of periodic temperature signals amplitude and phase images can be calculated. The depth image is independent of the emissivity of the surface and concerning to the frequency of the heating period it is linked with depth information.

A combination of mentioned methods represents the pulse-phase-thermography. The structural component is heated as the pulse-thermography method. Afterwards a Fourier transformation is determined from the time-dependent temperature profile, whereby as in the lock-in-thermography, the amplitudes and phase images can be evaluated. A big advantage of this method is the possibility to obtain the information of temperature from a depth greater than the lock-in-thermography.

The following examples give an insight into different areas of applications of the thermography method, which has become indispensable due to its non-destructive application in the construction sector.

2 DETECTION OF REINFORCEMENT

Another active thermography method is the induction thermography. In contrast to the direct irradiation of the entire concrete surface by use of heat sources, this method only heats in the construction lying reinforcing bars via electromagnetic induction. Even bars with

Figure 1. Performance of the induction thermography.

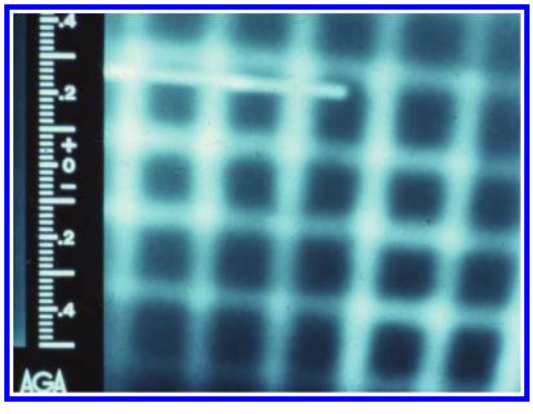

Figure 2. Thermography image of a reinforcement arrangement.

a concrete cover of 10 cm can be heated sufficiently (Hillemeier & Müller-Run 1980).

The heat of the inductively heated rebar spreads in the region of the rods and the heat front migrates to the concrete surface. With a thermography camera that heat propagation is observed on the surface and recorded (Figure 2). The apparent heat lines indicate the position of the individual rods and can be marked directly on the concrete. Through the analysis of temporal change in temperature the respective depths of the reinforcement bars can also be determined.

Further advantages of this method are:

→ the location of the bars can be determined with millimeter accuracy,
→ the thickness of concrete and the degree of reinforcement does not affect the applicability,
→ the necessary heating of the reinforcing rods will not take more than 1 minute depending on power of the induction system,
→ depending on the diameter of the rods up to four layers can be detected.

On the other hand, as a disadvantage, the induction procedure requires huge devices (Figure 1), so it

Figure 3. Measurement setup of the thermography camera and concrete sample with built-in inhomogeneities.

is replaced by the more portable magnetic and radar equipment very quickly.

3 STRUCTURE AND MOISTURE INVESTIGATIONS WITH THE IMPULSTHERMOGRAPHY

Due to the increasing importance of the pulse thermography in the building sector further investigations were performed in the course of a research project of the German Research Foundation (DFG) between the Technical University of Berlin (TUB) and the Federal Institute for Materials Research and Testing (BAM) (BAM & TUB 2005). The intention of this research project was to optimize, develop and apply the pulse-thermography in the field of nondestructive testing in civil engineering. Besides the adaptation of heat sources to different building structures and their materials with different thermal properties, the priority set on the possibility to detect inhomogeneities in concrete and masonry structures (Figure 3). Furthermore, the defects determined from temperature-time curves should be quantitatively assessed by comparisons with numerical simulations and analytical approaches.

For heating the surface of the building component, ideally, a heat source would be necessary to produce a homogeneous temperature field on the radiating surface of the component. Depending on the type of heat transport to the surface, there are three general heating methods: irradiation units, convection units and contact units. As a part of this research project four different heat sources were examined: infrared heater, hot air blower, heat mats and sunlight. An induction heating would have been possible (see above), however, because of the huge equipment this application is not very practical, and therefore the investigation of this heat method was not more pursued.

According to a common comparison the infrared radiator stood out due to the applied power and the uniform temperature distribution as the most suitable option. Starting from the surface, the heat pulse

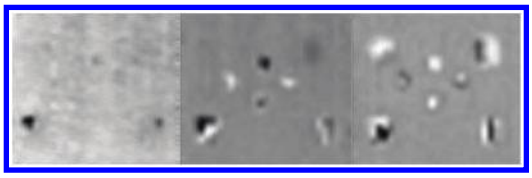

Figure 4. Illustration of the inhomogeneities inside the concrete sample in different depths.

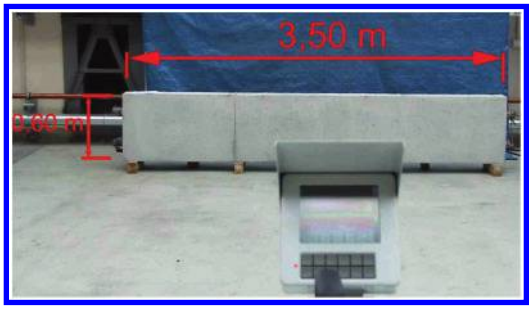

Figure 5. Test samples with incomplete grouted tendons.

of the pulse-thermography causes a transient thermography heat flow into the structural component. Depending on the thermal properties of the component (thermal conductivity λ, specific heat capacity cp, bulk density ρ), the engraved heat is spreading out. If inhomogeneities or defects with different material properties exist within this part, then the heat flow will change accordingly in this area. If voids are producing measurable temperature differences on the surface of the component as a result of the modified heat flow, they can be localized by the time variation of the temperature distribution with a help of an infrared camera. The data were analyzed with thermal images and the cooling curves of the individual data points on the surface were adjusted with different functions. By the application of the pulsephase-thermography a contrast improvement of the graphical illustration of the inhomogeneities has been reached. The determined phase images contain information about the time variation of the heat flow, which, in contrast to pulse-thermography, make deeper structures recognizable and a high-contrast display of the geometry defects is possible.

The results of the performed tests and the numerical calculations and simulations also showed an influence of different material parameters (degree of hydration, porosity, reinforcement density and percentage of steel fibers) to the detection and quantitative assessment of in homogeneities by using pulse-thermography.

Another interesting application in the context of this research project were the studies of the TUB concerning concrete structures with grouted tendons. Here, beam-like samples with tendons and different degrees of reinforcement were provided, whereby the grouting had several voids (Figure 5). On the one hand the test samples were heated by electric heaters; and on the other hand only the tendons were heated directly on

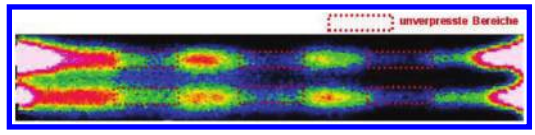

Figure 6. Thermography image of not-grouted areas of the tendons.

the exercise of its electrical resistance. Despite the relatively high concrete cover (5 to 8 cm) and the cladding tube, with both alternatives it was possible to detect the voids very well with the infrared camera. With the direct heating of the tendons, additional statements about the shape and the size of the non-pressed areas could be taken (Figure 6). The influence of the normal reinforcement was negligible in these studies.

The results of the research project have shown that the pulse-thermography is well suited for the detection of inhomogeneities or defects in concrete and masonry components and multilayer systems. However, it should be noted, that the efficiency of this method is limited to the near-surface region (about 10 cm) of the structural component. Measurements of deeper elements would take longer time (up to 1.5 hours).

4 PRACTICAL APPLICATION OF LOCATING VOIDS

As noted in the upper section, the pulsethermography is well suited for locating voids in structures. Partly due to the high cost of equipment (heat sources and infrared camera), however, more practical units of magnetic and radar technology are used. At inspections with an examination area of several thousand square meters, it is worth from an economic perspective to apply a corresponding active thermography method.

Corresponding structures in such a size are industrial floors of warehouses or similar (Walther & Hasenstab 2012). The floors of warehouse and production facilities are subjected to very high loads such as storage and forklift traffic. These heavy-duty floors are often designed as cementitious hardscreed with thicknesses up to 10 mm and can take loads up to 40 N/mm^2 in the respective base course. In general, these ground systems are produced by using of the "wet-on-wet" technique, i.e. that the screed layer is applied to the still fresh concrete base. By inadequate planning, the necessary steps and quality requirements are often not observed for a single-piece composite, which has a negative effect on the compound structure properties of the floor system. Poorly valued shrinkage behavior or incorrectly dimensioned concrete sections can damage the bond between the concrete and screed layer. The consequences are voids in the composite structure and shrinkage cracks.

To save time and cost in investigation of an industrial floor with an area of about 20,000 m^2, the pulsed-thermography was used instead of usual methods. An appropriate heater and an infrared camera were

Figure 7. Measurement of an industrial floor with the pulse-thermography.

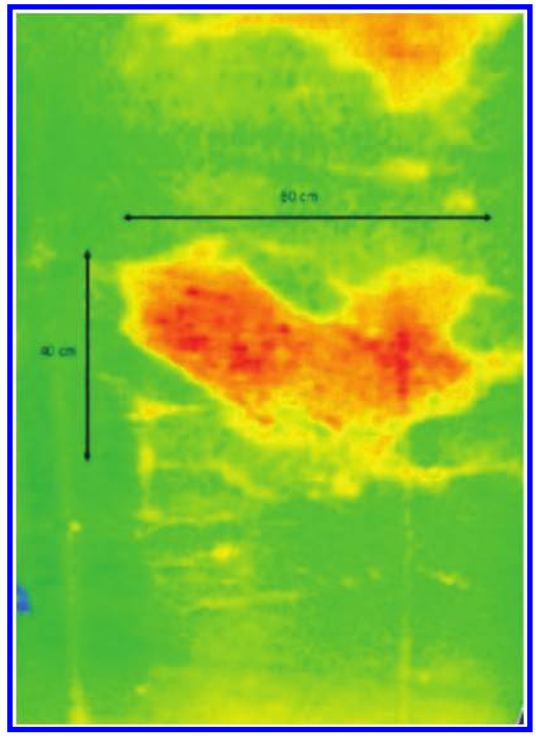

Figure 8. Thermography representation of voids in the floor area of an industrial hall.

installed on a trolley and the entire floor area of the hall has been investigated in a specific grid (Figure 7). The changes of respective coordinates were processed on a computer in conjunction with the associated infrared image, whereby a planar thermography image of the industrial floor was formed.

5 CONCLUSION

Active thermography methods such as the pulsethermography or the induction thermography can be successfully used for non-destructive testing in building structures.

These thermography methods allow among others the location of:

- voids and inhomogeneities in concrete structures up to 10 cm depth,
- delamination of screeds and coatings,
- injection faults in subsequent grouted tendons,
- the arrangement of reinforcement in concrete structures.

These are effective methods which can be used contactless; and also imaging and quantitative analysis of the results in connection with numerical simulations are possible.

Automated devices for inspection and maintenance

Eric Kuhn
CEO, Alpin Technik und Ingenieurservice GmbH, Leipzig, Germany

Carsten Zimmermann
Division manager, Alpin Technik und Ingenieurservice GmbH, Leipzig, Germany

ABSTRACT: Efficiency, minimum shut-downs, less traffic interruptions and the least amount of required time are key factors in construction and maintenance of small and large projects. Automated systems such as robots for inspection and maintenance of bridge stay cables and tunnels, however, can offer significant potential for efficiency and cost reduction. Use of such automated systems will enhance the operation safety as well as extending the useful life of the structures while the cost is reduced.

1 INSTRUCTIONS

Buildings, particularly infrastructural buildings like cable bridges, often not only combine high technical and design demands but are also particularly sensitive to impairment caused by inspection and maintenance measures due to their function. High direct costs from the actual measure and indirect costs due to impairment, e.g. of traffic, are associated with them. This often leads to the delay or non-performance of urgent inspections and maintenance work, which leads to a repair backlog, a delay and over proportional increase of future cost.

2 PREVIOUS APPROACHES

2.1 *Tasks*

In Germany, buildings like bridges are subject to the strict provisions of DIN 1076 that provide for the manner in and the intervals at which the buildings must be inspected (at least one main inspection every 6 years). In other EU states and elsewhere, building maintenance is provided for according to similar directives. The objective is achieving the originally planned service life of the buildings and to warrant that the building can be operated securely across this period. In particular the cable-stayed bridges used as examples here pose considerable challenges to operators and auditors, since the structural elements are often very difficult to reach, complicated in their forms and impairments of building operation are undesired and subject to high economic damage.

In addition to regular building inspections, regular maintenance and repair work is required for bridge cables and other structural elements to achieve the expected service life of the building and to prevent an accumulation of investments. This work is a particular challenge, since practical services are listed in addition to the already-high access effort already high during inspection due to material transport and removal.

2.2 *Time expenditure effect and consequences*

Traditionally and to this day, comprehensive scaffolding, heavy access lifts and cable lifts, cranes and cherry pickers are installed when working at cable-stayed bridges to take staff and technology to the construction site.

The procedures named often block setup areas during long construction and removal times, lead to considerable traffic impairment and thus to considerable access costs even before the actual work has started. A traffic-relevant consequence of conventional planning and setup of scaffolding can be explained using the example of the renovation measure of the Speyer bridge. A congestion of 17 km has been happening every day for the last year. Due building inspections have often been delayed or cancelled because availability of access technology, such as bridge cable inspection devices was limited and the time for setting up the device with its weight of several tons was up to 2 weeks.

In addition to the time aspects, practical aspects in implementation of the actual task are dealt with as well. The conventional access procedures often considerably limit the ability to work. Cables, for example, can only be inspected very conditionally across their entire circumference and, in particular, documented completely. Access lifts that move right on the cables and often weigh between 500 and 1300 kg may damage any possible coating, impair processing of the cable as such and may cause considerable damage particularly in PE-coated strand bundles at the anchors of the PE-pipes, as well as at the extruded corrosion protection sleeve of the upper strand layer in the PE coating when the radial welding seams are run over.

Figure 1. Traditional access methods for cable maintenance.

Figure 2. Traditional cable car system for cable inspection.erection time up to three weeks.

Cranes and cherry pickers are the most progressive ones among the conventional methods. They require an increasing setup area depending on the necessary height and reach. They lead to impairment of the traffic flow. Their use is limited particularly in bridges with cable fans or cable harps running diagonally from the centre of the bridge to the outside. These systems, as well as the access lifts, cannot or only with difficulty be integrated into processing of a bridge cable (e.g. corrosion protection).

3 AUTOMATED SYSTEMS

3.1 *General Approach*

Considering the complex interrelations between maintenance requirements, operating requirements of the

Figure 3. Heavy cable gantry.

building, costs, time budgets, safety aspects, weather aspects, quality requirements, the question will arise of whether some of these aspects can be positively influenced by the development and use of state-of-the-art machines and technologies.

Generally, “extra tasks”, repeating tasks, safety-critical tasks and tasks with a claim to high, consistent quality are considered in more detail.

The positive potentials of automation of processes are particularly in the above tasks. Another aspect that is of importance in assessment is the examination of technologies. Only the willingness to break open “old and loved” processes and changing them by use of state-of-the-art devices, such as robots, and to change processes, will permit considerable increase of efficiency. An example would be the introduction of digital cameras. Once, lots of time was used to frame slides of just a few images. Now, a lot more time is needed to manage a multiple of images. Instead of saving time and dealing with things that may be more pleasant, the new technology has clearly increased time effort without adjustment of own photographing and archiving conduct. Transferred to the use of automatic systems, this means that their true success will only be possible if adjacent processes are adjusted. This is explained by the example of a visual cable inspection with documentation with an ATIS cable robot by untangling previous processes.

3.2 *Automated Visual Inspections*

Once,an cable inspection was executed in that way that a costly access system was installed (bride cable inspection device, crane, cherry picker) before a cable inspection. Than the inspector had to document and measure the cable manually, assess and categorise the damage, move the access system and often only had the chance of recording the entire cable surface with a mirror. Documentation of the intact surfaces or surfaces almost assessed as damage, was impossible. However, documentation of the intact or borderline surfaces is sensible as well in particular in the light of later assessment of possible damage development. Earlier results

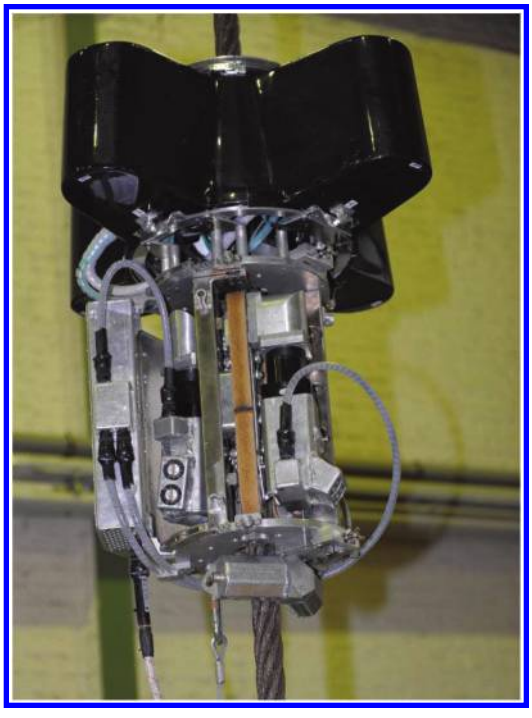

Figure 4. ATIS cable robot with 360° visual inspection module.

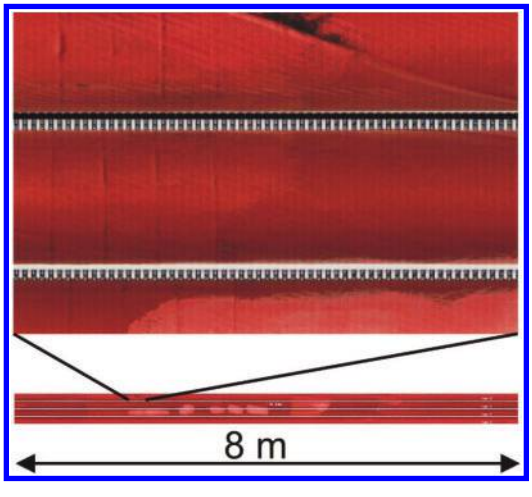

Figure 5. 8 m 360° panorama image and zoomed section.

thus can be compared to current ones and conclusions to damage mechanisms can be drawn. Only the automated visual inspections with robots offer these options. A 360° panorama image of the whole cable surface is usually drawn up to map the original cable length and the complete surface.

This high-resolution figure then can be viewed and assessed in a special viewer and processed into a report.

The panorama images can also be printed on endless paper partially or as a whole.

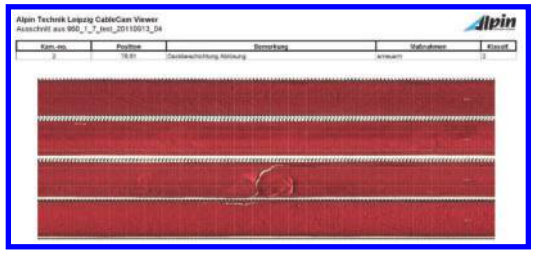

Figure 6. Sheet of a report created with panorama viewer.

Figure 7. A printed section of a cable surface 1:1 scale.

The results of later examinations can be mapped in addition to the results of earlier inspections and permit reliable assessment.

Systems like those described offer the possibility of illustrating other measuring results, such as layer thickness measurement, magnet-inductive results, etc. as well and to thus warrant good assignment to the visual results. Not only cables, but any kind of geometrically equal components, such as tunnels, shafts, facades and pillars, can be inspected and monitored with automated visual inspection methods.

3.3 *Automated Corrosion Protection Methods at Cables*

Automation is available for tasks that require a high degree of repeating, high time-dependence in performance and high secondary costs, such as access costs and high quality claims. These tasks include coating of full locked cables such as bridge cables.

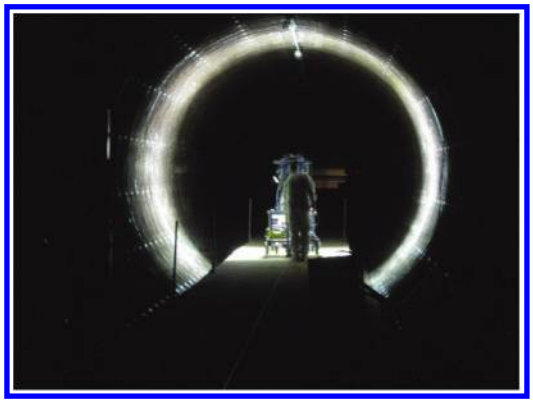

Figure 8. Automated visual inspection of a tunnel with creation of 360° panorama images.

Figure 9. Corrosion protection for cables ATIS Cableskin®, Description

There are diverse reasons for additional coating. In most cases, the causes are in damage to the outer corrosion protection of the cables during construction, the age of present cables and the connected abrasion of the zinc-plating and design reasons. Usually, such cables are protected from outward climatic conditions with multi-layered coating systems after preparation of the substrate by sand blasting and elaborate scaffolding with casings. Application is a synonym for considerable costs, long performance duration, high potential environmental strain and a service life limited to 25 years at most.

Due to these factors, a robot-supported procedure that permits application of butyl rubber-based corrosion protection tapes that have proven their worth for more than 45 years to the cables was introduced in 2008. The tapes optimised for this application form a sleeve virtually impenetrable for water vapour and oxygen with a thickness of approx. 2.6 mm. Their outer, visible layer of UV-stabilised PE can be coloured. Their service life is at least 35 years, with the present experience and independent barrier effect of 4 tape systems, leading to a longer expected service life. Butyl rubber welds into a completely homogeneous sleeve based on interdiffusion once the layers were wrapped with a 50% overlap.

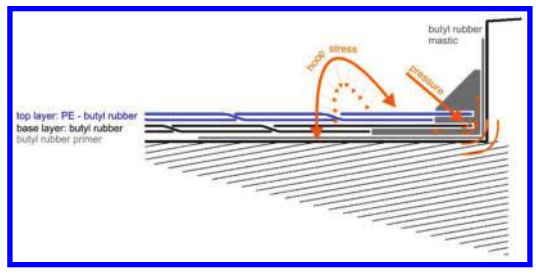

Figure 10. Connection of ATIS Cableskin® with an anchor.

Figure 11. ATIS cable robot with wrapping module for butylrubber tapes on Obere Argen Bridge, Germany.

The system with the brand name ATIS Cableskin® is generally technically approved by construction supervision in Europe as well as in Germany.

Since no requirements are posed to the underground pre-treatment so that sand blasting is not required, drying and airing-off times do not need to be observed, the procedure is perfect for time-critical use. The high plasticity of the butyl rubber provided by the integrated PE films at concurrently high resistance that, e.g., escaping grouting agent and the movement of cables can be easily compensated. The plasticity in particular and the ring tension of the belts that is applied during coiling generate a longitudinal movement conduct of the corrosion protection system that ensures permanent transfers at connection to anchors or interim anchors.

Automation of the process with robots now permit coating work in approx. 10% of the usual time and at approx. 15%–80% of the usual coating costs at clearly increased service life of the system.

Another application area of the butyl rubber based corrosion protection system system is use on PE-coating of parallel wire bundles and parallel strand systems in extend the service life if the plastic is damaged by UV-light.

3.4 *Automated Plastic Welding Methods at Cables*

Not only full locked cables, but also PE-sheathed parallel strands and parallel wire systems require regular maintenance. In particular the outer protective cover

Figure 12. Changing of red color to white due to environmental reasons and composition of PE.

Figure 13. Broken duct after strong vibration.

of these cable systems is subject to diverse strain. This includes UV irradiation, mechanical strain resulting, e.g., from the elongation, creeping for example from the continuous load on the lower sections in systems that move at the top.

Access systems were designed and used until now for running on such cable systems. They have dead weights between 800 kg and 1500 kg. These systems are pulled by steel cable winches, run on rolls and are asymmetrically loaded due to their geometric design. This leads to forces between the system and PE-duct that may cause considerable longitudinal forces.

Another problem is running over radial welding seams that may be present. Usually, the seams have welding beads on the inside of the pipes. The beads push the important corrosion-protecting extrusion of the upper, outer strands when run over and may penetrate this layer. The consequence of this may be the corrosion of the affected strands.

The problems named were, among others, the reason for development of automated methods and robots for the cable test and cable repair in such state-of-the-art cable systems.

3.4.1 *PE-Welding of ducts*

There are diverse reasons for having to weld PE ducts. On the one hand, these may be assembly-technology reasons that require welding hemispheres on present strand bundles longitudinally as well as radially. Furthermore, damages to present cables (UV-resistance

Figure 14. Damage due to impact.

Figure 15. Too short ducts.

Figure 16. Automated longitudinal and radial PE-welding with ATIS cable robot and PE-welding module

not applicable, broken pipes,outer damage or assembly defects) may require performance of sophisticated welding in exposed situations.

Specialists can use robots to implement PE welding in high quality in such situations in state-of-the-art light-weight cableway systems.

Additionally, they can complete repairs in very short times without expensive scaffolding and traffic impairment. A mandatory requirement is highly qualified staff that combines expert knowledge in the areas of cableway construction, plastic welding methods and rope access technology.

3.4.2 *Subsequent Helical Welding*

Rain-wind-induced vibrations of cables are a known but still complex phenomenon. To eliminate this kind of vibration, it is important to right the causes before dealing with the symptoms. An important and particularly effective measure is providing for the assembly of helixes on the cable surface in addition to the structural design of the entire building. Older buildings that

Figure 17. Subsequent welding of helical fillets wit ATIS cable robot and PE-welding module.

did not intend for this measure yet tend to suffer more badly under the harmful vibrations. Therefore, development of a robot that permits subsequent application of a helix like this to the cable surface was important.

This process is fully automatic, so that no person must be in direct proximity of the welding robot. A particular challenge is the underground preparation of the helical seam, since the cables to be processed are often aged and subject to environmental contamination (e.g. diesel adherences). The robots used use, among others, a special procedure that mixes the materials to be welded together and does not cause any significant abrasion of the old material. If such systems are used, this not only avoids traffic impairment but also reduces the direct repair costs and in particular the subsequent maintenance costs.

4 COMPARISON

Renovation of the cables of the Obere Argen Bridge in Germany, for example, would have required blocking of the entire busy motorway A96 more than 40 times. The costs for the scaffolding alone would have corresponded to the final complete cable renovation.

The renovation measure of the cable-stayed bridge in Speyer would have not only led to a clear increase of the coating system's service life with state-of-the-art renovation methods. It would not have taken far more than one year, but only 3 months.

The costs for renovation of the Köhlbrandbrücke cables, including all secondary work and double complete automated cable inspection corresponded to one third of the forecast alternative scaffolding costs.

Without use of robots, the subsequent welding of ca. 35.000 m helixes to the ANZAC bridge in Sydney, Australia would not have been impossible.

5 SUMMARY

Automated machines like robots, in combination with state-of-the-art access systems and expert know-how, offer enormous potentials in maintenance of buildings. According to the current status, significant cost savings concur with a clear quality increase at concurrently low impairment of operations (e.g. traffic) and the shortest duration of execution.

Cable maintenance and other measures at large infrastructure projects do not need to be tantamount with time- and cost-critical activities. The quality of the work to be performed can be much increased as compared to conventional methods.

Structural health monitoring of the Basilica S. Maria di Collemaggio

V. Gattulli, F. Graziosi, F. Federici, F. Potenza & A. Colarieti
CERFIS, University of L'Aquila, L'Aquila, Italy

M. Lepidi
DICCA, University of Genoa, Genoa, Italy

ABSTRACT: The work deals with the main findings obtained during the development of a permanent structural health monitoring system for a monumental church, the Basilica S. Maria di Collemaggio, strongly damaged by the 2009 L'Aquila earthquake. Ongoing studies on the causes of the partial collapse occurred in the transept area have accompanied the monitoring system design and field testing. Benefits and critical issues related with the use of the wireless sensor networks technology are analyzed in the specific case of monumental buildings monitoring. The specific features of the implemented system, purposely designed to detect low-amplitude earthquake-induced vibrations, are discussed. The information collected during one-year data acquisition is summarized, together with critical observations on the operating system. The modal signature extracted from the acceleration measurements has been compared with finite element models, furnishing valuable results to evaluate the effectiveness of the temporary scaffolding structures. Finally, specific features concerning a secondary wireless network of crack propagation sensors are presented.

1 INTRODUCTION

Structural health monitoring is an emerging tool for reliable structural assessments. Efficient monitoring programs may help in the characterization of the progressive decay of structural performances, both in the short and in long term, providing useful information for optimized maintenance and safety.

Although the importance of monitoring action is widely recognized, the deployment of monitoring systems is still limited by some critical factors: high costs of the measurement equipment, difficulty in installation due to large instruments size and need of a wired communication and power infrastructure.

In recent years, wireless communication, low power computing and sensing technology has paved the way to overcome these problems, with the application of Wireless Sensor Networks technology to face Structural Health Monitoring problems (Federici et al 2012, Liu et al. 2012).

The paper describes the design, deployment and validation of a wireless sensor network for structural monitoring of a monumental structure, the Basilica Santa Maria di Collemaggio at L'Aquila, Italy. The system is specifically designed for seismic and dynamic response analysis based on acceleration, crack opening and wall inclination measurements.

Since 1999 the Structural Engineering Department (DISAT) of the University of L'Aquila pursued a wide campaign of experimental measurement on the building, leading to the formulation and updating of finite element models (Antonacci et al. 2001).

In April 2009 a 6.3 Mw earthquake struck the city of L'Aquila, causing considerable damage to the Basilica. A partial collapse occurred in the transept area, caused the breakdown of the dome, and dramatically altered the whole structural characteristics.

The assessment of the changes occurred in structure's behavior, together with the analysis of the structural modifications coming out from successive consolidation and restoration interventions, required the setup of a permanent monitoring system. Such a monitoring system is part of a wide monitoring program supported by the Italian Civil Protection, and it is one of the first totally based on Wireless Sensor Networks technology (Antonacci et al. 2011).

The system development can be broadly divided into two distinct phases: the design and deployment of an accelerometric monitoring network (essentially designed to capture the global seismic response) and the design and deployment of a second network for wall inclination and crack width local measurement.

The paper is structured as follows: Section 2 briefly summarizes the state-of-the-art of monitoring systems of infrastructure, specifically concerning systems based on wireless sensor networks. Section 3 briefly describes the operational scenario and details the implementation of the monitoring networks. Section 4 illustrates the analysis of the data collected. Concluding remarks are finally pointed out.

2 WIRELESS SENSOR NETWORKS FOR STRUCTURAL HEALTH MONITORING

In recent years, progressive developments in wireless communication, low power computing and sensing technology has led to the application of Wireless Sensor Networks technology to Structural Health Monitoring problems.

A wireless sensor network consists of multiple autonomous sensing devices communicating to each other via a radio connection. New generation sensors (e.g. MEMS technology based accelerometers, fiber optic sensors, piezoelectric sensors) with small size and low power consumption provide greater deployment flexibility.

Wireless technology, however, presents some serious drawbacks: for example, measure synchronization can be extremely more problematic than in the wired case. Moreover, battery-powered nodes heavily relies on duty cycling techniques for energy saving. This aspect is extremely limiting for long term monitoring applications (Park et al. 2005). Several solutions have been presented in literature to address these issues (Paek et al. 2005, Niu et al. 2010, Boyle et al. 2011). Illinois Structural Health Monitoring Project presented a hardware and software wireless sensing platform specifically designed for structural health monitoring applications. The solution (Mechitov et al. 2006) is based on a general purpose wireless communication and computation platform, the Imote2 wireless node manufactured by Memsic. The platform is supplemented by a sensor board (SHM-A) specifically designed for structural monitoring. A custom management software (ISHMP Toolsuite) based on TinyOS operating system allows easy management of sensor data acquisition and communication. The software tool suite integrates a multi-hop routing protocol (AODV) in addition to an original data synchronization protocol, which combines FTSP network synchronization and a specially developed local delay correction algorithm (Rice et al. 2011). ISHMP solution has been successfully employed in Korean Jindo Bridge monitoring project (Nagayama et al. 2011, Cho et al. 2011).

Anyhow, the experimental applications of wireless sensor networks are still limited, with traditional monitoring solution remaining on a dominant position. The Italian Department of Civil Protection maintains and utilizes an extensive accelerometric monitoring network (Spina et al. 2011). The system is often integrated and strengthened by temporary monitoring networks (e.g. after catastrophic events in order to monitor relevant or strategic sites during the post-catastrophe emergency phase), which are managed also by the Department, by local governments or other entities, such as Universities. OSS main monitoring network is an accelerometric monitoring system installed on public buildings, bridges and dams. Each structure is monitored by up to 32 force balance accelerometers wired connected to a central acquisition and transmission unit. Recently, the RAMSES monitoring system, comprising three MEMS accelerometer based sensing wireless unit per building has been introduced. Moreover, a GSM communication based mobile monitoring system (OSM) is frequently used in post-disaster damaged buildings monitoring.

3 STRUCTURAL HEALTH MONITORING OF THE BASILICA DI COLLEMAGGIO

The basilica S. Maria di Collemaggio is the most important church in the city of L'Aquila, Italy. The church has a central nave, which measures 61 m in length and 11.3 m in width and two side aisles measuring 7.8 m and 8.0 m in width respectively. Naves and side aisles are separated by two series of seven columns with a height of 5.3 m and an average central section of about 1 m in diameter. Four external walls, with a masonry thickness varying from 0.95 m to 1.05 m are connected on two sides with the church façade and transept area. Other adjacent structures are partially connected with the Basilica main body: an octagonal tower connected on one side of the façade and another masonry building adjacent for about 40% of the external walls. The church has a wooden roof supported from trusses placed in a cross-sectional direction respect external walls. The dynamic behavior of the Basilica was characterized by means of numerical and experimental studies conducted before the occurrence of the 2009 L'Aquila earthquake. The earthquake caused a partial collapse of the structure in the transept area.

The will to deepen collapse possible causes and to investigate possible modification of structure dynamics response after retrofitting has led to the development and successive deployment of a structural monitoring system along the damaged church. In order to explore possible advantages arising from the use of innovative technologies (e.g. wireless communication and innovative sensing elements), the system has been based on a wireless sensor network. According to the project requirements, the work consists in the implementation of two main system: an accelerometric network for dynamic response measurement and a secondary network for crack width and wall inclination monitoring.

3.1 *Accelerometric Monitoring System*

The first phase of the system deployment has included the design, implementation, installation and test of an accelerometric monitoring network. The main goal was an accurate measurement of the building dynamic response, both to environmental actions and to the low-amplitude seismic events which occasionally continue to interest the site.

Memsic Imote2 wireless communication platform, along with ISHMP derived SHM-A board were chosen as main monitoring platform. Each SHM-A board includes ST microelectronics LIS344ALH MEMS triaxial accelerometer, Sensirion SHT11 temperature

Table 1. LIS344ALH mechanical characteristics.

Cross Axis	± 2 %

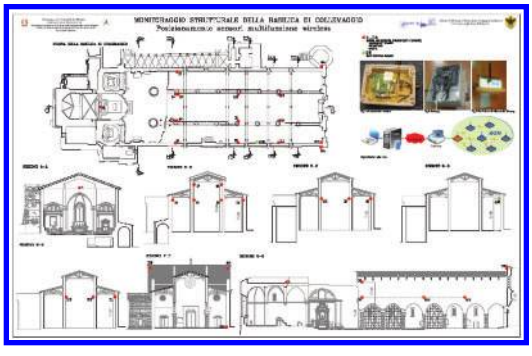

Figure 1. Drawings for the placement of the 16 smart sensors installed at the Basilica di S. Maria di Collemaggio.

and humidity sensor, and TAOS 2561 luminosity sensor. The board features also an advanced 16 bit analog to digital converter, the QF4A512 model by QuikFilter. Performance characteristics of MEMS accelerometer relevant to the present analysis are resumed in Table 1.

Imote2 wireless communication platform includes Marvell Xscale PXA271 processor and Texas Instruments CC2420 2.4 GHz, 802.15.4 compliant radio transceiver. Processor chip features a processor core with a clock frequency of up to 416 MHz, with the possibility of radical downscaling (down to 13 MHz) for low power consumption, SRAM and Flash memory bot for an amount of 32 MB.

The board is actively supported by TinyOS operating system, both in 1.x and 2 versions. ISHMP developed a software tool-suite based on TinyOS 1.x, which address specific problems of Structural Health Monitoring application. Implemented wireless sensor nodes, along with FTSP based synchronization and AODV multi-hop routing from ISHMP tool-suite are the main software components used in the accelerometric monitoring system.

A total of 16 sensor nodes, conveniently installed in custom IP-45 compliant packages, were deployed along the church on June 2011.

The majority of sensor nodes were placed inside the structure, ten along the main nave, one at the base of a column base and one in the transept area. Two sensor nodes were instead placed externally, at the top corners of the church facade (Fig.1).

Figure 2. Installation phases of the monitoring system: a) b) sensor positioning on the central walls of the nave, c) sensor positioning beyond the facade, d) f) sensor views, g) on-site testing, h) sensor positioning at the end of the nave walls.

A single board computer, connected with a network apparatus, acts as monitoring system gateway. The network apparatus guarantees 3G connectivity (for the automatic uploading of the measurement results to a remote server) and Wi-Fi local connectivity (for the direct access to the monitoring system; this feature is useful when performing local tests – as the operator don't needs an internet access to interact with the network – and as a backup redundant system in case of down of the 3G network access).

The gateway is connected to an Imote2 node, which acts as sink for the network: it forwards operating commands from the gateway to the leaf nodes and collects measurements data. Each leaf node communicates with the sink by means of a multi-hop routing protocol, thus allowing to effectively cover the wide area of the church. The central gateway runs a measurement scheduling application, which automatically handles data acquisition on leaf nodes, measured data collection, data compression and load on a remote server machine.

Both the gateway subsystem and leaf nodes are network powered. This choice, apparently counterintuitive, has two main motivations. First, the research for a coverage of the dynamic response as far as possible temporally extended prevents from the use of duty cycling energy savings techniques. Moreover, any maintenance intervention (such as node battery replacement) requires the use of heavy-duty vehicles (trucks and cranes are needed to reach the heights at which sensor nodes are placed), and should then be avoided given the precarious state of the Basilica. An Uninterruptible Power Supply Device guarantees the continuity of monitoring system operability. Reduced possibility of TinyOS 1.x scheduler prevents the sensor nodes from simultaneously acquire data from sensor and transmit data to the sink node. A scheduling algorithm able to alternate two groups of node in the mentioned operation was developed. In such way it is still possible to obtain a continuous coverage of the dynamic response of the building.

Figure 3. Light model (scale 1:3) of modular steel-made 3D frame: (a) basic configuration, (b) sensor-node of wireless network; (c) comparison with sensor of traditional wired network.

3.2 *Crack and wall inclination monitoring system*

Phase two of the monitoring system development involves the deployment of crackmeter and inclinometer sensors in the Basilica. Some of the limitations described in section 3.1 (especially those related to software implementation), along with the end of commercial life cycle of Imote2 platform has led to the development of a novel custom sensing platform. The developed wireless sensing platform is currently at a prototype stage and is going to be installed in the Basilica in the near future. The node is based on Atmel Zigbit 900 module, which features Atmel AT86RF212 868 MHz, 802.15.4 compliant radio transceiver. Software stack won't be based on TinyOS system and will fully implement 802.15.4 protocol stack. Nodes will be battery powered: this choice is appropriate in case of crack width and inclination measurements, as the reduced measurement frequency allows an extensive use of duty cycle power saving techniques. The possibility of implementing energy saving techniques in the case of accelerometric time-extended measures will be also further investigated.

4 DATA COLLECTION AND ANALYSIS

The analysis of the data collected by the monitoring system has been anticipated by a preliminary phase, devoted to compare the performance of each single wireless node with a reference wired sensor in a controlled laboratory environment (Fig.3).

4.1 *Preliminary validation phase*

The validation phase of the monitoring system had two main goals: the characterization of each wireless sensor node performances and the analysis of the structural dynamic response by means of the measured acceleration signals.

Two different types of test have been conducted using a modular structural steel frame to characterize a SHM-WSN in a laboratory environment. In the first series a direct comparison between a single wireless sensor (the above described IMOTE 2 type) and a wired accelerometer (SA107LN-Columbia) has been conducted (Fig. 3). With this configuration the frame responses both to a little impulse in longitudinal direction and under environmental noise have been recorded. Others tests have been made using six wireless sensors, two for each slab, placed at diagonally opposite corners. This particular experimental setup has been used to identify the main modal frequencies, shapes and damping. Again both impulsive and ambient tests have been performed. The results, here not reported for sake of brevity, were largely satisfying to the project purposes.

4.2 *Available on-site pre-earthquake data*

Before the occurring of the 2009 earthquake a numerical and experimental study permitted to characterize the dynamic behavior of the Basilica (Antonacci et al. 2001). The experimental data were firstly used to identify a modal model and then to determine suitable FE models of the church. Preliminary numerical analyses were carried out on the basis of several assumptions regarding: (1) mechanical parameters of masonry, (2) timber trusses of the roof, (3) restraints in walls and columns, (4) links among structural components. Afterwards the Basilica was excited at low vibration levels by an instrumented hammer and a tunable, mono-frequent mechanical exciter (vibrodyne). Several tests have been carried out, with different positions of the instruments and impact locations, in order to excite and to measure as many modes as possible.

The vibrodyne was located on the top of a lateral wall. The frequency responses were directly measured around the first two modes; these are the most important ones that describe the dynamic response of the church. Experimental data were used to identify natural frequencies, modal displacements and damping factors. The first campaign of tests permitted to recognize at least four major resonance peaks in the in the frequency range $0.8 \div 3.0$ *Hz*. The first two peaks were close to the frequency values 1.25 and 1.7 *Hz*. Other peaks were present over 2 *Hz*. Two of them, around 2.5 and 2.7 *Hz*, were well defined in all tests. Secondary peaks, around 2.2, 2.3 and 2.6 *Hz*, were not always visible in all the responses; they indicated highly coupled modes. These peaks, however, were estimated to be less important: numerical analysis indicated that the participating mass of first two modes is at least 85% of total mass in the transverse direction of the church.

After retrofitting, all peaks were shifted to higher frequencies. The first two moved around 1.45 *Hz* and 2.12 *Hz* respectively. Other peaks were clearly visible around 2.6 and 2.95 *Hz*. Secondary peaks, which were not always visible in all the responses, were recognizable even in this case. Higher frequencies were a consequence of the increasing stiffness brought about by retrofitting. Other dynamic testing, performed on the façade, permitted to evidence that out-of-plane

Table 2. Recorded response of Basilica di Collemaggio.

Earthquake	Date	Time (UTC)	Magnitude	Peak Response Acceleration [g]
Main Shock Emilia	May 5th 2012	2:03 AM	5.9	0.0054
Aftershock Emilia	May 5th, 2012	1:18 PM	5.1	0.0018
Shock Ravenna	June 6th, 2012	6:08 AM	4.5	0.0014
L'Aquila	October, 14, 2012	4:32 PM	2.8	0.0072
L'Aquila	October 10, 2012	2:52 AM	3.6	0.0073
L'Aquila	November, 11, 2012	3:37 AM	3.2	0.0082

local modes of this element were in a frequency range higher than the transversal mode of the nave. Recently, the available data from the previous on-site dynamic campaign have been used to develop complete finite element models of the Basilica, able to reproduce the main modal identified characteristics and the collapse scenario (Gattulli et al. 2013). A campaign of numerical simulations has been conducted to evaluate the dynamic response of the Basilica together with the temporary retrofitting under small earthquakes.

4.3 *Experimental on-site post-earthquake data*

During the months following the installation, the monitoring system has been continuously enhanced and brought to complete and automatic management to sense seismic induced vibrations. During this path, test campaigns have been conducted with different induced source of vibrations such as hammer, ambient vibrations and free-vibration tests.

To date, six major events have been detected. Three are associated with the Emilia region and three are local events at L'Aquila. Table 1 shows the maximum accelerations registered during each earthquake. Recorded structural responses show prevailing out-of-plane oscillations of the nave walls.

Low magnitude events furnish a sufficient level of energy to overcome the noise threshold of the monitoring system, allowing acceleration data recording characterized by sufficient vibration signature. Consequently, spectral analysis has been used to extract preliminary information from recorded data clearly evidencing the change in the main natural frequencies with respect the values measured in the pre-earthquake configuration. Table 3 summarizes the main findings emerging from spectral analysis of the recorded data. The main peak frequency of the out-plane acceleration spectra at different sensors located on each macro-element (Fig. 4a) are reported in Table 3, as

Table 3. Main peak frequency of measured acceleration spectra.

Earthquake	Macro-element D (Hz)	Macro-element C (Hz)	Macro-element B (Hz)
20/5/2012 (main)			0.85
20/5/2012 (after)	0.95	0.95	
06/6/2012			1.02
14/10/2012	0.95	0.95	
30/10/2012	1.00	1.00	
16/11/2012			1.00

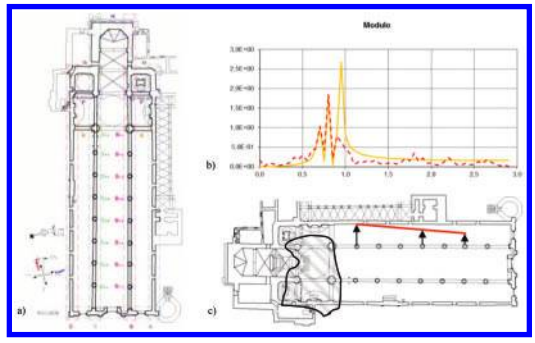

Figure 4. Basilica S. Maria Collemaggio: a) macro-elements definition, b) amplitude of the experimental transfer function c) identified modal shape.

extracted by different occurred earthquakes. Similar frequency values have been obtained for the first mode of the finite element model of Basilica in the post-earthquake configuration, including temporary scaffolding structures.

Fig. 4b compares the amplitude of the experimental transfer function (red dotted) with the transfer function amplitude of a modal model identified through the modal identification results obtained by the Goyder technique.

Additional information is provided by the comparison of pre- and post- earthquake experimental data. A stiffness reduction of the current configuration with respect to the pre-earthquake is evident. The current configuration is more flexible, since the principal mode period moves from 0.69*s* to 0.95*s*, suffering therefore a 37% increase.

4.4 *Numerical models*

Structural analyses have been conducted through a finite element model (Fig.5a,c), allowing the characterization of the seismic adequacy, in the pre-earthquake state (Gattulli et al. 2013) and in the post-earthquake taking into account temporary scaffolding structures (Fig.5b,d). Pre-earthquake linear structural analyses using the design response spectrum provided by the Italian code have evidenced the strong vulnerability of the nave walls, especially the interior ones, with respect to transversal seismic actions,

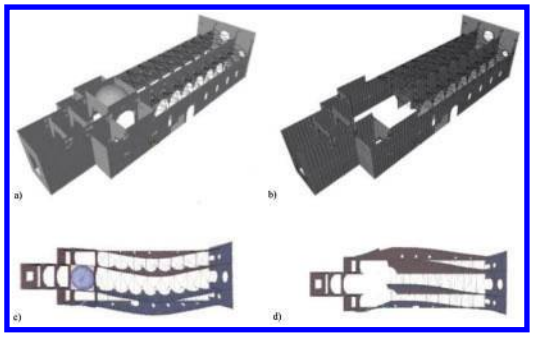

Figure 5. Finite element model and first mode shape: a), c) pre-earthquake, b), d) post-earthquake.

Table 4. Modal period and frequency inferred from Basilica finite elements model, pre and post earthquake comparison.

	Pre-earthquake model		Post-earthquake model	
Mode	Period [s]	Frequency [Hz]	Period [s]	Frequency [Hz]
1	0,6902	1,4490	0,9488	1,0540
2	0,4520	2,2123	0,5161	1,9375
3	0,4048	2,4701	0,4209	2,3758
4	0,3450	2,8986	0,3703	2,7005
5	0,3268	3,0604	0,3365	2,9719

even in the presence of the light steel bracing systems connecting them.

The absence of the transverse main arch due to the collapse of the transept reduces the transversal seismic adequacy.

5 CONCLUSIONS

This paper described the design, deployment and verification of a structural health monitoring system for a monumental building, the Basilica S.Maria di Collemaggio in L'Aquila, Italy. Measured and numerical data have been continuously integrated during one-year activity in order to perform a safety assessment before and after the earthquake, which struck the structure in 2009. It has been possible to analyze various critical issues related to the use of a wireless network of sensors, such as synchronization issues and MEMS sensors noise. Among the main results, monitoring action has allowed to identify reliable finite element model which have permitted the evaluation of the seismic adequacy according to the Italian code.

Experimental study on bridge damage identification based on wavelet packet energy curvature difference method

Zhu Yu, He Xia & Jiawang Zhan
School of Civil Engineering, Beijing Jiaotong University, Beijing, China

ABSTRACT: Among those damage identification methods, the Wavelet Packet Energy Curvature Difference (WPECD) Method is an effective one. However, most of the existing methods rely on numerical simulation and are unverified via experiment, and very few of them have been applied to practice. In this paper, the validity of WPECD in structural damage identification is verified by a numerical example. A damage simulation experiment is taken on a real replaced girder from a road bridge in Cangzhou, China. Two damage cases are applied and the acceleration responses at the measuring points are obtained, based on which the damages are identified with the WPECD Method and the influence of wavelet function and decomposition level is studied. The results show that the WPECD Method can identify structure damage efficiently and can be put into practice.

Keywords: wavelet packet analysis, WPECD, damage identification, experiment

1 INTRODUCTION

The key components of structures will get accumulative damage and defect along with the service, which will influence structure safety. For this reason, Structural Healthy Monitoring (SHM) becomes quite important to the performance evaluation of engineering structure. Generally speaking, SHM can be divided into Local Detection and Integral Detection. Local Detection obtains the damage information via technologies such as infrared and ultrasonic inspection, while Integral Detection evaluates the damage by the change of structure vibration characteristics. As for most of the traditional damage identification methods which are based on structure vibration, the modal parameters are obtained by means of Fourier Transform. However, Fourier Transform is insufficient in high frequency modal analysis and it will lose the time domain information during the transform. As a result, it is impossible to evaluate the damage characteristic accurately.

The Wavelet Transform (WT) is a signal analysis method which can overcome the shortcoming mentioned above. Wavelet is composed of a cluster of primary functions which can describe the signal local characteristic whatever in time or frequency domain. Due to this reason, wavelet analysis can reflect the damage information hidden in the test data. There are many research results on damage identification based on WT. However, the WT resolution in high-frequency range is at a low level.

In order to overcome this disadvantage, the Wavelet Packet Transform (WPT) is proposed which can provide integral decomposition of different levels. Ding and Li et al. apply Wavelet Packet Energy Spectrum to structure damage alerting. Sun et al. takes the wavelet packet signal energy as the input of neural network to identify structure damage. Han and Ren propose a damage identification index as Energy Gradient based on WPT and verify it by lab experiment.

Among these method based on WPT, most of them are during theoretical research and a few of them are verified under laboratory condition. However, the actual damage is relatively more complex. In this paper, a method based on Wavelet Packet Energy Curvature Difference (WPECD) is proposed. By means of numerical simulation and site test, this method is verified.

2 DAMAGE IDENTIFICATION BASED ON WAVELET PACKET ANALYSIS

2.1 *Introduction to Wavelet Packet Theory*

As for WT with multiresolution, it only decomposes the low-frequency part of the signal, leading the bad resolution in high-frequency signal. Therefore it is not applicable for all kinds of signals. However, WPT decomposes every sub-band into two bands at every level, covering whatever high or low frequency part, shown in Fig. 1

For this reason, WPT can provide a more accurate signal analysis method, which can improve the resolution.

The wavelet packet function can be expressed as $\psi^i_{j,k}$, where i,j,k are modulation, scale and translation parameter respectively.

$$\psi^i_{j,k}(t) = 2^{j/2}\psi^i(2^j t - k) \quad i = 1,2,\ldots\ldots \tag{1}$$

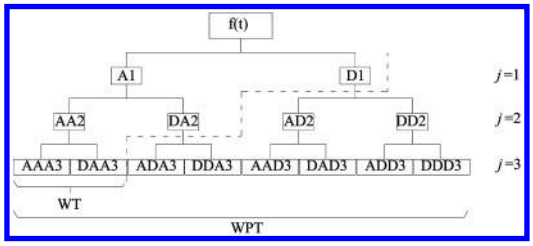

Figure 1. Wavelet Transform and Wavelet Packet Transform.

Here, ψ^i can be obtained by the following recurrence relation.

$$\psi^{2i}(t)=\sqrt{2}\sum_{-\infty}^{+\infty}h(k)\psi^i(2t-k) \tag{2}$$

$$\psi^{2i+1}(t)=\sqrt{2}\sum_{-\infty}^{+\infty}g(k)\psi^i(2t-k) \tag{3}$$

where ψ is the Mother Wavelet, $h(k)$ and $g(k)$ are integral mirror filter coefficients which are correlative to scale function and Mother Wavelet.

The recurrence relations of the jth and $j+1$th wavelet packet decomposition are shown as follows,

$$f_j^i(t)=f_{j+1}^{2i-1}(t)+f_{j+1}^{2i}(t) \tag{4}$$

$$f_{j+1}^{2i-1}(t)=Hf_j^i(t) \tag{5}$$

$$f_{j+1}^{2i}(t)=Gf_j^i(t) \tag{6}$$

where H and G are filter operators corresponding to $h(k)$ and $g(k)$ respectively.

$$H\{\bullet\}=\sum_{k=-\infty}^{\infty}h(k-2t) \tag{7}$$

$$G\{\bullet\}=\sum_{-\infty}^{\infty}g(k-2t) \tag{8}$$

The initial signal $f(t)$ can be expressed as follows via jth wavelet packet decomposition.

$$f(t)=\sum_{i=1}^{2^j}f_j^i(t) \tag{9}$$

The wavelet packet component signal $f_j^i(t)$ can be expressed as the linear combination of wavelet packet function.

$$f_j^i(t)=\sum_{-\infty}^{+\infty}c_{j,k}^i(t)\psi_{j,k}^i(t) \tag{10}$$

The wavelet packet coefficient $c_{j,k}^i$ can be derived as follows,

$$c_{j,k}^i=\int_{-\infty}^{+\infty}f(t)\psi_{j,k}^i(t)dt \tag{11}$$

where these coefficients meet the orthogonality condition.

$$\psi_{j,k}^m(t)\psi_{j,k}^n(t)=0 \quad when \quad m\neq n \tag{12}$$

In practice, wavelet packet decomposition is often applied in the energy monitoring. The energy of wavelet packet signal can be defined as

$$E_f=\int_{-\infty}^{\infty}f^2(t)dt=\sum_{m=1}^{2^j}\sum_{n=1}^{2^j}\int_{-\infty}^{\infty}f_j^m(t)f_j^n(t)dt \tag{13}$$

Substitute Eq. (10) to (13), with the orthogonality condition in Eq. (12), one obtains

$$E_f=\sum_{i=1}^{2^j}E_{f_j^i} \tag{14}$$

where the wavelet packet component energy E_{fj} can be regarded as the energy stored in component signal $f_j^i(t)$.

$$E_{f_j^i}=\int_{-\infty}^{\infty}f_j^i(t)^2dt \tag{15}$$

As for Eq. (14), it can be explained that the total energy of the signal is the sum of wavelet packet component energy corresponding to different frequency bands.

The component energy is very sensitive to the change of signal characteristic, which can reflect the inherent feature of signal. If there is damage in the structure, a certain frequency of response will fluctuate, thus the energies of some signal components will change. Therefore, the change of energy distribution of measured response signal can be used to identify structure damage.

2.2 *Solution of unevenly spaced curvature*

In practice, curvature can be obtained by second order difference of dependent variable, which is the gradient of slope, as shown in Fig. 2.

For unevenly spaced case the curvature can be expressed as

$$K_i=y_i^{''}=\frac{\frac{y_{i+1}-y_i}{h_{i+1}}-\frac{y_i-y_{i-1}}{h_{i-1}}}{\frac{h_{i+1}+h_{i-1}}{2}} \tag{16}$$

where the numerator is the slope difference of the two curves around the node and the denominator is the space of the two curves. If the nodes are evenly spaced, that is $h_{i-1}=h_{i+1}$, then

$$K_i=y_i^{''}=\frac{\frac{y_{i+1}-y_i}{h}-\frac{y_i-y_{i-1}}{h}}{h}=\frac{y_{i+1}-2y_i+y_{i-1}}{h^2} \tag{17}$$

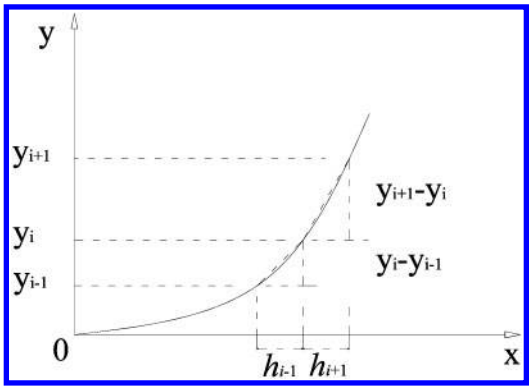

Figure 2. Curvature sketch.

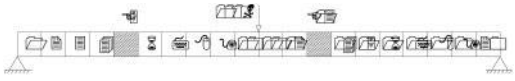

Figure 3. Sketch of the damaged girder.

which is just the formula to solve curvature with Second Order Finite Difference Method.

Substitute wavelet packet energy $E_{f_j^i}$ for y in Eq. (16), one can get the Wavelet Packet Energy Curvature (WPEC). The Wavelet Packet Energy Curvature Difference (WPECD) is the difference of WPEC under undamaged and damaged cases, defined as

$$\Delta K_i = K_i^u - K_i^d \tag{18}$$

where K_i^u and K_i^d are WPEC under undamaged case and damaged case respectively. This index will be applied to structure damage identification.

3 NUMERICAL EXAMPLE

Take a 20 m simply-supported girder for example, as shown in Fig. 3 with $E = 1 \times 10^8$ Pa, $\rho = 2500$ kg/m^3, $A = 1$ m^2, $I = 0.083$ m^4. There are altogether 20 elements with 21 nodes. An exciting force of 100 N is imposed on the middle point of the girder. Then transient analysis is done by ANSYS. Here, damage is simulated as the decrease of stiffness. Assume the stiffness of elements E5 and E13 decreases by 5% and 10%, respectively. Take WPT on responses of all the 21 nodes under the exciting force before and after damage respectively. The Daubechies Wavelet with order $N = 15$ (Db 15) is chosen as the wavelet function and the decomposition level is 7. The WPECDs of the first 8 components are shown in Fig. 4.

It can be observed that the magnitude of the first component energy is much higher than those of others. The sum of these 8 components is calculated, shown in Fig. 5.

It can be seen that there are peaks on the WPECD curves where there are damage. Even the damage is quite slight (E5), the peak is still obvious, which proves

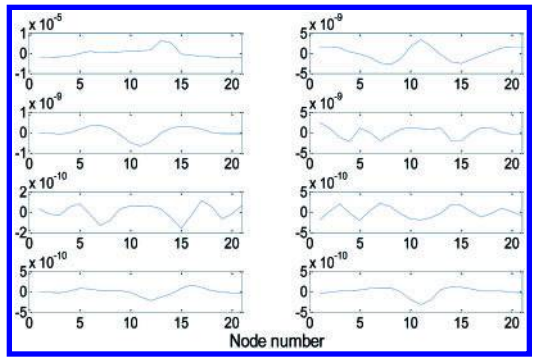

Figure 4. WPECD of damaged girder (First 8 components).

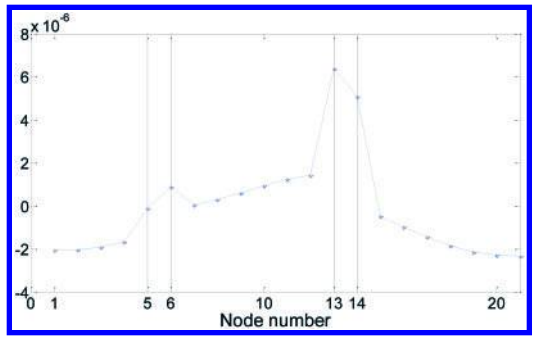

Figure 5. Sum of the first 8 WPECD components.

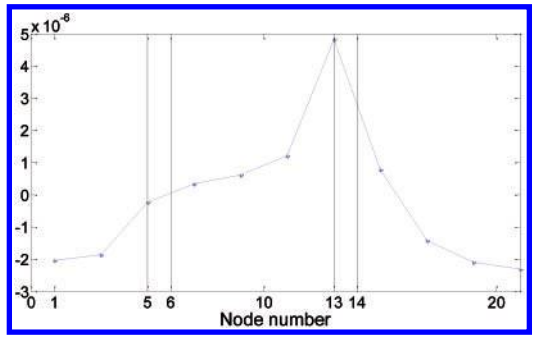

Figure 6. WPECD under sparse measuring points.

that this method is sensitive to damage. Besides, the peak of E13 is higher than that of E5, which indicates the fact that the damage degree in E13 (10%) is higher than E5 (5%).

The influence of sparse measuring points is investigated. Only 11 nodes (1, 3, 5, …, 21) are taken as measuring points and the result is shown in Fig. 6.

It can be seen that the damage of E13 can still be identified. However, the damage information of E5 is not as obvious as before, since the damage degree is too slight. This shows that there is some influence of fewer measuring points on slight damage and in actual test the measuring points should be as intensive as possible where there may be some damage.

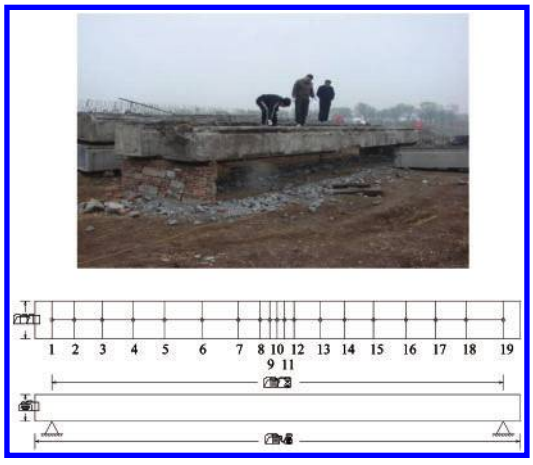

Figure 7. Sketch and measurement arrangement of the girder.

Figure 8. Excitation of hammer.

4 EXPERIMENTAL STUDY

4.1 *Experimental introduction*

The experimental girder is removed from a bridge located on the Ziyaxin River, Cangzhou, China, as shown in Fig. 7.

The length and width of the girder are 12.06 m and 1 m, respectively. There are 19 accelerometers fixed on the middle line of the girder, and those near the midspan (damage location) are relatively intensive. The girder is excited by a hammer between Node 14 and 15. The hammer free falls from the same height every time in order to make sure that the forces are the same in different cases.

4.2 *Damage cases*

There are two steps to simulate the damage.

Case 1: The 10-cm-thick concrete at the bottom of mid-span is removed and 2 steel bars on one side of the midspan bottom are cut. There is no visible crack on the girder. The damage location is corresponding to Node 10 in Fig. 7

Case 2: More steel bars are cut, only two left. A whole-length crack appears with the width 3 mm at the bottom.

Figure 9. Damage case (left: Case 1; right: Case 2).

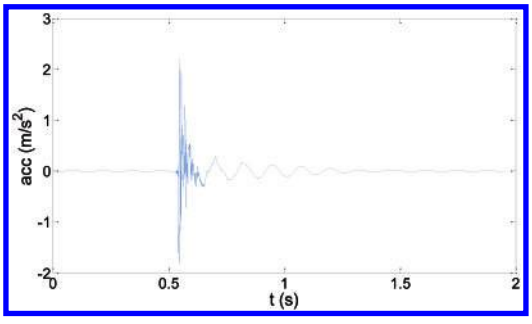

Figure 10. Measured acceleration time-history.

Table 1. The 1st order frequency and variation of the girder.

Case	1st freq. (Hz)	1st freq. variation V^*	Damage location
Undamaged	8.704	—	—
Damage 1	8.192	−5.88%	Node 10
Damage 2	6.144	−29.4%	Node 9, 10

As for damage Case 2, although the steel bars are cut at midspan, the actual crack appears to 25 cm left of the midspan, shown in Fig. 9. Thus the actual damage location should be between Node 9 and 10, and more likely to be in Node 9.

4.3 *Vibration measurement*

The accelerations of the 19 measuring points under undamaged case and the two damaged cases are measured. Take Node 14 as an example, the acceleration time history under Case 1 is shown in Fig. 10. Moreover, the frequencies under the 3 cases are shown in Table 1, in which $V^* = (f_d - f_u)/f_u$, where f_d and f_u are frequencies under undamaged and damaged cases

The reduction of frequency can be used to indicate the appearance of damage. The more the frequency reduces, the more the damage is. However, the damage location should be paid more attention.

4.4 *Damage identification based on WPECD*

Take WPT on all of the node responses under the undamaged case and the two damaged cases with 7 decomposition levels. The wavelet function is Db 15. The WPECDs of the two damage cases are shown in Fig. 11.

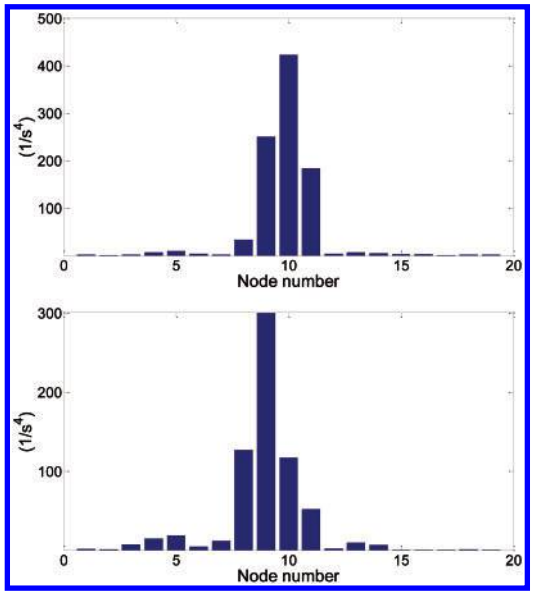

Figure 11. WPECD (upper: Case 1; lower: Case 2; db15).

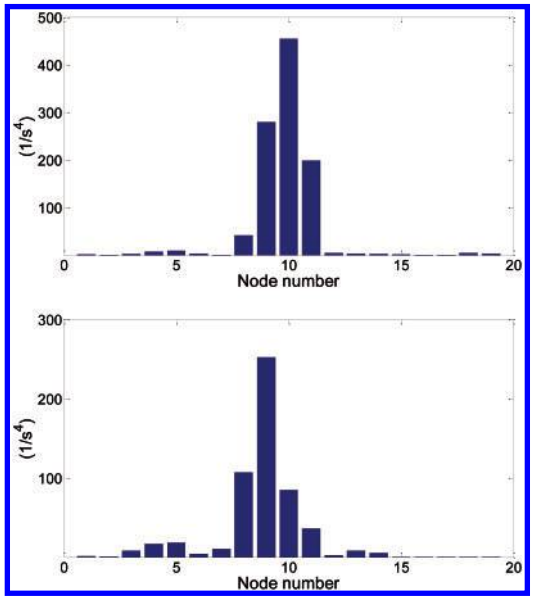

Figure 12. WPECD (upper: Case 1; lower: Case 2; coif5).

It can be noticed that for damage Case 1 there is an obvious peak at Node 10 where the damage appears, while for Case 2 the peak appears at Node 9 where the crack just locates, which suggests WPECD is quite effective in damage localization.

4.4.1 *Influence of wavelet function*

The wavelet function Coif with order $N = 5$ (Coif 5) is chosen and the decomposition level is still 7. The result is shown in Fig. 12.

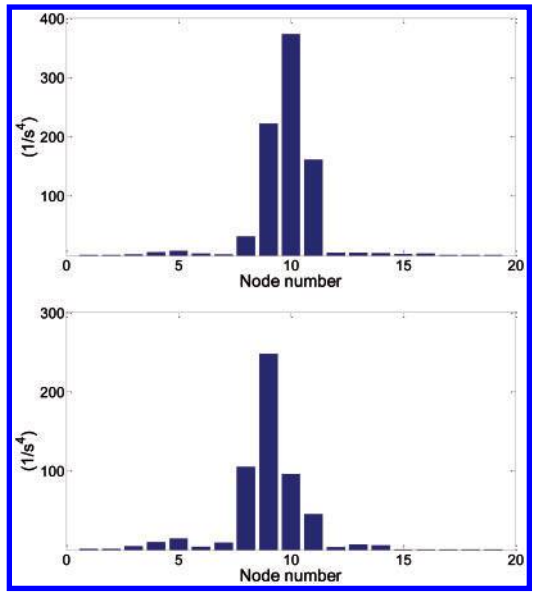

Figure 13. WPECD (upper: Case 1; lower: Case 2; db15).

Compared with Fig. 11, the difference is quite small. Both of the two wavelet-functions can achieve reasonable results. Moreover the calculation time for Db 15 and Coif 5 are also very close, those are 50s and 48s, respectively. Thus these two wavelet functions are both effective and can be verified each other.

4.4.2 *Influence of decomposition level*

Generally speaking, the more the decomposition level, the better the result, but the more the calculation time will be. Still take Db 15 as wavelet function while the decomposition level is 8 and the result is shown in Fig. 13.

Compared with Fig. 11, the peak value is a little smaller but the identification results are the same. As for calculation time, it is 101s, nearly two times of that when decomposition level is 7. That is because when the decomposition level increases, the number of wavelet packet components will double, which will make calculation time increase. For this reason, an appropriate level should be chosen to guarantee the identification quality as well as reduce calculation time as much as possible. In this example, level 7 has already met the requirements.

4.4.3 *Summary of damage identification method based on WPECD*

Based on the analysis above, the procedure of damage identification based on WPECD can be summarized as follows.

(1) Measure the vibration responses of concerned nodes when structure is undamaged.
(2) Monitor the node responses of structure in service.
(3) Chose appropriate wavelet function and decomposition level, take WPT on responses under relevant cases.

(4) Calculate the WPECD of each node. Where there is a peak on the WPECD curve there may be some damage, which should be paid attention.

5 CONCLUSIONS

In this paper, a numerical simulation is taken to indicate the effectiveness of WPECD on damage localization, and an experiment on a real bridge girder is taken to verify this method. The conclusions are as follows.

(1) Numerical calculation shows that WPECD is sensitive to damage and is effective to identify the damage even when the damage is slight (5%). However, if the measuring points are quite sparse, the slight damage information may be hidden.
(2) The WPECD Method is verified by an experiment on a real bridge girder which provides references for structure healthy monitoring.
(3) Different wavelet functions can be chosen for damage identification and verified each other.
(4) Higher decomposition level will cost more calculation time, so an appropriate decomposition level should be chosen to guarantee the identification quality as well as calculation efficiency.

Damage detection on reinforced concrete framed structures using a band-variable filter

F.C. Ponzo, R. Ditommaso, G. Auletta & A. De Muro
School of Engineering, University of Basilicata, Potenza, Italy

ABSTRACT: Structural Health Monitoring (SHM) aims to increase the knowledge about linear and non linear dynamic behaviour of structures in order to develop accurate strategies of analysis for the safety assessment. Particularly, structural monitoring, especially for structures located in seismic prone areas, assumed great importance for the possibility to provide useful information about the state of the health of strategic structures and infrastructures over time and to perform an objective quick estimate of the damage occurred on structures just after a seismic event. It is known that the occurrence of structural damage, for any kind of structure, it is able to changes its dynamic characteristics over time. Generally, the main parameters conditioned by this problem are periods of vibration, equivalent viscous damping factors and mode shapes. Several authors showed that also the variations of the modal curvature are strictly related to the damage occurred on a structure. Moreover, using the mode curvature as a control parameter it is also possible to localize where the damage occurred along the height of the structure. In order to analyze the nonlinear behaviour of a general structure, and localize a possible damage, a band-variable filter based on the Stockwell Transform has been proposed. Basing on the results of nonlinear numerical analyses and shaking table tests on a scaled model, this paper shows some example of application of the proposed methodology to identify and localize damage occurred on framed reinforced concrete structures after an earthquake.

1 INTRODUCTION

Structural Health Monitoring (SHM) aims to increase the knowledge about time-varying bahavoiur of structures, especially after seismic events, in order to develop accurate strategies of analysis for the safety assessment. Especially for structures located in seismic prone areas, SHM assumed great importance, for the possibility to provide useful information about the state of the health of strategic structures and infrastructures over time and to perform an objective quick estimate of the damage occurred on structures just after a seismic event. SHM performed on both weak and strong motion can also facilitates the understanding of structural behaviour during earthquakes and related damage mechanisms. In the last years many researchers worked to set-up new methodologies for Non-destructive Damage Evaluation (NDE) based on the variation of the dynamic behaviour of structures under seismic loads (Dinh *et al*., 2012; Bisht and Singh, 2012, Ponzo *et al*., 2010).

The NDE methods can be classified into four different levels (Stubbs *et al*., 2000) as a function related to the type of information provided by the different approach (Rytter, 1993):

- **First level methods:** only able to evaluate the presence of a possible damage to the structure;
- **Second level methods:** able to assess the presence of any damage on the structure providing also information about the related position;
- **Third level methods:** able to identify any possible damage occurred on the structure by providing information about both location and severity of the damage;
- **Fourth level methods:** able to detect the presence of damage on the structure, estimate severity and position as well as providing information related to the impact that impairment has on the structure.

Each method, according to the level where it takes place, requires information and algorithms characterized by an increasing in complexity when the level increases. Therefore, the development of high level refined methodologies requires, in general, high costs, great computational effort and often needs experts people to understand the complex results. Using a complex approach it can result very difficult to control a relevant number of structures and infrastructures, especially in automatic way. This kind of approach is indicated to perform scientific studies or more in depth control on a limited number of structures. It is, then, clear the importance to set-up fast and simplified methodologies for SHM and NDE. These methodologies must be based exclusively on few sensors installed within the structure and able to capture the main modes

of vibration characteristics. Most of methods proposed in the past were based on the eigenfrequencies variations of the structure, but it is now well know that frequency variation could be related to other factors also, as well as the external temperature variations or the soil-structure interaction (Xia *et al*., 2012).

2 THE STOCKWELL TRANSFORM AND THE NONLINEAR FILTER

This paper discusses the possibility to use a Band-Variable Filter (Ditommaso *et al*., 2012) to point out the evolution of the dynamic characteristics of systems, over the time, by acting simultaneously in both time and frequency domain. The filter was built using the properties of convolution, linearity and invertibility of the S-Transform. As discussed in Ditommaso *et al*. (2012), the proposed band-variable filter can be written as:

$$h_f(t) = \int_{-\infty}^{+\infty} \left(\int_{-\infty}^{+\infty} [S(\tau, f) \cdot G(\tau, f)]\, d\tau \right) \cdot e^{i \cdot 2 \cdot \pi \cdot f \cdot t}\, df \qquad (1)$$

Where $S(\tau,f)$ is the S-Transform of the signal $h(t)$, $G(\tau,f)$ is the filtering matrix and $h_f(t)$ is the filtered signal. A generic k-th column $G(\tau,f)$ identifies a filtering window at a given time step. In order to better clarify the filtering procedure a worked example will be provided in the next section. The definition of the filtering matrix could be a time-demanding process, since each filtering window should be defined over a varying frequency recursively with a fixed time lapse. Moreover, the band-pass portion of the filter must be enlarged or reduced for each time step according to the desired bandwidth and the rectangular shape of the matrix. In order to simplify this process, it is convenient to try to automate it. We propose an implementation that defines the filtering matrix using a graphical user interface (GUI) that visualizes the amplitude spectra of the S-transform of the signal allowing for a point-and-click selection of the desired portion of the time-frequency domain. The routine is designed so that the user can select a few points and the computer performs a cubic spline interpolation. In order to build the filtering matrix we used the *pimf* function of MATLAB©, which is a convenient approximation of a boxcar function. This spline-based curve is so named because of its Π shape. It is possible to obtain more details about this function from www.mathworks.com. The matlab routine of the proposed Band Variable Filter can be downloaded from http://roccoditommaso.xoom.it.

3 MODE SHAPES EVALUATION AND DAMAGE LOCATION

The band-variable filter discussed in the previous section gives the possibility to extract from a non-stationary and/or non-linear signal just the energy content of interest, preserving both amplitude and phase in the region of interest, as discussed by Ditommaso *et al*. (2012). Using this kind of approach and a suitable distribution of sensors along the height of the monitored structure it is possible to extract the time-varying behaviour of each mode of vibration starting from a nonlinear signal recorded on a damaging structure during an earthquake. The proposed procedure has been applied on reinforced concrete framed structure to detect and localize the damage occurred after an earthquake. As mentioned before, the basic idea is to identify, using the band-variable filter (Ditommaso *et al*., 2012), the fundamental mode shape over time and evaluate its changes in temrs of shape and related curvature. It is possible to demonstrate that mode curvature variation is strongly related with the damage occurred on a structure (Pandey *et al*., 1991). To apply the proposed procedure it is necessary to focus the attention on three most important instants for a structure subjected to an earthquake: (A) before the earthquake, (B) the instant of maximum inter-storey drift and (C) after the earthquake. Comparing the mode shapes characteristics evaluated in the instant A, B and C it is possible to unserstand if damage occurred after the earthquake and to localize it on the structure. The instant A is the reference instant and it is necessary to compare the difference in terms of mode curvature between B-A and C-A. In order to better explain the proposed procedure two examples have been considered. The former is related to a nonlinear numerical model of a reinforced concrete framed structure (plant 15 × 12 m), regular in plan and in elevation, with five floors, as shown in Figure 1. The considered structure has been designed following the criteria of the Italian seismic code (NTC2008)

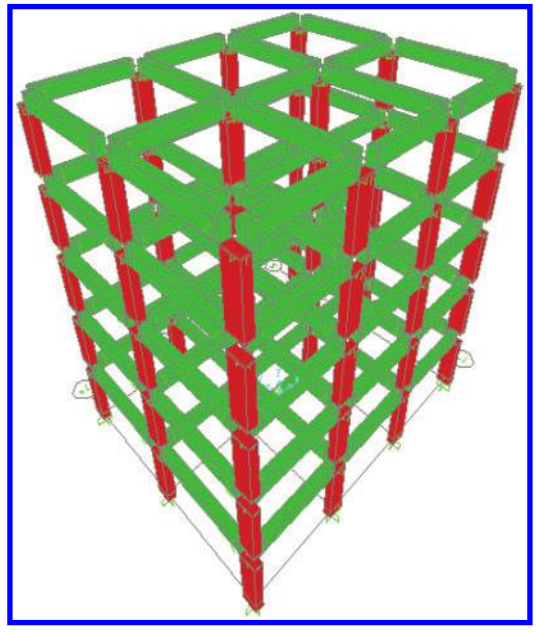

Figure 1. Numerical model.

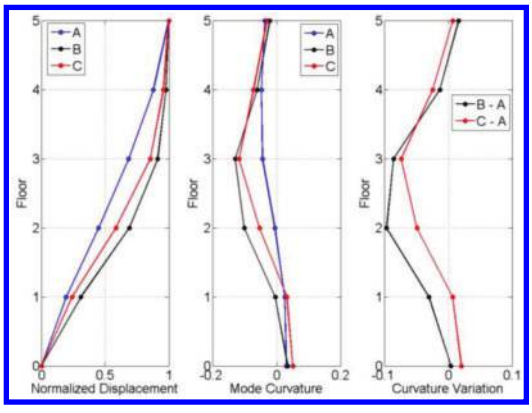

Figure 2. From The Left: Mode Shapes And Curvatures evaluated at time instances A, B and C, And Curvature Variations B-A And C-A.

for high ductility class (CDA), high seismic intensity (PGA 0.35g) and for soft soil type D. The height of each storey is 3m, for a 15m total height of the building. In order to take into account the presence of infill panels within the structural R/C frames and their interaction with the columns, both the masonry strength and stiffness contribution have been considered (Mainstone R.J. 1974) by inserting two equivalent structural elements in the models. Using SAP2000 finite elements program, these elements were modelled by means of multi-linear plastic link, with a Takeda hysteretic behaviour. It is possible to find more details about this numerical model in Ponzo *et al.* (2010). The Figure 2 shows the mode shapes evaluated over time: Mode Shape B has a curvature bigger than Mode Shapes A and C. It is known that mode curvature is strongly linked to the building damage during a seismic event (Pandey *et al*., 1991). Therefore, being able to evaluate the mode curvature during the maximum excursion in nonlinear field and isolating it from superimposed signals, we can achieve a better understanding of the mechanisms of damage as well as a more precise location of the damage on the structure. In this example the maximum curvature variation (B-A) is located at the second floor where the maximum interstory drift occurred. On the contrary, using the curvature variation associated to the mode shapes A and C, related to the stationary behaviour before and after the earthquake, the maximum curvature variation is associated to the third level, but it is in contrast with the maximum measured intersory drift (Figure 2). The latter example is related to a 1:4 reinforced concrete scaled experimental model, designed for vertical loads only and tested at the Structural Laboratory of the University of Basilicata in Potenza, as part of the POP project (Dolce *et al*. 2005), through the mono-axial shaking table test (Figure 3a). The model was tested using two different conditions: fixed base (phase I) and with isolation system (phase II). With regards to the tests in the fixed-base configuration mentioned above, the effective peak acceleration of the table was progressively increased from 0.05 up to 0.35 g, using different

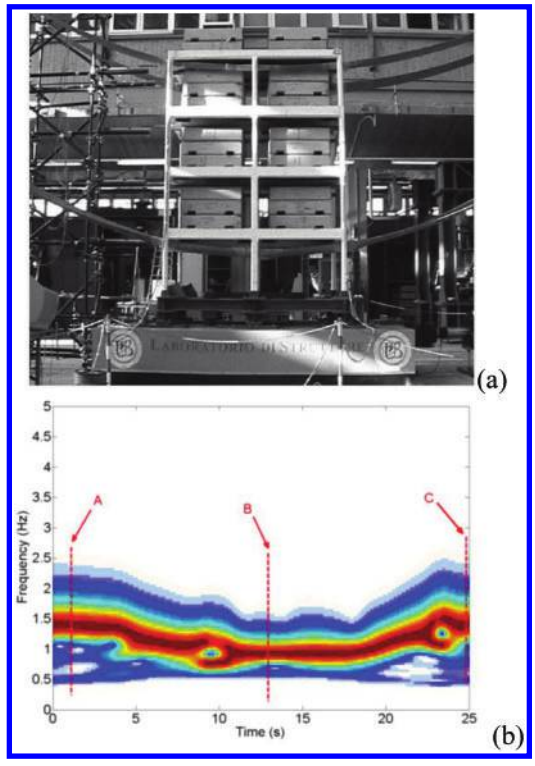

Figure 3. (a) POP model (Ponzo et al. – 2010) (b) Normalized S-Transform and selection of the time instants A, B and C.

spectral shapes. All floor displacements were measured through Temposonic digital transducers, fixed to an external steel reference frame.

The floor accelerations were acquired through a system of horizontal servo accelerometers. Figure 3b shows the S-Transform related to the accelerometric recordings at the last level of the structure.

The starting frequency is 1.4 Hz, the minimum frequency is 0.90 Hz and the final frequency is 1.35 Hz. Figure 3b shows also the time-point from which the mode shapes were evaluated: Mode Shape A, B and C (starting frequency, minimum frequency and final frequency). In order to highlight the frequency evolution of the POP model a normalized S-Transform has been used. Figure 4 shows the mode shapes evaluated over time. In order to compare the performance of the proposed technique the variations of the modal curvature were calculate for both numerical and experimental models and compared with those evaluated using a classical band-pass filter to isolate the dynamic characteristics related to the fundamental mode.

The results obtained using the classical approach are coherent with those related to the time-instants A and C, but are very different from those related to minimum frequency (B) reached during the nonlinear phase of the motion. This kind of result was expected because the classical approach, commonly adopted to analyze the stationary motion of a system, fails when

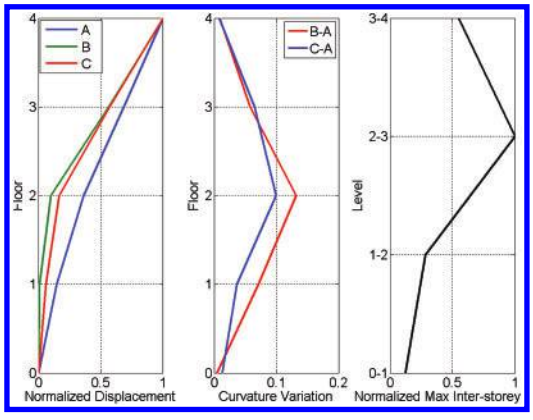

Figure 4. From The Left: Mode Shapes And Curvatures Variations B-A And C-A And Normalized Max Inter-storey.

it is used to analyze the nonstationary behaviour of the same system. The results obtained for both numerical and experimental models highlight the capacity of the proposed approach of evaluating the fundamental mode shapes during the maximum excursion in the plastic field (minimum frequency reached over time). This is a crucial aspect for a correct detection and localization of the damaged occurred on the structure during the strong motion phase. In fact, the results obtained from the experimental model shown that also using the modal curvature variation (C-A) it is possible to localize the damaged floor, but the amplitude of this kind of variation is very different from those obtained using the modal curvature variation evaluated using the approach proposed in this paper (B-A), that better approaches the real variation reached during the nonlinear motion.

How can be seen from Figure 4, the maximum modal curvature variation occurs in correspondence of the same plane in which the maximum inter-storey drift focuses. Using the band-variable filter, taking into account the possibility to evaluate the maximum mode shapes variation over time, further study are necessary to find a relationship to link the damage level with the maximum modal curvature variation reached during the nonlinear motion of the structure forced by a strong earthquake.

4 DISCUSSION AND CONCLUSIONS

Techniques based on Fourier transform provide good results when the response of the system is stationary, but fail when the system exhibits a non-stationary, time-varying behaviour. To hamper classical techniques, it is not necessary that a building reaches damage: even the non-stationarity of the input and the possible interaction with the ground and/or adjacent structures can show the inadequacy of classic techniques (Ditommaso *et al*., 2010). In 1996, Stockwell introduced a new powerful tool for the signals analysis: the S-Transform (Stockwell *et al*., 1996). Compared with the classical techniques for time-frequency analyses, this transformation shows a much better resolution and also offers a range of fundamental properties such as linearity and invertibility (Ditommaso *et al*., 2012). By exploiting these properties, it was possible to develop a filter whose band varies both in time and in frequency domains, being very useful to study the characteristics of non-stationary signals (Ditommaso *et al*., 2012). As discussed in the previous sections, this tool becomes necessary when one wants to isolate the response of individual time-varying modes of vibration of soil and buildings (e.g., when their dynamic characteristics evolve over time as a result of seismic events). The ability to investigate the non-stationary response of structures opens new scenarios, giving the opportunity to explore new possibilities. For example, the ability to isolate individual modes of vibration of a building make possible to explore their variation over time, evaluating the change in mode curvature. It is known that this parameter is strongly linked to the building damage during a seismic event (Pandey *et al*., 1991). Therefore, the possibility of evaluation of the modal curvature during the maximum excursion in nonlinear field and isolating it from superimposed signals, allows for a better understanding of the mechanisms of damage as well as for a more precise location of both structural and non-structural damage.

In this paper the results of the proposed procedure for damage detection and localization have been proposed. The methodologie appears able to localize the damage occurred on a reinforced concrete framed structure after a strong earthquake. Particularly, the methodologie has been tested on both a numerical model and a 1:4 reinforced concrete scaled model damaged using several shaking table tests. It is worth noting that the procedure is completely based only on accelerometric data, then, it is not necessary to integrate the data to evaluate velocities or dislacements. In this way the damage localization is very fast. Using the band-variable filter, taking into account the possibility to evaluate the maximum mode shapes variation over time, further study are necessary to find an empirical relationship to link the damage level with the maximum modal curvature variation reached during the nonlinear motion of the structure forced by a strong earthquake.

ABSTRACT: Damage detection in the turbomachinery bladed system is of prime concern as a growing fatigue crack that leads to the blade failure threatens the survival of the entire engine. Therefore damage to the blades needs to be detected primarily during its initiation or early propagation stage before the ultimate failure occurs. In addition to that, the presence of mistuning in the constituent bladed sectors complicates the damage detection procedure because of the associated problems of mode localization and peak splitting in the mistuned bladed structures. This study presents an effectual approach for damage detection in the mistuned turbomachinery bladed system utilising statistical approach to the vibration–based damage detection paradigm involving the Outlier analysis. A simplified bladed disc, in the damage and undamaged conditions, is considered in this work for the varying mistuning levels. Possibility of utilising the frequency domain data (in the form of Frequency Response Functions (FRFs)) and the time domain data (in the form of time signals obtained for swept sine excitation) for the damage detection is explored for varying signal-to-noise ratios. The effectiveness of the developed damage detection strategy is also investigated for the blade tip timing data.

1 INTRODUCTION

Timely detection of damage in bladed structures is of significant importance as growing fatigue damage threatens the survival of whole system. Amongst various damage detection procedures developed over the last few decades, statistical approach to damage identification has been given great attention by the researchers. Statistical approaches to vibration-based damage detection are based on the principle that the vibration response measurements contain damage sensitive features which can be utilized for damage identification by quantifying the observed changes in those features. Therefore, this technique can be regarded as a statistical pattern recognition paradigm. Vibration response measurements usually contain inherent uncertainties, therefore statistical analysis procedures are required to detect whether any deviation in the vibration response is from the damage or due to the operational variability or inconsistency in the measurement chain [1].

The problem of damage detection has a hierarchical structure comprising several levels [2]. In order to satisfy the higher levels, complicated information regarding the expected life of a structure (after a detailed prognosis) is required, but at the lowest level, damage detection is only a two class problem – whether the structure is damaged or not? The requirement of robust low-level damage detection is fulfilled by the principle of "Novelty Detection", which tries to identify if a structure has deviated from the normal condition. Outlier analysis is a novelty detection technique and falls into the unsupervised learning category. It involves processing of a large data set of samples representing the undamaged state of the structure. When a new data set is available, it is compared with that of the undamaged state and the occurrence of a significant deviation from the undamaged state leads to a conclusion regarding the presence of damage in the structure. Outlier analysis highlights the potential outlier from a given data set, which might be thought of being produced due to some different mechanism in comparison to the rest of the data. It also compares the status of any data set against a threshold level. This threshold level is obtained by using a Monte Carlo method. If a data set is lying above the threshold level, this indicates a different mechanism being responsible for generating that data set in comparison to the rest of the data [3, 4].

The outlier analysis technique has been successfully applied to variety of engineering problems in the past. The most important development in the utilization of outlier detection as a possible damage indicator evolved in the three phase experimental damage investigation reported in [5-7], as previously this method was largely only applied to synthetic data. The first phase of this investigation dealt with the experimental verification of the novelty detection method

considering a laboratory structure (an aluminum panel stiffened with ribs and stingers). The features used for this analysis were transmissibility FRFs and the damage was induced by making a progressive saw-cut through one of the stringers. The method was successful in identifying all the damaged states for depth of crack exceeding 5mm. The second phase of the experiment proved successful in highlighting local damage on a full-scale structure (a Gnat aircraft wing). Damages of various forms were introduced in different inspection panels and transmissibility measurements (across the panels) were used to detect damage using outlier analysis. In the last phase of this research, the objective was to move from level 1 (detection) to level 2 (location). A network of sensors was used to establish a set of novelty detectors, each sensitive to different sections of the wing. The results confirmed to establish a level 2 damage detection system (detection and location) using outlier analysis. Since this detailed study, outlier analysis has been successfully applied to detect damage in various applications which include: annular components [8], plates [9], and stiffened composite panels [10].

An important aspect of the vibration-based damage detection is its sensitivity to the uncertainties in the measurement chain. Vibration response measurements are always associated with some form of measurement noise or error. The effect of noise on the damage detection is investigated in detail in [11-13]. The presence of noise in a signal complicates the problem of damage detection and can lead to a faulty diagnosis. In order to reduce the probability of a faulty diagnosis, the effect of noise must be taken into consideration [11]. It has been reported in [12] that the influence of input noise (noise added to the input parameters to the system e.g. force, displacement, velocity etc. input) is slightly less significant on damage detectability as compared to the influence of an output noise (noise added to the response of a system). The effect of input noise is lessened by the structure whereas the effect of output noise is independent at each response location and tries to hide the damage to a larger extent.

For damage detection using outlier analysis, increasing noise level results in complicating of the damage detection [14]. A very promising approach to consider uncertainty, in the form of noise, in the FRFs obtained from dynamic testing is explained in [15]. The confidence bounds, in terms of the standard deviation, for the measured FRFs are obtained in terms of the standard coherence function and the number of averages used to compute the FRF.

In this paper, statistical approach to the vibration-based damage detection is considered for a simple, representative bladed structure. Different mistuning levels are considered along with the cracks of varying depths. Both, frequency and time domain data was acquired from the blades and Outlier analysis was utilized to highlight the damage in one of the blades. Effectiveness of the developed methodology is also examined for the operational uncertainties by adding noise to the data.

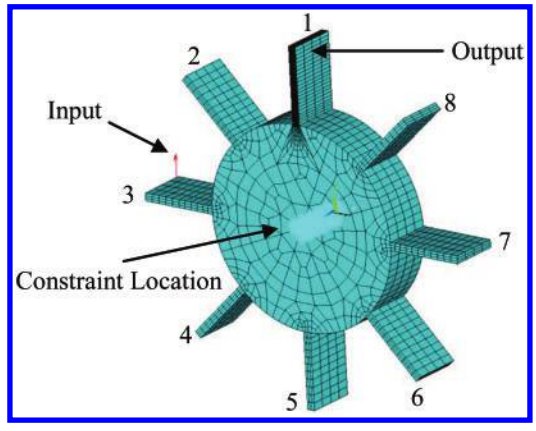

Figure 1. 3D FE model of bladed disc.

2 3D FE MODEL OF BLADED DISC

The 3-D FE model of the bladed disc specimen is shown in Figure 1. It is comprised of eight blades mounted on a thick circular base. The interface between the blade and the circular base was modeled as a rigid single piece to represent the geometry of a blisk. The thickness of each blade was 6 mm; blade length was 60 mm; the inner diameter of the disc was 40 mm and the outer diameter was 160 mm. The bladed disc was meshed using a 3-D 20-node structural solid element with mid-side nodes. The total number of elements along the width of a blade was set to be three for Blades 2-8 and twelve for Blade-1; thirty along the length of the blade and four along the bladed disc thickness. The higher number of elements for Blade-1 was chosen in order to model the cracks of smaller depths precisely without disturbing the mesh density. This resulted in 3356 elements for the whole bladed disc model. The FE model was constrained radially from the centre and the material assigned to it was steel ($E = 200$ GPa, $\upsilon = 0.3$, *density* $= 8000$ Kg/m^3).

The actual blades in a physical bladed disc are always slightly mistuned due to the small differences in the individual blade sectors because of inevitable manufacturing constraints. In order to obtain an equivalent spread of mistuning modes for the numerical bladed disc model, and to simulate the numerical mistuning, different modulus of elasticity (E) ranges were considered. Random E values (equivalent to the number of elements of the blades) were obtained for a given E range and were randomly distributed across all the elements of the blades of the FE model (Figure 2).

3 FREQUENCY DOMAIN DAMAGE DETECTION

3.1 *FRFs of Tuned and Mistuned Bladed Disc*

The FRFs for the varying mistuning levels were obtained by applying a unit force on Blade-3 and the

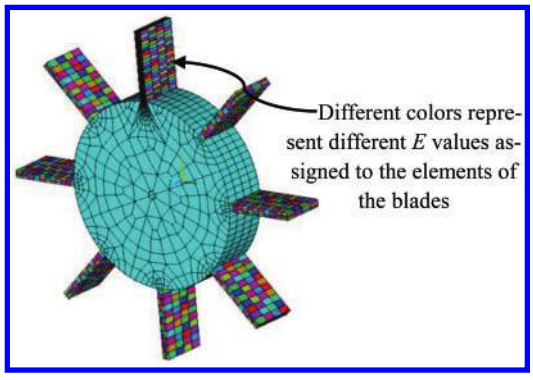

Figure 2. Random distribution of 'E' across the bladed disc.

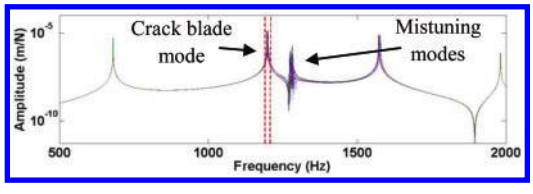

Figure 3. FRF of the bladed disc for a/d = 0.25 crack.

response was taken on Blade-1. The blade numbers and input/response locations are shown in Figure 1. The bladed disc model was considered in the pre-crack condition and also with cracks of varying depths ($a/d = 0.04, 0.08, 0.25, 0.5$), at the first crack location on Blade-1. Crack depth and location parameters were defined in accordance with [16]. The crack was modeled by two separate surfaces resting on each other with no material removal between them. This represented a hair-line crack. The crack depth has minimal effect on the damping levels, which are significantly affected by the increasing excitation levels instead [17]. Therefore, a friction-free contact was considered at the crack interface of the bladed disc. The presence of crack in one of the blades resulted in the occurrence of a crack blade mode peak in the FRF plot. For the larger crack depths ($a/d = 0.25$ and 0.5), the crack blade mode itself can provide useful information about the presence of damage in the structure by just visualizing the FRF plots – for example see Figure 3. But for the smaller crack depths ($a/d = 0.04$ and 0.08) some additional steps are required to highlight the damage in the mistuned environment [18].

3.2 *Outlier Analysis*

For damage detection in the bladed disc model using outlier analysis in the frequency domain, the feature used was the transfer function between Blade-3 (input) and Blade-1 (output). At first, the bladed disc without a crack was considered and 10 FRFs were obtained, each corresponding to a different mistuning level. These FRFs were then sampled at 20 regularly spaced points

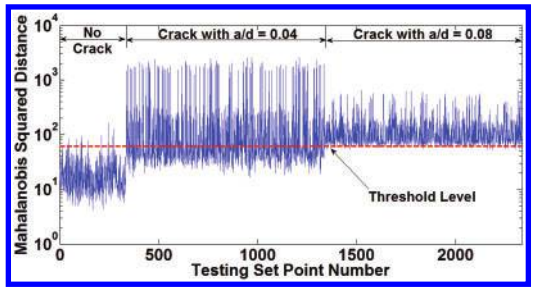

Figure 4. Mahalanobis squared distances for damaged and undamaged cases (Frequency domain).

(a 20 dimensional feature) between the frequency interval of 1270-1290 Hz to provide the pattern to be used as reference/undamaged condition in the analysis. In order to account for the effect of noise in the simulated FRFs, each of the FRFs was corrupted with a noise level corresponding to the coherence estimate, as described in [15]. The coherence level considered was varied from 0.99 to 0.95 within the frequency range of interest (where all the resonance peaks of mistuning modes were lying). The undamaged pattern of each FRF was copied 100 times and each copy was corrupted with a Gaussian noise vector obtained for a given standard deviation corresponding to each mistuned FRF.

The 100 copies for all 10 mistuning levels were concatenated vertically to form a 1000×20 feature matrix for the undamaged bladed disc. Rows of this feature matrix were then randomly rearranged to rectify the block effect of each mistuning level FRFs stacking on the top of each other. Two-thirds of the undamaged data were classified as healthy data and one-third as testing data. These 666 (2/3rd of feature matrix), 20-dimensional observations for the healthy data were used to calculate the mean vector, $\{\bar{x}\}$, and a covariance matrix, [S], for the unfaulted condition. The values for the exclusive MSD measure, D, were then calculated for each row of the testing data. After that, testing data of the undamaged case were subsequently replaced with the feature matrices (each having dimensions of 1000×20) of the damaged cases i.e. the bladed disc specimen with a crack depth ratio of 0.04 and 0.08 and the MSDs were calculated. The results are plotted as shown in Figure 4. To decide about a data set being an inlier or outlier, a threshold value was computed using Monte Carlo simulations. The threshold value for a 1000 observation, 20 dimensional problem was found to be 61.2 after 1000 trails. This process was repeated ten times to obtain an averaged threshold value.

Figure 4 indicates that the undamaged data points are lying below the threshold level and are classified as "inliers", as expected. The bladed disc with a crack having $a/d = 0.04$ was partially detectable as the threshold level was crossing approximately 25% of the MSD values. All the observations corresponding to crack depth ratio 0.08 were diagnosed as "outlier" and are detectable. An interesting point to note is the drop

in the magnitude of MSD for $a/d = 0.08$. This was because of the fact that the frequency range considered for this analysis was 1270-1290 Hz and the FRF peak for the crack having $a/d = 0.08$ was just lying outside this frequency range. When the displaced mode was still within the frequency range there are two sources of discordancy: (a) the mode was not where it should be and (b) the mode was somewhere it shouldn't be. If the mode leaves the frequency range of interest, only the first source of discordancy is present.

4 TIME DOMAIN DAMAGE DETECTION

As the ultimate objective of this paper is to develop a damage detection strategy that utilises blade tip timing data, damage detection in the bladed disc is now addressed considering the time domain data. A discrete convolution integral approach, as described by Equation 1, was utilised to generate the time domain data from the modal properties of the bladed disc, obtained numerically.

$$x(t) = \int_{-\infty}^{\infty} f(t-\tau).h(\tau)\,d\tau \qquad (1)$$

Blade-3 of the bladed disc was subjected to a swept-sine excitation from 1100-1600 Hz for 2 seconds and the response was obtained on Blade-1. One data point per cycle was obtained to represent the tip-timing data obtained from a single sensor attached to the turbomachinery casing. For the two or more sensors, the number of data points per cycles can be increased accordingly.

Once the time domain data was obtained, the outlier analysis was utilised to highlight the crack in the bladed disc. The procedure to obtain the MSD measure, D, was exactly the same as it was in the frequency domain case. The bladed disc without damage was considered first for the 10 mistuning levels. The time domain signal of the bladed disc is shown in the Figure 5. The presence of "beating" phenomenon in the time response of the bladed disc is due to the closely spaced cluster of mistuning modes in the frequency range of 1250 – 1300 Hz. The time interval chosen for the subsequent analysis was from 0.7 – 1 second, which corresponds to the frequency range of the mistuning modes cluster. The time domain signal of the undamaged bladed disc was sampled at 40 regularly spaced points between the selected time interval, resulting in a 40 dimensional feature problem.

Data was then copied 100 times and each copy was corrupted with a Gaussian noise vector having noise-to-signal ratio (NSR) of 0.025%. A 1000×40 dimensional feature matrix was obtained by vertically concatenating the 100 copies of the undamaged time domain data corresponding to 10 mistuning levels. Two-thirds of this feature matrix was designated as healthy data and the rest of the data was classified as testing data. The mean vector, $\{\bar{x}\}$, and a covariance

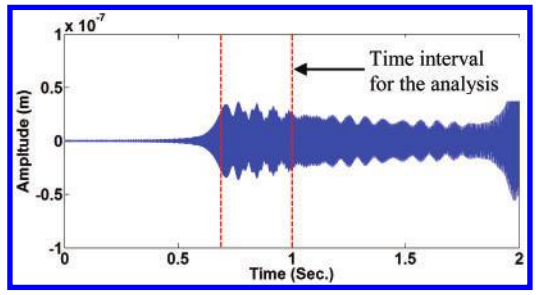

Figure 5. Time domain response of the bladed disc.

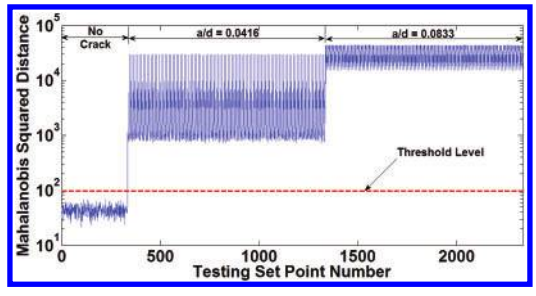

Figure 6. Mahalanobis squared distances for damaged and undamaged cases (Time domain).

matrix, [S], for the unfaulted condition were obtained from the healthy data and the exclusive values of MSDs were calculated. After that, the undamaged testing data were replaced subsequently by the time domain, 1000×40 feature matrix of the damaged bladed disc having cracks of 0.04 and 0.08 depths. The results are plotted in Figure 6.

The threshold level for 1000 observations of a 40 dimensional problem was found to be 96 after 1000 iterations using the same procedure as described earlier. The data points for the unfaulted case occurred below the threshold level. The MSD measures for the bladed disc having $a/d = 0.04$ and 0.08 were lying above the threshold level, indicating that the damage is completely detectable.

The time domain damage detection technique described above worked satisfactorily to highlight the damage in the mistuned environment considering low NSR. In order to investigate the effectiveness of this method when the data is corrupted with the higher levels of noise, two further cases were considered which included: a) NSR – 0.25%, b) NSR – 1.0%. The results for the two noise levels are shown in the Figures 7 (a) and (b) respectively.

Increasing NSR resulted in lower magnitudes of MSDs as the Euclidean distance between the two data sets (faulted and unfaulted) decreases with the increase in noise levels. For NSR – 0.25%, considering $a/d = 0.04$, the threshold level was crossing approximately through 10% of the MSD values. Therefore, the crack having $a/d = 0.04$, was partially detectable. Whereas all the observations for the crack having

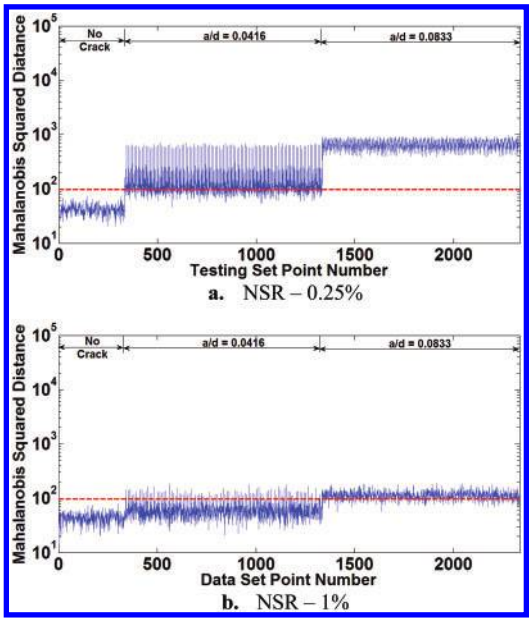

Figure 7. Mahalanobis squared distances for damaged and undamaged cases (Varying noise level).

$a/d = 0.08$ were lying above the threshold level and it was completely detectable. When the noise level was further increased, considering NSR – 1.0%, the majority of the data points for $a/d = 0.04$ were lying below the threshold level and were classified as inliers (not detectable). Whereas, the MSD values obtained for the crack with $a/d = 0.0833$ were lying above the threshold level and the crack was detectable.

5 CONCLUSIONS

The damage detection in the bladed disc was addressed in this paper considering a statistical approach. Outlier analysis was utilized to highlight the damage considering varying mistuning levels present inside the bladed disc. Damage detection was addressed for the frequency domain and for the time domain data (representing the tip timing data). Both the techniques worked satisfactorily in highlighting the damage in the bladed disc. The presence of a varying level of mistuning in the bladed disc resulted in widening the span of mistuning modes. For the frequency domain data, considering larger crack depths, the resonance peaks of the crack blade modes were well separated from the cluster of mistuning modes in the FRF plot and could be easily highlighted. However for smaller cracks, the crack mode merged into the group of mistuning modes and could not be distinguished at all. The outlier analysis successfully detected these smaller crack depths. In addition to that, the frequency domain method also detected the crack whose resonance peak was lying outside the frequency range considered for the analysis. For the time domain data, one data point per cycle was selected to represent the tip timing data from a single sensor. The method also highlighted the cracks in the bladed disc precisely with varying NSRs.

ABSTRACT: Crack initiation and propagation in a bladed system typically alters its overall dynamic response by causing local variation in the stiffness. The presence of a crack in one part of the repeating structure, such as a set of rotor or stator blades, affects the modal characteristics (natural frequencies, mode shapes and modal damping values) of the entire system. Changes in the modal characteristics will differ for each mode as they depend on the size and location of the crack. Thus, there exists an opportunity to utilize modal properties for crack detection. Accordingly, this work includes an investigation of modal characteristics-based damage detection techniques to highlight damage in repeating structures.

Modal Assurance Criterion (MAC) – based damage detection is an effective way to track damage growth in simple repeating structures by comparing the mode shapes of a structure in damaged and undamaged conditions. However, MAC is not a sensitive indicator to identify small damages accurately. To address this issue, further two modal characteristics-based parameters are considered in this work involving the first and second derivatives of the mode shapes – the slope and the curvature. Damage detection sensitivities are then compared for the modal vectors, slope and curvature considering a simple repeating bladed disc structure. Damage is considered in the form of a crack in one blade of the repeating structure which is represented by two crack surfaces resting on each other with no material removal in between. This represents a hair-line crack with no surface breathing or friction as modal analysis ignores any nonlinearity. However, the damage severity is varied by considering different crack depths at varying locations along the length of the blade.

1 INTRODUCTION

Repeating structures, in the form of multiple bladed sectors of a turbomachinery, are widely employed in aerospace, process and power generation industries worldwide [1]. Accurate functioning of any repeating structure depends on the structural integrity of the constituent components, as any damage developed in one part of the repeating structure can destroy the whole system and lead to a catastrophic failure. Therefore, any developing damage in the form of a crack must be timely detected before the ultimate failure occurs [2]. Various damage detection procedures have been developed over the recent decades to address damage detection in turbomachinery bladed system. These procedures involve utilization of various structural health monitoring (SHM) techniques and condition monitoring (CM) methodologies along with non-destructive testing (NDT) routines [3, 4, 5, 6]. Amongst these, modal characteristics of a system have also been given great concentration by the researcher to address damage detection in turbomachinery blades [7].

Modal characteristics of any structure comprise of its natural frequencies, mode shapes and modal damping ratios. These modal properties are highly dependent on the structure's physical and material properties, for example – density, modulus of elasticity, shape and size etc. Any change in these physical and material properties ascertains a corresponding change in the modal characteristics. This statement provides the basis for the modal characteristics – based damage identification in repeating structures [8].

Amongst the modal properties of any physical structure, mode shapes have proved to be a sensitive indicator for damage detection in repeating structures as compared to the shift in natural frequencies due to the presence of damage [turbo-expo paper]. Utilising the natural frequencies of a system for damage detection is reviewed in detail in [10]. The natural frequency is proportional to the square root of stiffness, thus a relatively large stiffness change is required before significant frequency change can be detected. The extent of the drop in the natural frequency depends on the location and position of damage with respect to the

mode shape of a particular mode of vibration [11]. Any damage or crack of a given size would result in a relatively small shift in the natural frequency as compared to the damage or a crack of the same size but located in a region of high stress [12]. This indicates that damage detection using frequency shifts might be unreliable due to the positioning of damage in the structure. Thus, the frequency shifts alone might not provide sufficient information regarding the existence and location of damage in the structure.

Mode shapes are sensitive indicators of the presence of damage in structures. Damage growth tracking can be accomplished by comparing two sets of modes in the experimental and/or numerical domains. The most commonly used method to compare the two sets of mode shapes is the utilization of the Modal Assurance Criterion (MAC). The MAC can take any value between zero and one. If the MAC indicates a value near zero, no correlation exists between two mode shapes. If the MAC indicates a value near one, the two sets of modes are fully consistent [13].

Detection of a structural fault by tracking changes in the mode shapes utilising the MAC was first reported in 1984 [14]. Besides the MAC, different criteria have been used over the years for model correlation. Amongst them, the Coordinate Modal Assurance Criterion (COMAC) attempts to identify the measurement degree of freedom contributing negatively to a low value of MAC. The Inverse Modal Assurance Criterion (IMAC) increases the sensitivity of the MAC to small mode shape changes by taking the inverse of modal coefficients. The Frequency Response Assurance Criterion (FRAC) compares any two frequency response functions having the same input/output relationship. These developments in the MAC have been precisely reviewed in [15]. The model correlation process usually involves a MAC plot, an auto-MAC plot and a natural frequency comparison. These three parameters can be viewed simultaneously using the Frequency-Scaled MAC on (FMAC) [16, 17].

Despite the applicability of the mode shape-based crack detection techniques to a wide range of applications, they still have some drawbacks. Extracted mode shapes are affected by noise issues, inconsistent sensor positions and the choice of the number of chosen sensors and their coordinates. In addition to these, the presence of damage in any structure has a less significant influence on the lower modes that are usually measured from the vibration tests [18], until the damage is severe enough to change the lower modes.

Another technique to detect and locate damage in structures is mode shape curvature and modal strain energy analysis. Mode shape curvature is more sensitive to local reductions in the stiffness due to damage in the structure than the modes shapes themselves. The first derivative of the mode shape is slope while the second derivative is curvature or strain. Both of these quantities suddenly change when damage appears in the structure and are dependent on the size of damage. Investigating any change in these mode shapes derivatives can help detecting and locating the damage inside the structure [19, 20]. The squared ratio of the undamaged structure's modal curvature to the damaged, referred to as the Fault Index (FI), is also found to be a sensitive indicator to the presence of damage but is strongly influenced by the presence of noise in the mode shape measurement [21]. The higher derivatives of the mode shapes are even more sensitive to damage but the experimental variations are amplified in the differentiation process. This problem can be overcome by selecting a mode shape based feature that is sensitive to the fault but insensitive to the noise. The first derivative of the mode shape (slope) has proved to be appropriate to rectify this issue [22]. In the absence of the availability of the undamaged structure's modal data, the possibility of utilising this technique for damage detection is investigated in [23]. Another modal strain energy-based damage detection study is reported in [24] where this method detected and located damage (in the form of a saw-cut crack) with an accuracy of less than 21 mm over a 725 mm stringer. Application of this method to detect damage in repeating structures has not yet been examined and is currently addressed in this paper.

In this paper, modal characteristics–based damage detection is addressed considering a simple repeating structure. Modal vectors, slope and curvature are utilized to compare the effectiveness of the MAC for damage identification. Different mistuning levels and patterns are also considered in addition to the varying crack depth and location along the length of the blade. Damage index, based on tracking the mode shapes, due to increasing damage severity, is correlated to the crack depths and is compared for modal vectors, slope, curvature.

2 FE MODEL OF BLADED DISC

A two dimensional disc type structure was considered as a representative base model for an actual turbomachinery bladed system. It is comprised of eight blades mounted on a thick circular base. The interface between the blade and disc was modeled as a rigid single piece to represent the geometry of a blisk. The geometry of the bladed disc model along with its finite element (FE) model mesh is shown in Figure 1. To keep

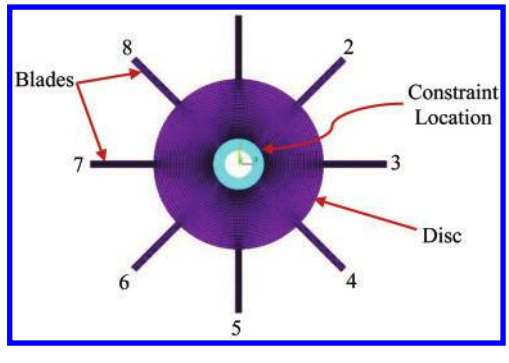

Figure 1. FE model of bladed disc.

the FE model simple, the bladed disc was meshed using 2-D plane stress (eight node quadrilateral) elements with mid-side nodes. The total number of elements in the bladed disc model was 7040. Out-of-plane mode shapes were not considered and the material assigned to this FE model was steel ($E = 200$ GPa, $\upsilon = 0.3$, $density = 8000$ kg/m^3). The model was constrained radially at the centre, indicating a rigid connection between the rotor and the connecting shaft. The blade thickness (d) was 6 mm, blade length (l) was 60 mm, the outer radius of base was 80 mm whereas the inner radius was 20 mm. Crack depth and location parameters were defined according to the guidelines described in [9], considering crack depth ratios (a/d) ranging from 0.01–0.9, at three different locations along the length of the blade ($b/l = 0.14$, 0.5 and 0.8). Cracks were simulated by the material removal crack modeling technique as accomplished in [9].

3 BLADED DISC MISTUNING PATTERN

The presence of mistuning in the bladed disc was simulated by attaching lumped masses to the blade tips. The quantity of these lumped masses and their distribution pattern was varied. It is useful to note here that a 0.1g lumped mass attached to one of the blade tips of the bladed disc results in a frequency drop of approximately 1.23% for the lower modes. In order to investigate the effect of different mistuning patterns in the presence of a crack on the modal characteristics of the whole bladed disc, the following mistuning patterns were considered:

3.1 *No Mistuning Present in the System*

In this scenario, the bladed disc was assumed to be a perfectly tuned system with all the sectors perfectly identical to each other. This case provided a reference for comparing the behaviour of the mistuned system with the tuned one in the presence of a crack in one of the blades of the bladed disc.

3.2 *Arbitrarily Mistuned System (Low Mistuning Level) – Model 1*

In this case, the bladed disc was arbitrarily mistuned by attaching an equal quantity of small lumped masses (0.1g) at the tips of Blades 1, 4 and 6. The purpose was to distinguish between the effects of the alternately mistuned system and tuned system.

3.3 *Arbitrarily Mistuned System (High Mistuning Level) – Model 2*

The bladed disc model was once again arbitrarily mistuned but this time, the level of mistuning was high in comparison to the previous case. Blades 1, 3, 4, 6, 7 and 8 were mistuned by attaching 0.2g, 0.1g, 0.2g, 0.1g, 0.1g and 0.5g respectively.

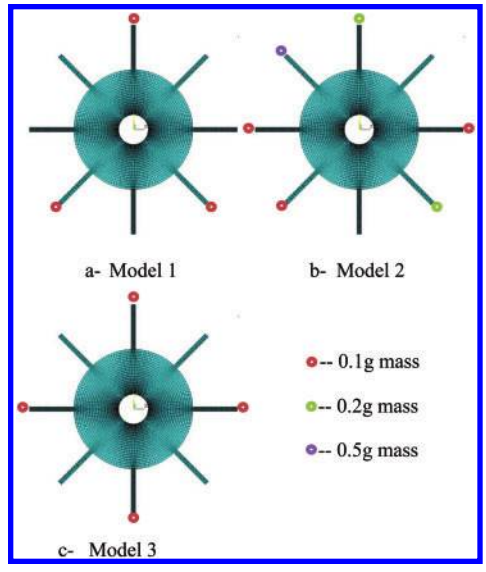

Figure 2. Bladed disc mistuning patterns.

3.4 *Alternately Mistuned System – Model 3*

In the alternately mistuned system, each alternate blade sector was equally mistuned. Blades 1, 3, 5 & 7 were mistuned by attaching 0.1 g of mass.

4 DAMAGE INDEX CURVES

For each of the crack depth ratios ($a/d = 0.01$-0.9) at different crack locations ($b/l = 0.14$, 0.5 and 0.8), displacement vectors were obtained for twenty modes. The MAC matrices were then generated comparing each case with a crack with the reference model (without crack). All mode shape matrices were obtained using data acquired from nodes at the same geometric locations. These MAC matrices were subtracted from the AutoMAC matrix of the reference case. The resulting matrix represents the MAC change and gives a measure of disorder due to the presence of the crack. A single scalar value for this matrix was obtained by calculating its Frobenius norm which therefore provides a measure of the extent of that disorder. The Frobenius norm of a matrix is defined as the square root of the sum of the absolute squares of its elements. Its mathematical definition can be obtained from Equation 1:

$$\|A\|_f = \sqrt{\sum_{i=1}^{m}\sum_{j=1}^{n}|a_{ij}|^2} \quad (1)$$

The Frobenius norm was calculated for each crack depth and location and plotted against crack depth ratios giving three curves, each representing different crack locations. In this way the extent of damage (damage index) due to crack initiation and propagation inside the blade was estimated.

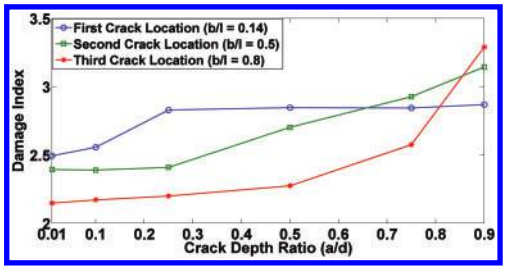

Figure 3. Damage index curves for tuned bladed disc.

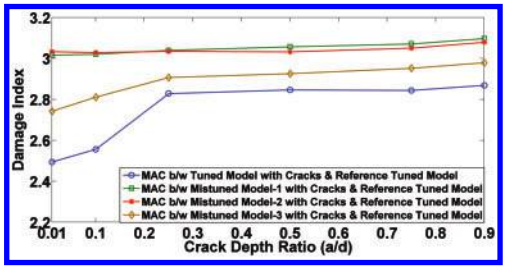

Figure 4. Damage index curves for mistuned bladed disc.

4.1 *Tuned Bladed Disc*

The damage index versus crack depth ratio plot is shown in Figure 3. The magnitude of the damage index for the first crack location represented by $b/l = 0.14$ was higher than for the second ($b/l = 0.5$) and third ($b/l = 0.8$) crack locations. The first crack location, $b/l = 0.14$ gave a steep damage index curve up to a crack depth ratio of 0.25 and then followed a continuous horizontal pattern in the magnitude. For the second crack location near the middle of the blade, $b/l = 0.5$, and third crack location near the blade tip, $b/l = 0.8$, the analysis showed an approximately smooth increase rate in the magnitude of the damage index considering crack initiation and then propagation. It was found that a very minute damage in one of the blades of the bladed disc model resulted in a sudden increase in the magnitude of Frobenius norm and this was indicated by a steep rise in the damage index curve. The extent of this sharp increment is greater for a crack of a certain depth near the blade root as compared to a crack in the middle or tip of the blade.

4.2 *Mistuned Bladed Disc*

In order to investigate the effect of the presence of mistuning on the damage index, the MAC matrix between the perfectly tuned bladed disc without any crack and three mistuned models, having cracks of various depths were computed. That MAC matrix was then subtracted from the AutoMAC of the perfectly tuned bladed disc without a crack. The damage index curves are plotted in Figure 4.

Mistuning causes mode shapes to be highly localized, corresponding primarily to the oscillation of a single blade. Besides this, vibration energy is no longer distributed along all the blades but confined to limited

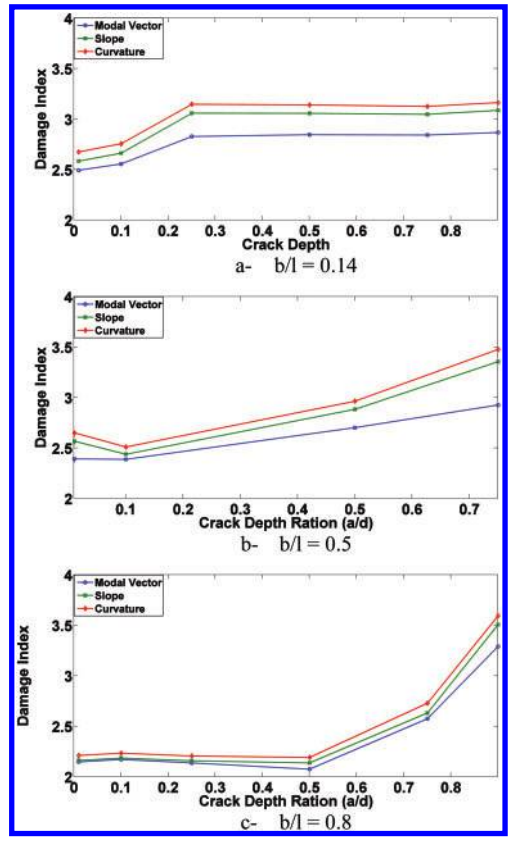

Figure 5. Damage index curves for modal vector, slope and curvature – Tuned bladed disc.

sets of blades. As the damage index plots are strictly dependent on the mode shapes obtained, higher magnitudes of the damage index can be attributed to the presence of localized modes due to mistuning. These localized modes for the tuned system, arbitrarily (low level) mistuned system, arbitrarily (high level) mistuned system and alternately mistuned system are shown in [2, 8].

5 MODAL VECTOR, SLOPE & CURVATURE

In damage index curves for the tuned and mistuned bladed disc, higher magnitudes of damage indices indicates a larger deviation in the modal behaviour of structure having cracks of various depths from the reference model and makes damage detection easier. In order to investigate this, two further parameters were considered to obtain damage index curves for the tuned and mistuned bladed disc. These were slope (first derivative of mode shapes) and curvature (second derivative of mode shapes). Bladed disc models having cracks near the blade root (b/l = 0.14), in the middle of the blade (b/l = 0.5) and near the blade tip (b/l = 0.8) were considered for this study and results for tuned bladed disc are shown in Figure 5a, 5b and

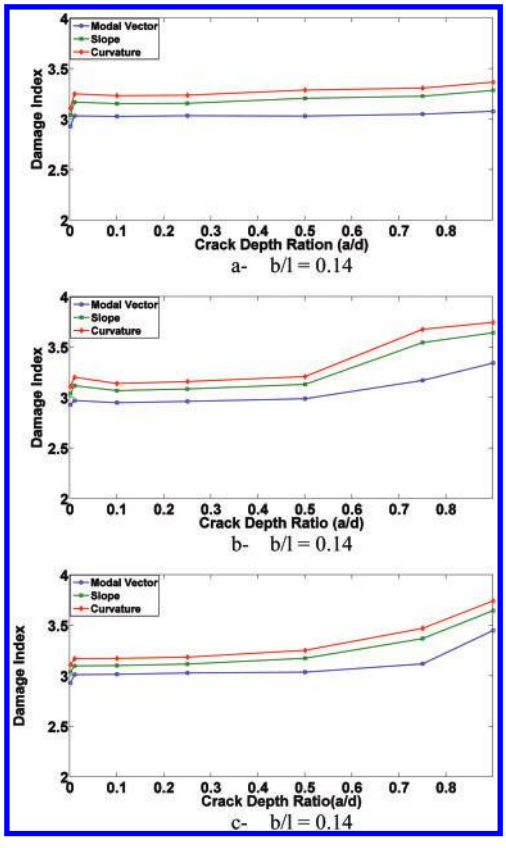

Figure 6. Damage index curves for modal vector, slope and curvature – Mistuned bladed disc.

5c respectively. Second derivative of mode shape, curvature, indicated higher sensitivity to the presence of crack in a blade by resulting in higher magnitudes of damage index as compared to the slope and modal vectors for all the three cases. However, the difference in the trend lines for modal vectors, slope and curvature for b/l = 0.8 is very small as compared to b/l = 0.14 and b/l = 0.5. This indicates that for any crack developed near the blade root or in the middle of blade, modal curvature indicates significantly higher sensitivity towards damage detection. Whereas for a crack near the blade tip, all three parameters indicate almost the same level of sensitivity for damage identification by resulting in similar values for the damage index.

In order to investigate the effect of mistuning on modal vectors, slope and curvature, damage index curves were obtained for a bladed disc having cracks of various depths considering mistuning model 2 (as defined in the previous section). Results are shown in Figure 6. Presence of mistuning resulted in higher magnitudes of damage indices due to mode localization. However, the trend comparison of the modal vector, slope and curvature follows the same pattern as in case of tuned bladed disc. It should also be noted that for the mistuned bladed disc, separation between the damage index curves of the modal vector, slope and

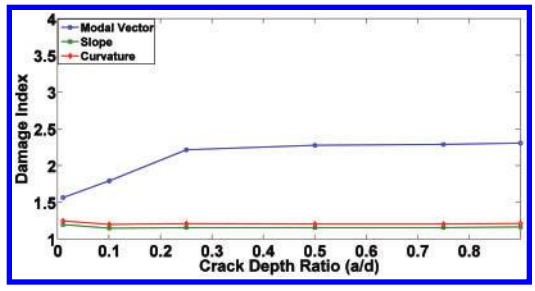

Figure 7. Damage index curves for blade tip data.

curvature is nearly the same for all three crack locations. This indicates that the selection of best suited parameter for damage detection is overwhelmed by the effects of presence of mistuning in the repeating structures. For all the three crack locations, modal curvature may be a better option to estimate crack in mistuned structures.

Applicability of this technique for a reduced data set from the blade tips (representing blade tip data) was also investigated and the results are shown in Figure 7. Slope and curvature indicated less sensitivity towards damage detection considering reduced data set from the blade tips by resulting in smaller damage indices. This is due to the fact that data acquired from the blade tip do not truly represent the actual modal deflection of a blade. Selection of modal vector as a damage detection parameter is a better option in comparison to its counterparts in this case.

6 CONCLUSIONS

A modal characteristics–based damage investigation was carried out in this paper considering a simplified repeating structure in the form of a bladed disc. Three modal parameters (modal vectors, slope and curvature) were considered for this study. It was found that for a tuned system, modal curvature indicated greater sensitivity to the presence of damage if the damage is present in the region between blade root and half way along the length of blade. However, for a crack developed near the blade tip, any of these three parameters can be used for damage estimation. For the mistuned system, the presence of mistuning resulted in similar trends of modal vectors, slope and curvature for any crack location (separation between the damage index curves is similar). For the reduced data set from the blade tips, slope and curvature proved to be insufficient to highlight the damage by resulting in lower damage index magnitudes.

Research on corrosion monitoring for steel-reinforced concrete structures using fiber optic sensing technique

X.F. Zhao, L. Wang, Q. Liu, S.J. Shan, H. Dong, Y.F. Zhu, Y.H. Jiang & Y. Yu
School of the Civil Engineering, Dalian University of Technology, Dalian, China

ABSTRACT: One novel kind of Brillouin corrosion sensor was proposed and tested in this paper. Distributing strain sensing ability was utilized to monitor the corrosion expansion which is the key reason for concrete corrosion deterioration. Strain sensitivity test was designed to obtain the strain coefficient. And then one kind of Brillouin corrosion sensor packaging structure was designed and developed. The test results show that there is good linear relationship between Brillouin frequency shift and strain, and also corrosion expansion strain can be monitored using corrosion sensor developed precisely.

1 INTRODUCTION

Steel corrosion is the key factor leads to deterioration of steel reinforcement concrete structures and the consequent corrosion of steel will lead to severe damage of structures. The detection and measurement of corrosion are essential for damage evaluation and prevention, and also safety maintenance (Metha 1991, Matta 1992). Lots of research work has been conducted to monitor corrosion. Common corrosion monitoring methods reported are based on electrochemical method, whose durability and stability are the obstacles to long time span corrosion health monitoring. Comparing with traditional corrosion sensing technique, fiber optic sensing technique provides new approach for corrosion monitoring, with its advantages, such as good durability, good stability, electromagnetic interference immunity, high precision, etc (Lee 2003, Gafsi 1999). P. L. Fuhr and D. R. Huston developed the fiber optical chloride detector, whose sensing mechanism relies on spectroscopic analysis of a chemical reaction of chloride and reagents (Fuhr 1996). K. D. Bennett designed a prototype optical fiber sensor for monitoring corrosion on large steel structures and the sensor works by pulling a multimode fiber into a tight bend and securing it with a "corrosion fuse"(Bennett 1995). And Xueming Li proposed a Fiber Optic Corrosion Sensor (FOCS) fabricated by electroplating a Fe-C alloy film onto an optical fiber core within the sensing region (Li 1998). Research works mentioned above need extra packaging structure or sensing materials to transfer corrosion related parameters to fiber optic sensitive parameters detectible, which will affect durability and stability of corrosion sensors, inevitably. Fiber optic Brillouin sensing technique is deployed in this paper to provide one new approach to corrosion monitoring for good durability and stability measurement.

The fiber optic Brillouin sensing technique is based on Brillouin scattering phenomena. Fiber optic is utilized both as sensing element and signal transmission medium. When a short light pulse is launched into and transmitted along the fiber, the frequency of the Brillouin backscattering light can be measured at the same end. The time interval between sending the pulse and backscattering light arriving provides the spatial information, while the frequency of the backscattering light provides information of the temperature or strain distributed along the fiber optic. The backscattered Brillouin frequency is shifted from ... the incident light frequency because of the temperature variation and strain variation along the optic fiber. The Brillouin frequency shift is determined by the following equation (Horiguchi 2002):

$$f_B = 2nv_a / \lambda \tag{1}$$

Where f_B is Brillouin frequency shift, n is refractive index of fiber, v_a is the acoustic wave velocity and λ is wavelength of incident light.

The relationship between the Brillouin frequency shift at a certain location along the fiber and its corresponding temperature and strain change can be described as the following equation:

$$f_B = k_{ft}\Delta T + k_{f\varepsilon}\Delta\varepsilon + C \tag{2}$$

Where ΔT is temperature change, k_{ft} is temperature coefficient, $k_{f\varepsilon}$ is strain coefficient of Brillouin frequency shift, $\Delta\varepsilon$ is strain change and C is a constant.

In the case of pure strain variations, the relation can be simplifies as :

$$f_B = k_{f\varepsilon}\Delta\varepsilon + C_1 \tag{3}$$

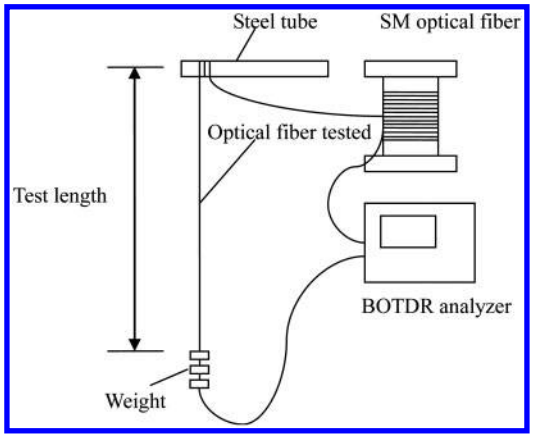

Figure 1. sensitivity test set up.

As a result, by measuring the Brillouin frequency shift we have access to the local temperature and strain conditions along the fiber optic.

When corrosion coursed by Cl- penetration or carbonation happens, there will be one rust accumulation layer on the steel rebar surface with cross section reduction. Generally, rust volume of corrosion is 2–4 times than steel volume lost, which is the reason for corrosion expansion of steel rebar in reinforcement concrete structure. If single mode fiber optic was winded around the steel rebar into coils, the rust expansion will lead to the elongation of fiber optic. According to the sensing principle of Brillouin sensing technique, strain distribution along the fiber optic coils can be detected by Brillouin Optical Time Domain Analysor (BOTDA).

2 STRAIN SENSITIVITY TEST

Single mode fiber optics with sensing lengths of 1 m and 2 m were studied, and strain calibration experiments were designed and conducted to obtain the strain coefficients for monitoring corrosion expansion strain In the experiments, a steel tube with 5 cm of diameter was used to support fiber optics with sensing lengths of 1 m or 2 m, respectively, as Figure 1 shows.

Weight was loaded and unloaded using weights ranging from 0 to 200 g, in increments of 50 g. Two load cycles were conducted for each kind of test length. Spatial resolution of 1 m, and a sampling interval of 0.41 m was used for every experiment. The Brillouin frequency was measured using BOTDA analyzer in every load step.

Diameter of fiber optic is 0.125 mm, and Young's modulus is 0.72×105 N/mm^2. According to elastic theory, there should be uniform strain distribution along the test length of fiber. When the weight of 50 g is loaded at the end of fiber, the strain change along the fiber is 558 $\mu\varepsilon$.

In the fiber optic circuit, only the sensing fiber optic with length of 1 m and 2 m is under extension load.

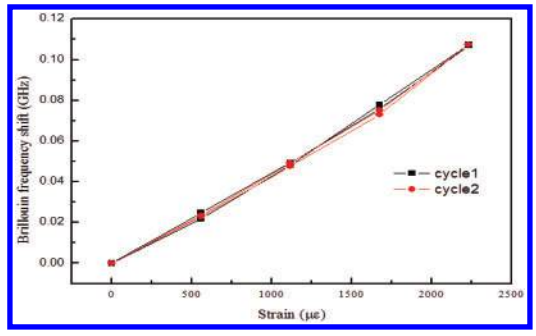

Figure 2. Strain sensitivity result of sensor with length of 1 m.

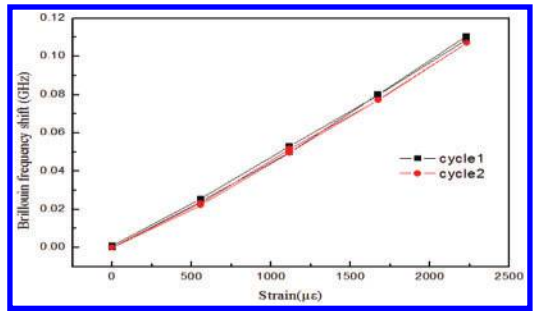

Figure 3. Strain sensitivity result of sensor with length of 2 m.

There is signal change of the Brillouin frequency in the sensing fiber area, and no apparent signal change is found in any other part of fiber optic circuit, as Figure 11 shows. The signal peak grows gradually as loads from 0 g to 200 g were added in increments of 50 g. The maximum value at each signal peak is used to calibrate the strain coefficient.

There were very good linear relationships between load and Brillouin frequency, when test length is 1 m and 2 m, as figure 2 and 3 show Also, good linear relationships between strain loaded and Brillouin frequency are found. Averaging strain coefficient of 0.048 MHz/$\mu\varepsilon$ was obtained.

The strain calibration experimental results show that single mode fiber optics with sensing lengths of 1 m and 2 m can serve as strain sensors. The strain coefficients obtained with the two kinds of length show very good agreement. There is very good linearity of the results with the BOTDA analyzer using the spatial resolution of 1 m and sampling interval of 0.41 m.

3 CORROSION MONITORING TEST

3.1 *Corrosion sensor design*

Design scheme of Brillouin corrosion sensor is illustrated in Figure 4 and sensor packaging method follows the steps as described below: 1) polish the surface of a 50 mm-length part of a steel rebar with diameter of 22 mm(ϕ22), after which the diameter in polishing

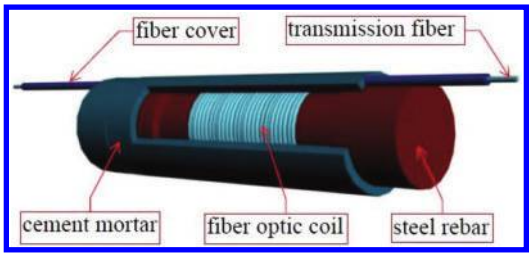

Figure 4. Packaging structure of Brillouin corrosion sensor.

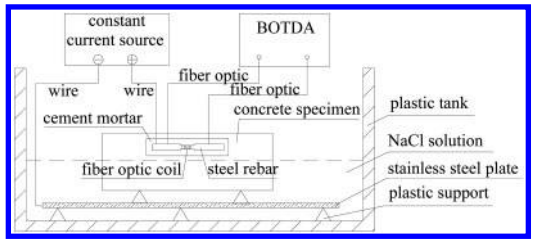

Figure 5. Schematic diagram of the electrochemical corrosion accelerating test system.

area decreased to 18 mm. 2) wind about 50 circles of single mode fiber optic into coils with a little pretension, which will guarantee the close contact of fiber optic and steel rebar surface. The total winding length of the fiber optic is about 3.0 m. 3) fix both ends of the fiber optic on the rebar using epoxy glue, and draw out the fiber optic along the steel rebar. 4) Put one layer of cement mortar with depth of 4 mm outside the fiber optic to prevent damage to fiber optic coil winding. Cement mortar mass mix rate is Cement: Water: Sand = 1:1.15:3.Cement mortar layer can provide better packaging structure with little interference to corrosion interface than other packaging materials, which make the steel rebar inside corrosion sensor have one corrosion development close to real corrosion development. In the sensing structure, fiber optic in coil winding area serves as sensing element, and the other severs as signal wire for light transmission. There are two ends of fiber optic were lead out of the cement mortar layer for connection with BOTDA.

Single mode fiber optic used is Corning G.657.A/B, minimum bending curve radius of the fiber optic is 7.5 mm, which will keep optical loss in a very low level after dozens fiber optic coils were winded.

3.2 *Corrosion test*

In order to study the sensitivity of Brillouin corrosion sensor developed, one electrochemical corrosion accelerating testing system was designed and built to accelerate the steel rebar corrosion process in concrete specimens, as shown in figure 5. In the system, the steel rebar was the a node and the stainless steel plate was the cathode. When electric current was applied, the circuit between the steel rebar and the plate was conducted by Cl^-, which will transport Cl^- ion in the solution to the surface of the rebar continuously. Cl^- is one of the most important factors influencing the corrosion of the steel rebar, and therefore this kind of experiment setup can accelerates the rate of corrosion enormously. During the test, the mass concentration of the solution of NaCl is 5.0%, and the constant current source was applied. The current through the specimen was 0.05A.

Before the test, the corrosion sensor was embedded into concrete specimens by concrete casting. The size of concrete specimen was 100 mm * 100 mm * 300 mm. Ultimate strength of concrete was 30 MPa. The cement using was P.O 32.5, and the concrete mix mass ratio Cement: Water: Sand: Aggregate = 1: 0.4: 1.26: 2.24. One sensor was embedded into concrete specimen, and placed along the axis of the specimen close to upper surface, as shown in figure 5. Half immersing accelerating corrosion method used here can guarantee relatively high corrosion speed and less corrosion rust leakage. The specimen was putted into the steam maintaining room for 10 days, after casting, and kept at room temperature at 22°C for 3 days before it was tested.

BOTDA analyzer used was DiTest STA202-C made by Omnisens Company. It was used to collect monitoring data during the tests, whose sampling interval is 0.41 m, and spatial resolution 1.0 m, and strain resolution is 2 $\mu\varepsilon$. BOTDA analyzer was set up to scan the optical circuit every one hour automatically, during the tests.

3.3 *Result analysis*

Electrochemical corrosion accelerating test was conducted on the specimen continuously until the signal of sensing fiber optic became very week that BOTDA analyzer cannot detect it. The test lasted for 32.5 hours. There is no crack found on surface of specimen after test. Figure 6 shows the relationship between distance and Brillouin frequency at different time sampling point. There is one signal peak of Brillouin frequency shift at the distance 33.78–37.03 m, where is the fiber optic coil of corrosion sensor located in the fiber optic circuit of experiment system. No apparent signal change was detected in other locations of fiber optic. The signal peak grows gradually as the test proceeded. Results reveals that the corrosion sensor can monitor Brillouin frequency variation in fiber optic coil area coursed by the steel rebar corrosion expansion in the specimens.

Frequency value of every sampling point monitored is average Brillouin frequency along area in certain length of fiber optic in backward direction (the length of the area equals to spatial resolution specified).The area is called sampling area of one sampling point. If sampling area is fully located in sensing area, the point is called Valid Monitoring Point (VMP). If only one part of sampling area of one sampling point is located in sensing area, the point is called Invalid Monitoring Point (IMP). The other points are called Transmitting Point (TP). Considering the spatial resolution, sampling interval and length of sensing fiber

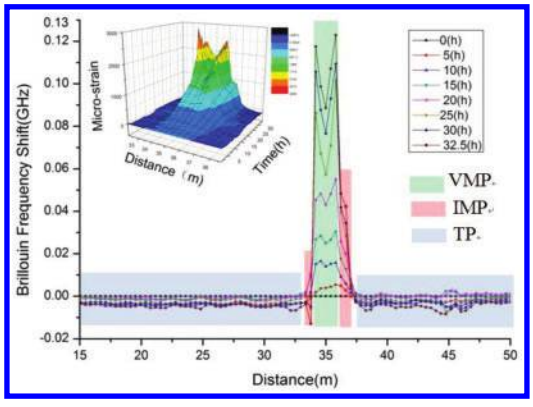

Figure 6. Brillouin frequency result of Brillouin corrosion sensor.

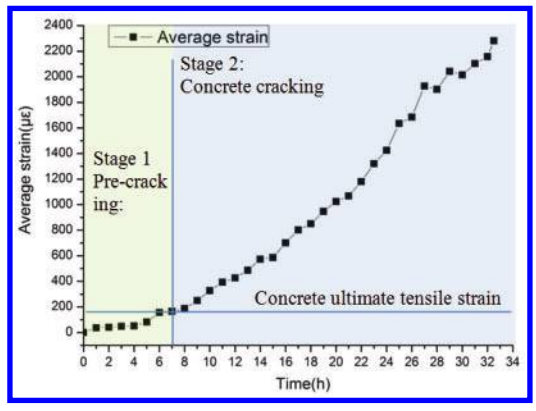

Figure 7. Average strain result of Brillouin corrosion sensor.

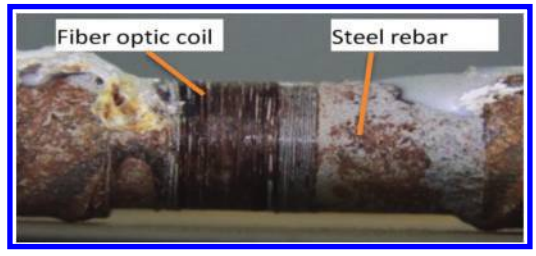

Figure 8. *Corrosion status of steel rebar inside Brillouin corrosion sensor after test.*

optic, five valid monitoring points was selected, as shown in figure 6. Five valid monitoring points were located in 34.18 m, 34.59 m, 35 m, 35.4 m and 35.81 m in fiber optic circuit, respectively. From 3D view of the Brillouin frequency shift monitored, increasing trend of Brillouin frequency can be seen clearly. There are two small peaks in two sides of fiber optic coil area, which means that corrosion expansion monitored is not very evenly distributed along the steel rebar in sensing area. Maximum value of 0.12286 GHz was monitored at sampling point at 35.81. There is little change in transmitting fiber optic area, which is because of that there is little environment temperature change. Because of that there is good linear relationship between Brillouin frequency and strain applied, strain coefficient of 0.048 MHz/$\mu\varepsilon$ obtained from strain calibration test was used here to calculate the expansion strain. Average expansion strain around steel rebar surface was obtained using values from five valid monitoring points, as shown in figure 6. Result show the expansion strain increase gradually as accelerating test proceeded. At very beginning, expansion strain of 37 $\mu\varepsilon$ by corrosion is monitored one hour after test started. And then strain increases gradually. Ultimate tensile strain of concrete is about 160 $\mu\varepsilon$, beyond which expansion crack will occur. Strain monitored at 7th and 8th hour is 156 $\mu\varepsilon$ and 165 $\mu\varepsilon$, respectively. There will be crack occur at this moment, after which bigger expansion strain increasing slope can be observed. Corrosion speed increases as the interface between steel rebar and concrete was damaged by crack development. Then corrosion expansion strain increases with a high speed, until maximum average strain of 2282 $\mu\varepsilon$ is monitored.

Test results show that Brillouin corrosion sensor is very sensitive to corrosion expansion strain, and can detect the strain change at first hour. And also this kind of sensor can capture the corrosion speed different at crack occur moment around concrete ultimate tensile strain value, with which corrosion status can be evaluated to two stages: pre-cracking stage, cracking stage, as shown in figure 7.

After the test, concrete specimen was broken to inspect corrosion status of steel rebar inside. There is one corrosion rust layer on the steel rebar surface, as shown in figure 8; there is no spot corrosion found. The fiber optic coil is not broken, it can be seen that there are rust between fiber optic coil and steel rebar. Reason of the signal detection failure at the end of corrosion accelerating test is the big optical loss by micro bending from corrosion expansion.

4 CONCLUSIONS

One novel kind of cement mortar packaged Brillouin corrosion sensor was proposed in this paper. Single mode fiber optic coil winding with cement mortar protection layer was used to monitor strain change by corrosion expansion of steel rebar. Test results shown that Brillouin corrosion sensor is very sensitive to corrosion expansion strain, can detected the strain change at first hour. And also this kind of sensor can capture the corrosion speed different at crack occur moment around concrete ultimate tensile strain value, with which corrosion status can be evaluated to two stages: pre-cracking stage, cracking stage. And with assumption of even corrosion, diameter of steel rebar can be calculated using average strain monitored. This kind of sensor is featured with low cost, long durability, and expansion strain monitoring ability, which can be used for corrosion monitoring and evaluation of steel reinforcement concrete structures in a long time span.

ABSTRACT: The base theory and principle of ultrasonic guided waves was briefly presented. By using finite element analysis program ANSYS to establish the steel model, and imposed excitation load on the terminal of the steel, to simulate the spread of ultrasonic guided waves and the reflected echo of defects. Through the analysis of the received signal, we could find the position accurately, and systematic analysis of the depth factor and axial length factor. The result of simulation was proved by experiment, The results obtained by numerical simulation agree well with that of experiments previously conducted by former investigators.

1 INTRODUCTION

Steel bars have been widely used in civil engineering, such as anchor bolt in geotechnical engineering, suspender in construction engineering, and steel wire in the cable-stayed bridge. These structures usually play a major bearing role in the project, easily influenced by the external environment, emerging the defects, resulting in huge economic losses and casualties. The detection in the course of using has a very important significance. The most common methods to detect the steel bars corrosion are as follows, drill cores, half-cell measurement, ultrasonic waves and radar [2–3]. But all these methods have their own shortcomings. Drill cores can only get the local information of test point, bringing the damage to the whole structure. Half-cell measurements are easily affected by resistance and pH of concrete. Ultrasonic waves and radar propagate short distance and only sensitive to significant defects. Thus, a more precise and efficient method is urgently needed.

UGW, as a developed tool, have many advantages comparing to traditional detective methods. First, it can propagate a long distance, because of its little attenuation in steel [4]. This characteristic is especially suitable for detection of the long range bridges; Second, high sensitivity is another merit of the method. UGW have many different modes at a single frequency and these modes are sensitive to different defects. Third, UGW have broad coverage. The whole information of the rebar and concrete can be obtained using a pair of transducers. The reason is that the sound field spreads all over the waveguide instead of a single point or surface. Therefore, it is meaningful to investigate the propagation characteristics of UGW.

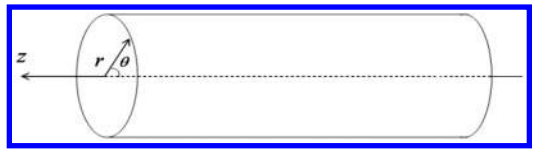

Figure 1. Geometry profile of steel rebar.

2 THE THEORETICAL BASIS

2.1 *Ultrasonic guided waves in rebar*

The propagation of guided waves is in accordance with elastic theory in elastic media, while in non-elastic media, they follow the viscoelastic theory. Pipes, anchor molts, rails and steel rebar are typical waveguides. The geometry profile of rebar is presented in Fig. 1.

There are three different modes propagating in cylindrical waveguide, longitudinal modes L (0, m), torsion modes F (n, m) and flexural modes F (n, m). In this expression, m and n stand for circumferential order and modulus, respectively. The displacement is symmetrical corresponding to $n = 0$, while $n = 1, 2, 3 \ldots$, refer to asymmetrical displacements. Therefore, L (0, m), T (0, m) are symmetrical modes and F (n, m) are asymmetrical modes.

The longitudinal modes that propagate in steel rebar have only two types of displacement, radical displacements and axial displacements. The boundary condition is $u_\theta = 0$, and u_z u_r are independent of θ. Taking into account of the boundary condition $\sigma_{rr} = \sigma_{rz} = 0 (r = a)$, Pochhammer frequency

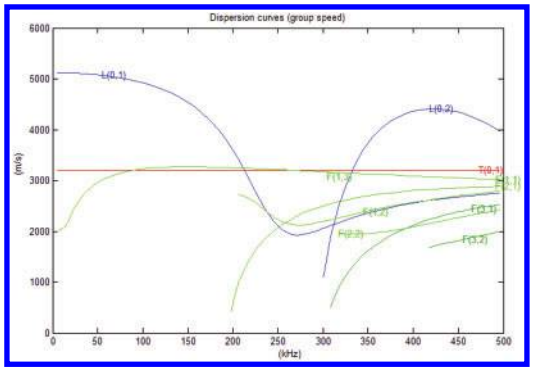

Figure 2. Disperse curve for the 12mm diameter steel.

equation can be achieved by solving the wave equation.

$$\frac{2\alpha}{a}\left(\beta^2+k^2\right)J_1(\alpha a)J1\left(\beta a\right)-\left(\beta^2-k^2\right) J_0(\alpha a)J_1\left(\beta a\right)-4k^2\alpha\beta J_0\left(\beta a\right)=0 \quad (1)$$

where λ is the length of guided waves, ω is angular velocity, k is wave number, J is Bessel function and coefficients $\alpha^2=\omega^2/c_L^2$, $\beta^2=\omega^2/c_T^2-k^2$, c_L is velocity of longitudinal guided waves, c_T is velocity of transverse guided waves , c_P is phase velocity. This is a transcendental equation with independent variables ω and k. Basing on the theory of mathematics, we know there are more than one solution to a single frequency ω. This phenomenon corresponds well with the fact that many modes are existed at a single frequency. This is the multiple modes property of UGW.

2.2 *Dispersion curves*

The curves that depict the relationships between frequency and phase velocity, frequency and group velocity are called dispersion curves. The phase velocity is defined as the speed of the phase of wave propagation in the waveguide while group velocity corresponds to the speed of wave packet propagation. Above definitions are the two fundamental parameters that describe the characteristic of wave propagation. All waveguides, both symmetrical ones and asymmetrical ones, have special dispersion curves.

Take the 18 mm rebar as an example, its area of cross section is 201.1 mm^2, density is $\rho=7858.5$ kg/m^3, and Young's modulus, passion ratio are 206 GPa and 0.28, respectively. We can neglect the influence of ribs when the ratio of diameter to length is less than 0.4. The ratio of diameter to length is 0.025. Thus, we can ignore the effect of steel ribs. Dispersion curves showed in Fig. 2 can be achieved by numerical calculation.

2.3 *Steel rebar corrosion damage detection principle*

When guided wave is propagated in the medium encountering defects, it is occurred reflection, transmission and mode conversion, resulting in the echo which brings the whole structure information. Dealing with the received signal we can determine the location of the defect, Figure 3 for the defect locations principle.

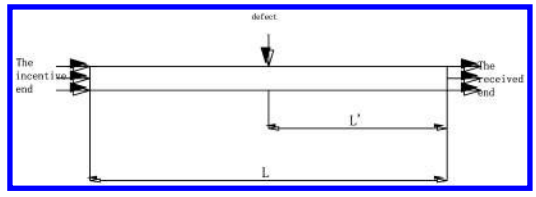

Figure 3. Principle of defect position.

Incentive side and the receive side are both at the end of the rod, the distance between the receiving end of the defects at the distance is L′, time interval between the incentives end and receiving end of the echo signal received is t, time interval between the defect echo and echo is t′, velocity of longitudinal wave is c, using the formula $L=ct'=ct'/2$, we can determine the length of the rod and the location of the defects.

2.4 *Reflection coefficient*

When guided waves speed to the rod-shaped structure defects, it will occur the phenomenon of reflection and transmission .In order to accurately analysis the impact on the detection for of the crack size, define the dimensionless reflection coefficient R.

$$R_c=\frac{V_b}{V_t} \quad (2)$$

Among them, V_b is the peak of the wave packet which defects back, V_t is the peak of the first signal wave packet. The reflection coefficient is a dimensionless parameter, which does not contain the size of the parameters, of the excitation signal, so it can be widely used to characterize the size of the defect echo. The quantitative research of guided-wave defect detection is of great significance.

3 NUMERICAL SIMULATION

3.1 *Steel rebar corrosion damage detection principle*

Numerical Simulation we selected diameter is 12 mm, length 1.2 m, round steel, elastic modulus 210 Gpa, Poisson's ratio is 0.3, the density of 7800 kg, and unit type is solid45 units.

For the transient dynamics analysis type, we select the FULL method, select the superposition of a single audio signal after 5 cycles hanning window regulator, the signal frequency is 100 KHZ, shown in Figure 4. The cell size selection within each wavelength range consists of 10 units to meet the requirements of the calculation accuracy. so we Can calculate the wavelength of $\lambda=4900/100\ 000=0.049$ m $=49$ mm, so choose

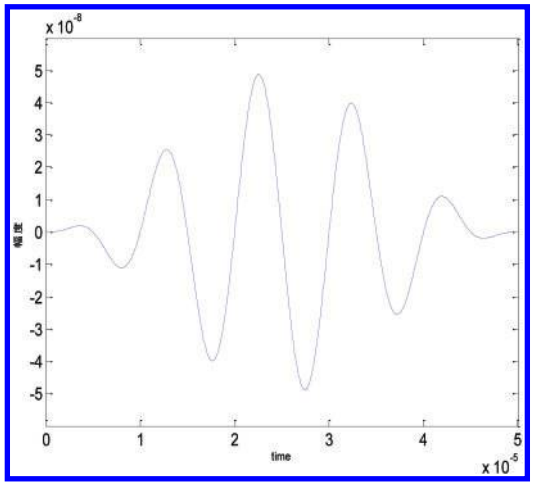

Figure 4. Sketch of exciting signal.

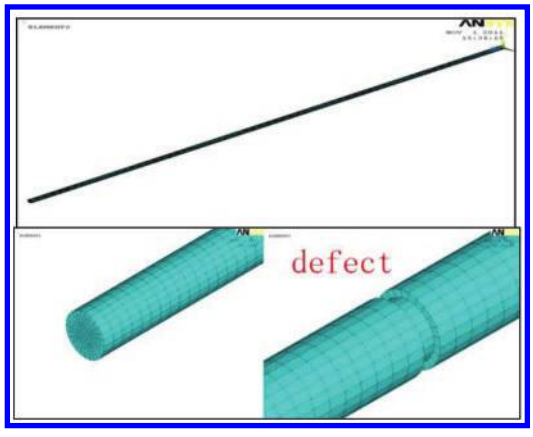

Figure 5. Model and meshing by ANSYS.

the 3mm divided into a unit. The finite element model was shown in Figure 4. The defects are Circumferential defects, and the defect length is divided into an integer multiple of the grid.

4 NUMERICAL SIMULATION

4.1 *Signal processing*

As guided waves is multi-modal, usually includes a variety of modes in its received signal. Simulated depth of 0.6 mm, 1.2 mm and 1.8 mm, the length of 3 mm, 6 mm, 9 mm, 12 mm and 15 mm defects, the results are shown in Figure 6 to Figure 9.

Then simulated two defects, the distance between defect and the receiving end are 600 mm and 300 mm, the length of defect is 3 mm, the depth of the defects were 0.6 mm, 1.2 mm and 1.8 mm. The simulation results are shown in Figure 9.

According to the dispersion curves, around the frequency of 100 kHZ, group velocity is huge difference

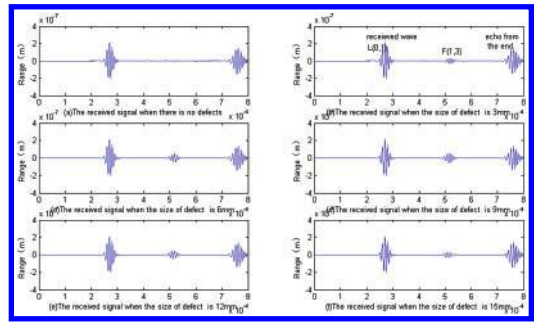

Figure 6. Signal from the terminal, 0.6 mm in defect depth, 3 mm, 6 mm, 9 mm, 15 mm in axial separately.

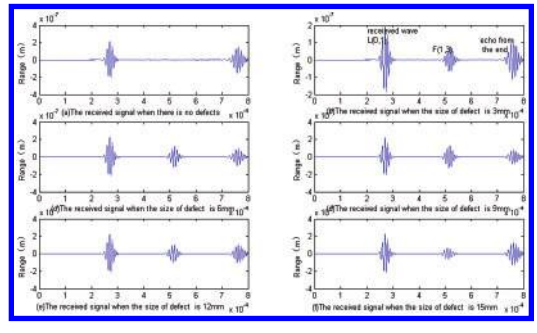

Figure 7. Signal from the terminal, 1.2 mm in defect depth, 3 mm, 6 mm, 9 mm, 15 mm in axial separately.

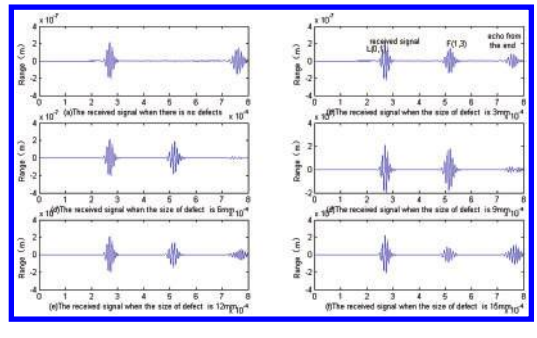

Figure 8. Signal from the terminal 1.8 mm in defect depth 3 mm, 6 mm, 9 mm, 15 mm in axial separately.

between the L (0,1) mode guided wave and F (1,1) mode guided wave difference, so their wave packet will separate ,it is easily indicated, it is easy obtained to identify. In addition, because around 100kHZ group velocity curve is sharper than the other modes, so dispersion phenomena is more serious than the other modes, the length of wave packet is longer for than the other modes wide in the time domain, in Figure 6 to Figure 9, this phenomenon can be found. When the guided wave meet the defects, it will occur modal transformation, and inspire the F (1,3) mode guided wave, at last, it will be received at the receiving end. Figure 6 to Figure 9 also made a corresponding identity. These are consistent with the theoretical analysis of guided wave dispersion.

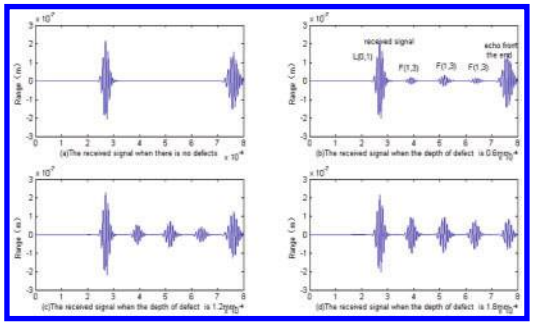

Figure 9. Signal from the terminal, 3 mm in axial, double defects, 0.6 mm, 1.2 mm, 1.8 mm in defect depth.

As for the case of two defects, there will be three defect echoes, because the receipt of the second defect echo, it will continue to reflect, the reflected waves encounter the first defect will occur launch and received, so it will form of the third defect echo. Because it had produced a modal superposition, so it did not get the effect that the margin getting smaller and smaller.

4.2 *Defect detection results and analysis*

In the diameter of 12 mm, length 1200 mm steel rebar, there is a circumferential defect in the distance from the receiving end of 600 mm, Figure 5 to Figure 8 is the echo chart. We can conclude that, guided wave which generated from the incentive side, encountered defects and the transmitted wave reach the receiving end reflect, once again encountered the defect, the defect echo is received by the receiving end. Therefore, the clearer defect echo must be received in the first $L(0,1)$ and the second received L (0,1). when the frequency is100 kHZ , the speed of L (0,1) mode is 4914 m/s, take the defect depth is 0.6 mm, length is 0.3 mm for example, the first wave of the echo signal 0.2444 ms defect echo signal 0.4876 ms calculated, we can see the length of the reinforcement 4 914 * 0.244e-3 = 1.201 m, the location of the defect (0.4828e-3-.2444) * 4914/2 = 05946, the actual length and defect location is 1.2 m and 0.6 m, so the relative error of 0.087% and 0.895% respectively. in the allowable error range. All the calculation results are shown in Table 1.

It should be stated that, the main features of the guided wave technology is the large detection range, long distance detection, for use of defect detection of large-scale structure, the relative error in this article works within the error range. The source of the error is the error of the data read from the time domain graph, and this is the recognition by the human eye. Therefore, the ultrasonic guided wave detection of reinforced length and positioning defect location is feasible.

4.3 *The variation between the reflection coefficient and crack size*

Figure 10 indicate the depth of 0.6 mm, 1.2 mm and 1.8 mm, relationship between axial length of

Table 1. Results of calculation of the reinforcement length and defect location for a single defect.

Items	Calculation the length	Calculation the location of defect	Error for length	Error for defect location
No defects	1.2030	none	0.251%	none
defect length:3 mm depth:0.6 mm	1.2011	0.5951	0.087%	0.813%
defect length:6 mm depth 0.6 mm	1.1971	0.5976	0.240%	0.403%
defect length:6 mm depth: 1.2 mm	1.2030	0.5966	0.251%	0.567%
defect length:6 mm depth: 1.8 mm	1.2050	0.5956	0.415%	0.731%

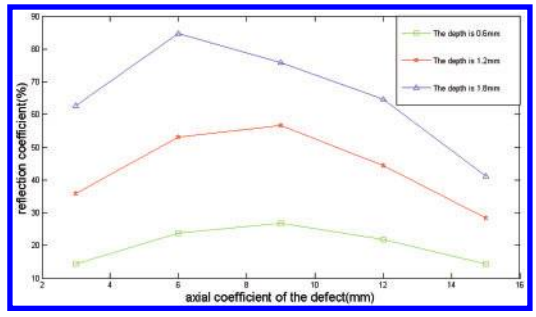

Figure 10. Relationship between the axial length and reflection coefficient.

reinforced the circle distribution defects of and the reflection coefficient.

It can be seen from Figure 10, the reflection coefficient will reach the maximum when the length of defect axial is 6 mm or 9 mm, when the length of defect axial is less than 6 mm or greater than 9 mm, the reflection coefficient reduce. This may be due to the echo in the front section of the defects and in the cross-section of the defects mutual interference. When the distance between back and forth section is even multiple as wavelength of the incentive guided wave, it will occur Mutual enhancement interference, so that the reflection coefficient increases; When the distance between back and forth section is odd multiple as wavelength of the incentive guided wave, it will occur Mutual counteract interference, so that the reflection coefficient is minimum.

Figure 11 shows the axial length of 3 mm, 6 mm, 9 mm, 12 mm and 15 mm, the affection of the defect depth on the reflection coefficient. In figure, the horizontal axis is the ratio between the defect depth and the radius.

It can be seen from Figure 11, the depth coefficient and reflection coefficient are essentially linear

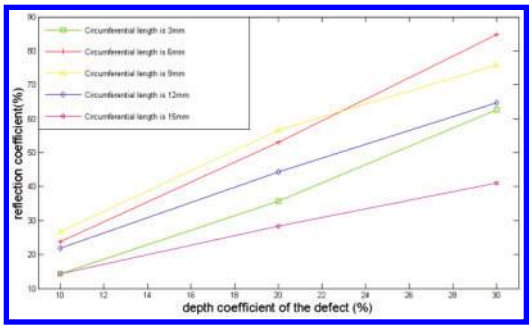

Figure 11. Relationship between the depth and reflection coefficient.

variation. That is, the deeper the defects, the greater the reflection coefficient. This may be due to that along with the defect depth increasing, the guided wave through defects will be reduced, the peak will fall, after echo through the defects, and then return to the receiving end receives, the defects increases, the peak of the defect echo will increase, therefore, the reflection coefficient will increase.

5 CONCLUSIONS

Through theoretical analysis, numerical calculation and experimental research can draw the following conclusions:

(1) The time of cracks reflected wave can accurately determine the crack location. The time of cracks reflected wave has nothing to do with crack size, but with crack position and material parameters.

(2) With the increase of axial length of defects, the emission coefficient changes erratically; when the defect depth changes, the emission coefficient is of linear change. That is, it is not sensitive to the axial width of the axial crack width for the reflection coefficient.

The main error comes from the calculation of material constants (such as wave velocity, density, etc.) different with the experimental material constants and the error of the defect echo time read from the oscilloscope.

Structural condition assessment based on modal flexibility from operational modal analysis and model updating

L.-M. Zhang, T. Wang & X.-K Lin
Dynamic Testing & Analysis Center, Nanjing University of Aeronautics & Astronautics, P.R. China

ABSTRACT: The deflection of a bridge under predetermined loading is widely utilized for bridge condition assessment. A modal flexibility method based on advanced operational modal analysis (OMA) and finite-element model (FEM) updating is proposed. Modal frequencies and mode shapes can be identified directly from OMA based on traffic-induced bridge vibration response measurements. In order to obtain modal masses accurately, a fine FE model of the bridge is built followed by model updating using modal parameters obtained from OMA. Flexibility matrix, and hence deflection shape with known static loading, can then be derived and applied for condition assessment instead of running an expensive and time consuming static testing. Both narrow band and broadband OMA techniques, based on frequency-spatial domain decomposition (FSDD) and polyreference Right Matrix Fraction Polynomial (RMFP) modal identification algorithms, are utilized for OMA. The influence of traffic mass loading and modal truncation to the accuracy of the final deflection results are studied via computational simulation based on updated FE model. Finally, modal flexibility method, which combines OMA and FEM updating, is utilized for structural condition assessment. The method has been successfully applied to a few prestressed concrete box-girder highway bridges. The modal flexibility method is validated via comparison of deflection derived with the ones obtained directly from static reflection testing. Encouraging results are obtained with major deflection errors less than 5%. Issues to be answered and further studied relating to structural condition assessment are summarized in the concluding remarks.

1 INTRODUCTION: STRUCTURAL HEALTH MONOTORING AND CONDITION ASSESSMENT

Structural health monitoring (SHM) has obtained increasingly attention in recent years due to associated potential for significant life-safety and economic benefits (Doebling et al. 1996, Farrar et al. 2001, Sohn et al. 2003). SHM can be referred to a process of implementing damage identification or detection for engineering structures. Damage can, in general term, be defined as changes to the material and/or geometric properties of the structures, including boundary conditions and structural connectivity, which adversely affect the structure's performance. As the damage grows and reaches a point where it affects the system operation and is no longer acceptable to the user. This point is referred to as failure.

Damage can be detected by local non-destructive evaluation (NDE). However, the majority of SHM research conducted over the last three decades has attempted to identify damage in structures on a more global basis. SHM involves the spaced measurements of a structure over time, the extraction of damage-sensitive features, or damage indices, from these measurements and the statistical analysis of these features or condition indices to determine the current state of system health.

On the other hand, visual inspection is typical routine applications for condition assessment of civil engineering structures (CES) for evaluating vulnerability post typhoon and earthquake damage or after accidents.(Catbas et.al. 1998, Akta et al. 2000, Brownjohn 2007) However, the relation between such visible signs of damage and the corresponding "condition" or "reliability" of the structure is often very difficult to establish. Civil engineering community has long been aware of the limitations and shortcomings of the visual inspection with subjective condition assessment. Objective condition assessment for making meaningful management decision and for cost-effective management has drawn great attention in the last 30 years.

One of the most important issues of damage or condition assessment for CES is to device appropriate features or damage indices. The selected feature, or damage index, should be effectively related to structural damage with small dimension and can be analytically predicted from computational model, and derived from field measurement of the structure as well. An array of dynamic features (or damage indices) has been developed for damage detection and condition

assessment. However, quite a few of them, e.g. modal parameters, are insensitive to the damage, and, hence, cannot be effectively applied for the damage detection or condition assessment.

In the bridge engineering static load testing is conducted to measure deflection shape, which is acceptable for condition assessment. However, such static testing has serious drawbacks, such as high cost, time consuming, and blogging normal traffic.

Modal or dynamic flexibility approach is proposed based on operational modal analysis (OMA). Dynamic flexibility, which actually is the frequency response function of the structure, can be synthesized via modal parameters identified via OMA of the structure subjected to, e.g. traffic excitation. Static flexibility, the elements of which is the displacement influence factors of the structure, can easily be obtained as special case of FRF as dynamic flexibility. Deflection shape is then calculated from flexibility matrix multiplying by pre-scribed static loading vector.

2 THEORETICAL BACKGROUND OF STRUCTURAL CONDITION ASSESSMENT BASED ON MODAL FLEXIBILITY

Frequency response function (FRF), or dynamic flexibility, model can be built via identified modal parameters:

$$[H(j\omega)]=\left[\frac{X(j\omega)}{F(j\omega)}\right]=\sum_{r=1}^{n}\frac{\phi_r\phi_r^T}{m_r\left[\left(\omega_r^2-\omega^2\right)+j2\xi_r\omega_r\omega\right]} \quad (1)$$

where flexibility can easily be obtained from dynamic flexibility, i.e. FRF, letting w = 0,

$$\underset{\omega\to 0}{[H(j\omega)]}=[W]=\sum_{r=1}^{n}\frac{\phi_r\phi_r^T}{m_r\omega_r^2} \quad (2)$$

Static deflection shape (d) can then simply be determined from known static load (f) with static flexibility matrix W: $\{d\}=[W]\times\{f\}$. Static flexibility can be determined for modal frequency, mode shape plus modal mass or modal scaling, where $r=1,2\ldots,n$.

Modal parameters can be identified via traditional experimental modal analysis (EMA) or operational modal analysis (OMA). Artificial excitation is required for the EMA, and therefore traffic normally should be blocked, that is unfavorable for the traffic administration. OMA makes use of natural excitation under operational condition. Actually traffic provides appropriate excitation for a bridge, which can be utilized for OMA. A variety of modal identification procedures have been developed for OMA. The 2-stage FD OMA approach would be appropriate for industry application, which estimating power spectrum density (PSD) via digital signal processing of random responses measurements as the first stage, and then conducting modal parameter estimation based on PSD data (Zhang et al. 2005a).

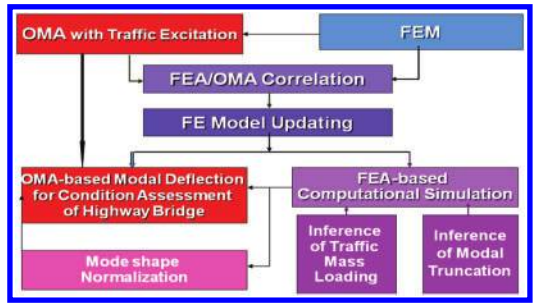

Figure 1. Flow diagram of modal flexibility procedure for bridge condition assessment procedures.

However, due to lack of excitation force measurement, only modal frequencies and unscalled mode shapes can be identified from OMA. In this project, in order to obtain accurate modal scaling factors, a fine finite element model of the structure is built and then updated (calibrated) based on identified modal parameters from OMA. Figure 1 shows flow diagram of the proposed modal flexibility procedure for structural condition assessment.

3 MODAL FLEXIBILITY METHOD APPLIED TO A HIGHWAY BRIDGE

A typical pre-stressed concrete continuous box-girder highway bridge is utilized for flexibility-based structural condition assessment study. The bridge is divided into left and right part, each of which includes a main bridge and two flanking bridges. The main bridge of the right part is composed of three-span pre-stressed concrete continuous box-girder. The total span is 236.33 m (Figure 2).

An operational modal analysis with traffic excitation on the right main bridge was carried out. Force-balanced-type of acceleration sensors were utilized with 32-channel dynamic data acquisition system. The sampling rate is 50 Hz, and all signals were recorded simultaneously with duration of 20 min. Traffic-excided dynamic responses at 30 points with half at left and half at right sides in vertical direction of the bridge were recorder. Fig. 3 gives typical time series recorded and power spectrum density (PSD) estimated via dynamic signal processing based on field measured response data (Zhang et al. 2010).

An advanced modal parameter identification technique, based on Frequency-Spatial Domain Decomposition (FSDD) algorithm (Zhang et al. 2005b), is utilized for modal parameter identification. The modal indication function MIF (Figure 4) of the FSDD shows there are 13 modes were clearly located in the frequency band of 0–25 Hz. The identified modal frequencies, damping ratios and mode shapes are presented in Figure 5.

Since there are no input force measurements in the OMA, only unscaled mode shapes can be obtained. However, flexibility matrix can only be calculated with

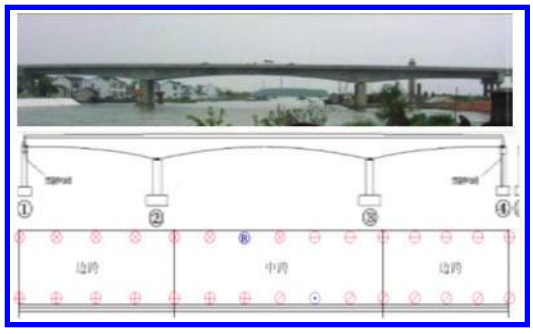

Figure 2. A pre-stressed box-girder bridge and OMA test setups.

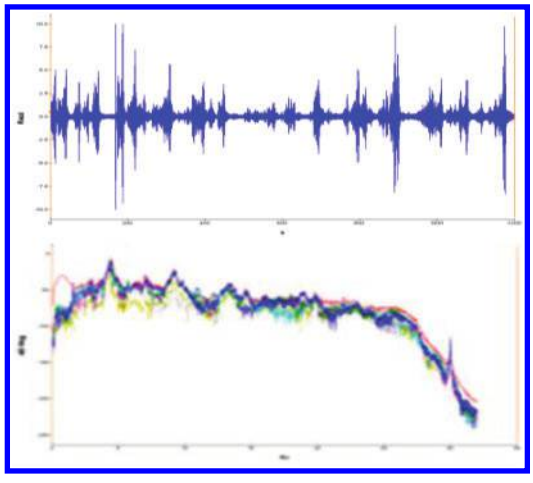

Figure 3. Typical time series and PSDs of the traffic induced dynamic responses of the bridge.

modal frequency and scaled mode shapes. In order to have an accurate modal scaling factor, a fine finite element modeling with model updating (calibration) was conducted based on rather accurately identified modal parameters via OMA.

A full 3-D FEM of the right main bridge is built making use of MSC.Patran, an advanced FEA software widely used in the aerospace and mechanical engineering [10]. The main structure, four piers, lateral guardrails, connections, the layer of bitumen and concrete fiber web, anchor, etc. of the bridge are discretized with different FE types. The main structure of the bridge is modeled by 5149 shell elements with four piers modeled by 288 solid elements and lateral guardrails modeled by 133 beam elements. The connections of the main structure and four piers of the bridge are modeled by 72 MPC (Multiple-point Constraints) elements; the layer of bitumen and concrete fiber web and anchor are merged into the main structure of the bridge. The complete FEM consists of 5,782 nodes and 5,570 elements resulting in 34,692 active degrees of freedom (DOFs) (Lin et al. 2009).

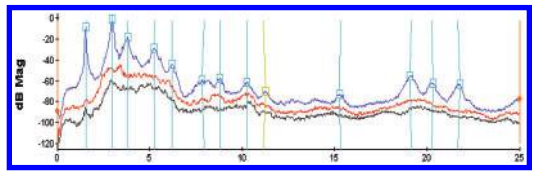

Figure 4. Modal indication functions of FSDD clearly indicate 13 modes in the frequency band of interest.

For the very complicated engineering structure, the maximum difference of modal frequencies computed via FEM to the ones obtained from OMA reaches 30% as shown in Table 1. It evidences the necessity for model updating (calibration). It can also be seen from the Table 1 that modal correlation before and after model updating improved significantly in both modal frequency and mode shape (via MAC values).

There are three key parts for FE model updating. The first key part of FEM updating is appropriate selection of physical parameters to be updated (calibrated) (Zhang 2012). Considering that the shell element is the majority type of elements in FEM, the elastic modulus and equivalent density of pre-stressed concrete and their thickness of geometrical characteristics are highly sensitive to the modal parameters, and they are selected as updated parameters. MPC elements between four piers and main structure are important factors affecting the precision of the FEM and also be selected as updated parameters.

The second key part of model updating is the selection of updating criterion which is closely related to the feature for model updating. Modal frequency and mode shape are classical features for model updating. For this project flexibility of the bridge is applied for structural condition assessment, and therefore, it is also utilized as dynamic feature for model updating. The third key part for model updating is to select an appropriate optimization algorithm to minimize the residue of selected feature/index. A real-coded accelerating genetic algorithm (RAGA) is applied to solve the minimization problem. Table 1 also shows the errors in modal frequencies and mode shapes, represented by MAC after updating. It can be seen, the FEM have been improved significantly after model updating (calibration). Except the 6-th torsional mode, the most modal frequency errors are less than 5%, and MAC values increased to more than 0.9. Figure 6 gives comparisons of the first six modes from OMA and updated FEA.

From updated FEM, modal scaling factor is extracted and modal flexibility is then calculated together with modal frequencies and unscaled mode shapes identified from OMA. Deflection shape under predefined external static loading is finally obtained. To study the impacts of the modal truncation and traffic mass loading to the accuracy of the deflection obtained from modal flexibility, computational simulations are conducted based on updated FEM. It has been shown

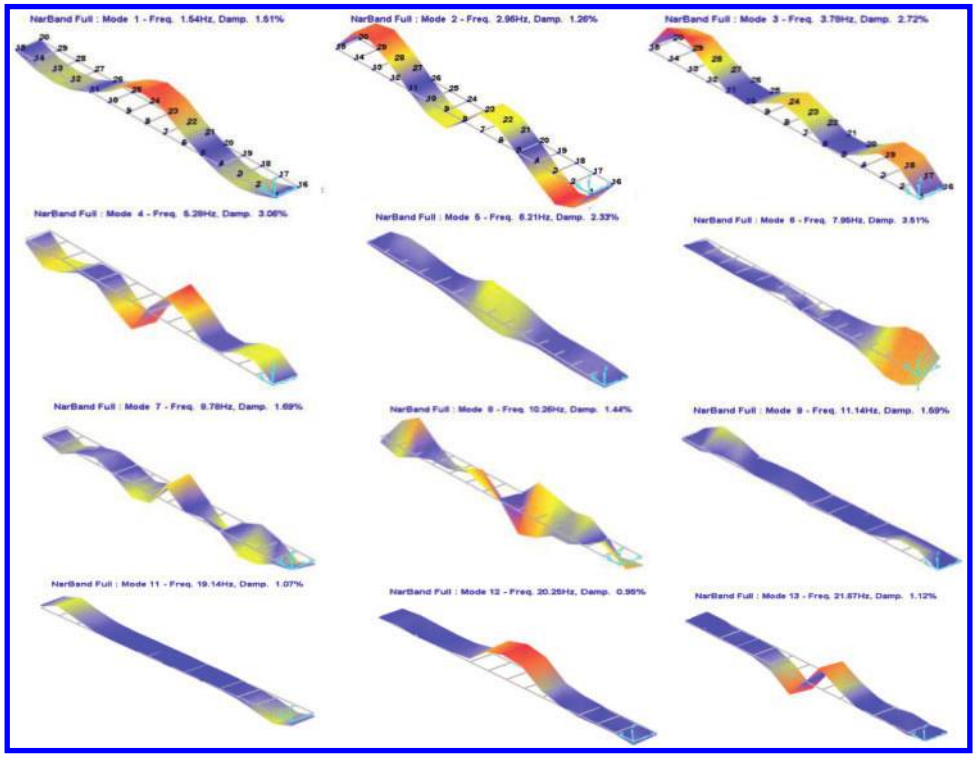

Figure 5. OMA identified 12 modes based on FSDD.

Table 1. Modal frequencies and MAC identified from OMA and predicted by initial and updated FEM.

No.	f_{Exp} Hz	f_A Hz	f_U Hz	ε_{fA} %	ε_{fU} %	$\varepsilon_{\phi A}$	$\varepsilon_{\phi U}$
1	1.54	1.45	1.59	−5.63	2.91	0.994	0.995
2	2.96	2.53	2.81	−14.4	−5.15	0.871	0.88
3	3.79	3.7	4.05	−2.41	6.4	0.965	0.939
4	5.28	5.18	5.59	−1.85	4.53	0.958	0.969
6	7.95	5.53	6.74	−30.4	−15.1	0.583	0.919
7	8.78	8.14	9.09	−7.26	3.41	0.892	0.929
8	10.3	8.41	9.84	−17.9	−4.05	0.828	0.893
10	15.3	13.3	15.2	−13.0	−0.47	0.87	0.87
12	20.3	15.7	18.5	−22.69	−8.7	0.927	0.958
13	21.7	19.2	21.2	−11.51	−2.04	0.977	0.982

that the errors due to modal truncation and traffic mass loading are all within engineering tolerance (Zhang et al. 2010).

To validate the accuracy of the modal flexibility approach, a static truck-loaded testing is conducted and compared with predicted deflection based on modal frequency, mode shape identified from OMA and modal scaling factor calculated from updated FEM. Fig. 7 shows the deflection shapes predicted by the modal flexibility method and 8 deflection points measured in four sections of the bridge by static traffic-loading tests. The errors are mostly within 5% with a largest one near to 10% error, which are within the engineering tolerance.

4 CONCLUDING REMARKS

A modal flexibility method is proposed to obtain deflection shape under pre-described static loading based on operational modal analysis (OMA) and updated finite element model (FEM), and applied to a pre-stressed concrete continuous box-girder highway bridge. Modal frequencies and mode shapes are identified from dynamic response measurements of the bridge subjected to traffic excitation. A fine FEM is built and updated based on modal parameters identified from OMA. Modal scaling factors are calculated from fine updated finite element model. Modal flexibility is then synthesized from modal frequencies and scaled mode shapes. Rather accurate deflection shape under pre-described static loading is then obtained to replace the one normally measured via expansive and time consuming static loading test for bridge condition assessment.

The modal flexibility method based on OMA and FEM updating for structural condition assessment has been validated via comparison of deflection shape obtained from identified modal parameters with mode shape normalization using updated FEM and

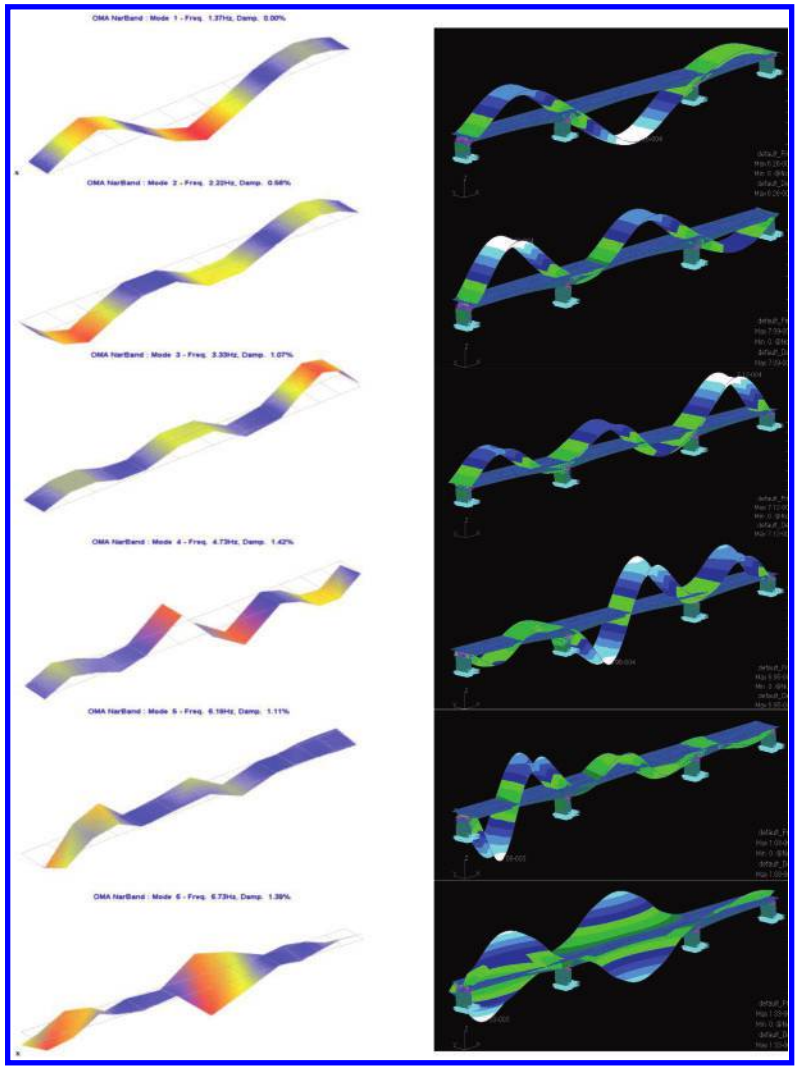

Figure 6. Comparisons of 6 the first 6 modes from OMA and updated FEM.

deflection directly measured from static truck-loading testing. The errors of deflection shape between them are within 5% at the 7 points with largest error at rest one point near 10%, which are within engineering requirement

To study the errors due to modal truncation and traffic mass loading, a series computational simulations based on updated FEM is conducted. It is shown that the approximation introduced by modal truncation and mass loading is within engineering tolerance.

In the bridge engineering, static deflection shape under pre-described loading is widely applied as indices for bridge condition assessment. However, many issues still remain to be solved between the deflection shape and damage, reliability, serviceability and life-cycle safety. Other condition indices should also be studied with following questions to be answered: What are the most suitable condition indices for global health, preferably by correlating to structural reliability for serviceability and safety. How stationary are the directly measurable condition indices? What are their sensitivity thresholds to various type of damage? Is it possible to assess condition and damage without a baseline? How can we optimally integrate various experimental approaches and related technologies such as modal testing, controlled load testing and instrumented monitoring for condition assessment of constructed structures? Besides, better understanding the civil engineering structure, foundation and soil characteristics, the load paths, critical load carrying capacities, and possible failure mechanisms are important for condition assessment of civil engineering structures, such as bridges and buildings.

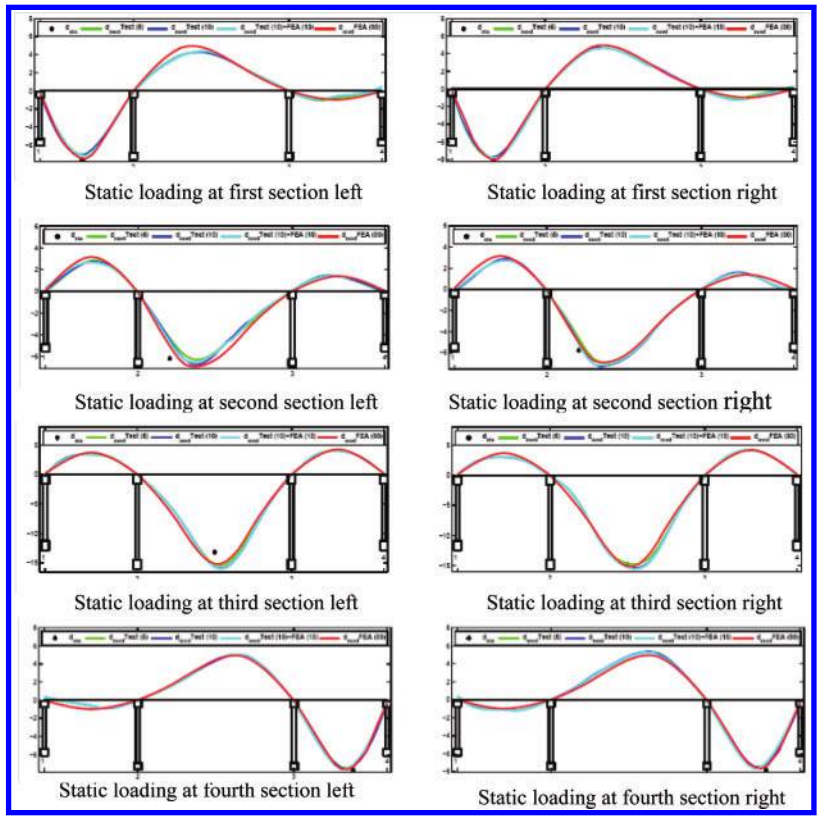

Figure 7. Validation of deflection shape obtained from OMA and updated FEM and static truck-loading tests. Where the results from static tests are denoted with black dots in four sections.

The art of the forensic engineer

Donald Charrett
Chairman, AMOG Consulting

ABSTRACT: The first part of the paper discusses the role of the forensic engineer in investigating and determining the causes of structural failures, and how that role differs from that of the design engineer. The forensic engineer's "deliverables" and "clients" require specialised skills directed to answering and communicating "why" the failure occurred. Recommendations are made for the appropriate engagement of a forensic engineer. The second part of the paper reviews the application of forensic engineering in the public reports of several structural failures. The direct "technical" causes of failure were accompanied by contractual and project execution deficiencies that did not prevent or detect the onset of disaster before it was too late. The "non-technical" lessons learnt include implementing the appropriate contractual mechanisms for managing the project risks, the appropriate engagement of the design and checking engineers, the designer's involvement during the construction, and the ongoing requirement for monitoring and inspection of constructed facilities.

1 THE ROLE AND ENGAGEMENT OF THE FORENSIC ENGINEER

1.1 *Introduction*

One definition of forensic engineering is: the application of the art and science of engineering in the jurisprudence system, requiring the services of appropriately qualified and experienced professional engineers. Forensic engineering may include investigation of the physical causes of accidents and other sources of claims and litigation, preparation of engineering reports, testimony at hearings and trials in administrative or judicial proceedings, and the delivery of advisory opinions to assist the resolution of disputes affecting life or property (Carper 2001).

However, the scope of forensic engineering is broader than in connection with the legal system, as forensic engineers may also be required to provide a report to a client as to the cause and reasonable options for replacement or repair, or desirable procedural changes to avoid future failures.

Forensic engineers are usually, although not exclusively, involved in investigations of "failures", where a failure is an "*unacceptable difference between expected and observed performance"* (Leonards 1982). Perceived "failure" of a structure is thus not confined to a failure to carry the required load, but includes any shortcoming in meeting the client's expectations in respect of time, cost or quality.

1.2 *The forensic engineer's role in legal disputes on structural "failures"*

There are two distinct roles that a forensic engineer may undertake in connection with a (potential) legal dispute – an expert consultant who acts as part of a legal "team", and an independent expert who is not part of the legal team, and gives testimony in a court or arbitration hearing on the basis of his/her independent assessment of the cause of the failure.

It is important that a forensic engineer understands clearly the role that she/he has been engaged for, as it determines how she/he is engaged and instructed, what documents are provided, what investigations should be conducted and what type of report will be required.

1.2.1 *Expert consultant*

An expert consultant acts as a member of a legal "team", and accordingly may be privy to confidential details about the legal "case", including the client case theory and the opinions of other experts acting for the client. Given such close association with the legal preparation of the client's case, it may be difficult for an expert consultant to be seen by a judge or arbitral tribunal to exercise his/her independent judgement, without regard to the exigencies of the case.

An expert consultant (sometimes referred to as a "dirty" expert) can provide forensic engineering advice at all stages of a dispute on a structural failure, including the identification and engagement of suitable independent experts. However, because such an expert consultant may be perceived as "tainted" by the client's case, she/he is usually not the appropriate person to give forensic engineering evidence in court or before an arbitral tribunal.

1.2.2 *"Independent" or "clean" experts*

An independent (or "clean") expert who is not part of the legal team and is not privy to confidential aspects of the client's case will be suitable to provide an expert opinion on forensic engineering issues that will be seen

by a tribunal to be independent. To maintain the independence of such an expert, it will be necessary to ensure that she/he is appropriately briefed, does not have any inappropriate contact with the legal team and is not provided with any documents that could taint his/her independence or ability to express an independent view.

Engagement of an independent expert requires careful documentation by the legal team so that all communications are transparent and the evidentiary material on which the expert opinion is based is clear. Independent experts in some jurisdictions have obligations to formally acknowledge that they have formed an independent opinion, and that they are not acting as an advocate for their client's case.

1.3 *The forensic engineer's skills*

Forensic engineering, in common with every other branch of engineering, involves the application of both science and art.

The fundamental skill needed by a forensic engineer is a deep knowledge of the science of engineering relevant to the issues that need to be investigated. This is gained through training, study and experience. A perceived lack of this relevant expertise by a legal tribunal may disqualify an independent expert from giving expert evidence.

Equally important to the science of engineering is the "art" of how a forensic engineer should apply his/her engineering knowledge to prepare and conduct investigations to determine the facts, apply the relevant engineering principles to effectively determine the cause of failure, and to prepare reports or testimony that are soundly based, relevant, cogent and persuasive.

The art of the forensic engineer who is required to investigate and report on a failure is fundamentally different to the art of the engineer who designs a facility. The fundamental question addressed by the design engineer is "how" to apply the art and science of engineering to synthesise all the required elements into a functional and operating whole to satisfy the client's requirements. By contrast, the fundamental question addressed by the application of the forensic engineer's skills is "why" did the failure occur. The forensic engineer must keep an open mind whilst making observations, collecting evidence and planning and conducting the necessary investigations. She/he may need to carry out complex and sophisticated analyses to determine why the failure occurred. The results of theoretical analyses will need to be reconciled with all the available evidence of the failure.

The forensic engineer needs to have refined observation and recording skills, to take note of and document all possibly relevant features observed at a site inspection of a "failed" structure. It is important that a forensic engineer takes note of all matters that may have an influence on the cause of the "failure", whether or not they appear to be consistent with a particular theory of failure.

The "art" of the forensic engineer importantly includes good written and oral communication skills. The design engineer communicates the design to be constructed by means of drawings and specifications to those in the construction industry who understand the "language". The forensic engineer usually communicates his/her findings to those not knowledgeable in engineering or construction – a Board of Directors, corporate counsel or a judge. The ability to communicate complex engineering concepts in simple understandable terms is an essential aspect of the art of the forensic engineer. Appropriate photographs, models or simplified diagrams or animations are usually more effective in communicating complex technical issues to lay people than a detailed technical description. A brief but comprehensive executive summary at the start of a report is important to convey the fundamental findings to senior people.

A forensic engineer may be engaged to provide an opinion as to whether the original design was prepared on a reasonable basis. In such a case the forensic engineer should have relevant recent design experience and maintain an analytical approach to determining whether the original designer acted reasonably, rather than opining on what the forensic engineer might have done if she/he was the designer.

This emphasises the importance of the forensic engineer maintaining the highest professional and ethical standards. A forensic engineering report may have dire consequences for the professional career of the designer of a failed structure. A further aspect of the forensic engineer's ethics is the obligation to advise the client if she/he does not possess all the skills required for the investigation.

1.4 *Engagement of a forensic engineer*

A forensic engineer is usually engaged by a lawyer acting on behalf of a client with an interest in a structure to be investigated. This is particularly important if legal professional privilege is to be asserted. If it is not known whether or not litigation or arbitration might ensue, it may be appropriate in the first instance to engage an expert consultant who can assist the legal team in whatever manner is appropriate and to the fullest extent possible, recognising that an independent expert may have to be engaged at a later time.

In principle, engagement of a forensic engineer is no different to engaging an engineering consultant for any design or construction task. It is necessary to define the scope of the forensic engineer's work, select a forensic engineer with the appropriate skill and experience to carry out the scope of work, and execute a consulting agreement with appropriate terms and conditions that specify the requirements of time, cost and quality.

Defining scope with precision is fundamental to selecting the most appropriate forensic engineer, because it is the scope that determines the threshold issue of the skills required. Of course, the scope may evolve over time: the engaging lawyer may not understand the full ramifications of the issue at the outset, or

have insufficient knowledge of the technical requirements, or the forensic engineer's investigations may go in a different direction to that initially anticipated.

Part of the scope of the forensic engineer may be to define the full scope of services required, after an initial investigation of the facts and the issues. Nevertheless, the initial scope should be defined by the engaging lawyer as clearly as possible, particularly what are the "deliverables": those outputs of the forensic engineer's intellectual property provided to the client, e.g. a report on the causes of failure, or a presentation to senior management as to the recommended further investigations necessary.

Inevitably there is a trade-off between the conflicting demands of completing the scope to the appropriate quality within the required time frame at an acceptable cost. In selecting the most appropriate forensic engineer, the engaging lawyer will have to make his/her own value judgment on where the appropriate balance lies. In this author's experience, the emphasis should undoubtedly be on the quality of the forensic engineer and his/her support organisation, and not on ad hoc determinations of budget cost or timeframe. Typically, the skills and experience that will be required for a high-level forensic investigation will only be available in very senior individuals with years of experience. Such individuals are usually very busy, and inevitably have a high charge rate, particularly in circumstances where they are required to commit significant periods of time for court appearances.

It is suggested that typically, a forensic engineer should be selected on the basis that she/he can provide the required quality, and the conditions of engagement should be tailored to ensure that the services are delivered within the required time and budget. Detailed suggestions for the engagement of forensic engineers are made by Charrett & Potts (2012).

2 PUBLIC INQUIRIES INTO STRUCTURAL FAILURES

2.1 *Introduction*

Public inquiries into structural failures are important not only for establishing the causes of the failures, but for identifying changes that need to be made to avoid future failures from similar causes. Such public inquiries invariably rely heavily on forensic engineers to assist the investigating tribunal to determine the causes of failure, both technical and non-technical. This paper draws on some reports of public inquiries into high profile structural failures to identify some relevant "non-technical" issues that have invariably accompanied the direct "technical" causes of failure.

Public inquiries have a number of unique features that make them an especially valuable resource for the assessment of structural failures. Although only conducted for a small number of high profile failures, typically involving loss of life, public inquiry reports are of greater significance then their conclusions on the particular failure. In contrast to the judicial inquiry a judge or arbitrator makes in civil litigation to determine legal liability for failure as between the litigants, a public inquiry is an administrative process in which the objective is to determine the cause of the failure and the lessons learned from it, in order to guide actions in the future to avoid a repetition. Typically, the report of a Public inquiry contains detailed technical information on the engineering "state of the art" relevant to the failure.

In the common-law world, public inquiries are conducted along similar lines to adversarial court proceedings. Counsel are appointed to assist the tribunal, and interested parties engage their own counsel to represent their interests in the inquiry. Lay and expert evidence is adduced in a similar way to court proceedings. Forensic engineers may be called as expert witnesses on behalf of the inquiry itself, or a party whose interests may be affected by the outcome of the inquiry.

The details of the failures discussed in this paper, as revealed by the reports of the public inquiries that ensued, highlight many issues relevant to the contracts and the execution of those contracts. In each case the direct "technical" causes of failure were accompanied by contractual and project execution deficiencies that did not prevent or detect the onset of failure before it was too late. No doubt all of the disasters had their genesis in human failings, generally and perhaps invariably in a combination of individual failures. The importance of identifying the "non-technical" issues contributing to failures is in determining what changes to project execution procedures and contractual arrangements are required to prevent a repetition of failures from similar causes.

The failures listed in the following sections all resulted in loss of life, and were followed by public inquiries that determined and documented both the technical and non-technical causes of failure. Following a brief description of each of the failures and its subsequent inquiry, some of the lessons learned from these failures are discussed. The discussion of lessons learned highlights the similar findings on important contractual and procedural issues that have contributed to the different failures. Further details on the public inquiry reports referred to can be found in Charrett (2008), Charrett (2009) and Charrett (2012).

It will be noted that most of these failures occurred a long time ago, and are still remembered by structural engineers today for the technical issues they identified, and the impact they have had on the practice of structural design. However, in this author's view, the contractual and procedural lessons learned appear to be forgotten by subsequent generations. Revisiting these historical reports reinforces the importance of designing and constructing structures within contractual arrangements that encourage and support clear lines of authority and communication, with appropriate allocation of risks and an appropriate balance between the required time, cost and quality for project execution.

2.2 *Québec Bridge, Canada (1907)*

The Québec Bridge over the St Lawrence River is a steel cantilever bridge with a main span of 548 m. It was procured by a company specifically incorporated to finance, build and operate a toll bridge, which called tenders on minimal documentation, including a clearance diagram and specifications. The company's consulting engineer, Theodore Cooper, recommended an increased span and increases in the allowable steel stresses, significantly above those in common use at the time.

The construction contractor, Phoenix, entered into a contract to design and construct the bridge to the satisfaction of Cooper and the company's engineer. Whilst Phoenix was responsible for preparing the design, Cooper approved all of the designs on behalf of the company. However, he was only concerned with the bridge in its final constructed configuration, and had no involvement with the erection engineering, or with any inspections in the shop or in the field, and made no inspections during construction.

During erection of the suspended span the south anchor arm of the bridge collapsed completely, resulting in the death of 74 men. Many of the joints were not fully riveted, and major compression members suffered from increasing lateral deflections, which gave prior warning of substantial structural distress. Unfortunately, the site personnel did not have sufficient experience to recognise the impending danger, and Cooper was only made aware of it too late.

After the collapse, the Government appointed a Royal Commission, comprising two practicing civil engineers, and a professor of engineering. The Commission's report determined the technical causes of the failure, and made a number of observations on the contractual and procedural issues that were relevant. This report was for many years regarded as a classic of its kind, and many of its conclusions are still relevant to the practice of structural engineering today.

The technical reason for the collapse was the failure of the lower chords in the anchor arm near the main pier, due to their defective design. The stresses that caused the failure were not due to abnormal weather conditions or accident, but arose because of the errors in judgment on the part of the designer and Cooper.

The collapse of the bridge is still remembered by engineers because it drew attention to the lack of knowledge on the behaviour under load of built up columns with lattice bracing. It is interesting to note that although considerable theoretical work on the design of large compression members was carried out after the failure of the Québec Bridge, testing of major compression members were still regarded as prudent in structures designed in the 1920s such as the Sydney Harbour Bridge.

2.3 *Westgate Bridge, Melbourne Australia (1970)*

Westgate Bridge comprises a total of 21 concrete spans, with five steel box girder spans over the Yarra River. It was procured under a forerunner of modern Public-Private Partnership. The design of the steel box girder spans was prepared by consulting engineers engaged directly by the Principal, and contractors under the consulting engineer's supervision carried out fabrication and construction.

After the original contractor for fabrication and erection fell seriously behind schedule, the Principal appointed an erection contractor to complete the erection under a "cost plus" labour management contract. The method of erection chosen by the original contractor was unusual, using two half spans jacked into position and joined along the longitudinal centreline. The erection contractor experienced difficulties because of unequal deflections of the half spans, and applied kentledge to correct the difference in camber. The application of this additional weight caused a buckle near a splice at the middle of span 10–11. In an attempt to eliminate this buckle, about 30 bolts were removed. The span collapsed and 35 workers died.

The Government appointed a Royal Commission, comprising a Supreme Court judge, a professor of civil engineering and a distinguished bridge engineer. The Royal Commission sat for 80 days, hearing evidence from 52 witnesses. It was required to enquire into and report on the circumstances surrounding and the cause or causes direct and indirect of the failure of span 10-11, and whether any aspect of the design was inadequate or undesirable.

The Royal Commission found that the immediate cause of the collapse was the removal of the bolts. However it made forthright comments that the design was approached in a "*disorganised and unsystematic manner and without any real guidance being given to the engineers doing the work*" and "*the calculations contain a great many errors of arithmetic and engineering principle*". It found that the primary cause of the collapse was that the consulting engineer "*failed altogether to give a proper and careful regard to the process of structural design*".

2.4 *Milford Haven Bridge, Wales UK (1970)*

Westgate Bridge collapsed shortly after the steel box girder Milford Haven Bridge in Wales (now the Cleddau Bridge) collapsed during construction. The UK Government appointed a technical Committee of Inquiry to investigate the collapse of the Milford Haven and West Gate bridges, their terms of reference being to consider whether it was necessary to reconsider the design and method of erection of box girder bridges about to be erected in the UK, to draw up technical guidelines for bridge engineers, to advise on any special matters affecting contract procedures and to recommend further research and development.

The 5 man Committee was chaired by Dr Merrison, whose name is often associated with the technical recommendations on the design of box girder bridges made by the Committee. It concluded that the collapse of the bridge was caused by the inadequacy of the design of a vertical pier support diaphragm, which failed in compression over the column.

The lessons from Milford Haven primarily concerned the inadequacy of the design methods used for the permanent design and checking the safety during erection. The "Merrison Rules" in the final report, comprehensive design and workmanship rules for the stress analysis and design of steel box girder bridges, are still used today in the design and checking of steel box girder bridges.

In its Final Report, the Committee accepted the Royal Commission's assessment of events which led to the collapse of the Westgate Bridge, and drew considerable support from its recommendations on contractual and procedural aspects: *"While there were also fundamental defects in the erection procedure and permanent design of the West Gate Bridge, we regard the failures of site organisation and of communication between the principal parties – client, engineers and contractors – as of more general significance in this case."*

2.5 *De La Concorde Overpass, Quebec Canada (2006)*

The de la Concorde Overpass was a prestressed concrete bridge, built in the 1970s and designed and constructed generally in accordance with the prevailing standards. In 2006 a span collapsed under light traffic load, killing five people. The Government established a Commission of Inquiry, with an attorney President and two engineer Commissioners.

The Commission conducted its inquiry in accordance with the principles defined by the Canadian Supreme Court, and concluded that, whilst there were a number of defects and shortcomings, both technical and procedural, none of those by itself would have caused the collapse which resulted from a chain of causes.

The reason for the failure of the overpass was a shear failure in a reinforced concrete cantilever slab, the concrete of which had deteriorated over the years. The reinforcement design satisfied the code requirements at the time, but would not do so now, nor would the detailing of the reinforcement be regarded as satisfactory today. The weakness of the detail was due to errors in placement of the reinforcement (a quality-control failure during construction), and low quality concrete that was not suitable to resist freeze-thaw cycles (arising from ambiguity in the specification). There were further contributing causes that the thick slab was not watertight (the specified waterproof membrane had apparently not been installed) either originally or during subsequent refurbishment), and refurbishment work in 1990 caused damage that was not evaluated.

In addition to these technical issues, the Commission identified a number of procedural failures in respect of both design and construction.

2.6 *Procedural and contractual lessons*

The following are some of the contractual and project execution lessons relevant to major engineering projects extracted from the public inquiry reports discussed above.

2.6.1 *Quebec bridge*

- The difficulties and time involved in raising finance for a project should not preclude sufficient time allowance for the preparation of initial studies, the design, tender documentation and the execution of the works.
- Unquestioning reliance on the skill and experience of an individual engineer may be misplaced without adequate peer review.
- A project owner requires adequately qualified and experienced technical staff with the appropriate authority for both the design and erection phases, even if it procures its project via a design and construct contract.
- An independent engineer should review the engineering design of a major project, without reference to the designer's calculations.
- The scope of the engineer's engagement should include responsibility for both design and erection, with compensation commensurate with the proper execution of that scope.
- An owner with limited financial resources may be subject to cost pressures that result in inappropriate engineering decisions.
- The construction contractor needs to have an appropriately qualified and experienced erection engineer on site with an understanding of the design and full authority for the erection.
- Appropriate allowances should be made for the additional risks inherent in unusual structures or structures of a scale not attempted before, and this may require testing of components.

2.6.2 *Westgate bridge and Milford Haven bridge*

- The client must be assured that the engineer will have adequate and appropriate resources.
- A certified independent check should be carried out to confirm that the permanent design is adequate and complies with the relevant technical requirements.
- There should be a clear division of responsibilities between engineer and contractor, and the contracts between the parties in a major project should reflect their practical engineering relationship.
- A certified independent check of the erection method should be performed by an engineer independent of the design engineer, who should be given full details of the erection method and have a right of veto over it.
- The contractor should submit a construction programme to the engineer for its approval.
- The independent checks of the permanent design and of the erection method should be complete when work starts and the erection of the relevant part of the superstructure starts respectively.
- The contractor should be allowed sufficient time to prepare itself for the start of work and the client

and the engineer should be prepared to consider a revision of the programme in the event of slippage.
- The engineer should carefully monitor the progress of construction to ensure compliance with the agreed erection method, and should scrutinise the contractor's site staff and where necessary exercise the powers under the contract.
- The client should satisfy itself as to the adequacy of the engineer's site representatives, and the functions and tasks of the engineer's site representatives should be defined in writing.

Note the close similarity to the issues identified by the Quebec Bridge Royal Commission, 65 years previously.

2.6.3 *De La concorde overpass*

- A transparent process should be used for selecting consulting engineers based on competency and past performance, with cost only considered for those firms meeting the competence criteria.
- A responsible engineer should validate the concept, drawings and calculations of structural designs.
- Contractors should be prequalified on the basis of their ability for the type of structure to be built, with cost only considered for contractors meeting the competence criteria.
- When awarding contracts for consulting engineering or construction, it is important to ensure that the key personnel on which prequalification was based will be available for the duration of the work.
- Subcontracting requirements should be identified in bids, and contractors required to produce a work quality control plan for their own and subcontract work.
- On completion, an engineer should certify that the structure was built in accordance with the drawings and specifications and all the documents associated with the work and structure should be assembled and kept during the entire life of the structure to assist with inspection and maintenance programs.
- Owners of structures need to evaluate the performance of consulting engineering firms and contractors on completion of a project, and keep the evaluations on record.

Lessons for structural engineers: The Hillsborough disaster

R.A. Smith
Department of Mechanical Engineering, Imperial College London, UK

ABSTRACT: Although the Hillsborough disaster occurred more than 20 years ago, new evidence is still being evaluated. In particular, the extensive findings of the Hillsborough Independent Panel have removed blame from the spectators onto deficiencies of the ground, the arrangements on the day, the response of the emergency services after the accident and attempts by the police to smear the spectators involved. However, this short paper concentrates on the generic lessons to be learned for engineers who are concerned with advising about safety at venues where large crowds are expected.

1 INTRODUCTION

1.1 *Personal involvement*

The author was living and working in Sheffield at the time of the Hillsborough Football Stadium disaster in 1989. He was invited to assist inspectors from the Health & Safety Executive, also by coincidence located in Sheffield, in their investigations of technical aspects of the disaster.

His personal view is that the various inquiries that have taken place have underplayed the technical deficiencies of the ground and the arrangements, in their concentration on spectator behavior, police actions and the response of the emergency services. However the most recent inquiry report, of the so-called Hillsborough Independent Panel, has spotlighted some of these concerns, and the purpose of this paper is to draw some conclusions of a general applicability for engineers working and advising on situations which involve crowd management.

1.2 *Background description*

On 15 April 1989, a football match between Liverpool and Nottingham Forest was to be played as the semi-final of the Football Association Challenge Cup competition. By tradition, such games are played on neutral grounds; in this case Hillsborough Stadium, the home of Sheffield Wednesday, was chosen. After only six minutes of play, the game was stopped when it was realised that a major incident was occurring behind one of the goals. Ninety-five people died during the incident, one death occurred four years later, and over 400 people received hospital treatment.

1.3 *The development of the stadium*

Sheffield Wednesday, a club named because it played its early fixtures in mid-week, moved to Hillsborough in 1899. The area was then an out-of-town greenfield site, but the provision of a tram line provided the necessary transport to allow spectators to reach the ground. Over the intervening years, the site has become extremely constrained, see Fig.1, surrounded as it is by roads, a river and houses. The tram line was removed in 1950's, only to be replaced by a modern system in 1995, some six years after the accident of 1989. Parking for cars (now, of course, the dominant mode of transport) is extremely limited and difficult, and for most spectators necessitates a considerable walk after finding a parking space in a back street some distance from the ground.

The Stadium itself has developed over the years. The two tiered South Stand on one side of the ground is the largest of the stands and is of attractive lines. It was originally opened in 1914 and was designed by the famous football ground architect Archibald Leitch. Named after a hill that was the scene of a famous battle in the Second South African Boer War, the Spion Kop is built into a natural hill at the east end of the ground. In 1914 concrete terracing was installed on the bank, which was further extended in 1927. The final expansion of the hill came in 1954.

A new cantilever North Stand was built in 1961; the West Stand was added in 1965, in time for the ground to be a venue for World Cup games, when the competition was hosted (and won!) by England in 1966. The much admired North Stand established the popular view that Hillsborough was one of the leading grounds in the country, "There is not a misplaced line in this remarkable stand. From any angle (it) is quite breathtaking. It is *like an architect's model of the dream* stand of the future, a space age stand." Finally, the West Stand was originally built at the turn of the last century as a covered terrace housing up to 3,000 fans. In the 1920s this was joined by the North West terrace before the Leppings Lane stand was replaced by a 12,000 capacity partially covered terrace. Before the 1966 World Cup the West Stand was demolished again

and replaced by a two-tiered structure with 4,471 seats in the upper tier and retaining a terrace in front of the stand, its condition at the time of the accident.

Referring again to Fig. 1, before 1965 the Leppings Lane end consisted entirely of terracing (i.e. stepped standing space). The new West Stand (i.e. seating accommodation built over the rear of the terrace), truncated the space available and restricted access to a tunnel under the West Stand and passages round both ends of the stand.

During the early 1970s, the problems of hooliganism and pitch invasions made it necessary to prevent access to the playing area and caused perimeter fences to be erected in 1977. In an FA Cup semi-final in 1981, incidents of crushing occurred and the police suggested that the terrace be divided into sections by the erection of radial fences, which were fitted in November 1981. The idea was that these sub-divisions would enable a more even distribution of the crowd to be achieved and would allow the segregation of opposing supporters, if necessary by having an empty 'pen' (as a sort of no-man's land) between them. The consequences for pens 2 and 3, see Fig. 1, should have been obvious. Entry to these pens was via the tunnel under the West Stand. Because of the upward slope of this tunnel, spectators could not judge the condition of crowding in the pens until they had exited the tunnel and arrived on the terrace. Further, and crucially important, pens 2 and 3 now formed closed boxes, since the only access to the larger pens 1 and 4 at either side was by small gates at the back of each pen–gates which were extremely difficult of access for spectators in crowded conditions. In view of the closed-box nature of these pens, and the fact they would be attractive positions for spectators immediately behind the goal, it was imperative that a method should be available for monitoring the numbers entering and cutting off further access when the pens were judged to be full. No such method existed.

2 INQUIRY TIMELINE

In the immediate aftermath of the disaster an inquiry was instigated under Lord Justice Taylor. An preliminary interim report was produced by August 1989 in which the police were criticised for failing to close off the tunnel leading to the pens where supporters had been crushed and for failing to control the build up of fans outside the stadium. In January 1990 the second final part of Lord Taylor's report recommended the removal of terrace fences and the introduction of all-seater stadia in the UK. Subsequent history has shown that these changes were the catalyst for a major revolution in UK football and led to, inter alia, to the establishment of the Premier League. In March 1991 after lengthy inquests into the deaths of the victims of the accident a verdicts of accidental death were recorded and a ruling that they were all dead by 3:15 pm on the day of the tragedy.

In June 1997 following a TV dramatized reconstruction the then Home Secretary Jack Straw ordered evidence to be re-scrutinised. A report by Lord Justice Stuart-Smith failed to uncover any new compelling evidence. However, the following year the Hillsborough family support group brought private manslaughter charges against two police officers who had been in charge on the day of the disaster. In July 2000 following a six week trial a jury found one of the police officers not guilty and failed to reach a verdict on the other but the judge refused permission for a retrial.

In April 2009 the Hillsborough Independent Panel was set up in the wake of the 20th anniversary of the tragedy. This panel reported in September 2012. Its major finding being that the police orchestrated a cover up, falsified documents and blamed innocent supporters. It further found that up to 40 of the fans who died might have been saved if action had been taken sooner and the report cleared supporters of wrongdoing or blame for the disaster. Following this report the Director of Public Prosecutions announced that he was looking at all the new evidence unearthed to see if it could support charges that the authorities chaotic response led to lives being unnecessarily lost.

The report of the Hillsborough Independent Panel was a major publication of nearly 400 pages: it was generated from an archive of an exhaustive mountain of accumulated evidence. It contained dramatic evidence of a police conspiracy to tamper with evidence in order to shift the blame onto Liverpool spectators. It also contained severe criticism of the organization and delivery of emergency services following the disaster it led to the quashing of the original inquest findings and re-opening of new inquests.

Of particular relevance to this paper the Panel's report contained details of the physical shortcomings of the ground itself and of the arrangements for the admission and distribution of spectators within the ground. It noted that in 1981 in a previous FA cup semi-final played at Hillsborough there was severe and serious congestion at the Lepping's Lane turnstiles and crushing on the confined outer concourse there was also a serious crush on the terraces in which many people were injured and fatalities narrowly avoided at that time lateral fences did not divide the terrace into pens and funds were able to move sideways thus escaping the consequences of the crush. Further problems arose at semi finals played at the ground in both 1987 and 88. The serious accusation was made that these experiences had not been used to improve safety matters by the club and their safety engineers.

3 LESSONS TO BE LEARNED

Amongst the lessons to be learnt from the engineering background of the Hillsborough disaster, the following are of importance:

3.1 The dangers of ad hoc and piecemeal developments over a long period of time. Unless rigorous

system wide thinking is employed, the law of an unintentional consequences can kick in. In this case the installation of dividing terraces and a perimeter fence at different times had the effect of confining the spectators without egress routes from the terracing. Furthermore the layout of the crush barriers on the terracing was modified by the installation of the fences and had consequence on reducing the number of spectators that could be comfortably accommodated.

3.2 Although the testing of crush barriers was covered by instructions in the then current edition of the Green Guide for the design of sports grounds, the methods suggested were open to considerable freedom of interpretation and were inadequate. It is not unreasonable to have anticipated that engineers in charge of such testing would be questioning and critical of the then requirements. Even cursory examination of the barriers at Hillsborough led to the discovery of significant areas of rust which in some cases extended right through the steel tubes which comprised the barrier structure. In almost all cases this rust was in the load bearing joints of the barrier structure and arguably should have led to the condemning of the so affected barriers and their replacement by new ones. The heights of the barriers in the ground were extremely variable, ranging from upper chest height to lower groin height for an average build of spectator.

3.3 It was a matter of simple arithmetic to calculate the terms style capacity needed for crowd entry in a reasonable time before the start of the game. The maintenance of the turnstiles left much to be desired and they were unable to operate at their best capacity because of the pressure of the waiting crowd causing the turnstiles to in effect jam it was therefore inevitable that the numbers entering the ground on this occasion would cause huge congestion at the areas immediately before the turnstiles and in fact this was a trigger which caused the police to open large gates usually used for egress in order to relieve crowd outside the ground. That a crush outside the ground in the area immediately in front of the turnstiles was inevitable can be seen at a glance when the converging area between Leppings Lane and the turnstiles is examined on Figure 1. The turnstiles marked A-G are clearly inadequate for the large number of spectators due to enter the standing areas marked 1-4 in front and to the wings of the West Stand.

Furthermore it was also a matter of simple arithmetic to calculate the capacity of the various parts of the ground and the reductions in that capacity caused by the installation of radial fences and the perimeter fence. The fact that there was no formal method of estimating the number of people entering sub division of the ground and closing such sections when they were full is quite in explicable.

3.4 The prior organization of major crowd events for example, like a football match or a pop concert, should lead to a clear understanding of the division of responsibilities of the various parties involved in the case of Hillsborough there was a confusion of responsibility between the club and its stewards and the police. Were the police there to maintain order or to assist in the disposition of the crowd? Did the police have different roles outside the ground or within (where they were guests of the club)?

3.5 Complacency prior to the disaster was an attitude shared by both the club and the police. We have organized and hosted major games before and therefore it is a matter of routine to do the same once again. The lessons of near-misses of previous crowd disasters in 1981, 1987 and 1988 were largely ignored.

3.6 It was the responsibility of the Sheffield City Council to inspect the ground and to issue a safety certificate. There is evidence that this process was inadequate and less than rigorous. Following the disaster, the system has been tightened and augmented by a national system of licensing to enforce the application of uniform standards for the all-seater accommodation of major stadia.

3.7 In general there was a blurring of the recognition of the role of the spectators. On the one hand they were paying guests on whom the club depended: on the other they were potential troublemakers who were to be offered minimal comfort facilities within the ground. It is perhaps one of the few positive legacies of the Hillsborough disaster that grounds have been rebuilt and reorganized and now spectators are offered considerably more comfortable accommodation.

4 BIBLIOGAPHY

The literature produced in the wake of the Hillsborough disaster is enormous and still growing. It includes several books, reports of the various investigations, endless articles from newspapers and magazines and comment on the many types of social media now available.

The best and most convenient single source is the website of the Hillsborough Independent Panel inquiry http://hillsborough.independent.gov.uk/

Here can be found an archive of material disclosed to the enquiry. Complete copies of the original Taylor reports and the collected volume of technical evidence gathered by the Research and Laboratory Services division of the Health and Safety Executive are available. The report of Lord Justice Stuart-Smith on his scrutiny of evidence is also available together with the extremely detailed report of the Hillsborough Independent Panel which was published in September 2012.

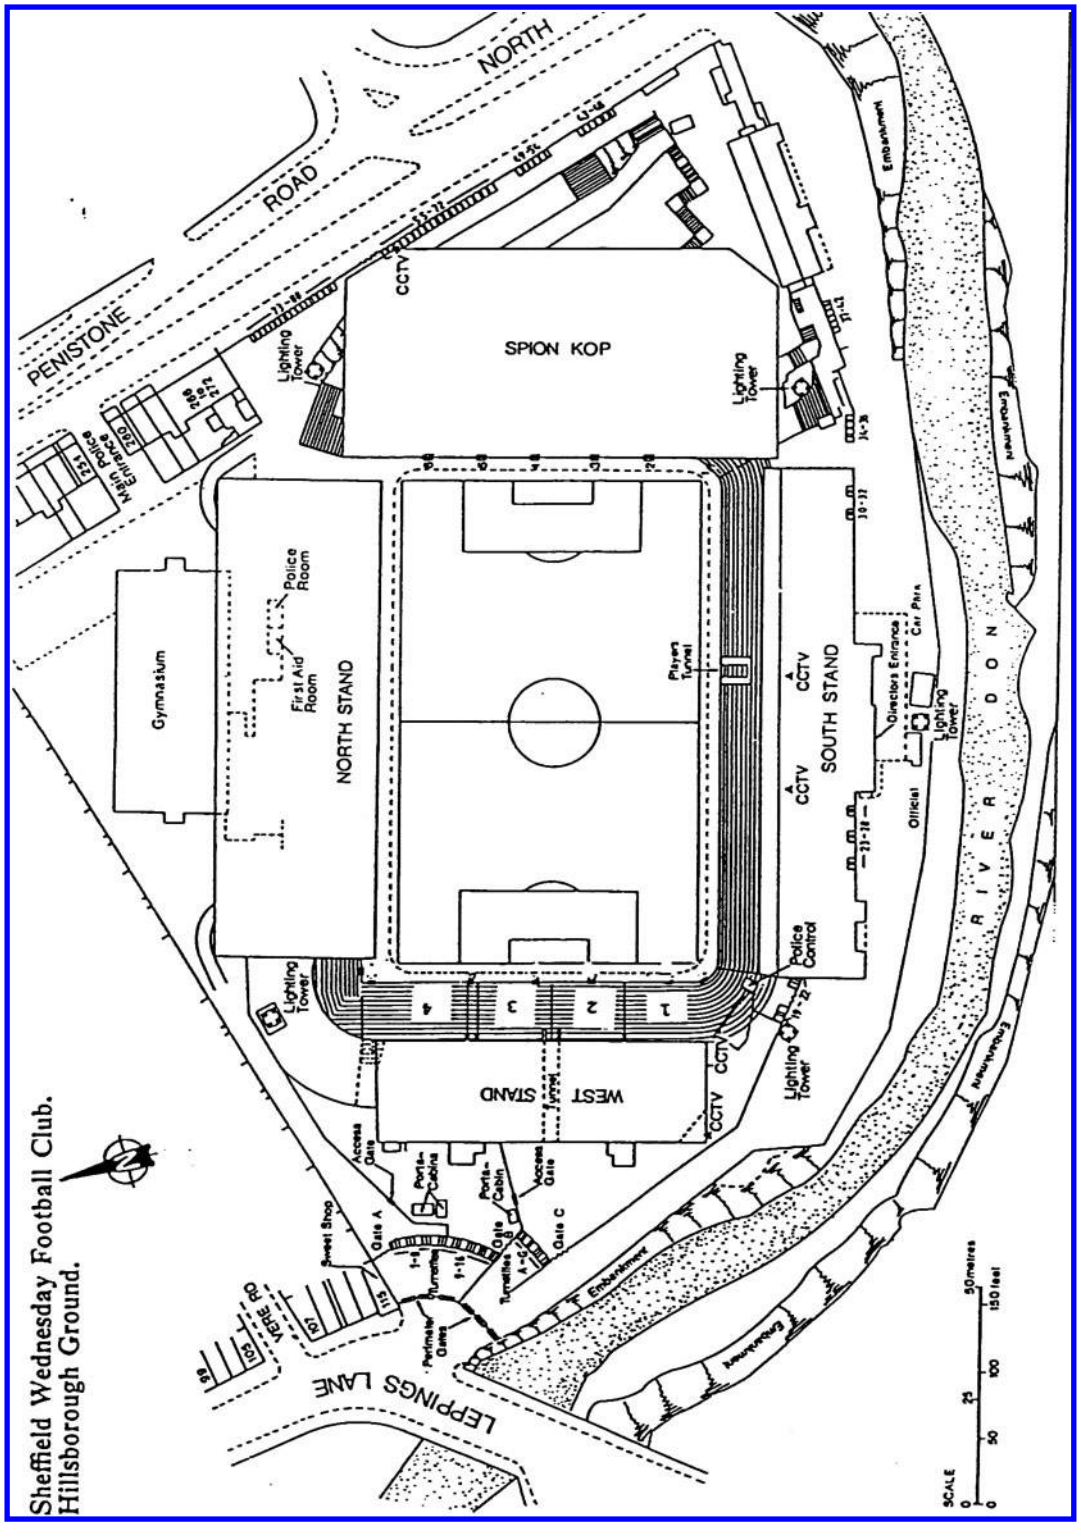

Figure 1. The Hillsborough Ground of Sheffield Wednesday Football Clob.

5 APPENDIX

An eyewitness account was published in The Times on September 15 2012. The author, Adrian Tempany, was on the terraces in Sheffield that day, and this is a shortened account of his experiences. It is reproduced here not for sensationalism, but to be a stark reminder of the responsibilities we have in trying to design a safe environment for people attending large events.

On April 15, 1989, I walked through a set of creaking turnstiles, on to a dilapidated concourse and down a tunnel into Hillsborough. At the end of the tunnel stood a radial fence, and I turned right, into pen three. I took my usual position on a terrace, about halfway up and to the right of the right-hand goalpost. As the sun beat down, a beach ball was launched along the terrace. People stood to read their programmes. FA Cup semi-final day. Where would you rather be, I thought?

But by 2.35 pm, we were fixed in position, and this seemed to be getting tight. People around me began to jockey for space, and by 2.40 pm, sweating and increasingly agitated, men, women and children were using their heads, shoulders or knees to try to move people off them. Someone's breath was blowing hot on my head. Around me, the same cry, "Please, get off me". And the reply, always the same: "Sorry lad, I can't move."

The entire Leppings Lane terrace was designed to hold 10,100 people. Lord Justice Taylor found that if its capacity was exceeded that day it was by no more than 24. However, poor signposting and an absence of police supervision meant that pens three and four — the two behind the goal — were filled with about 3,000 people; Lord Justice Taylor ruled in 1989 that they should have held 1,693.

The crush in pen three began at about 2.35 pm, 25 minutes before the kick-off. It would go on, getting worse, until at least 3.10 pm, when the gates in the perimeter fence were finally unlocked. Many people died, slowly and agonisingly, over the course of nearly 40 minutes. Some died over the course of at least an hour.

The next time you watch a game of football, imagine being crushed for almost the entire first half of that match. How badly? Well, take an old red phone box, strip out the phone and the fittings, and settle yourself in. Now the door opens behind you, and a group of people are shoved in. How many? Talking to fellow survivors, we reached a conservative estimate of seven, at least. So, you are now one of at least eight people in a phone box. The door is closed again. It will not be opened for half an hour.

By 2.50 pm, I was trapped in that box. The paralysis was terrifying; but there was something else. I could feel an energy building up behind me: it would swirl and grind, and as it broke, 50 or 60 of us were picked up, one lump of tangled, compacted limbs, and ground against each other; the crush barriers, the fence. "I got through that," I thought, but I was tiring.

Two minutes later, 2,000 people were invited to enter a large exit gate by the turnstiles, to relieve a crush simultaneously building up outside the stadium. Without anyone to direct them elsewhere, they headed for that tunnel. A bottleneck developed, and because that tunnel had a 1 in 6 downward gradient they were picked up and thrown down it, in a wave of limbs, into the two already overcrowded pens behind the goal.

Arms were now bent at impossible angles. One survivor recalls people being driven off their feet, into the air, and deposited on his head; another how the glass face on his watch popped out. But there was no release for us: the new influx of fans created an even bigger swirl of energy.

We were lifted up again, and like garments in an overfull washing machine, slowly we went, round and round, ground and ground. We couldn't see where this was coming from, or why. I could move my mouth and my eyes, and no more. Occasionally a hand popped up in front of me — mine — and I tried to manoeuvre a shoulder away from my face, to stick my head into a patch of air. But my arm was dragged down again, and I was starting to lose hope.

With my head twisted to the left, I could see through the gap between the North Stand and the huge Spion Kop at the far end, and out to the hills around Sheffield. Cars were pottering along country lanes; people were going to the shops, for a spring drive. I wondered if they were listening to the radio. If they knew we were in trouble, they might call the police.

What exactly were the police doing that day? One of the lines now being trotted out is that Hillsborough couldn't happen today, because communications are so much better than they were in 1989. Certainly, police radios broke down at Hillsborough, and communication was patchy. But surely the police did not need technology to realise that people were dying in front of their eyes in pens three and four. Our fans at the front were crushed into the metal perimeter fence with such impact the fence was bulging towards the pitch. The blue paint on the fence was ground to spots of powder on their cheeks.

Behind them, 10 or 12 feet back, I was one of hundreds of people screaming for my life — for half an hour. In those two pens, people were turning blue, their faces contorted in pain, and confusion. Some were crying. Others had vomit trailing from their chins. There was a smell of excrement and urine, as people's organs began to fail.

I do not want to talk here about what it is like to accept that your life is over. But I had to. I was 19, and it is a long way back from there. Suffice to say that after trying to resist that crush for half an hour, and failing to escape, I gave up. I was exhausted, and I made my peace and said my goodbyes. Only at about 3.10 pm, four minutes after the match was abandoned, was the gate in the perimeter fence finally opened. Drifting in and out of consciousness, I heard a voice in my head, "If you can hang on for another two minutes, you'll live."

I did, to fight for this day.

Causal models for the forensic investigation of structural failures

S. Arangio, C. Crosti & F. Bontempi
Sapienza University of Rome, Italy

ABSTRACT: The structural collapses are rare events that are characterized by complex dynamics: the identification of their causes and the explanation of their developments are not straightforward processes and depend on numerous different factors. A fundamental aspect is that, even if sometimes it is possible to identify the trigger that have materially caused the collapse, usually there is a complex background of situations that have made the event possible and that need to be accurately analyzed. The investigation of the interrelated aspects and concurrent causes is a fundamental task to assign conveniently the civil and criminal responsibilities. Starting from these considerations, the aim of this paper is to present some concepts that, in the Authors' opinion, constitute a basis for the framework of the investigation activities. In the first part of the work two concepts are discussed. The first one is the concept of structural complexity, which is an attribute of the civil constructions that are characterized by significant interactions, strong nonlinearities, and large uncertainties. The second concept regards the extension to the Civil Engineering field of a model for the development of failures proposed by Reason (Swiss Cheese Model, 1990). In the second part of the paper some operational approaches are briefly introduced: the breakdown of the problem and the analysis of the timeline; they are essential tools for the assignment of the various responsibility profiles. At the end of the contribution, the concept of structural dependability is recalled as an antidote to avoid failures providing high-quality structural design.

1 INTRODUCTION

The investigation of the causes of a structural failure is a delicate and challenging process that bares the intimate behavior of a structure and points out its relationships with the project environment.

The forensic engineer should be able to identify and explain the causes of the structural failures, intending with "failure" not only the catastrophic collapses that may even result in loss of life, but including all those situations where there is an unacceptable difference between the expected and observed performance.

The solution is found in an iterative way, through the accurate examination of all the available documents, including the declarations of the involved people, and by carrying out the necessary experimental and numerical analyses. On the whole, it is an incremental and nonlinear process that needs precise strategies for its convergence. In fact, even if sometimes it is possible to identify the trigger that has materially caused the collapse, usually there is a complex background of situations that have made the event possible.

A fundamental task of the investigation process is the analysis of the conduct of the various involved parts (designers, managers, contractors, users, etc). Their civil and criminal responsibilities have to be attributed according to the relevance of the consequences of the failure for the Civil Society (Carper, 2002).

The aim of this paper is to present some concepts that, in the Authors' opinion, constitute a basis for the framework of the investigation activities. The first one is the concept of structural complexity while the second one regards a model for the development of failures adapted from the Reason's Swiss Cheese Model (1990).

These two concepts can be profitably applying by making use of some operational tools, which are briefly discussed in the second part of the paper: the breakdown of the problem and the analysis of the timeline; they are essential tools for the convenient assignment of the responsibility profiles.

At the end of the contribution the concept of structural dependability is proposed as an antidote to avoid failures providing an effective approach for a high-quality structural design.

2 COMPLEXITY

2.1 *Definition of complexity*

An interesting definition of complexity (of a system or a problem), that can be easily interpreted in an operational way, comes from the graph in Figure 1 (adapted by Perrow, 1984). The plot shows a three dimensional reference system where the axes indicate:

1. The *nonlinearities* of the system/problem. In the structural field, the nonlinearities affect the behavior at different levels: at a detailed micro-level, for example, they influence the mechanical properties of the materials; their effect depends on the type of materials: it is weak in case of ductile materials

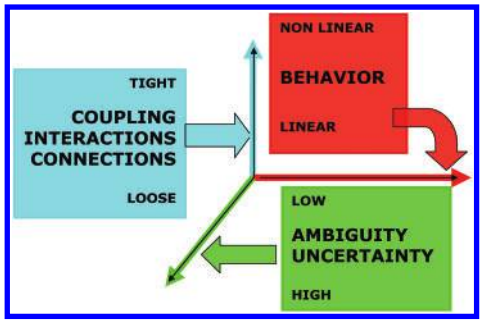

Figure 1. Aspects that increase the complexity of a problem.

while it is significant for example in case of no-tensile materials; at a macro-level the nonlinearities have effects on single elements or even on the entire structure; an example is given by the instability phenomenon that can lead to strong nonlinear behavior.

2. The *interactions* and the *connections* between the various parts: if they are tight, the situations is considered complex while when the connections are slack some tolerance exists.
3. The intrinsic *uncertainties* of the problem/system; they could have both stochastic and epistemic nature.

In this reference system the overall complexity of the problem/system increases as the values in the axes increase, so passing from linear to nonlinear behavior, from loose to tight interactions, from low to high uncertainty.

In the Civil Engineering field, a practical (and also common) case that presents the three components of complexity indicated above, is the intervention on existing adjacent masonry buildings.

According to the Eurocode 8-3, when we are dealing with existing masonry buildings there are some general aspects that should be carefully examined:

- physical condition of masonry elements and presence of any degradation or modification respect to the original situation;
- configuration of the masonry elements and their connections, as well as the continuity of load paths between lateral resisting elements; it is important to keep in mind that the buildings show the level of knowledge at the time of their construction and some defects in the design or in the manufacturing can exist, even if it is not evident at a first sight;
- properties of in-place materials of masonry elements and connections;
- the presence of nonstructural components and the distance between partition walls;
- information on adjacent buildings potentially interacting with the building under consideration.

For the definition of the structural models it should be considered that:

- the geometry, the details and the dead load are assigned but our knowledge depends on the available documents and on the accuracy of the investigations;
- the knowledge on the mechanical properties of the material are related to the accuracy and reliability of the investigation;
- the design approach depends on the completeness and reliability of the gathered information. In order to take into account the uncertainties, the capacity parameters can be modified by using specific confident factors that vary according to the level of knowledge.

Figure 2. Example of an aggregate of buildings and identification of a single structural unity (from Borri and De Maria, 2009).

From these recommendations it is evident that, in case of interventions on existing adjacent buildings, a preventive evaluation of the interactions between the buildings and an accurate and reliable investigation are necessary. Moreover, even if the works will affect only one of the buildings, the entire design process should be carried out considering the effects of the various steps of the work on the adjacent ones.

The Italian Building Code (NTC 2008), that could be considered as a draft of the Italian national annex of the Eurocodes, is even more specific on this topic. Particular attention is devoted to the assessment of the historical heritage and it is introduced the concept of "aggregate of buildings" in order to standardize the procedure for dealing with adjacent buildings.

An "aggregate of buildings" is delimited by an open space and it is composed by various adjacent non-uniform constructions (Figure 2). The constituting buildings have been built in different epochs, with different materials. They had different owners and usually experienced different uses and modifications during time. In the analysis of a single structural unit it is necessary to take into account the possible interactions arising from the structural contiguity with the adjacent buildings. Neglecting these aspects can have significant consequences on the structures even up the occurrence of catastrophic collapses (Figure 3).

Among the possible interactions between adjacent buildings, it should be considered the influence of loads (both vertical and horizontal) transmitted by floors or walls of adjacent units and the actions of arches or vaults that belong to contiguous buildings. The accurate representation of the unit under investigation through plants and sections will allow the evaluation of the stress distribution and the effect of the interactions. In addition to the standard procedure that are carried out for isolated buildings, in case of adjacent buildings it should be evaluated also

Figure 3. An example of an aggregate of building that experience a catastrophic collapse: some interventions on an internal unit were carried out without taking into account the interactions with the adjacent units (Barletta, Italy, 2011).

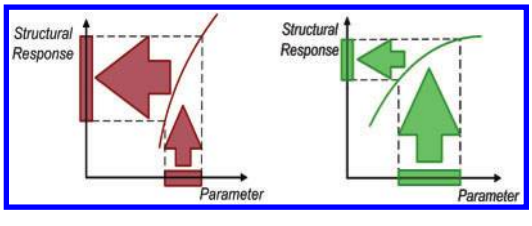

Figure 4. Sensibility of the structural response to the variation of a parameter.

the local effects due to not non-aligned floors or facades, the influence of differences in height or stiffness between adjacent units, the possibility of rotations or translations of the external walls of aggregate.

2.2 *Sensibility and structural robustness*

There are two other aspects that are strictly related to the complexity of a system/problem.

The first one regards the sensibility of a response to a specific parameter: Figure 4 shows the difference in the structural response between a parameter that strongly influences the behavior (on the left) and another one that needs a large variation for changing significantly the results (on the right).

The mechanical interpretation of the concept of sensibility lead to the concept of structural robustness, which is schematically represent in Figure 5. The graph shows the variation of the quality (y-axis) in time (x-axis) of two different structural systems. The first

Figure 5. Variation in time of the performance of a robust system (in blue) and a not robust system (in green).

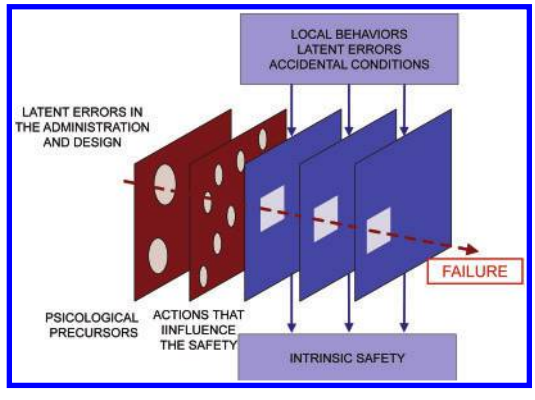

Figure 6. General model for the development of a failure – Swiss Cheese Model (Reason, 1991).

one (green curve) shows a better performance at the beginning respect to the other one (blue curve), however its performance decreases rapidly in time and it crosses the threshold that represents the minimum required performance earlier. On the other hand, the blue one, even if it shows a lower level of performance at the beginning, it is able to maintain it longer and after time it is still above the limit also in presence of some damage. The blue curve is representative of a system with a robust behavior.

Those structural situations that show to be very sensible to some parameters or that are lacking of robustness will exhibit a complex behavior and would need specific investigations (Bontempi et al., 2007).

3 SWISS CHEESE MODEL

It is interesting to observe that, even if the accidental situations have different nature and each one has peculiar characteristics, a general model able to represent in a synthetic way the origin and the development of a failure can be proposed.

According to Reason (1991), it is possible to consider a model of development composed by various steps. They can be conceptual or actual steps and can regard material aspects or human behaviors: each of them can be seen as an ideal layer (Fig. 6).

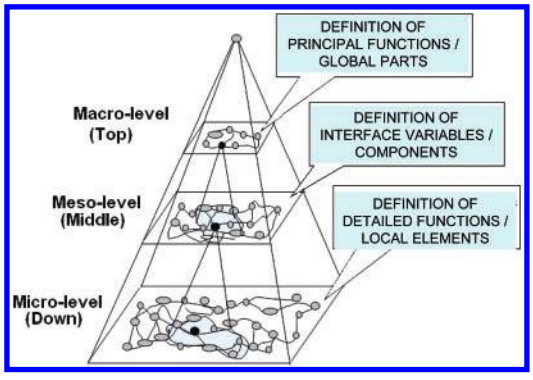

Figure 7. Functional/hierarchical breakdown of a problem/system.

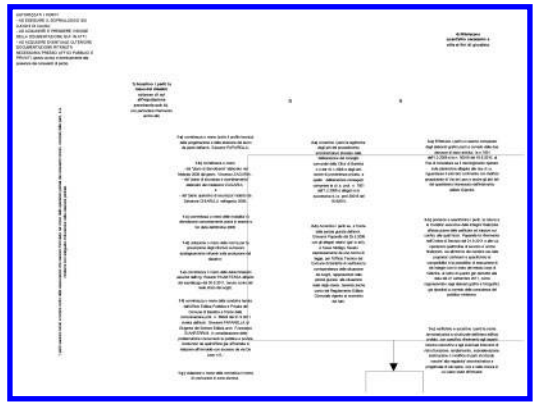

Figure 8. Example of the logical breakdown of the question asked by the magistrate to the expert witness (the details are not visible for privacy issues).

Actually, each layer has imperfections and deficiencies that represent fault and errors for the system (Minato, 2003; Chong & Low, 2006). In Figure 6, these are represented by holes in the layers. The model predicts that, also if a single shortage is not critical, an alignment of these weaknesses (hazards), can lead to a failure. The graphical representation of the model explains its original name: the Swiss Cheese model (Reason, 1991).

4 BREAKDOWN

The previous sections dealt with the concept of complexity and with the extension of a model for representing the development of a structural failure. This framework is still missing the operational point of view; two operational tools that can significantly help in the investigation are the spatial decomposition of the problem (*breakdown*) and the analysis of its temporal evolution (*timeline*).

The hierarchical/functional breakdown of a problem (or a system) can be represented graphically (as shown in Figure 7) by a pyramid, set up with various objects positioned in a hierarchical manner. The peak of the pyramid represents the goal (the whole problem), the lower levels represent a description of fractional objects (the sub-problems in which the problem can be divided), and the base corresponds to basic details. By applying a *top-down* approach, a problem can be decomposed by increasing the level of details one level at a time. On the other hand, in those situations where the details are the starting point, a *bottom-up* approach is used for the integration of low-level objectives into more complex, higher-level objectives. In common practice, however, actual problems are unclear and lack of straightforward solutions. In this case, the strategy becomes a mixed recipe of top-down and bottom-up procedures that may be used alternately with *reverse-engineering* approaches and *back analysis* techniques.

The expert witness applies the breakdown approach to the various phases of the forensic investigation. A first application is the decomposition of the question asked by the magistrate. Usually these questions are complex and need to be accurately analyzed and deconstructed.

An example is shown in Figure 8; for privacy issues the details are not visible, but it is possible to identify clearly three main tasks with 7, 2, and 3 subtasks respectively.

5 TIMELINE

In the previous section a first operation toll has been discussed, the hierarchical breakdown.

Another useful tool for the investigation of an event is the analysis of its timeline.

An example in shown in Figure 9 where it is shown the timeline of an event that started as a demolition and reconstruction of a building but ended with a catastrophic collapse. The chain starts with the conception of the intervention and the relative administrative practices needed to have the feasibility of the work verified by the public administration; then, there is the design phase that lasts up to the realization. For each phase the attention is focused on different aspects and different people are involved:

1) during the administrative practices, the technicians of the public administration should verify the feasibility of the intervention from the point of view of the existing city plan;
2) during the design phase (considering both architectural and structural design) the attention is focused of the conception of the work; the entire project will be analyzed and the respect of the codes will be verified by architects and engineers. In this phase, specific aspects, as for example the influence of adjacent building, should be investigated in detail;
3) during the realization phase, the attention is focused both on the people that materially make the works and on the managers of the site; specific documents and plans need to be drafted (as the safety plan and

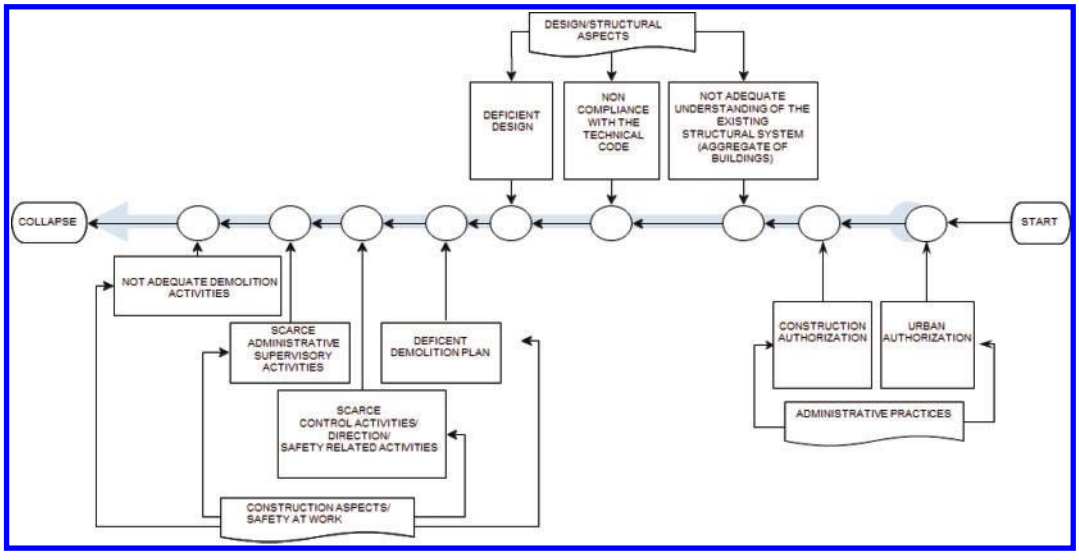

Figure 9. Example of timeline for the analysis of a work of demolition and reconstruction that turned into a collapse.

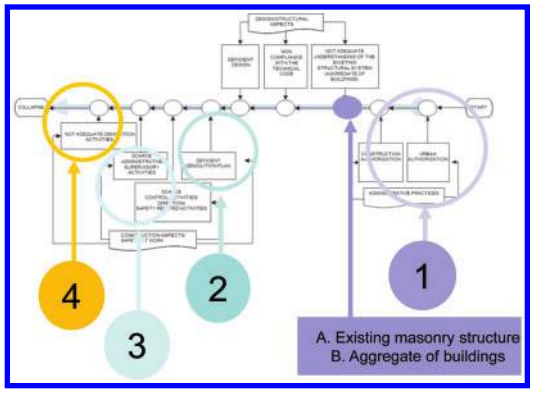

Figure 10. Example of the identification of the causal joint of the timeline in Figure 9 and definition of the various triggers.

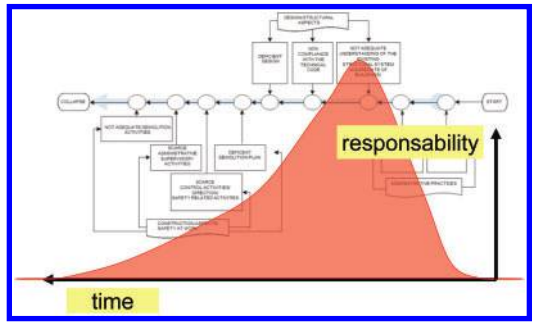

Figure 11. Example of the responsibility profile associated to the timeline of Figure 9.

the demolition plan); all the involved people (contractors, managers, designers, etc) have to carry out activities of control. Also some representatives of the institutions should carry out supervisory activities.

Even if the phases are represented separate and sequential, between them numerous overlapping and mutual influences exist (Suraji et al., 2001).

An accurate analysis of the entire process will show that one of these steps plays a central role: this one can be considered the causal joint of the entire process; all the events that led to the collapse rotate around this point.

Once the causal joint is identified, the other steps, that led to the failure, can be consequently ordered and the entire event is understood (Figure 10).

It is important to point out that, according to Reason's model, even if the collapse has been materially activated by a specific trigger (number 4 in the Figure), it was prepared and made possible by other acts, that sometimes are also distant in time, and that usually cannot be detected by a superficial interpretation of the event (Augenti & Parisi, 2009; Brady, 2012; Love, 2008; Petrosky, 1992).

6 RESPONSABILITY PROFILE

Starting from the timeline in Figure 9 and according with the identified causal joint, it is possible to define a profile that measures the responsibility of the involved people, as schematically shown in Figure 11.

It is possible to note that also this representation is coherent with Reason's model that states that it is not the last actor that necessarily should be considered the most, or even the only, responsible of the disaster, but the whole process should be evaluated.

7 CONCLUSIONS

In this work, some general concepts that, in the Authors' experience, constitute a basis for the framework of the forensic investigation activities have been discussed. It has been shown that it is necessary to start analyzing the peculiar complexities that characterize each problem. In this sense it is often useful to evaluate the sensibility to specific parameters and the existence (or not) of structural robustness. Then, Reason's model for the development of failures has been extended to the case of Civil Engineering structures, showing that a failure is usually caused by multiple concurrent causes. Even if a collapse is materially activated by a specific trigger, its initial causes should look for in other acts, which sometimes are also distant in time. This aspect should be considered also when the various responsibilities are assigned.

Tragic events as the structural collapses make the technicians reflect on the approach that are commonly used for the structural design and facilitate the introduction of new concepts, as that of structural *dependability* that has been recently proposed. It is a global concept that describes the aspects assumed as relevant to describe the quality of a system and their influencing factors (Bentley, 1993). It has been originally developed in the Computer Science field but it can be reinterpreted in the Civil engineering (Arangio et al., 2010). The dependability reflects the user's degree of trust in the system, i.e., the user's confidence that the system will operate as expected and will not 'fail' in normal use: the system shall give the expected performance during the whole lifetime.

The use of this concept would include the structural Performance-Based Design in a holistic framework.

Capacity assessment of damaged school buildings after 2011 Van earthquake

R.A. Oyguc
University of Illinois at Urbana-Champaign, Illinois, USA
Istanbul Technical University, Istanbul, Turkey

ABSTRACT: On October 23, 2011 a devastating earthquake with M_w of 7.2 hit Van province, which is located in the east of Turkey. The epicenter was Tabanlı village which is 30 km far from the city. 16 days afterwards the first earthquake, a second earthquake with M_w 5.6 again hit Van province. This time the epicenter was 18 km far from the city. Due to the large number of unqualified structures, the damage was more than expected. In this study, 3 damaged school buildings which were subjected to Van earthquakes were chosen. To overcome the soil effects, the buildings were chosen in the same era. Although they had the same structural properties, 1 of them were heavily damaged, 2 had minor damages and were in use. After conducting time-history analysis on the 3D models of the selected buildings, the reasons of the damages were discussed according to the assessed capacities.

1 INTRODUCTION

Two earthquakes, on October 23, 2011 (10:41 GMT) and November 9, 2011 (19:23 GMT) hit Van province, which is located in the eastern part of Turkey between Lake Van and the Iranian border. It is 20000 square km in area and has a population of 1million approximately. The peak ground acceleration values of the earthquakes were measured as 178.5 gal in the north-south direction and 102.6 gal in the east-west direction respectively. According to the governmental reports at least 600 people died, and more than 4000 are injured due to the earthquakes. More than 2000 houses are heavily damaged or collapsed. Comprehensive data about the earthquakes can be found in Table 1.

To carryout reconnaissance studies in the region, Government of Van signed a protocol with wide-known universities of Turkey. They want to know which buildings they should demolish and which they should support credits for retrofitting. Figure 1 shows the epicentral distances of the earthquakes.

Table 1. October 23, 2011 and November 9, 2011 Van earthquakes characteristics.

Earthquakes	October 23		November 9

Depth (km)	5.0	16.0	5.0	5.0
M. Magnitude	7.2	7.1	5.6	5.6

2 SEISMO-TECTONIC CHARACTERISTIC OF THE REGION

It is known by the seismologist that Lake Van is a key factor in the Arabian-Eurasian plate boundary. It lies near the intersection of two transform fault zones and a subduction zone. It is also assumed by NASA that, the southern edge of Lake Van lies along the extension of the right-lateral strike slip North Anatolian fault (Fig. 2). The Dead Sea and East Anatolian fault zones are classified as left-slip faults. Central Turkey is being squeezed west (to the right) by the northward movement of the Arabian Plate. Beyond Lake Van are the folds and thrust faults straddling the boundary between the Arabian Plate from the Eurasian Plate (NASA).

It is also reported that, the region had affected from the historical earthquakes between the periods 1101-1900 B.S. The intensity of them were in the range V-X. It was a known fact that there had been a fault trace

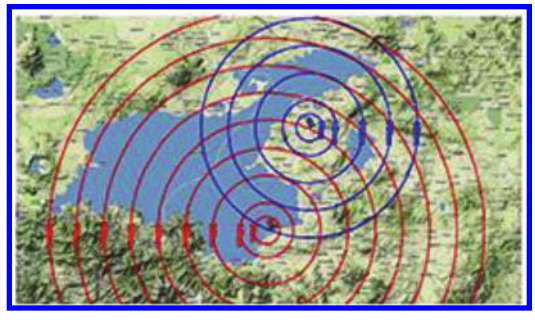

Figure 1. Epicentral distances of Van earthquakes.

Figure 2. NASA picture of Lake Van (NASA).

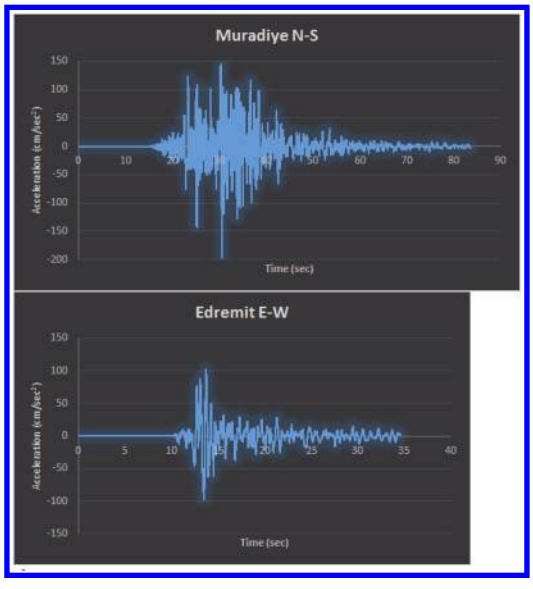

Figure 3. Filtered earthquake records of Muradiye and Edremit.

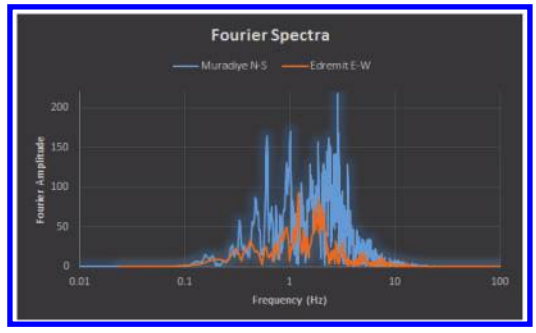

Figure 4. Fourier spectra of Muradiye and Edremit earthquakes.

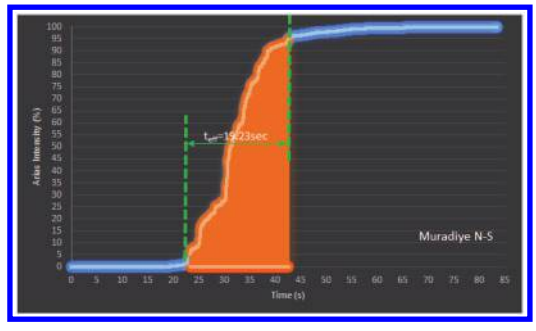

Figure 5. Arias intensity of Muradiye N-S component.

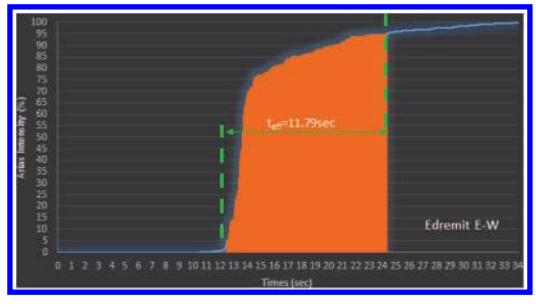

Figure 6. Arias intensity of Edremit E-W component.

in the region, it did not accepted as an active fault in the 1992 dated map of MTA (Mineral Research and Exploration Institute) though.

Regarding this issue, it is later accepted and marked in the seismological maps that there is an active left-lateral strike slip fault line called Van Fault.

The gathered ground motion records from Muradiye and Edremit stations were then filtered using *Seismo-Signal* (Seismosoft) program respectively. It was first performed baseline correction to the records. Later on, in order to bypass the undesirable noise contents in the records, quadratic Butterworth band filter had been applied to the acceleration records. Since N-S components of Muradiye and E-W of Edremit had the peak ground acceleration values, the processed values of those records are given in this paper. Figure 3 shows the acceleration-time graphs of the mentioned earthquakes.

The comparison of Fourier spectrums for both earthquakes are given in Figure 4. The effective durations of the horizontal components are determined assuming that the effective time is the time interval between the 95% and 5% values on the Arias intensity curves. The calculated effective times for Muradiye and Edremit records are shown on Arias Intensity plots on Figure 5 and Figure 6. The effective time for Muradiye N-S and Edremit E-W records are calculated as 19.23sec, 11.79sec respectively.

For the 5% damped acceleration response spectra of the filtered ground motions recorded at Muradiye and Edremit are compared with the design spectrum defined in Turkish Earthquake Resistant Design Code

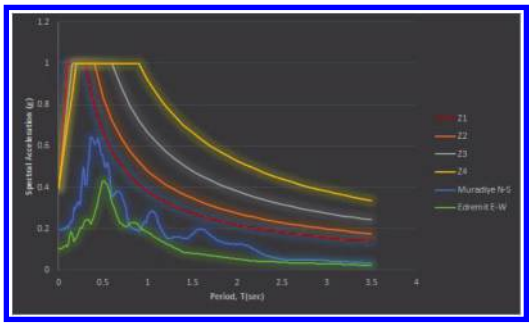

Figure 7. Comparison of acceleration response spectra with the design spectra of TERDC.

(Ministry of Public Works, 2007) for all soil types. Figure 7 shows the comparison plot. Here Z1 represents the most stiff soil and Z4 the softest one.

It can easily be seen from Figure 7 that, the gathered 5% damped elastic response spectrums are all below the design spectrum values defined in TERDC, for all types of soils. Due to this fact, it can be stated that it is in fact not the earthquake that demolished the structures, it was the result of poor designed structures. Not obeying the engineering rules, using out of standard materials were the cause of the damage.

3 DAMAGE ASSESSMENT

3.1 *General characteristics of the building stock*

The building stock of Van can be categorized in to two, the reinforced buildings and the masonry ones. It can be stated that, the scene is not so much different from the other parts of Turkey indeed. Majority of the buildings were lack of engineering care. Most of the citizens of the province build up their own buildings without obeying engineering rules.

After the reconnaissance studies completed in the field, the reasons causing the damage in the reinforced buildings due to the earthquake excitation were resulted as follows;

a) It was just after 1999 Marmara earthquake that ready-mixed concrete started to use in the east of Turkey. The tested core samples of the 6–7 story buildings were astonishing. The strength results of the concrete samples were found to be 3–4 MPa.
b) Poor detailing of reinforcing bars can be stated as the second factor. The stirrups and the loops were not curved due to the regulations. There were also no stirrups in the column-beam connections.
c) Usually ribbed slabs were preferred. To overcome the rigidity deficiency of ribbed slabs, structural wall elements were not implemented in the buildings.
d) In the majority of the high-rise apartments, the entrance floors were used as car galleries or supermarkets. To expand free space in this floors the middle columns were cut off.

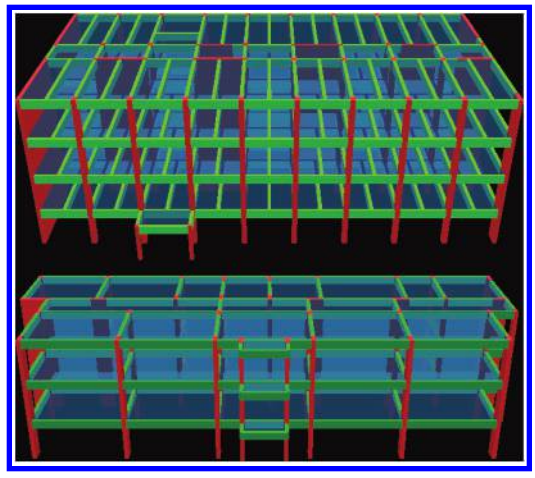

Figure 8. 3-D model of Building of (a) A and B (b) C.

e) Irregularity effects were not taken into account in the design.
f) The non-structural elements, clads, ceramics etc fell with the started excitation and caused injuries.
g) Adjacent buildings. There were no dilation. Due to hammering effect of different story levels, majority of the buildings were destroyed.

When the masonry buildings investigated, the causes of the failures can be stated as;

a) Heavy clay roofs due to protect the residents from bad weather condition caused the most damage in masonry structures.
b) Poor quality of the mud mortar binder.
c) Inadequate corner connections of the walls.
d) Excessive lengths of walls without any lateral support.
e) Majority of the brick masonry structures were unreinforced. They did not have any vertical and horizontal tie beam elements.

After the reconnaissance studies completed, the Government started to demolish the poor qualified structures and maintain the minor damaged ones. The reconnaissance field observations were not limited to residential buildings, as well as the school and governmental buildings. After the studies were completed, the retrofitting stage started in the region.

3.2 *Selected school buildings for assessment*

The selected school buildings were all built as three story, 12-class, and they were constructed in the same region. They all had structural shear-wall elements since they were school buildings. Two of them had been detailed using the same structural project prepared by the Ministry of Education of Turkey. Their design concrete strength was 20 MPa and design steel strength was 420 Mpa. The 3-dimensional ETABS (CSI) models of the selected buildings are given in Figure 8.

Table 2. Material properties of the selected school buildings.

Building name	Concrete strength (MPa)	Steel strength (MPa)
A	8	420
B	14	420
C	12	420

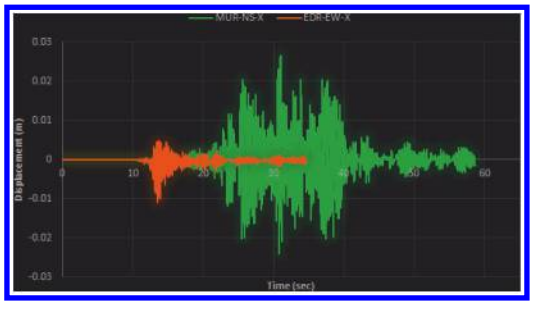

Figure 9. Time history trace of Building A for X-direction.

Concrete core samples were taken from the buildings implementing the stated procedures in TERDC. The test results were found to be different from the design projects. The concrete strength of the buildings which had the structural detailed projects by the Ministry of Education had been found to be 12 MPa and 8 MPa. The other school buildings concrete strength was found as 12 MPa. The experimental results of the concrete and the rebar samples were given in Table 2.

Here in the paper, the building with the lowest strength will be named as "Building-A", the highest one as "Building-B" and the other one as "Building-C".

3.3 *Time-history analysis results*

Time-history analysis were implemented on the selected three school buildings using the filtered ground excitations of Muradiye-NS and Edremit-EW. Following the sequence of the earthquakes, the buildings were first subjected to Muradiye-NS earthquake and then Edremit-EW in both X and Y-directions. Figure 9-11 shows the time-history displacement trace of the buildings. The displacement traces of the building were found to be slightly different in X and Y directions, so that only X-direction had been chosen to plot.

The earthquakes peak ground acceleration values were not big enough to produce large energy. The established displacements were not found to be considerable though.

After completing the time-history analysis, the probability of failure in the structural elements according to the implemented analysis, were matched with the reconnaissance observations in the following section.

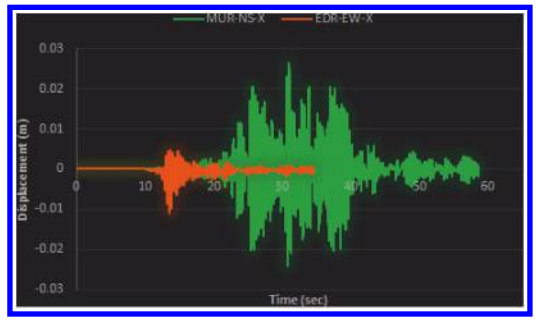

Figure 10. Time history trace of Building B for X-direction.

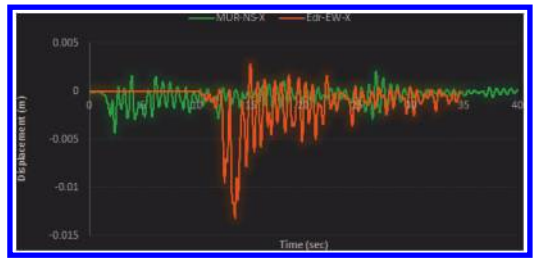

Figure 11. Time history trace of Building C for X-direction.

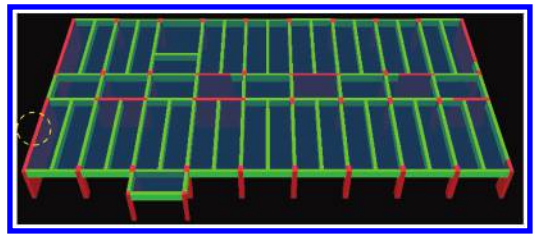

Figure 12. Plan view of Building-A.

3.4 *Matching the results with the field observations*

The results showed that even if the structural system properties were the same, the concrete strength and quality of workmanship directly effects the performance of the buildings. Building-A, with the lowest concrete strength showed the worst performance. Its companion one Building-B had just minor cracks and were in use. Also Building-C was not damaged heavily.

Figure 12 shows the plan view of heavily damaged Building-A. The damage was excessive though to the shear-walls. The interior walls were demolished, and there were diagonal cracks in the shear-walls.

Figure 13 shows the outer view of the school building and the identified damages inside the building. The damaged shear wall were marked in Figure 12.

4 CONCLUSIONS

Three school buildings were selected to be analyzed to betray the behavior of buildings due to Van-Turkey 2011 earthquakes. Three buildings were established in

Figure 13. Outer and inside view of the school building.

the same region. Two of them were built conducting the same static detailed projects prepared by the Ministry of Education of Turkey. All of them were 3-storied and had shear-walls. Their design concrete strength was 20 MPa. The buildings had irregularity in one-direction.

The earthquakes record were filtered and scaled before using them. The unnecessary noisy parts were pulled out. After conducting time-history analysis on the selected buildings, the followings were resulted.

a) The peak ground accelerations of the earthquake records were found to be 178.5 and 102.6 gal. That was below the design limits. In Figure 7 it was shown that the earthquakes acceleration response spectra were below the design spectra of TERDC 2007. The damage caused by the ground motions on the buildings were astonishing though.
b) The majority of the buildings concrete strengths were found to be different and considerable lower than their design strengths. This is believed to be the main reason of the determined damage.
c) In the analyzed 3 school buildings, the building with the lowest concrete strength had the most damage, the interior walls were demolished and the shear-walls had diagonal cracks, the building did not collapse though. The one from the same executed project (A and B) with a higher concrete strength were in good position after the same earthquakes.
d) It can be concluded that, whether if the detailed project is perfectly designed, the application of that project on the field is another concern. Poor quality of the established buildings in the region made the damage excessive.
e) Not using ready-mixed concrete and not properly detailing the reinforced elements may be classified as the most important deficiencies.
f) It is believed that if the analyzed buildings were built-up with higher stories they would collapse, like the others, due to their deficiencies.

In many parts of Turkey and many other countries there are many non-engineered buildings indeed. To betray the future possible damage in this type of buildings, they should be demolished or strengthened before earthquakes demolishes them.

Structural failures and monitoring of structural health with use of WiSeNe^{MONIT} system

S. Wierzbicki, M.A. Gizejowski & Z. Stachura
Warsaw University of Technology, Warsaw, Poland

ABSTRACT: Extreme loading events associated with climatic conditions can have a severe impact on building structures leading to local damage that can trigger the instant failure or progressive collapse. Extreme wind action associated with a high wind speed and gust may cause a local damage to façades and roof claddings or even the total destruction of lightweight building load bearing systems. Extreme snowfall, snow-on-ice, rain-on-snow or rainfall ponding actions may lead to catastrophic roof failures. In this paper, the outcome of studies related to forensics of specific climatic-induced failures is summarized. Such events would have in many cases been avoided if certain safety measures were applied. One of the most effective tools of safety assurance is to install an efficient structural health monitoring system that could inform about the actual state of the structure and warn in advance about forthcoming dangerous situations. In case of snowfalls, an early warning sign would initiate an immediate action for the arrangement of snow removal procedure, or in case of a heavy snow storm - a snow removal procedure combined with the building evacuation. In this paper, the WiSeNe^{MONIT} monitoring system is presented together with its pilot installation. The system was customized for the purpose of monitoring of large span steel roof in a hypermarket located on north-east of Poland. The data recorded from sensors distributed over the roof area is evaluated for periods between December 2011 and February 2013, and presented in the paper together with some practical observations.

1 1 INTRODUCTION

Warehouses, factories, exhibition halls and commercial buildings of lightweight bearing systems, especially those of flat large span roofs, are among the most common low-rise buildings affected by failure incidents. Failures were attributed to many factors, mainly arising from unforeseen climatic conditions and errors undetected during design or/and execution processes. Among climatic actions, the excessive wind speed and gust, overloading by snow, rain-on-snow mixes, and rain water ponding are the causes of building damages with reported fatalities and injuries. There is a trend of increasing number of such events said to be associated with accelerating global climate change influencing the patterns of snowfall and rainfall frequency and density.

There have been many research papers dealing with climatic actions and their influence on buildings; Gizejowski et al. (2011), Geis et al. (2012) & Goliger et al. (2013). The latter one deals with wind loading while the former one examines the risk of building failure and damage due to snow loading, characterizing the relative susceptibility of different types of structures as well as the human and economic impacts of these incidents. High profile American building failures due to snow have included the Hartford Arena in Connecticut and the C.W. Post College Theater on Long Island, both taking place in 1978. Reported international failures include the collapse of the Basmanny Marketplace in Russia and the Katowice Exhibition Hall in Poland, both of which occurred in the spring of 2006, killing a total of 131 people.

In the first part of this paper, the issues related to survey of failure causes are reported. In some countries, including Poland, there is an obligation requiring timely inspections of certain large span roof structures by building owners in order to monitor their technical conditions and to eventually react in an early stage. The other failure preventive measure is to install the structural health monitoring system (SHM system). Structural design execution strategies cannot define a priori all the extreme actions the structure may be subjected to during service that may lead to a danger of structural collapse. The only reliable information about the actual performance can be obtained from the SHM system controlling climatic actions and the most important action effects of structural response.

In the second part of this paper, issues related to monitoring systems that can prevent structural failures are addressed. WiSeNe^{MONIT} monitoring system is dealt with in details that allows for controlling vertical deflections of building roof structures due to winter climatic loads, as well as due to temperature of structural elements. Temperature of individual structural elements is interpolated from records obtained in the points of deflection measurements. The laser distance measurement and multi-hop radio data

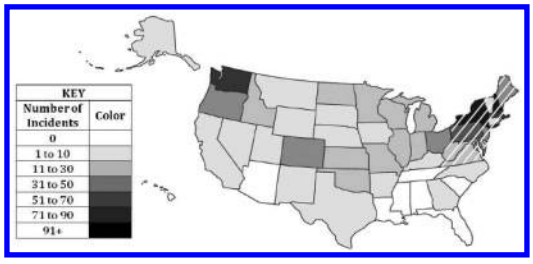

Figure 1. Distribution of the U.S. database failure incidents; Geis et al. (2012).

transmission are utilized for monitoring of deflections. The WiSeNe^{MONIT} system systematically collects, processes and evaluates information about the response of the roof structure, i.e. change of representative deflections due to climatic loads such as snow, ice or rain water, taking into account the effect of temperature on the deflection.

Moreover, the WiSeNe^{MONIT} SHM system supports the maintenance management process by providing users with the warning signals to take preventive actions of snow or rain water removal at the right time, therefore reducing the number of unnecessary operations and avoiding the risk of damages caused during the operational processes.

2 STRUCTURAL FAILURES

2.1 *Survey conducted by Geis et al. (2012)*

Factors such as building location, time of year, and weather patterns affecting a building's susceptibility to extreme snow loads were considered in research. Incidents were reported in all the U.S. states and clustered in northern regions of the country (Fig. 1). The majority of reported incidents (58%) occurred in the Mid-Atlantic and New England states, delineated in Figure 1.

The study has also been conducted to relate semimonthly periods of snowfalls and the number of failure incidents. A positive relationship was observed between snowfalls in a semimonthly period and the number of incidents in a semimonthly period, with increasing snowfalls tending to be associated with a larger number of incidents (Fig. 2). Data points along the vertical axis showing incidents without any record of snowfall may reflect snow build-up on roofs over days or weeks before the incident, or the additional weight from rain and ice in addition to snow, which could not be determined from available weather data. Large snow depths causing no incidents for data points located along the horizontal axis may represent snow falling on unpopulated areas, or less-dense or quickly-melting snow that imparts smaller loads to buildings. Using the available weather data, it was not possible to determine whether or not snow loads exceeded code design loads for any particular incident.

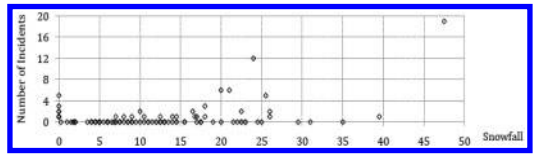

Figure 2. Database failure incidents vs. snowfall depth (in.) for Massachusetts between 1993 and 2009; Geis et al. (2012).

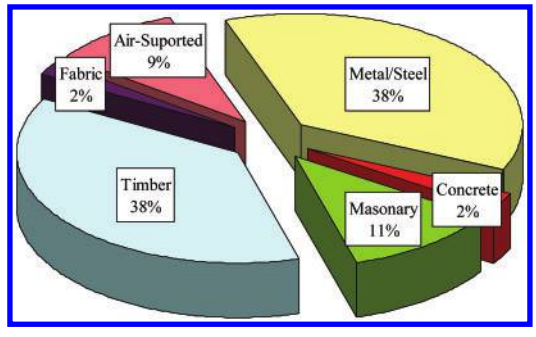

Figure 3. U.S. reported database incidents by construction type.

Other considered features of buildings impacted by failures were structural systems, function and age up to the event occurrence. Of the total number of 1,029 snow-induced building failure incidents in the U.S. between 1989 and 2009, and 91 international incidents between 1979 and 2009, 233 (23%) incidents were identified with information about construction type. Figure 3 represents the classification of the number of database incidents in the U.S. by construction type.

The majority of impacted buildings are reported by Geis et al. (2012) to be metal/steel (38%) and timber (38%) constructions. Steel structures of low-rise buildings consist of various combinations of lightweight cold-formed and hot-rolled steel members for roof systems with different types of walls. As was clearly indicated in Geis et al. (2012), such buildings are subjected to a high live to dead load ratio and are particularly at risk under snow loads. The number of air-supported and fabric structures reported in the database is also notable, although these structures make up a relatively small percentage of the overall considered building stock. They are at risk due to their small dead load, vulnerability to uneven loading, and difficulty associated with clearing snow and ice when overloaded (Geis et al. 2012).

Figure 4 presents the classification of the number of database incidents outside of the U.S. by construction type (Geis et al. 2012).

Although the number of incidents considered in this case are relatively narrow, the same tendency is observed like in case of a broader survey done for the U.S.

2.2 *Survey conducted within the MONIT project*

In the framework of MONIT Project led by the Warsaw University of Technology and carried out by several

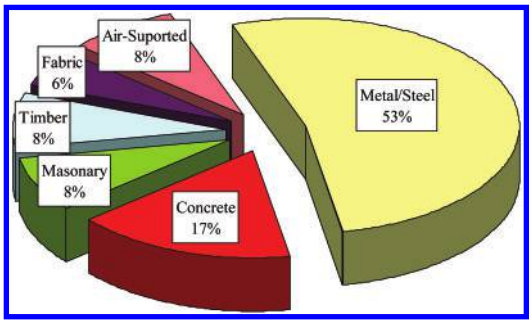

Figure 4. Internationally reported database incidents by construction type.

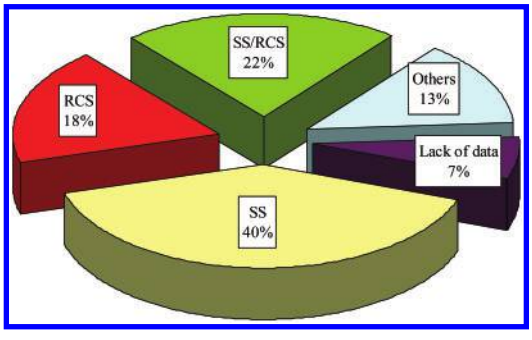

Figure 5. MONIT database incidents by construction type.

partners (see http://www.monit.pw.edu.pl/), a task of collection of building failures and collapse events in Poland in the years 1995-2010 has been completed. From the building surveillance offices, the data of 443 officially submitted cases were reported. Because only 12 of them were concerned with large span roof buildings, independent investigations were undertaken in order to bring this number closer to reality. The additional 48 cases of incidents reported for large span roof buildings were included from other sources, giving the number of 60 in total.

Figure 5 presents the MONIT database incidents by construction type. It is indicative from this survey that failures and collapses of buildings with steel structural load bearing systems (SS) or with mixed reinforced concrete supports and steel roofs structural systems (RCS) have been dominant. Although the incidents reported above were in majority related to climatic actions resulting from snow-ice overloading events, the real causes of failures and collapses would be somewhat different. Figure 6 indicates what are the factors responsible for structural failures and collapses.

The total number of reported cases for which the factors responsible for incidents were given is shared almost equally between all three selected types of reasons, namely design, execution and exploitation.

The most dangerous factors are related to errors inherited in the structure during the phase of execution because they are difficult to detect after the construction has been finished and their existence appears

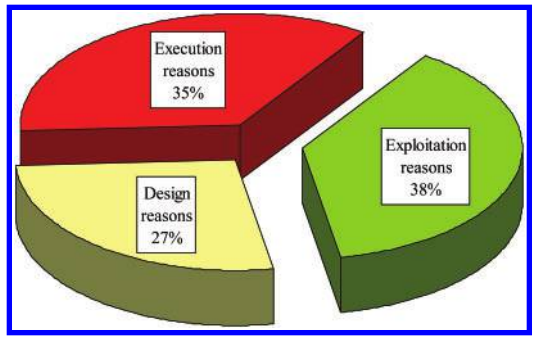

Figure 6. MONIT database factors responsible for building incidents.

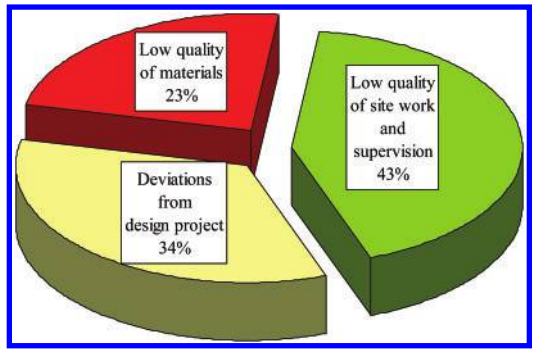

Figure 7. MONIT database factors affecting the execution reasons.

suddenly and frequently under climatic overloading. Figure 7 shows the factors affecting the execution reasons relating incidents of failure or collapse to execution reasons. The low quality of site work and supervision are the dominant factors.

3 MONITORING OF STRUCTURAL HEALTH USING THE SYSTEM DEVELOPED WITHIN THE MONIT PROJECT

3.1 *General*

One of the most efficient means of controlling the amount of snow or rain-water ponding loads on building flat roofs is to monitor the temperature and structural response in terms of deflections and compare them with deflection limits evaluated on the basis of calibrated numerical model of the whole structural system (Gizejowski et al. 2012). This idea has resulted in the development of SHM systems that control online the safety and serviceability criteria, enabling the recalculation of the structural deflection limits in relation to monitored temperature of structural elements. In the last decade, wireless sensing network technologies became superior monitoring solutions because of low installation cost, fast communication time and efficient online assessment capability.

Figure 8. Integrated measuring device mounted on the purlin.

3.2 *WiSeNe*^{MONIT} *structural health monitoring system*

The monitoring system WiSeNe^{MONIT} consists of two main subsystems, namely the on-line subsystem and the off-line subsystem that supports the former one by a numerical module (Gizejowski et al. 2012). The on-line subsystem is responsible entirely for recording, storing and evaluating the structural deflections under climatic actions (snow, ice, rainwater) in representative number of nodal points, and recording the temperature changes in respective structural elements. The off-line subsystem utilizes the temperature data from the on-line subsystem and performs numerical evaluation of action effects, displacements in all the nodes and stress resultants in all the line elements of the monitored structure.

On-line subsystem consists of three types of hardware devices interconnected in a radio multi-hop data transmission network. They are integrated measuring devices, retransmitting devices and central controlling unit (for details refer to Gizejowski et al. 2012).

Figure 8 shows the integrated measuring device installed over the bottom chord of truss purlin being the secondary element of roof structure transferring the load onto the main frameworks. The measurements of displacements are done by the laser's optical device evaluating the distance between the point to which is attached and the stable point that is not subjected to movements, or its movement can be related to the other reference point of known displacements. This device is equipped with a radio transmission capability so that it serves as a node in radio network being able to communicate with other such devices, as well as with retransmitting devices and central controlling unit. The other task of measuring device is to integrate the displacement related measurements with the temperature. The temperature is recorded inside the measuring device and outside it with use of a satellite thermometer (see Fig. 8). Measuring devices are mounted by means of special slings seen in Figure 8 to secondary and primary substructures of building roof or to other reference points in order to avoid obstacles disturbing the laser's optical axis to go through.

Table 1. Reaction levels corresponding to four threshold levels of structure health assessment.

	System state		End user state	
Displacement state*	Reaction type	Sampling frequency	Signal	Activity
$\delta \leq$ L1	Normal	T	None	None
L1 $< \delta \leq$ L2	Raised	T/2	Alert	Observation
L2 $< \delta \leq$ L3	High	T/4	Warning	Inspection
L3 $< \delta \leq$ L4	Higher	T/8	Alarm	Intervention
$\delta >$ L4	Highest	T/8	Closure	Evacuation

* δ – displacement due to climatic actions.

The calculated values of deflection are compared with threshold values to determine the corresponding climatic action level for the roof structure. Based on the results of this evaluation, the subsystem sends an appropriate message of different types, namely the information type, warning type or alarm type. The four threshold levels (levels L1-L4; for details refer to Gizejowski et al. 2012) correspond to five reaction levels that are given in Table 1. It is important to note that the sampling interval time T (see the third column of Table 1) at which all the displacements controlling the actual state of the structure safety are recorded, is not of a constant value but is implemented in the system as a variable value being dependent on the season and upon reaching the threshold values of displacements of representative structure nodes. The base value T is being set in accordance with the consultation with the owner/user of building subjected to monitoring.

3.3 *Pilot installation*

Pilot installation of WiSeNe^{MONIT} system was done for a large span steel roof of hypermarket located in the north-east of Poland, in the region of usually severe snowfalls in wintertime.

The on-line subsystem installed in the considered building consists of 18 measuring devices, 9 retransmitting devices and one controller with ratio module and GSM router. Figure 9 shows the distribution of measuring devices over the roof structural elements. As one can note, measuring devices are distributed over the entire roof structure and installed on both the secondary structural elements (truss purlins) and main structural elements (rafters of rigid frames transferring loads from purlins onto the foundations). Installation was done in December 2011 when there was no snow on roof, and the initial measurement of roof elements deflected profile was evaluated for known permanent loading conditions. On the basis of this initial record, the off-line numerical model of the entire structure (consisting of both secondary and primary elements) was constructed and calibrated to conform with initial measurements. The numerical model was

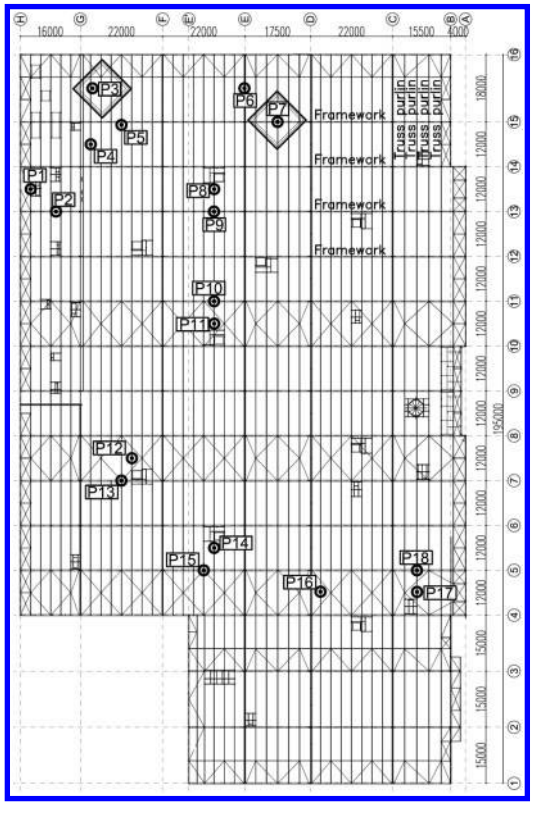

Figure 9. Location scheme of integrated measuring devices.

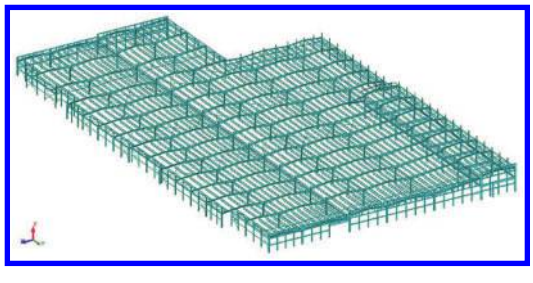

Figure 10. Printout of constructed numerical model from the off-line subsystem of WiSeNe^{MONIT}.

developed with help of Autodesk Robot Structural Analysis Professional software and it is shown in Figure 10.

It consists of 19041 elements and 12783 nodes, and the number of equations needed to be solved is 75600. Because the constructed model consists of cable elements, the nonlinear structural analysis option is applied together with a Newton-Raphson solver.

The calibrated numerical model was used for the evaluation of displacements produced by permanent and climatic load combinations.

Figure 11 shows the displacement coordinates for all the measuring devices corresponding to the uniformly distributed snow load of 0.91 kN/m^2 that corresponds to the displacement of approximately 5 mm

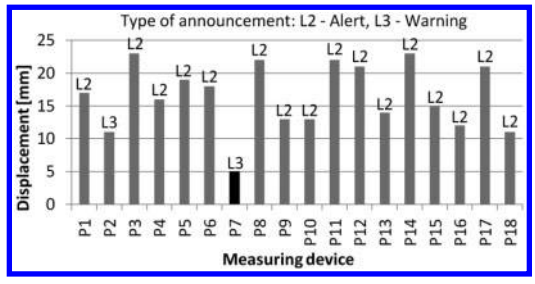

Figure 11. Displacement coordinates for measuring devices corresponding to a chosen value of snow load.

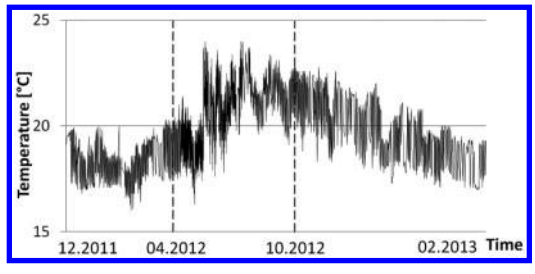

Figure 12. Temperature records from the measuring device P3.

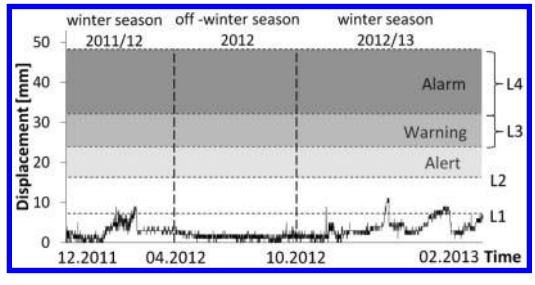

Figure 13. Displacement records from the measuring device P3.

for the measuring device P7. This snow load level is about to activate the warning announcement from two measuring devices while the others are in an alert state.

Since the pilot installation of WiSeNe^{MONIT} monitoring system, the results are constantly recorded and interpreted for the client. Typical records for the winter season 2011–2012, off-winter season 2012 and consecutive winter season 2012–2013 are presented herein. Both winter seasons were not associated with very heavy snowfalls. Figures 12 & 13 show the records of the temperature and displacement from the measuring device P3. The similar illustrations of the records from the measuring device P7 are given in Figures 14 & 15.

The temperature of roof steel structure varies from about 16°C in winter season and rises up to about 24°C in summer. As it has been indicated by the off-line numerical module, this change of temperature results in the displacement change of around plus/minus 1 mm, so that it is in the range of measurement tolerances. The effect of temperature may

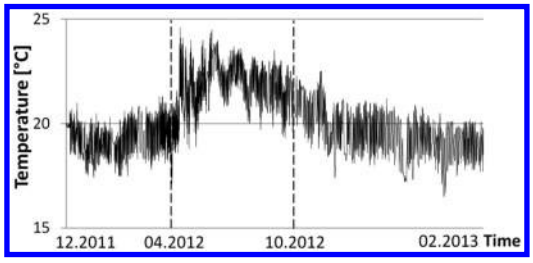

Figure 14. Temperature records from the measuring device P7.

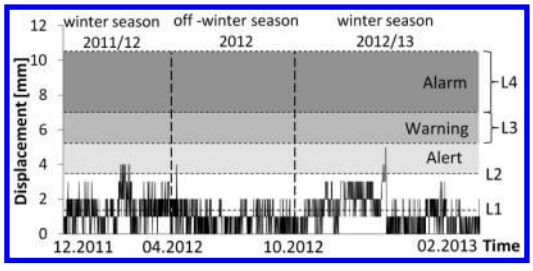

Figure 15. Displacement records from the measuring device P7.

threfore be omitted in monitoring of considered roof structure. It has to be noted that the effect of temperature is generally important in controlling the structural behavior since the residual deflections due to temperature may have a significant influence on the deflection level in statically determinate structures and both on the deflection and stress levels in case of structures with a high degree of structural redundancy.

Because the winter season 2011–2012 was in Poland without substantial snowfalls, the picks of displacements are for this season below those indicative to reaching the bottom line of warning signals. Contrarily, the winter season 2012–2013 resulted once in a more heavy snowfall. The pick of displacement for the measuring device P7 almost reached at this time that corresponding to the bottom line of warning signals. Although it was not yet the situation requiring the inspection, the building owner decided to remove snow from the roof. The fact of snow removal is clearly visible from the records of device P7 because the pick value suddenly drops down to the level oscillating around quasi-permanent load level.

4 CONCLUDING REMARKS

Topics related to structural catastrophic events and monitoring of structural health are dealt with. Independent databases of reported structural incidents indicate that lightweight large span steel roofs, especially those flat and composed of segments placed at different heights, are the most vulnerable systems to failures and collapses.

The monitoring system WiSeNe^{MONIT} is developed for typical single-storey buildings of steel lightweight roof structures. It facilitates the assessment of safety criteria allowing for suitable maintenance procedure to be undertaken during service.

Approaches to quantify the safety gain for existing concrete bridges due to surveillance

C. Siegert, L. Eckfeldt & M. Empelmann
Institute for Building Materials, Concrete Construction and Fire Protection (iBMB), Concrete Construction Department, TU Braunschweig, Germany

ABSTRACT: If the recalculation of an existing bridge due to deficient verifications is not successful, in Germany, the recalculation guide for existing road bridges offers the possibility of arranging compensatory measures. The guide differentiates between traffic-oriented compensatory measures and compensatory surveillance. The safety gain due to traffic-oriented compensatory measures is already well quantifiable. However, objective methods to quantify the safety gain due to compensatory surveillance, especially of permanent monitoring, are rare and not very detailed. Therefore, in this paper general approaches based on the probability theory are shown. With the help of these approaches compensatory surveillance can be used by roadway authorities as a sensitive but effective measure in the future.

1 INTRODUCTION

New design standards as well as increasing traffic on German motorways produce high demands in recalculating existing bridge structures. The recalculation of road bridges is regulated in Germany in the recalculation guide (BMVBS 2011). Experience shows that the design checks often show shortfalls of safety. To preserve structural integrity, the guide offers the possibility of arranging compensatory measures. The definition of a compensatory measure is that it ensures the continued use of a structure for a given bearing capacity. Thus, it causes a safety gain. The guide differentiates between traffic-oriented compensatory measures and compensatory surveillance.

Traffic-oriented compensatory measures may include bans on passing, minimum distances, speed and weight limits. Typically, roadway authorities enforce these kinds of compensatory measures. However, if such measures cause difficulties, like an undesired influence on the traffic, or if they compensate the given deficit insufficiently, compensatory surveillance can be another option to maintain an existing bridge without the need of strengthening.

Experience shows that avoiding bridge collapse is closely related to its surveillance. The better and more systematic the surveillance is conducted, the greater is the likelihood that damaged components are identified, assessed and, if necessary, measures are taken before an actual bridge collapse occurs. Thus, surveillance can be used as compensatory measure as well. Currently, various compensatory surveillance measures are undertaken. However, due to the lack of knowledge, decision makers do not base their decision pro or contra compensatory surveillance on a precise assessment of the expected safety gain, but on intuition. Thus, to verify objectively the target failure probability, strategies to quantify the safety gain are of great interest.

2 BASICS OF THE APPROACHES

A reliable quantification of the safety gain due to compensatory surveillance measures can be performed by using the probability theory.

2.1 *Basics of the probabilistic design*

The reliability of a structure can be expressed by the limit state equation:

$$G = R - E \tag{1}$$

where R = resistance and E = effect. Thus, G is the difference between the resistance and the effect.

As the resistance and the effect are generally subjected to scatter, there is always a possibility that for the realizations $r < e$ is true. Thus, the region $G < 0$ describes the failure region (grey area in Fig. 1). The failure probability P_f can therefore be expressed as:

$$P_f = P[G < 0] = P[(R - E) < 0] \tag{2}$$

As the failure probability P_f in construction engineering is generally very small and sensitive to variations of the input parameters, the reliability index β

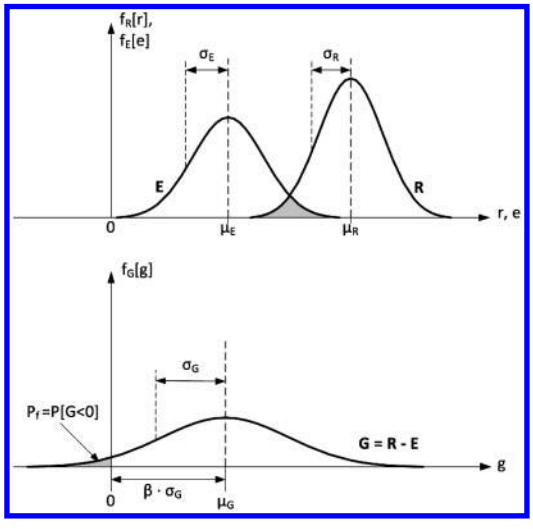

Figure 1. Definition of probability of failure P_f and reliability index β.

is often used for designs. The reliability index β is given by:

$$\beta = \frac{\mu_G}{\sigma_G} \tag{3}$$

where μ_G = mean value of G and σ_G = standard deviation of G (cf. Fig. 1).

The design method directly based on this concept is called the 'full probabilistic concept'. An acceptable reliability of the structure is verified, if the calculated failure probability of the analyzed structure P_f is lower than the target failure probability $P_{f,t}$ (resp. if its reliability index β is higher than the target reliability index β_t):

$$P_f \leq P_{f,t} \quad resp. \quad \beta \geq \beta_t \tag{4}$$

Target reliability indexes β_t are usually defined in standards (i.e. EC 0).

2.2 *Quantification of a safety gain due to compensatory surveillance*

According to the definition of compensatory surveillance, a compensatory surveillance system compensates deficits. That means that the arrangement of a compensatory surveillance system on a bridge in deficit leads to a safety gain for it.

In the full-probabilistic context, the safety gain $\Delta P_{f,s}$ can be expressed as the decrease of the failure probability due to the surveillance measure. Thus, it is obtained by subtracting the failure probability of the structure that takes the surveillance into consideration $P_{f,s}$ from the failure probability of the structure without compensatory surveillance P_f:

$$\Delta P_{f,s} = P_f - P_{f,s} \quad resp. \quad \Delta\beta_s = \beta_s - \beta \tag{5}$$

The compensatory surveillance measure is successful, if the safety gain $\Delta P_{f,s}$ is as high or higher than the investigated deficit ΔP_f:

$$\Delta P_{f,s} \geq \Delta P_f \quad resp. \quad \Delta\beta_s \geq \Delta\beta \tag{6}$$

3 TYPES OF COMPENSATORY SURVEILLANCE

Compensatory surveillance systems can be generally differentiated according to their temporal arrangement into:

- singular compensatory surveillance measures,
- recurring compensatory surveillance measures and
- continuous compensatory surveillance measures.

3.1 *Singular compensatory surveillance measures*

Singular compensatory surveillance measures performed on existing concrete bridges are for example:

a) the determination of the compressive strength of the concrete,
b) the determination of the force of the prestressing steel,
c) the geodetic survey of the geometry,
d) the determination of the actually existing traffic on the bridge and
e) the execution of a load test.

During the design process of a bridge, assumptions have to be made regarding the statistical description of the variables of the limit state equation. Those assumptions are usually based on experience. All of the singular aforementioned compensatory measures have in common that they deliver additional information to the ones based on experience for the statistical description of the input variables.

In detail, the measures a) to d) deliver additional samples to describe the statistical distribution of a specific input variable. With the help of this information, a Bayesian Update can be performed for the investigated variable. The idea of the update is to enhance the original statistical description of the variable due to the new information gained. Usually that leads to a decrease of the standard variation of the variable and thus to lowered failure probability of the structure and to a safety gain, while recalculating the investigated existing structure. For the computation algorithm of a Bayesian Update it is i.e. referred to Faber (2012).

The new information gained by executing a load test, in which the bridge is surcharged until a test target load, which is higher than the calculated maximum, measure e), has to be assessed differently. In this case, the part of the uncertainty of the resistance up to the test target load is eliminated, so that the concerning part of the failure probability disappears and thus the failure probability decreases. For a more detailed description and the probabilistic quantification of the enhanced failure probability and the safety gain it is referred to Spaethe (1994) and Siegert et al. (2012).

3.2 *Recurring compensatory surveillance measures*

Examples of recurring compensatory surveillance measures performed on concrete bridges are:

a) in time intervals recurring inspections (i.e. bridge inspection according to the standard with reduced intervals) and
b) recurring load tests.

Bridges have to be inspected in regular time intervals according to the existing standards. The aim of these inspections is to detect serious damage in time to be able to react before an actual bridge collapse occurs. Both aforementioned recurring compensatory surveillance measures have in common that the probability of detecting serious damage in time is higher than for the regular inspection plan. Structures, for which a recurring compensatory surveillance measure is applied, thus exhibit a lower failure probability.

The Probabilistic Model Code of the JCSS (JCSS 2001) contains the basics of a probabilistic approach for considering the effect of recurring compensatory surveillance while determining the failure probability of a structure. The safety gain due to performing inspections with reduced intervals can then be derived from the comparison of the failure probability of the structure under consideration of performing inspections according to the existing standards and the failure probability of the structure under consideration of performing inspections with reduced intervals. For computational details it is referred to Siegert et al. (2012).

The safety gain due to recurring load tests can be determined analogously.

3.3 *Continuous compensatory surveillance measures*

Continuous compensatory surveillance measures performed on concrete bridges are for example:

a) threshold value monitoring and
b) traffic-weight control.

The idea of a threshold value monitoring is to directly monitor the limit state in deficit and in the case of exceeding a threshold value triggering an alert. An example is the exceedance of a defined crack width which heralds an imminent failure of the monitored bridge.

A threshold value monitoring is the most effective compensatory surveillance measure for an existing bridge as it relates directly to the limit state. Therefore, the uncertainties of both the effect on the bridge and the resistance of the bridge are affected. However, threshold value monitoring is only possible in case of the existence of an adequate monitoring system that announces the failure of the structure in time. Threshold value monitoring for deficits with brittle failure modes is therefore difficult to set up. Another difficulty is the determination of the threshold values for the monitoring system.

Recurring inspections relate directly to the limit state as well. However, in the case of the arrangement of an adequate monitoring-system, the failure probability of the threshold value monitoring is significantly lower than the one of the recurring inspections.

The concept of a traffic-weight control is the determination of potential traffic loads on the investigated bridge (i.e. by a Weigh-in-Motion System) before they actually impact on the bridge. In the case of an exceedance of a threshold weight, the bridge is blocked before the detected vehicle can pass (i.e. with the help of a barrier or a traffic light system).

An extensive literature review with the topic of approaches to quantify the safety gain provided by continuous compensatory surveillance shows that available methods are rare. The only approaches known to the authors are by Allen (1992) and Bergmeister & Santa (2004). Both follow the approach of reducing the target reliability in dependence of the intensity of the surveillance. However, the quantification of the reduction is based on experience and is only available for the categories “no surveillance”, “regular surveillance” and “continuous surveillance”. Thus, a consideration of neither the type of the surveillance (e.g. threshold value monitoring or traffic-weight control) nor the value of its failure probability is possible.

3.4 *System identification*

Both a threshold value monitoring and a load test offer the possibility of gathering more information about the bridge in order to gain an advanced knowledge of it. An improved model can not only be used to recalculate the structure, moreover, the standard deviations of the model uncertainties, which have to be applied in a full-probabilistic analysis, can be reduced as well.

Both the resistance R and the effect E are described using models. Such a model is complete and accurate, if the model returns exactly the experimental results. As most models do not fulfill this demand, usually two multiplicative model uncertainty factors are introduced into the limit state equation (one on the effect and one on the resistance side). Is the model improved by a system identification, the model uncertainties decrease so that the standard deviations of the model uncertainty factors can be reduced. On the effect side, examples for causes of a decrease are a better knowledge of the support conditions and of changing stiffness ratios of the examined concrete bridge. On the resistance side, an example is the time dependent concrete behavior. The decrease of the standard deviations of the model uncertainty factors results in lower variations of the effect and the resistance and thus in a calculative reduction of the failure probability of the bridge.

A study that investigates the safety gain due to a decrease of model uncertainty due to system identification is unknown to the authors.

3.5 *Conclusion*

Several varying compensatory surveillance measures for existing concrete bridges are available. All of them

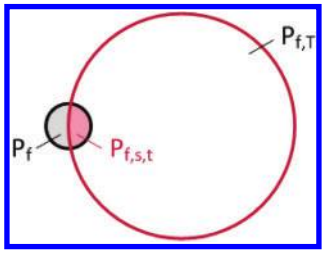

Figure 2. Failure probability under consideration of threshold value monitoring $P_{f,s,t}$.

require different methods to quantify the resulting safety gain. Quantification approaches for singular and recurring compensatory measures exist. However, for the continuous compensatory surveillance measures, which are the most effective compensatory surveillance measures, no sensitive quantification approaches exist. Therefore, in the following section such quantification approaches are developed mathematically. Moreover, the idea of a safety gain due to a decrease of model uncertainty by system identification is analyzed.

4 SAFETY GAIN DUE TO COMPENSATORY SURVEILLANCE

4.1 *Safety gain due to threshold value monitoring*

The safety gain due to threshold value monitoring can be derived analogously to the safety gain due to inspection. However, in a figurative sense only one inspection is performed, but this one continuously.

Based on the law of total probability, the failure probability under consideration of the threshold value monitoring $P_{f,s,t}$ is given by:

$$P_{f,s,t} = P[G < 0 \mid T > 0] \cdot P[T > 0] + P[G < 0 \mid T < 0] \cdot P[T < 0] \tag{7}$$

where T is the result of the threshold value monitoring (negative values represent the detection of damages).

Under the assumption that in the case of surpassing the threshold value the structure is refurbished Equation 7 reduces to:

$$P_{f,s,t} = P[G < 0 \mid T > 0] \cdot P[T > 0] \tag{8}$$

Reformulated, the failure probability under consideration of the threshold value monitoring $P_{f,s,t}$ results from the cut-set of the failure probability of the structure without surveillance P_f and the failure probability of the threshold value monitoring to detect serious damage successfully $P_{f,T}$. This context is illustrated in Figure 2. The corresponding calculation formula is:

$$P_{f,s,t} = P[G < 0 \cap T > 0] = P_f \cap P_{f,T} \tag{9}$$

If both failure probabilities are fully uncorrelated, the total failure probability $P_{f,s,t}$ results from the multiplication of the individual failure probabilities. Therefore, the total failure probability $P_{f,s,t}$ is reduced and a safety gain is created.

$$P_{f,s,t} = P_f \cdot P_{f,T} \tag{10}$$

However, if both failure probabilities are fully correlated, the total failure probability $P_{f,s,t}$ equals the minimum of the individual failure probabilities. A safety gain can only be created if the failure probability of the threshold value monitoring $P_{f,T}$ is very small. This is rather unlikely.

$$P_{f,s,t} = \min[P_f;\ P_{f,T}] \tag{11}$$

In reality, the individual failure probabilities are neither fully uncorrelated nor fully correlated. Therefore, the total failure probability lies between the following bounds:

$$\min[P_f;\ P_{f,t}] \leq P_{f,s,t} \leq P_f \cdot P_{f,T} \tag{12}$$

The safety gain due to threshold value monitoring is given by the comparison of the failure probability of the structure without monitoring P_f and the failure probability under consideration of the threshold value monitoring $P_{f,s,t}$:

$$\Delta P_{f,s,t} = P_f - P_{f,s,t} \quad resp. \quad \Delta\beta = \beta_{s,t} - \beta \tag{13}$$

The required safety gain in order to comply with the given target failure probability $P_{f,t}$ determines the maximum admissible failure probability of the threshold value monitoring max $P_{f,T}$. For the fully uncorrelated case it is:

$$\max P_{f,T} = 1 - \frac{\text{pres}\,\Delta P_f - P_{f,t}}{P_f} = 1 - \frac{\text{req}\,\Delta P_{f,s,t}}{P_f} \tag{14}$$

In Figure 3 the relationship between the present reliability index pres β and the resulting maximum admissible failure probability of the threshold value monitoring max $P_{f,T}$ is illustrated for varying target reliabilities β_t for the fully uncorrelated case. One can see the exponential decrease of max $P_{f,T}$ with decreasing pres β. Thus, for severe deficits a very low failure probability of the threshold value monitoring max $P_{f,T}$ is necessary to compensate for deficits in compliance with standards.

Resuming, for the design of a reasonable threshold value monitoring with the aim of compensating for deficits the knowledge about its reliability is necessary. However, for a given probability of failure of the measure $P_{f,T}$ the effectiveness of it can already be ensured in the planning stage.

4.2 *Safety gain due to traffic-weight control*

In the context of the probability theory the safety gain due to a traffic weight-control resembles the safety

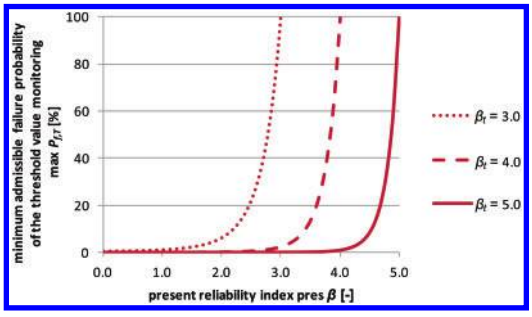

Figure 3. Admissible failure probability of the threshold value monitoring max $P_{f,T}$ versus present reliability index pres β (fully uncorrelated case).

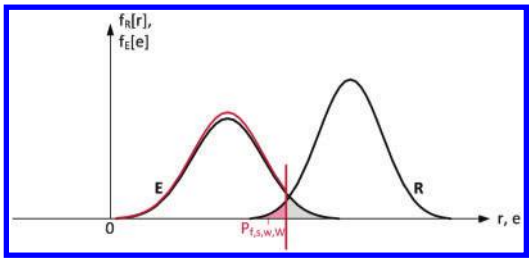

Figure 4. Failure probability under consideration of traffic-weight control $P_{f,s,w}$.

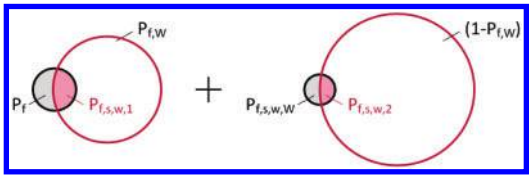

Figure 5. Failure probability under consideration of traffic-weight control $P_{f,s,w}$.

gain due to a load test. In a simplified consideration, the difference is that instead of part of the uncertainty on the resistance side part of the uncertainty on the load side is eliminated. That is the part above the threshold value of the weight-control system. This relationship is illustrated in Figure 4. E represents the acting load and R the load the bridge can bear.

The approach just described is simplified as a traffic-weight-control can fail with a certain failure probability $P_{f,W}$. For example, the Weigh-in-Motion System or the barrier system may be defect. Taking into account this fact, the failure probability under consideration of a traffic-weight control $P_{f,s,w}$ results as well according to the law of total probability. In Figure 5 the context is shown graphically.

Two different cases have to be distinguished: The first case represents the non-serviceability of the traffic-weight control. The corresponding probability is $P_{f,W}$. The second case represents the complementary event, the serviceability of the traffic-weight control. The corresponding probability is (1-$P_{f,W}$).

In case of a default of the traffic-weight control the structure fails with its original failure probability P_f. A partial failure probability of $P_{f,s,w,1}$ results.

In contrary, is the traffic-weight control functioning, the structure fails with a probability of $P_{f,s,w,W}$ (see Fig. 4). The partial failure probability is $P_{f,s,w,2}$.

The total failure probability $P_{f,s,w}$ is then given by the sum of the two partial failure probabilities $P_{f,s,w,1}$ and $P_{f,s,w,2}$. The calculation formula is:

$$P_{f,s,w} = P[G < 0 \mid W > 0] \cdot P[W > 0] + P[G < 0 \mid W < 0] \cdot P[W < 0] \quad (15)$$

where W is the result of the traffic-weight control (negative values represent the serviceability of the control measure). Rephrased it is:

$$P_{f,s,w} = P_f \cap P_{f,W} + P_{f,s,w,W} \cap (1 - P_{f,W}) \quad (16)$$

where:

$$P_{f,s,w,W} = P[G < 0 \mid G_W > 0] \quad (17)$$

$$G_W = R - E_W \quad (18)$$

where E_w is the threshold value of the weight-control-system.

The safety gain due to traffic-weight control is given by the comparison of the failure probability of the structure without traffic-weight control P_f and the failure probability under consideration of a traffic-weight control $P_{f,s,w}$:

$$\Delta P_{f,s,w} = P_f - P_{f,s,w} \quad resp. \quad \Delta\beta = \beta_{s,w} - \beta \quad (19)$$

Resuming, the resulting safety gain can be controlled by both the reliability of the traffic-weight control and its set load limit. For a given reliability of the traffic-weight control the necessary load limit to compensate for the existing deficit can be determined directly. Thus, if the required safety gain can be achieved by the traffic-weight control, it can already be checked in the planning stage.

4.3 *Safety gain due to system identification*

A decrease of the standard deviations of the model uncertainty factors θ_E and θ_R due to system identification results in lower variations of the resistance R and the effect E and thus into a reduction of the failure probability of the structure $P_{f,s,i}$. This context is illustrated in Figure 6.

The failure probability under consideration of a decrease of model uncertainty factors due to system identification $P_{f,s,i}$ is obtained by the following equation:

$$P_{f,s,i} = P[G_i < 0] \quad (20)$$

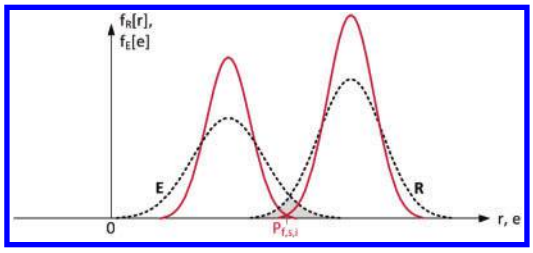

Figure 6. Failure probability under consideration of system identification $P_{f,s,i}$.

where:

$$G_i = R_i - E_i \tag{21}$$

$$R_i = \theta_{R,i} \cdot R \tag{22}$$

$$E_i = \theta_{E,i} \cdot E \tag{23}$$

The safety gain due to system identification thus results from:

$$\Delta P_{f,s,i} = P_f - P_{f,s,i} \quad resp. \quad \Delta\beta = \beta_{s,i} - \beta \tag{24}$$

The difficulty within this approach is that model uncertainty factors can only be described insufficiently in the required degree of detail by the current state of knowledge. For example, a manual calculation with the help of design charts and a FE-calculation should require the use of two different model uncertainties. However, due to lack of experience and only recipient research this is not performed in practice. Appropriate investigations that allow a hedged quantification of reduced model uncertainties exist barely. Further research is needed.

Thus, with the help of system identification basically two different safety gains can be achieved. On the one hand improved models, which describe the behavior of the structure, lead to a safety gain. This benefit cannot be determined in the planning stage, but it is dependent on the results of the surveillance. The second safety gain due to a decrease of the model uncertainty factors could be determined in advance. However, the current state of knowledge does not allow quantification.

5 SUMMARY AND PROSPECTS

Compensatory surveillance is nowadays not used on a precise, objective assessment of the expected safety gain. The reason is the lack of knowledge of detailed quantification methods. This paper shows general approaches to quantify safety gains due to continuous surveillance measures based on the probability theory. The approaches are set up in the full-probabilistic concept and allow the consideration of the type of the surveillance measure and its failure probability. Further research steps are the quantification of the failure probabilities of the surveillance measures and the transformation of the approaches into the semi-probabilistic concept.

With the help of quantifiable compensatory surveillance, roadway authorities have a sensitive but effective measure available to compensate for deficits and therefore to be able to preserve large parts of the aging bridge portfolio in the future.

ACKNOWLEDGEMENT

This report is based on parts of the research project carried out at the request of the Federal Ministry for Transport, Construction and Town Planning, represented by the Federal Highway Research Institute, under research project No. FE 15.0544/2011/LRB. In the first part of the research project the theoretical background of designing compensatory surveillance is developed, in the second part the methods are analyzed on a practical example. The author is solely responsible for the content.

An investigation on the collapse sequence of an RC frame during L'Aquila 2009 earthquake

M.G. Mulas, L. Martinelli & F. Perotti
Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

ABSTRACT: The partial collapse of a seven-story reinforced concrete building designed in 1965 is investigated starting from previous results. The building was hosting a university dorm, named "Casa dello Studente", and suffered the partial collapse of one of its three wings during the April 6, 2009 earthquake of L'Aquila (Italy). Two distinct collapse zones were detected in the collapsed wing: a soft/weak story mechanism at the ground floor, and the failure of three columns along the height. In a previous study, encompassing only linear analyses, the lack of flexural strength of ground story columns was detected as the main cause of the collapse. Here non-linear static analyses of a refined numerical model of the structure, including the reinforcement data, allow for a better insight on the disproportionate effects that the partial soft-story collapse had. The results clarify the role of lack of shear strength of a beam on the collapse of the three columns.

1 INTRODUCTION

On April 6th 2009 at 3.32 am a magnitude Mw 6.3 earthquake struck Central Italy, with devastating effects in the city of L'Aquila and causing the failure of several reinforced concrete (RC) buildings in the urban area. Among them, the "Casa dello Studente" building (CdS, in the following), located at about 6 km from the epicenter, suffered a partial collapse. The death toll was very high, with eight students killed and one suffering serious injury.

The CdS building is a seven-story RC building hosting a University dorm ("Casa dello Studente" means Student House, in Italian). It was designed in 1965, following the Italian Seismic Codes of 1937 and 1962 (RDL 2105, L 1684), for a mixed use (residential/commercial). The plan of the residential part, in the upper four stories, was subdivided in three wings, connected through the stairwell. Ground story and basement were common to all the wings. A second underground level was present below the South wing. In 1979 the building was bought by a University Institution to be used as student house, and in 1982 it became a property of the Abruzzo Region, in force of State and Region Laws. A wide refurbishment intervention, not covering the structural system, was performed during the years 1999–2001.

The partial collapse of the building was limited to the North wing (see Figure 1). Within this wing two distinct collapse zones were detected, from both pictures of the collapsed part and on-site observations: the failure of all the columns at the ground floor, with a soft/weak story mechanism, and that of three columns along the height of the building. A previous study, reported in (Mulas et al. 2012, 2013), performed for legal reasons, showed that neither the poor quality of material properties nor the ground motion at the building site could be considered – from the Italian laws viewpoint – among the causes of the collapse. The most likely collapse sequence was established by crossing the design criteria adopted in 1965, the results of modal analyses of the building in its original configuration and after refurbishment, and all the experimental data coming from the analysis of damage in the part of building that survived the earthquake. The lack of flexural strength of ground story columns was detected as the main mechanical cause of the collapse itself.

Figure 1. Aerial view of the building in the configuration at the date of the 2009 seismic event.

Starting from the previous results, the collapse sequence has been investigated further in this study. The availability of data on the geometry of the reinforcement has allowed the derivation of a complete and refined numerical model. Non linear static analyses are performed to compute the capacity curve of the structure, with the aim to further investigate on the disproportioned effect that arose by the partial soft-story collapse at ground floor. The results obtained help to clarify the role played by the lack of shear strength of a beam at floors 1–4 on the collapse of the three columns along the height of the building.

2 THE BUILDING AND ITS RENOVATION

The CdS building is a 7-story (including two underground floors) RC framed structure (see Mulas et al. 2013) having an irregular T-shaped plan composed by three nearly rectangular "wings" (Figs 1, 2a, b).

The building was designed for a mixed use (residential/commercial) in 1965. The code adopted in the structural design was the Italian Seismic Code of 1937 (RDL 2105), even though newer provisions were enforced by the Seismic Code of 1962 (L. 1684).

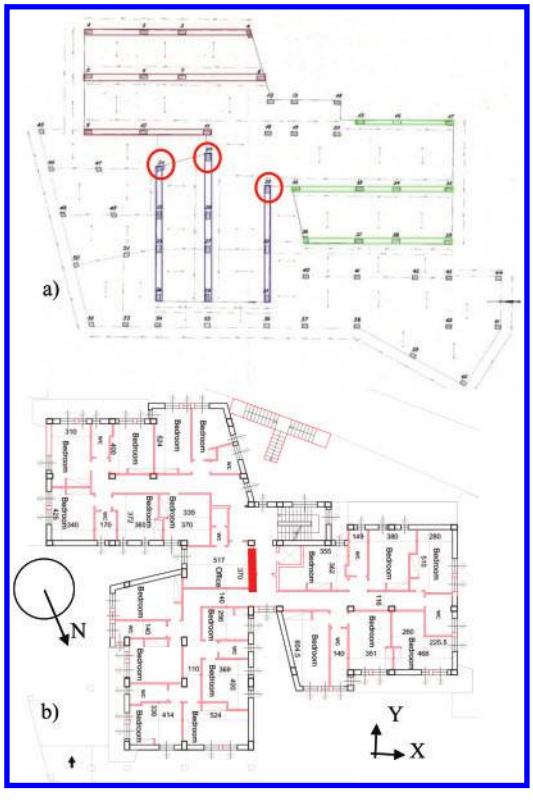

Figure 2. (a) layout of the vertical members. The colored lines highlight the positions of the main frames, circles show the collapsed columns # 21, 25 and 29. (b) typical plan of the building after refurbishment in 2000. The thick line marks the position of a fire resistant wall on Beam 18–29 which triggered the collapse of this beam at several floors.

The design principles of both Codes were based on the application, at the centre of mass of each floor, of a set of equivalent static forces, equal to 7% (as prescribed by the 1962 Code of permanent loads plus 1/3 of variable loads. These forces should have been applied both in transverse and longitudinal directions according to the 1937 Code; in any horizontal direction according to the 1962 Code. Vertical loads had to be computed as the maximum between a) 1.25 times the sum of permanent loads and 1/3 of variable loads, b) the sum of permanent loads and variable loads. These criteria were used for designing the main lateral load resisting system, i.e. the three longitudinal moment-resisting RC frames located in each wing (Figure 2a). However, horizontal loads acting on each frame were apparently derived according to tributary areas Given the building plan configuration, the procedure led to substantial underestimation of seismic forces in the NS direction encompassing only three longitudinal frames.

A wide refurbishment intervention, not covering the structural system, was performed during the years 1999–2002. The layout of the internal partitions was changed to better adapt the building to its use as a university dormitory. To comply with fire safety regulations, a fire resistant wall (denoted, from the French acronym, as "REI wall" in the following) composed of lightweight concrete hollow blocks, 20 cm thick, was placed at floors from the first to the fourth (thick red line in Figure 2b). This wall spans from column 18 on roughly half of the beam 18–29, that in turn is part of the beam that connects columns 18, 29, 30, and the corner column 31 (beam 18-29-30-31).

The role that this non-structural element, inserted in a non-engineered way, had on the collapse will be investigated in the following.

3 EARTHQUAKE GROUND MOTION AT THE BUILDING SITE

The ground motion at the CdS site was estimated according to the procedure described in (Mulas et al. 2013). The elastic response spectra along the principal directions of the CdS building (namely: N23°E and E23°S; directions Y and X, respectively in Fig. 2) are plotted for a 5% damping ratio in Figure 3. The prevailing amplitude of the N23°E component at the

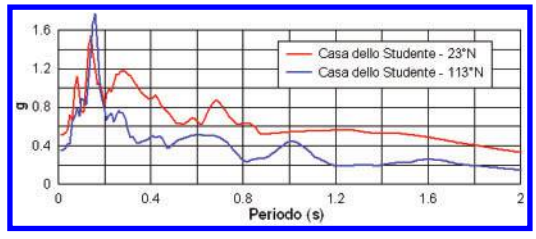

Figure 3. Reconstructed elastic response spectra along the principal directions of the building: 23°N = N23°E, 113°N = E23°S.

longer periods is a consequence of the directionality of earthquake ground motion in L'Aquila records along the fault normal direction, as pointed out by different studies (e.g., Paolucci & Smerzini 2010). The estimated motion has been deemed compatible (Mulas et al. 2013) with the magnitude of the static horizontal forces, equal to 7% of gravity loads, prescribed by the 1962 Code (L. 1684) in a design process based on a working stress approach.

A ratio close to 3 to 1 can be assumed for the spectral ordinates in the likely ranges of period (0.83–1.63 s and 0.81–1.45 s, respectively), estimated in Mulas et al. 2012, 2013 for the first and the second mode. This is confirmed by the ratio of the extreme values of ground acceleration: the acceleration in direction E23°S was 35% of that in direction N23°E. This fact will be accounted for in the direction the capacity curves are computed.

The wide period ranges depend on the boundary conditions assumed for the model, on the amount of reduction of member stiffness and on the presence of the added fire resistant wall. The boundary conditions addressed the action of the basement wall towards XX Settembre street.

4 NUMERICAL MODEL OF THE BUILDING

In previous studies (Mulas et al. 2012, Mulas et al. 2013) a comprehensive model was developed to achieve an accurate representation of the geometry and masses of structural and non-structural elements, and of the stiffness of the structural ones. The geometry of the structural elements (beam, columns and floor slabs) derives from both the results of on site surveys and the blueprints recovered by State and County archives damaged by the April 6th, 2009 earthquake. Blueprints describes both the original design and the renovations of the building.

A modification of this model was derived for the static non-linear analyses, to reduce the number of degrees of freedom. The new model retains the total mass but disregards the balconies (their weight and mass is applied to the perimeter beams). Moreover, the floor system is considered to be sufficiently rigid in its plane to act as a diaphragm. A view of the solid model is depicted in Figure 4. The new model has been validated by comparison with the previous one in terms of modal periods and correlation of the modal shapes. As in the linear models, the REI wall on beam 18–29 is modeled through 2D quadrilateral and triangular plane-stress (membrane) elements.

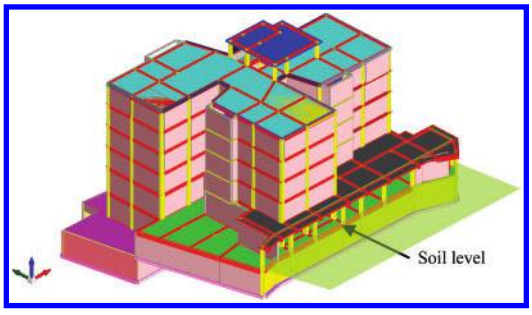

Figure 4. Geometrical model obtained by disregarding the cantilevered balconies.

A static non linear analysis, involving non linear material behavior, requires that beams and columns are properly discretized to avoid strain localization effects. In this work beams and columns were discretized in elements of length 20 cm and 40 cm, near the members ends and elsewhere respectively. The cross-sections were discretized in rectangular sub-domains having the longest side less than 7 cm (see Fig. 5). The computer code (SISMICAD v.12) used in the static non linear analyses assigns 9 Gauss points per sub-domain to follow locally the stress-strain law of the concrete material. A single Gauss point is assumed at the location of a reinforcing bar, as well as perfect bond between concrete and reinforcement. Concrete follows different laws depending on the confinement (confined or unconfined concrete). The elements behave nonlinearly for axial force and in bending only, being elastic in shear.

4.1 *Materials models and values of the mechanical parameters*

Concrete has no strength in tension and follows a parabola-rectangle law in compression up to a strain value ε_{c0}. Compression failure is attained at a strain value ε_{cu}. Unconfined concrete has the design nominal values of strength and strain $f_{ck} = 16$ MPa, $\varepsilon_{c0} = 0.2\%$, $\varepsilon_{cu} = 0.35\%$. Confinement has a small effect, due to the low amount of stirrups in columns and in beams, and to a larger extent to the lack of longitudinal reinforcement along the long sides of the rectangular cross-sections. Confinement effectiveness, estimated on a sample column cross-section, accounts for the following values of strength and deformation: $f_{ck.c} = 1.033\, f_{ck}$, $\varepsilon_{c2,c} = 1.067\varepsilon_{c2}$ and $\varepsilon_{cu2,c} = \varepsilon_{cu2} + 0.13\%$.

Steel reinforcement follows an elastic-plastic law, symmetric in tension and compression, and has nominal strength and Young's modulus values $f_{yk} = 380$ MPa, $E_s = 2.6$ GPa.

Analyses were carried out with both the nominal design values of the mechanical parameters and the average values coming from on-site and laboratory material testing: concrete average compression

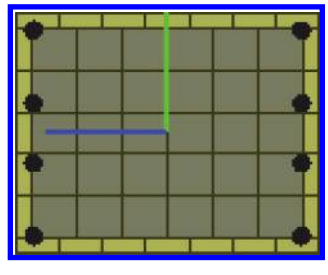

Figure 5. Sample or cross-section discretization for the static non-linear analyses. A lighter color denotes unconfined concrete.

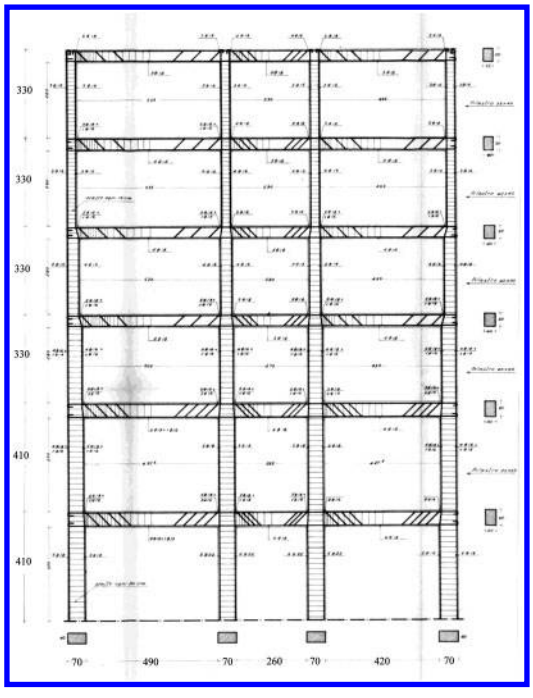

Figure 6. Reinforcement and dimensions of typical main frame.

strength $f_{cm} = 13.3$ MPa, steel average yielding strength $f_{ym} = 388$ MPa. While the yielding strength of the steel reinforcement corresponds to the prescribed value, the one of the concrete is far lower than its prescribed value corresponding to a concrete of class C8/10, instead of C16/20, according to the classification in the Italian code D.M. 14.01.2008 (NTC2008).

4.2 *Details of reinforcement*

Original design drawings (as in Fig. 6), on-site surveys and typical details from manuals of the time allowed to define the reinforcement distributions in the members of the primary frames (colored lines in Fig. 2a). As an example, Figure 7 details the reinforcement considered for the critical beam 18–31 in the span that supports the REI wall. This span failed in shear at the location of the REI wall.

Bending reinforcement at mid-span is $4\phi18$ mm + $1\phi16$ mm in the lower part of the cross-section, $3\phi18 + 1\phi6$ in the upper part. The symbol ϕ denotes the bar diameter in mm. At the supports, bending reinforcement is $6\phi18 + 3\phi16$ in the upper part and $2\phi18$ in the lower part. Shear reinforcement is provided by $\phi6$ stirrups at a variable spacing: 240 mm in the central part of the beam and in between 50–75 mm at the supports.

Table 1 lists the geometry, at ground floor, of the cross-sections of the columns of the North Wing. The reinforcement is located along each short side of the rectangular cross-section of the columns

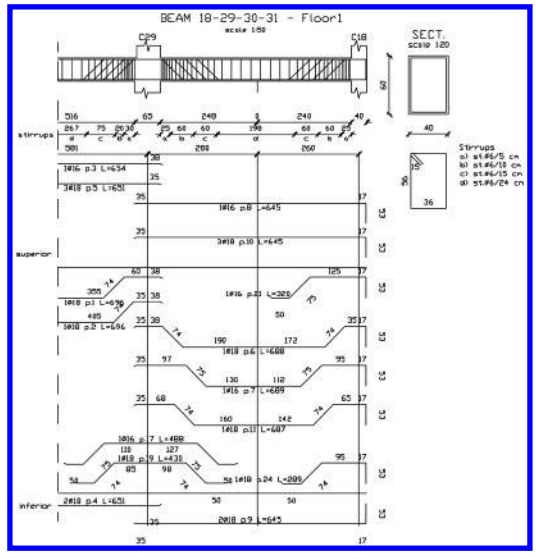

Figure 7. Detail of the reinforcement in beam 18-31 at first floor.

39	65 × 40	4	18

*The reinforcement is located along each short side of the rectangular cross-section.

(see Fig. 5). Shear reinforcement for the columns is provided by 6 mm diameter closed stirrups. On average, the stirrups spacing is 200 mm for most of the columns, without provisions for closer spacing at the ends.

5 NON-LINEAR STATIC ANALYSIS OF THE BUILDING

The non linear static analysis procedure in the code NTC2008 has been adopted to compute the capacity curves for the CdS building, to the aim to gain a better

insight on the disproportioned effect that arose by the partial soft-story collapse at ground floor.

The nonlinear static analysis, or pushover analysis, in NTC2008, has to be performed applying to the structure first the gravity loads and then, for the considered direction of the seismic action, a fixed pattern of horizontal forces proportional to the inertia forces and having as resultant (base shear) the force F_b. The horizontal forces, acting at the floors, are increased monotonically up to the condition of local or global collapse. The horizontal displacement d_c of a control point, located at the center of mass of the last level, is monitored and the diagram F_b-d_c is the capacity curve of the structure.

According to NTC2008, this analysis has to be performed with two different distributions of horizontal forces, named primary (Group 1, GR1), and secondary (Group 2, GR2) force distribution The force distributions relate to the largest value of participating mass of the natural modes for a chosen direction of the seismic action.

Whenever the largest participating modal mass is less than 75% of the building mass in the seismic configuration and the period of the first mode is larger than the corner period T_c between the constant–spectral–acceleration and the constant–spectral–pseudo–velocity ranges of the response spectrum, as it is the case here, the GR1 force distribution is derived from the seismic floor shears calculated in a linear dynamic analysis for the chosen direction of the seismic action. Group 2 distribution adopts a uniform distribution of forces, that would correspond to a uniform distribution of accelerations along the height of the building.

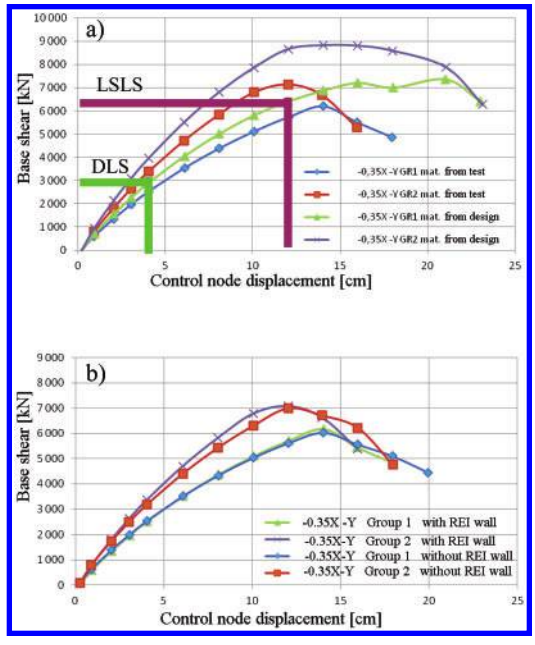

Figure 8. Capacity curves for Group 1 and Group 2 forces distributions: (a) REI wall included, material parameters from design and from tests; (b) with and without the REI wall, material parameters from tests.

5.1 *Analysis details*

The nonlinear static analysis is carried out on a three-dimensional model of the structure, derived from the geometrical model in Figure 4, discretized in elements with distributed inelasticity. Axial force is released at one end for all members having both nodes belonging to the same "rigid floor" to avoid spuriously enhancing the bending strength due to moment-axial force interaction.

Two structural configurations were analyzed, namely: with and without the REI wall on beam 18–29. In addition, two sets of material parameters were considered, derived either from design specifications or from material testing. For each structural configuration and set of material parameters, several pushover analyses were carried out applying the seismic action in different directions. The floor forces were obtained from linear dynamic analyses with the NTC2008 response spectrum, combining the effects of the seismic action in the X and Y direction (see Figure 2b) as it follows ±X, ±Y, ±0.3X, ±0.3Y. The most severe combination turned out to be as −0.30X−Y. This combination is very close to that corresponding to the extreme values of the ground acceleration at the site, characterized by an X-acceleration that is 35% of the Y-acceleration. For this ratio of seismic actions the effects of accidental eccentricities equal to 5% of the floor X and Y dimensions were also introduced.

6 ANALYSES RESULTS

For the sake of brevity, only the results obtained for a direction of the seismic action −0.35X−1.0Y will be presented in the following. Figure 8 depicts the capacity curves of the structure, for GR1 forces distribution, as well as the estimate of the displacement demands at the Damage Limit State (DLS) and the Life Safety Limit State (LSLS). The last one corresponds to the ultimate limit state for seismic loading in EN 1998-1:2005. Figure 9 shows the displaced configurations with and without the REI wall for a displacement of the control node $d_c = 23$ cm.

Absence of the REI wall, however, would probably not have saved the building, as the estimated displacement demands in Figure 8 clearly highlight.

From the analysis of the sequence of local collapses, it can be observed that, when the REI wall is included, the beam 18–29 fails in shear at the first floor for a displacement of the control node $3 \le d_c \le 4$ cm, then at the upper stories for $4 \le d_c \le 6$ cm. The collapse of the North wing columns at ground floor starts at $4 \le d_c \le 6$ cm with failure in shear of column #29. The structural configuration without the REI wall sees the first collapse at a displacement of the control node $6 \le d_c \le 8$ cm, when some of the North wing columns at ground floor fail in shear.

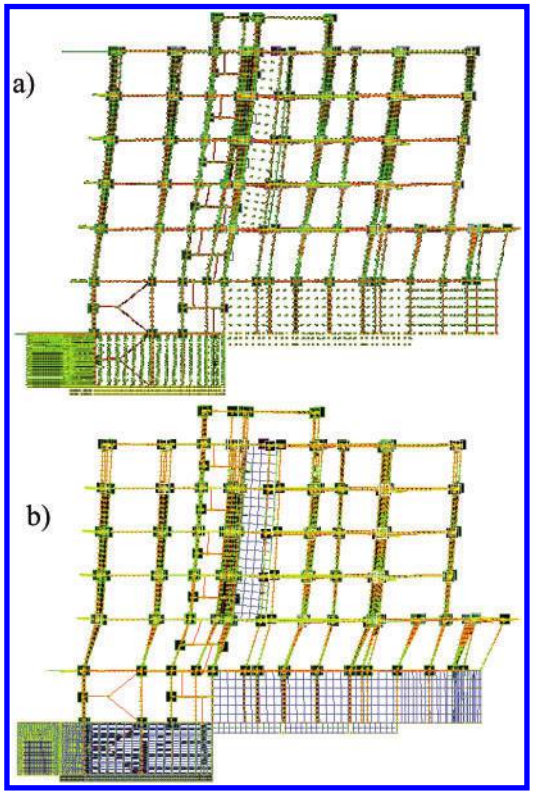

Figure 9. Displaced structure for Group 1 forces distribution and seismic action −0.35X−1.0Y without the REI wall (a). With the REI wall (b). Displacement of control node is in both cases 23 cm.

As Figure 9 also points out, the presence of the REI wall tends to exacerbate formation of a soft story at ground floor and induces early failure in shear of beam 18–29. The failure of this beam accounts for the collapse of portion of the floor system in the zone from the end of the REI wall to column #29. This failure can be clearly detected at several floor in the pictures taken immediately after the seismic event of April 6th, before the remains of the North wing were taken down. The collapse of column #29 can be ascribed to the increased shear force at the beam interface, causing ultimately the collapse of the column joints in shear.

7 CONCLUSIONS

The results of the pushover analyses confirm the activation of a partial collapse mechanism, restricted to the part of the building where it actually took place, as already found from linear analyses and simple hand computation in Mulas et al (2013). From the numerical results here presented the effects that the REI wall, inserted during refurbishment works, had on the structural behavior are well highlighted. The collapse sequence points out that the combined effect of the REI wall and of the lack of shear strength of beam 18–29 is responsible for the collapse of one of the three failed columns, column #29. For the other two, the collapse can be ascribed to the soft/weak story mechanism at the ground floor, in turn triggered by shear failure of the columns. A partial soft story collapse would have taken place also in the original configuration of the building.

The numerical code here adopted detects a shear failure according to the rules of the Italian Code NTC2008, and accounts for a linear behavior in shear even after detecting a failure. Further analyses with a research oriented code are thus needed to better describe the collapse sequence.

DISCLAIMER AND ACKNOWLEDGEMENTS

The content of the paper reflects the Authors opinion and does not intend to anticipate any legal conclusion. Andrea Iadanza e Matteo Rossato performed the numerical analyses as a part of their MS thesis in Civil Engineering under the guidance of the second Author. Structural assessment during the demolition of an arch bridge by advanced modal techniques

K. Islami
Department of Civil, Environmental & Architectural Engineering, University of Padua, Padua, Italy

R. Betti
Department of Civil Engineering and Engineering Mechanics, Columbia University, New York City, NY, USA

ABSTRACT: An old arch bridge was subject to demolition due to life-cycle damage and environmental issues, in a central-east region of Italy. During the demolition process, several dynamic tests were executed in order to evaluate the structural behavior before, during and after the demolition. The classical Modal Analysis methods revealed difficulty in determining the modal parameters, so these results were validated with a newly developed technique of modal parameter identification and then verified with sophisticated finite element models. The structure revealed some relatively surprising results in the dynamic characteristics before and after the partial demolition.

1 INTRODUCTION

Many bridges, due to intrinsic weakness, deterioration process and environmental changes, showed inadequate structural performance and necessity to be upgraded to current standards. Structural characterization via dynamic tests is an immediate and cheap technique for bridges in order to understand the structural behavior and damage of the structure. The dynamics of the system are represented by a set of matrices that are not based on physical laws. These kinds of models are derived from realization theory and their only requirement is to relate the input-output data without any consideration of physical parameters, like mass, damping and stiffness. Various methods that perform in frequency domain (Brincker et al., 2001) or in time domain (Peeters and Roeck, 2001) can be used to identify the global modal parameters such as natural frequencies, damping ratios and mode shapes. Most of the modal techniques show great achievement in detecting the amplified modes but are unsuccessful to detect the modes that are not well excited. An overcome to this problem is the realization of stabilization diagrams (Peeters and Ventura, 2003) and clustering analysis, by observing the sensitivity of modal properties of a mode to the change in the model's order and so discrimining structural modes from the noise modes. When considering damaged structures, a modification of the response due to damage is observed. Variations in the behaviour of the system can be associated with the decay of mechanical properties.

In the context of this study, an arch bridge was subject to a demolition process, after the construction of a new steel bridge. During the demolition progression, several dynamic tests were carried out with different kinds of measurement sensors and different configurations. The main aim of the study is to give a dynamic assessment of the structure by evaluating its modal parameters from ambient output-only measurements, observing the effects of the damaging process. Therefore, it is appropriate to evaluate the modal parameters of the bridge, before and after the partial demolition, not only with the classical modal techniques aforementioned but also with a recently developed approach (Hong, 2010), called Enhanced Canonical Correlation Analysis. This technique, together with an advanced cluster analysis developed, will help to get consistent results which will confirm the unexpected behavior of the bridge before and after the partial demolition. All the experimental data are then used to update FE models representing the demolition procedure that will validate what has been captured in the field measurements.

2 DEMOLITION PROCESS

The bridge was composed of 5 spans with an overall length of nearly 80 m and each of 15.5 m. In transverse direction, its width was about 11.0 m and composed of two parallel concrete arches connected together with a reinforced concrete slab. The average thickness of the arch was 0,60 m. The maximum height of the piers was 6.5 m and their section was rectangular with dimensions 2.5×12.50 m (Figure 1). The upper structure was carried by masonry piers and abutments that had a core made of infill material with poor mechanical

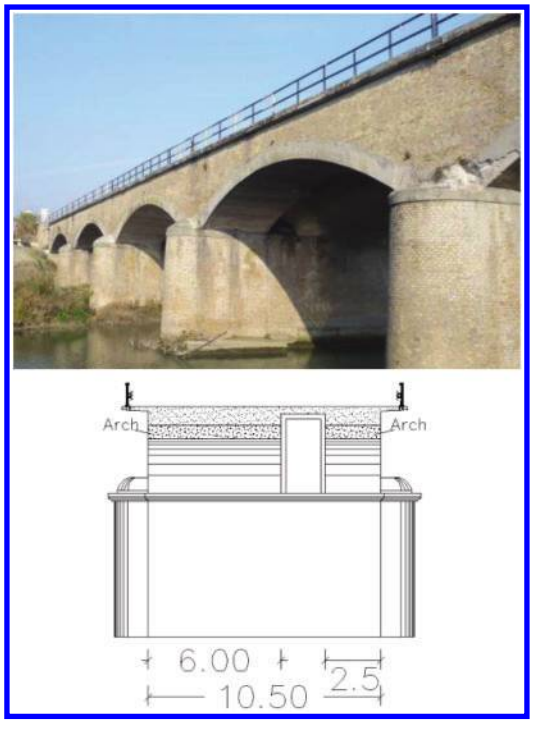

Figure 1. Photo and cross section of the analyzed bridge.

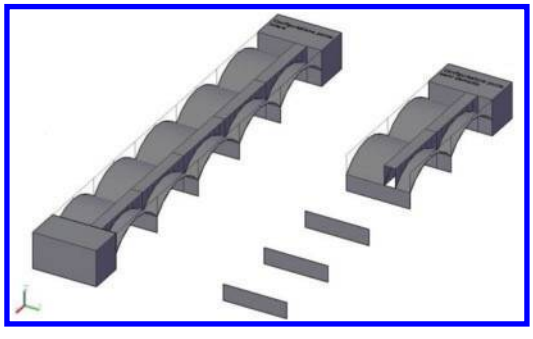

Figure 2. Two principal demolition configurations: a) five spans with some infill material, b) two spans without infill.

characteristics, containing loose material, stones and pebbles.

The demolition process began on the 14th of November 2011 and the first step was to remove the pavement and the roadbed. After a few surveys and core drillings for testing the strength of concrete, the contractor began to empty the infill material present above the arches of the old bridge. The four principal sequences of the demolition process were:

- Removal of the roadbed and emptying of the infill material.
- Demolition of the first three arches (Figure 2).
- Demolition of the first three piers.
- Demolition of the two remained arches and their piers.

Figure 3. Sequential demolition process of the bridge.

3 MEASUREMENT CAMPAIGNS

Dynamic identification allows us to determine modal parameters (natural frequencies, mode shapes, damping ratios) from experimental data. In Operational Modal Analysis the natural excitation (wind or vibrations induced by traffic) is used as an excitation source in order to capture the response of all possible modal contributions. In our case, the natural excitation was represented by traffic on the adjacent new bridge, but also the demolishing machines and excavators near the tested structure. The tests of the entire bridge were performed In November 2011, while the tests on the partly demolished bridge were executed in December 2011. The side on which the tests were performed, is the part which was demolished at the end, in hypotheses to repeat the measures after the demolition of three spans. In this description, configurations will be considered in order to evaluate the differences encountered before and after the demolition of the 3/5ths part of the bridge. In the first case, the measurements were recorded with 16 velocity sensors for nearly 4 minutes with a sampling frequency of 200 Hz.

In the second case, three of the five spans were demolished, and two spans remained. Tests were performed in overlapping, but not simultaneously, with velocity and acceleration sensors (Figure 4).

4 MODAL ANALYSIS BEFORE AND AFTER THE PARTIAL DEMOLITION

As previously mentioned, measurements have been taken before and after the demolition of three spans. In fact, the different results will be presented in this paragraph in terms of analysis conducted before and after the partial demolition. As a first step, the extraction of modal parameters from ambient vibration data was carried out by using standard methods as Frequency Domain Decomposition (FDD) developed by (Brincker et al., 2000), and the data-driven Stochastic Subspace Identification (SSI) technique (Peeters and Ventura, 2003). The analysis included frequencies corresponding to several Eigen-modes, but considering more accurate the first 4 values (Figure 5). From the very beginning it was seen that noisy data were recorded and the structure was not sufficiently excited in order to capture its dynamic characteristics, so it was difficult to get clear results.

The plots in Figure 5 present similar features but more importantly show a shift in the natural frequency

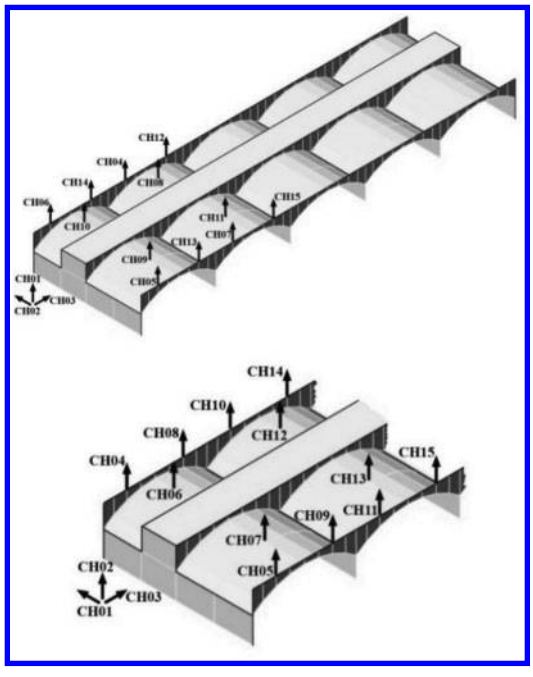

Figure 4. Example of local configurations: before and after the demolition.

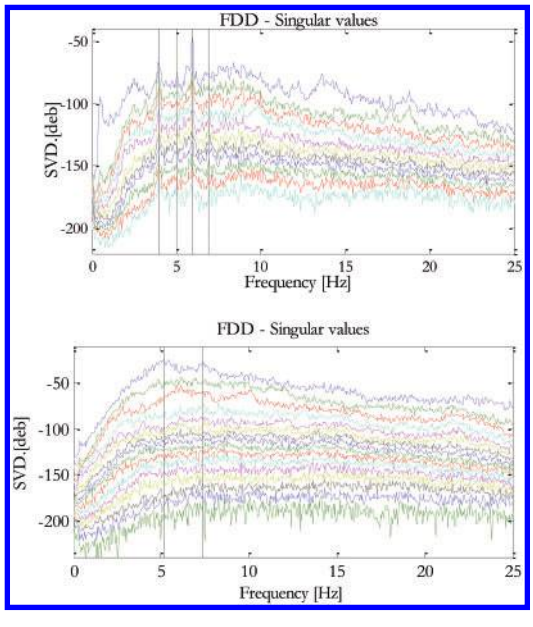

Figure 5. The FDD method with velocity data before and after the partial demolition.

values. In particular the first peak present in the first graph has a shift of nearly 1 Hz in relation to the second graph, resulting in an increase from 3.97 to 5.20 Hz, respectively before and after the partial demolition.

Although, the SSI and FDD methods weren't capable of identifying many natural frequencies (noisy results), they revealed that the structure after the partial demolition seems to be more rigid than the entire structure. These surprising results will be reviewed and exalted in the next paragraphs, but also validated with a theoretical model that represents the demolition process. While already in the first plot of Figure 5 the selection of the modes was not simple, when we consider the second plot, regarding the tests after the demolition, it is impossible to identify more than two modal modes. For this reason, another study and some cluster analyses will be developed to get the best results from this interesting demolition process.

5 MODAL PARAMETER IDENTIFICATION VIA ECCA CLUSTER ANALYSIS

During the previous analysis with the standard modal methods we encountered some difficulties in finding the principal modal parameters of the studied structure. In this paragraph, some of the results obtained from the analysis with the Enhanced Canonical Correlation Analysis (Hong, 2010) method will be shown. In this case, it was possible to identify more dynamic parameters and at the same time confirm the previous results. The stabilization diagram permits to identify the modes whose properties do not change significantly when varying the model order. Modes classified as "stable" are considered as structural modes. However, such modal parameter estimates, particularly the damping ratios, are influenced by the particular selection of the model order, as presented in Figure 6. It can be noticed how the frequency values related to the model order number show a stable trend, especially for the first modes. In the frequency range of 3–30, 11 structural modes were identified with the ECCA (far more than the standard techniques). The results reveal again that every vibrating mode, after the partial demolition, has a shift towards higher values. This might be an unpredicted result that can complicate the demolition processes for this kind of structures.

5.1 *Cluster analysis*

In order to develop this automated technique, the initial ideas have been taken not only from the stabilization diagram of the SSI method, but they are also based on the advanced SSI technique called ECCA. Essentially, the main element, which detects the stable modes, in this case is the damping vs. frequency plot. As will be described in the following paragraphs, the procedure consists in applying the modal analysis for varying parameters, by obtaining a large amount of system identification data. Then, after cleaning the data by specific rules, some cluster analyses are performed to consistently determine the structural modal parameters. Finally, the technique is repeated for each dataset (which is filtered and overlapped) coming from a possible SHM system.

Some of the parameters which can influence the identification results are the number, i, of the block

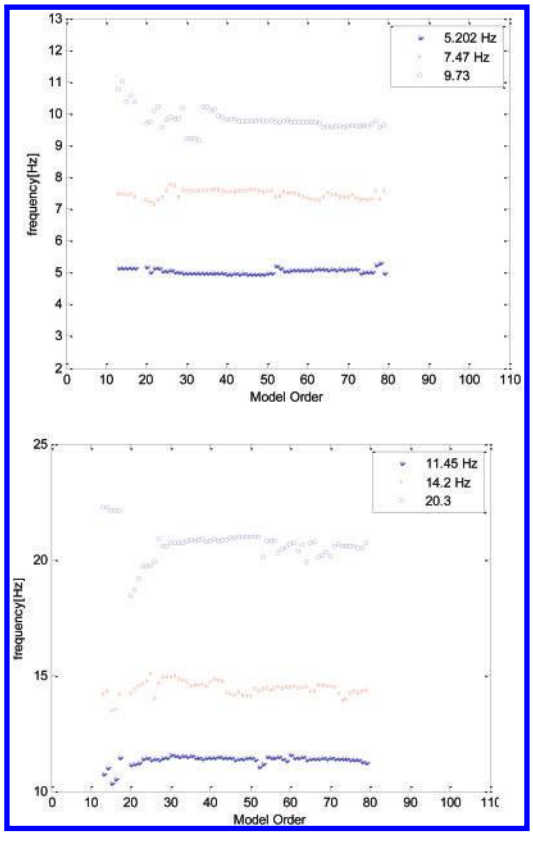

Figure 6. Natural frequencies identified vs. system's model order (after demolition).

rows of the output data matrix and the model's order, n. So, by combining these parameters in infinite ways, we can get different results, but as we know, only the stable modes can be considered as structural modes (Ubertini et al., 2011). The presented approach for automatic estimation of modal parameters is composed by the following steps: (a) run modal analysis with different values, i, and the model's order, n; (b) apply rules in order to clean the noise modes; (c) apply a cluster analysis; (d) plot frequency vs. damping results of stable modes; (d) determine mean values of structural modes and their 95% confidence intervals; (e) loop the cycle for all the recorded data and extract the modal parameters for the entire monitored period.

Modes are identified from each analysis conducted by using a different pair of (i, n). Among the identified poles from all the possible pairs (i, n), modes that can be considered as noise ones are eliminated first, then, the remaining modes are grouped with respect to their frequencies and mode shape vectors. Noise modes can be detected by considering the fact that:

- the estimation of structural modes is not affected by the specific selection of i and n;
- mode shapes corresponding to structural modes are likely to be similar in different analysis;
- and probably large damping values belong to noise frequencies.

A single mode should be identified within a single cluster at least 30 times using different combinations of n and i.

5.1.1 *Cleaning and clustering the identified poles*

In order to lead to a more evident mode selection, before applying the clustering rules, a cleaning procedure has been developed. First of all, after extracting all the poles from all analyses, modes whose damping ratio is negative or larger than 14% are eliminated. In our case, similar noise eliminating rules used in a stabilization diagram are applied; however, these include not only variations of model's order, but also the number of block rows. Considering only modes remaining from the previous step, the identified modes are compared: modes are grouped on the basis of analogous frequency, damping and mode shape values, and after that, modes having frequencies that differ from each other by more than 1% are eliminated. The algorithm distinguishes only stable modes which are stored in a matrix. Among all the poles identified with the previous analyses, only *some* of them are considered to be physical modes and meet frequency, Δf_{lim}, damping ,$\Delta \xi_{lim}$ and Modal Assurance Criterion, MAC_{lim} tolerances. The *n-th* mode is said to be stable when it is similar, in terms of frequency, damping ratio and mode shape to a minimum number of other modes.

To remove further noise modes, at this point, mode shapes, that show irregular behavior in relation to the group, are eliminated by operating with the following cluster analysis containing only those poles that correspond to the same mode. The aim of cluster analysis is to group all modes, cleared from the previous step, into separate sets belonging to the same structural mode. At the end, each cluster will contain only the stable frequency, damping and mode shape of the particular mode. The separation procedure is obtained by the use of a mutual distance between all clusters as follows:

$$d(j,l) = | f_j - f_l | + 1 - MAC(\phi_j, \phi_l)$$

where f_j and f_l are frequencies of modes j and l and $\Phi_j$and Φ_l the corresponding mode shapes.

At this point, two clusters that are close together are collected in a single cluster, and the mutual distance between all clusters is recomputed. As a last step, the average of the elements of all clusters is calculated and the clusters that contain less than the average value are eliminated. Clusters containing a minimum number are selected for the candidate modes, otherwise they are rejected. The merged cluster available can now be described by means of statistical parameters. Each modal parameter is characterized by a mean value (f, ξ), standard deviation σ and its 95% confidence intervals can be calculated.

5.1.2 *Cleaning and clustering the identified poles*

In this study, considering values of the model's order n ranging from 40 to 160 with increments of 5, and by

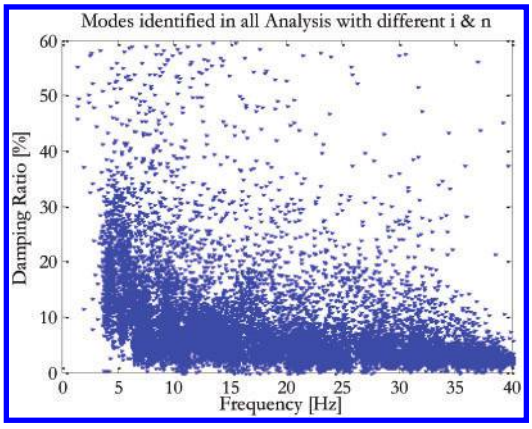

Figure 7. All damping ratios for all the modes identified.

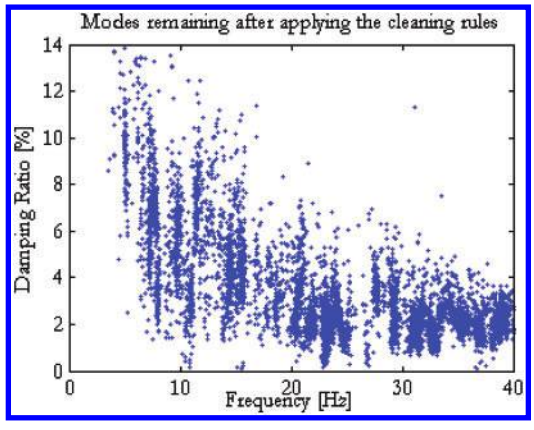

Figure 8. All values of damping ratios for all the modes identified.

considering the value of *i* number of blocks ranging from 40 to 120 with increments of 4, a total of 480 analyses have been conducted (Figure 7). The results of clustering steps are presented in Figure 7 – Figure 9, where modal properties are plotted in terms of frequency and damping ratio. Figure 7 shows all modes that have been identified by the total parametric analysis and Figure 8 shows modes remaining after eliminating modes with damping larger than 14% and after applying the cleaning rules (similar to a stabilization diagram, but with the damping values in the y axis).

Figure 9 is showing the modes identified with the cluster analysis. A total of 20 groups were identified, indicating that a total of 20 structural modes are recognized from the cluster analysis. Mean values and confidence intervals (Table 1) confirm the estimated modal parameters with very small uncertainties. In such analysis, even close modes seem to be well distinguished whereas noise modes are efficiently eliminated. Comparing Figure 7 and Figure 9, most of the noisy modes are eliminated by inspecting the consistency between modes estimated using different pairs of *n* and *i*.

With regard to modal parameters estimation, the natural frequencies and damping ratios can be calculated from the individual groups in relationship to their statistical properties (e.g. mean, standard deviation). Table 1 presents the mean and standard deviation values of 12 natural frequencies identified in this study from the cluster analysis.

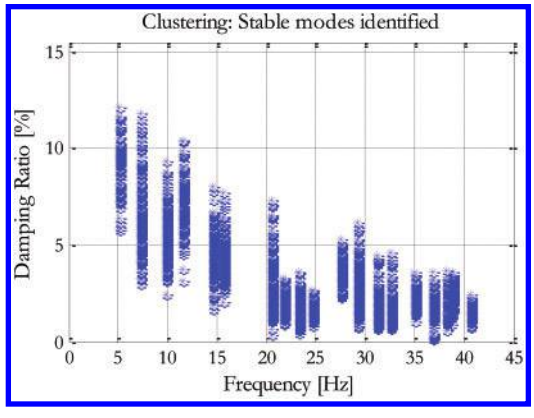

Figure 9. All values of damping ratios for all the modes identified.

6 VALIDATION OF THE DEMOLITION PROCESS WITH FE ANALYSIS

In this case, the FE model was not only updated from the experimental results, but also served as a means of demolition scenario validation. In order to create the same situation existing during the tests, only the standing spandrel walls and part of the infill material were modeled, without the roadbed or slab. After defining the base model and updating it according to the experimental data, a second model group has been generated. This model wants to reproduce what was left in site after the demolition of three spans of the bridge; from the previous model only the first

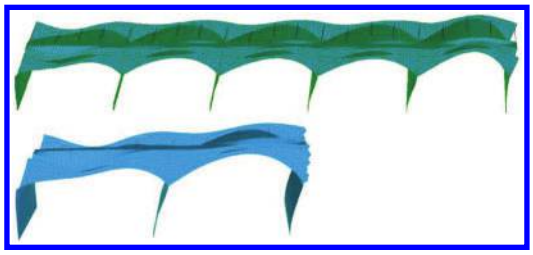

Figure 10. First mode of the entire model and the partly demolished one.

Table 2. Comparison between experimental and theoretical models **before** and **after** the demolition.

	Experimental		MAC	FEM	
Mode	Before	After	Exp.	Before	After
1	3.959	5.204	0.46	3.989	5.226
2	5.949	7.466	0.56	6.011	7.264
3	6.950	9.729	0.60	6.413	8.245
4	10.58	11.460	–	10.02	10.25
5	12.95	14.209	–	12.50	13.42

two spans were present and a small portion of the infill material was extracted. In summary, we have two groups of models representing the bridge before and after the partial demolition, in accordance with the measurement configurations.

Figure 10 and Table 2 show the results of what was carried out from the model updating and demolition scenario. In Figure 10 it can easily be noticed that the first mode shapes and natural frequencies of the entire structure are similar to the results that were captured during the dynamic tests before the demolition of the three spans.

A better view of what happened in both cases of the experimental and analytical model, before and after the demolition, is shown in Table 2, where one can notice that the overall frequency values in both cases have augmented. We can now state that what was observed in the field from the experimental tests is also confirmed by the FE models. This result, at the beginning unexpected, is probably due to the order change of the mode shapes, to the different boundary conditions and small change of material present before and after the demolition.

7 CONCLUSIONS

In this work, detailed analysis of the ambient dynamic response of an existing arch bridge has been carried on, starting from the identification of its modal parameters from field measurement during its demolition process and ending with a calibrated FE model that has been used to reproduce the demolition scenarios. Measurements before and after the demolition of three, out of five, spans were recorded. The principal scope of this study was to understand the dynamic behavior of this kind of structure and to validate the results with a newly developed technique of modal analysis.

The first principal mode shapes were difficult to be identified through the FDD and the SSI methods. It was observed immediately that the structure revealed higher values of natural frequencies after the demolition, which was surprising because the opposite thing was expected. Straightaway, the results aroused some inquiring doubts that needed further study of the event. Modal parameter identification via Enhanced Canonical Correlation Analysis technique and cluster analysis has been implemented in order to better detect what the noisy data contained.

From the analysis with different combinations of the model order and the number of rows of the output block matrices was observed that most noisy modes are eliminated. In the frequency range of 3–30, a total of 20 structural modes have been identified. This cluster analysis and another similar data elaboration established clearly the principal mode shapes involved in the structural change of the bridge before and after the demolition.

Finally the natural frequencies of an updated FE model of the Bridge have been compared with the ones of the field test models in the cases of the entire bridge and also in the case of the partially demolished one. The comparison confirmed once again the initial affirmation that the structure was behaving in a different way: the overall frequency values in both cases of analytical and experimental models have increased.

EQvis: A consequence based risk management software tool

D. Schäfer, M. Pietsch & H. Wenzel
VCE – Vienna Consulting Engineers ZT GmbH, Vienna, Austria

ABSTRACT: The possible applications of disaster-management-software are not reduced to theoretical case-studies. Contrariwise, one of the main aims while developing EQvis was to cover also the needs and ease the work of rescue-teams. Severe earthquakes can be accompanied by a partly or total breakdown of communication, failure of road networks, electrical power supply systems, sewerage systems, water supply systems etc. Embedded in the platform are various plug-ins. In general the platform comprises a consequent based risk management tool for seismic events. The field of analyses that can be performed with EQvis is very large, e.g. Hazard Computation, Structural Damages, Functionalities, Repair Cost Estimations, Cost Benefit Analyses, Utility Network Damages, Multi Attribute Utility Analyses, Shelter Needs, Social Vulnerability, Temporary Housing, etc. The modularity of EQvis is the key for such a successful software tool. The earthquake real-time simulations admit the quick generation of an overview with the detail of the estimated damages to structures or buildings, as soon as magnitude data and epicentre coordinates are available. With this data, a simulation can be run and results can be obtained within some minutes. Inspection teams are sent out to the most damaged structures (indicated by EQvis) in order to confirm or controvert the results of the simulation, by reporting their observations. The IRIS-exercise in Hungary has shown how the effectiveness of rescue workers can be improved with the help of an appropriate disaster-simulation-program.

1 INTRODUCTION

Catastrophic events, particularly natural disasters have devastating consequences on society.

The damages occurring in case of an earthquake do not depend exclusively on the earthquake-resistance of buildings and infrastructures. The most severe earthquakes that occurred in the last years show that many victims are caused by secondary impacts. A faster organization of rescue facilities such as availability of medical services, drinking water, allocation of emergency accommodations etc., could have contributed to avoid many victims.

When handling all helping hands, the decisions time has to be minimized. This achievement can be pursued by developing realistic disaster-scenarios within which the efficiency of rescue teams can widely improve. By training in those situations, the rescue teams can develop a better interaction with other subjects involved, with a consequent improvement and optimization of their response in emergency situations. The development of evacuation plans requires emergency managers to understand the potential impacts in terms of location, direct and secondary consequences, the needs of society both short- and long-term, as well as economic ramifications. Analytical impact assessments for natural disasters provide the potential to inform emergency managers and support the development of appropriate and effective response plans for catastrophic events. In the case of analytical earthquake impact assessment, models and data are used to provide estimates of damage to infrastructures and network performance, as well as secondary damage due to cascading effects, social impacts and uncertainty quantifications.

2 DESCRIPTION OF EQVIS MODELLING

EQvis is an advanced seismic loss assessment, and risk management software which stands on the Consequence-based Risk Management (CRM) methodology. CRM provides the philosophical and practical bond between the cause and effect of the disastrous event and mitigation options. EQvis follows the CRM methodology using a visually-based, menu-driven system to generate damage estimates from scientific and engineering principles and data, test multiple mitigation strategies, and support modelling efforts to estimate higher level impacts of earthquake hazards, such as impacts on transportation networks, social, or economic systems. It enables policy-makers and decision-makers to ultimately develop risk reduction strategies and implement mitigation actions. In EQvis, a wide range of user-defined parameters are introduced. The breadth of user-defined parameters enables emergency planners to model a virtually unlimited number of scenarios.

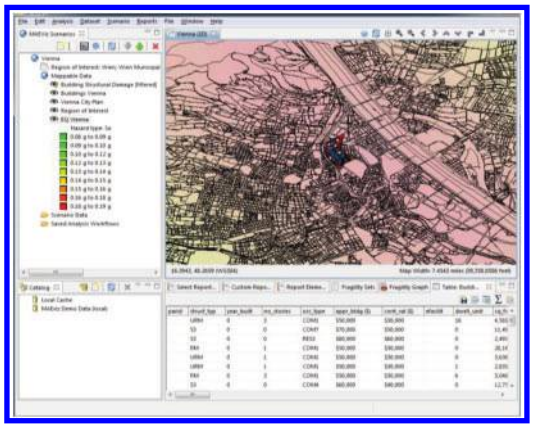

Figure 1. Interactive surface of EQvis: scenario manager, data catalogue, tables, hazard map.

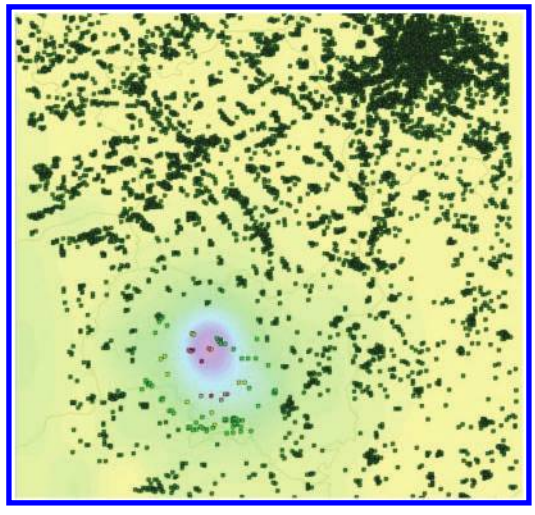

Figure 2. Built areas in Central Hungary represented with building-aggregates; the map also shows the results from an earthquake-simulation in the region of Tolna county.

3 APPLICATION OF EQVIS DURING THE IRIS-EXERCISE 2011 IN TOLNA COUNTY/HUNGARY

The possible applications of disaster-management-software are not reduced to theoretical case-studies. Contrariwise, one of the main aims while developing EQvis was to cover also the needs and ease the work of rescue-teams. Severe earthquakes can be accompanied by a partly or total breakdown of communication, failure of road networks, electrical power supply systems, sewerage systems, water supply systems etc. An additional problem is very often panic among inhabitants.

The earthquake real-time simulations admit the quick generation of an overview with the detail of the estimated damages to structures or buildings, as soon as magnitude data and epicentre coordinates are available. With this data, a simulation can be run and results can be obtained within some minutes. Inspection teams are sent on the most damaged structures (indicated by EQvis) in order to confirm or controvert the results of the simulation, by reporting their observations.

By means of these inputs, the operation controllers can better identify the rescue priorities in order to decide where to send the rescue staff, and if it is necessary to ask for more help. On the other hand, the observation team reports could also be used to refine and calibrate the computer-model. Other simulations could be subsequently run in order to get more accurate results.

On 24th of May 2011, EQvis was tested under realistic conditions in the region of Tolna County/Hungary. Tolna county is situated west of the Danube river, south of Budapest. It covers an area of 3703 km^2 with a population of 238400 inhabitants. It is remarkable, that Hungary's only nuclear power station is situated in Tolna County close to the city of Paks. Its four reactors produce more than 40 % of the electrical power generated in Hungary. All rescue and observation teams, that participated in the exercise on 24th of May 2011 were coordinated from the county's fire brigade headquarter situated in the city of Szekszard (capital of Tolna county).

3.1 *Population density*

It was necessary to gain information about the allocation of the population in a certain area. As a first approach, the public census data can be used. The problem about census data is that the inhabitants are assigned to counties, districts, and communities. Since these administrative units cover also unpopulated areas, this would cause the falsification of the results. Exactly for this reason, the census data were combined with satellite data from satellite-image-recognition. Satellite images of Tolna County were used indeed to distinguish the populated areas, using algorithms developed in-house by VCE. In combination with the available census-data, a more accurate population-density-map has been drawn.

3.2 *Building inventory*

VCE developed a routine to update fragility functions by visual assessment. The aim was to find a routine which enables anybody to perform the assessment, only after a short period of instructions and training. The assessment-routine was developed according to international standards (as FEMA 154 *Rapid Visual Screening of Buildings for Potential Seismic Hazards*) and was applied to 150 selected buildings in the cities of Szekszard, Tamasi and Paks. The aim consists in the application of this visual screening to all of the buildings within the regions with high seismic hazard. In case there is no chance to scan the buildings, an extrapolation of the results can be discussed. Of course, visual assessment cannot replace more detailed investigations as they have to be made for essential

Figure 3. Building assessment: photo, map, assessment-protocol.

structures. The advantage of the visual assessment is that usually it does not take more than 15 minutes per building and it is not necessary to access the building, which would not be possible in many cases.

3.3 *Soilmap*

During a seismic event, the structures react in a variety of ways. Oftentimes substantial differences in damage are discovered in buildings in close vicinity. The reason for such deviations is the variation of the subsoil supporting the structures and various local geological discrepancies. The design codes support a certain classification of subsoil to incorporate differences in seismic loading. The basic classification parameter in the Eurocode is the $V_{S,30.}$ This value represents the average shear wave velocity of the upper 30 metres of the stratum. To accurately determine the value of this variable, a sound estimation of the seismic performance of the designed structure is essential. . The direct measure of the shear wave velocity is invasive and expensive. This is the reason why this research was oriented to assess the local soil conditions in an unintrusive way.

The methodology to reconstruct the soil profile is based on surface testing, mathematical modelling and inverse calculation. The connecting feature between these parts is the dispersion curve.

Generally, the subsoil can be described by a great number of parameters. When dealing with wave propagation only a number of parameters are used. To fully describe the propagation of waves in an elastic medium the compressional wave velocity, shear wave velocity, density and Poisson's ratio are sufficient. Of these the shear wave velocity is the parameter that is most descriptive of possible site related specifics of which amplification is the most notable.

VCE developed and approved a procedure to determine $V_{S,30}$-values using field tests within the SEISMID-project. SEIMSID measurements consist mainly of 3 parts:

- Impact measurements
- Harmonic measurements

Figure 4. Assumed earthquake event in Tolna county used for the IRIS-exercise 2011.

- Ambient measurements

Due to time and in particular space restriction it was possible to perform the impact and the harmonic measurements, which in this case is not a problem.

In the IRIS 2011 Demonstration one task was the ground characterization of the nuclear power plant in Paks. For this reason some measurements have been performed.

3.4 *Sequence of events during the IRIS-exercise in Tolna county/Hungary 2011*

At 7:30 the simulation started with the assumption of an earthquake with epicentre in the Country of Tolna. Data about magnitude, location and depth were transmitted to the fire brigade's headquarter. Additionally to the main earthquake an aftershock was also assumed.

The acquired earthquake-data, including the data of the aftershock, were implemented to simulate the emergency scenario.

After some minutes, the results of the scenario computation were shown on the GIS-map. The computed damage can be shown within the geographic content in EQvis or either be exported as a shapefile and then be used in any GIS-application.

The degree of damage is displayed using different colours. Additionally, a damage-report for every single building or structure can be calculated.

Based on the results of the damage-calculation, two teams were sent out to the most likely damaged objects. Due to full interoperability with other GIS-applications as ArcGIS, the shortest route to all of the highlighted objects was calculated taking into account possible damaged streets. At 9:58 am, after the first instructions, the building inspection team left the headquarters in Szekszard.

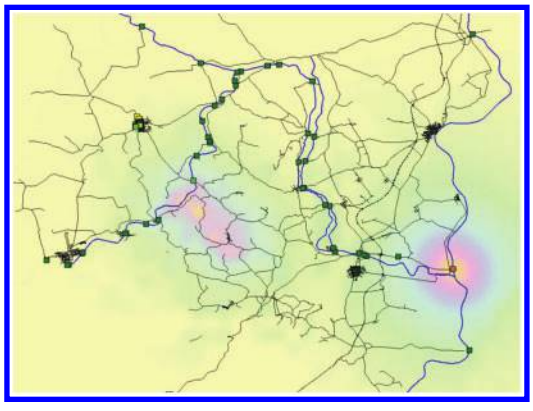

Figure 5. Computed and displayed scenario earthquakes in EQvis.

Figure 6. Building-damage protocol generated by EQvis.

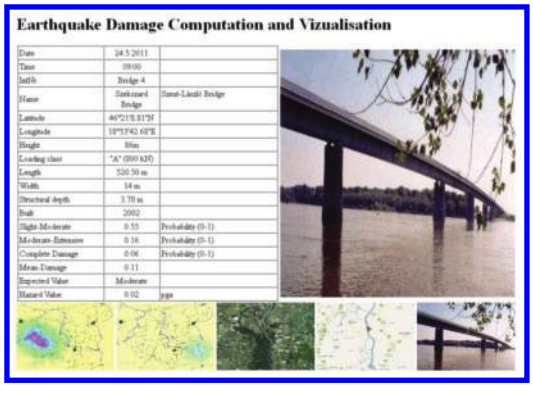

Figure 7. Bridge-damage protocol generated by EQvis.

At 10:32 the headquarters in Szekszard was informed of an accident in the chemical factory of Pincehely. Toxic gas escaped from the factory; because of its diffusion in atmosphere, roads had to be closed within a wide area. The building inspection team was informed immediately and the route was changed.

In the framework of the IRIS Demonstration, one of the biggest task was the simulation of the toxic cloud

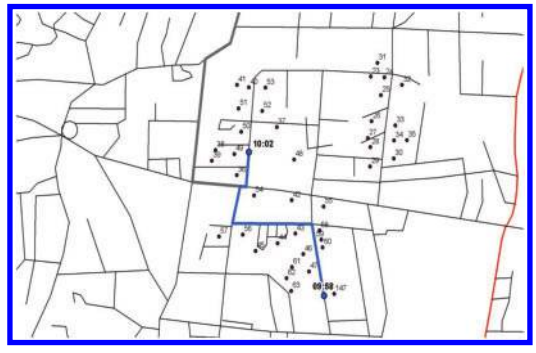

Figure 8. Route of the building inspection team (first minutes).

Figure 9. Route of the building inspection team; the toxic cloud coming from an accident in Pincehely had to be circumvented.

and the consequent management of all the linked difficulties. As the primary attempt was to create smoke and simulate the cloud. Due to uncertain wheather conditions, the creation of a back-up plan was decided.

In detail, the idea was to lay out markers in predefined positions. These markers represent the extension of the simulated cloud. 5 points were identified to mark the extension of the cloud. The identified points were white colored and they had the big size of 30×30 meters, in order to ease their recognition by the RapidEye satelite. Paper stripes where identified as the best technical solution to be used as markers. These stripes were carried to the point in rolls with 30×2 meters and were rolled out in the morning. The paper was fixed with earth material.

The markers worked very well and the points were visible from the airplane as well as from the satellite. The airplane took off in Tolna and was going south to the Szeksard bridge where a car accident was simulated. The next destination was the area around the chemical plant in Pincehely. The aim of the airplane was to first detect and collect information about the smoke cloud. The cloud did not perform as expected and the visibility was very poor, as one can see on the pictures. The plane did a few circles around the area of Pincehely in order to detect the smoke and the marker positions. The marker positions were photographed

Figure 10. Route of the airplane.

Figure 11. Markers simulating a toxic cloud in the area of Pincehely.

and documented. Also a message to the Management Team was sent out via SMS when a marker has been found. The Management Team documented the times and the coordinates and got a good impression how long it took to find all the marker positions. Around the area of Pincehely there have only been 3 Markers. 2 other markers were placed southwest with respect to the chemical plant. The pilot knew the wind direction and tried to find the rest of the markers. After finding all the markers, the plane was flying north again and looked at all the important bridges across the Danube. These bridges match with the bridges where damage calculations were performed in the simulation software. These bridges were also inspected by the Bridge Inspection Team.

This is the final flight route of the airplane. As one can see the important places were the marker positions around the chemical plant in Pincehely, then the

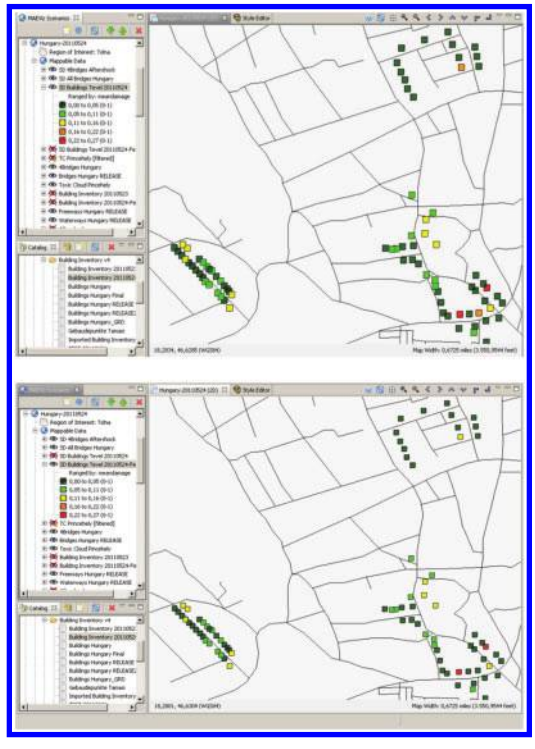

Figure 12. Damaged buildings in Tamasi, Tolna county before (upper image) and after (lower image) model update.

3 marker points southwest of the Picehely area, and the most important Danube bridges.

The inspection of all the probably damaged buildings finished at 11:50. The outcomes of the building inspection team were immediately transmitted to the headquarters in Szekszard and they were used for the model-updating.

4 CONCLUSIONS

EQvis enables to study the earthquake resistance of buildings in an analytical way. The weakest points of the infrastructure can be shown up and in this manner it is helpful for decision makers to make necessary improvements.

Whether modelling disaster consequences or alerting residents to impending disaster-events, GIS-driven maps and applications help emergency personnel to save lives, mitigate property damage, and speed recovery. The key to effective emergency management is situational awareness. EQvis is designed to be used not only by earthquake-engineers, it can also support the work of rescue workers.

The IRIS-exercise in Hungary should show how the effectiveness of rescue workers can be improved with the help of an appropriate disaster-simulation-program. This could be proven in an impressing way, and also many suggestions for further improvements could be formulated.

Measuring degree of interdependencies at the infrastructure level during emergencies

D. Solari & G.P. Cimellaro
Department of Structural, Building and Geotechnical Engineering, (DISEG), Politecnico di Torino, Turin, Italy

A.M. Reinhorn
Department of Civil Structural and Environmental Engineering, University at Buffalo, Buffalo, NY, USA

ABSTRACT: Communities today have a complicated structure, in which various infrastructures overlap and depend on each other. Infrastructures have a certain degree of interdependency at different levels: national, regional, local, etc. This is highlighted when the community is subject to a shock (earthquakes, hurricanes, floods, etc.). Measuring the degree of interdependency is crucial to take appropriate actions on various infrastructures before, during and after the event, in order to minimize the loss of functionality of the various infrastructure networks, thereby reducing severe social and economic losses and optimizing the interventions on the existing infrastructures. In this article we use time series analysis based on cross-correlation functions as a tool for the evaluation of the degree of interdependency at the infrastructure level, on the basis of data provided from the restoration curves of power, natural gas and water supply networks in different regions of Japan after March 11th, 2011 earthquake in Japan.

1 INTRODUCTION

In the last years the scientific community increased the interested in lifelines interdependencies and resilience evaluation (Cimellaro et al., 2010a,b, Cimellaro 2013). In literature there are several papers related to the evaluation of the interdependency index among infrastructures (Arcidiacono et al., 2012). All the articles mainly concentrate on the last decade and they are all using the taxonomy of lifeline interdependencies which is given in the fundamental work by Rinaldi et al. (2001). Paton & Johnston (2006) have given a numerical quantification of the dependencies among different infrastructures, by using an empirical approach in which the degree of dependency among different infrastructures is function of the strength of dependency (high, medium, low dependence). Bigger et al. (2009) have collected different interdependent lifeline information associated with the 2004 hurricane season in Florida. Delamare et al. (2009) have studied the potential effect of interdependencies that may occur between the telecommunication and the electrical network and they have proposed a model that describes the behavior of these interdependent systems. More recently Kakderi et al. (2011) summarizes the available methodologies and models for the vulnerability and risk assessment of systems of systems. They reported illustrations, identification and definitions of the interaction of complex dependencies available in literature. The classification schemes of dependencies are reviewed, and the available methods for the simulation of interdependencies are summarized and classified in five categories. Furthermore, the main characteristics, ad-vantages and limitations of each category of interdependency are also reported. Instead, in the work proposed by Kongar & Rossetto (2012) it is provided a review of the literature using a matrix approach, describing the gaps in knowledge. Based on the review outcomes it conceives a methodological framework for the assessment of infrastructure vulnerability accounting for interdependencies. Kjølle et al. (2012) have used contingency analysis (power flow), reliability analysis of power systems and cascade diagrams for investigating interdependencies, while Poljansek et al. (2012) have studied the seismic vulnerability of the European gas and electricity transmission networks from a topological point of view; network interdependency is evaluated using the strength of coupling of the inter-connections, together with the seismic response. Recently Dueñas-Osorio & Kwasinski (2012) have proposed an approach based on the post-analysis of the restoration curves. The interdependency index between infrastructures is calculated with an empirical equation that depends on the maximum positive value of the cross correlation function (CCF) of the two data series. In this article it is proposed a method to evaluate resilience of a region affected by a disaster considering infrastructure interdependency. The resilience index of every infrastructure in the region is combined with others through weight coefficients, which are calculated starting from a modified version of the interdependence index

proposed in the work of Dueñas-Osorio & Kwasinski (2012) where the cross correlation functions (CCF) are adopted. A new method to evaluate interdependency index is proposed and compared with other methods available in literature. The regional resilience index is evaluated taking in account the weights coefficients which are evaluated for every region and infrastructure considered in the analysis. Finally, a method for the treatment of the restoration curves is proposed where aftershocks are included in the restoration curves. The method is described using the restoration curves (Nojima, 2012) of the physical infrastructures of the twelve regions in Japan which were affected by March 11th 2011 Tohoku Earthquake.

2 RESTORATION CURVES OF PHYSICAL INFRASTRUCTURES AFTER 2011 TOHOKU EARTHQUAKE

The proposed method for the evaluation of the interdependency index and the weights coefficients necessary to evaluate the regional resilience index is based on the evaluation of the CCF among different restoration curves. In this paper, the restoration curves used for the analysis are the time series recorded during March 11th 2011 Tohoku Earthquake (Nojima, 2012), in the twelve Japanese regions which are: Miyagi, Ibaraki, Fukushima, Yamagata, Akita, Ibaraki, Tochigi, Aomori, Chiba, Gunma, Saitama and Kanagawa (listed according to the distance from the epicenter). In particular, are available the restoration curves of three different types of lifelines (Power delivery, Water supply, City Gas delivery) for the regions of Miyagi, Iwate, Fukushima, Ibaraki, Aomori and Saitama. Instead for the region of Yamagata, Akita, Tochigi and Gunma are available only the data of Power delivery and Water supply, whereas for Chiba and Kanagawa prefecture are available only the restoration curves of the Power delivery and City Gas delivery. In this restoration curves it can observe the effects of two main aftershocks, which occurred on April 7th (M=7.2) and on April 11th (M=7.0), on the different infrastructures and regions respectively. The first aftershock reduced the serviceability in the regions located near the epicenter of the main shock and the first aftershock, whereas the second aftershock reduced the serviceability of the lifelines in Fukushima prefecture only. City Gas delivery were not influenced from the two aftershocks in any region.

3 EVALUATION OF INTERDEPENDENCY INDEX

In order to calculate the CCF functions of the different restoration curves, it is necessary that the time series would be at least weakly stationary (Shumway & Stoffer, 2006). To minimize the effects of non-stationary and obtain meaningful statistical analyses, the time series data have been logarithmically transformed and second-differenced (Figure 1a). This transformation stabilizes the variability, and the mean

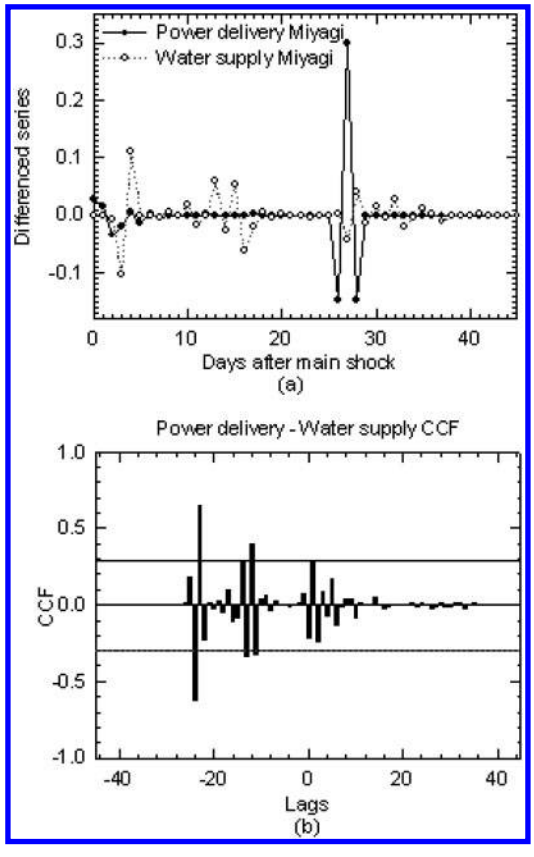

Figure 1. Miyagi power delivery and water supply restoration curves logarithmically transformed and second differenced (a); Cross correlation function of power delivery and water supply in Miyagi region (b).

value which remains constant through the time, while the auto-covariance values decay rapidly and only depends on the time-difference $h = t_1 - t_2$ between the data series, where t_1 and t_2 are arbitrary points in time (Shumway & Stoffer, 2006). An example of the results of the transformation, about Power delivery and water supply for Miyagi region is shown in Figure 1a. After the logarithmical transformation and the second-differenced of the data series, it is possible to evaluate the CCF functions ($\rho_{i,j}(h)$) for different combinations of the restoration curves. In Figure 1b is shown an example of CCF function between Power delivery and water supply for Miyagi region. Four equations for the evaluation of the interdependency index $S_{i,j}$ among different infrastructures are proposed (Eq. (2), (3), (4), (5)), and compared with the results of Equation (1) which has been proposed by Dueñas-Osorio & Kwasinski (2012).

$$S_{i,j} = \begin{cases} \dfrac{\rho^{+}_{i,j}(h)}{1+\sqrt{|h|}} \times \mathrm{sgn}(h) & when \quad h \neq 0 \\ \rho^{+}_{i,j}(h) & when \quad h = 0 \end{cases} \qquad (1)$$

where $\rho^{+}_{i,j}(h)$ corresponds to the maximum positive CCF value, which occurs at the peak lag time value h with absolute value $|h|$, and the sign function (sgn) is used to keep track of the dominant system. The ith system leads [lags] the restoration of the jth system when $S_{i,j}$ is positive [negative] (Dueñas-Osorio & Kwasinski, 2012).

$$S_{i,j} = \begin{cases} \dfrac{\rho^{+}_{i,j}(h)}{h} & when \quad h \neq 0 \\ \rho^{+}_{i,j}(h) & when \quad h = 0 \end{cases} \tag{2}$$

$$S_{i,j} = \frac{1}{N}\sum_{k=1}^{N}\left(\begin{cases} \dfrac{\rho(h_k)}{1+\sqrt{|h_k|}} \times \mathrm{sgn}(h_k), when \quad \rho(h_k) \geq \rho_{tr} \cup h_k \neq 0 \\ \rho(h_k) \qquad\qquad , when \quad \rho(h_k) \geq \rho_{tr} \cup h_k = 0 \end{cases} \right) \tag{3}$$

$$S_{i,j} = \frac{1}{N}\sum_{k=1}^{N}\left(\begin{cases} \dfrac{\rho(h_k)}{h_k} & when \quad \rho(h_k) \geq \rho_{tr} \quad and \quad h_k \neq 0 \\ \rho(h_k) & when \quad \rho(h_k) \geq \rho_{tr} \quad and \quad h_k = 0 \end{cases} \right) \tag{4}$$

$$S_{i,j} = \left|A_{i,j}\right|^{\frac{1}{N}} \cdot \mathrm{sgn}\left(A_{i,j}\right) \tag{5}$$

where

$$A_{i,j} = \frac{1}{N}\sum_{k=1}^{N}\left(\begin{cases} \dfrac{\rho(h_k)}{\sqrt{|h_k|}} \times \mathrm{sgn}(h_k) & when \quad \rho(h_k) \geq \rho_{tr} \quad and \quad h_k \neq 0 \\ \rho(h_k) & when \quad \rho(h_k) \geq \rho_{tr} \quad and \quad h_k = 0 \end{cases} \right) \tag{6}$$

and where $\rho^{+}_{i,j}(h)$ corresponds to the maximum positive CCF value, which occurs at the peak lag time value h, $\rho(h_k)$ corresponds to the CCF values which occur at lag time h_k, ρ_{tr} is the value of the positive threshold of statistical significance (the threshold is shown in Figure 1b with the two horizontal solid lines), N corresponds to the number of CCF values that exceed the upper bound of statistical significance. n-infrastructure restoration curves are analyzed and the results are organized in a matrix of dimension (n × n) in which every element ranges between −1 and 1. Positive values of this index shows that the ith infrastructure (row) leads the restoration process of the jth infrastructure (column), while negative value of the index shows that the ith infrastructure (row) is lags behind the restoration process of the jth infrastructure (column). The magnitude of the dependence is given by the absolute value of the index, which, when it is close to 1 the dependency is high, while when it is close to 0 the dependency is weak (zero value indicates absence of dependency). The results of March 11th 2011 Tohoku Earthquake are shown in Table 1, while in Figure 2 is shown the comparison of the different interdependency indices $S_{i,j}$ evaluated with the different equations for the regions of Miyagi and Iwate respectively. Equation (5) generally gives the highest values of the interdependency index, while the other equations have lower values of $S_{i,j}$. Equations (3) and (4) have the lowest values of the interdependency index, because the $S_{i,j}$ index are evaluated from the average of the values of the CCF function which exceed the positive threshold of statistical significance. From Table 1 it is observed that the interdependency index relative to the Power-delivery evaluated with the different equations using the restoration curves of 47 days, often has negative value, which has no physical meaning. This behavior is well highlighted also in Figure 2 where are reported the interdependency index resulting from all the different equations taken into consideration. All equations used for the evaluation of the $S_{i,j}$ index have a sign agreement, while differences are observed in the absolute values.

4 DISCUSSION REGARDING THE PROPOSED EQUATIONS

The following discussion aims to find a mathematical formula that improves Equation (1) proposed by Dueñas-Osorio & Kwasinski (2012) for the calculation of the interdependency index ($S_{i,j}$). Equations (1), (3) and (5) have the denominator term proportional to the square root of |h| that has the effect of amplifying the interdependency index with respect to Equations (2) and (4) that have the denominator term proportional to h (Figure 2). This happens because the equations that have the denominator term proportional to the square root of |h| give more importance to the terms far from lag 0 with respect to the equations that have the

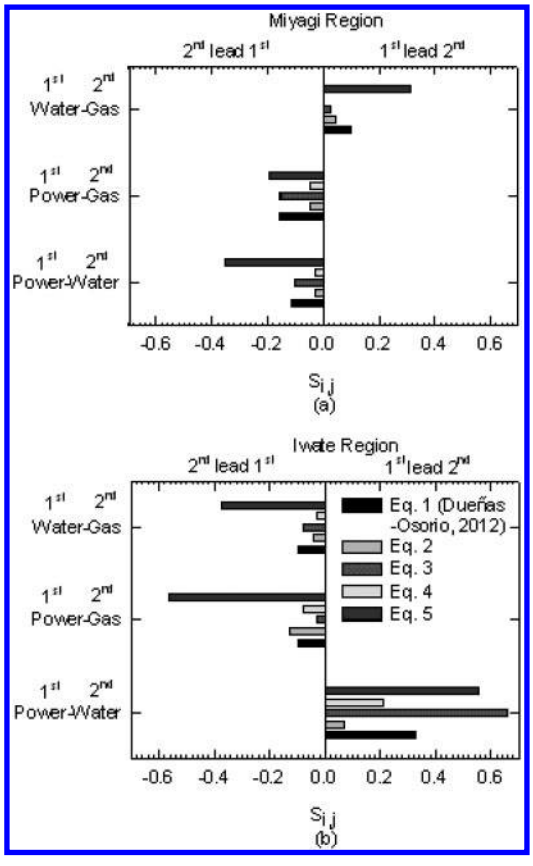

Figure 2. Comparison of different interdependency index proposed for Miyagi (a) and Iwate regions (b).

denominator term proportional to h. If CCF function has only one peak to lag ±1 (most common for CCF function about power delivery), Equations (1) and (3) give a value of $S_{i,j}$ that is a half of that which would be obtained using Equations (2), (4) and (5). Equations (1) and (2) take into consideration only one value (the positive peak) of the CCF function, without taking into account the threshold of statistical significance of the same function CCF, while the Equations (3), (4) and (5) take into account all the positive values of CCF function over the positive threshold, which is a more meaningful approach, because all values below the threshold might not have any statistical significance. This last consideration leads to discard the Equations (1) and (2), and focusing the analysis on the other remaining equations. Equation (3) give a value of $S_{i,j}$ that is half of what would be obtained using equation (4) and (5), if CCF function has only one peak to lag ±1. This behavior (that is due to the mathematical composition of the denominator) leads to low value of $S_{i,j}$ for CCF functions in which for example one infrastructure is power delivery. This happens because, immediately after the main shock, power delivery suffering a rapid drop of the functionality curve that precedes the loss of functionality of the other infrastructures (Nojima, 2012); and it is also the first lifeline that is repaired after a disaster. This behavior is due to the physical nature of electric network and because other lifelines in the community depend on electricity, therefore if it fails they reduce their functionality. These considerations lead to disregard also Equation (3).

The structure of the denominator of Equation (4) makes it less sensitive to the values of CCF far from lag 0, and, in general, gives a low value of interdependency index with respect to the other equations as is it shown in Figure 2. Moreover, if the CCF function has more than one value over the positive threshold (which is often a low value, because it is distant from lag 0), the structure of the formula, which considers the average (1/N) among these values, always provides a low value of interdependency index, in this way, instead of increasing the index of interdependence for those lifelines that have more than one value of the CCF function beyond the positive threshold, it is obtained the opposite effect. These considerations lead to reject Equation (4). Equation (5) is the only one that provides a value of $S_{i,j}$ higher, compared to Equation (1), when there is more than one value of the CCF function over the positive threshold of statistical significance. Furthermore, as shown in Figure 2b, Equation (5) provides the highest $S_{i,j}$ value for power delivery and lowest values (maximum negative values of $S_{i,j}$) for other infrastructures dependent on this. Equation (5) is the only one that provides meaningful results on the basis of the considerations so far shown and it is there-fore adopted for the calculation of the interdependency indices $S_{i,j}$.

In Cimellaro et al. (2013) is shown the behavior of Equation (5) for different hypothetical CCF functions, in order to test its sensitivity with respect to the Equation (1) proposed by Dueñas-Osorio & Kwasinski (2012). Figure 3 shows the value of the behavior threshold, based on the ratio between the CCF value at lag 0 and the CCF value at lag 1; if the value of this ratio is less than the curved line, it follows that Equation (5) gives a lower value with respect to Equation (1). If the value of this ratio is located on the curve, it follows that Equation (5) gives the same result of Equation (1). If the value of this ratio is higher than the curved line, it follows that Equation (5) gives a higher value compared to Equation (1).

Finally, if the first value of the CCF function at lag 0 is comprised between 0 and 0.5, the Equation (5) provides a greater result with respect to Equation (1) for any positive value assumed by the CCF function at lag 1. This theoretical analysis of the response of Equation (5) as a function of the first two values of the CCF function to positive lag has been developed in order to test its confidence limits of the equation in order to highlight some potentialities (such as an increasing of the index of interdependency in case more than one value of the CCF function exceeds the threshold of statistical significance), and some limits (such as the negative effect of the Equation (5) on the index of interdependency when the ratio between the value of the CCF function at lag 1 and the value of the CCF

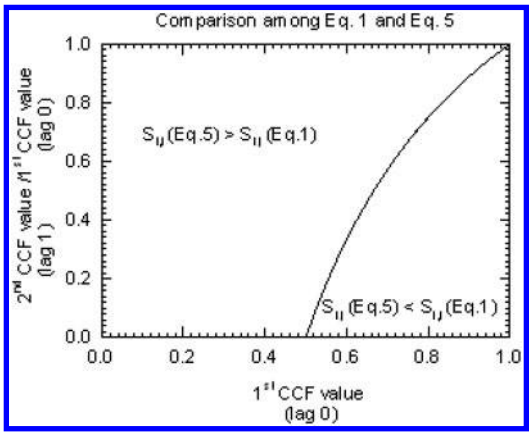

Figure 3. Comparison of CCF values between Equation (1) proposed by Duenas-Osorio & Kwasinski (2012) and Equation(5)

function to lag 0 is situated below the curve shown in Figure 3). Equation (1) does not take into account the information given by the threshold of statistical significance. Equation (5) is more conservative because if no value of the CCF function exceeds the positive threshold, the index of interdependence relative to those two lifelines is equal to zero.

5 DECOMPOSITION OF THE RESTORATION CURVES IN INTERVALS RANGING BE-TWEEN TWO CONSECUTIVE SHOCKS

From the critical analysis of the results shown in Figure 2a an anomalous behavior of the interdependency index in Miyagi region was observed, which gives a negative value for the combinations Power-Water and Power-Gas. This means that Power delivery is controlled by Water supply and Gas delivery. This does not have any physical meaning, because normally electricity leads the other networks (for example electricity is needed for the operation of pumps, valves, etc. which are them-selves essential for the proper functioning aqueducts, gas pipelines, etc.). This behavior of the inter-dependency index appears also in Figure 2b for Iwate region, in which the index of interdependency gives a negative value for the combination Power-Gas. This anomaly affects all equations considered, including the one proposed by Dueñas-Osorio & Kwasinski (2012) and it might be caused by the nature of the restoration curves under consideration. The problem is in the data collected after the main shock in which have occurred two strong after-shocks. These events have affected the functionality of lifelines, perturbing the restoration curves.

The problem can be solved by dividing the data into homogeneous parts of the restoration curves corresponding to the elapsed time between two consecutive strong shocks (Cimellaro & Solari 2013). For each period, the cross-correlation analysis of the restoration curves are performed after the logarithmic transformation and the second differences as described above. In Table 2 are shown the S matrices calculated using Equation (5) for two different time intervals: 47 days and 27 days respectively, which are the maximum duration of the series of recordings and the time interval between the main shock and the first strong aftershock which occurred on April 7th. In the same table, the values of interdependency which pass from negative values to positive values when moving from 47 to 27 days are highlighted in gray, for the row pertaining to the Power delivery. It should be noted that the interdependency index of a given lifeline with respect to itself is 1, therefore all the terms of the diagonal in the matrix in Table 2 are 1. It is observed how the interdependency indices of the row corresponding to the Power delivery have a positive value, if one considers the interval of 27 days to compute it. So the interdependency index has physical meaning when the time interval is shorted to 27 days. The same operation is repeated using Equation (1) proposed by Dueñas-Osorio & Kwasinski (2012). If only the data range between the main shock and the first strong aftershock is considered, the index of interdependence assumes a meaning that is related to the physical nature of the problem, regardless of the type of equation which is used for the calculation of the index $S_{i,j}$.

Table 2. Comparison of interdependency index among different time: in gray are highlighted the values that increase.

Region		Eq.(5) 47 days	Eq.(5) 27 days
	Power - Water	−0.35	**0.00**

Kanagawa	Power - Gas	0.55	0.54

6 CONCLUSIONS

In this article, a detailed analysis of the interdependency index is performed and a new equation for the

calculation of the interdependency index using CCF function among different restoration curves has been proposed. The proposed equation takes into account the level of statistical significance for each CCF function, considering only the values above it. It is also given more weight not only to the peak value, but to the number of times in which the CCF function exceeds the threshold of statistical significance. The proposed methodology has been developed using the restoration curve data of 2011 Tohoku Earthquake. Numerical results may have been influenced by the reduced number of restoration curves of only three lifelines used in the analysis. Further research may clarify this behavior testing the proposed methodology for the calculation of the regional interdependency index using more than three restoration curves for each region.

Back-analysis of the collapse of a metal truss structure

C. Crosti & F. Bontempi
School of Civil and Industrial Engineering, Department of Structural and Geotechnical Engineering, Sapienza University of Rome, Italy

ABSTRACT: This paper is organized in two parts. The first one describes a case history of few collapses of metal truss structures designed to be used as entertainment structures for which the structural safety gains therefore much more importance due to the people that can be involved in the collapse. In the second part, a specific case of the collapse of an entertainment structure made by aluminum is taken under study. A back analysis of the collapse of this metal truss structure is developed and produces a flowchart that points out the possible causes that led the structure to the collapse. By means of non linear analyses by Finite Element Model (FEM) the failure sequence of this particular structure is shown and forensic investigation concerning the whole phase of the construction phase is performed, starting from the design one, through the assembling and ending with the rigging phase.

1 INTRODUCTION

Particular attention recently has been given to the design and to the construction of entertainment structures due to the recent collapses that have had them as object.

Those kinds of structures are defined as temporary demountable structures and most of the time used as stages for music concerts. The stability of these structures becomes therefore important especially because of the need to assure the safety of people (Andi and Minato 2003).

The preparation of these kinds of structures for an event can be divided into separate phases:

- Management and Administration, where all the agreements necessary for the construction are obtained;
- Design, where it is contemplates the analysis of suspended loads and the design of the supporting structure;
- Build-up, that means the construction of the structures;
- Load in, that includes the rigging and installation of sound, light, and similar equipment (including artist specific stage equipment);
- The event;
- Load out, removal of sound, light, video, etc;
- Break down or deconstruction, dismantling and removal of temporary demountable structures.

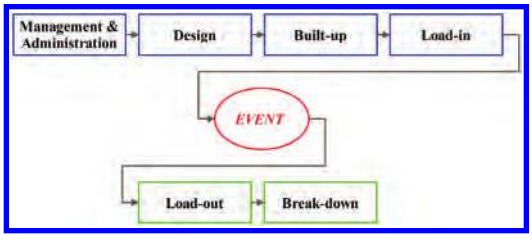

Figure 1. Phases for the construction of an entertainment structure.

Errors that could lead the structure to the collapse can be found in each of the phases above described.

2 CASE HISTORY

Unfortunately, there have been recent collapses of temporary stage structures in the United States and in Europe during entertainment events. These have resulted in fatalities and numerous injuries, below few cases are listed:

- 2007, June 15th, Parco San Giuliano di Venezia, Italy, Heineken Jammin' Festival;
- 2009, July 20th, Marseille, France, Madonna's concert;
- 2009, August 1nd, Camrose North America, Big valley Jamboree;
- 2011, August 14th, Indianapolis, USA, Country music concert;
- 2011, December 12th, Trieste, Italy, Jovanotti's concert;
- 2012, March 5th, Reggio Calabria, Italy, Pausini's concert;
- 2012, June 16th, Toronto, Canada, Radiohead's concert.

Most of these listed collapses define wind as a contributory cause of the collapse. These temporary

Figure 2. Collapses of entertainment structures.

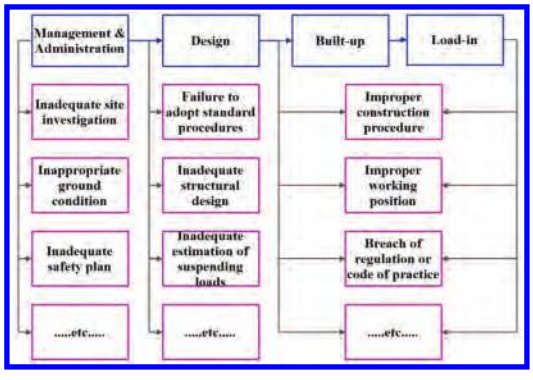

Figure 3. Most frequent errors in the phases before the event.

structures are exposed to vertical imposed loadings from attached lighting and sound equipment and also, when outdoor, to lateral loadings resulting from wind.

The risk is that when the structure is subjected to combined vertical equipment loads, to the horizontal wind loads and to the eccentric vertical loads, the resulting forces can cause catastrophic failures which may result in collapse if the structure is not competently designed, constructed, and managed in use.

Learning from the past it is possible to point out some frequent errors which could lead structures to collapse, (Sebastiani, 2012), (Sgambi, 2012).

Where error is defined as "something that has been done, which was: not intended by the author; not desired by a set of rules or an external observer; or that lead the task or system outside its acceptable limits" (Senders, 1991).

Focusing on the phases previous the event Figure 1 shows some of the most frequent errors that could be seen as principal factors for structural failure. Most of them can be classified as human errors due to the poor knowledge, to the carelessness and negligence (Love, 2008).

Inadequate site investigation, inappropriate ground condition, inadequate structural design, failure to adopt standard procedures or failure in realizing what prescribed in the design and in the regulations, are all factors that can contribute to a catastrophic event, (Suraji, 2001).

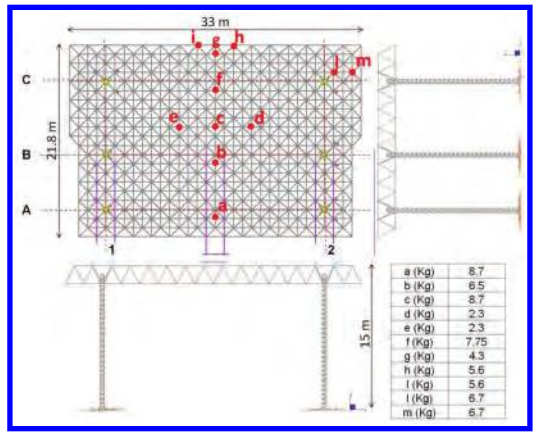

Figure 4. Structure under study.

3 CASE STUDY: NUMERICAL MODELING

The structure under study is an entertainment structure that collapsed skidding on the stage left before the event had started.

The structure was made by precast aluminum elements which composed a space roof, six vertical towers and a small truss necessary for suspending scenographic lighting, speakers and videos, Arangio (2011).

The structure was built with EN AW-6082 T6, with modulus of elasticity (E) equal to 7×10^{10} Pa, density (ρ) of 2700 Kg/m^3, elastic limit for the strength (σ_y) of 2.5×10^8 Pa and ultimate strength (σ_u) of 2.9×10^8 Pa, (Mazzolani, 2012), EN1993 1-1 (2005).

Using Strand7/Straus7, a Finite Element Model is defined as shown in Figure 4, with 2148 nodes and 5275 beams.

In order to take account of the weight of the connection between the elements, made in cast iron, an additional uniform pressure of 115 Pa is considered on the roof. The suspending loads present at the moment of the collapse are applied as shown in Figure 4. In this way, the weight of the whole structure is about 28.5 tons.

4 INVESTIGATION ON TECHINAL CAUSES OF THE COLLAPSE

Three are the main aspects investigated to individuate the cause of the collapse of the structure: failure to adopt standard procedures, inadequate structural design, improper construction procedure, see Figure 2.

4.1 *Failure to adopt standard procedures*

A failure to adopt standard procedures could have been for example to design the structure not including in the global analyses the nonlinearities, in particular the

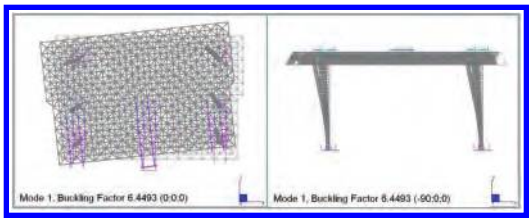

Figure 5. Deformed shape of the first mode of buckling.

geometric ones. The EN 1993-1-1: 2005 at point 5.2.1 says that:

"*The effects of the deformed geometry (second-order effects) should be considered if they increase the action effects significantly or modify significantly the structural behavior*"

This consideration can be neglected only when:

$$\alpha_{cr} = \frac{F_{cr}}{F_{Ed}} \geq 10; \text{for elastic analysis} \quad (1)$$

Where α_{cr} is the factor by which the design loading have to be increased to cause elastic instability in a global model, F_{ED} is the design loading on the structure and F_{cr} is the elastic critical buckling load for global instability mode based on initial elastic stiffnesses.

Running linear buckling analysis on this specific structure, the buckling factor α_{cr} is 6.44, Figure 5. Since it is smaller than 10 the second order effects have to be taken into account in the global analyses. In the next paragraph it will shown how much difference gives to neglect them.

4.2 *Inadequate structural design*

Another important aspect investigated is that the structure is designed to be indoor; therefore the structural elements were designed to carry vertical loads but may not have been designed for lateral loads. That could be an important consideration in the design phase, in fact, following what prescribed in the UNI ENV 1999-1-1:2007, in order to run global analyses, it is necessary to take account of horizontal forces due to the imperfections of the elements composing the structure.

At point C4.1 of the UNI ENV 1999-1-1:2007 it is explained how to take into account of the imperfection in the global analyses. Therefore, rather than applying to each element a lateral imperfection, three horizontal forces, in correspondence of lower elements composing the space roof have been applied to the structure.

4.3 *Improper construction procedure*

The latest consideration will be conducted on the possibility of improper construction procedures.

The attention is focused on the realization of restraints between the paving and the columns in order to assess how and how much an error in defining or in realizing them could compromise the whole structural behavior, (Crosti, 2012).

Table 1. Horizontal forces applied to simulate the imperfections.

ϕ	0.005	
kc	1.225	> 1
n_c	1.000	
ks	1.225	> 1
n_s	1.000	
ϕ_0	0.005

ϕN	1.13E+03	N

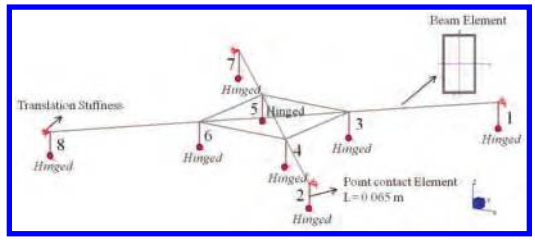

Figure 6. Unilateral restraint on the bottom of each column.

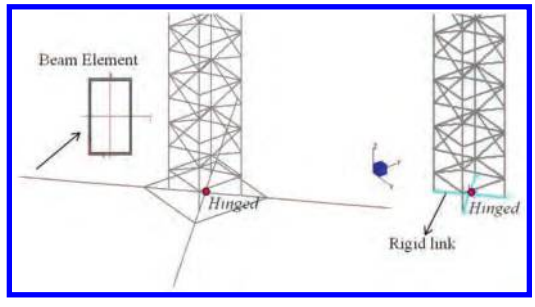

Figure 7. Cases with hinged restraints, on the left with outriggers and on the right with no outriggers.

Three different models are considered in order of taking account of some aspects:

- the possibility that, due to horizontal displacements caused by the structural imperfections, the outriggers could lose the contact with the paving. To simulate this case, eight point-contact elements are set to simulate the contact between those elements and the paving, Figure 6. The point contact element in the Finite Element Code Strand7/Straus7 is used to model a gap between two surfaces or edges, stiffness is provided in compression but zero stiffness is given in tension;
- it could happen that during the phase of the construction for example, what it is designed to be a rigid connection, could be realized for a while as able to rotate. To simulate this aspect hinged restraints are considered on the bottom of each column, Figure 7; and

Table 2. Definition of the studied models.

Model	GNL	MNL	Imperfection	Restraint	Outriggers	ULf
0	X			Fixed	X	6.942
1	X	X		Fixed	X	4.000
2	X	X	X	Fixed	X	3.946
3	X	X	X	Unilateral	X	4.019
4	X	X	X	Hinged	X	1.122
5	X	X	X	Hinged		0.853

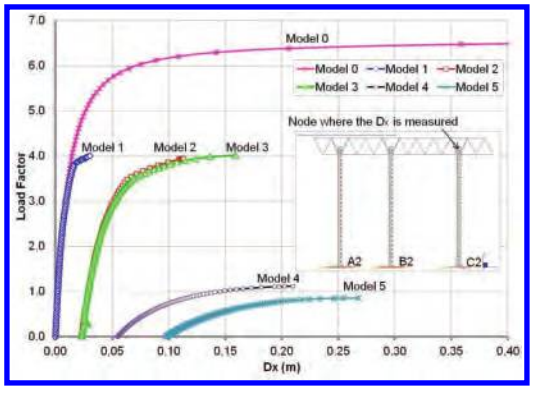

Figure 8. Load Factor-Horizontal Displacement of the node.

– the case where hinged restraints are on the bottom of each column but no outriggers are set, Figure 7.

5 NUMERICAL RESULTS

Five different models were run in order to assess the influence that the above mentioned errors give to the global response of the structure under study.

Table 2 summarizes the different models considered, where MLN means Nonlinear Material, GNL stays for Nonlinear Geometry, Imperfection means that horizontal forces simulating the structural imperfection defined by Eurocodes are applied, Unilateral means that the bottom column is modeled with unilateral restraint, see Figure 6, Hinged considers as restraint the ones in Figure 7 and U.L.F. stays for Ultimate Load Factor.

Looking at Figure 8 it is possible to recognize that Model 1 has the classical bifurcation trend, while Model 2, thanks to the introduced imperfections, shows an asymptotic one. Reaching the peak load at both ends of the columns, the elements are in an intermediate condition, being neither elastic nor having a fully developed plastic hinge mechanism, therefore laborious step-by-step elastic-plastic analyses were necessary to obtain the failure load (ULF) of 3.95.

Moreover, interesting is to point out that there is no difference in terms of Ultimate Load Factor as well as of horizontal displacement trend between Model 2 and Model 3. Modeling the contact between the outriggers and the paving does not seem to be a relevant issue in terms of global response of the structure. In fact,

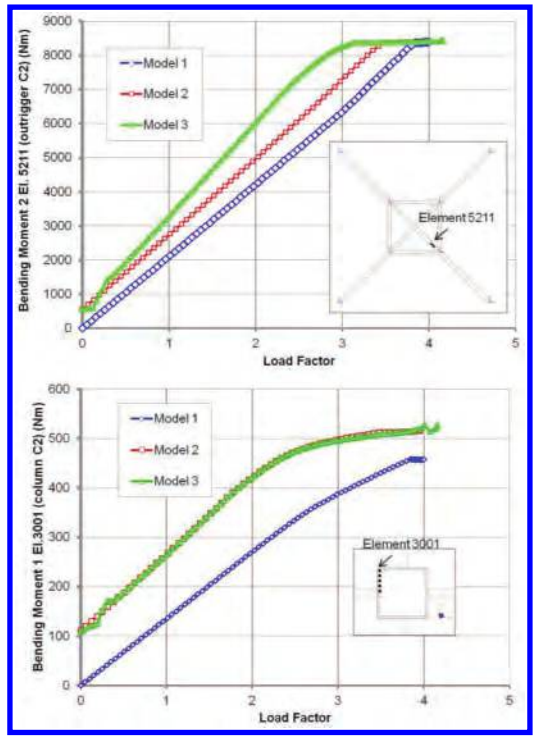

Figure 9. Comparison of the Bending Moment trend for element 5211 of the outrigger and element 3001 of the column.

looking at Figure 10, it is possible to assess that as soon as the horizontal loads are applied to simulate the structural imperfections, the external points of the outriggers lose the contact with the paving not giving any contribution to the stability of the structure.

Model 1, 2 and 3 have more or less the same Ultimate Load Factor at that peak load they reach the same cause of collapse: elastic-plastic failure of the outriggers and of the column elements where the roof is connected, this allows the structure to rotate much more and to buckle.

Figure 9 shows the reaching of the elastic-plastic failure for the two elements mainly stressed with the increasing of the Load Factor.

Figure 10 shows instead a comparison in terms of deformed shape and of maximum vertical displacements reached in the outriggers behind column C2 at the moment of the collapse.

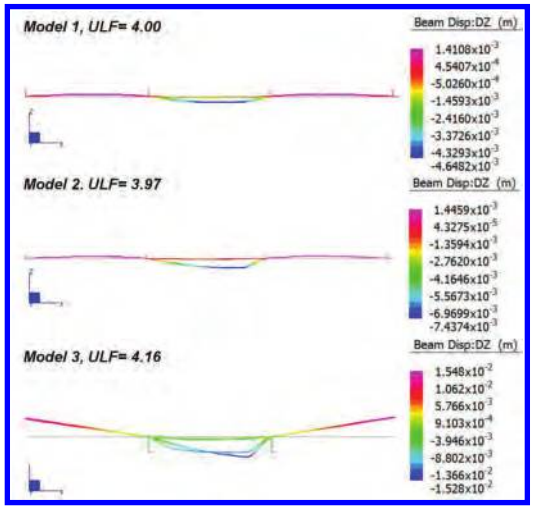

Figure 10. Deformed shape (20%) of the outrigger elements of column C2.

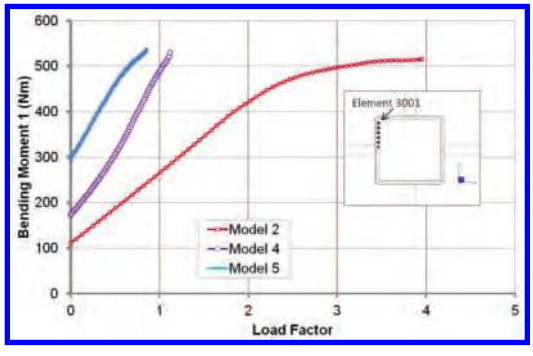

Figure 11. Bending moment 1 trend of element 3001 (column C2).

A different case is the one of Model 4 that, having different restraints on the bottom of the columns, reaches an Ultimate Load Factor of 1.122 which means the structural collapse is due just to the nominal loads applied.

In this particular configuration once the columns reach the yielding stress the structure loses its stability and the analyses cannot find the solution.

The difference shown in Figure 8 between Model 4 and Model 5 is given by the presence of the outriggers. Their presence does not give much contribution in terms of structural stability: in fact the Ultimate Load Factor for Model 5 is 23% smaller than the one of Model 4; however looking at the initial displacement their presence decreases them of about 50%.

From Figure 11 it is possible to evaluate that for Model 4 and 5, due to the different restraints, as soon as the element reaches the yielding load, the analyses stop, while Model 3 shows a better redistribution of the stresses when they reach the failure load.

This large difference in terms of ultimate load shown going from Model 0 to Model 5 shows the

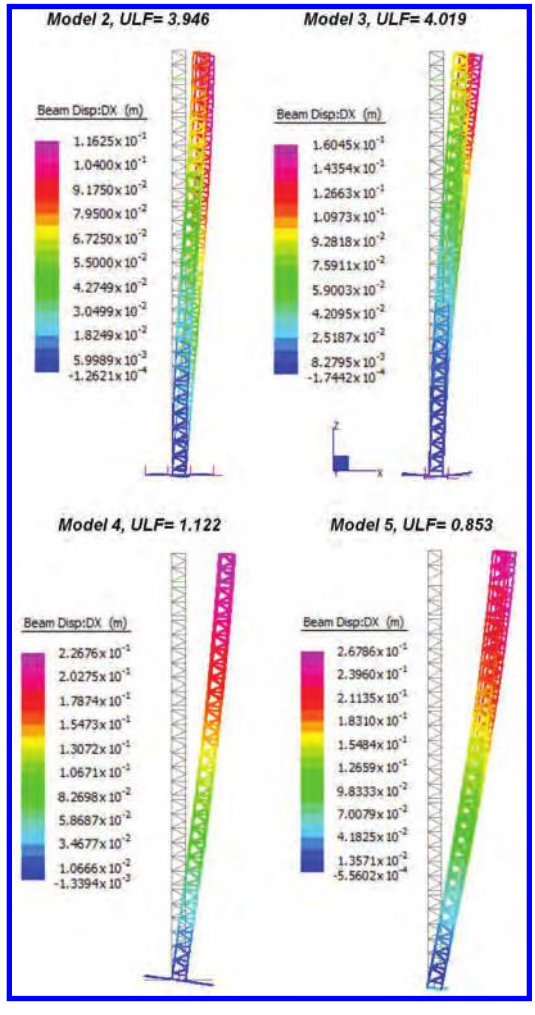

Figure 12. Deformed shape of column C2 at the corresponding Ultimate Load Factor.

sensitivity of the structure to the modeling of the restraints which involve the columns.

6 CONCLUSION

Following the whole construction process of entertainment structures, some of the most frequent errors that can be present in it, have been taken under consideration and applied to a specific metal structure.

By means of Finite Element Analyses it has been possible to point out that:

- Linear analysis can be used just for evaluation of structure critical buckling load, but then, especially for these kinds of structures, proper nonlinear analyses should have been run.
- Not accounting of the initial imperfection, leads the results to be different from the real structural behavior that they have especially when the restraints are subjected to improper construction procedures.

– The importance of taking into account, even in the design phase, of what can happen during the built up phase. Particular importance has to be done to the restraints on the bottom of the columns, which represent the key elements for this structure. During the phase of construction for example, what it is designed to be a rigid connection (Model 1 ad 2), could be realized for a while as able to rotate (Model 4 and 5). That shows the need of considering the design in all the cases which could make a modification in the static scheme of the structure. Introducing bracing member for example, the designers could defend the structure from such possible changes in the structure and avoid failure, (Arangio, 2012). This solution could be especially effective in cases where the structures are not designed for horizontal forces that are the indoor ones.

A further development could be to take into account of the stiffness of the paving which can be an issue that compromises the structural stability.

FE models for evaluating damages in churches hit by L'Aquila earthquake

G. Brando, E. Criber & G. De Matteis
Department of Engineering and Geology, University "G. d'Annunzio" of Chieti-Pescara, Italy

ABSTRACT: The behavior of churches during an earthquake is very complex, mainly due to the peculiarities of the buildings, which usually were conceived more for pursuing stylistic aims rather than structural goals. On the other hand, churches are often the result of continuous stratifications generated during their life, which led to constructions characterized by heterogeneous parts working with different modalities. As a consequence, the observation of damages produced by earthquakes could represent a rare occasion for improving the knowledge about the structural behavior of these buildings. In this framing, the current paper deals with the interpretation of the vulnerabilities observed, after the 2009 seismic event, on a church belonging to the district of L'Aquila, the St. Gemma Church in Goriano Sicoli. In a first step a careful analysis of the damage revealed after the 2009 earthquake on similar churches belonging to the same regional area is provided. Then, a suitable FEM numerical model, able to reproduce the revealed damages and properly calibrated by means of Ambient Vibration Tests, is set up for the church under consideration, with the aim of providing a sophisticated tool for weighing up the most important phenomena of failures and to provide some information about the most appropriate retrofitting techniques to be adopted.

1 INTRODUCTION

The small town of Goriano Sicoli represents a typical example of historical urban center belonging to L'Aquila district which was severely stricken by the 2009 seismic event. One of the most interesting building in the village is surely the church of St. Gemma, which due to both architectonic and structural features, can be considered as a representative sample of a wide population of churches erected in the same regional area in the last ten centuries. As the last earthquake proved, such churches are very vulnerable and they are characterized by a complex structural response that need to be deeply investigated. In addition, the significant stratifications carried out after the seismic event of the pasts have to be duly accounted for, with the aim of defining specific retrofitting strategies to be implemented for their conservation.

In view of this demand, in the immediate aftermath of the 2009 seismic event, the authors carried out a wide post-earthquake survey (Criber et al., 2011), in order to detect recurrent damages and failures mechanisms. The attention has been focused on the south-east area of the L'Aquila district, also known as the territory of the Sulmona-Valva Diocese, where three nave churches have been investigated by means of kinematic analyses that allowed justifying the main observed damages (Brando et al., 2011). Furthermore, Ambient Vibration Tests have been conducted on two of these churches, i.e. St. Gemma and St. Maria Nova Church, both located in the centre of Goriano Sicoli (Tashkov et al., 2010). Then, on the basis of these tests, a sophisticated FEM model has been defined for the St. Gemma case study (De Matteis et al., 2011).

In this paper, the main outcomes of a response spectrum linear dynamic analysis are presented, with the aim of validating the above modeling process, by a comparison of the model parts subjected to the most severe stress concentrations and the church zones in which damage has been identified.

2 DAMAGE IDENTIFICATION

2.1 *Territorial analysis*

The Sulmona-Valva Diocese is one of the three administrative area of the Roman Curia in the Abruzzi region. It is composed by 49 municipalities, where almost 250 religious buildings are nowadays present. Among these, rural churches, churches belonging to religious institutes (convents) and cathedral churches have been identified. Rural churches are usually composed by one nave only (80% of the investigated cases, see figure 1), whereas the later ones can be classified as "central plan" (2%), "two-", "three-" and "five-"naves churches (3%, 14% and 1% respectively).

With particular regard to the three-naves typology, a set of 20 churches has been considered. These are characterized by almost homogeneous geometric features, as it is shown in figure 2, where both the plant Length/Width (most frequent value equal to almost 2) and Façade Length/Height ratios (most frequent value equal to almost 1.3) are depicted.

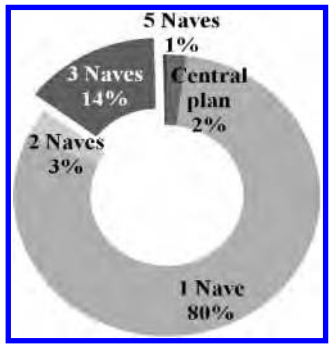

Figure 1. Percentage of structural typologies of churches in Sulmona-Valva Diocese.

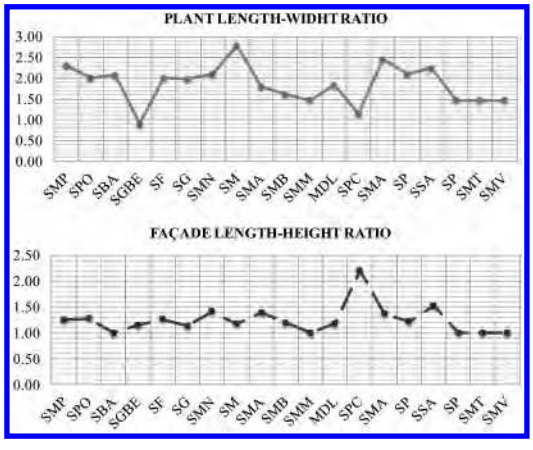

Figure 2. Geometrical ratios characterizing the observed churches: a) plant length/span and b) façade length/height.

The most recurrent damages revealed on the above churches have been therefore observed and classified according to the Guidelines for the Cultural Heritage (Circular n.26, 2010).

2.2 *Revealed damage mechanisms*

In order to identify typical damage mechanisms, macro-elements behaviors have been critically analyzed and compared, this allowing to note that, in most of cases, the churches having the same distance from the earthquake epicenter and characterized by both the same geometrical ratios and architectonic features (type of vaults, pillars cross section shape, etc.), apart from the cases in which different retrofitting techniques have been applied, presented the same damage level. Cross diagonal cracks have been recurrently found on lateral walls, bell towers and domes (fig. 3), owing to the composition of the masonry fabric, which, in the great part of cases, resulted poor and chaotically organized.

As far as the vault systems is concerned, the elliptical vaults resulted to be the most vulnerable. For these elements, fractures along both the diagonal directions and the circular spring-lines have been highlighted

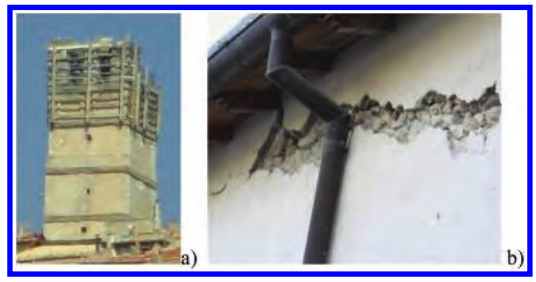

Figure 3. Observed damages on a) bell tower of St. Marco Evangelista in Castel del Monte and b) lateral wall.

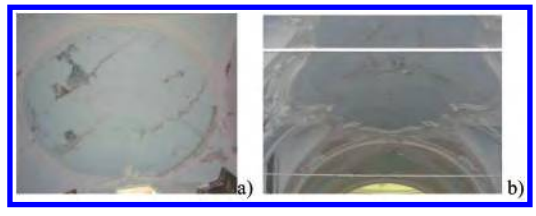

Figure 4. Observed damages on a) elliptical vaults and b) barrel vaults of St. Maria Nova church in Goriano Sicoli.

(Fig. 4a). Different type of damage have been found at the top of the barrel vaults, where longitudinal cracks along the key-vault recurred in a more or less extended way according to the presence of ties in the orthogonal direction (Fig. 4b). Lower damage levels have been detected on the groin vaults, where some fractures developed along the diagonal lines.

With regard to the pillars, vertical cracks due to crushing phenomena have been sometimes surveyed, as in the case of St. Gemma church in Goriano Sicoli. These have been probably induced by the increasing compression stresses, due to the earthquake vertical component, which, even far from the epicentre, resulted significant during the 2009 seismic event. The above failures are particularly evident on those columns built with rubble masonry techniques, where cracks along the mortar, often followed by significant vertical openings on the elements, have been highlighted (Fig. 5a). On the contrary, in the case of monolithic pillars, built with superimposed stones, none damage has been found (Fig. 5b).

Heavy sliding damages have been detected on the churches where reinforced concrete roof or beams have been built in past years (Fig. 6a). This obsolete practice provoked damages on arches (fig. 6b) also, because of the outward thrust of the heavy roof, amplified by the horizontal seismic component. The presence of iron ties certainly constrained this effect; nevertheless, in some cases, punching phenomena of the ties-key (Fig. 6c) or breaking of ties have been detected (fig. 6d).

Out-of-plane mechanisms were very dangerous for the global stability of the buildings, when these resulted not correctly endowed with a proper number of well dimensioned ties. For the churches under investigation, three main out-of-plane phenomena

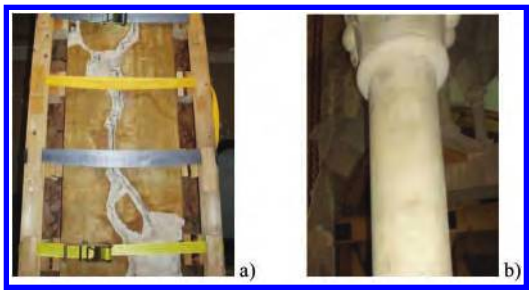

Figure 5. Observed damages on the a) rubble masonry pillars of St. Gemma church in Goriano Sicoli and b) not damaged monolithic columns in St. Pietro ad Oratorium, Capestrano.

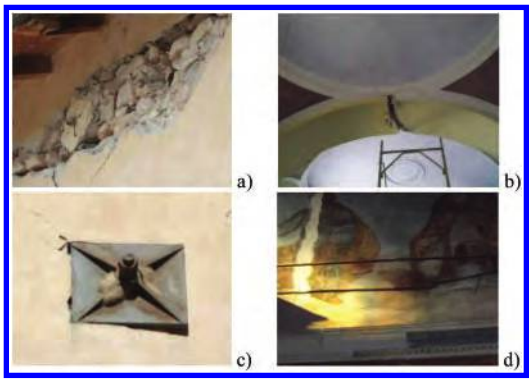

Figure 6. a) Sliding cracks due to the reinforced concrete roof; b) damages on arches, c) punching phenomena and d) tie breacking.

have been recognized: the rigid facade overturning, the facade top-corner overturning and the apse overturning.

For the first type, only one church (St. Gemma church in Goriano Sicoli) showed a mechanism completely developed, where a detachment between the wall and the orthogonal ones of about the thickness of the facade has been revealed (Fig. 7). In other cases the longitudinal ties constrained the rigid overturning, even though the corner connection was clearly inefficient. On the analyzed buildings, in fact, a material discontinuity between the lateral walls and the facade is often recognizable, probably due to the fact that this element was generally built at the end of the church erection process, with different material and different techniques.

Another typical rigid mechanism is the apse overturning, generally due to bad connections or wide openings. For example, in the case of St. Martino church in Gagliano Aterno, both the diagonal crack along the apse and the breaking of one tie demonstrated the activated overturning (Fig. 8a). As far as the façade top corner overturning is of concern, this type of mechanism has been clearly recognized on the majority of the flat facades through diagonal cracks (Fig. 8b), where efficient devices to contain the mechanism usually are not present.

Figure 7. Façade overturning in St. Gemma church.

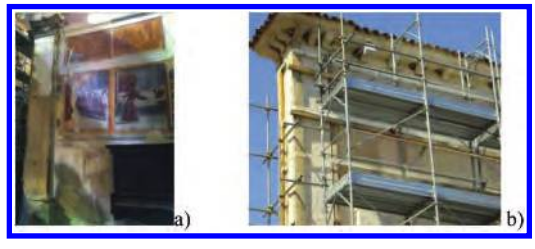

Figure 8. a) Apse overturning on St. Martino church in Gagliano Aterno and b) top-corner overturning on St. Maria della Pace church in Capestrano.

3 THE CASE STUDY OF ST. GEMMA CHURCH IN GORIANO SICOLI

3.1 *General*

Among the observed cases, the St. Gemma church in Goriano Sicoli represents the one with more intense damage. This is due to the many collapse mechanisms developed, probably due to site effects ascribable to the subsoil structure.

Considering that this church is representative also of the others in terms of geometrical features and structural elements type, it has been selected as case study for a deeper comprehension of its behavior, to be pursued by means of a sophisticated FEM numerical model.

3.2 *Architectonic features*

The current building configuration is a clear example of architectonic stratification, often observed in the Abruzzi region for others churches. The global space is a typical Renaissance space, with the intersection between nave and transept (Latin cross).

The church plant is constituted by tree naves, a transept and a dome. The central nave is covered by a barrel vault with lunettes, supported by cross section shaped masonry columns connected by arches. The aisles present characteristic elliptical vaults on arches, constrained by ties. The transept has plane ends and is surmounted by barrel vaults. It crosses the central nave in its central span, which is towered above by a 5.50 m diameter dome. The latter is supported by a circular drum with lateral squinches. On the two sides of the apse, two small compartments covered by pavilion

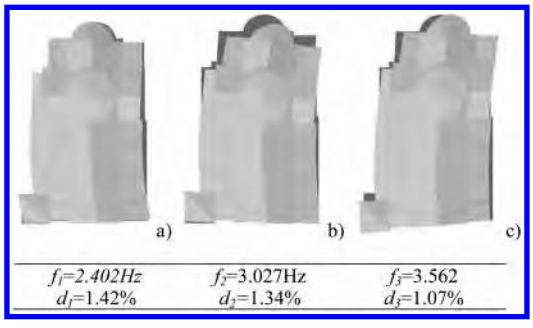

Figure 9. Main mode shapes of the St. Gemma church.

vaults are present. In these, two sacristies are included. The façade has a central part crowned by a tympanum. On the left of the façade a three storey tower bell is present. Behind this, there is a stretched corridor with a reinforced concrete roof supported by reinforced concrete ring beams. The same roof typology has been revealed also on the other lateral aisle.

3.3 *Ambient vibration test*

For the dynamic characterization of the Santa Gemma church, non destructive ambient vibration tests have been conducted. Three seismometers Ranger type were used and the measured signal was amplified by four channel Signal Conditioner. The amplified and filtered signals from the seismometers were then collected by a high-speed data acquisition system which transforms the analogical signals to digital. A special software for on-line data processing has been used to plot the time history and the Fourier amplitude spectra of the response at any measuring point. After recording, the ARTEMIS software was used to define the Spectra density curves and mode shapes of the structures. In Figure 9 the measured first three mode shapes are depicted.

In the same figure, the main natural frequencies f with the associated damping values d are also shown. The first mode ($f_1 = 2.402$ Hz, $d_1 = 1.42\%$) is mainly translational in the transversal direction, the second in the longitudinal one ($f_2 = 3.027$ Hz, $d_2 = 1.34\%$), the third is a torsional mode characterized by a natural frequency of $f_3 = 3.562$ Hz and a modal damping of $d_3 = 1.07\%$ (Tashkov et al. 2010).

3.4 *FEM model set up and analysis results*

The in-situ test outcomes allowed the calibration of a suitable linear FE numerical model, aimed at providing a more refined interpretation of the occurred damages (De Matteis et al. 2011). In a first phase, this has been assembled by referring to the current conditions of the building, namely by reproducing both the geometrical features and the revealed crack patterns of the damaged structure (Fig. 10). The ABAQUS 6.7 software has been used to this purpose. The geometrical model has been suitably meshed by finite tetrahedral solid C3D4 elements of sizes ranging between 0.3m and 0.4m, validated by sensitivity analyses.

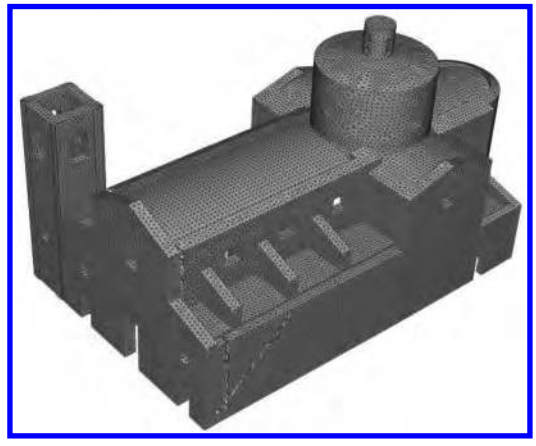

Figure 10. The Fem model of the cracked church.

Table 1. Materials mechanical properties.

Material	E	Id	Ee
Poor mortar Masonry	870 MPa	−40%	522 MPa
Good mortar Masonry	1305 MPa	−30%	914 MPa
Brick Masonry	2400 MPa	−60%	960 MPa
RC beam	20000 Mpa	−0%	20000 MPa

The reinforced concrete roof has been considered as a load weighting the RC beams, whereas its diaphragm action has been simulated by coupling-kinematic constraints. To simulate the iron rod ties, a wire type connector has been defined and a preload force of 50% of its yielding strength has been imposed. The most significant local cracks have been reproduced by deleting the finite elements of the corresponding parts. The material elastic modulus has been selected depending on the quality of the masonry fabric, as listed in Table 1. This values have been taken by the Italian Code "Circolare n.26", on the basis of visual inspections, and modified in a proper way. In detail, they were firstly amplified in order to account for the possible presence of good mortar (increase of 50%, as indicated by the code), and then reduced by a proper "damage reduction factor" I_d in order to account for the diffused cracks revealed during inspections

In order to validate the model, a modal analysis has been run. In Table 2 the data of the first six modes are given, compared with the AVT results. The reliability of the model is proved by the fact that numerical results well fit the experimental ones.

3.5 *Response spectrum linear dynamic analysis*

On the basis of the above model, a response spectrum linear dynamic analysis has been implemented, with the aim of giving a more careful interpretation of the seismic response of the church occurred during the L'Aquila earthquake. To this aim, the continuity of the model, which was broken in some parts during the calibration process, has been re-established. Moreover,

Table 2. Eigenvalue extraction analysis.

Mode	Frequency (AVT)	Frequency (FEM)	Δ%
1	–	2.006 Hz	–
2	–	2.019 Hz	–
3	2.402 Hz	2.391 Hz	−0.45 %
4	3.027 Hz	3.105 Hz	+2.58%
5	3.652 Hz	3.827 Hz	+4.79%
6	–	4.277 Hz	–

Table 3. Materials mechanical properties.

Material	Compression f_{Cmax}	Tension f_{Cmax}
Poor mortar Masonry	0.87 MPa	0.09
Good mortar Masonry	1.30 MPa	0.13
Brick Masonry	2.40 MPa	0.24
RC beam	–	–

the elastic modulus values have been incremented, by setting to 1.0 the above reduction damage reduction factors I_d. On the basis of these values, both the maximum and the minimum stresses of the masonry materials, which will be useful for the interpretation of the analysis results, have been found. In absence of in situ direct tests, the maximum compressive stress has been conventionally assumed equal to f_{Cmax} =E/1000, whereas the maximum stress in tension is given by $f_{Tmax} = f_{Cmax}/10$ = E/10000 (see Table 3).

In a first stage a static analysis under permanent loads only has been carried out, so to establish the state of the church immediately before the main- shock. The revealed tension-compression stress distribution highlighted a satisfying global condition for the structure, with tensile stress always lower than the above limits (figure 11). Then, a response spectrum analysis has been carried out. Due to the absence of time-history registrations of the 2009 earthquake in Goriano Sicoli, both the horizontal and the vertical spectra used for the analysis have been referred to the data retrieved by the closest station (Ortucchio, ORC. Fig. 12). The horizontal spectrum has been therefore scaled to the PGA equal to 0.150 g, which has been previously evaluated by means of attenuation laws.

Moreover, the vertical PGA has been scaled to the value of 0.061g, which has been assessed considering that the crushing of the columns could be provoked only by this level of vertical acceleration.

The seismic input has been applied in the three directions, 100% in X, 30% in Y and 100% in Z. The modal results have been combined by applying the SRSS (Square-Root-of-Sum-of-Squares) summation method. The obtained outcomes have been therefore superimposed to the effects of gravity loads.

In figure 13 some results are described in terms of maximum principal stresses. It is possible to observe that the peak values are concentrated in those zones on which the most important damages have been revealed. For example, with reference to the aisle triumphal

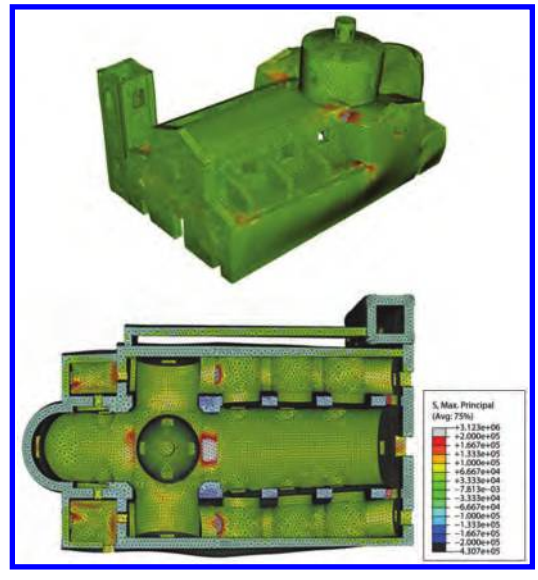

Figure 11. State of the church for gravity loads only.

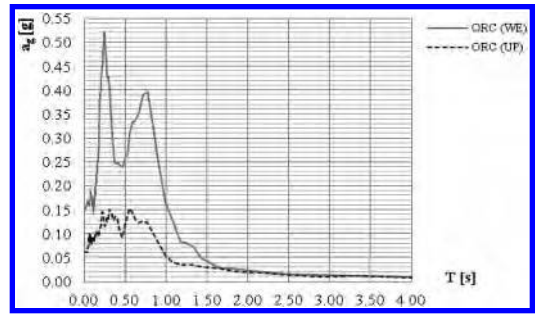

Figure 12. The scaled response spectra of the ORC (Ortucchio) Station used for the analysis.

arcs, maximum tensile stresses of 0.62 MPa have been detected, where deep cracks at the keystone have been surveyed. Also, in the vaults tensile principal stresses equal to five times the limit stress have been revealed, as they appeared the most damaged parts of the church. Finally, the model shows that on both the bell tower and the façade, the maximum tensile stresses evidenced by the numerical model (around 0.33 MPa vs. a limit value of 0.13 MPa) are consistent with the diffused state of crack provoked by the 2009 seismic event.

What has been stated above means that, although both the proposed analysis and modeling process are not able to capture the non linear behavior of the building, they allow to predict where the damages occur, giving important indications to well detect the possible interventions to be applied for retrofitting purposes.

4 CONCLUSIONS

This paper has provided a careful investigation on the damages provoked by the 2009 L'Aquila earthquake

Figure 14. Numerical stresses vs. revealed damages.

on the St. Gemma church in Goriano Sicoli, which has been selected as a representative sample of a wide population of churches belonging to the Sulmona-Valva diocese. After a careful survey conducted at regional level in order to highlight the main vulnerabilities activated during the seismic event on other similar buildings, the main outcomes obtained by Ambient vibration tests on the church under consideration have been described. These has allowed to put in evidence the presence of local modes of single macro-elements, as well as to calibrate a suitable FEM model that, subjected to a response spectrum linear analysis, provided a more careful interpretation of the occurred damages. These have been completely reproduced, as proved by the comparison between the model parts characterized by higher stresses and the cracked church zones. The validation of the proposed model allows to state that it is reliable for carrying out further analyses devoted to the identification of the most appropriate retrofitting techniques.

The strengthening and widening of the Okavango River Bridge in Northern Namibia

W. Martin
SMEC South Africa, Consulting Engineers

ABSTRACT: The Okavango River Bridge in northern Namibia near Divundu was originally designed and constructed in the 1970's to carry a 60 tonne army tank on a deck width of 5.5 m. The route across the bridge has become a major access between the harbour at Walvisbay and Zambia. This required the bridge to be widened to two lanes plus sidewalks and strengthened to carry abnormal loads. The prestressed concrete box girder deck was widened by extending the cantilevers along with a deck overlay. The strengthening was done using external prestressing inside the box along with vertical prestressing bars to increase shear capacity.

1 INTRODUCTION

The Okavango River Bridge is located in Northern Namibia at the start of the Caprivi Strip near the village of Divundu. The Okavango River drains southern Angola, passing through Rundu, then turning south at the start of the Caprivi Strip and finally flowing into the Okavango Delta.

The bridge, constructed in the 1970's, was originally designed to carry a 60 tonne army tank on top of the 5.5 m wide deck and to allow army troops to walk through inside the deck. As a result, all structural elements are robust and heavily reinforced.

The bridge was constructed via the Incremental Launching Method (ILM) with only concentric prestressing in the top and bottom slabs. There was no secondary stage draped prestressing after launching. This approach is rare in ILM decks. The long section of the bridge is shown in **Figure 1** while the deck cross-section before widening is shown in **Figure 2**.

After the construction of the Zambezi River Bridge near Katima Mulilo, this road now became a major access for heavy and abnormal vehicles travelling

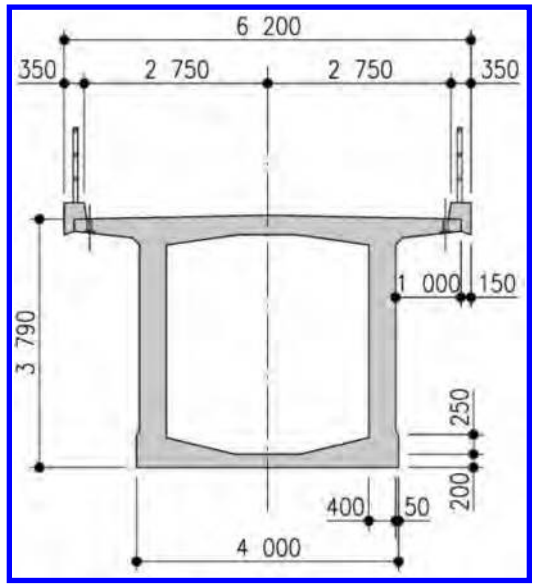

Figure 2. Deck cross-section before widening.

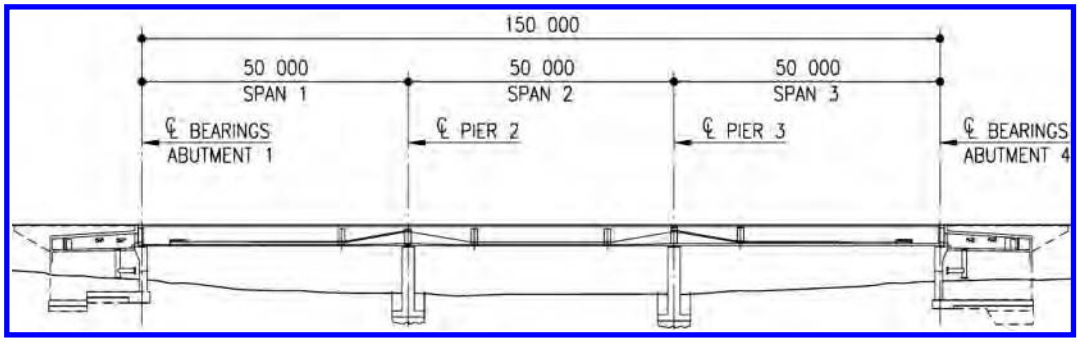

Figure 1. Long section of bridge.

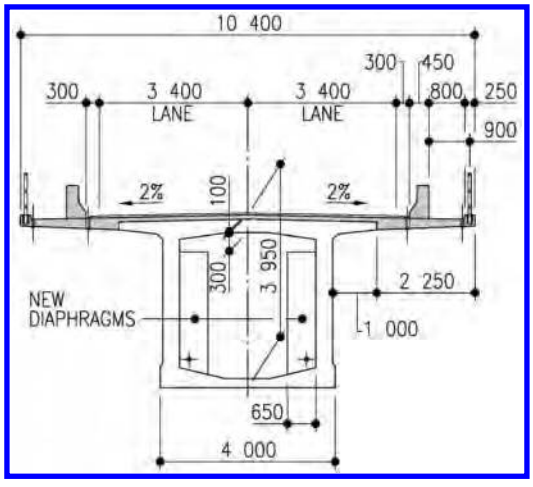

Figure 3. Widened bridge deck.

from the harbour at Walvisbay to Zambia and beyond, especially the Zambian Copper Belt.

The roadway on the existing bridge consisted of two lanes of 2.75 m, giving a total deck width of 5.5 m. This meant that when a heavy vehicle was on the bridge, traffic had to slow right down to allow vehicles to safely pass each other. As pedestrians also used the bridge, the increase in traffic volume made it unsafe for the pedestrians. The bridge therefore had to be widened to carry traffic and pedestrians as well as be strengthened to carry abnormal and heavy loads. Photographs of the bridge before, during and after the construction are given in **Figures 5 to 12**.

2 PRELIMINARY DESIGN

The bridge widening had to accommodate two lanes of traffic plus pedestrian traffic. After examining various standards including the Namibian Roads Agency standards, the Southern African Transport and Communications Commission (SATCC) standards and other southern African standards, the following road widths for the widening was agreed to: 2/3.4 m lanes, 2/0.3 m shoulders and 2/0.9 m sidewalks. To reduce loading on the widened portion, a 700 mm high concrete traffic barrier was placed between the traffic lane and the sidewalk as opposed to the more conventional position of outside the sidewalk. This prevented vehicles from accidently encroaching onto the sidewalk and reduced the design load on the sidewalk from vehicle traffic to pedestrian traffic. The trafficked way would therefore increase from 5.5 m to 7.4 m and pedestrians would be separated from vehicular traffic. The deck cross-section of the widened deck is shown in **Figure 3**.

This layout significantly improved the safety of the new bridge as the original bridge did not have any parapets to retain traffic on the deck, even though the deck was in excess of 10 m above the water level.

With regards increasing the capacity of the bridge, the piers and abutments could carry additional load but the deck could not. Several options were examined for the widening and strengthening. These included:

- Concrete overlay with external prestressing inside the box: Differential shrinkage and the low concrete design strength of 30 MPa made it difficult for this option to work;
- Cutting the concentric prestressing where not required, namely at the top at the mid-spans and at the bottom at the supports: this would reduce the high P/A and increase the capacity to carry additional load;
- Adding piers: This would reduce the forces associated with the live load. Having concentric prestressing would mean that no additional prestressing would be required;
- Shortening the end-spans by extending the abutments: The span configuration of 50-50-50 m is not ideal for carrying live load. As the end spans work the hardest under this configuration, shortening them will increase the capacity of the deck;
- Internal frame inside the box: This would consist of a steel frame over the supports extending to the quarter points of the spans where load would be "picked up" and transferred to the piers via this separate structure;
- Take pedestrians off the bridge by constructing a separate pedestrian bridge;
- Take pedestrians off the top of the deck by suspending a pedestrian walkway under one of the deck cantilevers;
- Take pedestrians off the top of the deck by allowing them to walk through the box, which was the original intention for soldiers crossing the bridge;
- For the widening with a concrete overlay, various options of supporting the widened cantilevers were examined including stiffening with transverse beams under the cantilever, propping off the bottom of the box and thickening the cantilever root to take the additional bending moment.

What was clearly obvious when examining the various options in greater detail was that the original concrete design strength for the deck of 30 MPa was a limiting factor. This low strength severely restricted the allowable bending stress and shear that the bridge could carry. It would also limit the design concepts that could be used for the widening and strengthening. It was therefore important to know what the actual strength of the deck was.

To verify the strength of the existing deck, twelve cores were taken and tested. These gave a mean strength of 55.6 MPa with a standard deviation of 4.6 MPa. This yielded a characteristic strength of 48 MPa. We could now increase the design stresses on the concrete by up to 60% without exceeding capacity. This opened new possibilities for the options for strengthening and widening.

After a comparison of the various options, the chosen option was to widen the deck using a concrete

overlay than extended the cantilevers. To carry the additional load, external prestressing inside the box would be added and the bearings would be replaced as the original bearings could not carry the additional load.

3 STRENGTHENING USING EXTERNAL PRESTRESSING:

In examining the forms of strengthening, both external and internal prestressing options were considered. External prestressing has the advantages of ease of installation, lower weight and replaceability. The advantages of increased durability are less significant in Southern Africa as de-icing salts are not used on our roads. However, external prestressing is infrequently used on Southern Africa with very few contractors and suppliers having experience in this. Internal prestressing is more conventional and more familiar to contractors: For internal prestressing, reinforced concrete beams containing the prestressing ducts can be dowelled into the webs of the deck inside the box. This does increase the weight of the structure. After examining the options, external prestressing was chosen, mainly for the lower increase in dead load.

There are some fundamental differences between external and internal prestressing: Firstly, external prestressing is un-bonded – at serviceability limit state (SLS), the behaviour is quite similar to internal prestressing. However at ultimate limit state (ULS), the stress in the prestressing does not increase as much as internal prestressing and with severe cracking and deformation, the eccentricity at mid-span can actually decrease, depending on the placement of the deviators. Therefore there is generally very little additional bending capacity at ULS. Secondly external prestressing is generally installed between the top and bottom slabs, resulting in it not having the higher eccentricities that internal prestressing would have by extending into the bottom and top slabs. This is not as significant in deep decks but becomes quite significant as the deck depth decreases.

4 DETAILED DESIGN

The design loading for the widened bridge included:

- Dead load (25.5 kN/m^3) and superimposed dead load;
- 100 mm asphalt overlay: This was to allow for future asphalt overlays. The actual surfacing placed on the deck was a 19 mm double seal;
- Full abnormal traffic loading consisting of NA (36 kN/m per lane decreasing with loaded length along with a 144 kN knife-edge load), NB36 (Four axles of 360 kN each) and NC30 (30 kN/m^2 on a loaded area of 5 m by 40 m) loading;
- Earthquake analysis using equivalent load method (3.3 kN/m);
- Temperature range (+/−21°C) and gradient;
- Braking (2.7 kN/m) and accidental skidding (250 kN);
- Wind (1.5 kN/m^2) and flood action (180 kN plus 20 kN/m);

The analysis of the deck incorporated a full beam FEM model including the following phenomena:

- The deck was modelled as a composite section whereby the differential creep and shrinkage between the original deck and the overlay widening was examined at various stages during construction and under traffic;
- External prestressing is un-bonded. Therefore the behaviour at ultimate limit state is non-linear;
- Bearing eccentricities and fixities were accurately modelled using spring elements and rigid connections;
- Moment rounding at supports was taken into account by using a 45 degree spread from the centre of the bearing to the centroid of the section. This reduces the theoretical peak bending moment that occurs directly above a bearing when modelling the deck as elements with no thickness, a weakness when using beam elements;
- NA traffic loading was modelled as a series of line loads and point loads positioned to give the maximum eccentric loading. This causes maximum torsion in the deck and maximum bearing loads.
- Staged construction, creep and shrinkage in the deck were modelled from the construction of the original deck to the construction of the new top slab in stages and on to 100 years design life. The relevant creep and shrinkage factors are applied by the program, dependent on the creep and shrinkage model chosen and time steps between the various stages of construction.

In combining the various permanent actions, traffic loads, supplementary actions and imposed deformations, a matrix of combinations was set up at each end of each element. The six matrix columns consisted of N, Vy, Vz, T, My and Mz, representing the beam end-forces. The twelve rows of the matrix consisted of the maximum and minimum values of each of the above. After doing the combinations, the first row consisted of the maximum N with associated forces, the second row consisted of the minimum N what associated forces and so on to the last line which consisted of minimum Mz with associated forces. This method avoids the conservative approach of combining the maximum of each force, irrespective of whether they can occur concurrently.

The strength of the deck at ultimate limit state was checked using a post-processor written in-house using Pascal. This took the combination matrix from the program and checked the various combinations for combined bending, shear and torsion in a box girder. The program has subsequently been rewritten in Excel using Visual Basic, making it more transparent and easier to verify.

The effect of creep and shrinkage due to the additional external prestressing and the differential creep

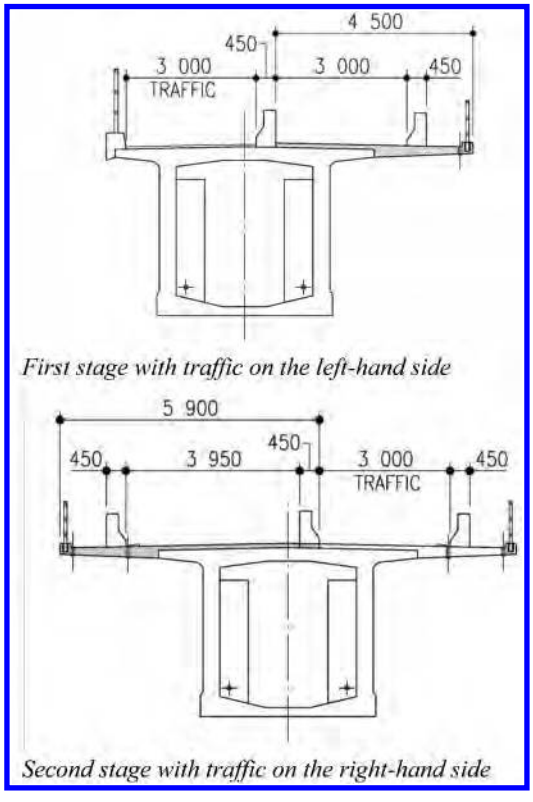

Figure 4. Bridge deck during construction.

and shrinkage due to the concrete deck widening was carefully modelled in the FEM model. As the original deck was in excess of 20 years old, creep and shrinkage effects in it were quite small once the axial shortening due to additional prestressing had taken place. Differential creep and shrinkage was significant due to the age difference between the widening and the original deck. This resulted in the stresses induced by the additional dead load becoming quite small in the widening, especially with time. However, under traffic the section behaves compositely with the additional stress being linear though the full depth of the section.

This also meant that the deck movement due to creep and shrinkage was quite small, resulting in less movement being required in the bearings and expansion joints than was required in the original deck

The longitudinal external prestressing was installed through reinforced concrete deviators above the piers, at the quarter points and at the deck ends as shown in **Figure 1**. The load was transferred from the deviators to the deck via dowels and through shear using Dywidag bars to create the normal reaction. As the concrete surface to the deck was scabbled before casting the deviators, the co-efficient of friction was taken as 1.0. The prestressing strand was cement-grouted in HDPE sheathing which passed though galvanized steel deviator tubes. These had bell-ends to accommodate construction tolerances. The external prestressing can be seen in **Figure 8**.

There was insufficient shear reinforcement in the existing webs close to the piers to carry the additional load. Vertical prestressing bars were installed inside the webs as shown in **Figure 8**. There was sufficient transverse reinforcement in the deck cross-section to carry this additional transverse bending.

On this project, traffic accommodation was a particular challenge. If the bridge were closed to traffic during construction, the detour for traffic from Walvisbay to Zambia would be several hundred kilometres longer and a ferry service would have to be provided for local traffic. The design therefor included the construction of the deck widening in two halves while keeping a 3.0 m lane open to traffic. This is shown in **Figure 4**.

During the construction of the first stage, a solid barrier was placed down the centre of the road to create a 3.0 m traffic lane while protecting the construction staff from traffic. The slab was dowelled into the exiting deck during this stage to ensure stability. The strength of the existing deck, the strength of the bearings and the stability of the whole structure had to be checked during the construction of this stage.

The deck widening was then completed during the second stage.

5 CONSTRUCTION

At the time of the design, funding for construction was limited and it was decided to do the construction in two stages: firstly strengthen the bridge to take abnormal loads, then secondly, when further funds became available, widen the deck. However, to keep overall construction costs down, it was decided to avoid duplication of construction actions in the two contracts as much as possible. The following design decisions were made in order to satisfy these requirements:

- Install all the external prestressing in the first contract.
- Replace the bearings in the first contract with bearings that would be able to carry the increased loads of the widening as well.

Fortunately the client was able to acquire sufficient funds resulting in both contracts going out as one contract.

Late delivery of the final bearings meant that the contractor had to replace the bearings while the top slab was being cast. This increased the load to be jacked and temporarily supported while the existing bearings were removed and replaced. This gave him little room to work in.

The contractor added an additional construction stage to the casting the top slab. The original design had this done in two stages. The contractor did this in three stages, giving him more space to work in. This also allowed more space for pedestrians to use the bridge at the same time as vehicle traffic.

The contractor was able to meet the very high specification for concrete mix design and curing.

Figure 5. Location of the bridge in the sparsely populated Caprivi Strip of northern Namibia.

Figure 6. The bridge before widening. The understrength and narrow deck has to share pedestrian traffic and heavy vehicle traffic.

Figure 7. Inside the box girder before strengthening. The inside was kept clear to allow people to walk through the deck.

This resulted in almost no plastic shrinkage cracks in the deck or subsequent differential shrinkage cracks. The deck surface was sprayed with bitumen before the double-seal surfacing was applied. This further reduced water-loss in the overlay, reducing shrinkage effects.

Figure 8. Inside the box girder after strengthening. Diaphragms, external prestressing and vertical prestressing is visible. Dywidag bars were used in the deviator diaphragms to increase the load transferred by shear.

Figure 9. Widening of the left-hand side under traffic. Panels were cast in lengths of 5 m.

Figure 10. Widening of the right-hand side of the deck under traffic: A cantilever frame was used above the deck to support the widening.

6 CONCLUSION

Widening and strengthening of large bridges do not happen too often so there is not much literature available

Figure 11. Bearing replacement after completion of the deck. Access platforms were used to finish off the cantilever soffits after removal of the formwork. Limited space for bearing replacement presented a challenge on site.

Figure 12. The widened bridge deck can now carry two lanes of vehicle traffic with two 900 mm sidewalks separated with a concrete barrier.

to assist in decision making. Some valuable lessons learnt from this project include:

- Deck width: in choosing the width for widening, the cost, additional load and most important of all, the long-term level of service needs to be considered. It is short-sighted to design for the next 10 years when the remaining design life is in excess of 50 years. At the time of design, the pedestrian traffic was quite low, hence the sidewalks of 900 mm. However, pedestrian traffic has increased significantly and the sidewalks are a little narrow when groups of people are passing each other;
- When adding diaphragms for strengthening, rather make them larger. The additional cost and weight is quite small compared to the increased flexibility and robustness. In attempting to keep the loads down, we made the diaphragms as small as possible. By making them a little larger, we would have made life easier for the contractor; and
- The vertical prestressing bars to carry additional shear did affect the construction programme as the top of the bar had to be anchored in the overlay slab. Access to the bottom anchor also presented a problem and at one stage the bottom anchor interfered with the installation of the replacement bearings. Alternative forms of strengthening such as steel plates or carbon-fibre sheets would have avoided these problems.

By providing an innovative deck overlay and external prestressing, we were able to prolong the life of a bridge without significant disruption to traffic during construction.

CFRP strengthening of steel I-beam against local web buckling: A numerical analysis

M.A. Ghareeb
Bemco Steel Industries, Saudi Arabia

M.A. Khedr
Faculty of Engineering, Benha University, Egypt

E.Y. Sayed-Ahmed
The American University in Cairo and Professor (on leave), Ain Shams University, Egypt

ABSTRACT: The use of Carbon Fibre Reinforced Polymers (CFRP) in strengthening of steel structural elements is growing every year. CFRP laminates offer an economic strengthening alternative for steel I-beams. The common method of using CFRP laminates in strengthening steel beams is by bonding the laminates (usually high modules type) to the lower flange of the beam to increase its flexural strength. However, for thin walled "slender" I-section steel beams, the risk of local buckling failure is also a major concern. Recently, it was found that bonding CFRP laminates to steel slender I-section web can enhance the local buckling of the steel section. Here, a numerical investigation is performed to investigate the effect of bonding CFRP laminates to the webs of I-section steel beams on the beam's flexural strength. The main advantage of this technique is delaying the onset of local buck-ling of the beam's web thus allowing the slender I-section to reach its yield flexural capacity. The study reveals that bonding the CFRP laminates to the web of I-sections significantly increases the critical load and may allow the beam to reach its yield capacity.

1 INTRODUCTION

Traditional strengthening techniques of steel beams involve an expensive process of welding/bolting steel plates to the beams' cross section. These plates are heavy, impractical and face many difficulties in site-installation. Fibre Reinforced Polymers (FRP) which are characterized by their high strength to weight ratio may offer an attractive strengthening alternative. FRP laminates/strips are currently adopted as one of the most successful strengthening techniques for different reinforced and prestressed concrete elements. On the other hand, investigations on strengthening steel structures using FRP are still limited, in most cases, to applying the laminates/strips to the tension flange of the beam in order to increase its flexural strength (Miller et al. 2001; Liu et al. 2001; Teng and Podolny 1998; Chajes and Swinehart 2002; Miller 2000; Moy 2001; West 2001; Cadei et al. 2004).

Furthermore, for thin walled I-section beams the risk of buckling failure is also a major concern. Steel I-sections subject to flexure are classified into compact, non-compact and slender sections. Compact sections of can develop the cross-section full plastic moment while non-compact sections are guaranteed only to develop the cross-section yield moment, then the section would fail by local buckling of its component plate elements before reaching the plastic moment. Slender sections suffer local buckling of the component plate elements before reaching the yield moment. FRP laminates may offer a good strengthening technique for slender section by delaying its local buckling and as such, changing the section class.

On another front, steel plate girders are widely used in buildings and bridges. They have good flexure capacity and serviceability performance due their deep webs. Environmental effects and substandard maintenance of plate girders can cause their main strength element to rust. Rehabilitation of such damaged sections could be very tricky. The traditional rehabilitation techniques are based on welding steel plates and stiffeners to the damaged web. However, one of the many disadvantages of this technique is the resulting elevated temperature due to the welding process which may cause more damage to the steel section. So FRP laminates may offer an attractive alternative in such cases.

Failure modes of CFRP strengthened steel I-section beams may take place via steel yielding, flange and/or web local buckling, rupture of the CFRP laminates, and/or de-bonding of CFRP laminates from the section (Buyukozturk et al. 2004). In most cases, an interactive failure mode between more than one of the previously mentioned modes may govern failure of the FRP

strengthened steel I-beam. An experimental investigation conducted by Lam and Clark, 2003 showed that bonding CFRP laminates to the tension flange of a compact I-section is not as effective as it is thought to be: only 9% increment on the strength of the compact section were achieved. The final and sudden failure occurred by shattering of the epoxy layer after the steel had reached its yield strength. The strength of the CFRP laminates was not fully utilized. The investigation also pointed-out that bonding CFRP laminates to the web of non-compact I-section beam increased the ultimate load by about 23% and also improved the buckling behaviour. Similar numerical investigation was conducted by Sayed-Ahmed (2004, 2006) which yielded the same previously mentioned conclusions.

More interestingly, the non-compact sections with web-bonded CFRP laminates in some cases were able to achieve steel yielding followed by formation of plastic hinge, and then the CFRP laminates deboned from the steel sections. It was found that bonding CFRP strips in such configuration may increase the critical load by a ratio ranging between 20% and 60% (Sayed-Ahmed 2004, 2006).

Here, a numerical model is developed based on the finite element technique and solved using a commercially available FE package. The model is used to analyse the effect of bonding Carbon Fibre Reinforced (CFRP) laminates to webs of slender steel I-beams. The numerical analysis is also used to investigate web buckling of these strengthened I-beams. The main objective of this work is to investigate the benefit of using high modules CFRP laminates in strengthening steel I-beams. The study also investigated the effect of increasing the thickness of the adhesive layer on the web stability of the CFRP strengthened I-beams.

2 FINITE ELEMENT MODEL

Steel beam composed of a built-up section (Figure 1) with a total length of 12.0 m is numerically modeled. The beam's web depth is 573 mm with a thickness varying between 2 mm and 12 mm which corresponding to compact, non-compact and slender sections. The two flanges of the beams are composed of 229 mm × 20 mm plates. Sections proprieties for the analyzed beams are listed in Table 1.

The beam is subjected to four points loading with points of applications shown in Figure 1. CFRP laminates are bonded to the beam's web with the configuration shown in Figure 1.

To prevent lateral torsional buckling, the beam is laterally supported every 3.0 m. The beam is simply supported at both ends. It is restrained against rotation around its longitudinal (weak) axis.

As shown in Figures 1 and 2, horizontal CFRP laminates are bonded to the web at mid height (mimicking plate girder's horizontal stiffeners). Other vertical CFRP laminates mimicking plate girder's vertical stiffeners are welded to the web in the configuration shown in Figures 1 and 2. All the CFRP strips are 100 mm wide by 1.4 mm thick. To study the effect of increasing the thickness of the adhesive layer which bonds the laminates to the steel web, two thicknesses are assumed, 1.0 mm and 1.4 mm.

Layered shell element (Figure 3) is adopted for modelling the steel and both the adhesive and the CFRP laminates. The element has 8 nodes with 6 degrees of freedom per node. For the web parts with the bonded CFRP laminates, five layers are used: central steel layer modelling the steel web, two layers modelling the epoxy adhesive and two outer layers modelling the CFRP laminates.

The constitutive model of steel beam follows a bilinear elastic-plastic stress-strain curve which has identical behaviour in tension and compression. The strain hardening modulus was assumed to be 5% of Young's modulus. The assumed initial yield stress of the steel material is 300 MPa and the Young's modulus was taken as 200 GPa. Poisson's ratio of 0.3 was adopted.

Two types of CFRP laminates are modelled: normal modulus laminates (S), and high modulus laminates

(H). The mechanical proper-ties of the CFRP laminates and the epoxy are shown in Table 2. Table 3 shows the mechanical properties of the adhesive material.

The layered shell element requires linear isotropic and multi-linear isotropic material properties to properly model the adhesive. The multi-linear isotropic material uses the von-Mises failure criterion (Willam and Warnke 1974). The modulus of elasticity of the adhesive and Poisson's ratio are obtained from the manufacturer's datasheet. Implementation of the material material model requires 9 constants to be defined. Only 4 constants are affecting the behaviour of the adhesive layer: shear transfer coefficients for an open

crack, shear transfer coefficients for a closed crack, uni-axial tensile cracking stress, (assumed to be 5.9), and uni-axial crushing stress (assumed to be 1.0). Typical shear transfer coefficients range from 0.0 to 1.0, with 0.0 representing a smooth crack (complete loss of shear transfer) and 1.0 representing a rough crack (no loss of shear transfer). The shear transfer coefficients for open and closed cracks are assumed to be 0.2 and 1.0, respectively. The adopted finite element mesh, boundary conditions and loading are shown in Figure 4.

3 RESULTS AND DISCUSSION

A linear elastic buckling analysis on each steel beam is performed to evaluate the critical loads which initiate web buckling.

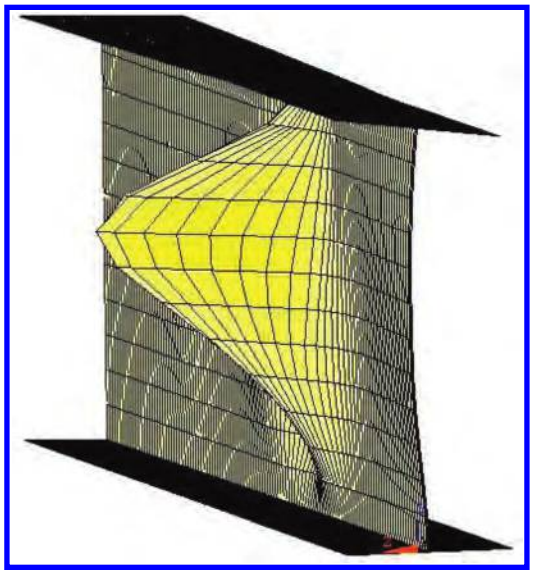

Figure 5. Modelled steel beam deformed shape at web buckling.

For each class of beams, five types of beams are analyzed. The first type (D1) is the control beam with no CFRP laminates bonded to it. The second type (D2-S-1) is strengthened with normal modulus CFRP laminates with the CFRP arrangement shown in Figures 1 and 2: the thickness of the adhesive layer is 1.0 mm. The third type (D2-S-1.4) has the same CFRP laminates arrangements and the same laminates type but the thickness of the adhesive layer is 1.4 mm. The forth type (D2-H-1) has the same CFRP laminates arrangements as the third beam but the type of laminates is high modulus CFRP: the thickness of the adhesive layer is 1.0 mm. The fifth type (D2-H-1.4) has the same CFRP laminates arrangements and the same type of laminates but the thickness of the adhesive layer used is 1.4 mm.

Eigen buck-ling analysis was performed for all the beams: Figure 5 shows the deformed shape of the one of the analyzed beams. The full results of these analyses are shown in Table 4. The Table reveals that bonding the CFRP strips to web of slender sections significantly delayed web buckling and increased the critical load by about 31%. For non-compact section, the enhancement in the critical load is in the order of 16%.

Using high modules CFRP laminates in the configurations shown in Figures 1 and 2 increased the critical load from 24% to 29% for slender sections. Increasing the adhesive layer thickness from 1.0 mm to 1.4 mm had no significant effect on the critical load: only a 2% strength enhancement is achieved. Table 5 shows a comparison between the calculated yield moment M_y and the calculated plastic moment M_p to the failure moment obtained from the finite element analyses. The results show that for beam no. 3, the use of the suggested strengthening technique increased the ratio of the failure moment to the yield moment from 0.49 to 0.56. For beam no. 4, the ratio is increased from 0.07 to 0.10.

4 CONCLUSIONS

The effect of bonding CFRP strips to the webs of thin-walled I-section steel beams on the beam's flexural strength is numerically investigated. The main advantage of this detail is delaying the local buckling of the beam's web. Nonlinear finite element analyses were performed on steel I-section beams with different web height-to-thickness ratios. The effect of bonding 100 mm × 1.4 mm CFRP strips on the critical load initiating web buckling is evaluated. It is found that bonding CFRP strips in such configuration may increase the critical load by a ratio of 24%. Increasing the tensile modules of CFRP strips will enhance the performance of the configurations by additional 5%. The effect of increasing the adhesive layer thickness is also studied and was found to be negligible.

Timber beams with external strengthening based on CFRP and GFRP composites

M. Karmazínová
Brno University of Technology, Brno, Czech Republic

ABSTRACT: The paper is focused on the possibilities of the usage of fibre-reinforced polymers or polymer composites respectively, to strength timber structural members of load-bearing civil engineering structures, in the case of reconstructions, for example. Strengthening timber beams using external reinforcement based on carbon-fibre-reinforced or glass-fibre-reinforced polymer (CFRP or GFRP) composites appears the advanced way. The paper deals with the problems of the application of externally bonded lamellas based on CFRP and GFRP composites for strengthening timber beams to increase their load-carrying capacity and stiffness, in the case of reconstructions of existing building constructions (e.g. historical buildings), for example. During the process of the beam resistance investigation the attention is mainly paid to increasing load-bearing capacity in connection with increasing stiffness of the beams strengthened by lamellas mentioned. In the paper, mainly the information obtained from the experimental research is presented, that means especially outcomes of the experimental verification of the actual behaviour, failure mechanism and load-bearing capacity of the beams strengthened. For this reason, loading tests of two sets of timber beams strengthened by CFRP lamellas have been performed and subsequently test results have been elaborated and statistically evaluated. For the solution of this problem the theoretical analyses using analytical and numerical tools and experimental verification using loading and material tests including advanced methods of the test results evaluation are used. The research has been oriented to several particular problems and in connection with this, to the following arising results: (i) results of the parametric and comparative studies to choose the available beam cross-sections for experimental investigations, (ii) results of the loading and material tests to obtain actual objective resistances and material properties for subsequent numerical analysis, (iii) the efficiency of the application of CFRP and GFRP for strengthening timber beams including their comparison.

1 INTRODUCTION

The strengthening lamellas considered are being developed and produced by the company of PREFA KOMPOZITY, Inc. at Brno city in Czech Republic. The examples of some available products – CFRP reinforcement commercially named PREFACARB, in the forms of lamella and matting, are shown in Fig. 1. These types of the lamellas are usually based on epoxy resin reinforced by carbon fibres.

Usually and recently even on a mass scale, these lamellas are being used for strengthening masonry and concrete load-bearing structures, especially to strength floor structures of existing building constructions. To the contrary, their usage for strengthening timber load-bearing members is not so wide, and for strengthening steel members, CFRP lamellas are used very sporadically only and GFRP lamellas are not used at all. In the case of strengthening steel structural members, the problematic usage is caused by GFRP and CFRP material properties in relation with material properties of steel. Carbon-fibre and also glass-fibre reinforced polymers have a high tensile strength, which is (much) higher than steel tensile strength, but the Young's modulus of elasticity is not so high, especially in the case of GFRP, even much less than steel modulus.

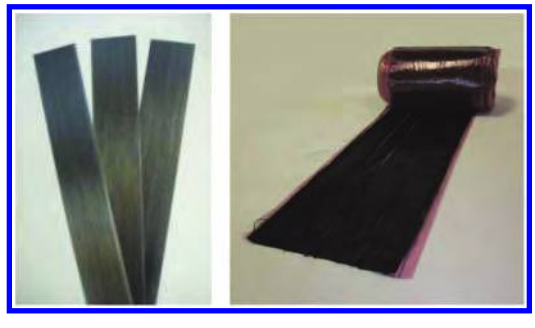

Figure 1. Examples of CFRP reinforcement PREFACARB (see www.prefa-kompozity.cz): a) lamella, b) matting.

For that, CFRP and GFRP usage for steel beams strengthening can give a higher load-bearing capacity, but not adequately high flexural stiffness, which negatively influences the deflections. However for timber beams strengthening, the values of tensile strength and Young's modulus of CFRP and GFRP composites are enough high in relation to the corresponding properties of timber.

2 EXTERNAL NON-METAL REINFORCEMENT BASED ON CFRP AND GFRP COMPOSITES

Non-metal reinforcements based on CFRP or GFRP are applied in the form of lamella externally bonded to the surface of the strengthened structural member.

In standard case, CFRP lamella material contains epoxy resin and high-strength carbon fibre reinforcement. The dimensions of cross-sections of produced lamellas vary in the range from 30×1.0 mm to 50×1.4 mm; the density of this CFRP composite is approximately in the range of 1 600–1 800 kgm^{-3}. The mean value of CFRP tensile strength derived from producer performed material tests is declared as $f_{CFRP} =$ 3 000 MPa, the mean value of Young's modulus of elasticity is given as $E_{CFRP} = 155$ GPa.

The material of GFRP lamella usually consists of polyester or vinyl ester (usually, for difficult long-term applications) resin and glass-fibre reinforcement. Usual produced GFRP lamella cross-sections are in the same range as CFRP lamella dimensions; the density is in the range from about of 2 000 kgm^{-3} (usually) to 3 000 kgm^{-3} (exceptionally). The mean value of GFRP tensile strength is $f_{GFRP} = 1\,000$ MPa, the mean value of Young's modulus of elasticity is $E_{GFRP} = 55$ GPa.

CFRP and GFRP lamella reinforcements mentioned above are used for the additional strengthening of concrete, timber, metal and other load-bearing structural members. The product may be used to increase the load-bearing capacity of existing constructions if the load has been increased, the load-bearing members have been damaged, and the improvement of utility properties or changes of static behaviour are required. The load increasing can be caused, for example, by operational loading effects increasing or heavy equipment adding. The damage of load-bearing structural members can occur as a result of the accidents (vehicle impacts, fire), degradation of building materials, corrosion of steel reinforcement in concrete, initiation and propagation of cracks and others. The improvement of utility properties means, for example, the requirement to decrease the deflections or to increase the ride height. The changes of the static behaviour can be caused by decreasing of the support number or creating new holes in horizontal and vertical structures.

The usage of composite reinforcement is appropriate in the field of the material properties, but also in the field of the realization. CFRP and GFRP composites have a low weight, which allows the simple installation and easy manipulation without supporting during glue hardening and application to vertical walls and to bottom side of floor structures. Due to the small thickness it is possible to cross the lamellas; the maintenance requirements are minimal due to the high resistance to environment influences. The most important advantages of reinforcing element are the high strength and high fire, chemical and corrosion resistance. Polymer composites also have a low temperature conductivity and are electrically non-conductive and electro-magnetic transparent.

3 THEORETICAL ANALYSIS OF LOAD-BEARING CAPACITY FOR "FRP-TIMBER"

For the determination of load-bearing capacity of the beam strengthened by externally bonded CFRP or GFRP lamella the approach similar to steel-concrete composite beams offers to be applied. However, it is necessary to take into account the actual behaviour of the strengthened beam regarding the character of the material of basic cross-section, i.e. timber. Due to the non-plastic character and inability of the full plastic behaviour, no typical plastic zones can occur in timber beams. For that, assumptions of the elastic behaviour have been applied to the determination of the load-bearing capacity of the strengthened beam.

3.1 *Normal stress*

Assuming the rigid shear connection between timber and FRP lamella the relative deformations of timber and FRP reinforcement in the contact are the same, i.e. $\varepsilon_{timber} = \varepsilon_{FRP}$. Then, for the calculation of normal stresses and determination of bending moment capacity, the general concept of composite ideal (substitute) cross-section (Ascione et al. 2007, Cadei et al. 2004, Gilfillan et al. 2003) based on parameter n

$$n = \frac{E_{timber}}{E_{FRP}}, \tag{1}$$

where E_{timber}, E_{FRP} are Young's modulus of elasticity of timber and FRP reinforcement, can be applied.

The assumed normal stress distribution in "FRP-timber" cross-section based on the elastic approach is shown in Fig. 1, where σ_{timber} is timber stress on the tensile edge of the beam and σ_{FRP} is the stress in FRP reinforcement. The values of normal stresses in the cross-section can be generally calculated as:

$$\sigma_{timber} = \frac{M}{I_i} \cdot z_{timber}, \tag{2}$$

$$\sigma_{FRP} = \frac{M}{n \cdot I_i} \cdot z_{FRP}, \tag{3}$$

where M is the bending moment, I_i is the second moment of area of the ideal cross-section, and z_{timber} and z_{FRP} are the corresponding distances from the gravity centre of the substitute cross-section.

Basic characteristics of the ideal cross-section of the composite member that means cross-section area A_i and the second moment of area I_i are generally given as follows:

$$A_i = A_{timber} + \frac{A_{FRP}}{n}, \tag{4}$$

$$I_i = I_{timber,i} + \frac{I_{FRP,i}}{n}, \tag{5}$$

Of course, the formulas for the cross-section characteristics of FRP parts and for normal stresses in

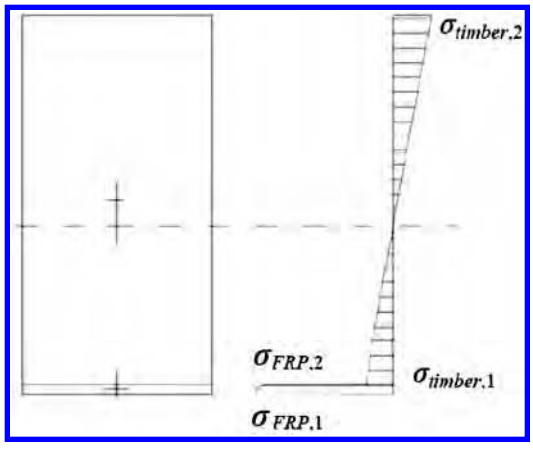

Figure 2. Elastic distribution of normal stress in "FRP-timber" cross-section.

FRP parts include parameter n, which arises from the principle described above and it is also evident from equations (3), (4), (5).

3.2 *Longitudinal shear stress*

Based on the ideal cross-section conception, the longitudinal shear force V_{long} (per unit of the length) at the interface between FRP reinforcement and timber can be calculated as

$$V_{long} = \frac{V \cdot S_i}{I_i} \quad [\mathrm{Nmm^{-1}}], \tag{6}$$

where V is the (transverse) shear force, S_i is the first (static) moment of the cut off part of the area, I_i is the second moment of area. Then, the longitudinal shear stress in the interface between timber and FRP can be given as

$$\tau_{long} = \frac{V \cdot S_i}{b \cdot I_i}, \tag{7}$$

where b is the width in the corresponding place of the cross-section, that means in this case it is the width of the glued area, i.e. the width of FRP lamella, because it is bonded over its all the width.

4 EXPERIMENTAL VERIFICATION OF LOAD-BEARING CAPACITY FOR "CFRP-TIMBER"

4.1 *Loading tests arrangement and realization*

For the experimental verification timber beams with CFRP lamellas have been chosen. The specimens of following geometrical and material parameters have been tested: (i) timber beams of rectangular cross-sections 100 / 220, 100 / 200, 100 / 180, 100 / 160, 100 / 140, 100 / 120 have been used; two spans in dependence of cross-section dimensions have been

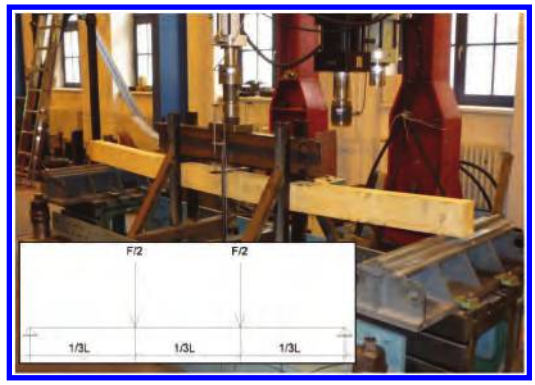

Figure 3. Arrangement and performance of loading tests.

Figure 4. CFRP lamella and strain gauges bonded to bottom (tensile) beam edge.

considered, i.e. $L = 4$ m (cross-sections of 100 / 220, 100 / 200, 100 / 180) and $L = 3$ m (cross-sections of 100 / 160, 100 / 140, 100 / 120); the grade of used timber was declared as the class of C 24 – timber quality of timber has been verified by material tests, that characteristic strength of 24 MPa and Young's modulus of elasticity 10 GPa have been confirmed; (ii) CFRP lamellas of cross-section of 50×1.2 with the tensile strength of 3 000 MPa and Young's modulus of elasticity of 155 GPa have been used.

Totally 18 non-strengthened timber beams (3 test specimens for each cross-section mentioned above) and 18 CFRP-strengthened timber beams (the same cross-sections with 3 specimens in each group) have been tested. The test specimens have been simply supported and loaded by the force F introduced as forces F / 2 to the beam span thirds, that means 4-points bending has been applied (see scheme and illustration in Fig. 3).

Illustration of the arrangement and realization of loading tests is shown in Fig. 3, CFRP lamella and strain gauges bonded to the bottom beam edge are seen in Fig. 4, as well as the examples of typical failure mechanisms, which are shown in Fig. 5.

4.2 *Particular test results*

Actual load-bearing capacities of "CFRP-timber" beams, that means ultimate moments obtained from loading tests, are listed in Table 1, as well as the predicted theoretical load-bearing capacities calculated as elastic bending moments with mean values

Figure 5. Examples of typical failure mechanisms.

Table 1. Load-bearing capacity of "CFRP-timber" beams: theoretical elastic moment capacity $M_{u,th}$ vs. experimental ultimate moments $M_{u,exp}$

Cross section	$M_{u,th}$ kNm	$M_{u,exp}$ kNm		
100 / 220-C	31.35	36.44	33.14	31.54
100 / 200-C	26.09	30.71	26.64	28.73
100 / 180-C	21.30	24.69	17.42	21.37
100 / 160-C	19.56	23.13	19.76	20.13
100 / 140-C	15.60	18.00	16.35	16.37
100 / 120-C	11.32	14.32	9.88	14.02

of measured timber strength and with mean values of Young's modulus of both materials.

In Figs. 6 and 7, the relationships of the deflections to bending moments during loading progress – "M – w" diagrams, are drawn. The theoretical elastic load-bearing capacities are added to these diagrams.

"M – w" diagrams mentioned may be used for the investigation of the rigidity of strengthened beams, to determine the actual flexural stiffness EI and the second moment of area I_i of the ideal cross-section, respectively. Using the actual moment I_i the interaction between CFRP lamella and base timber beam, among others, can be verified. The mutual interaction of both section parts, ensuring sufficient cross-section stiffness, assumes the fully rigid shear connection between both parts and is the necessary condition for the rightness of the elastic calculating approach based on the ideal (substitute) cross-section.

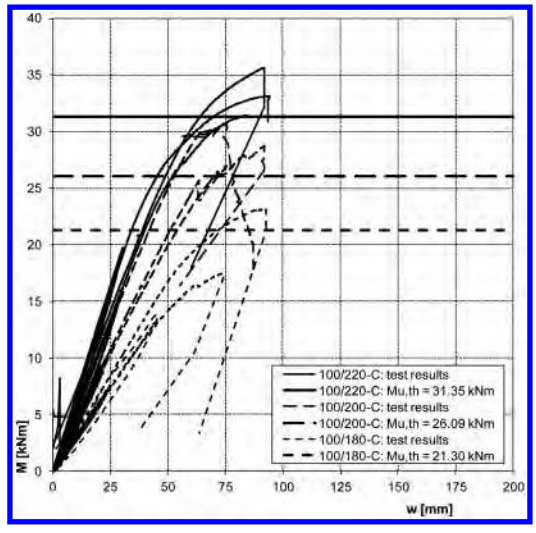

Figure 6. Test results and theoretical elastic capacities $M_{u,th}$: "CFRP-timber" sections 100/220-C, 100/200-C, 100/180-C.

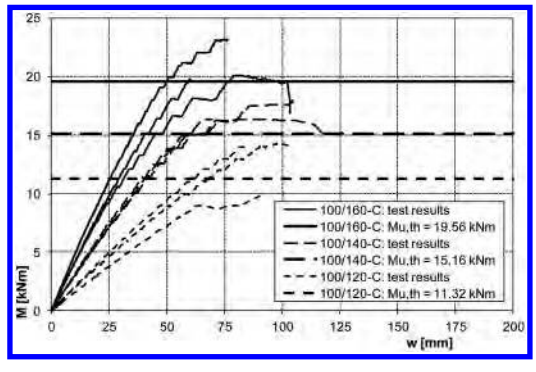

Figure 7. Test results and theoretical elastic capacities $M_{u,th}$: "CFRP-timber" sections 100/160-C, 100/140-C, 100/120-C.

From the deflection of simply supported beam loaded by forces F / 2 in the span thirds (4-points bending – see above), the flexural stiffness is

$$EI_i = \frac{23}{648} \cdot \frac{(F/2) \cdot L^3}{w} = \frac{23}{216} \cdot \frac{M \cdot L^2}{w}. \quad (8)$$

In the format (8), the ratio M / w can be substitute using this dependence taken from the linear part of "M – w" diagrams. Then, considering Young's modulus of timber by the value of 10 GPa (as above), the second moment of area can be expressed from the stiffness EI_i. The actual second moments of area $I_{i,exp}$ calculated according to the formula (8) using test results, in comparison with the theoretical second moments of area $I_{i,th}$, are listed in Table 2.

From Table 2 it is seen, that the actual second moments of area obtained rom the tests using formula (8) are in average by 2.4 % less only, than the theoretical. For comparison, the corresponding values have

Table 2. Second moment of area of "CFRP-timber" beams: theoretical $I_{i,th}$ vs. experimental $I_{i,exp}$

Cross section	$I_{i,th}$ mm^4	$I_{i,exp}$ mm^4	$I_{i,exp}/I_{i,th}$ —
100 / 220-C	$99.65 \cdot 10^6$	$102.22 \cdot 10^6$	1.026
100 / 200-C	$75.66 \cdot 10^6$	$77.44 \cdot 10^6$	1.024

100 / 120-C	$17.57 \cdot 10^6$	$16.52 \cdot 10^6$	0.940
Mean value of $I_{i,exp}/I_{i,th}$			0.976

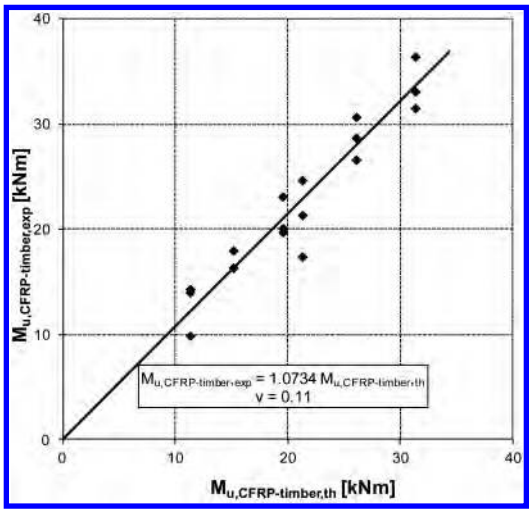

Figure 8. Comparison of experimental and theoretical load-bearing capacities (i.e. elastic moment capacity calculated for actual material properties) of "CFRP-timber" beams.

been also derived from the normal stresses measured on the surface of CFRP and timber on the bottom edge of the beams. The stresses have been obtained from the strains measured by strain gauges. The stress analysis going, among others, to the flexural stiffness, is in detail described in (Karmazínová 2013), for example. Based on that stress analysis, the mean value of the actual second moment of area derived from the tests was by 2.2 % more than the theoretically calculated value. The insignificant difference is probably caused by the errors of measuring instruments, which usually vary in the range of about from 2 % to 3 % and fully covers the differences. Thus, these two methods how to determine actual stiffness and the interaction of both cross-section parts give the same results and may be considered as essentially equivalent. In addition, using both procedures the results of one of them can be verified by the second one.

According to the experimental results described above, it may be assumed, that the concept of the capacity calculation arising from the elastic approach based on the ideal cross-section is applicable and appropriate. It can also be proved by Fig. 8 (see also test

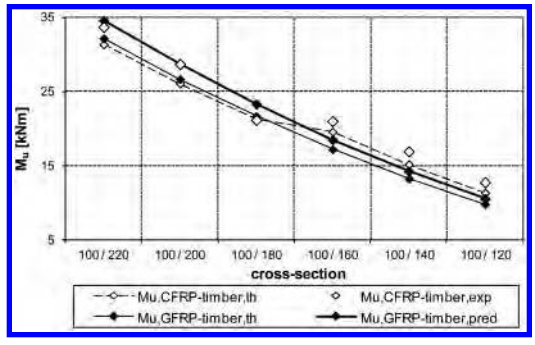

Figure 9. Comparison of load-bearing capacities: theoretical and experimental capacity of "CFRP-timber" beams; theoretical and predicted capacity of "GFRP-timber" beams.

evaluation in Karmazínová 2012a), where the comparison of test results with elastic calculation is seen and relationship and variation coefficient also show the suitability of elastic approach.

The effect of CFRP strengthening to the timber beams resistance increasing is significant related to the elastic behaviour only, if the lamellas of given geometrical and material parameters used; then, the usage of GFRP lamellas could be probably more effective because of more appropriate material properties, and thus because of more efficient utilization.

5 THEORETICAL PREDICTION OF LOAD-BEARING CAPACITY FOR "GFRP-TIMBER"

Because the configuration and technology of timber structural members strengthened by GFRP lamellas, here "GFRP-timber" beams, are practically identical with "CFRP-timber" beams, it may be expected, that the behaviour is very similar. So that, it is assumed, that the load-bearing capacity of both types of FRP-strengthened timber beams may be calculated according to the same approaches and principles.

Therefore, the theoretical prediction of expected load-bearing capacity of "GFRP-timber" beams is also based on the elastic concept using ideal (substitute) cross-section. The load-bearing capacities of "GFRP-timber" beams have been determined for the same timber and GFRP lamella cross-sections and the same timber properties as for "CFRP-timber" beams, and for the following material parameters of GFRP lamella: tensile strength of 1 000 MPa and Young's modulus of elasticity of 55 GPa.

To predict the expected load-bearing capacities of "GFRP-timber" beams, it is possible to arise from experimentally verified results of "CFRP-timber" beams, which confirm, that the actual bending moment capacity is about by 7.5 % higher (see Fig. 8) in comparison with theoretically calculated capacity. Because the cross-section configuration of "GFRP-timber" beams is analogical and the technology is the same as in the case of "CFRP-timber" beams, it may be concluded, that increasing in load-bearing capacity also

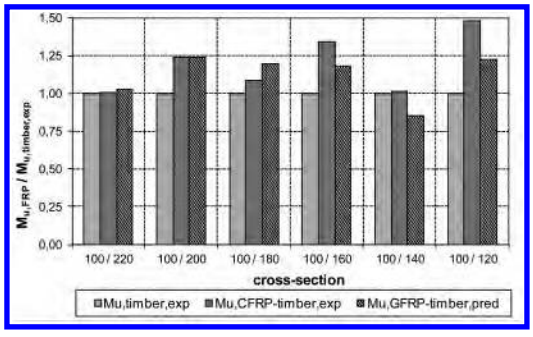

Figure 10. Relative comparison of load-bearing capacities: experimental capacities of "CFRP-timber" beams and predicted capacities of "GFRP-timber" beams in relation to experimental capacities of timber (only) beams.

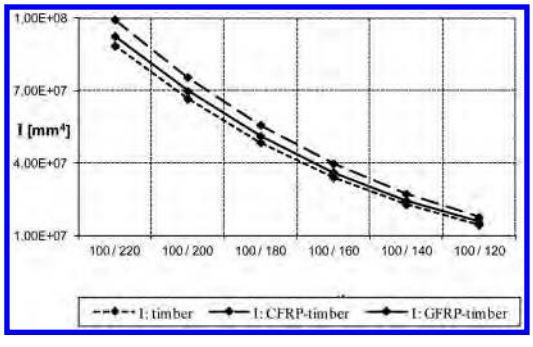

Figure 11. Comparison of second moments of area: "CFRP-timber", "GFRP-timber", timber only.

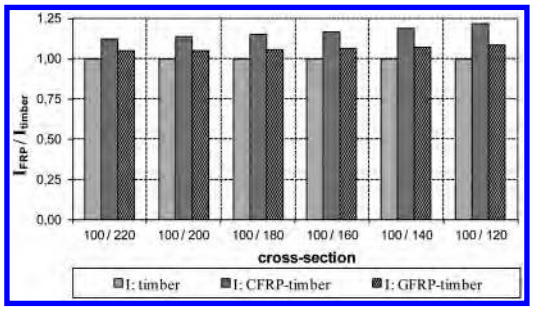

Figure 12. Relative comparison of second moments of area: "CFRP-timber" and "GFRP-timber" in relation to timber only.

can be in the range from about 7 % up to 10 % maximally, related to the theoretical elastic calculation, as shown in Figs. 9 and 10.

The same principle can be also used for the prediction of the second moment of area. In the text above it is seen, the actual second moment of area of "CFRP-timber" section is practically the same as the theoretical value based on the ideal cross-section principle. Then, the second moment of area of "GFRP-timber" section can be also calculated using the elastic approach based on ideal cross-section concept. The comparison of the second moments of area is depicted in Figs. 11 and 12.

6 CONCLUSIONS

From particular results verified experimentally, for "GFRP-timber" or "CFRP-timber" beams following partial conclusions may be deducted: (i) actual load-bearing capacity can be derived using the elastic calculation and increased about by 7 to 10 %; (ii) actual flexural stiffness can be determined as the stiffness of the ideal cross-section, practically exactly.

ACKNOWLEDGEMENT

The paper has been elaborated within the solution and financial support of the research projects of the Czech Ministry of Education, Youth and Sports: CZ.1.05/2.1.00/03.0097 (Centre of "AdMaS") and FAST S-11-32/1252 (university specific research).

Bond characterization between historical concrete substrate and SRG/SRP strengthening systems

E. Stievanin, F. da Porto, M. Panizza, E. Garbin & C. Modena
Department of Civil, Environmental, Architectural Engineering, University of Padova, Italy

ABSTRACT: Strengthening of existing reinforced concrete structures by using composite materials has been growing in popularity, since they are characterized by high strength-to-weight ratios and good versatility. Recently, beside common Fibre-Reinforced Polymers (FRP) that consist in various types of fibres (e.g. carbon, glass, aramid, basalt, etc.) embedded in a plastic matrix, mostly epoxy, new composites have been introduced; they are characterized by the use of small high-strength twisted steel wires as resisting elements, combined either with cementitious grouts (SRG) or epoxy (SRP) as matrix. Epoxy resins are widespread as composites matrix and adhesive, however they require special attentions like fireproof and UV protections; moreover, their substantial impermeability might cause compatibility problems, especially in the case of historical RC structures. Based on these observations, SRG have been developed to combine traditional materials, i.e. cementitious mortars and steel, in order to reach structural performances comparable to FRP materials, and meet additional requirements such as a lower cost, a simpler application and an improved compatibility with the original substrates. However, the structural performance of such strengthening systems strongly relies on the bond between reinforcement and substrate. The present work deals with the bonding performance of both SRP and SRG composites applied to a historical concrete substrate, investigated through pull-off and tangential shear tests. The influence of steel fibres and matrix (organic or inorganic) has been studied by combining two types of steel wires with either epoxy or cementitious mortar. Concrete samples were removed from the decommissioned St. Francesco bridge in Veneto (Italy), built in the Fifties: this allows testing the reinforcement bond performances on an historical concrete characterized by a mix design completely different from current ones. Pull-off and shear tests were carried out after a preliminary phase of material characterization, aimed at identifying materials mechanical properties, namely substrate, cementitious mortar and steel fibres.

1 INTRODUCTION

Repair of existing structures is often coupled with interventions needed to increase their load bearing capacity or their resistance against seismic actions.

The use of FRP (Fibre Reinforced Polymers) has become widespread during last decades (Meier 1995, Valluzzi 2008) for the strengthening of concrete and masonry structures. They are characterized by high strength, also in fatigue (Kim et al. 2008), and stiffness, low density, and versatility of application (da Porto et al. 2012). They exhibit excellent properties against corrosion and wear, combined with a low impact due to their good structural performances, related to very high strength-to-weight and elastic modulus-to-weight ratio.

FRP consist of fibres (mostly carbon and glass, but also aramid, basalt, and others) coupled to organic matrices (mostly epoxy) that bind fibres together and transfer stresses between fibres and substrate. On the other hand, these materials present some shortcomings to be accounted for, like an overall linear elastic behaviour until failure, a low shear resistance (perpendicularly to the fibres), a certain vulnerability to high temperatures, beside the absence of vapour permeability and relatively high costs.

Moreover, epoxy resins require certain additional precautions during their application. Catalysis reactions of the epoxy resin are strongly influenced by temperature: above 25–30°C, they considerably accelerate, while below 5°C the hardening hardly triggers. The presence of moisture can worsen the normal catalysis reaction as well, therefore substrates should be dry and possibly protected from rain. Skilled manpower and protective equipment are required, as epoxy resins have a certain toxicity.

Furthermore, in case of fire, high temperatures change epoxy properties and may compromise the effectiveness of the strengthening, therefore fireproof systems and protective coatings are required.

To overcome some of the limitations related to FRP, the use of steel fibres as resisting element, or composite materials with inorganic matrices, has been promoted in recent years (Huang et al. 2004). These systems are generally obtained coupling thin high-strength steel wires with either epoxy (SRP) or cementitious grouts (SRG), or adopting meshed fibres element suitable to be impregnated with mortars

Table 1. Cementitious mortars compared to epoxy resins as matrices for composite materials

	matrix type	
behaviour to high temp.	cementitious as the substrate	epoxy resin loss of consistence above 80°C
substrate moisture	helps adhesion	must be absent
workability	good	quick curing; temp. dependent
vapour permeability	yes	no
viscosity	high (tricky impregnation)	rather low
toxicity	rather low	protective equipment required

(TRM). A comparison of the main features / differences between cementitious and epoxy matrices is depicted in Table 1 (Stievanin 2012).

2 SCOPE

This paper presents and analyses the preliminary results of an experimental investigation about the effects of matrix type and steel fibres type on the bonding performance between historical concrete substrates and steel-based composite materials. Two commercially available thin steel wires (labelled as *fid* and *db*) were used as resisting element, while a cementitious mortar and a bi-component epoxy resin were adopted as matrix, thus obtaining four matrix/fibres combinations. Concrete samples used as substrate were extracted from the deck of St. Francesco bridge, a decommissioned structure located in Veneto (Italy) and built in the Fifties, therefore having mix design and mechanical properties rather different from modern concrete elements.

The experimental program was carried out in two phases. In the first one, pull-off tests were carried out on two strips of composite materials made by the cementitious mortar coupled with the two types of steel wires; epoxy was not tested since its behaviour is supposed to be known and, therefore, not relevant in this case. In the second phase, eight tangential bond tests (shear tests) were performed using four combinations of matrices (organic and inorganic) and steel fibres.

3 MATERIALS

3.1 *Concrete substrate*

In order to test concrete mechanical properties, nine cores were cut from a piece of slab obtained during the demolition of the bridge: six of them tested in compression (according to UNI EN 12390-3: 2003), the other three used to measure the elastic modulus (according to UNI 6556: 1976).

Table 2. Mechanical properties of concrete substrate and cementitious mortar (matrix).

ID	f_c [N/mm^2]	f_f [N/mm^2]	E_c [N/mm^2]
concrete	52.5	4.46*	33500
mortar	26.7	5.43	17800

* estimated according to Italian Building Code

Values of compressive strength (f_c), flexural strength (f_t) and elastic modulus (E_c) are shown in Table 2.

3.2 *Mortar matrix*

The cementitious mortar used as matrix is characterized by a fine particle size (less than 0.8 mm) to allow an easier and more effective impregnation of the steel fibres.

Compressive strength, flexural strength and elastic modulus were obtained by testing prismatic specimens ($40\times40\times160$ mm^3), according to UNI EN 1015-11: 2007 and UNI EN 13412: 2007, respectively.

Average values ?are listed in Table 2.

3.3 *Steel fibres*

The tested strengthening systems were made using two different steel reinforcements, characterized by similar mechanical properties, but different density and strand geometry.

The first one, Fidsteel 3X2-B 4-12-500 (herein labelled *fid*) is produced by Hardwire LLC. It is made of unidirectional twisted wires of Ultra High Tensile Strength Steel (UHTSS), about 6 mm spaced (1.57 strands/cm). Each steel strand is made by 5 wires: 3 straight filaments wrapped together by other 2 having a high curvature radius.

The second steel reinforcement (labelled *db*) was provided by Dalla Betta Group. It is composed by brass-coated unidirectional steel cords, about 3 mm spaced (3.15 strands/cm). Each strand is made by 19 wires twisted together.

For each reinforcement type, characterization tests were performed on both single wires and strands, according to ISO 6892-1.

Results are summarized in Table 3.

4 PULL-OFF TESTS

4.1 *Specimens preparation*

A concrete slab 16 cm thick, extracted from the deck of St. Francesco bridge, was used as substrate for the application of two SRG systems made coupling *fid* and *db* steel reinforcements to the inorganic matrix. Concrete surface was mechanically roughened to facilitate the adhesion of the composite materials. Dust was

* value from experimental tests

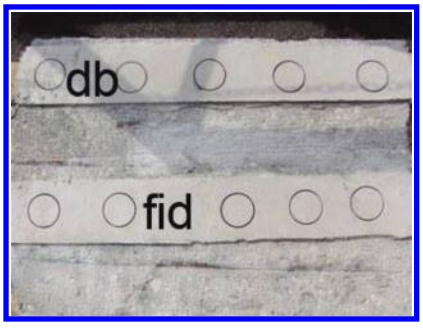

Figure 1. SRG strips applied to the concrete slab, after the cuts.

accurately removed using compressed air, and the surface was properly wet to avoid an excessive absorption of the matrix mixing water.

Two strips of SRG, 60 mm wide, were applied to the concrete substrate. After a curing period of 28 days, 5 circular cuts (50 mm of diameter) were made on the surface of each SRG system (Figure 1), several millimetres deep into the substrate, according to EN 1542 (2000).

4.2 *Pull-off test method*

Compared to other tests, the pull-off test is a simple and popular way to basically evaluate adhesion properties of layered materials (such as plasters or composites), in terms of failure modes and tensile strength (Bonaldo et al. 2005).

This test consists in applying a force, normal to materials' plane, to a metallic plate glued to the external surface of an area isolated by a cut that goes through materials' layers into the substrate.

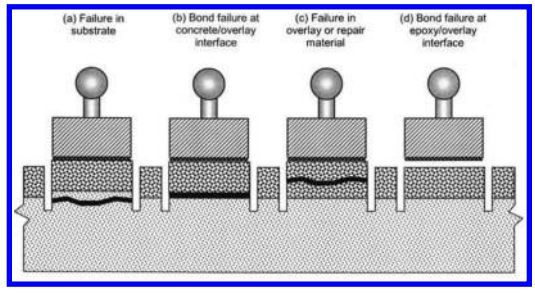

Figure 2. Pull-off failure modes (ASTM C 1583-04: 2004).

In this work, a core diameter of 48 mm, cut approximately 15 mm deep into the substrate, was adopted.

The pull-off strength f_h is defined as the maximum tensile force F_h divided by the area of the cut (Eq. 1, where D = cut diameter).

$$f_h = \frac{4F_h}{\pi D^2} \quad (1)$$

Possible types of failure, according to the American standard ASTM C 1583-04 (2004), are shown in Figure 2.

4.3 *Results*

Pull-off tests showed mainly failure type "b", that is bond failure at concrete/overlay interface (Figure 2). This failure indicates that there are no weaker elements in the strengthening system, being the matrix able to bind the steel strands together.

Photos in Table 4 show that traces of mortar and concrete coexist on both the failure surfaces.

The strengthening system with fibres type *fid* reached a slightly higher average tensile strength, 1.25 N/mm^2, compared to fibres type *db* (1.11 N/mm^2). Actually, being the failure located at the mortar-to-concrete surface, density and strand geometry of steel fibres should not affect the measured pull-off strength, therefore this difference could be imputed to factors like local superficial differences, preparations, etc.

Pull-off strengths and related photos of failure modes are reported in Table 4.

5 SHEAR TESTS

5.1 *Specimens preparation*

Eight concrete prisms 145 mm wide, 280 mm long and 110 mm thick, taken from St. Francesco bridge deck, were used as concrete substrate for tangential bond tests (shear tests).

Four strengthening systems were tested, made coupling each steel reinforcement (the same used for pull-off tests) either to the cementitious mortar or to an epoxy resin. Composite strips were 60 mm wide, hence, according to the different reinforcement density, 10 strands of *fid* fibres and 19 strands of *db*

Table 4. Summary of failure modes

ID *fid*	Pull-off strength (N/mm^2)	Photo	Failure type
FID1	0.57		B
FID2	1.32		B
FID3	1.20		B/C

Average:	1.11		

fibres were applied. Specimens details are reported in Table 5.

The surface of concrete prisms was mechanically roughened before bonding SRP and SRG strips, then dust and any trace of dirt was accurately removed before the application of composites (the surface was properly wet in the case of inorganic matrix). A reinforcement strip was applied on each prism, bonded for 250 mm along the main axis. About 200 mm of steel, protruding out above the prism edge, were used to clamp the reinforcement to the universal machine used for tests.

EPO_DB_01		epoxy resin
EPO_DB_02		

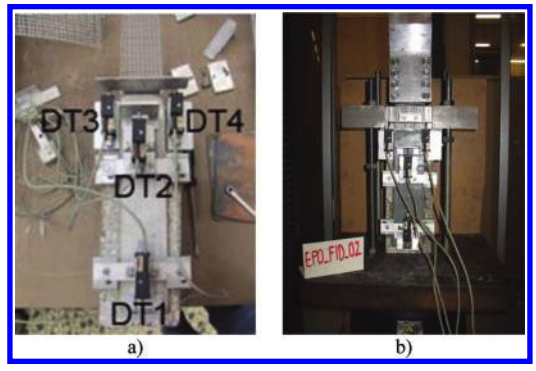

Figure 3. An instrumented specimen (a) and a sample ready to be tested (b).

5.2 *Shear test method*

Shear tests consist in reproducing the typical load condition of composite materials (reinforcement in tension) in order to produce tangential stresses at the composite-to-concrete interface and therefore test their bonding behaviour.

Force was recorded by a load cell, while four displacement transducers (Fig. 3a) were adopted to measure the mutual slip between substrate and reinforcement.

Specimens (Fig. 3b) were blocked into a universal machine by means of two stiff steel plates, and the protruding reinforcement was clamped to the moving beam in order to apply the axial load.

5.3 *Results*

The predominant failure mode was the debonding at the interface between concrete substrate and strengthening system. This happened for all samples, except *db* fibres coupled to mortar matrix, which showed a relevant slippage of strands into the matrix, without failing at the composite-to-concrete interface. The debonding mechanism was rather brittle, but reached higher load values.

Diagrams of axial force (P) vs. total displacement (δ) are given in Figure 4, while maximum loads and

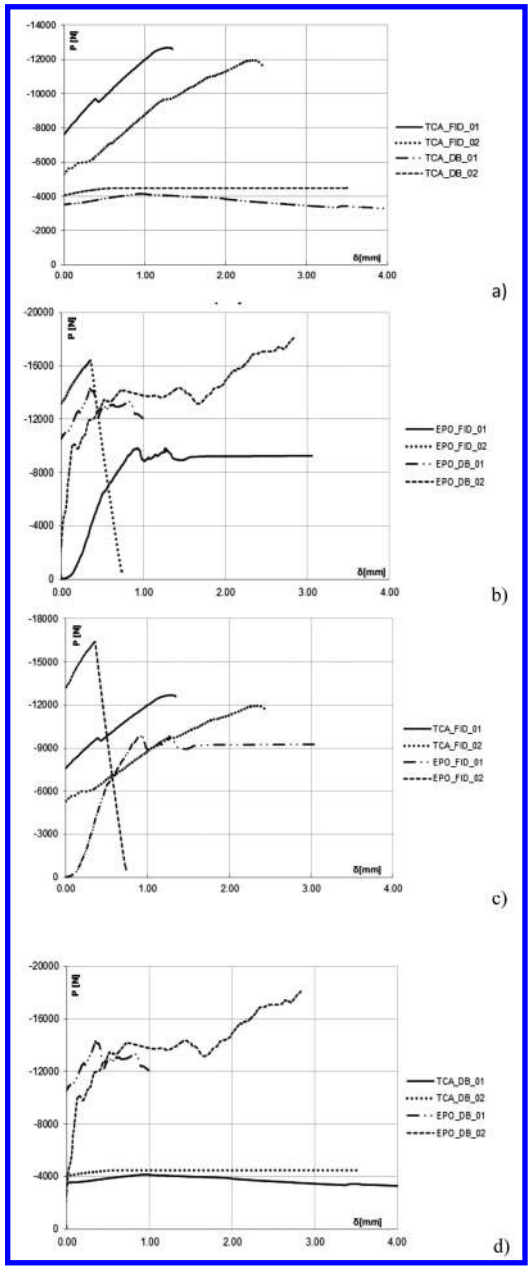

Figure 4. Load –displ. plots for: cementitious matrices (a); epoxy matrices (b); *fid* steel fibres (c) and *db* steel fibres (d).

related displacements are listed in Table 6. Charts in Figg.4-5 were obtained from data recorded by transducers DT3 and DT4 (Fig. 3). DT1, placed at the bottom, did not record displacement of composite material until failure, whereas DT2, located at the top of the strip, showed that the SRG/SRP slip became relevant only close to maximum load values, as shown in Figure 5.

All *fid* fibres showed a brittle failure (debonding failure or steel rupture), and allowed reaching load

Table 6. Shear tests: result summary

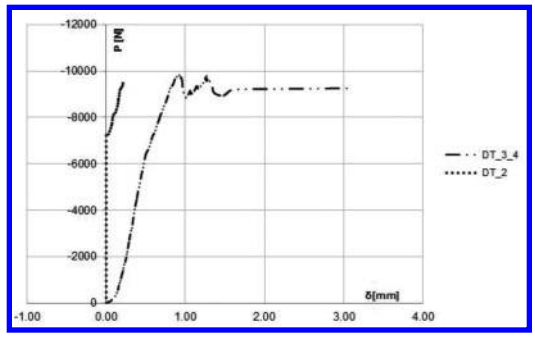

Figure 5. Example of displacements measured by DT3-4 compared to DT2.

values higher than in case of *db* fibres. Moreover, maximum loads were similar for mortar and epoxy matrix, 12.33 kN and 12.95 kN respectively. Reinforcement made of *db* fibres and mortar achieved lower values of maximum load (4.32 kN) and after the peak load *db* fibres slipped into the mortar matrix without reaching the bonding failure. On the other hand, steel type *db* coupled with epoxy reached an average maximum load of 16.23 kN, even higher than *fid* fibres, showing a brittle debonding failure at the composite-to-concrete interface.

6 CONCLUSIONS

This paper presents the preliminary results of an experimental activity aimed at investigating the bond between steel-based composite materials and historical concrete substrates, taking into account the effects of matrix (organic/inorganic) and type of steel fibres. The experimental program included the investigation of bond along normal (pull-off test) and tangential (shear tests) direction. The historical concrete substrate was extracted from the deck of a decommissioned bridge built in the Fifties.

About pull-off tests, specimens with *fid* steel fiber exhibited average pull-off strength of 1.25 N/mm^2, whereas average pull-off strength of SRG with *db*

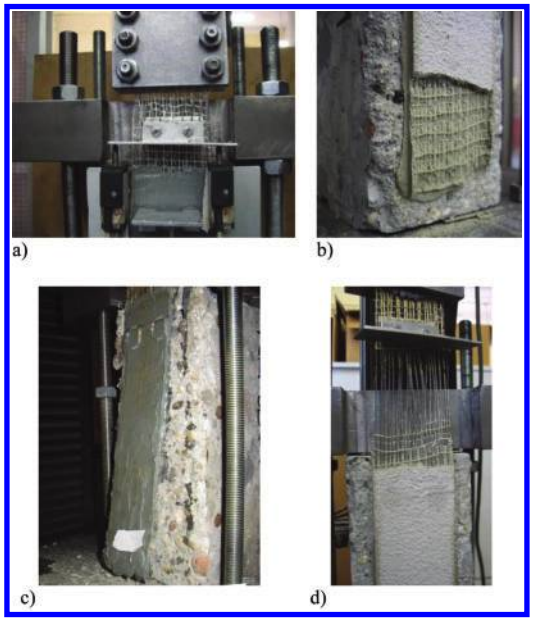

Figure 6. Fibres tensile failure (a); fibres slip into the mortar matrix (b, d); interface debonding (c).

fiber was slightly lower (1.11 N/mm^2). In general, failure occurred at the mortar-to-concrete interface, highlighting a rather good adhesion of the composite materials to substrate.

In the case of shear tests, *fid* fibres revealed a good adhesion with the matrix which caused debonding failure at the concrete interface. On the other hand, *db* fibres, although no particular problem was shown by pull-off tests, exhibited a loss of adhesion when impregnated with mortar which produced high slippage values, at rather low loads. This was probably due to a less effective strands arrangement and probably too low strands spacing that may worsen the impregnation with mortar.

Methods of silo strengthening walls in practice.

M. Kaminski & M. Maj
Institute of Building Engineering Technical University of Wroclaw, Poland

ABSTRACT: Same methods of strengthening of concrete reinforced silo walls are presented in this article. Some methods of repairing silo are used in the same type of silo construction: external pressurising by using type "x" of connecting tendons, application of a discharge device reducing pressure of material, gunite with additional reinforced steel bars, using pressurised methods by external steel hooping. Additional the reliability of this strengthened silo were computed for rape silo with 19 diameter and about 30 m of height which were erected in '70 last century. The durability of strengthened silo walls were discussed. The article present discussion of increasing safety of silo construction by European Standards.

1 INTRODUCTION

After many years of exploitation some silos constriction need to be reconstructed, strengthened or changed in their static solution. It caused by such parameter as degradation of property of existing construction materials, increase standards alive loads as pressure, temperature, patching loads, decreasing value of parameters of construction designing materials, changing functions of silo etc. It is almost certain than each silo built more than twenty years ago must be strengthened. Strengthening of silo construction (silo walls, bottom, foundations or overlap) can be carried out generally in two ways, according to formula (Kaminski & M. Maj, M 2000):

$$A_c <= R_e \quad (1)$$

where A_c = effect of designed acting loads against silo construction (ex. tension), R_e = designed effect of resistant of silo contraction (ex. strength).

Decreasing of value of left side of this equation and increasing value of right side of this equation separately or simultaneously makes silo construction more safety.

Decreasing value of A_c can be achieved by decreasing mean value of loads or decreasing the value of coefficient of variation of loads separately or simultaneously. It follows from formula of design loads, which are function of mean value of load and coefficient of variation of loads and loads coefficient. The first simplest solution used for silo is reducing the level of filling of the silo of material stored in silo. The second solution is using perfect control of kinematic of discharging material. This allows to predict characteristic value of pressure and using appropriate load factors.

Perfect control of parameters of stores material as bulk density, moisture, internal temperature etc. reduce the value of coefficients of variation. Changing the flow material to chimney flow during discharging, what is possible for the discharging device, decrease value of material pressure. The same applies to reduce the flow velocity of the material.

The value of right side of discussed equation can be higher by such solutions as increasing the size of the silo wall, using materials of higher strength or strengthening of silo construction (adding new elements to the structure). The value of right side of equation (smaller or larger) is connected with static scheme used by designer and with designer's engineering experience, of course.

All these presented above methods were used by Authors to strengthen silo wall in their engineering and scientific practise.

2 CONCRETE RAPE SILO

There are 4 rape companies in Poland where are built the same rape batteries, i. E. in Bodaczów, Brzeg, Kruszwica and Pyrzyce. Concrete battery of 18 freestanding rape silos was built in '60 last century (Figure 1, 2) . Silo diameter is 19 m, high of silo is about 30 m, silo thickness is 0,25 m (Figure 1). Authors of this paper were involved in research of loads of pressure of rape against silo wall. They investigated the basic parameters of wall strength either. Pressure was investigated by sensors inserted into stored material. The sensor is presented on Figure 3.

Measured pressure was compared with the pressure calculated according to silos codes. Comparison of this values of pressure are shown on Figure 4. where; z = distance from the top surface of the filling, D = diameter of silo, α = no dimension coefficient from the formula for pressure $p_h = \alpha\gamma_s D$: where γ_s = specific weight of stored material, 1 = pressure according to the guidelines of the 60s last century, 2 = pressure adopted in the design of the silo in the 70 s of last century, 3 = experimental pressure by (Borcz &

Maj &Trochanowski 1991), 4 = pressure calculated for discharge device according to (Eurocode 1), 5 = calculated by polish code (PN-89/B-03262), 6 = pressure calculated according to (Eurocode 1).

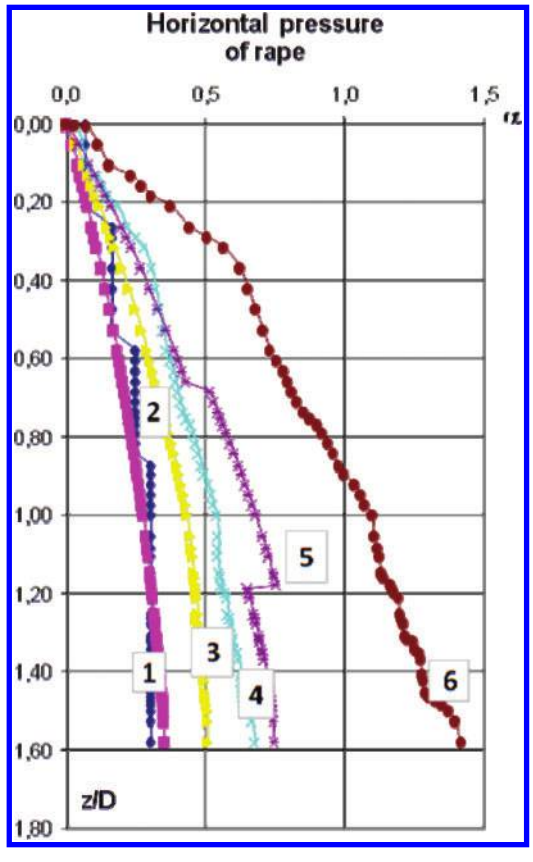

Figure 4. Pressure Comparison by different sources.

3 METHODS OF SILO STRENGTHENING WALLS IN PRACTICE OF 4 SILO BATTERIES

These batteries in each of the said four places were taken into account by experts and engineers from the beginning, when it was built for the period between 1995 to 2012. After first few years of exploitations their decided to strengthen silo walls. It was caused by changing standards requirements for the material pressure. Additional quality of silo wall was poor: many defects, imperfection, deficiencies in the number of horizontal reinforcement steel bars, low strength concrete. During the test of strength parameters of the silo walls it was found that values of coefficients of variation of parameters as steel bar diameter, distance between bars, concrete cover, concrete strength are rather high. They achieve value 0,4 and more. That means that significantly is reduced the value of strength of silo walls. Silo walls were strengthened using different technique. sby additional prestressed steel rings. After next 10 years of exploration appeared cracks on silo wall. In this time was developed the first polish silo code in 1984. From this time during next 30 years silo codes modified three times. In accordance with the requirements of the new standards increased value of silo pressure, loads caused by temperature etc. There were changed requirements for construction

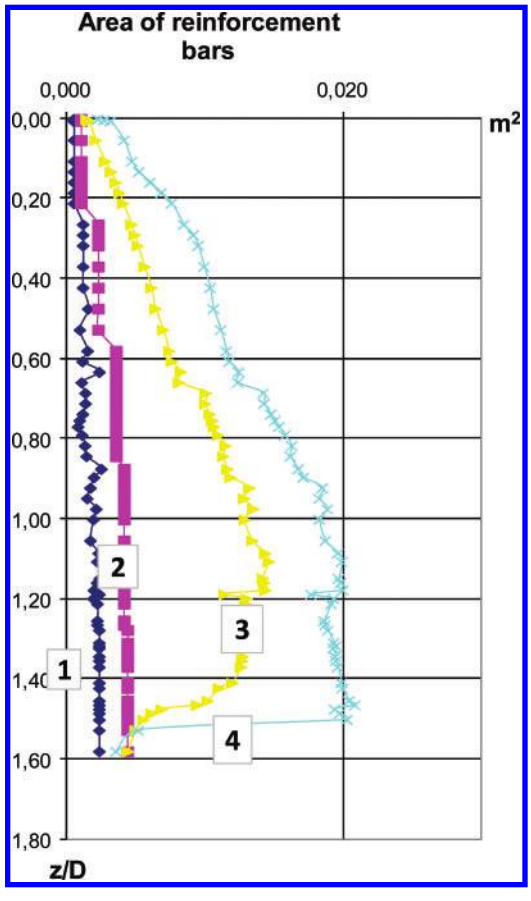

Figure 5. Comparison of reinforcement steel bars in rape silo.

Figure 6. Rape silos strengthened by steel hops.

Figure 7. Corrosion of steel hoops after more than 40 years of exploitation.

i.e for reinforcing bar diameters, laps, concrete cover, minimal concrete class for silo wall etc. Authors of this paper took part in strengthening these batteries in this period time. Depend on financial condition, depending on the strength of the walls of the silo, various methods have been used in strenghtening silos. The following methods of strengthening the silos:

1 shotcrete with additional reinforcement
2 prestresing tendons combined with the strengthening of concrete
3 reprofiling walls and cleaning reinforcement steel bars and supplemnt missing bars
4 using steel hoops instead of prestresing tendons
5 using low-height discharge device. It allow for decreasing pressure of flowing material about 20% – 30%.
6 reprofiling and reduce the level of filling a silo.

In this way in Bodaczów was used method of shotcrete and partially prestresing tendomns. In Kruszwica were used reprofilation and installation of low-height discharge device. In Brzeg three solutions were used prestresing tendons, steel hoops and low-height discharge device. On silos non repaired was used limited filling of silo to a designated height of the silo. In Pyrzyce reprofiling and low-height discharge device and limited filling of silo to a designated height of the silo.

On Figure 5 is shown amount of reinforcement steel bars existing and expected according to calculation, where 1 = area of existing reinforcement bars in silo wall before renovation, 2 = area of design reinforcement bars more than 40 years ago, 3 – area of reinforcement bars calculated according to polish code (PN-89/B-03262), 4 – area of reinforcement bars calculated according to (Eurocode 1).

In the silo battery repaired in Brzeg used all ways of reparation except the shotcrete. On Figure 6 it is shown silos strengthened by steel hops

After many years steel hoops and joins rings have corrosion, which is shown on Figure 7.

During renovation corroded parts were listed. Steel used before many years had a large relaxation and during renovation was changed to steel stronger. Some of

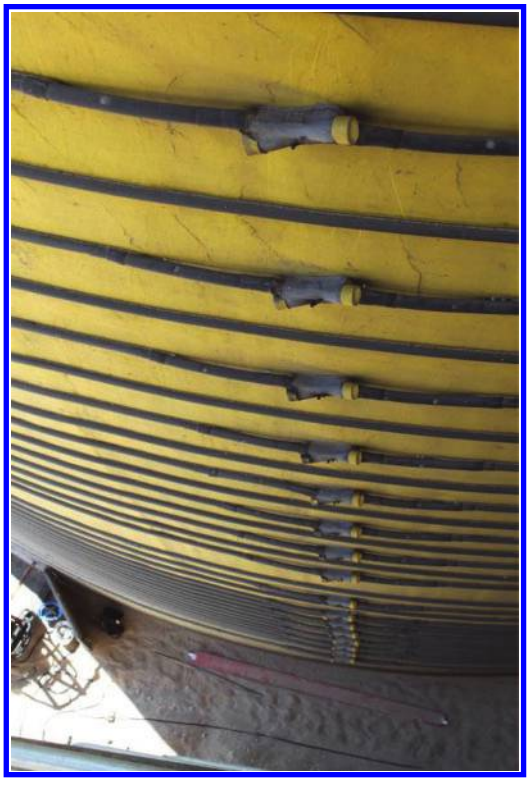

Figure 8. Silo wall strengthened by prestresing tendons.

Figure 9. Framework placed on the whole silo wall.

silos renovated in “90 last century were strengthened by prestresing tendons, which is shown on Figure 2, 8.

Figure 4 shows value if pressure of material against rape silo wall for different codes. Based on Authors investigation.

In the case of prestressing tendons concrete wall must be carefully prepared. Weak concrete must be replaced with a stronger. Reinforcement bars have again reinforced by welding and and re-connected with the concrete. This reparation presents Figure 9.

Figure 10. Framework placed on the whole silo wall.

Repair works are very complex and costly. Repair shall be subject to all of the silo wall. It shown on Figure 10.

4 CONCLUSIONS

Almost each silo after twenty years of service is suitable for repair Silo repair techniques depend on the changing standards first at all. The choice of the optimal service consists of a number of factors, including economic. In Poland, enjoying great success method mixed, including strengthening by tendons, using discharging devices, reduce the amount of filling materials stored etc.

In the decision of choice of strengthening methods are very useful own measurements of pressure and resistance parameters. The authors of this paper who are members of the research team in the Institute of Building Engineering of the Technical University of Wroclaw, for more than 40 years have been carrying out researches on silos for bulk materials. They had big influence on preparing polish silo codes . These investigations were carried out on silo batteries, free-standing silos and silo models. The researches include the evaluation of value of pressure and temperature field on the silo wall as well as temperature gradient, registration of simultaneity of these loads The researches include either the evaluation of influences of the wall stiffness and wall inclination on pressure changes, parameters connected with silo strength and geometry etc. (Kaminski, M. Maj, M 2006).

Study on mechanical behavior of circular concrete columns confined by HFRP under axial compressive load

Li-Juan Li, Shun-De Xu, Lan Zeng & Yong-Chang Guo
School of Civil and Transportation Engineering, Guangdong University of Technology, Guangzhou, Guangdong, China

ABSTRACT: The mechanical property of CFRP, BFRP, GFRP and their hybrid FRP were analyzed. The elastic module and compressive strength of CFRP, BFRP, GFRP and their hybrid FRP were tested. The experiment results show that the elastic module of hybrid FRP agree well with theoretical mixing rule while the tensile strength does not. The bearing capacity, peak strain, stress-strain relation of circular concrete columns confined by CFRP, BFRP, GFRP and hybrid FRP were analyzed under axial compressive load. The confining effectiveness of hybrid FRP on concrete columns was analyzed. Testing results show that the bearing capacity and ductility of concrete columns can be efficiently improved through hybrid FRP confining. A strength simulation model and a stress-strain whole process simulation model of hybrid FRP confined concrete columns were presented. The new stress-strain model has good simulation accuracy and does not need piecewise fitting compared with other hybrid FRP model. The new stress-strain simulation model is also suitable for single FRP confinement cases and is simple for use in design of structures.

1 INTRODUCTION

The superior mechanical properties of the fiber reinforced polymer (FRP) composite material, such as light weight, high strength, nice corrosion resistance, and its applicability to broad range of structural members, such as beams, columns, slabs, masonry and walls, led to the fast development of research of FRP materials (Teng et al. 2002, Saadatmanesh and Ehsani 1991, Sundarraja and Prabhu 2012). The advantages and disadvantages of using one kind of FRP materials, such as carbon fiber reinforced polymer (CFRP) glass fiber reinforced polymer (GFRP), or basaltic fiber reinforced polymer (BFRP) to strengthen concrete columns are obvious (Meier et al. 1993, Guo et al. 2009). Recently, research work about FRP strengthening method is focused on hybrid strengthening program, in which different FRP materials are used to achieve expected strengthening results (Chen et al. 2008, Li et al. 2009, Mosallam et al. 2012, Vanaja and Rao 2002), and obtain FRP confined new members (Guo et al. 2009).

The study on hybrid fiber reinforced polymer (HFRP) to confine concrete members had been mainly focused on HFRP reinforced concrete beams and columns (Li et al. 2009, Chen et al. 2012, Guo et al. 2012, Teng et al. 2012, Lau and Pam 2010, Rousakis and Karabinis 2012). To study the behavior of HFRP reinforced concrete structures, the fundamental step is to understand the basic mechanical behavior of the constitutive materials, reinforced concrete and FRP, separately. The nonlinear behavior of reinforced concrete such as concrete cracking, tension stiffening, shear retention, concrete plasticity and yielding of reinforcing fiber have been extensively studied by many researchers and numerous proper constitutive laws have been proposed (Chen 1982, Meyer and Okamura 1985, Hu and Schnobrich 1989, 1990). However, the studied on mechanics of HFRP confined concrete structures especially columns is limited. While, the stress-strain relation of HFRP confined concrete columns is necessary in design of structures especially for aseismic design of structures. Different stress-strain models of FRP confined concrete materials were presented by Farids and Khalili (1982), Miyauchi et al. (1999) and Samaan et al. (1998), however the most common one is the model presented by Teng et al. (2002), which had been accepted by most of the researches so far, but the model is still too completed to be used to engineering design easily. Therefore, appropriate modeling of the nonlinear behavior of HFRP confined concrete is still crucial.

2 TEST ON HFRP CONFINED CONCRETE COLUMNS

2.1 *Design of specimens*

In this paper, 30 cylinder specimens with diameter of 150 mm and height of 300 mm were cast for test, which is shown in Figure 1. The cubic compressive strength of concrete measured was 38.73 MPa. The frames of

Table 1. Mechanical properties of fibers Setting

Type of FRP	Tensile strength (MPa)	Elastic modulus (GPa)	Elongation (%)	Thickness (mm)
CFRP	4833	254.16	1.71	0.167
BFRP	1575	83.98	2	0.153
GFRP	1079	69.45	2.23	0.111

Figure 1. Specimen columns. (a) Specimen un-wrapped (b) Specimen wrapped.

specimens were removed in 24 hours after pouring, and the specimens were maintained in standard curing room for 28 days to attach HFRP, including CFRP, BFRP and GFRP. The related mechanical properties of the three fibers were measured in the test and are shown in Table 1.

2.2 *Wrapping and loading approach*

By using the method of wet sticking paste, HFRP was pasted on the surface of columns with resin completely infiltrated. The confining HFRP has a width of 300 mm. There is no lapping joint for HFRP in height of columns. The lapping joint length was set 150 mm in circumferential direction and joints were deliberately offset. Two layers of CFRP with 50 mm width were pasted on ends of FRP sheets in order to prevent the pre-fracture of top of columns. Specimen number and the types of FRP are shown in Table 2.

3 TEST RESULTS AND ANALYSIS

3.1 *Compressive strength and deformation*

The bearing capacity, circumferential and longitudinal strains of concrete columns were measured from the test and are shown in Table 3.

Compared with specimen P0 without FRP confinement, the compressive strength of specimen C1G1, C1B1and B1G1 with two layers of fibers is increased by 134%, 136% and 67% respectively. The compressive strength of C1G1 and C1B1 are nearly the same,

Table 2. Types of FRP confining

Specimen	Fiber wrapping approach	Numbers of specimen	Types of FRP
P0*	None	3	—
C2	Two layers of CFRP	3	1
B2	Two layers of BFRP	3	1
G2	Two layers of GFRP	3	1
C1B1**	One layer of CFRP/ one layer of BFRP	3	2
C1B2	One layer of CFRP/ two layers of BFRP	3	2
C1G1	One layer of CFRP/ one layer of GFRP	3	2
C1G2	One layer of CFRP/ two layers of GFRP	3	2
B1G1	One layer of BFRP/ one layer of GFRP	3	2
C1B1G1	One layer of CFRP/ one layer of BFRP/ one layer of GFRP	3	3

* P0 refers to the normal concrete specimen, while B, G, C refers to BFRP, GFRP and CFRP respectively.
** C1B1 means that the specimen is wrapped by one layer of CFRP and one layer of BFRP from inner to outside, and the others are the same.

but the circumferential strain of fiber in C1G1 is obviously better than that in C1B1, which suggests that if the fiber elongations are appropriate, C1G1 can take the advantage of the fiber with high elongation and delay the FRP damaging more effectively, which makes full use of the ductility of fibers and increases the strength of specimens.

The strength of concrete columns confined by three layers of FRP is higher than that by two layers. Moreover, the compressive strength of C1G2 and C1B2 is higher than that of C1B1G1 which is higher than that of C1B1 only by 1.57 MPa. It is suggested that the ways of bonding and connection have effect on specimens, but the confining effectiveness will not increase with the increase of fiber types. It is suggested that three kinds of fibers are not suitable to be used together in practice.

The circumferential strains of C2, G2 and B2 are 1.11%, 1.23% and 1.22% respectively when broken, while the circumferential strains of C1G1 and C1B1 are 1.39% and 1.26%, which is obviously higher than that of single type fiber, such as C2, G2 and B2, the reason is that hybrid fibers can make full use of the property of high elongation to enhance the ductility of specimens. However, the circumferential strain of B1G1 is lower than that of B2 and G2. The reason why the hybrid effect of B1G1 is not so well may result from the different material characteristics of BFRP and GFRP, such as GFRP is rather smooth on surface while BFRP is relatively rough. The mechanical properties of specimens are affected by the different properties of fiber surface along with the bonding and connection between fibers. The circumferential strains of the concrete columns confined by three layers of

Table 3. Experimental results

Specimen	Bearing Capacity	Relative value (MPa)	Longitudinal strain	Relative value (10^{-6})	Circumferential strain	Relative value (10^{-6})
P0	31.72	1.00	3017	1.00	2118	1.00
C2	92.87	2.93	27937	9.26	11173	3.70
G2	47.63	1.50	10805	3.58	12252	4.06
B2	57.29	1.81	13403	4.44	12254	4.06
C1G1	74.19	2.34	20277	6.72	13870	4.60
C1G2	83.81	2.64	21569	7.15	14088	4.67
C1B1	74.73	2.36	20597	6.83	12551	4.16
C1B2	87.77	2.77	24000	7.95	13106	4.34
B1G1	53.12	1.67	12153	4.03	11990	3.97
C1B1G1	75.56	2.38	20153	6.68	12869	4.27

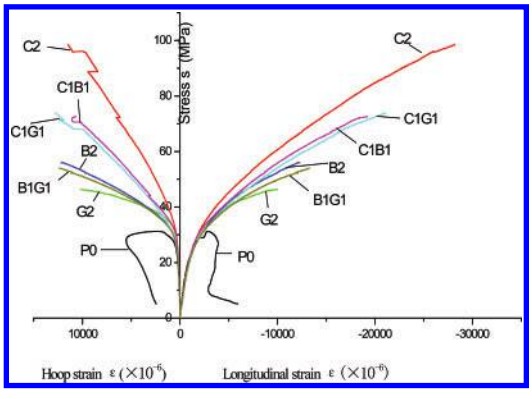

Figure 2. Stress-strain whole process curves of specimens with 2 layers of FRP.

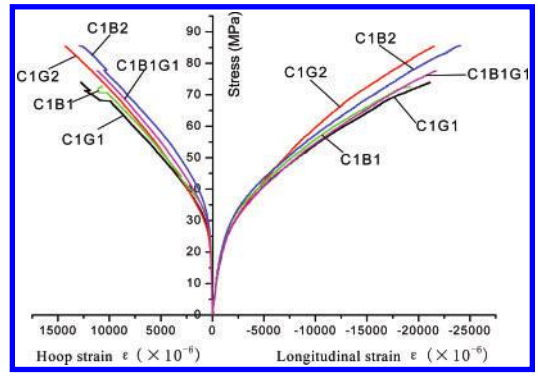

Figure 3. Stress-strain whole process curves of specimens with 3 layers of FRP.

HFRP, such as C1G2 and C1B2 are higher than that by two layers, such as C1G1 and C1B1 when broken, which indicates that with the increase of layers of FRP, the hybrid effect can be fully developed and the ductility of concrete columns confined by HFRP can be improved.

3.2 *Effects of fiber layers on stress-strain relations*

Stress-strain whole process curves of specimens are shown in Figure 2 and Figure 3. The longitudinal strain is calculated by the average value of LVDT, while the circumferential strain is calculated by the average value of circumferential strains.

It can be seen from Figure 2, that compared with columns without FRP, the stress-strain curves of circular concrete columns confined by FRP are nearly the same when the circumferential strains is smaller than peak strain of P0. The circumferential strain of concrete is small before reached peak strength and will increase greatly after peak point. At the period before peak point, the circumferential expansion of concrete was not big enough, and the confining effect of FRP could not be acted. When the strength reached pick strength of P0, the compressive strength of concrete columns rises considerably, but the slopes of stress-longitudinal strain curves dropped sharply, and are far more below than that of the first segment. The slopes of the curves in the second segment are related with the stiffness of HFRP, it seems a linear relationship basically. The intersection point of the extension line in the second segment of curve's with the stress axis is close to the peak strength of P0.

For the concrete columns confined by 2 layers of FRP, the slopes of longitudinal strain are nearly the same. That is to say, the trends of longitudinal strain are similar, but the slopes of circumferential strain are significantly different, whose trends are affected by types of hybrid fibers. The stiffness of the circumferential strain in the reinforced segment can be divided into four groups as (1) C2, (2) C1B1 and C1G1, (3) B2 and B1G1, (4) G2. The stiffness of specimen in hardening section has a little difference, and decrease from the first group to the fourth group. As to the stress-circumferential strain relation curves of columns confined by HFRP, the stiffness in the hardening segment is determined mainly by the fiber of low elongation, and affected by fiber of the high elongation. Circular concrete columns can take the advantage of inhibiting fiber cracks from extending of high elongation fiber, which helps the redistribution of internal stress in HFRP, decreases the development of circumferential strain and delays the fracture of structures.

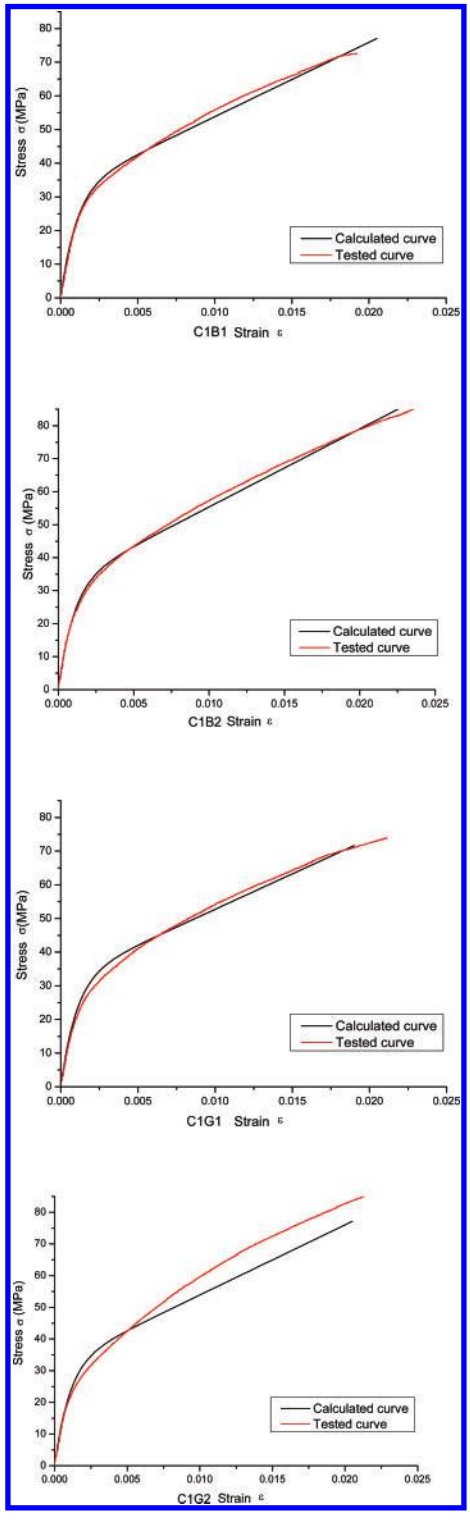

Figure 4. Stress-strain curves of HFRP confined concrete columns obtained in this paper.

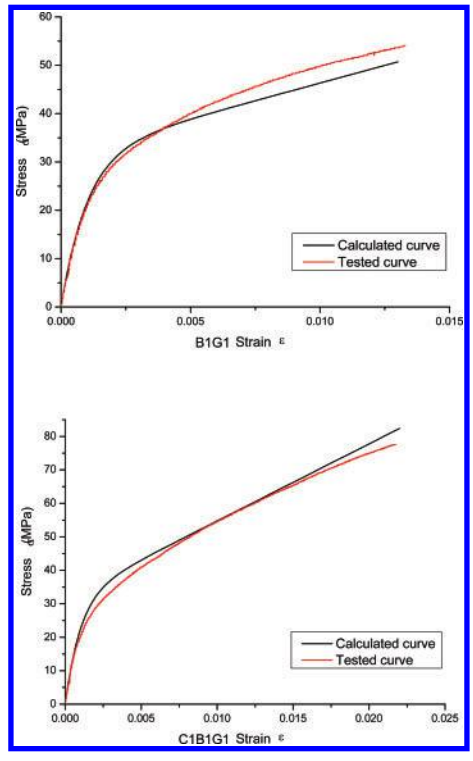

Figure 4. (*Continued*)

It can be seen from Figure 3, the stiffness of C1G2 and C1B2 in the hardening segment increases compared with that of C1B1and C1G1 when columns are confined by 3 layers of FRP. The increase of stiffness of specimen in the hardening segment can be achieved by increase of fiber layers and thus the effect of confinement can be improved. However, compared with that of C1B1, the slope in the hardened segment of C1B1G1 is not increased, which indicates that too many types of fibers may have a negative influence on confinement effect because of too many different fiber bonding and connections.

As for stress-circumferential strain relation curves of columns confined by HFRP, the stiffness in the hardening segment is various. It can be seen from Fig. 2 that the circumferential stiffness can be sorted as C1B2 > C1B1G1 > C1G2 > C1B1 > C1G1 when confinement increased from 2 layers to 3 layers, which matched the confining stiffness of FRP well. That is to say, the hybrid approach of fibers has great effects on the development of the hardening stiffness in circumferential direction. The bearing capacity of circular concrete columns confined by HFRP is controlled by the fibers of low elongation, while the fibers with high elongation helps to enhance the ductility of columns mainly, thus reduces the speed of development of the circumferential strain in hardening segment and postpones the fracture.

4 STRESS-STRAIN RELATION MODEL

According to the test results, a simple and accurate index model of stress-strain relation for concrete confined by HFRP is presented in this paper. The model is given as follows:

$$\sigma_c = f_{co}^{'}(1 - e^{-1000\varepsilon}) + E_2\varepsilon, when 0 \le \varepsilon \le \varepsilon_{cc} \quad (1)$$

$$E_2 = \frac{f_{cc}^{'} - f_{co}^{'}}{\varepsilon_{cc}} \quad (2)$$

where, E_2 is the slope of the second segment.

The stress-strain relations obtained from simulation model and test are presented in Figure 4. It can be seen from Figure 4 that the theoretical model presented in this paper agree well with experimental results of stress-strain relationship of concrete confined by HFRP.

5 CONCLUSION

The high elongation property of glass fiber can be fully used to prevent cracks from stretching if it is used by HFRP reinforcement to confine concrete columns. The fracture strain of hybrid FRP confined concrete columns can be obviously improved than that of single fiber confined columns. The fracture of columns can be delayed by reducing the speed of the development of circumferential strain. On the other hand, the stiffness of circular concrete columns confined by HFRP can be improved by taking the advantage of the low elongation of carbon fibers.

The confinement effectiveness is influenced by the bonding and connections of fibers, but does not increase with the increase of types of fibers. It seems using three or more kinds of hybrid fibers to confine concrete components cannot get better results. the confinement effectiveness of C1G2 is the best within the test extents of three-layer fibers.

Research on concrete repair materials

G. Lagoda
Warsaw University of Technology, Warsaw, Poland

T. Gajda
Road and Bridge Research Institute, Warsaw, Poland

ABSTRACT: The methodology and the repair materials essential research activity, which could ensure reliability of bridge structures, should be the choice base and the realization of investigations, which was simulated of material behaviour in time. The test to hasten age of the concrete repair materials, which estimates the durable adhesiveness executed layers to the concrete base and the mechanical properties change is investigated in freeze resistant test performed in the climate chamber. The freeze resistance test methods (cyclic freezing and thawing) may be different, as exemplified by tests repair mortars in accordance to the EN 1504-3 and tests commonly used in the Polish market according to the Polish Guidelines. The paper presents the most important issues concerning repair materials test methods used in Poland, which simulate their behavior during the cyclic freezing and thawing.

1 INTRODUCTION

The concrete bridge structures repair work durability is the main issue from the user point of view, when assessing the effectiveness of repair materials. As the durability one should understand the repaired structure ability to ensure the performance, not worse than before the repair, and to guarantee reliability in the assumed service life with the minimum maintenance costs. The greatest impact on the repair durability, with the use of repair materials, in Polish conditions has the resistance to the cyclic freezing and thawing. This is directly connected with the location of Poland in the transitional climate, which is something between temperate oceanic climate in the west and the moderate continental climate in the east of the country. The consequence of this location is a big difference in temperatures between winter and summer - summer temperature reaches above 30°C, and in winter often fall below −20°C. Additionally there are frequent passages through the freezing/thawing temperature 0°C. There are about 100 such passages through the temperature 0°C yearly in Polish climate. The use of concrete repair material characterized by the lack of resistance to cyclic freezing and thawing is often the main cause of repair failure. The structures damage repair caused by cyclic freezing and thawing are long-lasting and expensive. This is in particular important in case of bridge structures, which are most exposed to the temperature and weather conditions changes. It is therefore very important task to select the appropriate repair materials, which are characterised by high resistance to cyclic freezing and thawing for restoring the concrete structures.

Usually, the repair assessment, carried out on the basis of the immediate investigation, is based on the two elements. The one judges whether the repairing material adhesives to the repaired component and the other whether the fixing material has the required mechanical properties. The problem, however, is that no one is interested in the immediate adhesion which is the adhesion determined straight forward after the application, neither the immediate strength, determined usually after 28 days of hardening. Finding this values is not a problem at all, usually. The problem is that the durable adhesion has to be assessed, which is the repairing material adhesion presented after several or several tens of years. Moreover the material change strength properties in that time has to be predicted as well. Therefore, the implemented methodology and the repair materials essential research activity, which could ensure reliability of bridge structures should be focused on defining and implementation of ageing tests, which simulate the material behavior over the time in the best way. Further in this article there will be the methodology and the repair materials ageing tests types used in Poland presented.

2 CLASSIFICATION OF MATERIALS FOR REPAIRS

Repair materials for concrete bridge structures are used for example:

– to fill the losses in load-bearing elements, which have arisen as a result of mechanical damage and caused by the corrosion;

– to lay the levelling layer on bridge deck, in particularly loaded with pedestrian or vehicle traffic;
– to retrofit and level (smooth) carrying elements concrete surface;
– to replace damage elements.

The materials for concrete bridge structures repair can be divided into three groups, depending on type of used binders:

– CC (Cement Concrete) type hydraulic mortar and concrete – mortars and concretes based on hydraulic binder, which is blended together with graded aggregates and may include admixtures and additions and which, when mixed with water, set by a hydration reaction;
– PCC (Polymer Concrete Cement) type polymer hydraulic cement mortars or concretes - hydraulic mortars or concretes modified by the addition of polymer additives, which are added in sufficient quantity to give specific properties. The most commonly used polymers are:
  – acrylic, methacrylate or modified acrylic resins as water-soluble powders or aqueous dispersions,
  – vinyl mono-polymers, co-polymers and ter-polymers as water-soluble powders or aqueous dispersions;
  – styrene butadiene rubber as aqueous dispersions
  – natural rubber lattices;
  – epoxies;
– PC (Polymer Concrete) type polymer mortar and concrete – blended mixtures of polymer binder and graded aggregates which are set up by polymerisation reaction.

Due to the application objectives one can specify the following concrete bridge structures repair materials (mortar):

– smoothing mortars – mortars intended for laying the coatings to a thickness of 5 mm;
– repair mortars – mortars intended for laying the coatings to a thickness of 40 mm;
– fast acting mortars – mortars characterized by a very rapid increase in strength, such as the mortar used for tunnels leaks impound, manhole covers deposition;
– special mortars – mortars with unusual properties for special applications, e.g. to perform bearings grout, self-compacting.

According to the standard EN 1504-3, depending on user requirements, repair materials are divided into two groups:

– for non-structural repair, in which one can distinguish R1 and R2 class materials;
– for structural repair, in which one can distinguish R3 and R4 class materials.

The compressive strength is the main criterion for classifying repair material class according to the EN 1504-3 standard. According to this criterion, the compressive strength of repair materials for the relevant class should be at least:

- – 10 MPa in case of the class R1,
- – 15 MPa in case of the class R2,
- – 25 MPa in case of the class R3,
- – 45 MPa in case of the class R4.

In Poland, the concrete bridge structures are usually made of concrete from C25/30 to C50/60 class according to the PN-EN 206-1. Therefore, the repairs are performed with the use of repair materials class R3 or R4.

3 AGING TESTS OF REPAIR MATERIALS

The freeze resistance test in climate chamber is widely used for decades concrete repair materials ageing investigation in Poland. On the basis of that test the repairing layers and the base material durable adhesion and their strength properties changes are assessed.

The test is completed on the basis of the Road and Bridge Research Institute test procedures developed on the basis of the freeze resistance investigation according to the Polish standard PN-88/B-06250 *Concrete*.

The test is performed under the following conditions:

– temperature changes from $-18°C \pm 2°$ C to $18°C \pm 2°C$;
– the specimens thawing completed in the water;
– freezing specimens are soaked with the water, with the water pumped out form the chamber;
– there are 200 number of freezing and thawing cycles.
– freezing and storage in water cycle takes 4 h, while the defrosting one between 2 h and 4 h

There are following values identified on the basis of the above test:

– peel strength with the use of the pull-off method, after 200 cycles of freezing and thawing in water at the temperature of $-18 \pm 2°C / +18 \pm 2°C$;
– freeze resistance after 200 cycles of freezing and thawing in water, at the temperature $-18 \pm 2°C / +18 \pm 2°C$ (weight loss, flexural strength decrease and compressive strength decrease).

In case of repair mortars peel strength determination, in other words their adhesion, after freeze resistance testing, the mortar are laid on the frost-resistant C25/30 class concrete slabs. The minimum concrete slabs dimensions are 300 × 300 × 5 mm. There should be at least two slabs, which are covered with the repair material or repair complete system. After seasoning, one slab is tested for freeze resistance and the other one is kept in the laboratory. After finishing the required number of freezing and thawing cycles, which are usually 200 cycles, on both slabs 50 mm diameter discs are glued to perform adhesion test of the layer laid. The "pull-off" method is employed

Figure 1. The specimen after test “pull-off”.

Figure 2. The specimen after 200 freezing and thawing cycles – visible cracks grid.

Figure 3. The specimens that pass 200 freezing and thawing cycles.

Figure 4. The specimens that were damaged during 200 freezing and thawing cycles.

The basic criteria for assessing the repair mortar adhesion test are as follows:

– average adhesion repair mortar to the substrate after 28 days of hardening, which is the value of adhesion of the material not exposed to freezing and thawing cycles should be not less than 2.0 MPa (in case of smoothing mortar $\geq$ 1.5 MPa);
– average adhesion of the material exposed to the freezing and thawing cycles should be not less than 1.5 MPa (in case of smoothing mortar $\geq$ 1.2 MPa).

The figure 1 shows the repair mortar specimen after test "pull-off", and the figure 2 after 200 freezing and thawing cycles - visible cracks grid.

The freeze resistance determination is the test, which allows to assess the strength properties change in time, including drop in bending and compressive strengths as well as weight loss of the repair and re-profile concrete material.

The tested repair materials specimens are formed as 4 × 4 × 16 cm beams. There are 12 specimens in one test. After the stabilizing, all specimens are soaked in water to a solid mass, and then six specimens are stored in a climate chamber, and six other specimens are stored in water in the container. After completing the required number of freezing and thawing cycles, which is usually after 200 cycles, all specimens are weighed and tested for bending and compressive strength according to the PN-EN 1015-11/A1:2007. The mortar freeze resistance assessing criterions are:

– decrease of compressive strength should not exceed 20%;
– decrease of bending strength should not exceed 20%;
– weight loss should not exceed 5%.

The figure 3. shows specimens made of repair mortar, which passed 200 freezing and thawing cycles and the figure 4. – damage specimens while freeze durability tested the climate chamber after 200 freezing and thawing cycles.

Both ageing tests described above are contained in the Recommendations of the Road and Bridge Research Institute and fulfilling its requirements is the main decision criteria on issuing the Technical Approval.

The set of Standards EN 1504 *Products and systems for the protection and repair of concrete structures*,

together with the sheet EN 1504-3 *Part 3: Structural and non-structural repair* introduction to use, was to arrange and adapt to the current state of knowledge the repair materials test and requirements choice.

The durable repair material layer adhesion to the base material might be assessed on the basis of performing below listed tests, which concern thermal compatibility tests (after the EN 1504-3) according to the EN 1504-3:

– determination of resistance to freeze-thaw cycling with de-icing salt immersion according to the EN 13687-1;
– determination of resistance to thunder-shower cycling (thermal shock) according to the EN 13687-2;
– determination of resistance to dry thermal cycles according to the EN 13687-4;

However if the material meets the requirements concerning the freezing and thawing in saturated NaCl solution, according to the EN 13687-1, it should be deemed to satisfy the requirements of the other two tests.

Therefore, the test examination: resistance to thunder-shower cycling according to the EN 13687-2 and resistance to dry thermal cycles in accordance with the EN 13687-4 can be omitted if one receives a positive test result in freeze resistance according to EN 13687-1. In that case both mentioned test are treated as supplementary, performed exceptionally.

In case of resistance to freeze-thaw series according to the EN 13687-1 determination the repair material is applied on the concrete sample, prepared in accordance with the EN 1766. After seasoning, the specimen is exposed to cyclic temperature rapid changes between $+21 \pm 2°C$ and $-15 \pm 2°C$, together with the immersion in the de-icing salts saturated solution, the special set of test chambers (Figure 5-6).

If the temperature change cycles are finished, the noticeable spoils are recorded and the material or system repair to concrete basis adhesion is determined, with the use the of the "pull-off" method. Each test requires three samples, of which one is left as the reference specimen. When the specimens are ready, two of them should be immersed in the water and kept there for 24 h. After that period the proper test begins and lasts for 4 hours and includes following stages:

– immersion in the tank containing saturated sodium chloride solution at the temperature $-15 \pm 2°C$ for 2 h;
– storage in the water tank at the temperature $+21 \pm 2°C$ for 2 h.

When the test (50 cycles) is finished the repair layer adhesion is investigated. The repair materials adhesion should reach at least:

– 1.5 MPa for mortar for compressive strength $\geq$ 25 MPa (R3 class mortar according to the EN 1504-2);
– 2.0 MPa for mortar for compressive strength $\geq$ 45 MPa (R4c lass mortar according to the EN 1504-2).

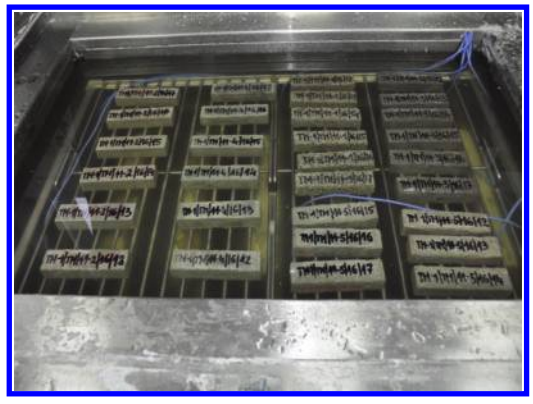

Figure 5. A set of special chambers for test according to the EN 13687-1.

Figure 6. The specimens during freezing in a saturated salt solution.

The PN-EN 1504-3 standard ignores mortar mechanical properties (compressive strength and bending strength) determination, once the freeze resistance in a saturated solution of NaCl is tested or the other two ageing test are performed. It must be stressed either that the flexural strength test was omitted in the PN-EN 1504-3 standard, though as an immediate test.

4 CONCLUSION

A new approach in accordance with the EN 1504-3 for ageing tests was to a new standard in the repair materials testing. According to the EN 1504-3 in the concrete repair materials testing and assessment the permanent repairing layers adhesion one may assess after the ageing test concerning the thermal compatibility execution. The basic thermal compatibility test is a new test method –cyclic freeze-thaw in NaCl saturated solution durability determination, which has not been known to the most repair materials manufacturers. Ageing tests listed in the PN-EN 1504-3 are focused primarily on repair materials used in general civil engineering, where one is dealing with the structure, usually heated on one side, and exposed

to climatic factors on the other. In bridge engineering, the entire structure is exposed to the climate factors.

Due to the EN 1504-3 new approach to the repair materials ageing test, a very important issue was to compare the two types of ageing investigation. Road and Bridge Research Institute has begun laboratory activity to assess the effectiveness (validity) of the two freeze resistance test methods. The comparison related to both values: bond strength of mortar, as well as determination the strength properties of mortar after 200 cycles of freezing and thawing in water, and after 50 cycles of freezing in a saturated de-icing salt solution and defrosting in water.

The hitherto obtained results confirm indirectly described in the literature dependence of de-icing salts concentration and its influence on the concrete damage. In case of de-icing salts (NaCl or $CaCl_2$) activity, the biggest frost damage occur when the concrete is exposed to relatively low concentrations of salts (solution of 2 to 4%). However, the higher is the salt concentration, then its influence is smaller. The highest compliance results trends were obtained in case of mortar adhesion test after 200 cycles of freezing and thawing in water, and after 50 cycles of freezing in a saturated de-icing salt solution and defrosting in water. The smallest trend compliance recorded in case of the bending and compressive strength test results, after 50 cycles of freezing in a saturated de-icing salt solution and defrosting in water, where the often significant increase of flexural strength was recorded, with the decrease in compressive strength.

Currently in Poland, the basic ageing research on the basis of frost resistance investigation, which should be performed for any repair material are:

- peel strength determination with the use of the pull-off method, after 200 freezing and thawing cycles in the water at the temperature of $-18 \pm 2°C$ / $+18 \pm 2°C$;
- freeze resistance determination after 200 freezing and thawing cycles in the water, at the temperature $-18 \pm 2°C$ / $+18 \pm 2°C$ (weight loss, flexural strength decrease and compressive strength decrease).

Performing these tests allow to assess materials for repairing concrete, regarding permanent adhesion of layers made of them to the base and their strength properties change in time, which in fact allows to assess the durability and effectiveness of repair made with the use of them.

Energy harvesting for the sustainability of structures and infrastructures

K. Gkoumas, F. Petrini, S. Arangio & C. Crosti
Sapienza University of Rome, Rome, Italy

ABSTRACT: In an energy sustainability context, and in the upward trend of renewable energy growth, several proposals have been made concerning energy harvesting in civil engineering structures and infrastructures. After a literature review on the topic, in the first part of this research, focus is given to the definition of an energy harvesting taxonomy in the civil engineering field and to the classification of energy extraction schemes. After that, this study focuses on the energy sustainability of complex structural systems. Within this topic, the possibility of using the air flow as an energy resource is explored.

1 INTRODUCTION

It is a common understanding that the society requires enhanced structures and infrastructures for the people's needs. Besides safety and functional requirements collectively defined in the so-called Performance-based Design (PEBBUH, 2005), today the attention focuses on the sustainability in the broader and profound sense of the word (Ehrenfeld, 2008). In this sense, the modern construction embraces the concept of smart structural systems that behave optimally with respect to the human needs, being at the same time coherently collocated in the environment (Srinivasan & McFarland, 2001) and inserted in a context of resilient cities.

Energy Harvesting (EH), i.e. the process of extracting energy from the environment or from a surrounding system and converting it to useable electrical energy, is a prominent research topic, with many promising applications nowadays in structural and infrastructural systems. Its areas of application are currently focused – though not limited – to powering small autonomous wireless sensors (thus eliminating the need for wires), while more recently proposals have been made concerning higher power EH devices, in the upward trend of renewable energy growth. In the latter case, the main objective is to supply power to auxiliary systems (e.g. road lights or information panels, in the case of transportation infrastructures), thus satisfying the requirement for sustainable structures and infrastructures.

EH is part of a global clean energy trend that encompasses other aspects, and focuses on the use of renewable energy sources. Advantages from the reduction of fossil fuel usage can be obtained at various levels, starting from a more sustainable (in terms of environmental sustainability) development (Adams, 2006), something that leads to CO_2 and greenhouse gas emissions reduction.

The idea of harvesting freely available energy is not new, and dates back to the windmills and watermills, in use since the ancient times. These have found their contemporary counterparts respectively in the form of wind turbines – solely in Europe, by the year 2020, wind energy is expected to account for most part of the 20% target share of renewable sources set by the European Community (EU, 2010) – and wave farms or underwater energy systems, currently at a proposal phase. Similarly, there great interest in wind power in the U.S., with wind power capacity representing more than 20% of the world's installed wind power (AWEA, 2012).

In what said above, the main objective is to produce a great amount of energy in order to supply the electrical grid. On the other hand, EH as intended nowadays, focuses in providing energy for powering sensors or other small electronic devices that require small amounts of energy, with the main purpose the elimination of traditional wire connections (e.g. in the case of sensors), while recently, the possibility to extract higher amounts of energy is possible, also with piezoelectric materials.

This study focuses on recent developments that highlight the possibility to extract energy in structures using the wind flow something that could specifically contribute to the energy sustainability of high-rise buildings. Before that, some aspects of energy sustainability of complex structural systems are inquired together with a literature review in the civil engineering field.

2 SUSTAINABILITY OF STRUCTURES

Sustainability in the urban and built environment is a key issue for the wellbeing of people and society. Sustainable development, defined as the "development that meets the needs of the present without

compromising the ability of future generations to meet their own needs" (UN, 1987) is nowadays a first concern for public authorities and the private sector, and is shaped by incentives and sanctions. Although sustainability goals are not uniquely identified, a total plan for sustainability requires, in a cost efficiency balance (ISE, 1999):

- Reduction of emission of greenhouse gases;
- More efficient use (and reuse) of resources;
- Minimization and constructive reuse of waste;
- Reduction of harmful effects from construction activities and building occupation.

The design, construction and operation of "green" buildings is nowadays regulated by international guidelines, codes and standards (see for example the green building evaluation and certification system USGBC, 2009). What emerges is a variety of widely acknowledged and recognizable standards, especially for what regards ranking and certification systems (Nguyen and Altan, 2011). In fact the whole concepts of "sustainable development" and "sustainable building" are cumbersomely defined, with different and sometimes contrasting definitions. Berardi (2013) deeply discusses several aspects of sustainable development (namely its time dependency, its multi-space and multi-scale levels, its multiple dimensions and its social dependencies) and arrives at a definition of what is a sustainable building by means of a number of principles.

It is important to add that even though sustainability has mostly a social character, benefits of sustainable design are not only to the general public but also for the building stakeholders, including owners, who benefit from the increased value of the property.

Sustainable design leads to innovation since it demands inventive solutions, and eventually is supported by a cultural shift, evident from national level reviews and surveys (Robin and Poon, 2009; Tae and Shin, 2009). Sustainability issues are wide-ranging, in the building industry but the main focus is the reduction of energy consumption in construction and use. Although the trend is to arrive to a so-called Net Zero Energy Buildings, for which a balance between energy flow and renewable supply options is established, the path to this goal is still very long (Srinivasan et al. 2011).

Ramesh et al. (2010) provide a breakdown of energy use in the various phases of building lifecycle (manufacture, use and demolition), and highlight the higher contribution of the operating phase, and the variability of the results for different climates, different building uses etc.

This is especially important for structural parts and systems, where recycling, reusing and material minimization can be important aspects (Vezzoli and Manzini, 2008). In the tall building design of diagrid and braced tube structures for example, stiffness provision is an important aspect of the design, and a material saving design methodology can be based on this aspect (Moon, 2010). In fact the diagrid structural scheme (with a perimeter structural configurations characterized by a narrow grid of diagonal members involved both in gravity and in lateral load resistance) has emerged as a new design trend recently for tall-shaped complex structures due to aesthetics and structural performance (Moon, 2011; Mele et al. 2012).

A second issue is the energy sustainability of structures and infrastructures, in terms of auto efficiency. For one thing it is possible to intervene on the energy balance of the structure using passive insulation systems. Alternatively, renewable energy sources could be implemented that contribute to the energy balance of the structure through "on-site" energy generation.

Several proposals and applications can be found in literature and practice, mostly using solar and wind energy. The latter is of particular interest for high-rise buildings, due to the superior characteristics of the wind field. The trend nowadays it to have a fully integration of aesthetically appealing wind turbines to the building, in harmony with its architectonic form.

Proposals are in the form of vertical wind turbines (Müller et al. 2009; Balduzzi et al. 2012a; Chong et al. 2013), innovative design and architectural integration (Sharpe and Proven, 2010), integration of wind turbine/solar generators (Chong et al. 2012). There are still some problems to overcome. The energy potential in urban environments is not fully assessed, and actually several researches focus on this issue. Walker (2011) provides a commented review of urban wind speed estimations, theoretical power curves and power production estimations for building mounted wind turbines. Balduzzi et al. (2012b) investigate by means of CFD the energy potential of rooftop wind turbines, focusing on the influence to the flow velocity of different geometric characteristics of the urban settlement (building height, distance between buildings etc.).

From what said above, the following principal sustainability measures can be identified for buildings.

- Passive systems. Focus is primarily on the use of more energy efficient materials and on the optimized design of structural and non-structural elements. The first mostly for the thermal isolation, the second for the minimization of the quantity of materials. Recently, innovative thermal isolation methods have been proposed (in the form of e.g. green roofs).
- Active systems. Focus is on the "on-site" energy production, something that leads to a lower energy need from the grid. Most applications so-far are in the form of wind turbines and photovoltaics. These applications can be considered as a part of a broader EH agenda.

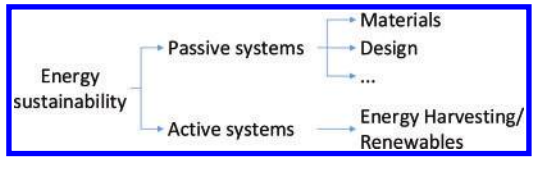

Figure 1. Sustainability measures.

Since EH is a rather innovative concept with many potential applications, it is useful to provide a taxonomy, based on the desired outcomes and the future potential.

3 ENERGY HARVESTING TAXONOMY

EH applications in structures and infrastructures can be divided in three groups:

- EH on a macro-scale
- EH on a meso-scale
- EH on a micro-scale

The proposed classification helps setting the framework for possible future applications, the assessment of their efficiency and their prospects.

Focusing on meso-scale EH applications, and in order to evaluate the energy production efficiency of the system, as a first step it is important to define the energy extraction patterns. In this sense, Section 4 focuses on energy production schemes (the reader is referred to Gkoumas et al. 2012 for additional details). Section 5 focuses on a meso-scale application that could use piezoelectric devices for harvesting the wind flow.

3.1 *Energy harvesting on a macro-scale*

Generally with macro-scale EH is in-tended the energy production for supplying the electrical grid. The produced energy is commonly known as renewable energy (the current exploitation of the energy sources does not affect their availability in the future). Geothermal, hydroelectric, solar thermal, geothermal, marine and wind energy are examples of renewable types of energy. Currently the produced energy is in the range of MWs.

3.2 *Energy harvesting on a meso-scale*

It is possible to define as H on a me-so-scale all those applications that have as an objective the supply of power to systems otherwise powered by the electrical grid. The energy produced in excess could supply the electrical grid. The energy sustainability of houses, structures and infrastructures provide an example of meso-scale EH implementation. Currently the produced energy is in the range of W/kWs.

Examples of meso-scale EH include piezoelectric roads and railways (see for example Innowattech, 2011) in which the movement of vehicles induces a strain to piezoelectric materials underneath the pavement or the railway track, thus producing energy. The East Japan Railway Company (JR East) is carrying out tests on piezoelectric floors in the Tokyo subway station, and the produced energy could be used to run the automatic ticket gates and electronic display systems (Techon, 2008). The duality is evident with the common practice of regenerative brake energy recovery in trains and cars (Robertson & Markham, 2007) or the energy that could be harvested inside a moving vehicle (e.g. a train) from vibrations (Romani et al. 2010). Numerous other applications are found in specialized journals, mostly in the form of conceptual design. Some worth mentioning are based on special wind turbines that can harvest wind-induced energy from passing vehicles in freeways. These are placed either over the road track (horizontal axis turbines – Ecofriend, 2011) or on the side (vertical axis turbines – Energy Harvesting Journal, 2010).

3.3 *Energy harvesting on a micro-scale*

Micro-scale EH aims to the powering of sensors or other small electronic devices, including those based on MEMS (Micro Electro Mechanical Systems) that require small amounts of energy. The objective is the elimination of traditional wire connections (in the case of sensors) and to provide an alternative to traditional limited energy sources (e.g. batteries). Currently the produced energy is in the range of μW/mWs.

Even though a great progress took place in the last decade, there are still issues to be solved and margins for improvement in the efficiency of micro-scale EH. Some of the key issues (power storage efficiency, communication standards, integration of devices, cost of ownership) are discussed in Kompis & Aliwell (2008). The same authors provide an overview of international centers of expertise in this field.

Applications in the last decade in the civil engineering field focus on the Structural Health Monitoring (SHM) of long span bridges and skyscrapers.

4 CLASSIFICATION OF THE ENERGY PRODUCTION SCHEME

This Section focuses primarily on the energy production schemes, typically for meso-scale EH applications, adapting findings from Gkoumas et al. (2012).

In order to evaluate the energy production of the system, as a first step it is important to define the energy extraction patterns. Consequently, the energy efficiency can be assessed.

4.1 *Definition phase of the scheme*

The energy production scheme can be classified following the scheme proposed in Table 1, based on the energy resource and the extraction system.

The first classification regards the resource type, in terms of the maximum extractable energy (E_H) and the energy cost of the structural system (E_C^{SS}). If the resource is natural (renewable resources such as wind and sun), E_H is infinite (since it is assumed that resources in nature are infinite) and E_C^{SS} is zero (since the sole purpose of the structure is the energy extraction). If the resource is artificial (e.g. bridge joints with piezoelectric devices), E_H is finite, since artificial resources are not infinite (e.g. in the case of energy extraction from a structural motion, since the latter

Table 1. Classification of the energy production schemes (adapted from Gkoumas et al. 2012).

RESOURCE Defined in terms of E_H, E_C^{SS} +		From natural resources $E_H = \infty; E_C^{SS} = 0$	From artificial resources $E_H < \infty; E_C^{SS} > 0$	From natural resources, modified by artificial systems $E_H = ?; {}^{*}E_C^{SS} > 0$ * Greater than if a system of extraction was implemented
EXTRACTION SYSTEM Defined in terms of E_C^{ES} =		Magnetic induction converter; Thermal energy converter; Electrostatic converter; Photovoltaic converter; RF converter; Piezoelectric converter; Radian energy converter; …		
COUPLED SYSTEM Defined in terms of E_C, $\hat{E}_H$, ΔE		Example: wind turbines for a wind farm.	Example: piezoelectric converters placed on deformable joints of a flexible structure.	Example: wind turbine on a skyscraper (the source is natural but it is placed in high attitude due to the skyscraper).
ΔE	ACTIVE (ΔE>0)	SUCCESSFUL[1]	SUCCESSFUL[3]	SUCCESSFUL[3]
	PASSIVE (ΔE<0)	UNSUCCESSFUL	SUCCESSFUL[1] UNSUCCESSFUL $\hat{E}_H - E_C^{ES} > 0$ $\hat{E}_H - E_C^{ES} < 0$	SUCCESSFUL[1] UNSUCCESSFUL $\hat{E}_H - E_C^{ES} > 0$ $\hat{E}_H - E_C^{ES} < 0$
	BALANCED (ΔE=0)	UNSUCCESSFUL	SUCCESSFUL[2]	SUCCESSFUL[2]

SUCCESSFUL[1]: Production of energy; SUCCESSFUL[2]: Production of an amount of energy equal to the one consumed;
SUCCESSFUL[3]: Production of an amount of energy higher than the one consumed
Definitions: E_H ~ Maximum extractable energy; E_C^{SS} ~ Energy cost of the structural system;
E_C^{ES} ~ energy cost of the extraction system; E_C ~ Total energy cost of the coupled system; $\hat{E}_H$ ~ Effective extracted energy of the coupled system; ΔE ~ Energy balance of the coupled system; ΔE' ~ Energy balance of the extraction system

is finite, accordingly it will be the extracted energy). E_C^{SS} is higher than zero since it is identified with the energy spent for construction and maintenance (illumination, etc.). A third case consists in natural resources modified by artificial systems. In this case E_H is indefinable since the resource is infinite but extractable only partially (this is the case, for example, of a wind turbine placed on a skyscraper, where only the part of wind flowing in the turbine location contributes to the produced energy). E_C^{SS} is higher than zero, and higher with respect to the same structure without an energy extraction system (additional cost is due to structural adjustment for the energy extraction).

The second classification regards the extraction system, defined in terms of the energy cost of the extraction system (E_C^{ES}). The extraction system of choice is specific to the resource type and consists in different parts, with the principal being the converter (e.g. piezoelectric, photovoltaic etc.).

The combination of the first two classification schemes leads to the definition of the coupled system. Therefore, the coupled system is essentially defined in terms of:

- the total energy cost of the coupled system (EC), which is the sum of ECSS and ECES;
- of the effective extracted energy of the coupled system ($\hat{E}H$); and,
- of the energy balance of the coupled system (ΔE).

The last one is defined as the balance between $\hat{E}_H$ and E_C.

4.2 *Evaluation of the system efficiency*

Based on the definitions given in paragraph 3.1, and with reference to Table1, the evaluation of the system efficiency is performed in terms of the energy balance of the coupled system ($\Delta E = \hat{E}_H - E_C$) and the energy balance of the extraction system ($\Delta E' = \hat{E}_H - E_C^{ES}$).

Regarding the first, if $\Delta E > 0$, the energy cost is lower than the produced energy, and the energy balance is active. If $\Delta E < 0$, the energy cost is higher than the produced energy and the energy balance is passive. Finally, if $\Delta E = 0$, the energy cost is equal to the produced energy and the energy of the coupled system is balanced.

Regarding the second, if $\Delta E' > 0$, the energy cost of the extraction system is lower than the produced energy. If $\Delta E' < 0$, the energy cost of the extraction system is higher than the produced energy.

Consequently, it is possible to define different "success levels", in order to obtain a qualitative view of the system efficiency.

For natural systems:

- If $\Delta E > 0$: Energy production
- If $\Delta E \leq 0$: Unsuccessful coupling

For artificial systems:

- If $\Delta E > 0$: Energy production
- If $\Delta E \leq 0$: Unsuccessful coupling

For natural resources modified by artificial systems:

- If $\Delta E > 0$: Energy production higher than the consumed energy
- If $\Delta E < 0$ and $\Delta E' > 0$: Energy production
- If $\Delta E < 0$ and $\Delta E' < 0$: Unsuccessful coupling
- If $\Delta E = 0$: Energy production equal to the consumed energy

Some limitations to this scheme are worth noting. The first one is that the energy balance refers to the system in operation and not for the entire lifecycle. The second and most important is that it doesn't take into account non-monetary aspects. Therefore, the decision to invest on a coupled system is often based on questions that are either non-monetary or driven by specific social or other interests.

The following section focuses on a meso-scale application, at the conception phase, that could use piezoelectric devices that harvest the wind flow.

5 EH AND SUSTAINABILITY USING PIEZOELECTRIC DEVICES

A very up to date research issue for Civil Engineering Structures is the sustainability of tall buildings, for example skyscrapers with 60-80 floors or more.

The main idea is to extract energy from the air flows in several parts of this complex system. Ventilation is an important part of the design of a high-rise building, and it is usually controlled by HVAC (heating, ventilation and air-conditioning) systems. Alternatively, natural ventilation is used, either in the form of the stack effect or using the wind. Regarding wind-driven ventilation, Khan et al. 2008 provides an overview of methods and applications, while Saadatian et al. (2012) review windcatcher technologies.

The implementation of EH from the air flow considers the allocation of a series of fins composed of piezoelectric materials ideally optimized in form and specifically characterized by special aerodynamics appendices consisting in small flexible elements. These modules immersed in the airflow channels, will lead to the extraction of energy, being able to develop all the necessary nonlinear and resonant behavior. An adaptive control strategy could be implemented to optimize in real time the flexible elements.

Such kind of application is not entirely new. Weinstein et al. (2012) investigate the possibility to extract energy by means of piezoelectric materials from the air flow in HVAC. In their study they focus on flow speeds of 2.5 and 5.0 m/s, and on using the vortex shedding effect from a bluff body placed in the air flow ahead of piezoelectric fins. Hobs and Hu (2012) propose piezoelectric cylinders placed in air flows of 1.8-4.3 m/s, where the ones upstream function as bluff bodies for those downstream so that they generate a Kármán vortex street. Energy-harvesting based on vibration induced by Kármán vortex street has been proposed recently also by Wang et al. (2012) at a smaller scale.

6 CONCLUSIONS AND DISCUSSIONS

Since this study focuses on an overview of sustainability issues and EH opportunities, no conclusions are provided in this stage. However, there are many other aspects that need to be inquired: the optimum (and cost effective) use of piezoelectric materials, the energy storage options, etc. However, the opportunity of using piezoelectric materials for EH is interesting, also for producing energy at remote locations. This has obvious advantages for powering micro-electronic devices, but the soundness for meso-scale applications needs to be tested.

ACKNOWLEDGEMENTS

The team www.francobontempi.org from Sapienza University of Rome is gratefully acknowledged. Sustainability considerations for tunnel projects

J. Sauer & O. Fischer
Chair of Concrete and Masonry Structures, Technische Universität München, Munich, Germany

ABSTRACT: Sustainability and the associated environmental protection is one main issue in present time. The question of sustainability is also interesting in civil engineering. So far the most research projects focused on sustainability of building structures. However infrastructure projects, especially tunnel construction, are not considered. Many public databases are available to get ecological parameters like CO_2E-emissions for construction materials and processes. Concrete is one of the most important materials for tunnel construction. The CO_2E-emissions of concrete are just given for a few different concrete strength classes in the considered databases GEMIS and Ökobau.dat. Exemplary mix designs are made for different concrete and cement strength classes to calculate the CO_2E-emissions and to evaluate the influence for the overall CO_2E-emissions of tunnel construction. The CO_2E-emissions will be evaluated monetarily to compare them with production costs and therewith life cycle costs. Indirect effects resulting from traffic situations and related indirect costs have to be taken into account.

1 INTRODUCTION

Sustainability and the associated environmental protection is one main issue in present time. The question of sustainability is also interesting in civil engineering. Most structures are made of concrete and therefore cement. During production process of 1000 kg cement nearly 1000 kg CO_2 will be released (Ulm 2012). For this reason the cement industry has a big influence on the releasing of CO_2-emissions worldwide (about 5%). The aim is to reduce the global warming potential (GWP) which is described by the CO_2-equivalent (CO_2E).

So far the most research projects focused on sustainability of building structures. However infrastructure projects, especially tunnel construction, are not considered. Concrete is one of the most important materials for tunnel construction. The relevance of different concrete and cement strength classes on the overall CO_2E-emissions will be analyzed for one exemplary tunnel project in this paper. The emissions will be evaluated monetarily to show the influences on the overall life cycle costs of tunnel projects. Additionally construction and maintenance works may have an impact on the traffic leading to an increase of 'indirect' emissions, so called indirect effects. These effects have to be taken into account.

2 DATABASES

Many databases are available to get ecological parameters like CO_2E-emissions for construction materials and processes like GEMIS (= Global Emissions Model for integrated Systems) (IINAS 2013) and Ökobau.dat (BMVBS 2013). Both are freely accessible programs but with one main difference: with GEMIS it is possible to model new materials and processes from the first step to the last which are not included in the given database. For example the mining of minerals is the first step in the process chain for the production of concrete. The product concrete is the last step. Many sub steps can be modeled with different input e.g. electricity. It is also possible to add transport routes of admixtures. In the end the CO_2E-emissions are calculated over the whole process chain. With Ökobau.dat it is not possible to model new materials. Fixed materials are included and their characteristics cannot be changed.

The CO_2E-emissions of concrete are just given for a few different concrete strength classes in both databases. As it is not possible to model new materials with Ökobau.dat the CO_2E-emissions for different concrete strength classes will be modeled and calculated with GEMIS in this paper.

3 CO_2E-EMISSIONS OF CONCRETE

To model different concrete strength classes with GEMIS it is necessary to have information about the mixture of each concrete strength class. For this reason exemplary mix designs for concrete strength classes C12/15 to C50/60 are made, which are not directly derived from current projects.

For the mixture portland cement (CEM I) is used. Three types of cement strength classes are available: 32.5 N/mm^2, 42.5 N/mm^2 and 52.5 N/mm^2. Mix designs with these three cement strength classes are made for every concrete strength class. For the

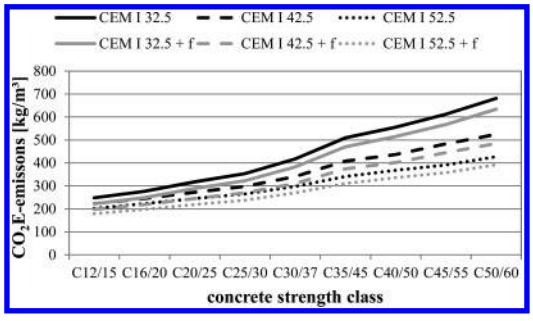

Figure 1. CO_2E-emissions for different concrete strength classes with different cement strength classes with and without fly ash (f).

aggregate a grain size distribution with maximum grain size Ø 16 is used. This grain size distribution often is used at our laboratory at Technische Universität München. The CO_2E-emissions are calculated for each concrete strength class with different cement strength classes. Additionally mix designs with fly ash are made for each concrete and cement strength class (Fig. 1).

With increasing concrete strength classes the CO_2E-emissions increase. Depending on the cement strength class the CO_2E-emissions of concrete C50/60 are 2–3 times bigger than for C12/15. The reason for this is the increasing cement content for higher concrete strength classes within one cement strength class. With increasing cement strength classes the CO_2E-emissions decrease in a certain concrete strength class due to the reduction of required cement content. However from Figure 1 it can be seen that the CO_2E-value for C30/37 with 32.5 N/mm^2 cement strength is in the range as for C45/55 with 52.5 N/mm^2 cement strength. This aspect is going to be discussed in the following sections.

The CO_2E-value of concrete is mainly influenced by the cement content of concrete. From our results it can be stated that a concrete mixture with e.g. 200 kg cement produces CO_2E-emissions in a range of 200 kg/m^3. Further process steps like mining of minerals have a very small influence and they could be neglected for a simple assessment of the greenhouse effect for concrete. Admixtures like fly ash reduce the cement value and with it the CO_2E-emissions for concrete (Fig. 1).

4 EFFECTS FOR TUNNEL PROJECTS

4.1 *Example project*

For the relevance of CO_2E-emissions for different concrete strength classes and their influence on the overall CO_2E-emissions for tunnel projects one example project is used.

The example project is a highway section in a region with varying topography closed to the Alps. In a study of alternatives six different options of alignment

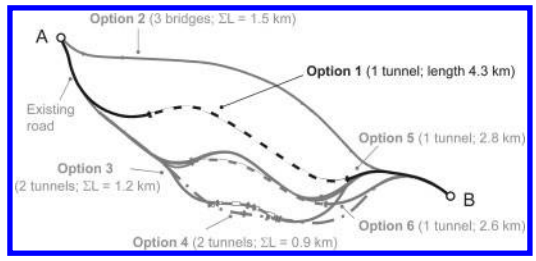

Figure 2. Scheme of options (TUM 2012).

were designed according to the German guideline "Richtlinie für die Anlage von Autobahnen" (RAA) (FGSV 2008): Five options have road and tunnel sections; option 2 has only road and bridge sections. Figure 2 shows a scheme of these in an abstract ground view.

The tunnel section of option 1 will be considered for the evaluation of CO_2E-emissions. The tunnel length is 4.3 km each for north and south tube. The standard cross section of the tunnel is defined as RQ 36t according to RAA. This cross section has three lanes of 3.50 m width per direction and no emergency lane which leads to other traffic safety measures. The tunnel has to be equipped according to the German guideline "Richtlinie für die Ausstattung und den Betrieb von Straßentunneln" (RABT) (FGSV 2006). According to the tunnel length the RABT determines the emergency equipment (number of breakdown bays, emergency call stations and cross passages). The tunnel is built with shotcrete method (NATM).

4.2 *Results*

For the relevance of CO_2E-emissions for different concrete and cement strength classes we will first consider the inner concrete lining of our example project. Resulting from chapter 3 we know that the CO_2E-value for C30/37 with 32.5 N/mm^2 cement strength is in the range as for C45/55 with 52.5 N/mm^2 cement strength. With a higher concrete strength it will be possible to reduce the depth of the inner concrete lining. A thinner inner lining reduces the structural bending stiffness. Accordingly the bending moments will be reduced leading to an increase of deformations and additional lateral subsoil bedding reactions. The influence on the normal forces is insignificant.

Based on the values from Table 1 the CO_2E-emissions are calculated for the reinforced inner concrete lining. The depth of the inner lining is varied from 0.50 m to 0.35 m (hereby also the required amount of reinforcement is considered depending on the depth). For the depth of 0.50 m lower concrete strength classes of C25/30 and C30/37 are used. For C30/37 also the cement strength class is varied from 32.5 to 42.5 N/mm^2. For the thinner inner lining of 0.35 m a higher concrete strength class of C50/60 with cement strength of 52.5 N/mm^2 is used.

Corresponding to the results of chapter 3 (Fig. 1) higher emissions for C30/37 with cement strength of

Table 1. Values of inner concrete lining for calculation of CO_2E-emissions.

	Cement strength	Depth of inner lining
	N/mm²	m
C25/30	32.5	0.50
C30/37	32.5	0.50
C30/37	42.5	0.50
C50/60	52.5	0.35

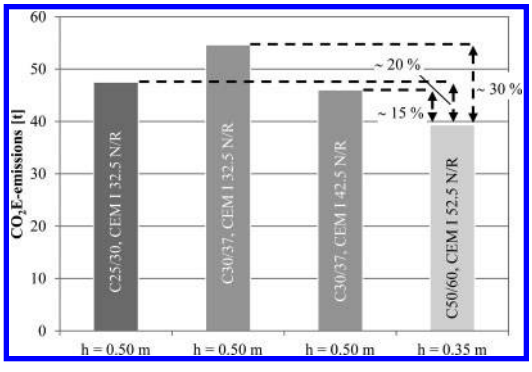

Figure 3. CO_2E-emissions for different concrete and cement strength classes with respect to the depth of the inner concrete lining including reinforcement for our example.

32.5 N/mm² are resulting than for C25/30 (Fig. 3, two columns on the left side). As the volume of concrete is not changing because of the same depth of the inner lining (0.5 m), the reason is still the higher cement content for C30/37 with 32.5 N/mm² cement strength. Lower CO_2E-emissions are resulting for C30/37 if we change the cement strength to 42.5 N/mm² (Fig. 3, third column from left) because of lower cement content for higher cement strength. The lowest CO_2E-emissions are resulting for C50/60 with 52.5 N/mm² cement strength and depth of the inner lining of 0.35 m for our example. The reason is the reduced volume of concrete by using nearly the same CO_2E-value as for C30/37 with 32.5 N/mm² cement strength.

With respect to the depth of the inner lining, the concrete and cement strength it is possible to save CO_2E-emissions of about 15–30% resulting from concrete for our example. The amount of saving is not a fixed value because it is depending on the cross section of the tunnel. It is reasonable to analyze the influence of using a thinner inner lining with a higher concrete strength class for tunnel projects to reduce the CO_2E-emissions. A higher concrete strength class is not necessarily related to higher CO_2E-emissions resulting from the production process of the structure. The same conclusion is drawn by Ulm (2012) for structures in general.

In order to illustrate the relevance of CO_2E-emissions we have evaluated them monetarily. Thus we can compare them with production costs and

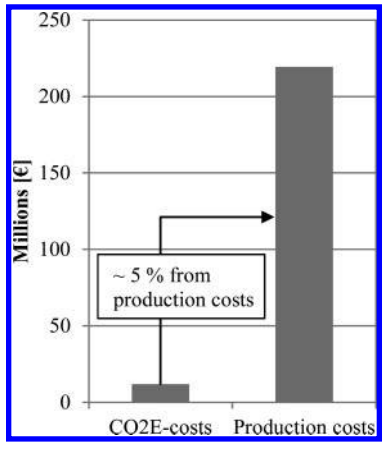

Figure 4. Comparison of CO_2E-costs and production costs.

therewith life cycle costs. To convert CO_2E-emissions into costs, a value of 70 €/t-CO_2E is used, which is a value from a report "Ökonomische Bewertung von Umweltschäden: Methodenkonvention zur Schätzung externer Umweltkosten" published by the Federal Environment Agency (UBA 2007). For the comparison with production costs the CO_2E-emissions for the whole production process of the tunnel (including emergency equipment e.g. cross passages and construction phases e.g. blasting) are calculated. From Figure 4 it can be seen that the CO_2E-costs are just in a range of some 5% in relation to the production costs.

The tunnel in our example is built with shotcrete method. Calculations from another project have shown that it is possible to save more CO_2E-costs by using the TBM-tunneling method utilizing precast segments, only, than the shotcrete method (TUM 2012). Main reason is the overall reduced volume of concrete of the segmental lining.

The production costs do not include costs occurring from maintenance work. Adding these costs on top of the production costs, the influence of CO_2E-costs from production process is getting more and more negligibly small although there are additional CO_2E-costs induced by maintenance works. Extending our point of view from the tunnel section to the whole route additional effects have to be taken into account. These effects are so called indirect effects resulting from the traffic situation. Emissions from only a free traffic flow exceed the CO_2E-emissions from production process in short time. Considering traffic jam situations leads to higher CO_2E-emissions and they are more significant. Influencing parameters on indirect effects are technical quality of construction and process quality which enable traffic flow or in contrast cause traffic interferences (Fig. 5).

5 CONCLUSION

In this paper we have analyzed the influence of different concrete and cement strength classes for

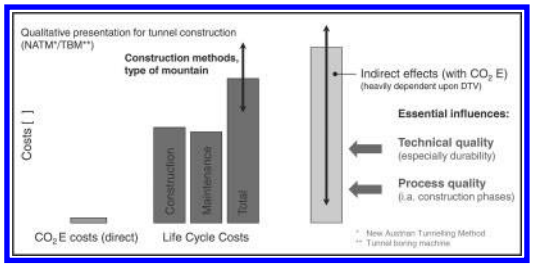

Figure 5. CO_2E-emission costs compared to life cycle costs and indirect effects (TUM 2012).

CO_2E-emissions of tunnel projects. We have calculated the CO_2E-emissions for concrete strength classes C12/15 to C50/60 with cement strength of 32.5 N/mm^2, 42.5 N/mm^2 and 52.5 N/mm^2. For a simple assessment of the greenhouse effect it can be said that a concrete mixture with e.g. 200 kg cement produces CO_2E-emissions in a range of 200 kg/m^3.

We have applied the results on an exemplary tunnel project. The depth of the inner concrete lining of the example project was varied and the CO_2E-emissions were calculated and analyzed for different concrete and cement strength classes. In order to illustrate the relevance of CO_2E-emissions we have evaluated them monetarily. Applying this parameter allowed us to compare the CO_2E-emission costs with production costs and therewith life cycle costs.

The results have shown that it is reasonable to analyze the influence of different concrete and cement strength classes for CO_2E-emissions of tunnel projects. A higher concrete strength class is not necessarily related to higher CO_2E-emissions. For a higher concrete strength class higher cement strength is used and with this the cement content of concrete is reduced. By using higher concrete strength it is possible to reduce structural dimensions leading to decreased concrete quantities and furthermore to a reduced volume of cement. The cement industry represents a large share on releasing CO_2E-emissions worldwide and these emissions could be reduced. Additionally with a thinner inner lining the excavated cross-section will be reduced. This leads also to reduced CO_2E-emissions and higher environmental protection.

In general it can be said that it is useful to reduce CO_2E-emissions during construction phase but it is more useful to optimize the life cycle of infrastructure projects during planning process. The CO_2E-emissions are mainly related to indirect effects resulting from traffic situations. These effects have to be reduced which is possible with an optimized life cycle of infrastructure projects. It is important to use sustainable materials but it is even more important to build more robust and durable structures with less maintenance work which enable traffic flow and cause traffic interferences. Direct production costs and also indirect costs resulting from maintenance and refurbishment can be saved. During planning process it is necessary to choose an optimum alignment with small longitudinal gradients or shorter routes to reduce emissions resulting from traffic situations and the use of fuel.

ABSTRACT: The feasibility of Epoxy to repair of cracks such as Flexural cracks and Shear cracks of various widths in the concrete were examined. The main focus of research investigation is in the areas of the concrete Repair and Rehabilitation which have been formulated by injection of Epoxy Resin under high pressure for their behaviour. The bonding characteristics of rehabilitated beams were suitably analyzed for their behaviour. The first stage of experimental programme involves studying the static behaviour of flexural member under two point static loading to obtain the load deflection behaviour having sectional dimensions 150 × 230 mm with an effective span of 2000 mm. Three test beam specimens were tested at 100%, 70% and 40% of the ultimate loads respectively to create flexural and shear cracks. Energy absorption capacity, toughness index and ductility index were evaluated. The second stage of experimental investigation involves flexural test of rehabilitated failed test specimen after epoxy resin injection. It is experimentally evident that the rehabilitated beams behaved much better with respect to the first crack load, energy absorption capacity, toughness index and ductility index as compared to the beam before rehabilitation. The proposed technique is simple and economical to execute and has resulted in an adhesively bonded joints without any additional effort such as jacketing or shear connectors.

Keywords: Epoxy resin injection, rehabilitated, flexural cracks, toughness index, ductility index.

1 INTRODUCTION

The present investigation deals with the studies on repair and rehabilitation of flexural member using synthetic resins such as epoxy. The relevant literature review available in this area has been critically studied and discussed on the use of polymers (Epoxy) for Repairs and Rehabilitation of RCC Structures. Most widely used polymers for the application in cementations repair work are urethane, modified acrylics, poly vinyl acetates, styrene butadiene rubber (SBR), chloroprene rubber (CR) poly acrylic ester (PAE), poly ethylene vinyl acetate

(EVA or VAE), poly styrene acrylic ester (SAE), in cementations mixture improves a host of properties (El-Hawary 2000, M. Haider 2007). Amongst the Epoxy resins (R. D. Maksimov1995) when cured with different hardeners offer a wide range of application to bond plastic concrete to hardened concrete, bond rigid materials to each other, enhanced resistance to crack propagation, increased tensile, flexural and bond strength resistance etc. Injection material epoxy resin (Paolo Gazzarrini1998) is traditionally used for filling cracks in concrete structures. The function of the injected material is mainly two fold - fill the crack to prevent water ingress and act as a structural filler to transfer loads across the crack were exploited for innovative repairs at a high security establishment. For repairing of concrete slabs (Alexander 2000, C. Li 2004) deteriorated due to the remarkable increase of traffic roads, the reinforcement of those defective slabs by bonding steel from underside using epoxy resins are recently becoming popular. Polymer being the costliest input in any repair and rehabilitation job, the selection of an appropriate brand assumes importance. Due to the rapid deterioration of concrete structures, more and more repair and rehabilitation works are being taken up. The majority of structures surveyed have been repaired, using a variety of technologies with varying degrees of success. Repaired materials included conventional concrete, fiber reinforced concrete, polymer concrete. In many instances, materials have been prototype repairs with limited or no laboratory evaluation of their effectiveness in the particular application. In practice a flexural member is usually subjected to combined flexure and shear and very rarely is under the action of pure shear since the performance of reinforced concrete member can be judged from the load

deformation characteristics of a member the same will be studied to understand the behaviour of the test beam specimen. Hence an attempt has been made in the present work to evaluate a detailed study on Flexural cracks and shear cracks which were experimentally created on the test beam specimen and rehabilitating the same using epoxy injection innovative technique.

2 MATERIALS

In the present work Special Grade Portland cement (53-S) conforming to IRS/T-40-1985, crushed granite angular aggregate of size 20 mm passing, conforming to IS 383 having specific gravity 2.67, natural river sand confirming to IS 383, Zone II, having specific gravity 2.63, water confirming to IS 456:2000 and Mix Design proportions 1:1.59:3.22 with w/c ratio 0.5 having target strength of 29.6 N/mm^2 for M20 grade of design were used. Fe 415 bars of 12,10,8 mm diameter as reinforcement for main, hangar bars and stirrups respectively. Synthetic Epoxy Resin a solventless crack injection material composed of suitable viscous liquid epoxy resin & amine hardener system were used to seal the cracks and bring the structure to stronger state. Epoxy resin adhesive for the pressure injection of cracks consists of

i. Component "A" shall be a modified epoxy resin of the epichlorohydrin biphenol A type containing suitable viscosity control agents.
ii. Component "B" shall be primarily a reaction product of a selected amine blend with an epoxy resin of the epichlorohydrin bisphenol A type containing suitable viscosity control agents and accelerators.
iii. The Component "A" and Component "B" shall be taken by 2:1 ratio by volume. Capping were carried out using Universal mortar which consists of modified cement mortar with Polypropylene fibre.

3 TEST PROGRAM

A series of three test beam specimen of size 150×230×2200 mm with effective span of 2000 mm were tested as shown in figure 1 under two point load condition in the loading frame of capacity 300 kN. The load increment was applied with a 200 kN capacity jack. The test beam specimens are loaded up to 100%,70%, 40% of ultimate load and then the failed test beam specimen is rehabilitated by using epoxy resin injection technique under high pressure to enhance the load carrying capacity of the test beam specimen as similar to the virgin beams.

4 METHOLODY ADOPTED FOR REPAIR WORK IN THE PRESENT INVESTIGATION

The repair work is focused on applying epoxy resin injection technique to the major diagonal cracks and

Figure 1. Test Setup.

Figure 2. Rehabilitated Beam with capping.

other cracks formed along the beam after the test specimen is subjected to loads, while hairline cracks are ignored because of their insignificant effect and the practical difficulty in treating them. The procedure for application of Epoxy resin injection involves the following steps.

1. Surface Preparation: Cleaning of the cracks that have been contaminated with oil, grease, dirt, or fine particles of concrete which prevents epoxy penetration and bonding.
2. Fixing of nozzles: The method entails drilling a hole into the crack into which a fitting such as a pipe nipple or tire valve stem is bonded. The surface of the cracks in between the nipples should be sealed with concrete repair mortars of 30-40 mm wide & 2-3 mm thick band.
3. Mixing the epoxy: This is done either by batch or continuous method. In batch mixing the adhesive components A and B are premixed usually with the use of a mechanical stirrer.
4. Inject the epoxy: Epoxy resin Injection grout should be used with standard injection equipment. As shown in figure 3. The injection pressure should be at least 0.2 N/mm^2 otherwise the use of excessive pressure may propagate the existing cracks, causing additional damage. After completion of the injection work, the injection system shall be allowed for 24 hours curing and shall be left undisturbed.
5. Capping: After the injected epoxy has cured the surface seal should be capped as shown in figure 2 for nozzles depending upon methodology adopted.

Figure 3. Epoxy Injection to damaged beams.

Table 1. Mechanical Properties of concrete.

Properties		M20 Grade concrete
Compressive strength (N/mm^2)	3 days	15.83
	7 days	22.55
	28 days	29.66
Split tensile strength (N/mm^2)	3 days	0.93
	7 days	1.43
	28 days	2.07
Flexural strength (N/mm^2)	3 days	1.42
	7 days	2.35
	28 days	2.85

5 TEST RESULTS

The test results obtained for Ductility index, energy absorption capacity, toughness index were evaluated from load deflection curve for the test beam specimen B1, B2, B3 and the rehabilitated beams specimen B1R, B2R (Beam B2, B2R are discussed) and the table 1. shows the properties of concrete matrix used.

5.1 *Load-Deflection Behaviour*

Typical load-deflection curves for test beam specimen beams, B1, B2, B3 and retrofitted beams B1R,B2R beams are shown in figure 4. The major stages are observed on load deflection curves as first cracking load, Yield point load and ultimate load respectively.

5.2 *Ductility Index* (μ_d)

The term ductility is defined as the ability of the material or member to sustain deformation beyond the elastic limit, while maintaining a reasonable load-carrying capacity before total collapse. Generally is defined in the case of member subjected to flexure as Ultimate Deformation to deformation at first yield. The Values of ductility are given in table 2.

5.3 *Energy Absorption Capacity*

The values of energy absorption capacity were computed from the area of load deflection curve for beam B2 are given in table 3. It is seen that the rehabilitated beam B2R has increased the energy absorption capacity as compared to the test beam specimen B2.

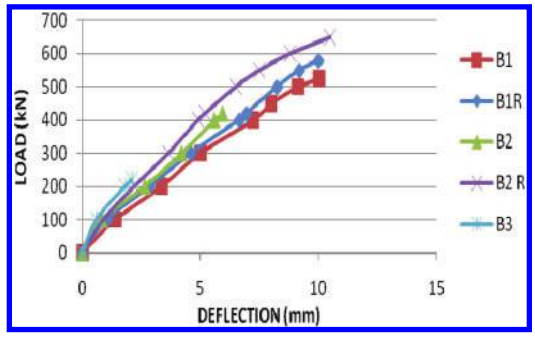

Figure 4. Load-Deflection Behaviour.

Table 2. Ductility Index.

Beam	P_U(KN)	Δ_U(mm)	P_y(KN)	Δ_y(mm)	μ_d
B2	420	5.95	315	3.89	1.21
B1-R	580	10.00	400	8.25	1.24
B2-R	600	10.50	420	7.90	1.40

Table 3. Energy absorption capacity.

Beam	Energy absorption capacity (KN-mm)
Test Beam specimen-B2	2.961
Rehabilitated beam-B2R	3.318

Table 4. Toughness Index.

Type of beam	Toughness Index
Test Beam specimen-B2	1.80
Rehabilitated beam-B2R	2.62

5.4 *Toughness Index*

It is defined as the ratio of area under the curve up to ultimate load to area under the curve up to first crack load. The value of Toughness index for different concrete mix under investigation and are given in table 4.

6 CONCLUSIONS

- The beam retrofitted with epoxy resin injection shows more deflection in B2R compared to B2. The cracking load and ultimate load carrying capacity increases significantly.
- As per the results tabulated in the table 2, it indicates that the ductility index increases by 14%, toughness

Figure 5. Details of Epoxy Resin Injection Treatment.

index increases by 25% energy absorption capacity increases by 10.75%. The enhancement in the strength level is observed in B2R among other retrofitted beams.

- In general all the retrofitted beams exhibits much load carrying capacity and the structural integrity due to epoxy injection.
- In the retrofitted beam no reopening of cracks were observed even at 70% of the ultimate load due to stiffness compared to before retrofitting.

The second order solution of Boussinesq's problem

E. Ferretti
DICAM, School of Engineering and Architecture – University of Bologna, Bologna, Italy

ABSTRACT: In this document, we have proposed a second order solution to Boussinesq's problem (Boussinesq 1885), which allows us to account for the new experimental evidence (Ferretti & Bignozzi 2012, Ferretti 2012b) on the stress field induced by aircraft traffic in concrete pavements. In particular, the second order solution is able to describe the tensile state of stress acquired in the proximity of the contact area and not accounted for in the classical solution of Boussinesq's problem for a homogeneous linear-elastic and isotropic half-space. The second order solution also allows us to evaluate the effect of the elastic constants on the stress field, improving the solution of Boussinesq in this second case also.

1 THE FIRST ORDER ELASTIC SOLUTION

1.1 *First integral of the equilibrium problem*

The first solution of Boussinesq is based on the similarity between the equilibrium equations in terms of displacements, with the body forces per unit volume, f_x, f_y and f_z, set equal to zero:

$$\begin{cases} (\lambda+\mu)\dfrac{\partial I_{1\varepsilon}}{\partial x}+\mu\nabla^2 u=0 \\ (\lambda+\mu)\dfrac{\partial I_{1\varepsilon}}{\partial y}+\mu\nabla^2 v=0 \\ (\lambda+\mu)\dfrac{\partial I_{1\varepsilon}}{\partial z}+\mu\nabla^2 w=0 \end{cases} \tag{1}$$

where $I_{1\varepsilon}$ is the bulk strain, and the three equations:

$$\begin{cases} \dfrac{\partial}{\partial x}\left(2\dfrac{\partial P}{\partial z}\right)-\nabla^2\dfrac{\partial(zP)}{\partial x}=0 \\ \dfrac{\partial}{\partial y}\left(2\dfrac{\partial P}{\partial z}\right)-\nabla^2\dfrac{\partial(zP)}{\partial y}=0 \\ \dfrac{\partial}{\partial z}\left(2\dfrac{\partial P}{\partial z}\right)-\nabla^2\dfrac{\partial(zP)}{\partial z}=0 \end{cases} \tag{2}$$

that are satisfied by any potential function P for which the Laplacian is equal to zero:

$$\nabla^2 P=\frac{\partial^2 P}{\partial x^2}+\frac{\partial^2 P}{\partial y^2}+\frac{\partial^2 P}{\partial z^2}=0\,. \tag{3}$$

The use of the equilibrium equations with the body forces set equal to zero for studying the stress field induced in the soil by a point-load is allowed by the superposition principle: assuming a linear-elastic behavior for the soil, we can separately analyze and superpose the stress field induced in the soil by the point-load and the stress field induced in the soil by the weight of the soil itself.

The similarity between the two systems of Equations 1 and 2 is established in the assumptions:

$$u=-\frac{\partial}{\partial x}(zP),\quad v=-\frac{\partial}{\partial y}(zP),\quad w=-\frac{\partial}{\partial z}(zP)+KP, \tag{4}$$

$$\frac{\lambda+\mu}{\mu}I_{1\varepsilon}=2\frac{\partial P}{\partial z}\,. \tag{5}$$

The function P chosen by Boussinesq is the logarithmic potential Ψ for the prefixed point (x, y, z) of the semi-space under the surface, at the distance r from the point $Q \equiv (x_1, y_1, 0)$ of the load surface:

$$r=\sqrt{(x-x_1)^2+(y-y_1)^2+z^2}\,, \tag{6}$$

$$P=\Psi=\int\log(z+r)\,dm\,, \tag{7}$$

where dm is given by $\rho(x_1, y_1)$, the mass density for unit surface at the point Q:

$$\int dm=\int\rho(x_1,y_1)\,dx_1dy_1\,. \tag{8}$$

The solution of the equilibrium problem in terms of potentials is:

$$(u,v)=-\frac{\partial}{\partial(x,y)}(z\Psi),\quad w=-\frac{\partial}{\partial z}(z\Psi)+K\Psi\,. \tag{9}$$

Since Equations 9 satisfy the conditions of equilibrium but do not provide the right displacement field for

$z \to \infty$ (Boussinesq 1885), Boussinesq used the first derivative $\partial\Psi/\partial z$ instead of the logarithmic potential Ψ for the potential P in Equations 2, which is allowable since $\partial\Psi/\partial z$ still gives a Laplacian equal to zero:

$$P = \frac{\partial \Psi}{\partial z} = \int \frac{dm}{r}, \tag{10}$$

$$(u,v) = -z\frac{\partial}{\partial(x,y)}\frac{\partial \Psi}{\partial z},\ w = -z\frac{\partial^2 \Psi}{\partial z^2} + \frac{\lambda+3\mu}{\lambda+\mu}\frac{\partial \Psi}{\partial z} \tag{11}$$

$$\begin{cases} \tau_{xz} = -2\mu\dfrac{\partial}{\partial x}\left(\dfrac{\mu}{\lambda+\mu}\displaystyle\int\frac{dm}{r} + z\int\frac{z dm}{r^3}\right) \\ \tau_{yz} = -2\mu\dfrac{\partial}{\partial y}\left(\dfrac{\mu}{\lambda+\mu}\displaystyle\int\frac{dm}{r} + z\int\frac{z dm}{r^3}\right) \\ \sigma_z = -2\mu\displaystyle\int\left(\frac{\mu}{\lambda+\mu}\frac{z}{r^3} + 3\frac{z^3}{r^5}\right)dm \end{cases} \tag{12}$$

For the points of the surface, Boussinesq provides the results:

$$u = 0,\ \ v = 0,\ \ w = \frac{\lambda+3\mu}{\lambda+\mu}\int\frac{dm}{r}, \tag{13}$$

$$I_{1\varepsilon} = -4\pi\frac{\mu}{\lambda+\mu}\rho(x,y), \tag{14}$$

$$\begin{cases} (p_x, p_y) = \lim\limits_{z\to 0} -2\dfrac{\mu^2}{\lambda+\mu}\dfrac{\partial}{\partial(x,y)}\displaystyle\int\frac{dm}{r} \\ p_z = 4\pi\mu\dfrac{\lambda+2\mu}{\lambda+\mu}\rho(x,y) \end{cases} \tag{15}$$

The third of Equations 15 and the first two of Equations 13 tell us that this is the case in which the boundary conditions consist in giving the normal component of the load and assuming the horizontal displacements on the surface to be equal to zero.

A discussion of the original treatment of Boussinesq (Boussinesq 1885) can be found in Ferretti (2012a), where it is pointed out how it seems unnecessary to perform integrals on the whole load surface – as Boussinesq does – since the aim of the treatment is to find the solution for a single point-load, and not for a distributed load. In effect, after obtaining the general solution, Boussinesq gives the point-load solution by substituting the integrals with their integrands, that is, by causing the dimensions of the load surface to vanish. It therefore seems possible, besides being simpler, to build the point-load solution directly, by defining the potentials for the infinitesimal superficial neighborhood of the point:

$$\psi = \log(z+r)\,dm, \tag{16}$$

$$P = \frac{\partial \psi}{\partial z} = \frac{1}{r}dm. \tag{17}$$

The solution following by the position in Equation 17 is:

$$\begin{cases} u = \dfrac{z(x-x_1)}{r^3}dm,\ \ v = \dfrac{z(y-y_1)}{r^3}dm \\ w = \dfrac{r^2(\lambda+3\mu)+z^2(\lambda+\mu)}{r^3(\lambda+\mu)}dm \end{cases} \tag{18}$$

$$I_{1\varepsilon} = -\frac{2\mu}{\lambda+\mu}\frac{z}{r^3}dm, \tag{19}$$

$$\begin{cases} \tau_{xz} = 2\mu(x-x_1)\dfrac{\mu r^2 + 3(\lambda+\mu)z^2}{(\lambda+\mu)r^5}dm \\ \tau_{yz} = 2\mu(y-y_1)\dfrac{\mu r^2 + 3(\lambda+\mu)z^2}{(\lambda+\mu)r^5}dm \\ \sigma_z = -2\mu z\dfrac{\mu r^2 + 3(\lambda+\mu)z^2}{(\lambda+\mu)r^5}dm \end{cases} \tag{20}$$

For $z \to 0$ (points of the surface), we find:

$$u = 0,\ \ v = 0,\ \ w = \frac{\lambda+3\mu}{r(\lambda+\mu)}dm \tag{21}$$

$$I_{1\varepsilon} = \begin{cases} 0 & \text{for } r > 0 \\ -\dfrac{2\mu}{\lambda+\mu}\rho(x_1,y_1) & \text{for } r \to 0 \end{cases}, \tag{22}$$

$$\begin{cases} p_x = \dfrac{2\mu^2}{\lambda+\mu}\dfrac{x-x_1}{r^3}dm,\ \ p_y = \dfrac{2\mu^2}{\lambda+\mu}\dfrac{y-y_1}{r^3}dm \\ p_z = \begin{cases} 0 & \text{for } r > 0 \\ 2\mu\dfrac{\lambda+2\mu}{\lambda+\mu}\rho(x_1,y_1) & \text{for } r \to 0 \end{cases} \end{cases} \tag{23}$$

1.2 *Second integral of the equilibrium problem*

The second solution follows from the position:

$$u = \frac{\partial P}{\partial x},\ \ v = \frac{\partial P}{\partial y},\ \ w = \frac{\partial P}{\partial z}. \tag{24}$$

Due to Equation 3, in this second case the bulk strain is equal to zero:

$$I_{1\varepsilon} = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = \nabla^2 P = 0, \tag{25}$$

and the equilibrium equations expressed by Equations 1 are identically satisfied.

By using the logarithmic potential given in Equation 16 instead of Ψ, the second solution of Boussinesq is substituted by the following (Ferretti 2012a):

$$\begin{cases} u = \dfrac{\partial \psi}{\partial x} = \dfrac{x - x_1}{r(z+r)} dm \\ v = \dfrac{\partial \psi}{\partial y} = \dfrac{y - y_1}{r(z+r)} dm \\ w = \dfrac{\partial \psi}{\partial z} = \dfrac{1}{r} dm \end{cases} \tag{26}$$

$$\begin{cases} (\tau_{xz}, \tau_{yz}) = -2\mu \dfrac{\partial}{\partial (x,y)} \left(\dfrac{1}{r} \right) dm \\ \sigma_z = 2\mu \dfrac{\partial}{\partial z} \left(\dfrac{1}{r} \right) dm = -2\mu \dfrac{z}{r^3} dm \end{cases} \tag{27}$$

and, for the points of the surface:

$$\begin{cases} u = \dfrac{\partial \psi}{\partial x} = \dfrac{x - x_1}{r^2} dm \\ v = \dfrac{\partial \psi}{\partial y} = \dfrac{y - y_1}{r^2} dm \\ w = \dfrac{\partial \psi}{\partial z} = \dfrac{1}{r} dm \end{cases} \tag{28}$$

$$\begin{cases} p_x = 2\mu \dfrac{x - x_1}{r^3} dm, \quad p_y = 2\mu \dfrac{y - y_1}{r^3} dm \\ p_z = \begin{cases} 0 & \text{for } r > 0 \\ 2\mu\rho(x_1, y_1) & \text{for } r \to 0 \end{cases} \end{cases} \tag{29}$$

1.3 *Third integral of the equilibrium problem*

For the third solution, Boussinesq assumes:

$$u = -\frac{\partial P}{\partial y}, \quad v = \frac{\partial P}{\partial x}, \quad w = 0 \tag{30}$$

which are the plane strain conditions.

As for the second solution, in this case also, the bulk strain is equal to zero and the equilibrium equations are identically satisfied, due to Equation 3

Since the bulk strain is equal to zero, the condition of plane strain implies plane stress in each point of the body. The stress field is given by:

$$\tau_{xz} = \mu \frac{\partial^2 P}{\partial y \partial z}, \quad \tau_{yz} = -\mu \frac{\partial^2 P}{\partial x \partial z}, \quad \sigma_z = 0, \tag{31}$$

where:

$$\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} = 0. \tag{32}$$

This is the solution for the case in which the normal component of the external load is set equal to zero and the two shear components stand in the relationship represented by Equation 32. The displacements take place horizontally.

1.4 *Elastic solution for a point-load perpendicular to the surface*

Due to the superposition principle, it is always possible to find further solutions to the equilibrium problem by combining the former three solutions with each other. Along these lines, Boussinesq formed two linear combinations of Equations 11 and 24. The linear combination giving the solution of the point-load perpendicular to the surface is obtained by multiplying Equations 11 by the inverse of $-4\pi\mu$ and Equations 24 by the inverse of $-4\pi(\lambda + \mu)$. The multiplying factors of the linear combination have been chosen specifically to equal p_z and $\rho(x, y)$:

$$p_z = \lim_{z \to 0} -\frac{1}{2\pi} \frac{\partial^2 \Psi}{\partial z^2} = \rho(x, y). \tag{33}$$

and, consequently, also the external load dF and dm:

$$dF = p_z dx_1 dy_1 = \rho(x_1, y_1) dx_1 dy_1 = dm. \tag{34}$$

Due to the superposition principle, the same multiplying factors can be taken to build a second linear combination, providing the solution in terms of stresses. In the case of infinitesimal load surface, the well-known solutions of Boussinesq for a point-load perpendicular to the surface is:

$$\begin{cases} \tau_{xz} = \dfrac{3}{2\pi} \dfrac{z^2}{r^5} (x - x_1) dF \\ \tau_{yz} = \dfrac{3}{2\pi} \dfrac{z^2}{r^5} (y - y_1) dF \\ \sigma_z = -\dfrac{3}{2\pi} \dfrac{z^3}{r^5} dF \end{cases} \tag{35}$$

where the stresses are independent of the elastic coefficients of the medium.

In Ferretti (2012a), the elastic solution for a point-load perpendicular to the surface has been derived as linear combination of Equations 18 and 26, for displacements, and of Equations 20 and 27, for stresses, providing:

$$\begin{cases} u = \dfrac{x - x_1}{2\mu} \left[\dfrac{z}{r^3} - \dfrac{\mu}{\lambda + \mu} \dfrac{1}{r(z+r)} \right] dF \\ v = \dfrac{y - y_1}{2\mu} \left[\dfrac{z}{r^3} - \dfrac{\mu}{\lambda + \mu} \dfrac{1}{r(z+r)} \right] dF \\ w = \dfrac{1}{2\mu r} \left[\dfrac{\lambda + 2\mu}{\lambda + \mu} + \dfrac{z^2}{r^2} \right] dF \end{cases} \tag{36}$$

$$I_{1\varepsilon}=\frac{1}{\lambda+\mu}\frac{d}{dz}\left(\frac{1}{r}\right)dm=-\frac{1}{\lambda+\mu}\frac{z}{r^3}dF\,, \tag{37}$$

$$\begin{cases}\tau_{xz}=3\dfrac{z^2}{r^5}(x-x_1)\,dF\\ \tau_{yz}=3\dfrac{z^2}{r^5}(y-y_1)\,dF\\ \sigma_z=-3\dfrac{z^3}{r^5}dF\end{cases} \tag{38}$$

for a point inside the soil, and

$$\begin{cases}u=-\dfrac{1}{2(\lambda+\mu)}\dfrac{x-x_1}{r^2}dP\\ v=-\dfrac{1}{2(\lambda+\mu)}\dfrac{y-y_1}{r^2}dP\\ w=\dfrac{\lambda+2\mu}{2\mu(\lambda+\mu)}\dfrac{1}{r}dP\end{cases} \tag{39}$$

$$I_{1\varepsilon}=\begin{cases}0 & \text{for } r>0\\ -\dfrac{1}{\lambda+\mu}\rho(x_1,y_1) & \text{for } r\to 0\end{cases} \tag{40}$$

$$\begin{cases}p_x=0,\;\; p_y=0\\ p_z=\begin{cases}0 & \text{for } r>0\\ \lim\limits_{z\to 0}-\dfrac{\partial^2\psi}{\partial z^2}=\rho(x_1,y_1) & \text{for } r\to 0\end{cases}\end{cases} \tag{41}$$

for the points of the surface.

2 THE SECOND ORDER ELASTIC SOLUTION

2.1 *A second order solution of the first integral*

Following the spirit of the superposition principle and noting that the partial derivatives of any arbitrary order of the function ψ, defined in Equation 16, have a zero Laplacian (i.e. they satisfy the condition $\nabla^2=0$), it is possible to refine the elastic solution of Boussinesq by adding to it a further solution of Equations 2, obtained by substituting ψ with one of its derivatives of second order. This observation will be used here in order to find a further form of the first integral, which, combined to the former form and the second integral, could provide a stress solution to the vertical point-load problem that also depends on the elastic constants of the soil.

Assuming:

$$P=\frac{\partial^2\psi}{\partial z^2}=-\frac{z}{r^3}dm\,, \tag{42}$$

we find:

$$\begin{cases}u=-3\dfrac{z^2(x-x_1)}{r^5}dm\\ v=-3\dfrac{z^2(y-y_1)}{r^5}dm\\ w=-\dfrac{z}{r^3}\left(3\dfrac{z^2}{r^2}+\dfrac{2\mu}{\lambda+\mu}\right)dm\end{cases} \tag{43}$$

$$I_{1\varepsilon}=\frac{2\mu}{\lambda+\mu}\left(3\frac{z^2}{r^5}-\frac{1}{r^3}\right)dm\,, \tag{44}$$

$$\begin{cases}\tau_{xz}=\dfrac{6\mu}{\lambda+\mu}\dfrac{(x-x_1)z}{r^5}\left[\lambda-5(\lambda+\mu)\dfrac{z^2}{r^2}\right]dm\\ \tau_{yz}=\dfrac{6\mu}{\lambda+\mu}\dfrac{(y-y_1)z}{r^5}\left[\lambda-5(\lambda+\mu)\dfrac{z^2}{r^2}\right]dm\\ \sigma_z=-2\mu\left(\dfrac{\lambda+2\mu}{\lambda+\mu}\dfrac{1}{r^3}+\dfrac{6\lambda+3\mu}{\lambda+\mu}\dfrac{z^2}{r^5}-15\dfrac{z^4}{r^7}\right)dm\end{cases} \tag{45}$$

inside the soil, and:

$$u=0,\;\; v=0,\;\; w=0, \tag{46}$$

$$I_{1\varepsilon}=\begin{cases}-\dfrac{2\mu}{\lambda+\mu}\dfrac{1}{r^3}dm & \text{for } r>0\\ -\infty & \text{for } r\to 0\end{cases} \tag{47}$$

$$\begin{cases}p_x=0,\;\; p_y=0\\ p_z=\begin{cases}2\mu\dfrac{\lambda+2\mu}{\lambda+\mu}\dfrac{1}{r^3}dm & \text{for } r>0\\ \infty & \text{for } r\to 0\end{cases}\end{cases} \tag{48}$$

for $z\to 0$.

Since p_x and p_y are equal to zero, Equations 45 may be added to the combined solution of first order without changing the nature of the solved problem, which still is a vertical point-load problem. Moreover, due to the infinite value achieved by p_z for $z, r\to 0$, the second form of the first integral seems to be useful for building the combined solution in all the points of the soil apart from the one of load application.

2.2 *Combined solution*

The combined solution of second order is built by multiplying Equations 45 for $-C$ and adding the result to Equations 38. The resulting stress field (for $r\neq 0$) is

now in relationship with the elastic constants of the soil:

$$\begin{cases} \tau_{xz} = 3\dfrac{(x-x_1)z}{r^5}\left[z + 2C\mu\left(5\dfrac{z^2}{r^2} - \dfrac{\lambda}{\lambda+\mu}\right)\right]dm \\ \tau_{yz} = 3\dfrac{(y-y_1)z}{r^5}\left[z + 2C\mu\left(5\dfrac{z^2}{r^2} - \dfrac{\lambda}{\lambda+\mu}\right)\right]dm \\ \sigma_z = -\dfrac{1}{r^3}\left[3\dfrac{z^3}{r^2} + 2C\mu\left(15\dfrac{z^4}{r^4} - 3\dfrac{2\lambda+\mu}{\lambda+\mu}\dfrac{z^2}{r^2} - \right.\right. \\ \left.\left. - \dfrac{\lambda+2\mu}{\lambda+\mu}\right)\right]dm \end{cases} \tag{49}$$

As far as the third of Equations 49 is concerned, we may easily verify that the new terms (the ones which are multiplied for C) significantly modify the normal stress when approaching the surface, while they are negligible at great depths. Indeed, for $z \to 0$:

$$-p_z = \lim_{z\to 0}\sigma_z = 2C\mu\frac{\lambda+2\mu}{\lambda+\mu}\frac{1}{r^3}dm, \tag{50}$$

while, for $z \to \infty$, the third of Equations 49 gives the combined solution of Section 1.4.

$$\lim_{z\to\infty}\sigma_z = -3\frac{z^3}{r^5}dm. \tag{51}$$

From the comparison between Equations 50 and 51, it is clear that, for $C > 0$, the normal stress for $z \to 0$ is opposite in sign to the normal stress for $z \to \infty$:

$$\operatorname{sign}\left(\lim_{z\to 0}\sigma_z\right) = -\operatorname{sign}\left(\lim_{z\to\infty}\sigma_z\right). \tag{52}$$

Therefore, near to the surface, the compressed soil is subjected to a normal stress of traction. This is a result not accounted for in the solution of Boussinesq and, together with the dependence of σ_z on the elastic constants, represents the most important novelty of the combined solution of second order.

From Equation 52 we can also argue that, as σ_z is a continuous function, there exists a finite value of depth for which the normal stress is equal to zero. Setting $z_0 = z_0(r, C, \lambda, \mu)$, the function giving the depth for which $\sigma_z = 0$, from Equations 49 we find the relationship:

$$z_0^2\left(10C\mu\frac{z_0^2}{r^4} + \frac{z_0}{r^2} - 2C\mu\frac{2\lambda+\mu}{\lambda+\mu}\frac{1}{r^2}\right) = \frac{2}{3}C\mu\frac{\lambda+2\mu}{\lambda+\mu} \tag{53}$$

in which the banal solution:

$$\sigma_z = 0 \quad \text{for } r \to \infty, \tag{54}$$

has been eliminated.

As can be easily verified, for $z \to \infty$ the combined solution of second order is equal to the solution of Boussinesq even for the displacement field.

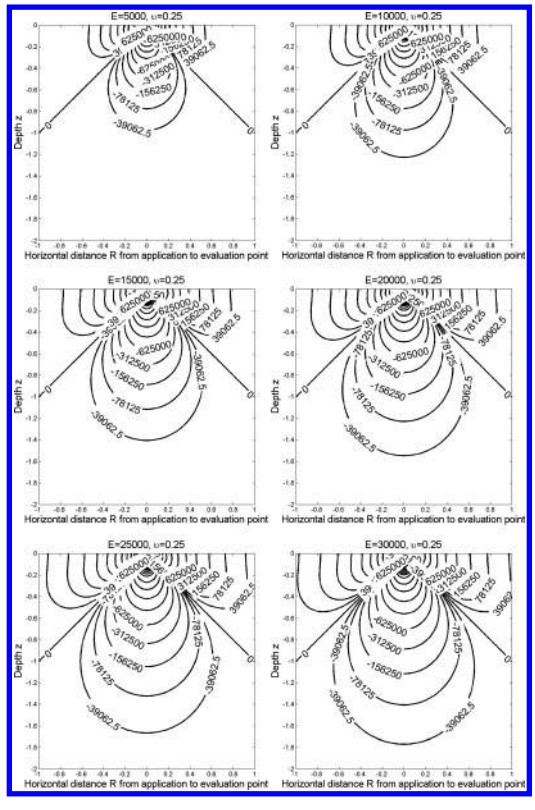

Figure 2. Parametric analysis on the Young modulus, for the vertical stress contours on the vertical cross-section (all distances are in *mm*).

3 NUMERICAL RESULTS

3.1 *Point-load perpendicular to the surface*

The plots of the vertical stress and the vertical stress contours of second order for a prefixed Poisson's ratio, υ, and variable values of Young's modulus, E, are given in Figure 1 for a plane near to the surface and in Figure 2 for a vertical cross-section passing through the point load, respectively. The parametric analysis on the Poisson's ratio for a prefixed E is shown in Ferretti (2012a).

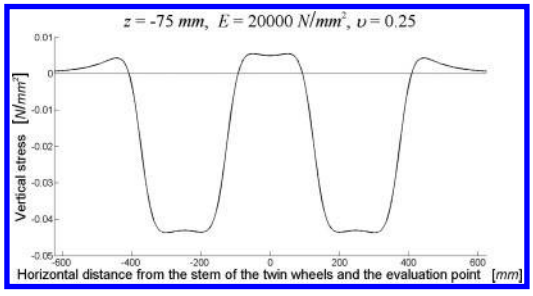

Figure 3. Vertical stress under the twin wheels of an aircraft for rectangular contact areas and uniform load.

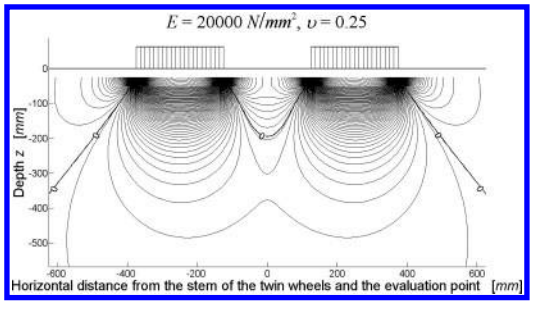

Figure 4. Vertical stress contours on the vertical cross-section for rectangular contact areas and uniform load (twin wheels).

The numerical solution of second order shows two positive peaks of vertical stress in the proximity of the application point of compression load (Fig. 1), in total agreement with the experimental data for vehicular loading shown in Ferretti & Bignozzi (2012) and Ferretti (2012b). This result gives a numerical proof that a tensile state of stress arises on the surface of soils and pavements when subjected to compression loads, with the point in which the vertical stress change in sign that is also a point in which the vertical stress does not depend upon the value of E (Fig. 1). Since both soil and concrete are assumed as not being resistant to traction – to be on the safe side – the tensile state of stress must be considered with particular attention in these materials.

Due to the tensile state of stress, there exist two families of stress contours (Fig. 2): one family for the tensioned soil and one family for the compressed soil, with the two families separated by straight lines. Moreover, the parametric analysis on the vertical cross-section shows that greater values of E increase the vertical stresses at each depth without modifying the shape of the iso-lines of stress, which change in size homothetically (Fig. 2).

3.2 *Distributed load perpendicular to the surface*

In order to evaluate which the interaction effect is of two adjacent loaded areas, the vertical stress and the vertical stress contours of second order for a vertical load that is uniformly distributed over two contact areas of rectangular shape have been plotted in Figures 3, 4, respectively. All the dimensions in Figures 3, 4 are those typical of two twin wheels in an aircraft. The existence of a tensile state of stress near the wheels is well evident even in this last case. Moreover, the interaction effect make particularly severe the positive stresses between the wheels.

Further results for contact areas of circular, rectangular and elliptic shape together with uniform and parabolic laws of external pressure distribution may be found in Ferretti (in prep.).

4 CONCLUSIONS

In this paper, we have discussed Boussinesq's solution in the light of new experimental findings on the stress distribution in a half-space subjected to point-loads. The original work of Boussinesq has been extended to provide a second order solution.

The second order solution has shown that a compression load always generates positive stresses at the surface, in the proximity of the load. The existence of a tensile state of stress, not accounted for in Boussinesq's solution, could explain the several observed mechanisms of premature damage that affect concrete pavements subjected to vehicular loading, particularly when twin wheels are involved.

The second order solution also allows us to evaluate the effect of the elastic constants on the stress field, which, in this second case also, is an improvement to Boussinesq's solution.

Upper and lower bound calculations of the bearing capacity of strip footings near slopes in cohesionless soil

Sven Krabbenhoft & Lars Damkilde

Kristian Krabbenhoft
Department of Civil, Surveying and Environmental Engineering, University of Newcastle, Australia

ABSTRACT: The calculation of the bearing capacity of a strip foundation located on the edge of or near a slope is commonly based on the well known bearing capacity equation applying so called slope factors, and expressions for these factors have been proposed by amongst others Brinch Hansen and Vesic. These factors only take into account the inclination of the slope, whereas other parameters, which may play a role, such as the distance from the footing to the slope, the width of the footing and the strength of the soil are ignored. The present work comprises finite element based upper- and lower-bound calculations, using the software OptumGEO, considering the influence of these factors for vertical loads, and also the effect of a possible surcharge is investigated. The results are given as design charts and tables suitable for practical design.

1 INTRODUCTION

The bearing capacity of a vertically and centrally loaded strip foundation located at the crest of a slope in cohesionless soil can be found from the bearing capacity equation proposed by Hansen (1970) and Vesic (1975) :

$$q_{ult} = 0.5\gamma B N_\gamma d_\gamma g_\gamma + q_s N_q d_q g_q \qquad (1)$$

where q_{ult} is the bearing capacity per unit area of the foundation, γ is the effective soil unit weight, B is the width of the foundation, N_γ and N_q are bearing capacity factors, d_γ and d_q are depth factors, which are always greater than unity and very often they are assumed equal to unity, as will be done in this study, q_s is the vertical effective stress at the foundation base level and g_γ and g_q are slope factors which are functions of the inclination of the slope. For the slope factors the following empirical expressions have been proposed by Hansen (1970):

$$g_\gamma = g_q = (1 - 0.5\tan\beta)^5 \qquad (2)$$

and by Vesic (1975) :

$$g_\gamma = g_q = (1 - \tan\beta)^2 \qquad (3)$$

where in both equations β is the inclination of the slope to the horizontal. The slope factors are independent of the magnitude of the friction angle of the soil and for a footing located a distance away from the crest of the slope neither Hansen nor Vesic gives any guidelines.

Gemberline (1988) carried out a large number of centrifuge tests on model footings located both at various distances from the crest of the slope and at various distances from the top of the slope and on that basis he proposed the following equation for the bearing capacity:

$$q_{ult} = 0.5\gamma B N_{\gamma q} \qquad (4)$$

where the factor $N_{\gamma q}$ depends on the friction angle of the soil, the distance of the foundation from the crest of the slope and the distance from the top of the slope to the level of the foundation base.

The bearing capacity of foundations near slopes has also been investigated by Saran et al (1989), Sarma and Chen (1996) and Castelli and Motta (2010) who all used the limit equilibrium method.

The results of the above authors for a surface foundation located at the crest of a slope are given in Figure 1 for a slope inclination 1:3 ($\beta = 18.44°$).

From Figure 1 it can be seen, that according to Hansen, Vesic and Gemberline the slope factor g_γ is independent of the friction angle of the soil, whereas the other authors all find some dependence of the friction angle on the slope factor. Sarma and Chen and Saran et al. have found decreasing values of the slope factor for increasing values of the friction angle and the opposite is the case with the findings of Castelli and Motta and roughly there is a discrepency up to about 100% between the smallest and the largest values.

The aim of the present study is – within an accuracy acceptable for practical design – to find the bearing capacity of a strip footing located near a slope, and also it is of interest to investigate, whether the

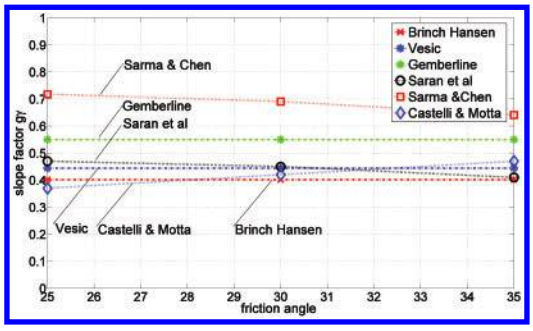

Figure 1. Slope factors g_γ for slope inclination 1:3

traditional bearing capacity equation (1) is providing results, that are reasonably accurate. For that purpose a series of numerical upper- and lower-bound limit analyses using the software package OptumGEO (2012) of the bearing capacity of a strip footing located near a slope in cohesionless soil with varying surcharges have been performed. The analyses are carried out for friction angles 30, 35 and 40° and slope inclinations of 1:2 ($\beta = 26.57°$), 1:3 ($\beta = 18.44°$) and 1:4 ($\beta = 14.04°$). The bearing capacity equation assumes, that the total bearing capacity can be found as the sum of the contributions from the selfweight of the soil and the surcharge and therefore also separate analysis have been done, making it possible to determine both g_γ and g_q and thus the dependency of the friction angle ϕ on the slope factors. The results are reported as tables and graphs suitable for practical design.

2 LIMIT ANALYSIS

2.1 *OptumGEO*

OptumGEO is a finite element program dedicated to geotechnical applications. A key feature of the program is that it allows for the calculation of rigorous upper and lower bound solutions to plasticity problems. The gap between the calculated upper- and lower-bound solutions can be reduced by using the automatic adaptive remeshing procedure available in OptumGEO. For typical problems, the gap between the upper- and lower-bound values of a specific problem can thus be reduced to a few percent or less.

2.2 *Soil characteristics and geometry*

All the simulations were performed for friction angles $\varphi = 30, 35$ and 40° and the unit weight γ of the soil was taken equal to 20 kN/m^3.

The geometry of the slope and the footing is shown in Figure 2. The total area of the domain was chosen large enough to avoid any effects from the boundaries. Likewise the height of the slope was chosen large enough in order for the bottom of the slope not to have any influence on the results.

The width B of the strip foundation was taken equal to 1.00 metre and the calculations were carried out for values of the distance a from the crest of the slope to

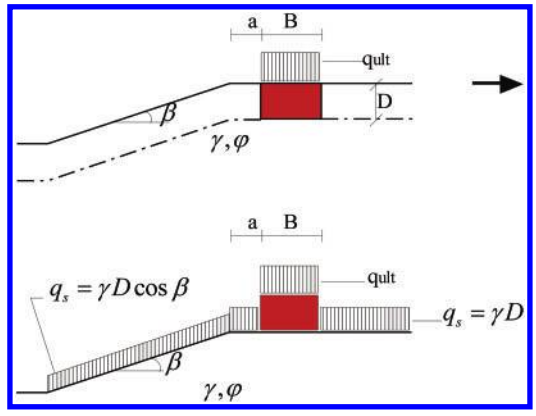

Figure 2. Geometry of slope and nomenclature

the edge of the footing in the interval 0-15 metres. The base of the footing was considered perfectly rough and for cases where the base of the footing is below ground level, the effect of the soil above the base is considered equivalent to a vertical uniform surcharge at base level as shown in Figure 2.

The surcharge is expressed by the surcharge ratio λ defined by:

$$\lambda = \frac{q_s}{\gamma B} \tag{5}$$

where $q_s$is the surcharge; i.e. the weight of the soil from the base of the footing to ground level, γ is the soil unit weight and B is the width of the foundation. For footings having the same value of the surcharge ratio λ and the same value of the relative distance a/B the bearing capacity can be normalized with respect to the quantities B and γ as shown by Krabbenhoft et al (2012).

3 RESULTS FROM THE ANALYSIS

The analyses yielded both upper- (UB) and lower-bound (LB) values of the bearing capacity of a strip foundation and these are given in Table 1, 2, 3 and 4 where the values in Table 4 are for weightless soil and a surcharge equal to unity. The values are given as functions of the relative distance a/B, the surcharge ratio λ and the friction angle φ and as can be seen from the tables the bearing capacity increases with an increase in any of these three parameters. Shadings of the values of the bearing capacities indicate, that for this particular combination of a/B, λ and φ there is no further increase in the bearing capacity even for an increase of the relative distance a/B. From the tables it can be seen, that the greater the friction angle the greater the discrepancy (also percentage-wise) between the upper- and lower-bound values. The relative discrepancy is taken as the difference between the upper bound values and the mean values divided by the mean value. For all slope inclinations the largest discrepancies occur in the case of no surcharge (5.4% for $\varphi = 40°$) and the smallest for a surcharge ratio

λ equal to 1.0 (0.30% for $\varphi = 30°$). This tendency for the relative discrepancy to decrease with increasing surcharge can be explained by the fact, that the determination of the bearing capacity factor N_γ associated with the selfweight of the soil poses a much harder challenge, than do the bearing capacity factor N_q and consequently the greater the contribution from the surcharge to the total capacity the more exact the result.

The bearing capacity equation (1) assumes, that the total bearing capacity can be found as the sum of the two contributions due to the selfweight of the soil and

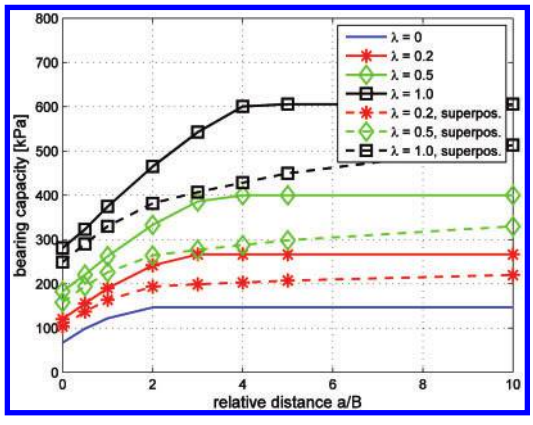

Figure 3. Bearing capacity, slope inclination 1:3, $\varphi = 30°$.

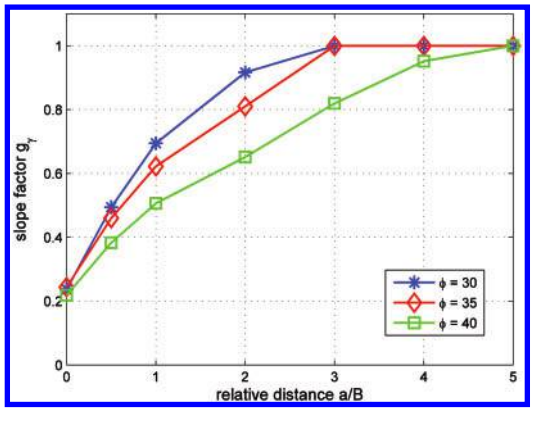

Figure 4. Slope factor g_γ for slope inclination 1:2

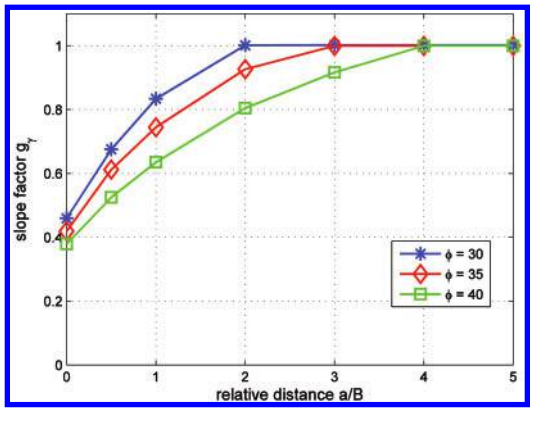

Figure 5. Slope factor g_γ for slope inclination 1:3

the surcharge, and as reported by amongst others Zhu et al. (2003) this assumption yields results that are conservative. The results from the present analyses confirm this fact and as a typical example the results for a slope inclination 1:3 and a friction angle equal to 30° are graphed in Figure 3. It can be seen that superposition gives results which are always the lesser

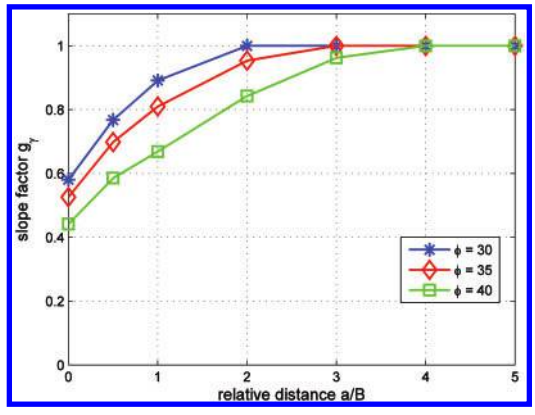

Figure 6. Slope factor g_γ for slope inclination 1:4

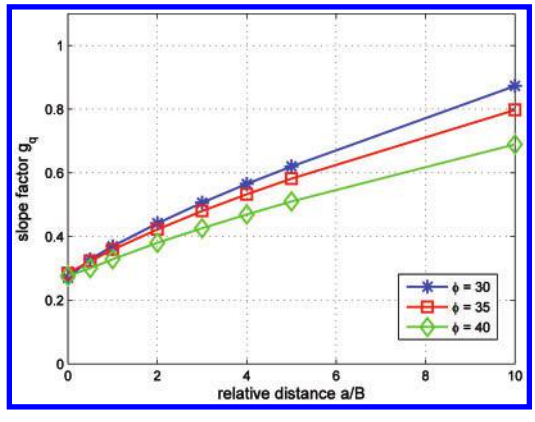

Figure 7. Slope factor g_q for slope inclination 1:2

but for smaller values (0–1) of the relative distance a/B, the discrepancy, being of the order of 10–20%, is acceptable for practical design.

As to the effect of the presence of the slope on the bearing capacity it can be seen from Table 1, 2 and 3, that the smaller the values of the surcharge ratio λ, the friction angle ϕ and the slope inclination angle β the smaller the value of the relative distance a/B where the slope has an importance and for a/B values greater than 5 the effect is ignorable in any case.

On the basis of the values in Table 1,2,3 and 4 diagrams showing the slope factors as functions of the slope inclination, friction angle and the relative distance have been prepared, and these are shown in Figure 4 through 9. It can be seen, that there is some dependency of the friction angle on the slope factors and that the greater the friction angle, the stronger the relative effect of the slope on the bearing capacity.

4 EXAMPLE

A strip foundation, B = 2.50 m is located at a distance a = 1.50 m from the crest of a slope. The inclination of the slope is 1:3 ($\beta = 18.44°$) and the foundation level is 1.00 m below ground level. The angle of friction is

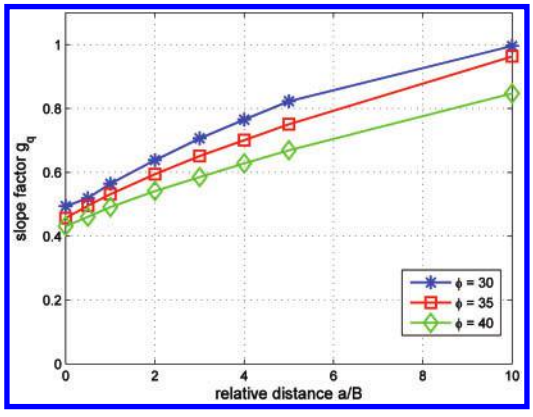

Figure 8. Slope factor g_q for slope inclination 1:3

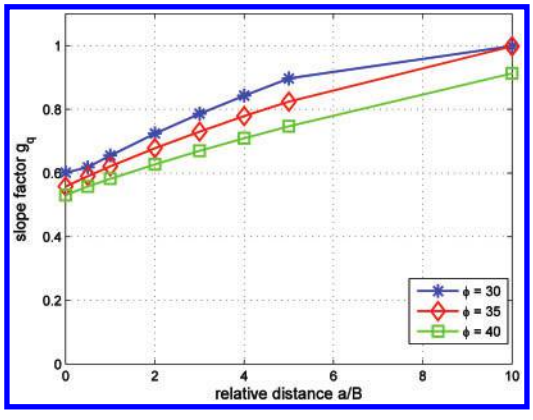

Figure 9. Slope factor g_q for slope inclination 1:4

33° and the soil unit weight is 18 kN/m^3. Determine the vertical bearing capacity.

This can be found by using the bearing capacity equation where the slope factors are found from Figure 5 and 8 or by using the values in Table 2. Only the first method is demonstrated.

From Figure 5 and 8 for a/B= 0.60 is read : $g_\gamma = 0.68$, $g_q = 0.53$.

$$N_q = \frac{1+\sin\varphi}{1-\sin\varphi} e^{\pi\tan\varphi} = 26.09 \quad \text{(Reissner 1924)}$$

$$N_\gamma = 1.5(Nq-1)\tan\varphi = 24.44 \quad \text{(Hansen 1970)}$$

$$q_{ult} = \frac{1}{2} 18kN/m^3 \cdot 2.50m \cdot 24.44 \cdot 0.68 + 18kN/m^3 \cdot 1m \cdot 26.09 \cdot 0.53 = 632.8kPa$$

This result has been verified by OptumGEO, which gives a bearing capacity of 749.0 kPa and the failure mechanism is shown in Figure 10.

When the tables are used to find the bearing capacity interpolation becomes necessary and it has been verified by the authors that linear interpolation can be used for a/B, λ and the slope inclination angle β whereas

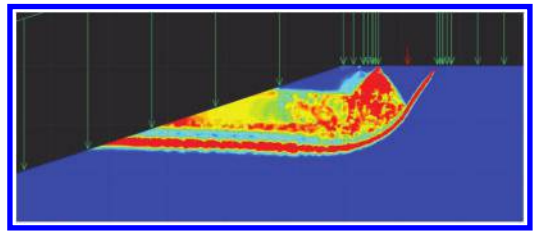

Figure 10. Failure mechanism, OptumGEO.

for the friction angle an interpolation function of the form $y = a \cdot e^{b \cdot x}$ is recommended.

5 CONCLUSIONS

Lower- and upper-bound, finite element based calculations of a vertically, centrally loaded strip foundation in cohesionless soil with friction angles 30, 35, 40° have been carried out for slope inclinations 1:2, 1:3 and 1:4 and these calculations have resulted in tables and graphs suitable for practical design. It has been shown, that the conventional slope factors depend on the friction angle of the soil, and that the greater the friction angle the greater the effect of the slope. A sample example shows, that the bearing capacity equation, i.e. using superposition, may produce a bearing capacity that is approximately 20% lower than found by limit analysis without using superposition.

Stress state of massive foundation slabs – Measurements and simulation

K. Stopp
Department of Civil Engineering, University of Wuppertal, Germany

ABSTRACT: Foundation slabs are generally calculated by using the plate theory. In the industrial sector some slabs are constructed with plate thicknesses of more than 2 meters. By taking their building area into account the criteria of a thin structure is fulfilled otherwise a massive cross-section exists. Against this background and under consideration of the soil-structure-interaction the use of the plate theory needs to be questioned. The paper will present measuring results and verifying simulations for a foundation slab of the main buildings of a power plant unit. It will discuss the considerable influences of seasonal temperature variations on the structural response of the slab during a construction period of 3 years where the stress state is much more caused by seasonal temperature than by loading during construction and extension of the boiler house.

1 1 INTRODUCTION

Plate structures are normally calculated providing the Kirchhoff-Love theory, straight lines normal to the mid-surface remain normal and straight during the deformation, which means that the strains are linear across the thickness. For bigger plate thicknesses this assumption is not valid anymore. Furthermore, the mechanical model assumptions of the plate theory provide that there exist no stresses perpendicular to the surface. For big slab thicknesses with a massive cross section on the one hand and related large slab dimensions on the other hand, it is not known for sure, how the load transfer from the column through the foundation slab occurs. Depending on the soil stiffness compression arches or compression struts may result. Because of simplifying assumptions – especially for the subsoil – numerical studies carry the risk of representing the reality insufficiently. They can be used as a supportive instrument but they have to be verified by respective measurements.

Experimental studies on the long-time behavior of shallow foundations in the serviceability state hardly exist. Conducted experiments had their focus on the punching behavior. On subsoil only single foundations were analyzed, but their behavior differs significantly from foundation slabs. Here only a small part of the soil pressure appears within the supporting area, whereas a huge part of the shear forces derive from the span area. Small-scale experiments of extensive foundation slabs in the laboratory are over-simplistic and do not accurately reflect the interaction of subsoil and extensive structure; therefore in-situ measurements are necessary, which were previously non-existent.

A research and development project, financed by the power company Vattenfall Europe Generation AG, has been initiated to monitor and analyze the load bearing and deformation behavior of a massive foundation slab, which has a thickness of 3.80 m, for carrying the main buildings of a new power plant unit in Boxberg/Germany. The aim is to verify existing soil-structure-interaction models and to get an idea about the settlement behavior and its influence on the total structure. As part of this project a monitoring concept for measuring the strains and temperatures inside the foundation slab and the stresses at intersection between boiler column and slab has been developed by the University of Wuppertal.

The analysis and evaluation of the measured values showed a highly unexpected impact of seasonal temperature variations on the stress state of the foundation slab during construction and extension. At this time heat of hydration no longer exists.

2 MEASURING PROGRAM

2.1 *Concept*

The research team consists of Bergische Universität Wuppertal, Erdbaulaboratorium Essen ELE and Gesellschaft für Montan- und Bautechnik GMB. An impression about the dimensions of the mainly investigated slab (140 m long, 80 – 100 m wide and 3.80 m thick) is given in Figures 1-2.

Geotechnical measurements with soil pressure pads, extensometers and inclinometers (Fig. 3) are conducted to examine the deep and broad effect of the foundation and the stress distribution in the foundation plane. With the example of the boiler column load scientific knowledge about the load transfer of big single loads through massive foundation slabs in the ground shall be made. Furthermore the activation of the stress in the slab shall be examined by

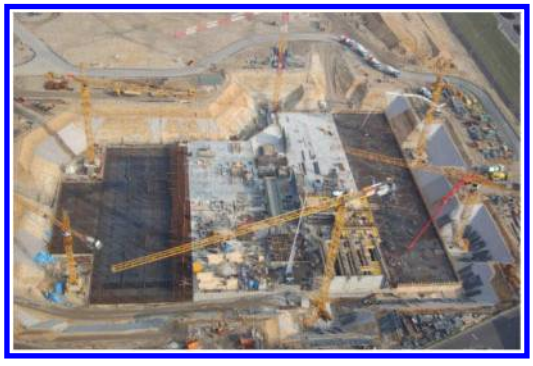

Figure 1. General view of the foundation slab under construction.

Figure 2. Reinforcement cage of the foundation slab.

measuring the strain distribution of the cross section in decisive places. In a measuring point additionally stress measurements are taken for comparison reasons. Furthermore the actual boiler column load will be validated by stress measurements with pressure pads in the base of the column. In order to derive a more general valid and accepted geotechnical model, additional measurements are taken at a medium and small sized foundation slab on site. All measurements should enable a formulation which is independent of scaling factors. For a detailed description of the whole measuring program and for a theoretical background of the modeling of the soil-structure-interaction as well see (Harte & Stopp 2008, Stopp 2010).

This paper will present selected measurement results only for the strains in the foundation slab. Figure 4 shows the principle arrangement of the built-in sensors in an idealized cross-section of the slab in the vicinity of the boiler column. At each measuring point the concrete strains are measured at the upper face and in the center of the slab in three directions perpendicular to each other, the steel strains at the horizontal reinforcement layers for plate bending in two directions and at the vertical bars for the punching proof in one direction.

The measuring points are arranged in three axes rotated by 45°. At one of the measuring points there

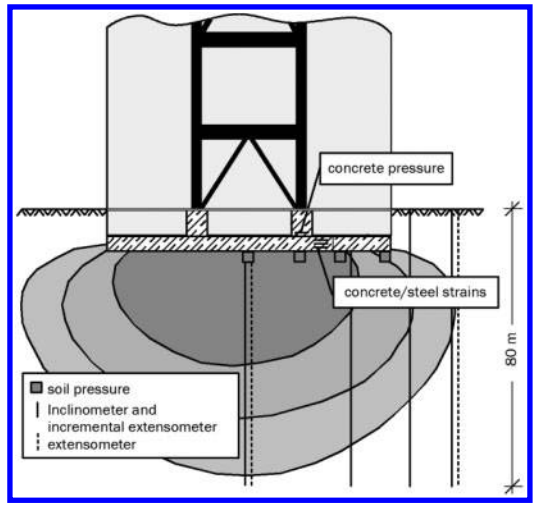

Figure 3. Cross section of the boiler house with built-in sensors.

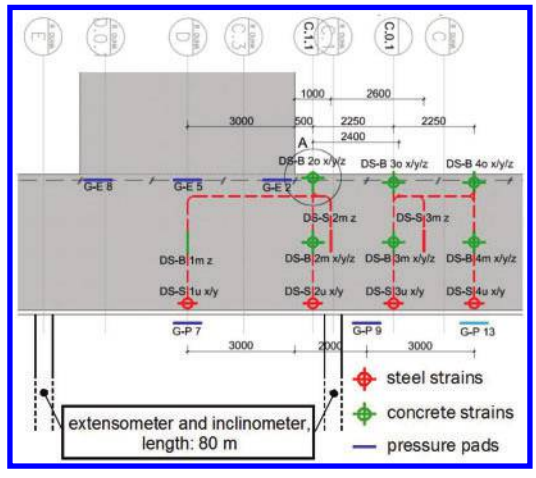

Figure 4. Measuring points in the vicinity of the boiler column.

are 8 strain and temperature sensors in plate thickness direction instead of only 3.

2.2 *Strain gauges*

The strains will be measured in the concrete and at the horizontal reinforcement layers for plate bending and at the vertical bars for the punching proof as well. The measuring devices are based on the principle of vibrating wire, which has proved long-term stability and robustness. All strain gauges have a measurement length of 250 mm and are equipped with a thermal element. The ends of the steel transducers are welded to the bars whereas the concrete transducers have been installed movable within the fresh concrete by hanging them at the reinforcement mesh (Fig. 5).

Strain gauges based on the principle of vibrating wire directly measure stress-generating strains. For

Figure 5. Built-in strain gauge.

non-constrained deformable structures under thermal effects no strains are monitored, if strain gauge and respective material have equal thermal coefficients and thus they will deform simultaneously. To receive real, existing strains ε_{real} the measured strains ε_{meas} need to be completed by the thermal strains of the strain gauge wire according to Equation 1.

$$\varepsilon_{real} = \varepsilon_{meas} + \alpha_{T_{wire}} \cdot \Delta(T_0) \tag{1}$$

In fully constrained structures a strain gauge will indicate thermal strains. They represent the stress-generating strains due to thermal changes, under the presumption that strain gauges and respective material are characterized by the same thermal coefficient. Otherwise the measured strains have to be corrected according to Equation 2.

$$\varepsilon_{stress} = \varepsilon_{meas} + (\alpha_{T_{wire}} - \alpha_{T_{object}}) \cdot \Delta(T_0) \tag{2}$$

3 TEMPERATURE MEASUREMENTS

3.1 *Temperature profile*

The temperature characteristics of all sensors vary with the season. The strength of the variation at the local measuring point $\Delta(T_0)$ is decisively dependent on the depth position of the sensor in the slab. Due to the heat input in summer and the cooling down in winter respectively there are more significant variations at the upper face of the slab. In Figure 6 the seasonal differences for all 8 sensors of a cross-section in the year 2008 are shown. At this time, the hydration of concrete and the corresponding heat evaluation have already vanished, characterized by comparable temperatures at the beginning and at the end of the year. During the year, the temperature distribution turns over twice. Due to the non-stationary heat transfer in the slab the full turn-over of the thermal gradient will appear in spring and autumn. As maximal temperature changes have occurred: $\Delta(T_0) \approx +18,5-1,0 = 17,5\,\mathrm{K}$ at the slab's upper face, $\Delta(T_0) \approx +17,0-4,0 = 13,0$ K at

Figure 6. Temperature profile across the slab thickness.

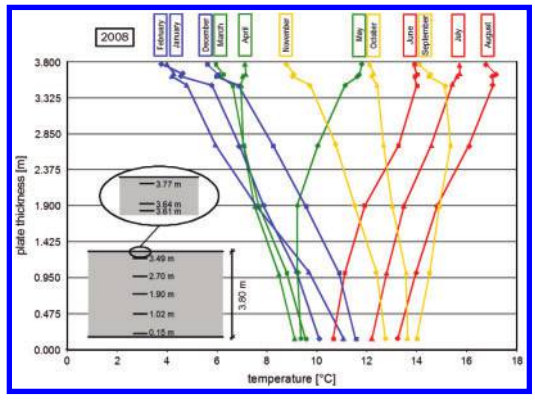

Figure 7. Seasonal development of the temperature gradient.

the height of the upper reinforcement layer and at the slab's lower face only $\Delta(T_0) \approx +14,0-9,0 = 5,0\,\mathrm{K}$. Visible are the almost identical changes in temperature in the first 20 cm from the upper face of the slab whereas compensation only starts in a depth of 30 cm from the upper face downwards to the lower face.

3.2 *Temperature gradient*

Figure 7 shows the seasonal pattern of the temperature gradient across the thickness of the slab as it appears after the cooling down of the slab arising from heat of hydration during the construction period. In winter there are the lowest temperatures at the upper face, whereas the lower face has not already cooled down yet. While the temperatures rise at the upper face during spring they still drop at the lower face. The same effect occurs in summer and autumn, but with a sign being reversed. The resulting gradient is all the time more or less linear across the slab thickness with exception of May and September. At this time there are the zero crossings of the gradient which means that the sign changes. The seasonal temperature difference $\Delta(\Delta T) = T_o - T_u$ between slab upper and lower face varies from about $-7,5$°C in January 2008 to $+4,5$°C in August 2008. The differences in January are comparable to the ones one month after the concreting of the slab in April 2007.

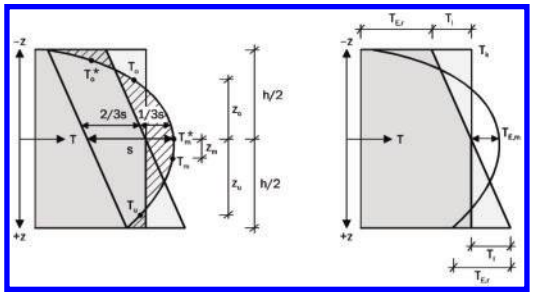

Figure 8. Separation of the temperature profile.

3.3 *Temperature parts*

For the interpretation of the resulting stress state of the slab due to the temperature its temperature profile was separated into a constant, linear and non-linear part. By means of the measured values it could be proven, that a parabolic separation is sufficient for this one dimensional temperature profile. Nevertheless a consideration of the exact location of each measured value is essential (Fig. 8). For massive structures with slab thicknesses of 3–4 m the determination of the temperature constraint of the curvature can be done by neglecting the non-linear parts in the upper 20–30 cm of the slab.

4 STRAIN MEASUREMENTS

4.1 *Temperature induced stress state*

In Figure 9 the real strains and in Figure 10 the stress-generating strains are shown during year 2008 (measuring point 2 in section C1.1 according Fig. 4). Both are given at the slab's upper and lower face and refer to the start of mounting of the boiler house. They are compared with the separation of their strain profile into constant, linear and non-linear parts. The thermal profile has been separated as well and the resulting thermal strains have been calculated. The clear correlation between the constant part of the real strains and the calculated constant thermal strains as well as the stress-generating strains and the calculated linear thermal strains are obvious. That means that the longitudinal extension of the slab is unconstrained whereas its curvature is constrained. In Figure 10 the calculated linear constraint strain part is bigger than the measured value because the linear temperature part refers to the upper face of the slab whereas the sensor is located 15 cm inside of the slab. The exact evaluation of the constraint degree of the linear part is complex, as the stress-generating strains due to temperature are superposed both by strains due to loading and by constraints due to soil friction at the slab-soil-interface. It is further difficult to identify the dependence on the respective thermal strain profile because of the continuously changing load situation due to the site activities. Additionally the degree of the constraint of the curvature is dependent on stiffness ratio of subsoil

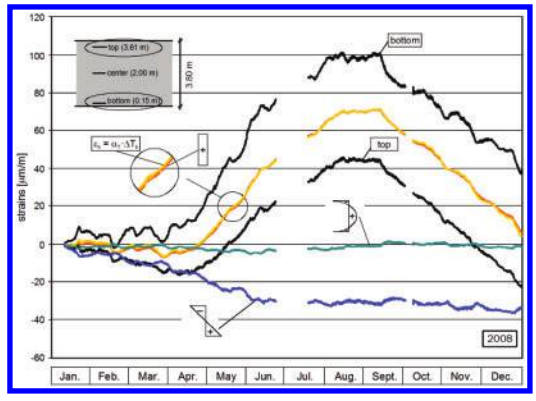

Figure 9. Real strains in axis C.1.1.

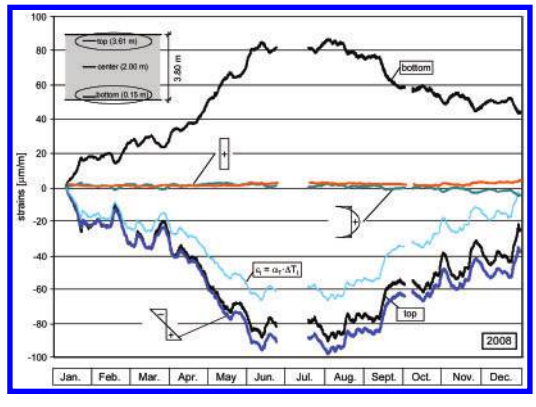

Figure 10. Stress-generating strains in axis C.1.1.

and structure. But nevertheless it is obvious, how significant the seasonal temperature changes affect the stress state in the foundation slab – much more than the load during construction of the boiler house. The residual stresses can be neglected.

The determination of the influence of the temperature for each of the local measuring points is not possible because of the superposition of the different impacts. In consideration of the before mentioned dependencies and the fact that there are almost no periods without construction activity to determine the degree of constraint, the following procedure has proven to be appropriate. For each measuring point both temperature and strain profiles are separated into their constant, linear and non-linear part. Calculating the regression line for each part, the related constant can be obtained and it is possible to derive the temperature caused strains for each local measuring point. This procedure was executed for both stress-generating and real strains. From a comparison of constant temperature and strain part (index k), linear temperature and strain part (index l) and non-linear temperature and strain part (index E) the dependencies and therefore the corresponding degree of constraint can be determined. Hence the resulting strain curve due to loading can be calculated for each local measuring point according

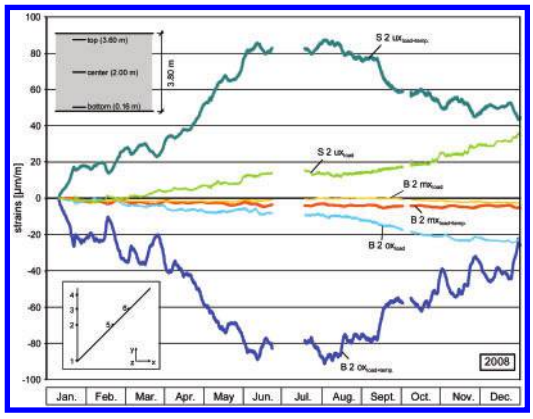

Figure 11. Influence of temperature gradient on the stress state.

to Equation 3 – presented as an example for the local measuring point 2 ox.

$$\varepsilon_{load}^{2ox} = \varepsilon_{\sigma}^{2ox} - C_k^{*2x}\Delta T_k^{MP2} - C_l^{*2x}\Delta T_l^{MP2}k_l^{ox} - C_E^{*2x}\Delta T_E^{MP2}k_E^{ox} \qquad (3)$$

The temperature constants correspond to the upper face of the slab (T_l) and to the center of the slab (T_E). The factors k_l and k_E consider the differing positions of the strain gauges. With the aid of simple geometric relations the location of each gauge can be considered through a percentage of the total value.

As a result of this procedure, Figure 11 shows the strains exclusively resulting from load. In addition, the actual stress-generating strains due to load and temperature are still given. To the end of the year, when the temperature conditions are equivalent to the reference value in January, both curves show comparable values as expected.

In summer the strain gauges at this local measuring point detect stress-generating strains resulting from temperature which are four times bigger than those resulting from loads. This result is rather caused by the small strains due to load than caused by big strains due to temperature. But it shows clearly the importance of the identification of the temperature strains to determine the size and nature of the stress state of the foundation slab.

The true scale of the restraint stresses, and therefore the scale of relaxation, is only identifiable in combination with stress measurements in concrete at the same measuring point. Figure 12 shows a comparison of directly measured stresses and stresses derived from measured strains at the upper face of the slab at measuring point 7 for the year 2008. The difference between the measured stresses σ_{meas} and the calculated stressesdue to the stress-generating strains $\sigma_{meas}^{*} = E \cdot \varepsilon_{meas}$ is obvious (elasticity modulus: 28,300 MN/m^2). Only about 50 % of the constraint stresses remain in the cross-section. By comparing the measured stresses with the ones calculated with the identified load strains $\sigma_{load}^{*} = E \cdot \varepsilon_{load}$, the total

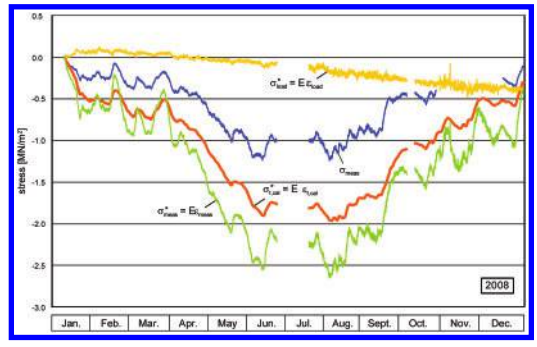

Figure 12. Comparison of derived and measured stresses.

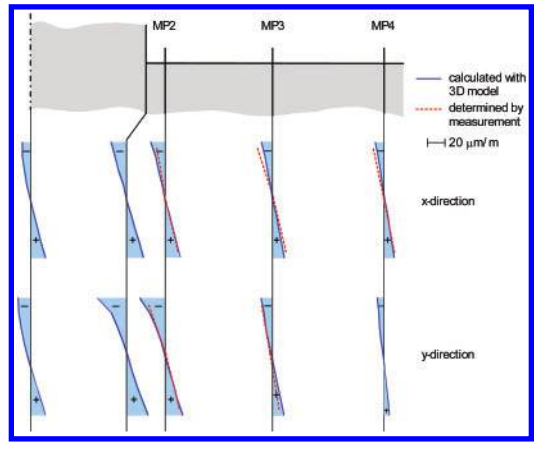

Figure 13. Comparison auf measured and calculated strains.

stress of load and temperature is still much bigger than the part of the stress resulting from load. Additionally the curve of the constrained temperature stresses $\sigma_{t,cal}^{*} = E \cdot \varepsilon_{t,cal}$, calculated by using the identified constraint temperature strains of the linear and non-linear part, is added.

5 COMPARATIVE SPATIAL ANALYSES

In comparative spatial analyses the qualitative stress distribution caused by the boiler column load and the seasonal temperature effects could be demonstrated and the quantitative load strains for discrete time steps could be determined in agreement with the measured values. The cross-section remains plane. Only in the area of the load transmission there are slight local variations, but those can be modeled via a volume model. For the design of the foundation slab the simplifying assumption of a plate is valid.

Figure 13 shows the comparison of measured and calculated strains for the 14th of June 2008. At this time the measured boiler column load was P = 10,000 kN. For the determination of the boiler column load temperature effects had to be considered as well. The separation of the temperature induced stresses at the base of the column is not as simple as the separation of the

temperature induced strains in the slab. The reason for this is a superposition of several non-linear influences. By means of a pragmatic approach the constrained stresses can be eliminated and the load can be continuously derived by integration (Stopp 2010). This load is taken for the numerical 3D analysis. The calculated strains in the area of the boiler column are compared to the strains due to load determined by the measurement with the explained procedure in Section 4. The determination of the load strains was only possible for measuring points with 3 local measuring points across the thickness. That is why the comparison is not made for all points. In addition, the calculated distributions are given for the face and the centre of the column.

6 CONCLUDING REMARKS

Knowledge about the load transfer behavior of massive foundation slabs is an important part for the understanding of the soil-structure-interaction of large-scale founded structures. While evaluating and interpreting the measured strain values it turned out, that the influence of the seasonal stresses due to temperature are much more significant than expected. During the construction period not only heat of hydration has to be considered but also seasonal temperature changes. After going into operation these changes will be minimized as the outside air will no longer have direct access to the foundation slab and the basement will be heated. Because of the successful separation and identification of the stress parts due to load and due to temperature, the investigation of the spatial load transfer was possible. Hereby scientific knowledge about the dependency of the structural behavior on soil stiffness, construction stage and redistribution effects could be achieved.

ACKNOWLEDGEMENT

The financial support of Vattenfall Europe Generation in Cottbus/Germany for installing the measuring devices and for evaluating the measuring results is gratefully acknowledged.

ABSTRACT: In common buildings the Soil-Structure-Interaction (SSI) is governed by the elastic behavior of the building. The best conditions to see the soil effect predominate would be a dynamic rigid body movement of a massive building. For this reason measurements were carried out on an old anti-aircraft tower from World War II on typical Viennese soil conditions. The dynamic properties of the soil could be determined in two different ways. The first one is the common way using the dispersion of the Rayleigh waves on the soil surface and the back calculation to shear wave profiles. The second approach is the back calculation of the soil stiffness based on the soil-structure-interaction.

With the simultaneous measurement of the dynamic movement of the building the kinematic behavior of the SSI could be determined. The tilting oscillations of the tower in both directions with different frequencies transmitted to the soil could be measured in the surroundings. The decay of these vibrations and their influence on the H/V-method results was studied.

The results of the dynamic measurements were compared with different methods of numerical simulation. The benefits and the disadvantages of the methods can be compared. The calculation values of the numerical models could be calibrated with the real dynamic properties of the measured SSI-system.

1 INTRODUCTION

The Leitturm in Augarten (Vienna) was part of an anti-aircraft defense system in World War II. It has not been used since those times. For the rigidity of the structure and its tall shape it is considered to be an ideal test object. Since there is a quiet park surrounding this building it was the ideal test field to carry out the measurements.

Measurements for the soil structure interaction were carried out separately on the soil surface for assessment of soil parameters and on the tower structure to record the building movements. The next step was to measure the influence of the tower oscillation on the soil and the decay of this influence with distance.

Numerical simulations were carried out based on different methods. The calibration of these methods with the measured conditions led to scientific findings and the opportunity to evaluate the different methods.

Figure 1. The Leitturm in Augarten, Vienna, built during World War II (left) and aperture in the 2.5 m concrete wall of the tower seen from inside (right).

2 MEASUREMENTS ON THE SOIL SURFACE

The vibrations of the soil surface were measured for the documentation of the surface wave propagation. The phase velocity of Rayleigh waves on the surface is not constant but it depends on the frequency of the wave. Usually the Rayleigh waves with low frequencies are faster than those with higher frequencies. This results in the fact that a vibration signal containing a wide frequency spectrum changes shape with the propagation. This phenomenon is called the dispersion of the wave because low frequency waves will reach

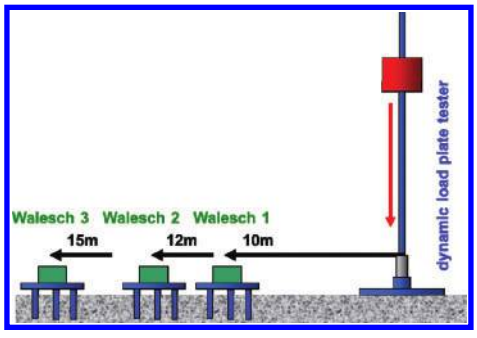

Figure 2. Surface-wave dispersion test setup with artificial impulse excitation using a light falling weight device.

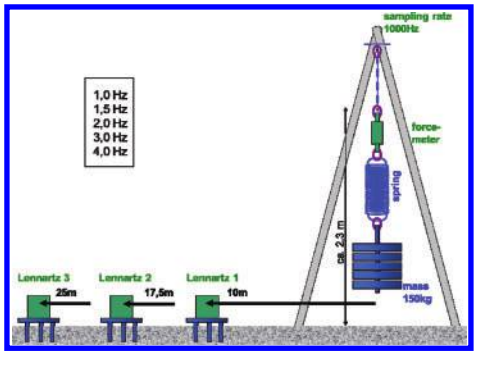

Figure 3. Surface-wave dispersion test setup with artificial harmonic excitation using a "shaker" as a mass-spring-system.

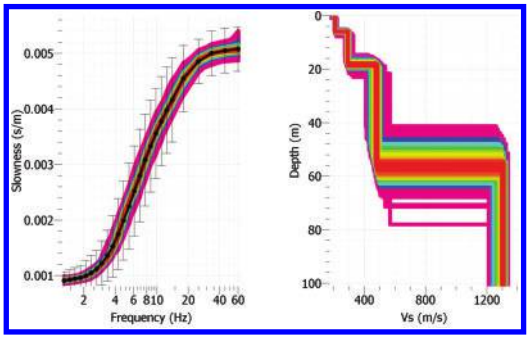

Figure 4. Triangle setup: dispersion of best fitting profiles (left) and shear wave velocities of best fitting profiles (right).

a measurement point distanced from the impact first and the high frequencies will follow later. To measure this effect, two artificial excitation types: an impulse (for the high frequencies) and a harmonic excitation of the soil (for the low frequencies) were applied. The ambient vibrations were recorded in several triangular setups with different dimensions.

By analyzing the measured vibrations the dispersion curve could be evaluated.

Since the natural soil is no homogeneous infinite half-space but consists of different layers of soil types

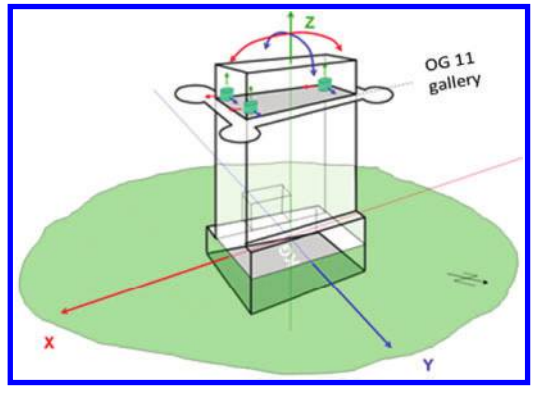

Figure 5. Sensor setup for the measurement on the gallery level inside the tower.

with diverse soil properties, the dispersion curve of the surface waves is influenced by this.

By means of numerical simulations of different layered soil profiles the corresponding dispersion curves can be evaluated. The artificial dispersion curve best fitting to the measured one can be found by a special optimization algorithm. This inverse analysis method does not give a unique result but a most likely soil profile can be found.

The results of these tests are the shear wave velocity profiles of the soil. The shear wave velocity is the leading parameter for assessment of the dynamic soil properties. The shear wave velocity is a real material parameter and it is constant for all frequencies (shear waves do not disperse).

3 MEASUREMENTS ON THE TOWER

The ambient vibrations of the Leitturm-structure were measured with three very sensitive geophones (Lennartz LE-3D-5s) on different levels. The Fast Fourier Transformation (FFT) analysis of the measured data of vibrations on the 11th floor shows the eigenfrequency of 1.6 Hz for the tilting motion in the "weak", y-direction (blue) and 2.0 Hz in the "stiffer", x-direction (red). The peak of the vertical oscillation is not as significant but can be found at 3.9 Hz. Because of the tower's rigid structure the soil-structure interaction behavior is governed by the mass of the tower and the stiffness of the soil.

By use of the Random Decrement Technique (RDT), the damping ratio of the vibrations can be detected for each frequency separately. The algorithm analyses ambient vibrations and looks for "events" in the signal. Averaging all detected events lead to an artificial event, where the decay of vibration can be evaluated and the damping ratio of the relating vibration mode can be determined.

The artificial excitation with impulses of a medicine ball (5 kg) on the gallery of the Leitturm (mass about 40.000.000 kg) could be detected inside the tower with its 2.5 m thick walls and a ceiling with more than 3.5 m

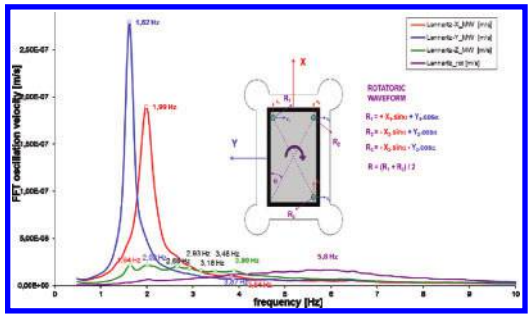

Figure 6. FFT-analysis of combined values from measure-ments in the corner of the gallery.

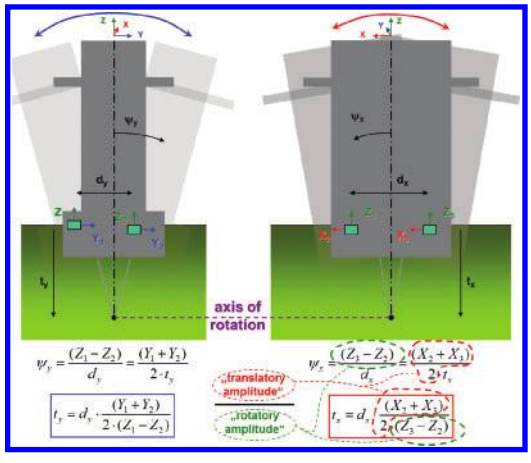

Figure 7. Determining the rotatory center of the rigid body by analyzing signals from two sensors on one level.

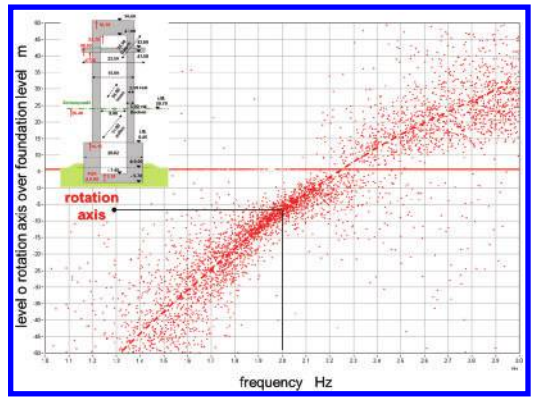

Figure 8. Level of the rotatory center for tilting oscillations in x-direction depending on the frequency. Only the oscillations in phase or out of phase are considered.

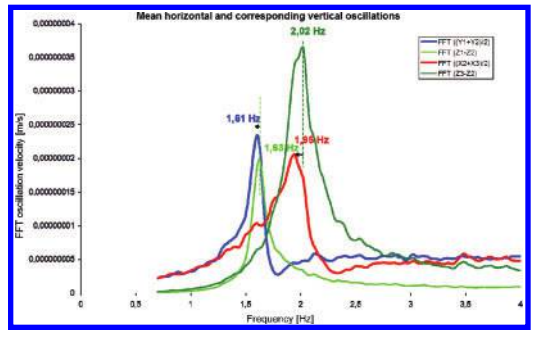

Figure 9. Translational and rotatory oscillation components of tilting oscillation whose maxima have different positions.

concrete slab. Each individual impact could be clearly detected. The analysis gives the natural frequencies caused by the soil-structure interaction in the low frequency domain, and after a gap without any significant peaks, the internal vibrations of the building in the high frequency domain.

It is the metrological evidence for the separation of internal vibration of the building from the global movements caused by the soil-structure interaction in this special Leitturm case. At usual buildings both effects are overlapping which leads to mixed effects in the measurement signals and difficulties for the interpretation.

In a first approximation the soil structure interaction of the Leitturm can be understood as a rigid body motion of a concrete block socketing in an elastic half space of soil. To answer the question if a center of rotation exists for both tilting modes and to find its position, vibration measurements in the cellar of the Leitturm were analyzed by the following procedure. Combining the signals of two sensors the tower movement can be divided in a translational and a rotatory component. The relationship of these components will lead to the position of the center of rotation in relation to the measurement level. A fixed rotation center exists only if both, the translational and the rotatory oscillation components are oscillating either exactly in phase or exactly out of phase.

The evaluation of the level of the center of rotation for the tilting movement of the Leitturm for each sample or the FFT analysis with correct phasing is shown in the Figure 8 as a cloud of red dots. The position of the rotation center at the eigenfrequency of the tower (2.0 Hz) is found. It is the highest density within the red dotted cloud in this domain.

It can be seen that a fixed center of rotation does exist but the position depends on the frequency. This moving center is the reason, why the frequency at the maximum of the translational component (red, blue) is lower than the related rotatory components (green) in Figure 9. That is not trivial because both of the peaks indicate the frequency of the same oscillation mode and should be exactly the same. But since there are also frequencies besides the eigenfrequency and the translational component is also influenced by the distance to the rotation center, the peak of this component is shifted according to the sketch.

3.1 *Measurements of soil structure interaction*

According to the soil-structure interaction mechanism the soil stiffness influences the movements of the

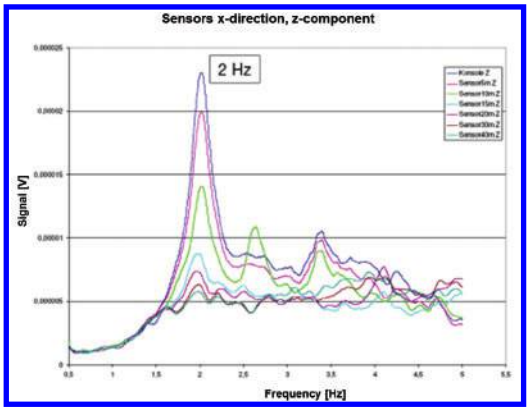

Figure 10. Acceleration measurements for the x-direction array: z-component of the sensors.

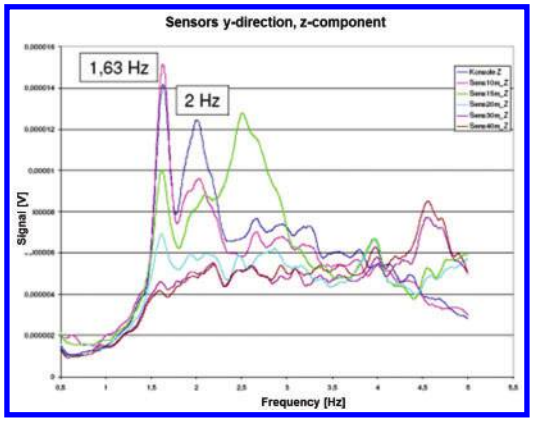

Figure 11. Acceleration measurements for the y-direction array: z-component of the sensors.

building just as well the building affects the soil. To measure the effect of movement in the interaction, the tower oscillation and the vibration on the soil surface was measured simultaneously. One sensor was fixed on the tower and the others placed in a line on the soil in both axis direction.

In the FFT-analysis of these measurements the influence of the tower with its significant eigenfrequencies of 1.6 Hz and 2.0 Hz can be detected. This influence (velocity V) decreases with the distance r to the tower. According to the influence depth of the different modes there is more damping in the propagation function in the y-direction. The deeper the influence, the less is the decay, which can be seen in the value of the damping exponent in this function.

Due to the eccentricity of the sensor setup in y-direction the peak of the x-direction (2.0 Hz) movement can be also detected in Figure 11. Due to the different damping exponents in the formula of propagation the effect of y-movement becomes dominant with increasing distance to the tower.

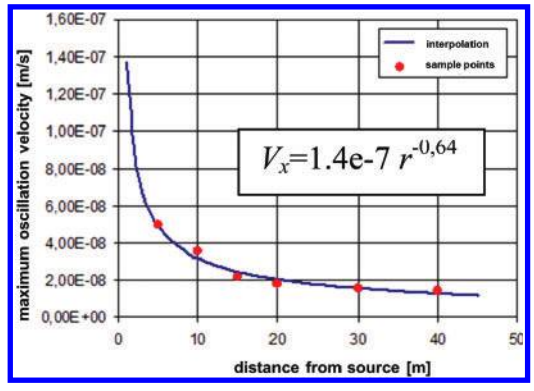

Figure 12. Damping function in x-direction of the tower.

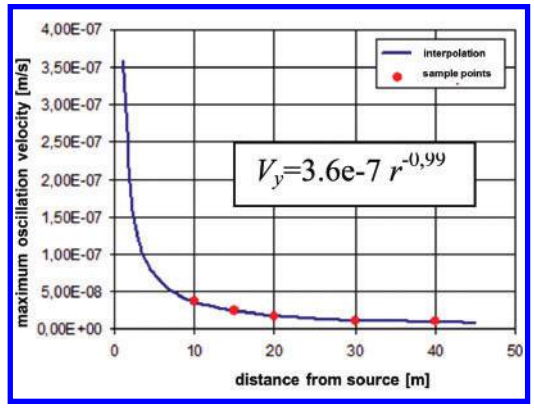

Figure 13. Damping function in y-direction of the tower.

4 NUMERICAL SIMULATION

4.1 *Method of modulus of subgrade reaction*

The method of modulus of subgrade reaction is the most common method. The effect of the soil is simulated by linear elastic springs distributed on the horizontal projection. The modulus of subgrade reaction k_s is this spring stiffness per square meter and it is not a real soil parameter because the geometry, shape, scale of the building and influence depth for layered soil profiles has to be taken into account.

The problem of the method of modulus of subgrade reaction is evident in Figure 15. There is no value for the modulus of subgrade reaction to fulfill all the oscillation mode frequencies measured in the field on the same soil conditions. This effect can be explained by showing the different soil loading and influence depth of the modes. The method is theoretically and practically not able to describe the real physical situation. It can only be used for simple estimations within the frame of existing experiences.

4.2 *Stiffness method*

The deformation of a single point in the area of contact between soil and tower depends on the loading of

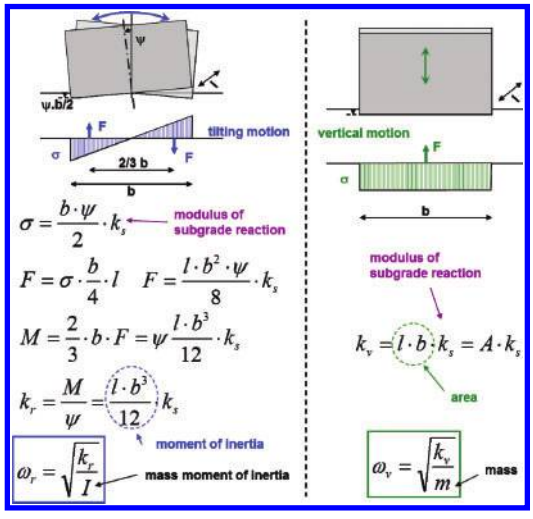

Figure 14. Eigenfrequencies with dynamical modulus of subgrade reaction method: tilting motion and vertical motion.

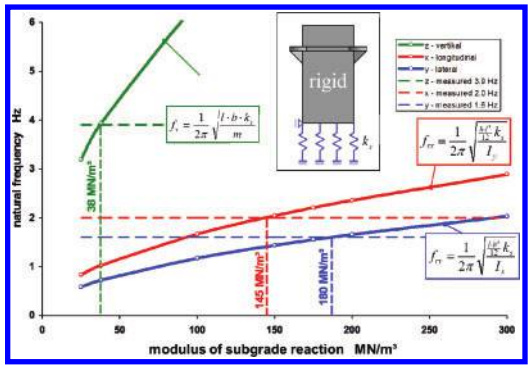

Figure 15. Coherence between modulus of subgrade reaction and eigenfrequency for different oscillation modes, comparison with measured values.

the point itself as well as the loading of the surrounding area. Moreover it is possible to take the flexibility of the tower structure into consideration. The method is based on the oedometric modulus, a real physical soil parameter. The oedometric modulus is assumed to be constant for the whole soil domain influenced by the foundation. A stress-dependency of the oedometric modulus and a layered soil structure were not taken into account. For the stiffness method the geometry of the tower is segmented into n single, finite elements. To determine the deformation characteristics of the interacting soil - tower system, a single element i is loaded with the single load $p = 1$, which causes a settlement trough with its maximum c_0 under the loaded element i. The settlement under the adjacent elements $(i-1)$ and $(i+1)$ is c_1 et cetera.

The settlement c_0 is evaluated for the characteristic point. The actual settlements can be calculated with these lines of influence and the real loads for each element. For the natural frequency of the vertical motion

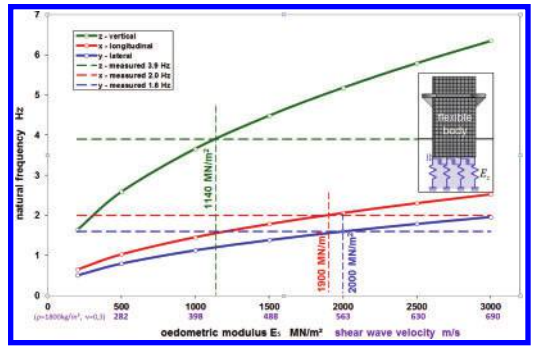

Figure 16. Results of back-calculation of eigenfrequencies with the stiffness method.

the settlements under the dead load of the tower are calculated. An equivalent stiffness per square meter k_s can be derived from the mean settlement w_m. The total equivalent stiffness can be written as

$$k_v = k_s \cdot A$$

where A is the ground area of the building. With the buildings mass m, the natural frequency of the vertical motion is d*efined as*

$$\omega_v = \sqrt{\frac{k_v}{m}} \quad .$$

The angle ψ of rotation is calculated for a tilting moment of $M = 1$ to evaluate the natural frequency for the tilting motions, which can be written as

$$\omega_r = \sqrt{\frac{k_r}{I}} \quad .$$

with $k_r = M/\psi$ and the mass moment of inertia I of the building.

4.3 *Analytic formulas for circular rigid body on linear elastic half-space*

Using analytic formulas for circular rigid bodies on linear elastic half-space provides reliable results if the foundation of the building is rigid and can be described with a corresponding circular shape. The method is based on real physical soil parameters (shear modulus). The results are corresponding very well with the measured tilting modes from the field test. The relationship between the damping ratios fits with the test results, but not the absolute values, because of the small amplitudes.

4.4 *Finite Element Method (FEM)*

The Finite Element Method (FEM) was used for two separate analyses. First, the method of modulus of subgrade reaction was carried out with FEM to take into consideration the flexibility of the tower structure. The problem of this method still exists. A modulus which

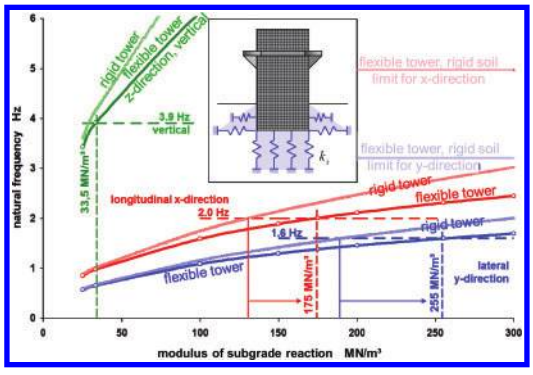

Figure 17. Coherency between modulus of subgrade reaction and eigenfrequency for different modes of vibration for rigid body movement and elastic building characteristic; comparison of FE-computations with measured results.

could fulfill the real dynamic soil conditions for all modes at the same time cannot be found.

In the second analysis with FEM the soil was modeled by linear elastic elements. Especially for the small amplitudes of the ambient measurements this is feasible. With updating the model according to the measured dynamic soil profile and by changing soil stiffness, it was possible to find a solution fulfilling the tilting mode frequencies, the position of the rotation center and the damping exponent for vibration decay with distance. The soil properties of the updated model are stiffer leading to higher shear wave velocities than the measurements in the field but with a fitting relationship between the layers.

5 CONCLUSION

The target of the research work was to find a method to determine dynamic soil parameters using dynamic surface measurements, to find calculation parameters for different numeric simulations and to check the results with dynamic measurements of soil-structure interaction on a simple test object. There are two main reasons for the demonstrated differences between the measured soil properties in the adjacent domain and the stiffer soil behavior from the back calculation: The water content of the soil has no relevant effect to the shear wave velocity (just the mass difference) but it is important for the dynamic compression stiffness of the soil because of the pore water pressure. The considered modes are dominated by the compression stiffness of the soil. The second reason for the stiffer soil properties beneath the Leitturm building is the soil consolidation. The average soil pressure of 610 kN/m^2 of the foundation slab of 31 m times 21 m has been loading the soil for the last 66 years. The measurements for the shear wave profiles were carried out on unaffected soil conditions in the adjacent park. Summarizing the experiments in and around the Leitturm in Augarten in Vienna led to two different metrological approaches for determination of the dynamic soil properties connected with numerical inverse analysis. The power and the disadvantages of several numerical methods which are used in engineering practice could be pointed out. There is a difference between the dynamic soil structure interaction for the usual load cases (live loads, ambient excitation) and for the extraordinary conditions of earthquake; the shear wave velocity profile and the H/V-method are developed for these conditions.

Numerical calculation of damping for monopile foundations under cyclic load during steady-state vibration

M. Bayat, L.V. Andersen, S.M. Andersen & L.B. Ibsen
Department of Civil Engineering, Aalborg University, Aalborg, Denmark

ABSTRACT: Dynamic loading and fatigue has significant effects on offshore wind turbine foundations. To obtain a proper design of a turbine and its foundation it is therefore important to understand how the structure and soil interact regarding damping. Especially, this paper demonstrates the damping and stiffness of the saturated soil within the seabed due to pore water flow generated by the cyclic motion of a monopile. The concept of a Kelvin-Voigt model is employed and combined with a Finite Element Method (FEM) model of the pile. The two-dimensional analysis of each individual soil layer is performed in ABAQUS by coding input files, utilizing Python and MATLAB. A parametric study is performed to illustrate the effects of model size, soil properties such as permeability, void ratio, Young's modulus, bulk modulus, and load parameters such as amplitude and frequency. It is found that by increasing the bulk modulus, the damping and stiffness in the soil increase; however, the increase is small. Further, it is observed that Young's modulus has a significant effect on the dynamic response of the soil. Finally, the permeability of the seabed has a strong influence on the damping of wind-turbine-tower vibrations.

1 INTRODUCTION

The recent developments of offshore industries such as offshore wind turbine foundations and also structures for oil and gas extraction lead to a growing demand for realistic predictions of the behavior of offshore structures. As the use of offshore foundations increases, new methodologies need to be developed to characterize and analyze offshore structural components due to dynamic loads.

Dynamic behavior of offshore structures is one of the most important parts in the design of such structures. The dynamic response varies significantly in time and is affected by inertial, damping and kinematic effects as well as the stiffness of the structure and the underlying soil. Large shear strains (greater than 10^{-4}%), pile–soil interaction, dynamic load rates and nonlinear material behavior lead to nonlinearity in the dynamic response (Ahangar et al. 2011). Dynamic analysis is carried out theoretically by numerical methods, analytical or semi-analytical methods.

In the case of analytical methods, Nogami & Konagai (1987) implemented nonlinear conditions in the time domain for dynamic response of pile foundations subjected to harmonic and transient load. Kazama & Nogami (1991) described the dynamic behavior of saturated two-phase layered media. They found that the permeability and loading rate (loading frequency) are critical factors to control the dynamic behavior of saturated soil. Bea (1992) described the effects of cyclic loadings on the axial capacity of piles driven in cohesive soils and supporting offshore platforms. An advanced analytical procedure was developed to estimate pile penetration and to evaluate the pile performance when a platform is subjected to intense cyclic loading. Bea (1992) found that loading rates, the ratio of steady to cyclic load amplitudes, the sequencing and numbers of cycles of loading, and the relative pile–soil stiffness are all important parameters that determine the pile performance. Chang et al. (2000) analyzed the time-dependent damping model by employing integration technique, an alternative time-dependent damping model was proposed by Chang & Yeh (1999) in modeling the pile response from direct wave equation analyses. Lanzo et al. (2003) presented frequency and time domain analyses by using computer codes PROSHAKE, DESRAMOD and QUAD4M. They have considered viscous damping which is generally assumed to be of the Rayleigh type, i.e. stiffness- and mass proportional, or in a simplified form, only stiffness-proportional. They have shown the dependency of damping from frequency. On the other hand, the numerical methods can be useful and implement easily.

Rajashree & Sitharam (2001) applied a FEM in order to present the nonlinear soil behavior by a hyperbolic relation for static load conditions and a modified hyperbolic relation which includes both degradation and gap for cyclic loads. They used an incremental-iterative procedure where the pile was idealized as beam elements and the soil as elastoplastic spring elements. Klar and Frydman (2002) presented 3-D models and Winkler models based on the commercial 2-D finite difference code FLAC under static, seismic,

and lateral dynamic loading. Karim et al. (2002) analyzed a saturated porous elastic soil layer under cyclic loading by using a 2-D mesh free Galerkin method by having periodic conditions. Liang et al. (2007) applied a 3-D FEM and presented the parametric study of laterally loaded drilled shafts in clay. A hyperbolic p-y criterion was developed for cohesive intermediate geometrical. Harada et al. (2008) employed a multi-Winkler model based on soil traction for nonlinear soil–foundation interaction during cyclic loading. The integration of the traction over the foundation area was efficiently treated numerically by employing the fiber element method. Al-Wakel et al. (2011) implemented a model of frequency-dependent damping by using 3-D FEM while a rectangular footing on saturated soil was subjected to cyclic and harmonic force. The coupled dynamic equations with an u-p formulation based on the dynamic consolidation theory were used to simulate the soil skeleton. The Beam on Nonlinear Winkler Foundation can be modeled in ABAQUS while the interaction nonlinearity can be accounted for. Trochanis (1991) presented the response of laterally loaded piles by using ABAQUS and compared the results with 3-D FEM. Boulanger et al (1999) employed ABAQUS to present the dynamic results of piles and validated the results with centrifuge experimental tests. Commercial software such as ABAQUS can be versatile, economical and friendly user software for various complicated conditions in a simple manner.

It may be noted that the existing literature on offshore monopile foundations as cited above presents experimental and theoretical solutions based on numerical or analytical approaches. To the best of our knowledge, no work has been reported till date that presents a comprehensive parametric study of offshore foundations by using FEM with presence of the pore pressure that is developed due to dynamic load. The influence of different parameters such as pore pressure, load amplitudes and frequencies, the bulk modulus of the grains, the permeability of the seabed and void ratio of the seabed, and Young's modulus of the matrix material are investigated. The FEM and a Kelvin-Voigt model are employed for analysis of a 2-D saturated soil model.

2 MODEL DESCRIPTION

Consider an axisymmetric solid circular cylinder with radius R, as shown in Figure 1. The arc-boundary which represents the common border between the solid cylinder and the saturated soil is subject to harmonically varying forced displacement with the cyclic frequency ω and applied in the horizontal (x) direction. The two-dimensional analysis of each individual soil layer is performed.

2.1 *Soil modeling*

The soil is considered as an isotropic and elastic material. For saturated soil, the permeability, specific weight and void ratio, porous bulk moduli (which encompass the bulk modulus of grains and the bulk modulus of fluid) are defined. The mesh consists of 4-noded quadrilateral elements with linear interpolation of the displacement and pore pressure (CPE4P).

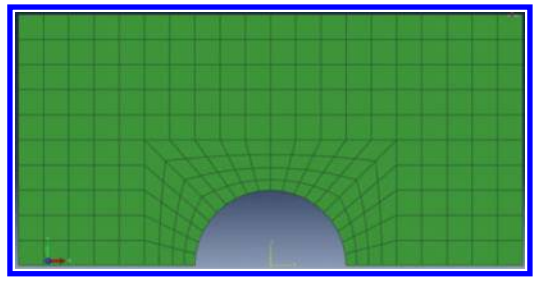

Figure 1. Two-dimensional finite-element model of an offshore wind turbine foundation and the surrounding soil.

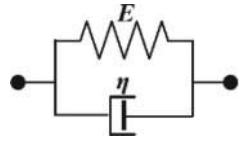

Figure 2. Kelvin-Voigt model.

2.2 *Theoretical approach*

The numerical calculation for dynamic analysis of offshore monopile foundations based on a one dimensional Kelvin-Voigt model by using FEM is presented. The dynamic analysis has been implemented within the framework of ABAQUS. Different model size for symmetry pile are applied. A numerical solution for the reaction force on the pile is given.

In the Kelvin-Voigt model as shown in Figure 2, the equation of motion can be written as:

$$C\dot{x} + Kx = F. \tag{1}$$

Here C, K and F are the damping, stiffness and reaction force, respectively, while x and $\dot{x}$ are the displacement and the velocity. By applying sinusoidal force-displacement, the reaction force F could be in sinusoidal form with phase angle respect to applied displacement, however the amplitude of force and applied displacement are different. By calculating the phase angle from numerical results in ABAQUS (Dassault Systèmes Simulia Corp. 2012) and using the flowchart as shown in Figure 3, the damping and stiffness can be calculated.

2.3 *Boundary conditions*

The pore pressure and displacement at the exterior boundary should be zero. Symmetry of the solution should apply across the center line of the model, while for the semi-circle carve, the sinusoidal periodic displacement in horizontal direction is applied as shown in Figure 4.

Bulk modulus of fluid (N/m^2)	2×10^9

3 NUMERICAL RESULTS

For numerical illustration of the elastic solutions of this study, a solid cylinder with radius $R = 3.0$ m is considered. The material properties listed in Table 1 are considered. A soil block with a circular cavity subjected to sinusoidal periodic displacement is analyzed, using different geometry and soil properties in order to illustrate the effects of changes.

3.1 *Results for different geometries*

Figure 5 (top and middle) illustrates the damping and stiffness due to sinusoidal periodic load for different geometry of the soil block around the pile. It can be seen from Figure 5 that for each dimension of the

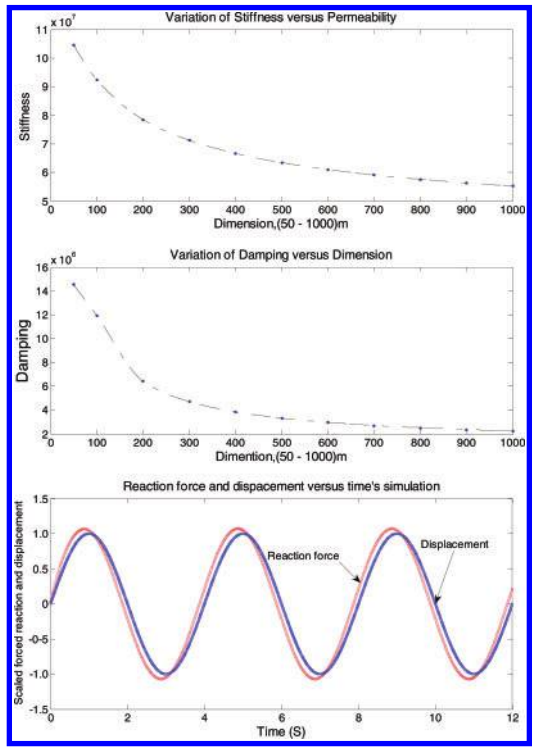

Figure 5. Variation of stiffness and damping versus model dimensions, and variation of scaled reaction force and displacement versus time.

model, the stiffness and damping have their maximum value for the smaller size of the model. It is seen that for large sizes of the model, the variations of the mentioned properties become small. As expected, the effect of the exterior boundary condition for large sizes of the model became smaller than those for a small model.

The graphs in Figure 5 (top and middle) are calculated based on reaching steady state conditions. The simulation is carried for 12 s as shown in Figure 5 (bottom) and then by calculating the phase angle between two graphs the damping is determined. It is worth to mention that the stiffness and damping are calculated after two periods in order to have the steady state results. It can be concluded that a bigger model can make better results by avoiding the effect of outer boundary conditions. Thus, in the rest of the analyses the larger model of this study is considered.

3.2 *Results for different void ratio*

Figure 6 illustrates the variation of stiffness and damping due to periodic loading for different values of the void ratio. It is seen that the values of stiffness and damping decrease by increasing the void ratio. It is noted that the variation of damping versus void ratio is greater than the variation of the stiffness.

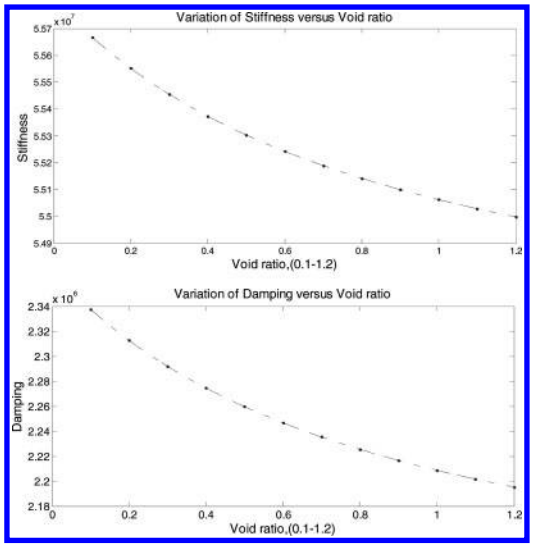

Figure 6. Variation of stiffness and damping versus variation of the void ratio.

3.3 *Results for different permeability*

The variation of stiffness and damping due to periodic load for saturated soil for different values of permeability are presented in Figure 7 (top and middle). As it can be seen the by increasing the permeability the damping increases, and for specific values of the permeability the maximum damping occurs, whereas for further increasing permeability the damping decreases. The stiffness decreases with increasing the permeability. A decrease of almost 30% can be identified. The following values of the permeability have initially been examined in the study: 0.5, 0.4, 0.2, 0.1, 0.07, 0.05, 0.03, 0.01, 0.005, 0.001, 0.0005, 0.0001, 0.00005, and 0.00001 (m/s). The behavior of damping makes awareness to investigate the variation of damping using smaller increments in the permeability. The following values have been applied in Figure 7 (bottom): 0.01, 0.02, 0.03, …, 0.27, 0.028, 0.29, 0.30 (m/s). The graph suggests that the maximum damping for the soil material properties and pile geometry occurs for a permeability of 0.15.

3.4 *Results for different load frequencies*

Figure 8 shows the variation of stiffness and damping in the soil due to harmonic forced displacement with different values of the excitation frequency. It is evident that the dynamic soil stiffness increases with increasing load frequency in the entire range of frequencies, the damping decreases with an increase of the excitation frequency. It can be noted that the relative variation of the damping in the considered frequency range is more than four times bigger than the relative variation of the stiffness, which means that the damping is much more sensitive to a variation of the load frequency than the stiffness.

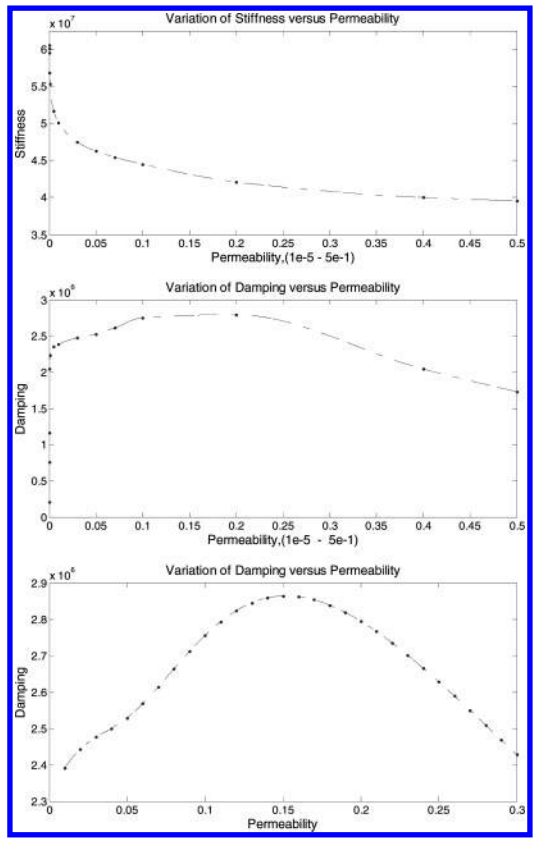

Figure 7. Variation of stiffness and damping versus variation of the permeability.

3.5 *Results for different load amplitudes*

Figure 9 illustrates the variation of stiffness and damping due to time-harmonic excitation with different values of load amplitudes. As it can be seen, the behavior of stiffness and damping are similar: by increasing load amplitudes, the stiffness and damping related to the soil increase up to the specific value of amplitude = 0.6 m. Hereafter they are going to decrease. It can be mentioned that the variations of the stiffness are very small, whilst the variations of damping are slightly greater with respect to the load amplitude variation.

3.6 *Results for different grain bulk moduli*

The variation of stiffness and damping due to harmonic loading for soil with different grain bulk moduli are presented in Figure 10. As expected the values of stiffness and damping increase with an increase of the grain bulk modulus. The relative variations of stiffness and damping are almost the same, and only small variations are observed.

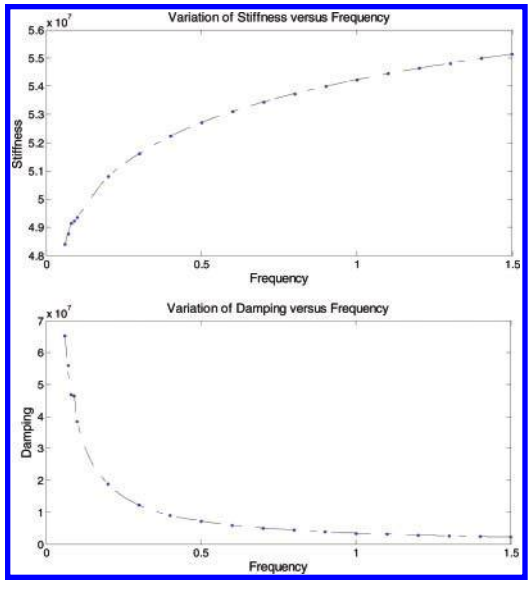

Figure 8. Variation of stiffness and damping versus variation of the load frequency.

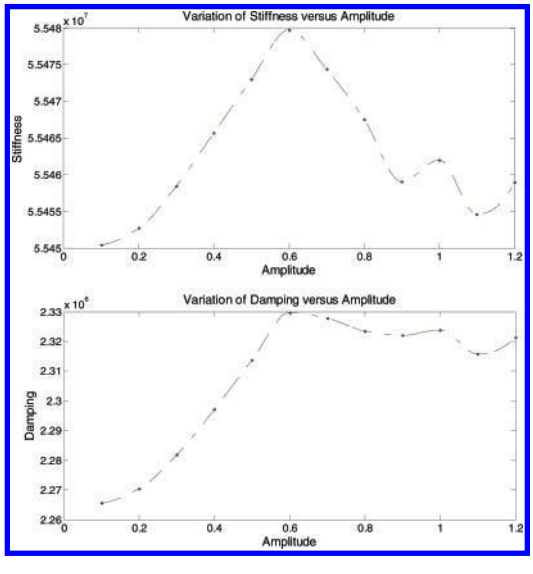

Figure 9. Variation of stiffness and damping versus variation of the load amplitude.

3.7 *Results for different Young's moduli*

It is evident from Figures 11(a) and 11(b) that the variation of stiffness and damping is almost linear versus the variation of Young's modulus.

As expected, by increasing the Young's modulus the stiffness and damping in soil increase. It is worth to mention that the variation of stiffness is higher than the variation of damping versus the variation of Young's modulus. For the mentioned model, the relative variation of the stiffness is about 1.5 times higher than

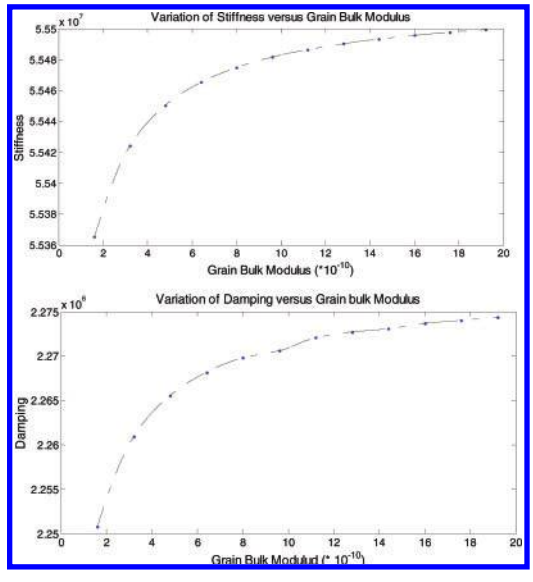

Figure 10. Variation of stiffness and damping versus different grain bulk modulus.

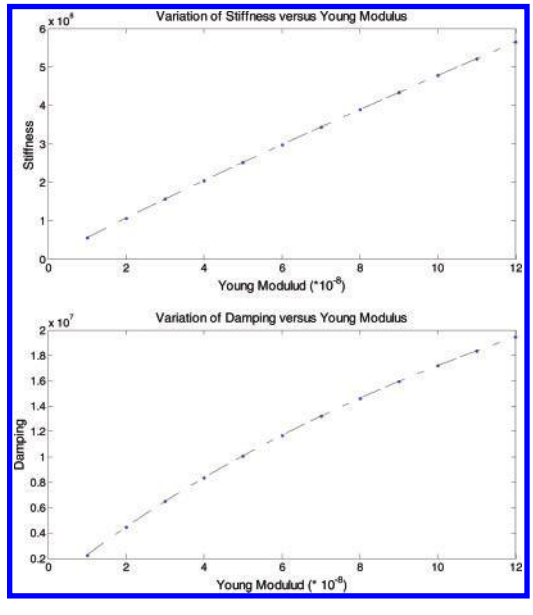

Figure 11. Variation of stiffness and damping versus different Young's moduli.

the relative variation of the damping. This implies that the stiffness is more sensitive than the damping with respect to variations of Young's modulus.

4 CONCLUSIONS

The dynamic response of isotropic elastic saturated soil is presented by using a finite-element model. The effects of model size, soil properties (such as Young's

modulus, bulk modulus of grain, void ratio, and permeability), load frequency and amplitude on the dynamic stiffness and soil damping are investigated.

Numerical results are presented by using the finite-element method by coding the input file and using Python scripting in ABAQUS and MATLAB. A sinusoidal forced displacement is applied and the simulation is carried out within 12 second.

Some general observations of this study can be summarized as follows:

- Dynamic stiffness and damping decrease with increase of void ratio and the variation of damping versus void ratio is greater than variation of stiffness versus void ratio.
- Damping increases to certain value for specific value of permeability and then decreases by increasing the permeability, whilst stiffness decreases by increasing permeability.
- Dynamic stiffness increases with increasing load frequency, whilst the damping decreases with the increase of load frequency.
- Dynamic stiffness is more sensitive than damping with respect to variation of Young's modulus.

Results of the frequency-dependent damping and dynamic stiffness are similar and in the same line to the results reported in Chang et al. (2000) and Kazama & Nogami (1991), respectively.

Improved subgrade reaction model in designing embedded piles exposed to static lateral head loads

Matthias Pulsfort & Tim Welskopf
Bergische Universitaet Wuppertal, Germany

ABSTRACT: Based upon the results of recent model tests with vertical piles exposed to lateral head loads, some new findings upon soil-pile head interaction are reported here. The bearing behavior of piles carrying off lateral loads at the pile head towards the surrounding soil is determined by the development of horizontal reaction stresses, as in prototype scale for instance at bridge abutments, in offshore piling (cyclic loading with low frequency due to wave excitation) or cantilevers of noise load reduction walls as to highspeed railway tracks (dynamic loading due to higher frequencies of wind shock waves). In daily design practice the pile-soil-interaction is commonly disregarded or represented in extremely simplified forms, like linear subgrade reaction models with stepwise control of the equilibrium between reaction stresses and passive earth pressure to be mobilized. This usually leads to an uneconomic - but safe sided - design, because a strong restraining effect at the toe of the pile is disregarded.

The main focus in this contribution is a simple approach to assess the development and redistribution of reaction stresses along the pile-axis due to the imposed head displacement of the pile in static monotonic loading.

1 INTRODUCTION

1.1 *Regarded Problem*

The bearing behavior of vertical piles exposed to lateral head loads can be physically studied in prototype scale with very expensive large scale measurements or in small scaled model tests, while taking into account the effect of the installation method - by means of driving or boring technique. The real excitations are for instance in offshore piling (in form of a cyclic loading with low frequency due to wave excitation) or cantilevers of noise load reduction walls as to high-speed railway tracks (dynamic loading due to higher frequencies of wind shock waves). But also static loading can be dominant for instance in foundations of bridge abutments (FLEMING et.al. 2009).

To study the latter, single floating piles were regarded in small-scaled physical simulation tests in a sand box with dry sand of different initial densities; the model piles were exposed to static lateral head loads by means of constant deformation velocity, leading to results like static load-displacement-curves of the pile top and the distribution of the bending moments, which were counted back from strain measurements at certain points along the pile shaft. The observed distribution of bedding stresses along the pile shaft could be recalculated from these measured strain values by means of inverse methods like IFEM.

1.2 *Physical Modeling*

The geometrical scale in the physical model was chosen to 1:12, representing in prototype scale a driven cylindrical pile made from reinforced concrete of 30 cm in diameter and 5 m in embedded length.

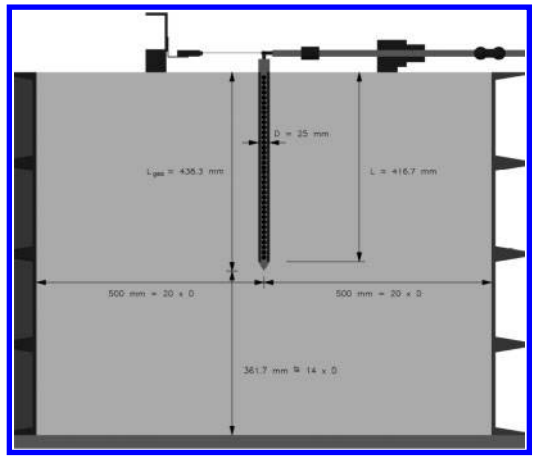

Figure 1. Cross section through sand box with model test loading equipment.

The model piles (diameter D=25 mm) were constructed from brass tubes surrounded with epoxy resin to assure a correctly scaled bending stiffness as well as the scaled geometric width of the pile according to the modeling theory. The concerning bending stiffness of the model piles has been measured to EI=486,69 kNcm^2.

The brass pile shafts were equipped with triple sets of strain gauges in 3 different depths. The model soil was dry medium coarse grained quartz sand, which

Figure 2. Physical model testing equipment.

was installed in layers by means of curtain raining method to achieve different initial densities between loose and very dense. The model piles were driven by means of a guided pushing process into the soil mass. Due to this, the effect of the installation process is taken into account. In this procedure, already a certain clamping effect could be observed.

1.3 *Theoretical approach*

Based upon the observations and results of these test series as well as numerical investigations by means of the Finite Element Analysis under three-dimensional conditions (using a hypoplastic material law for the surrounding soil) in this presentation an improved non-linear subgrade reaction model is proposed, taking into account the observed strong restraining effect at the piles toe. This calculation proposal is compared with the so called p- y- method, which is often used in the design of offshore piles, and it can be shown, that both methods lead to similar design results.

2 RESULTS OF MODEL TESTS

2.1 *Sand Installation*

The dry sand could be installed with 4 different methods of sand placement – varying in the effective falling height – leading to 4 different initial densities between very dense state ($I_d \geq 0{,}81$, method 1), dense (method 2, $I_d = 0,60 - 0,70$), medium dense (method 3, $I_d = 0,27 - 0,35$) and loose state ($I_d = 0,09 - 0,18$, method 4). Fig. 3 shows a satisfying reproducibility of these initial states.

2.2 *Pile Installation*

The model piles were installed vertically by means of a threaded control bar in a guiding frame, pushing the pile 43,83 cm deep into the soil. The development of the mobilized axial pile resistance with installation depth is shown in Fig. 4 for the different initial densities (in detail see WELSKOPF 2013).

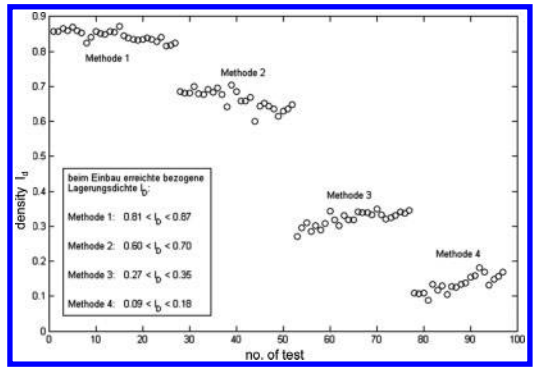

Figure 3. Initial density I_d of the sand due to 4 different methods of sand raining (1= loose to 4 = very dense) for all model tests (static, cyclic and dynamic loading).

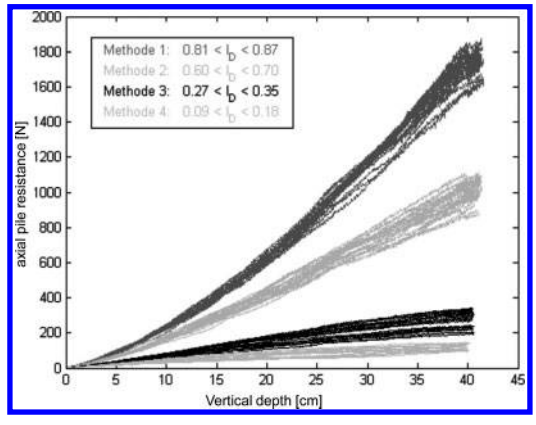

Figure 4. Mobilized axial pile resistance due to installation depth for 4 different methods of sand raining resp. initial densities.

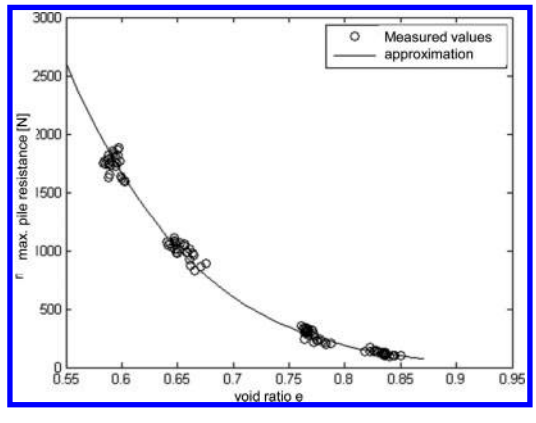

Figure 5. Max. axial pile resistance due to the different initial densities.

The maximum axial pile resistance at the final installation depth in each and any of the in total 100 model tests (Fig. 5) can be very well fitted by an exponential approximation curve as given in eq. (1):

with e= initial void ratio and α, β as parameters to be determined statistically by means of correlation to α =27564 N and β =7,797.

2.3 *Displacement-load curves*

The excitation by the horizontal head load was realized by means of a connection rod (see Fig. 1) to a horizontal pneumatic pulser cylinder, where the reaction load of the pile due to the imposed deformation rate can be measured according to the imposed head movement. The tests were performed with constant horizontal displacement rate, whereas the horizontal head load at the pile top was measured as effect of the "horizontal pile resistance". Typical results for the different initial densities I_d are given in Fig. 6, showing, that the tests have been conducted up to very large dimensionless deformation values of u/D > 0,50, which means in practice an approach to the ultimate limit state (ULS).

Suitable serviceability states in practice will be limited to dimensionless values of u/D< 0,10, so in detail, the lower parts of these curves are zoomed in Fig. 7 up

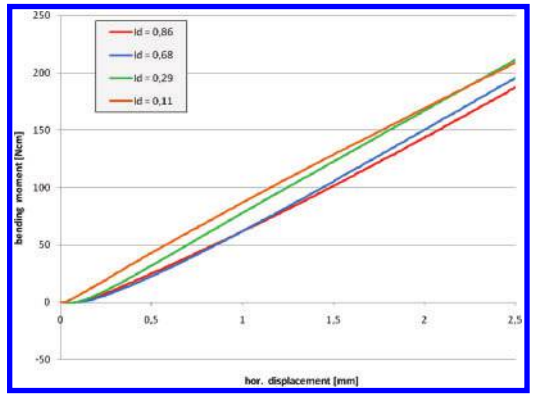

Figure 8. Development of the bending moment in the central point of the initial pile embedding length.

to a horizontal displacement u= 2,5 mm, meaning a dimensionless value u/D=0,10. Even though a strong effect of the initial density of the soil can be observed.

2.4 *Development of bending moments*

The development of the bending moment has been measured at the upper quarter point, middle point and lower quarter point of the pile length, leading to moment-displacement-curves as given in Fig. 8 for the middle point of the pile length. Depending on the initial density, a change in the freeboard value at the pile top could be observed, heaving like a soil wave for initially dense soil, but settlements for initially loose to medium dense soil. This results in a certain change of the effective cantilever length above the actual soil surface.

As can be seen in Fig. 8, the bending moment for the stiffer kinds of soil are beginning with a development of small negative values, whereas the bending moment for the looser soils are only increasing from zero. This is a clear sign for a certain clamping effect due to the installation process, because especially the piles in the stiff soils show a softening effect in the first deformation increments, obviously due to a loosening of the inherent stress condition due to the installation restraint (see Fig. 9).

3 NUMERICAL EVALUATION

3.1 *Method*

The following trial functions have been considered to implement an approximation of the measured values using the theory of beam bending, to be accommodated to the boundary conditions as measured in the 3 points and as given at the top and the toe of the pile.

$$f_1(\xi) = p_0 + p_1 \cdot \xi + p_2 \cdot \xi^2 + p_3 \cdot \xi^3 + p_4 \cdot \xi^4 + p_5 \cdot \xi^5 + p_6 \cdot \xi^6 \quad (2)$$

$$f_2(\xi) = p_0 + p_1 \cdot \xi + p_2 \cdot \xi^2 + p_3 \cdot \xi^3 + p_4 \cdot \xi^4 + p_5 \cdot \xi^5 + p_6 \cdot \xi^6 + p_7 \cdot \xi^7 \quad (3)$$

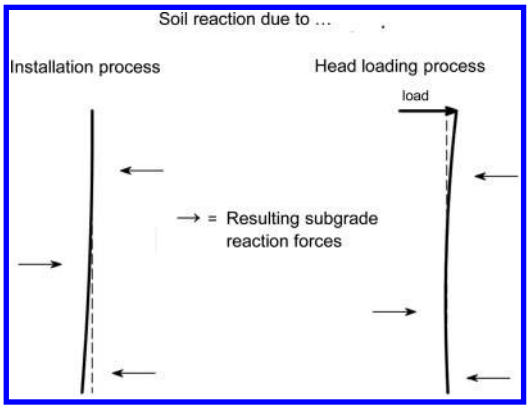

Figure 9. Interpretation of clamping effect due to the installation process.

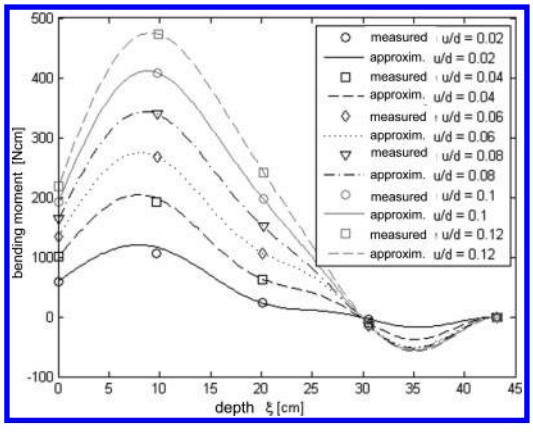

Figure 10. Distribution of bending moments in dense soil (I_d = 0,68) for different displacement stages up to u/D = 0,12.

$$f_3(\xi) = a_0 + b_0 \cdot \xi + a_1 \cdot \cos\left(\frac{2 \cdot \pi}{c_0} \cdot \xi\right) + b_1 \cdot \sin\left(\frac{2 \cdot \pi}{c_0} \cdot \xi\right) + a_2 \cdot \cos\left(\frac{4 \cdot \pi}{c_0} \cdot \xi\right) + b_2 \cdot \sin\left(\frac{4 \cdot \pi}{c_0} \cdot \xi\right) + a_3 \cdot \cos\left(\frac{6 \cdot \pi}{c_0} \cdot \xi\right) \quad (4)$$

$$f_4(\xi) = a_0 + b_0 \cdot \xi + a_1 \cdot \sin\left(\frac{2 \cdot \pi}{c_0} \cdot \xi\right) + b_1 \cdot \cos\left(\frac{2 \cdot \pi}{c_0} \cdot \xi\right) + a_2 \cdot \exp\left(-\left(\frac{\xi - c_1}{c_2}\right)^2\right) \quad (5)$$

with ξ = depth coordinate. By means of differentiation of these functions, the boundary conditions concerning bending moment, shear forces and deformations can be taken into account. This best fit analysis has been executed by a suited MATLAB-routine for all 4 trial functions and showed, that equation (5) leads to the highest degree of clamped support at the toe, at least for initially dense soil. An example of this evaluation is given in Fig. 10.

The distribution of bending moments shows a considerable increase of the negative clamping moment at the pile's toe with increasing deformation.

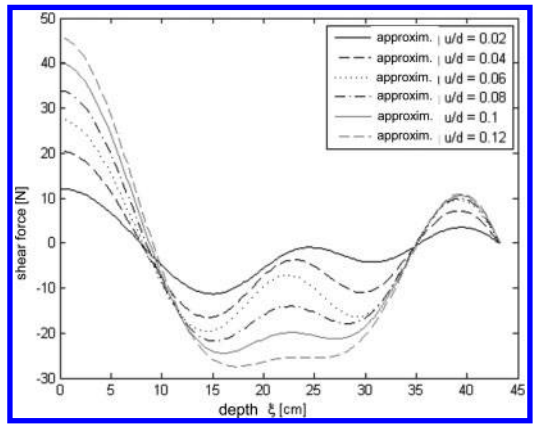

Figure 11. Distribution of shear forces in dense soil (I_d = 0,68) for different displacement stages up to u/D=0,12.

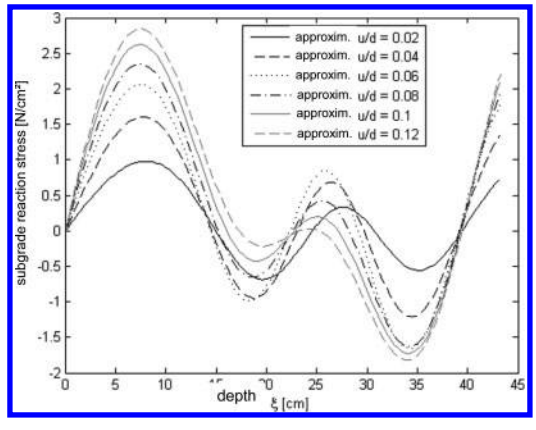

Figure 12. Distribution of subgrade reaction stresses in dense soil (I_d = 0,68) for different displacement stages up to u/D=0,12.

3.2 *Evaluation of subgrade reaction stresses*

Using eq. (5) one can achieve the distribution of shear forces and subgrade reaction stresses by means of multiple differentiation as shown in Fig. 11 and Fig. 12.

In Fig. 12 there can be seen 4 different areas of subgrade reaction stresses, combined with 4 zero points, whereas the classical suggestion allows only one. This apparent contradiction confirms the observation, that a strong clamping effect due to the installation is present in the model tests in dense or very dense sand.

4 CONCLUSION FOR PRACTICAL PURPOSE

The results of the model tests can be compared with a classical (see POULOS 1973), but nonlinear subgrade reaction calculation, performed in the model scale as well (for instance see Fig. 13), but combined with a substantial step increase in stiffness in the lower third

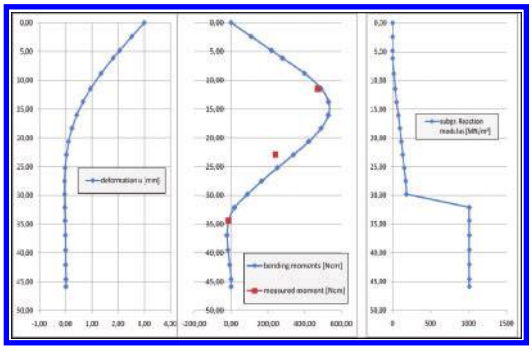

Figure 13. Results of classical subgrade reaction calculation with adopted distribution of subgrade reaction modulus for dense soil (I_d =0,68) and displacement stage u/D= 0,10.

of the pile. In this calculation, the passive earth pressure stress in relation to the depth has been used as plastic yield criteria, leading to a stepwise reduced subgrade reaction modulus at the top quarter of the pile length. The comparison between the calculated bending moment and the measured values at the three quarter points is rather satisfying.

In conclusion, a practical design calculation of a pile under statical and monotonous head loads can be performed with an adopted subgrade reaction modulus, concentrating a very high stiffness in the lower third of the pile.

The behavior of piles due to cyclic or really dynamic head loads, has been regarded e.g. in ABDEL-RAHMAN/ACHMUS (2005) and PULSFORT/ WELSKOPF (2010). In this cases, a subgrade reaction model is not sufficient due to loading/unloading effects, so a 3D-FEM analysis is necessary, using the hypoplastic material law for the soil behavior as published by NIEMUNIS/Herle (1997).

Field test of soil-steel arch with ribs and calculation of internal forces on the basis of measured strains

B. Kunecki & L. Korusiewicz
Wrocław University of Technology, Wrocław, Poland

ABSTRACT: Flexible corrugated steel culverts have been used in engineering for many years. This paper describes full-scale field tests and internal forces analysis of one of two identical large-span flexible structures built on the A4 motorway in Poland. The structures serve as a wildlife crossing. The tested 75 m long culvert is a low-profile steel arch with a span of 19.5 m and a rise of 6 m. The experimental results were used to verify the response computed using software called "Tunel2" based on the finite difference method. The basic input data include the material and geometrical characteristics of the tested culvert and the circumferential stresses calculated on the basis of the measured strains. The main procedures used in the software are described. The results of computations performed by the software for an experimental case are presented. The research project was sponsored by the European Community under Marie Curie European Reintegration Grants.

1 INTRODUCTION

Flexible metal culverts have been gaining in popularity in recent years. In Europe they have been used for over 40 years. Examples of such structures can be found in Janusz & Madaj (2007) and Machelski (2008).

As a result of the increased demand for culverts with large spans, varying barrel shapes and backfill depths, the suitability of the existing semi-empirical procedures for analysing the stress, strain and deflection characteristics of soil-conduit systems subject to both static (soil weight) and live vehicular loads has been questioned. Therefore, several full-scale tests have been carried out in the field to validate the long-term performance and great load bearing capacity of these structures (Vaslestad 1994, Flener & Karoumi 2009, Yeau et al. 2009, Korusiewicz & Kunecki 2012). The experimental results give an insight into the actual behaviour of such structures under service conditions and form the basis for creating and verifying computational models. The progress in finite element methods has contributed to the implementation of a new generation of soil-shell structures with spans of over 20 m.

2 TESTED STRUCTURE

In 2008 twin flexible large-span structures were built on the A-4 motorway in Poland (Figure 1). The structures are low-profile metal arches with a span of 19.5 m and a rise of 6.0 m. Each of the two structures, serving as wildlife crossings over the motorway, is about 75 m long.

An additional spiral type metal pipe was installed between the two main arches. The relief steel pipe with a diameter of 2.40 m was closed at its ends and covered with soil and a top layer of humus to a height of 2.60 m above the crown. The main structures were similarly backfilled with soil and humus to a height of 2.25 m above the crown. The twin metal arches were erected on three reinforced concrete footings. The steel material conformed to European Standard PN-EN 10025-2:2007, having the minimum yield stress of 315 MPa. The dimensions of a single corrugation were 381×140 mm and the steel was 7.0 mm thick. The steel plates were joined with 20 mm diameter bolts of grade 8.8. Over the crown and the haunch region the arches were intermittently reinforced with additional 5.5 mm thick corrugated plates, as shown in Figure 2. A detailed description of the tested culvert can be found in Kunecki & Korusiewicz (2010).

Figure 1. View of complete structures.

3 MEASUREMENTS

The behaviour of one of the arches during backfilling was to be closely monitored. This was done by taking measurements after each backfill layer was placed on both sides of the arches.

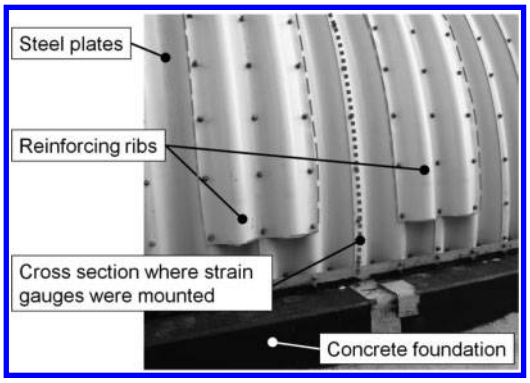

Figure 2. Reinforcing ribs on arch exterior.

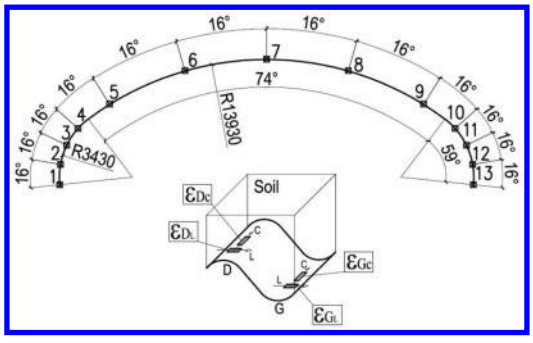

Figure 3. Location of strain gauges on inner side of structure.

Strain gauges were placed in 13 locations inside the west arch in the middle of the structure. Four gauges were fitted in each location: two at the crest of the corrugation and two in its valley (in total 52 strain gauges). Thanks to this configuration strains could be measured in longitudinal and latitudinal directions. Location of strain gauges is shown in Figure 3. The strains in each measuring point were used to calculate the axial and bending stresses from the equations derived by Korusiewicz and Kunecki (2011).

An example of the stress points distribution for the crown and final backfill level is shown in Figure 4. The axial and bending stresses of the tested steel arch for the crown and final backfill level are shown in Table 1 and 2, respectively. The experimental results are comprehensively presented elsewhere (Kunecki & Korusiewicz, in press).

4 DESCRIPTION OF SOFTWARE

The software, under the working name of "Tunel2", computes load intensities on the surface and generalized cross-sectional forces in the lining of a tunnel (culvert) on the basis of the circumferential stresses measured in two layers of the tunnel lining. Data from measuring points (in cross sections) uniformly distributed on the lining's average contour are input into the software. The software comprises two subprograms called: "Tunel2-D" and "Tunel2-O".

13	25,054	52,15	13,75

4.1 *Subprogram "Tunel2-D"*

This program is used to create a data file for program "Tunel2-O". The input data are:

- the task identifier,
- the number of strain gauge pairs (the number of measuring points) –*lpt*,
- the Young modulus of the culvert material – E,
- the lining membrane stiffness in the circumferential direction – D_φ,
- the lining flexural rigidity in the circumferential direction – K_φ,

Table 2. The axial and bending stresses of the tested steel arch for the final backfill level.

Point	s_i	Stresses	
		Axial stresses	Bending stresses
	m	MPa	MPa
1	0,000	−295,13	−1,15
2	0,958	−254,95	51,35
3	1,916	−250,95	−13,35
4	2,874	−234,40	−111,90
5	4,747	−155,25	−101,85
6	8,637	−95,00	−121,40
7	12,527	−22,35	90,95
8	16,417	62,25	116,95
9	20,307	180,30	36,50
10	22,180	241,90	−93,90
11	23,138	249,90	−121,30
12	24,096	237,40	−15,10
13	25,054	186,95	3,05

– the distance of measuring points D_i from the middle layer (the distance is positive for points D_i within the average contour of the lining) – g_{Di},
– the distance of measuring points G_i from the middle layer (the distance is negative for points G_i outside the average contour of the lining) – g_{Gi} ($g_{Di} = g_D =$ const and $g_{Gi} = g_G =$ const are assumed in the program),
– the length of the average lining contour – *SKOT* (the average lining contour should be understood as the arc of a curve, being the geometric locus of the centres of gravity of the considered tunnel lining segment cross sections).

For the next control (measuring) cross sections bearing numbers $i = 1, 2,\ldots, lpt$ and ordered according to increasing length s_i the following quantities are entered:

– the distance of a given measuring point from the adopted starting point, measured along the average lining contour – s_i,
– the radius of curvature of the average lining contour – ri,
– the circumferential stress in points D_i and G_i –σ_{Di} and σ_{Gi}.

Moreover, the program requires that it be specified whether the average lining contour is an open or closed curve and whether the radius of curvature along the whole length of the average contour is intervalwise constant. If so, the number of intervals in which the radius of curvature is constant needs to be input.

Into the program, data can be entered in the interactive mode and saved to a file with a name given by the user or read in from a file indicated by the user.

The terms used in program "Tunel2-D" are explained in Figure 5.

Circumferential stresses σ_{Di} and σ_{Gi} are calculated on the basis of the strains measured in the measuring points. If bidirectional strain rosettes are used,

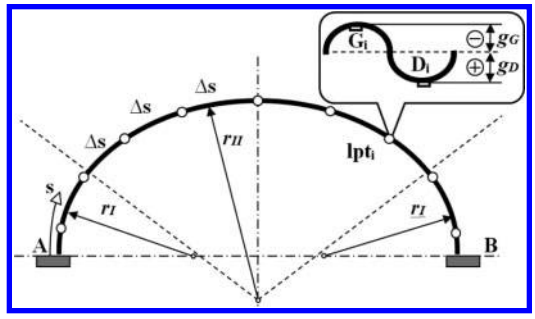

Figure 5. Diagram of terms used in program.

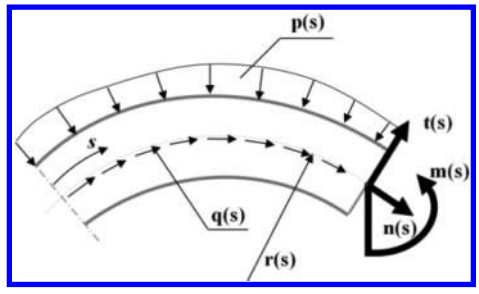

Figure 6. Internal and external forces acting on culvert structure.

the circumferential stresses are calculated from the following relation:

$$\sigma_D = \frac{E}{1-\nu^2}\left(\varepsilon_{D_C} + \nu\varepsilon_{D_L}\right), \tag{1}$$

$$\sigma_G = \frac{E}{1-\nu^2}\left(\varepsilon_{G_C} + \nu\varepsilon_{G_L}\right) \tag{2}$$

Membrane stiffness D_φ and flexural rigidity K_φ for corrugated culverts are expressed by the equations:

$$K_\varphi = E\,I_f, \tag{3}$$

$$D_\varphi = E\,A_f \tag{4}$$

where A_f and I_f stand for respectively the area and moment of inertia of the cross section (fold) per width unit.

4.2 *Subprogram "Tunel2-O"*

This computational program uses the data saved in program "Tunel2-D". The internal forces in the culvert shell and the external forces acting on the culvert shell from the surrounding ground are computed. The results of the computations are displayed in the form of tables and diagrams on the computer screen.

The symbols in Figure 6 stand for: $p(s)$ – the normal stress per middle lining layer unit area; $q(s)$ – the static load per middle lining layer unit area; $m(s)$, $n(s)$ and

$t(s)$ – the bending moment, the normal force and the shearing force in the cross section of the lining per cross sectional unit width.

First the program calculates bending moments m_i and normal forces n_i ($i = 1, 2, \ldots, lpt$) in the control (measuring) cross sections from the formulas:

$$m_i = \frac{K_\varphi}{E\left(g_{Di} - g_{Gi}\right)}\left(\sigma_{D_i} - \sigma_{Gi}\right)$$
$$n_i = \frac{D_\varphi}{E\left(g_{Di} - g_{Gi}\right)}\left(g_D\,\sigma_{Gi} - g_G\,\sigma_{Di}\right) \tag{5}$$

Then the coefficients of the Fourier-Bessel series of functions $m(s)$ and $n(s)$ are calculated and taking into account the statics conditions:

$$t = -\frac{\mathrm{d}m}{\mathrm{d}s} \tag{6}$$

$$p = \frac{\mathrm{d}^2 m}{\mathrm{d}s^2} + \frac{n}{r} \tag{7}$$

$$q = -\frac{\mathrm{d}n}{\mathrm{d}s} - \frac{t}{r} \tag{8}$$

the coefficients of the Fourier-Bessel series of functions $t(s)$, $p(s)$ and $q(s)$ are calculated. The user can choose the trigonometric interpolation method or the trigonometric approximation method. The program correctly solves the interpolation problem only when the distances between the control cross sections are constant $\Delta s = \text{const}$.

Two approximation selection methods: a standard method and a statistical method are available in the program. In both cases, the so-called approximation defect is calculated for successive tentative values of the number of harmonic components (LSH) in expansions $m(s)$ and $n(s)$ into Fourier-Bessel series. As the proper LSH value the user should select the value above which the approximation defects no longer significantly decrease. In the standard method one uses an approximation defect defined as the ratio of the sum square of the measured ordinate deviations from the calculated ordinates in the control cross sections to the sum square of the ordinates measured in the control cross sections. In the statistical method the approximation defect is an approximation error variance defined in the monograph by A. Ralston (1971).

The user can select from three methods of calculating the derivatives of functions in the nodes, mainly the method of Fourier series differentiation, the finite difference method with the five-point scheme and the finite difference method with the three-point scheme.

The calculation results can be saved to a file with a name given by the user as "Results table I" in which values m_i and n_i calculated from formulas (5) are stored and as "Results table II" which for j uniformly distributed cross sections (j – a number selected by the user, lower than 362) stores values $m(s)$ and $n(s)$ determined by the trigonometric interpolation method together with values $m(s)$, $n(s)$ and $t(s)$ determined (depending on the user's needs) by the trigonometric approximation or interpolation method and values $p(s)$ and $q(s)$ determined by the trigonometric approximation method or the trigonometric interpolation method.

A detailed description of the programs can be found in Korusiewicz (2012).

4.3 *Numerical calculation.*

The following case was used to calculation. For the structure shown in Figure 3 the following parameters values were adopted:

- area of the cross section A_f = 8,867 mm^2/mm per width unit,
- moment of inertia of the cross section I_f =21897, 45 mm^4/mm per width unit,
- length of arc AB = 25054 mm,
- number of strain gauge pairs lpt = 13,
- Young modulus E =205000 N/mm^2,
- membrane stiffness D_φ =1817735 N/mm,
- flexural rigidity K_φ = 4488977250 Nmm^2/mm,
- distance g_D =73,5 mm,
- distance g_G = −66,5 mm,
- radius r$_I$ = 3430 mm,
- radius r$_{II}$ = 13930 mm.

The results of the computations performed by program "Tunel2" (the interpolation method, the derivatives calculated by the finite difference method with the five-point scheme) are shown in Figure 7 and 8. Interpolation method was used to compute the quantities.

5 SUMMARY

The main goal of this paper was to present the results of field measurements of a super-span low-profile metal arch culvert in a twin-arch configuration and to describe the software based on the finite difference method. The tested culvert is one of the largest in Europe.

Strains (stresses) in 13 points on the steel plates were measured in the course of backfilling. The measured strain implied the maximum absolute axial stress of 295 MPa for the final backfill level on the side of the arch. The maximum absolute bending stress for the final backfill level amounted to 121 MPa. The distributions of bending and axial stress at this stage were asymmetrical.

The computer software for calculating the internal bending moments and normal and shearing forces in corrugated culverts was presented. The basic input data include the material and geometrical characteristics of the tested culvert and the circumferential stresses calculated on the basis of the measured strains. The results of computations performed by the software for a theoretical case are presented in Korusiewicz

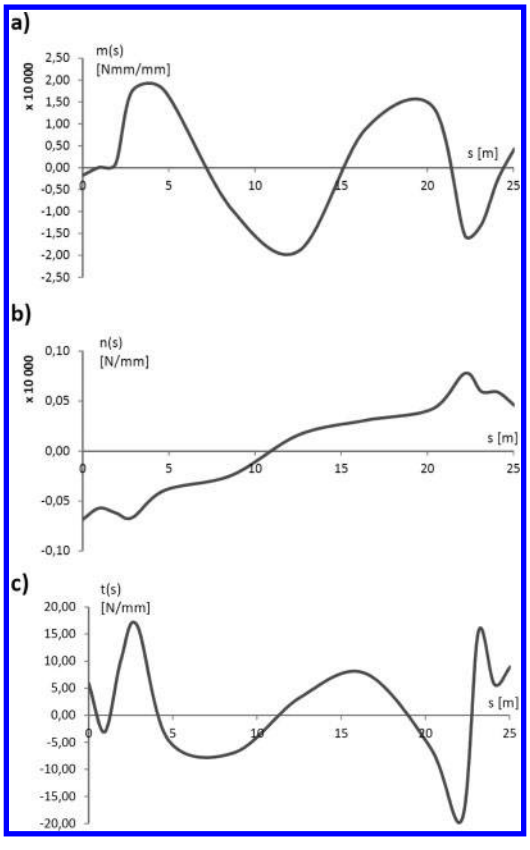

Figure 7. Internal forces distribution for crown backfill level (6.27 m): (a) the bending moment, (b) the normal force and (c) the shearing force in the cross section of the lining per cross sectional unit width.

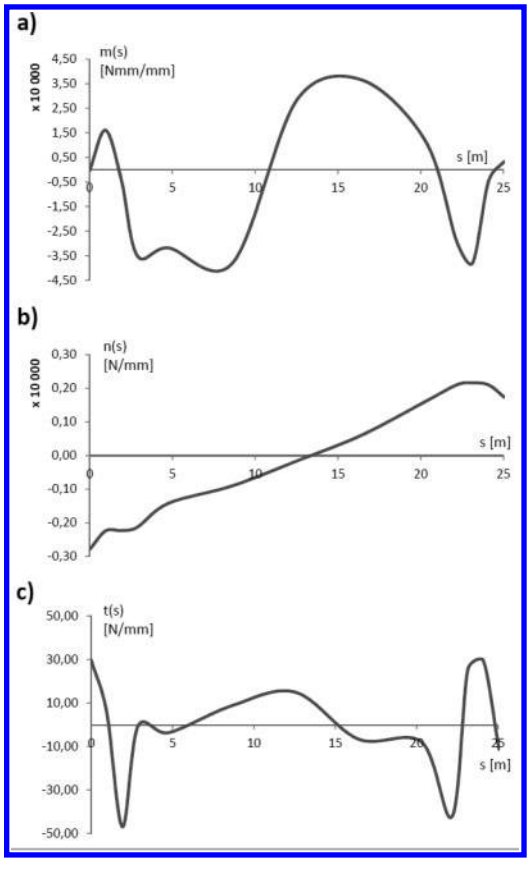

Figure 8. Internal forces distribution for final backfill level (8.31 m): (a) the bending moment, (b) the normal force and (c) the shearing force in the cross section of the lining per cross sectional unit width.

(2012) and a comparison of results shows that the theoretical and the ones computed are in very good agreement. Present paper shows the results of computations performed by the software for an experimental case.

According to the graph (Figure 7a and 8a) bending moments are changing in the range of −19100 to 17600 Nmm/mm for crown backfill level and from −38000 to 36600 Nmm/mm for final backfill level. The distributions of bending moments at both stages were asymmetrical and fluctuated.

The distributions of axial forces (Figure 7b and 8b) are changing in the range of −690 to 780 N/mm for crown backfill level and from −2800 to 2160 N/mm for final backfill level. Reasonably uniform axial forces change is observed.

Distribution of shear forces (Figure 7c) at the crown backfill level is asymmetric and it changes in the range of −19 to 17 N/mm, in contrast to final backfill level, where the distribution is more symmetrical and changed in the range of −47 to 30 N/mm (Figure 8c). The shear forces are not significant in comparison to other internal forces.

6 ACKNOWLEDGEMENT

The tests reported in this paper were supported by funding from The European Community under a Marie Curie European Reintegration Grants: Super-span soil-steel bridge (animal crossing) – backfill and long-term monitoring (EC Contract no: PERG03-GA-2008-230913).

Alternative shape of suction caisson to reduce risk of buckling under high pressure

S. Madsen, L.V. Andersen & L.B. Ibsen
Department of Civil Engineering, Aalborg University, Denmark

ABSTRACT: Using large suction caissons for offshore wind turbines is an upcoming technology also referred to as bucket foundations. During operation the bucket foundation is loaded by a large overturning moment from the wind turbine and the wave loads. However, during installation the bucket is loaded by uniform external pressure and vertical forces. The bucket foundation does not require heavy installation equipment, but since it is constructed as a thin steel shell structure, instability, in the form of buckling, becomes a crucial issue during installation. Typically, the bucket foundation is a large cylindrical monopod foundation made of steel. In this paper, an alternative design/shape of the suction caisson, having a smaller risk of buckling under high pressure is presented. The risk of structural buckling is addressed using numerical methods to determine the buckling pressures of the re-designed bucket foundation during installation. Further, the effect of the lateral restraint offered by the surrounding soil on the buckling pressures is analysed. It is found that the new design enables a significantly larger buckling load compared to the traditional design.

1 INTRODUCTION

The expenses related to the foundations of an offshore wind farm constitute about one third of the total cost. For wind turbines located on deeper waters, the cost of the foundations might be even higher. Thus, a new technology is needed to reduce the total cost of offshore wind turbines. This technology could be the bucket foundation. The first part of the seabed penetration is caused by self-weight. Secondly, suction is applied inside the bucket chamber. The suction creates a differential pressure across the bucket lid as shown in Figure 1, effectively increasing the downward force on the bucket while the water flow reduces the skirt tip resistance. As a result, this foundation does not require heavy installation equipment.

In deeper waters, the diameter of the bucket must be increased in order to accommodate the larger forces on the foundation. This leads to a larger aspect ratio between the skirt diameter and the wall thickness. Thus, instability in the form of buckling becomes a vital issue during installation.

A crucial buckling incident occurred in Wilhelmshaven, Germany, in 2005 (Bakmar 2009). To support a large offshore wind turbine, a bucket foundation was to be installed by both suction and skirt tip injection. The bucket had a skirt length of 15 m and a diameter of 16 m. However, as the skirt had penetrated 6.8 m into the soil, the bucket foundation buckled. Consequently, the installation failed completely.

By use of the commercial finite element package ABAQUS (Dassault Systèmes Simulia Corp. 2011), the authors have introduced a three-dimensional, nonlinear, finite element analysis including the "real" structure of the bucket lid. The soil is considered linear elastic. Previous work by the authors has shown that introducing an imperfect geometry based on the first linear buckling mode shape can increase the nonlinear buckling load significantly, if a sufficiently large scaling of the mode shape is introduced (Madsen, Andersen, & Ibsen 2011).

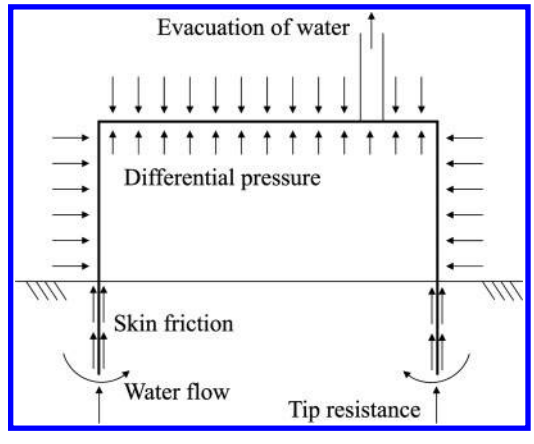

Figure 1. Principle sketch of the downward pressure on lid and skirt due to suction.

Instead of increasing the wall thickness to decrease the risk of buckling, an alternative cross section is presented in Figure 2. The cross section is denoted "multi-shell", since it is constructed of several shell panels with a radius smaller than the overall radius. The shell panels are joint together at the flanges of HEM profiles.

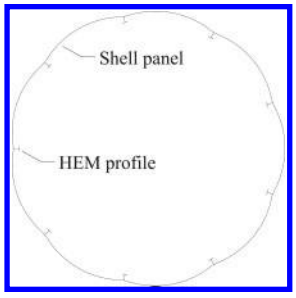

Figure 2. Cross section of the multishell.

During installation, the bucket skirt becomes partly embedded, and the degree of skirt fixation increases due to the lateral restraint offered by the surrounding soil. The lateral restraints provided by the soil to the embedded skirt may increase the buckling loads significantly. In the initial installation phase, the free height of the skirt above the seabed is large and a low suction pressure is needed. For subsequent installation phases, a larger pressure is required. Thus, a critical embedded depth, leading to the minimum difference between the required suction and the buckling load, can be identified.

2 METHODS OF ANALYSIS

Two kinds of boundary conditions are considered. In Section 3, the "classical" boundary condition S3 is used. The end displacements are axially free but circumferentially restrained in-plane (zero tangential deflection). This makes the ends free to warp. In Section 4, the surrounding soil and the "real" structure of the bucket lid is included.

2.1 *Geometry*

The multi-shell considered in this paper has 9 shells of radius 5 m joint together in HEM 300 profiles. The reference diameter is 15 m leading to a maximum diameter of 15.4 m. A cross section of the multi-shell is shown in Figure 4.

The bucket lid is made of a 50 mm steel plate and 9 stiffening ribs with flanges, as shown in Figure 4.

2.2 *Matrial Properties*

The bucket foundation consists of steel with a Young's modulus of $E = 210$ GPa, a Poisson's ratio of $\nu = 0.3$, and an initial yield stress of $\sigma_{y0} = 355$ MPa. The elastic properties of the surrounding soil are defined by Young's modulus $E = 25 \cdot 10^6$ Pa and Poisson's ratio $\nu = 0.25$.

2.3 *Numerical buckling analysis*

The steel is modelled as a linear elastic-perfect plastic material with yielding defined by the von Mises yield criterion. For S3 boundary conditions, the multi-shell

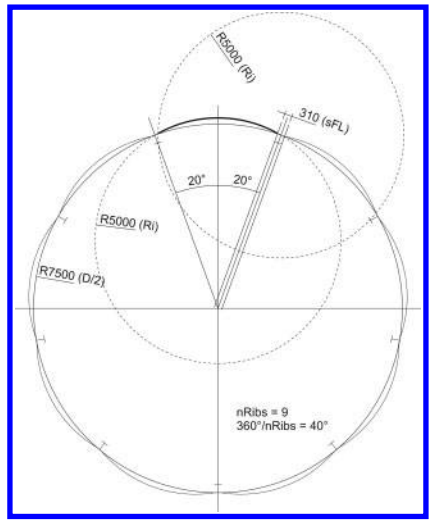

Figure 3. Cross section of the multishell.

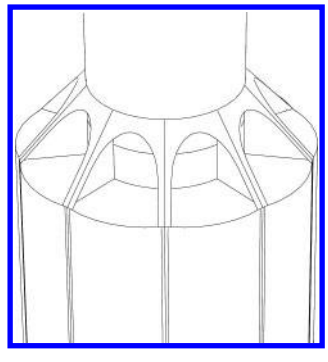

Figure 4. Geometry of the multi-shell bucket lid structure.

is modelled using 8-noded quadrilateral shell elements with quadratic interpolation and reduced integration (S8R).

When the surrounding soil is included the multi-shell bucket foundation is modelled using 4-noded quadrilateral shell elements with linear interpolation and reduced integration (S4R). The surrounding soil is modelled using 8-noded solid elements with linear spatial interpolation and reduced integration . The shell elements of the bucket are coupled to the solid elements of the soil by tie constraints which fuse together the surfaces of two regions even though they have dissimilar meshes and different degrees of freedom.

The numerical buckling analysis is made in two steps. Step one is a linear eigenvalue buckling analysis used to find an estimate of the initial imperfect geometry based on buckling mode shapes (eigenvectors). Also found in step one is a linear prediction of the buckling load (eigenvalue). Step two is a nonlinear analysis where an imperfection in the geometry is introduced by adding the buckling mode shapes determined in step one to the "perfect" geometry.

The linear eigenvalue problem solved is given by

$$\left(K_0^{NM} + \lambda_i K_\Delta^{NM}\right) v_i^M = 0, \tag{1}$$

where K_0^{NM} is the stiffness matrix to the base state including the effects of the preloads P^N, K_Δ^{NM} is the differential initial stress and load stiffness matrix due to the incremental loading pattern Q^N, λ_i are the eigenvalues, v_i^M are the buckling mode shapes, M and N are the degrees of freedom for the whole model. The Lanczos Eigensolver is used to extract the eigenvalues in this analysis.

Since the multi-shell is not a convex structure, as is the case for a circular cylinder, negative eigenvalues can emerge indicating internal pressure. Since external pressure is of interest, only positive eigenvalues are considered. Thus, in this paper, mode 1 refers to the first mode with a positive eigenvalue.

The buckling mode shape from the eigenvalue buckling analysis is introduced as an imperfect geometry. The imperfection has the form

$$\Delta x_i = \sum_{i=1}^{M} w_i \psi_i, \tag{2}$$

where ψ_i is the i^{th} mode shape (nodal displacements normalised to 1) and w_i is the imperfection scale factor, given by

$$w_i = \frac{u_{imp,i}}{U_{max,i}} = \alpha, \tag{3}$$

where $u_{imp,i}$ is the magnitude of the imperfection, and $U_{max,i}$ is the maximum deflection of the i^{th} linear buckling mode. Note that $U_{max,i} \geq 1$ since the nodal displacements of the mode shape are normalised to 1.

When the surrounding soil is included, the buckling mode shape corresponding to a certain penetration depth is introduced as an imperfection for each penetration depth. So, the imperfect geometry is different for each penetration depth.

A uniformly distributed pressure is applied incrementally, and the buckling load is determined as the load level where no further strain energy can be accumulated. Yielding is allowed.

Both the *Static, General* method, which uses the *Newton Rapson* solver, and the *Static, Riks* method, which uses an *arc-length* solver, are tested for comparison. The solutions from both solvers are found to be convergent. The *Static, General* method is used to find the nonlinear buckling load since this method enables automation of the numerical simulations more easily.

2.4 *Analytical solution to the buckling load of a circular cylinder*

The von Mises equation for the critical elastic pressure for a cylindrical shell subjected to uniform external lateral pressure (Windenburg & Trilling 1934, Eq. 2

$$p_c = 2E\frac{t}{D}\left(\frac{(t/D)^2}{3(1-\nu^2)}\left[n^2 - 1 + \frac{\lambda^2(2n^2-1-\nu)}{n^2+\lambda^2}\right] + \frac{\lambda^4}{(n^2-1)(n^2+\lambda^2)^2}\right) \tag{4}$$

where n is the number of circumferential lobes formed at collapse, and $\lambda = (\pi D)/(2L)$.

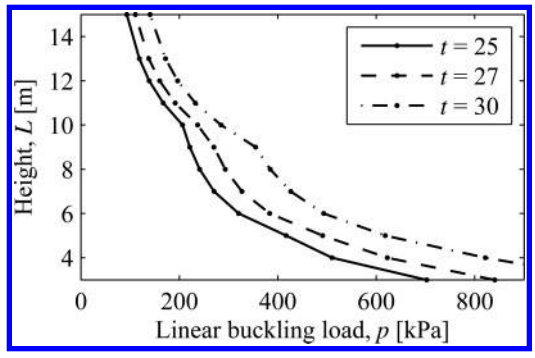

Figure 5. Buckling load versus skirt height at three different skirt thicknesses.

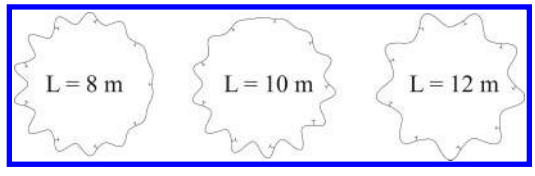

Figure 6. Cross section of buckling mode shape 1 for three different skirt he

ights. Wall thickness $t = 25$ mm.

3 LATERALLY LOADED MULTI-SHELL WITH S3 BOUNDARY CONDITIONS

In this section, the "classical" boundary condition S3 is used, and the shell is loaded by uniformly distributed lateral pressure.

3.1 *Linear bifurcation analysis*

In this section, the results of the linear bifurcation analysis are presented. In Figure 5, the linear buckling pressure is shown as function of the skirt height for three different skirt thicknesses.

From Figure 5 it seems that the linear buckling load follows one expression for skirt lengths lower than 10 m (9 m for $t = 30$ mm) and another expression for skirt lengths longer than 10 m (9 m for $t = 30$ mm). In Figure 6 the first buckling mode shape is shown for $L = 8$ m, $L = 10$ m and $L = 12$ m.

Apparently the circumferential lobes of the first mode shape for skirt lengths longer than 10 m are

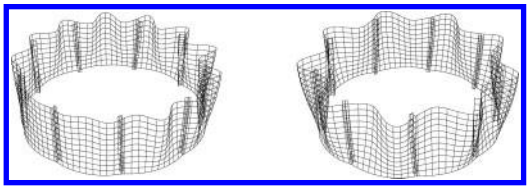

Figure 7. Buckling mode shape 1. Only half the model is shown. Left: $L = 10$ m. Right: $L = 11$ m. Wall thickness $t = 25$ mm.

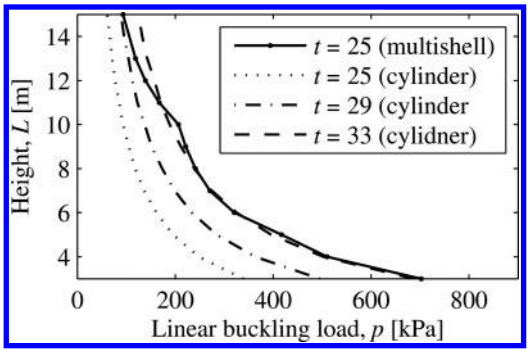

Figure 8. Buckling load as a function of the skirt length for both multi-shell and circular cylinder.

periodic, indicating overall global buckling. On the contrary, the opposite is the case for skirt lengths shorter than 10 m where mode one indicates a more localized failure mode.

In Figure 7 an isometric view of the first buckling mode shape is shown for $L = 10$ m and $L = 11$ m. From both Figures 6 and 7 it is clear that the HEM profiles warp.

3.2 *Equivalent circular cylinder*

A multi-shell cross section with 9 shells, HEM 300 columns, and of dimensions $D = 15$ m, $Ri = 5$ m, $t = 25$ mm has a cross-sectional area of 1.40 m^2 and a surface length of 107.1 m. The maximum diameter is 15.4 m. A circular cylinder of diameter 15.4 m and wall thickness of 29 mm also has a cross-sectional area of 1.40 m^2. In Figure 8 the buckling load is shown as a function of the skirt length for a multi-shell with a wall thickness of 25 mm and for cylinders of various wall thicknesses. The buckling loads for the cylindrical cross section are calculated using Eq. (4).

From Figure 8 it appears that the buckling load of a multi-shell of thickness $t = 25$ mm is equivalent to the buckling load of a circular cylinder of thickness $t = 33$ mm as long as the length is shorter than 10 m. For shells longer than 10 m, it seems that the buckling load for the multi-shell goes asymptotically towards that of a circular cylinder of thickness $t = 29$ mm.

3.3 *Nonlinear analysis with imperfect geometry*

In Figure 9 the nonlinear buckling load is plotted as a function of the imperfection amplitude for a

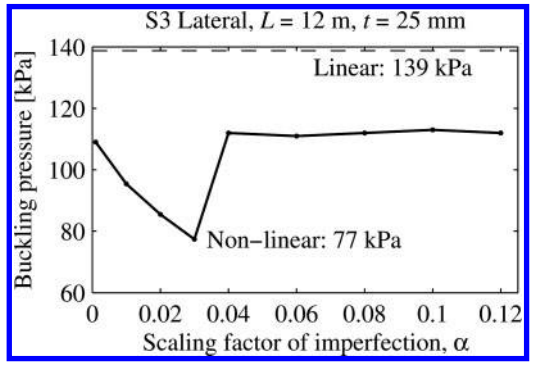

Figure 9. Nonlinear buckling load as a function of imperfection size. Skirt height $L = 12$ m.

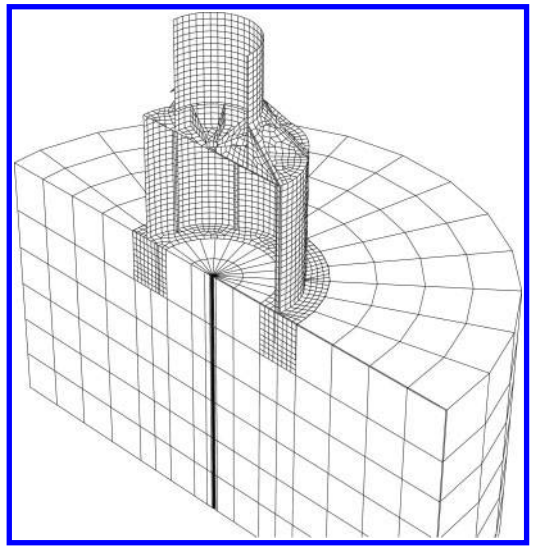

Figure 10. Mesh of multi-shell bucket and surrounding soil. Only half the model is shown.

skirt length of 12 m. Even for very small imperfection amplitudes, the nonlinear buckling load is significantly lower than the linear bifurcation load.

For $L = 12$ the nonlinear buckling load for an imperfection amplitude of 0.001 is 78.5% lower than the linear bifurcation load.

4 SOIL AND LID STRUCTURE BOUNDARY CONDITION

In this section, the "real" structure of the bucket lid is included. Also considered is the surrounding soil. For the soil, "interface elements" are added. The interface elements have similar element size as the bucket skirt. The interface soil elements are extended 2 m below the skirt tip. The mesh of the multi-shell bucket and the surrounding soil is shown in Figure 10.

A bucket with skirt height $L = 15$ m is considered. Penetration depths of $h = 3, 6, 9$ and 12 m are analysed.

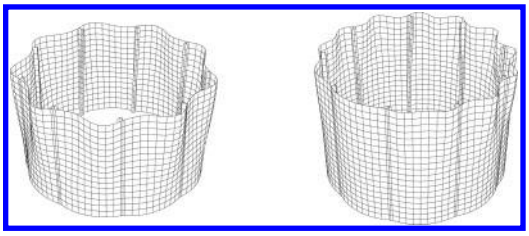

Figure 11. Linear bifurcation mode shape 1. $L = 15$, Soil stiffness is 25 MPa. Soil is omitted and the cylinder is cut at half the free height. Left: $h = 6$ m. Right: $h = 3$ m.

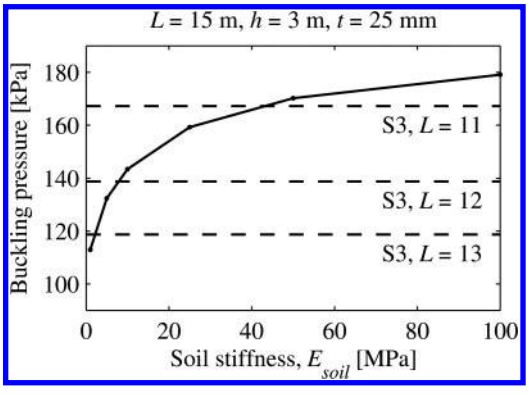

Figure 12. Linear bifurcation load as function of soil stiffness. Skirt height is 15 m and penetration depth is 3 m, i.e. the free height is 12 m.

4.1 *Linear bifurcation analysis*

From Figure 11 it is evident that the penetrated part of the HEM profiles is prevented from warping. Further, in Figure 11 it can be observed that the first buckling mode shape is periodic and symmetric for $h = 3$ m by contrast to the first buckling mode shape for $h = 6$ which is asymmetric. Buckling mode shapes for $h = 9$ and 12 are not shown here, but the first mode shape for $h = 9$ is asymmetric by contrast to the first mode shape for $h = 12$ which is symmetric.

In Figures 12 and 13, the linear bifurcation load is shown as a function of the soil stiffness for penetration depths of 3 and 6 m.

From Figure 12 it can be observed that the multi-shell surrounded by a soil with stiffness as low as 8 MPa corresponds to a pinned-pinned (S3) multi-shell of length equal to the free heigth (12 m).

From Figure 13 it seems that the multi-shell surrounded by soil with a stiffness as low as 5 MPa corresponds to a pinned-pinned (S3) multi-shell of length equal to the free heigth (9 m).

4.2 *Nonlinear analysis with geometric imperfections*

In Figures 14–17 the nonlinear buckling load is shown as a function of the imperfection amplitude.

From Figures 14–17 it is seen that the critical imperfection amplitude varies with the penetration depth. Also, there is a similar tendency of the imperfection

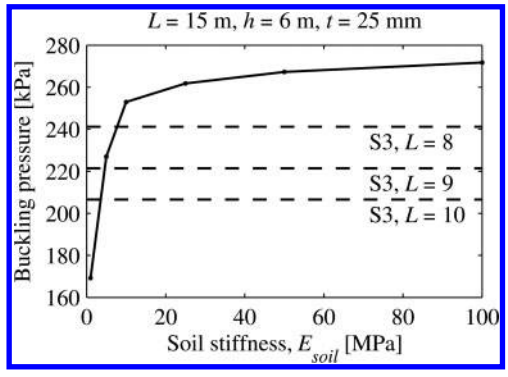

Figure 13. Linear bifurcation load as function of soil stiffness. Skirt height is 15 m and penetration depth is 6 m, i.e. the free height is 9 m.

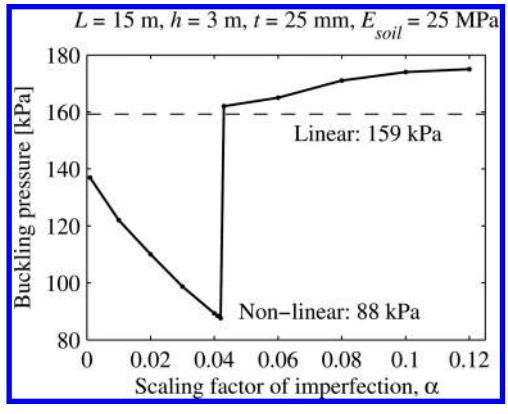

Figure 14. Critical buckling load as a function of imperfection size. Skirt height is 15 m and penetration depth is 3 m, i.e. the free height is 12 m.

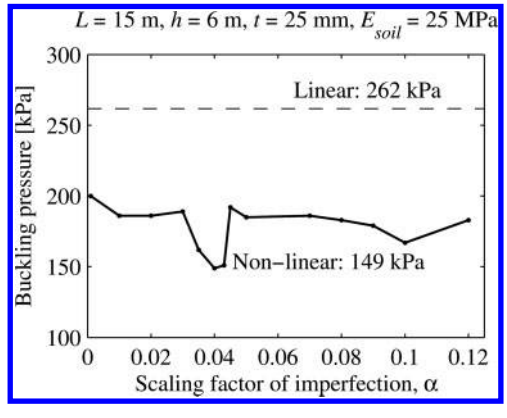

Figure 15. Critical buckling load as a function of imperfection size. Skirt height is 15 m and penetration depth is 6 m, i.e. the free height is 9 m.

sensitivity for the symmetric buckling mode shapes ($h = 3$ and $h = 12$). That is, for "small" imperfection amplitudes the buckling load is reduced significantly and a critical imperfection amplitude gives the lowest

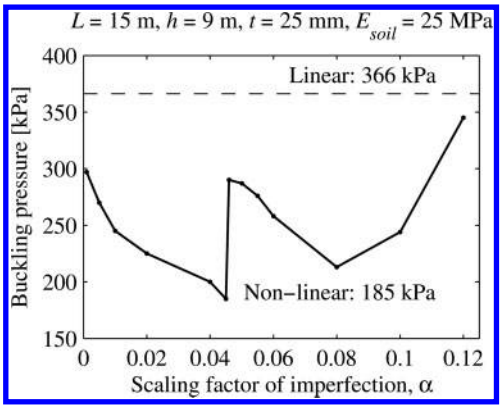

Figure 16. Critical buckling load as a function of imperfection size. Skirt height is 15 m and penetration depth is 9 m, i.e. the free height is 6 m.

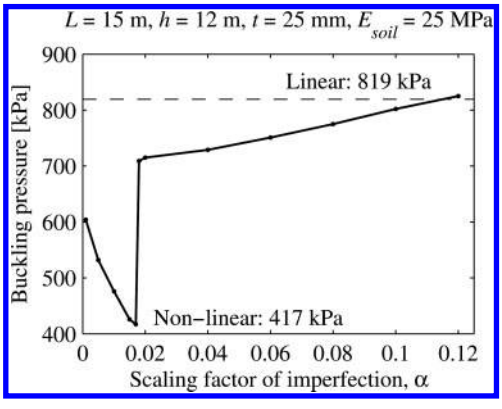

Figure 17. Critical buckling load as a function of imperfection size. Skirt height is 15 m and penetration depth is 12 m, i.e. the free height is 3 m.

buckling load. But, as the size of imperfections is increased above this critical value, the introduced imperfections act as stiffeners raising the nonlinear buckling load even beyond the linear bifurcation load.

In Figure 18 the linear bifurcation load as well as the nonlinear buckling load are shown as function of the penetration depth. These curves are to be compared with the suction required to penetrate the bucket. The penetration resistance of the bucket is the sum of the skin resistance and end resistance as shown in Figure 1.

5 CONCLUSIONS

This paper has introduced an alternative cross section to the bucket foundation called "multi-shell". The linear bifurcation load as well as the nonlinear buckling pressure has been found for both S3 boundary conditions and more realistic boundary conditions, taking into account the bucket lid and the lateral restraint from the surrounding soil. The buckling load of the multi-shell has been found to be significantly larger than

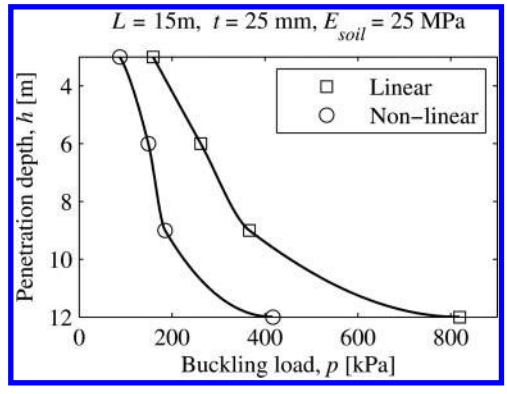

Figure 18. Buckling load as a function of penetration depth. Skirt height is 15 m. Both linear bifurcation load and nonlinear buckling load is shown.

that of a traditional circular cylindrical cross section with similar cross-sectional area. In terms of material consumption, it therefore provides a cost-effective alternative to a circular bucket foundation.

5.1 *Future research*

Instead of introducing the lowest linear buckling mode shape as the initial geometric imperfection for the nonlinear buckling analysis, several imperfect geometries could be considered to reveal the most critical mode shape if not the first. Also, an initial imperfect geometry obtained by combining two or more buckling modes could be considered if a single mode shape does not provide the worst case.

Qualitative and quantitative assessment of liquefaction in a saturated road embankment

A. Borowiec
Cracow University of Technology, Cracow, Poland

K. Maciejewski
Kielce University of Technology, Kielce, Poland

ABSTRACT: The paper deals with the liquefaction susceptibility of a saturated cohesionless soil subjected to dynamic loading. The analyzed soil structure is a road embankment built across a shallow water reservoir. Two cases of dynamic loading are examined: cyclic point loading (induced by a vibratory roller working on the top of the embankment) and an earthquake. In order to asses the liquefaction phenomenon, a Factor of Safety is introduced as a ratio of yield shear strength and shear stress in the soil.

1 INTRODUCTION

Liquefaction is a phenomenon most frequently observed in medium and fine grained saturated cohesionless soils subjected to dynamic loading. Due to rapid cyclic straining, the free drainage can not occur and the gravity loadings are transferred from the soil skeleton to the pore water. As a result, an increase of pore pressure is observed along with the reduction of shear strength and the capacity of the soil to sustain loading.

Liquefaction may lead to uneven and significant settlements of buildings, failures of soil structures such as road embankments and dams, landslides and other hazardous phenomena. In that context, there is still a lack of its quick and simple assessment in geotechnical practice.

2 CASE STUDY

The literature mentions a case of a failure of an road embankment across the Ackerman Lake induced by six Vibroseis vehicles conducting a geophysical survey (Jeffries). A Vibroseis is used to excite the ground via a vibrating metal plate moved by an eccentric weight. As the trucks were spread out over 74 m along embankment, they were set to operate in phase for 8 seconds. The excitation frequency changed linearly from 8 to 58 Hz to give a sum of 264 cycles. Soon after the equipment was activated the saturated soil liquefied sinking five trucks. The failure was rapid enough to cause 4.5 m wave on the waters of Ackerman Lake.

In the paper a similar case is examined. A road embankment built across a shallow water reservoir is analyzed in terms of susceptibility to liquefaction.

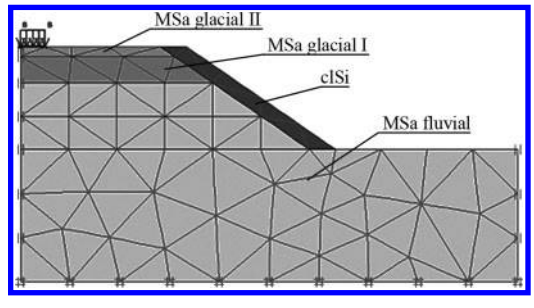

Figure 1. Model geometry and finite element mesh.

Two types of dynamic loadings are considered: first corresponding to an operation of a vibratory roller and second to an earthquake.

2.1 *Geometry*

The embankment is three meter high above the reservoirs bed with a ten meter wide crest. The structure has a slope of 1.5H : 1V with a approx. 0.8 m facing of clayey soil. The embankments core is mainly made of fluvial medium density, medium - grained sands topped by two layers of glacial dense sands (see Figure 1). The surface of water is set to 1 m and 2 m above the reservoir bottom giving the Water Table Level (WTL) at 5 m and 6 m respectively.

2.2 *FEM model in Plaxis 2D*

The 15-node Finite Elements are used to generate the mesh. Average element size less then 1.0 m is sufficient for this dynamic problem. To prevent the reflection and refraction of propagating waves, viscous boundary is introduced.

Table 1. Soil properties.

Soil	MSa fluvial	MSa glacial I	MSa glacial II	clSi	Units
Soil model	HS	HS	HS	M-C	-
D_r	0.6	0.7	0.8	-	-
γ	16	17	18	16	kN/m^3
γ'	18	19.5	20	20	kN/m^3
c	0.1	0.1	0.1	5	kPa
φ	35°	37°	40°	24°	-
ψ	5°	7°	10°	-	-
ν	0.2	0.2	0.2	0.35	-
m	0.5	0.5	0.5	-	-
E	-	-	-	2000	kPa
E_{50}^{ref}	35,000	40,000	45,000	-	kPa
E_{oed}^{ref}	35,000	40,000	45,000	-	kPa
E_{ur}^{ref}	10,500	12,000	13,500	-	kPa

The full geometry is used for modeling soil behavior during earthquake while for cyclic point load only a half of the embankment is considered. Thus both Plane Strain and Axisymmetry are employ.

2.3 *Materials*

The plastic behavior of the cohesionless soils is modeled by means of Hardening Soil constitutive relationship, implemented in Plaxis software. Soil parameters are accordingly modified but based on those found in the literatures (Tiznado). Material properties along with the model parameters, for each layer are specified in the Table 1.

2.4 *Types of loading*

In the first case a cyclic load simulating an operation of vibratory roller is introduced. The load positioned at the center of the embankments crest interacts with the soil through a stiff plate element 1.5 m wide. The loading itself has two components: static with a magnitude of 119 kN/m and harmonic with an amplitude of 350 kN/m and frequency of 55 Hz.

The second case of load is an earthquake excitation of magnitude 5.4 on the Open-Ended Richter Scale. Epicentral distance is 5.0 km and peak acceleration 240 cm/s^2. In Plaxis 2D, like in most FEM programs, earthquake is modeled by imposing prescribed displacements at the bottom boundary, here calculated from accelerogram.

3 FACTOR OF SAFETY CALCULATION

Simple and practical approach is to define a factor of safety against triggering of liquefaction as:

$$FS_{Triggering} = \frac{s_u(yield)}{\tau_{driving} + \tau_{dynamic} + \tau_{other}} \quad (1)$$

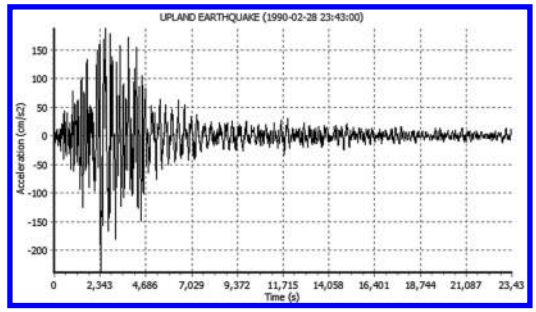

Figure 2. Earthquake accelerogram.

where $s_u(yield)$ = undrained yield shear strength; $\tau_{driving}$ = static shear stress; $\tau_{dynamic}$ = shear stresses caused by dynamic loading; τ_{other} = other shear stresses.

The undrained yield shear strength can be derived from the yield strength ratio expressed as:

$$\frac{s_u(yield)}{\sigma'_{v0}} = \tan\phi_y \quad (2)$$

where σ'_{v0} = vertical or normal effective stress; φ_y = mobilized yield friction angle.

Based on the field test regarding relationship between SPT blowcounts and CPT tip resistance and the yield strength ratio, the mobilized yield friction angle of the analyzed soils (MSa fluvial) can be of $\varphi_y = 13°$ (Olson).It can also be determine with *phi-c* reduction procedure during numerical analysis.

Having normal effective stresses and rewriting Equation 2 it is possible to compute the yield shear strength:

$$s_u(yield) = \tan\phi_y \sigma'_{v0} \quad (3)$$

The $FS_{Triggering}$ is therefore dependent only on two unknown variables: shear stress and vertical effective stress. For the considered structure they are calculated using finite element method program, here Plaxis 2D.

Eventually the factor of safety against triggering liquefaction at point $P_{x,y}$ can be written as:

$$FS_{Triggering}(P_{x,y}) = \frac{\tan\phi_y \sigma'_{v0}(P_{x,y})}{\tau_{dynamic}(P_{x,y})} \quad (4)$$

where $\sigma'_{v0}(P_{x,y})$ = vertical effective stress at point $P_{x,y}$; $\tau_{dynamic}(P_{x,y})$ = sum of dynamic and static shear stresses at point $P_{x,y}$.

4 CRITICAL TIME DETERMINATION

As the stress tensor varies in time during dynamic excitation, the $FS_{Triggering}$ has to be calculate for some particular moment of time when liquefaction is most likely to occur. For the purposes of this paper it is

named a critical time and established for reference point in which the pore pressures where traced in time. The reference point is located in the one-third of the embankment height, close to its core. The critical time takes place when pore pressure reaches its peak value. In case of cyclic point load (vibratory roller) the critical time is established as 0.08 second.

Finding critical time for earthquake excitation is much more demanding, though. It is well known that liquefaction can occur not only during the earthquake but also after it finishes. In the modeled embankment pore pressure is building up at the beginning and reaches its peak value, for the first time in the 9th second of excitation. Then, after showing some drop, it grows again. In order to select proper critical time, factor of safety distribution was generated – in the way described in the following paragraph – for the 9th and the 24th second of excitation, i.e. when the first peak occurs and after the earthquake is finished.

5 RESULTS FOR CYCLIC LOAD

Factor of safety distribution inside embankment is generated on the base of vertical effective stress and sum of dynamic and static shear stresses. Both stresses are taken from cross sections put up along the embankment in 1.0 m spacing, at the critical time.

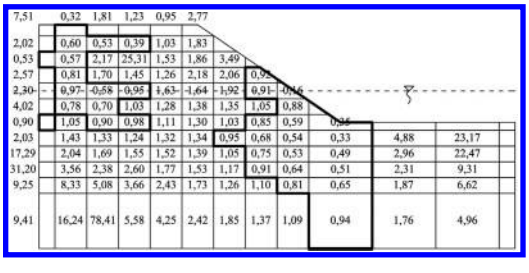

Figure 3. Factor of safety distribution inside embankment for cyclic load (WTL at 5 m).

The allocation of $FS_{Triggering}$ for cyclic load depending on water table is shown at Figure 3 and Figure 4. The liquefaction occurs when $FS_{Triggering}$ is lower than 1.0 and the areas susceptible to it are bold outlined.

In case of cyclic point loading regardless the water table level two regions of the embankment are especially exposed to liquefaction. As long as these two regions are separated the overall stability should be kept. Although very low values of $FS_{Triggering}$, at the foot of the slope indicate to the local stability loss which also can lead to total failure of the structure. Embankment sections lying straight below the dynamic loading are the second exposed to the risk of liquefying. Area prone to liquefaction observed on Figure 3 spreads above the free water surface due to suction in these glacial Medium Sands.

Map of those areas (created from slices of 1.0 m width around cross sections mentioned) with calculated $FS_{Triggering}$, gives qualitative and quantitative assessment of liquefaction in a saturated road embankment.

6 RESULTS FOR EARTHQUAKE EXCITATION

Analogical procedure is apply to asses liquefaction susceptibility of road embankment under earthquake excitation. Only the higher water table is considered as it is the most unfavorable.

Factors of Safety at 9th second do not indicate any possible liquefaction in any area so its distribution is not included in this paper. Figure 5 illustrates map of $FS_{Triggering}$ inside the structure at 24th second of earthquake excitation thus practically after it has finished. Despite short epicentral distance liquefaction do not penetrate into embankment core, influencing only the soil on the base of both slopes along with isolated local areas on the slope edges.

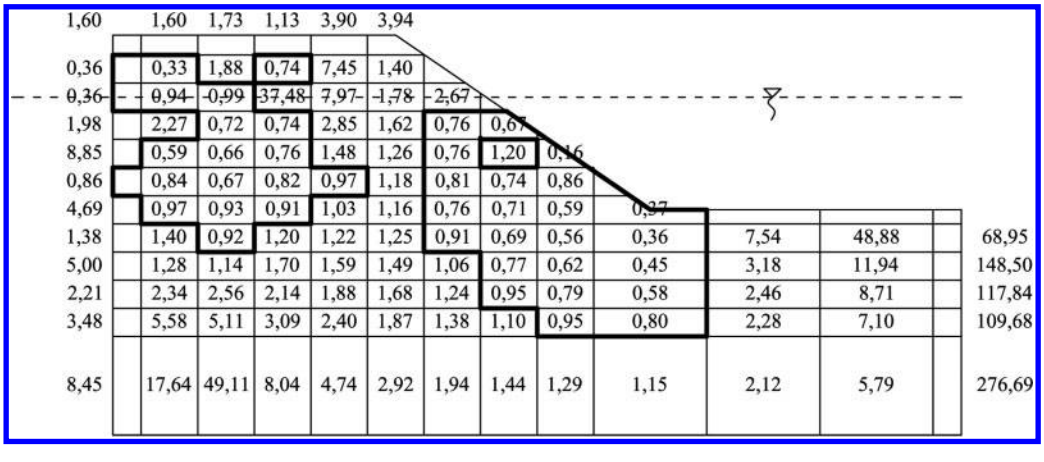

Figure 4. Factor of safety distribution inside embankment for cyclic load (WTL at 6 m).

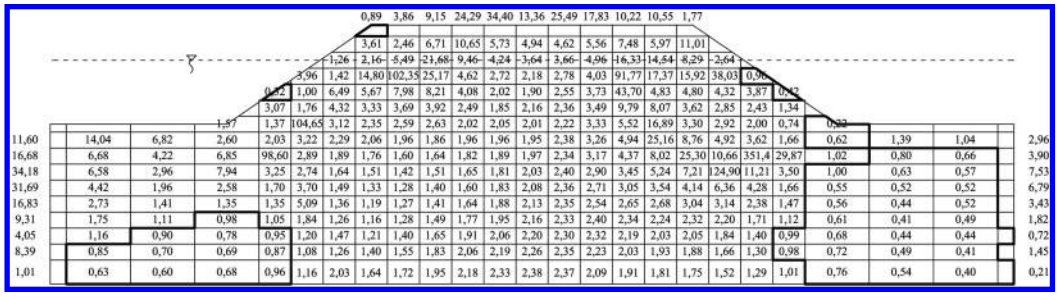

Figure 5. Factor of safety distribution inside embankment for earthquake excitation (WTL at 6 m).

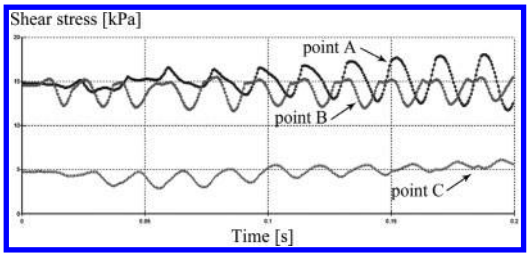

Figure 6. Shear stresses for cyclic loading in Plane Strain.

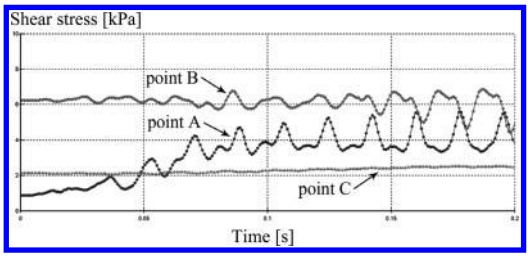

Figure 7. Shear stresses for cyclic loading in Axisymmetry.

7 PLANE STRAIN VERSUS AXISYMMETRY

In order to model properly wave propagation, as it is mentioned in the second paragraph, plane strain as well as axisymmetry is used.

Waves reflection and refraction is best illustrated by shear stress changes in time for points A, B and C. Those points are located at the bottom part of embankment in such way that propagating wave should reach them one by one starting from point A. But as it can be observed on Figure 6, representing Plane Strain, the negative phase displacement takes place.

Besides only in the Axisymmetry (see Figure 7) absorption is clearly visible and correctly modeled.

8 CONCLUSIONS

For the modeled structure, earthquake excitation appears not to be as dangerous as cyclic point load.

Method introduced in the paper presents an clear and easy way to locate and estimate liquefaction susceptibility of soil (not only in the road embankment). In that content it could be very helpful in geotechnical practice, as long as the stresses are obtained from program based on Biot's theory of dynamic consolidation.

A study of frictional interface properties between typical South African sands and construction materials

Z. Bhengu, D. Kalumba & F.C. Chebet
Department of Civil Engineering, University of Cape Town, Cape Town, Western Cape, South Africa

ABSTRACT: Numerous approximations are used to determine the footing material-soil interface friction angle for the design of foundations. The approximations are generalised and very often result in inaccurate estimations for respective soil/foundation materials interactions. This study investigated the interface properties of two common South African sandy soils and three different foundational construction materials with a view of obtaining more representative values so as to provide a possible guide to the local industry. A direct shear apparatus was used to conduct the interface tests to obtain the angle of interface friction between the soils and the foundation materials. As expected, it was found that the type and the degree of roughness of a foundation material greatly influenced the interface frictional resistance, and so did the soil's particle size and grading. It was also found that the typical interfacefriction values used in design are conservative estimations of the actual values for respective sands.

1 INTRODUCTION

The interfacial interaction between construction materials and soil is fundamental for the stability of structural foundation systems. Determination of soil-foundation material interface properties is therefor eessential to ensure the reliability of structural foundations dependent on the frictional resistance of the construction material relative to the soil material. Soil in contact with a dissimilar solid material exerts frictional resistance known as the interface friction which changes with each foundation material type. The values of frictional resistance which consists of the angle of friction and the interface friction are used directly in equations relating to foundations and retaining structures. The angle of friction, φ, also referred to as inter particle friction, is the main source of a soil's strength providing soil with the ability to resist failure to due shear (Powrie, 2004). Celik *et al.* (2011) maintain that in order to make a good estimation of the axial capacity of a pile foundation, the angle of interface friction, δ, must be established. This angle can be determined by conducting experiments in a controlled laboratory environment, from field observations, or from the pile driving resistance (Ampera & Aydogmus, 2005).

In engineering design, the angle of interface friction has been approximated as a function of the angle of internal friction for different foundation materials (Meidema, 2012). It is often estimatedto be $2/3\varphi$ as applied in the Coulomb theory of lateral earth pressures. This study was therefore undertaken to determine the critical relationship between the angle of internal friction and the interface friction in order to validate and facilitate improvement of current estimations particularly with regard to typical South African sands, Klipheuwel and Cape Flats sand relative to selected foundation construction materials.

2 LITERATURE REVIEW

2.1 *Interface friction*

The magnitude of frictional resistance changes with the degree of roughness of the surface with which the soil is in contact; the value of friction for smoother surfaces being lower than for rougher surfaces. However, the angle of interface friction between various materials will vary depending on the soil's characteristics. It is common practice to express the angle of interface friction (δ) in terms of the angle of internal friction (φ). Some researchers express it as a ratio while others deduce empirical formulae with various additional parameters. Subba Rao *et al.*(1988) proposed a correlation between the ratio of the peak interface friction angle, the peak angle of internal friction of sand and the relative roughness shown in Equation 1 below:

$$\delta/\varphi = 1.0 - 0.8\exp(-1.5R^{0.54}) \quad (1)$$

Where R is the relative roughness defined by the ratio of the average roughness, Ra, to the weighted average particle size of the soil.

According to Al-Mhaidib (2006), the preceding equation yielded values close to the average values obtained from laboratory tests conducted hence proving it a reliable method to deduce the angle of interface friction.

Table 1. Table 1. Interface Friction Angles (Meidema, 2012)

Interface friction angle	Material	Source

$2\varphi/3$	Piles	M. R. Lindeburg
$2\varphi/3$	Concrete walls	Coulomb Theory

*Naval Facilities Engineering Command.

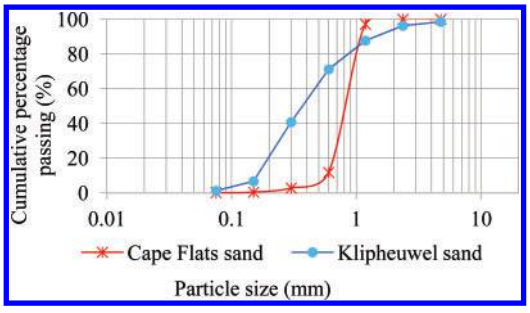

Figure 1. Particle distribution chart.

Table 1 provides a summary of the ratios of interface friction angle in terms of the internal friction angle, as determined by the respective researchers and engineering institutions. For some ratios, the soil types are not specified, thus disregarding the effect of particle size and grading. These ratios may not be accurate since it has been established that the angle of interface friction is a function of the particle size and distribution of a soil(Ampera and Aydogmus, 2005). The angle of interface friction is largely influenced by the relative roughness of the construction material which is also not specified.

3 RESEARCH MATERIALS AND METHOD

3.1 *Soil material*

Two soils were used in this research: Klipheuwel and Cape Flats sands. The Soils were cleaned and oven dried before the testing process commenced. The mechanical properties of each were determined using classification methods prescribed in the British Standards 1377:1990. The grading curves obtained from particle size distribution analysis of the soils is shown in Figure 1.

Cape flats sand is light grey quartz, uniformly graded coarse grained sand. The soil particles are predominantly of one particle size and therefore the sample is classified as poorly graded sand with little fines (SP). Klipheuwel sand is reddish brown quartz sand. It is poorly graded coarse grained soil. It is made up of a wider range of particle sizes with relatively more fines than Cape Flats sand. A summary of the soil mechanical properties are listed in Table 2.

Table 2. Soil mechanical properties of sands.

Properties	Cape Flats	Klipeuwel
Specific gravity	2.76	2.72
Optimum moisture content (%)	15.0	6.7
Maximum dry density (kg/m^3)	1710	1985
Particle size range (mm)	0.075–2.36	0.075–4.75
Mean grain size D_{50}	0.80	0.36
Coefficient of uniformity C_u	1.534	2.647
Coefficient of curvature C_c	0.977	0.753
Angle of friction	37°	40°

3.2 *Construction materials*

Common local construction materials such as South African pine timber, bright mild steel and concrete were selected for the tests conducted.

The concrete mixture was prepared to a ratio of1 kg 52.5 PPC cement, 1.5 kg Klipheuwel sand and 1.5 kg9.5mm stone aggregate. A water-cement ratio of 0.58 was used to obtain a compressive strength of at least 30 MPa at 28 days.

The concrete samples covered three ranges of surface roughness (i.e. smooth, medium-rough and rough). Specific techniques were employed to produce each of the desired three surface finishes. The smooth concrete surface was produced by finishing the wet concrete surface with a smooth metal plate. The medium-rough concrete surface was obtained by imprinting the wet concrete sample surfaces with a P40 sandpaper. This sandpaper has an average particle diameter of 0.425 mm (ISO 6344-2:1998). Cape Flats sand of particle size 0.600 mm–2.36 mm was used to imprint the finish of the rough surface.

3.3 *Methodology*

Direct shear interface tests were conducted to determine the shear deformation characteristics of the different soils at the interface of the different construction materials. The procedures according to the British Soil Classification System were used to conduct all laboratory experiments: BS 1377:1990 *Part 7: Shear Strength Test (Total Stress)*. The Wykeham Farrance SB1 constant strain rate direct shear apparatus was used, with a 100 mm × 100 mm shear box. An electric motor speed of 1.32 mm/min was used.

A total of 36 direct shear tests were conducted; 6control tests (internal friction tests) and 30 interface friction tests. The soils were prepared at optimum moisture content to achieve maximum dry densities for the samples tested. . Three normal stresses 25, 50 and 100 kPa were used in the testing schedule to obtain the Mohr-Coulomb failure envelope for analysis of the results.

The interface friction direct shear tests were conducted by placing the construction material at the bottom half of the shear box and the soil placed in the tophalf of the shear box. For timber, the blocks were placed in the shear box such that the direction of the grade of the timber was perpendicular to the shearing movement to which it was subjected. The other construction materials were uniform and had no lines of gradation.

3.4 *Data capturing and processing*

The readings were taken from the dial gauge of the direct shear apparatus in 10 seconds intervals, and entered into spreadsheets which were used to Compute the shear strength corresponding to the respective horizontal displacement. The relationship between the shear strength and the horizontal displacement of the specimen was determined from the results and the shear strength parameters obtained using the Mohr-Coulomb failure envelope (Equation 2 and 3).

$$\sigma = \tau \tan \varphi + c \quad (2)$$

$$\sigma = \tau \tan \delta + c_a \quad (3)$$

where σ: normal stress, τ: shear strength
φ : internal friction angle, c: cohesion
δ : interface friction angle, c_a: adhesion

4 RESULTS AND ANALYSIS

4.1 *Cape Flats sand: Shear strength and horizontal displacement*

The shear stress of the Cape Flats sand reached peak shear strength (τ_p) for all the normal stresses and gradually decreased as the shear displacement increased eventually reaching residual shear strength (τ_r).

The shear strength resulting from the interaction between Cape Flats sand and timber showed a similar pattern to that of the sand only control test, in which the shear stress increased rapidly to peak shear stress and then decreasing to a constant value. The residual shear strength was reached at a lower horizontal displacement of 2.0–2.4 mm, whereas in the control test the residual shear strength was reached at 5 mm horizontal displacement. Both the peak shear strength and residual shear strength for timber and Cape Flats sand test were found to be lower than that of the control test. The interface shear strength results are shown in Figure 2 below.

The Cape Flats sand and steel shear strength did not peak. The residual shear strength was lower than that of the control test, with an average drop of 4.63 kPa for normal stresses 25 kPa and 50 kPa, and a drop of 11.94 kPa for normal stress 100 kPa. There was interface peak shear stress exhibited. (Figure 3).

The smooth surface concrete responded in a similar manner as the Cape Flats sand-steel results with no peak shear strength. However, the shear strength

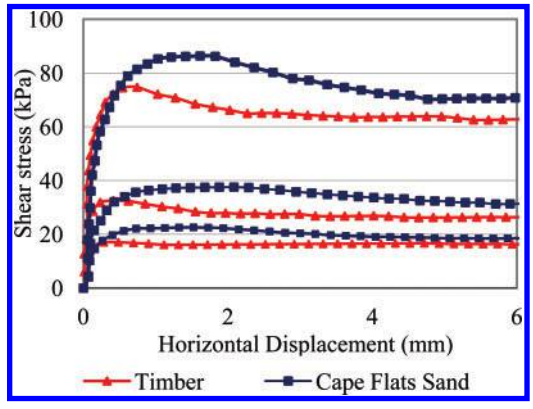

Figure 2. Cape Flats sand and timber shear stress and horizontal displacement relationship.

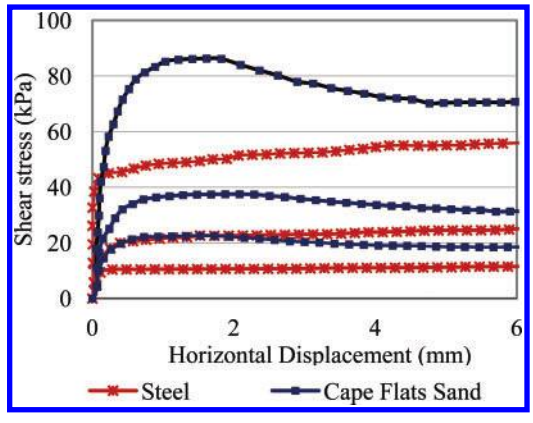

Figure 3. Cape Flats sand and steel shear stress and horizontal displacement relationship.

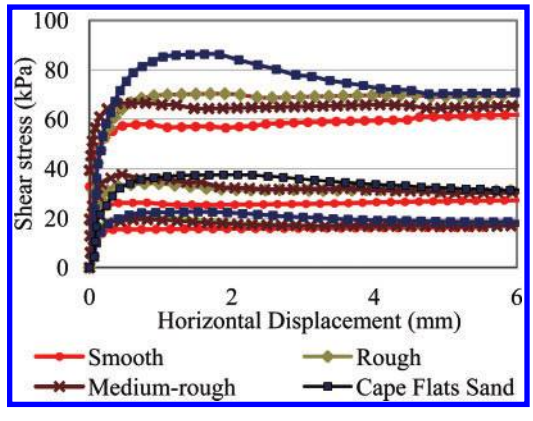

Figure 4. Cape Flats sand and concrete (smooth, medium-rough and rough) shear stress and horizontal displacement relationship.

results for the medium-rough and the rough concrete surfaces exhibited peak shear strength before gradually reaching residual shear strength. The difference between the peak and residual shear strengths were marginal as shown in Figure 4 below.

Table 3. Cape Flats sand interface peak shear strength.

Normal stress (kPa)	Shear strength (kPa)					
	Sand	Timber	Steel	CS*	CM *	CR*
25	22.6	17.1	13.5	16.3	19.5	20.3
50	37.5	32.6	27.1	27.6	37.7	34.0
100	86.3	74.6	62.0	62.0	66.6	71.3

*Where CS = Smooth concrete, CM = Medium-rough concrete, CR = Rough concrete, Sand = Cape Flats sand.

Table 4. Cape Flats sand interface residual shear strength.

Normal stress (kPa)	Shear strength (kPa)					
	Sand	Timber	Steel	CS*	CM *	CR*
25	18.4	15.0	13.5	16.3	16.7	17.2
50	31.5	27.6	27.1	27.6	30.8	31.7
100	73.9	60.8	62.0	62.0	65.6	71.1

*Where CS = Smooth concrete, CM = Medium-rough concrete, CR = Rough concrete, Sand = Cape Flats sand.

Overall, the peak shear strength of Cape Flats sand-concrete was lower than that of the control test. At normal stresses 25 kPa and 50 kPa, the residual shear strength was close to the value of the sand only test; however at 100 kPa there was a noticeable decrease in shear strength compared to the control test. The rough surface finish remained very close to the control test values with a drop of only 2.8kPa. The results of peak and residual shear strengths with the corresponding normal stresses are listed in Table 3 and 4.

4.2 *Klipheuwel sand: Shear strength and horizontal displacement*

For Klipheuwel sand, the shear strength rapidly increased however it did not reach a peak. As the shear displacement increased the shear stress eventually reached residual shear strength (τ_r). At a normal stress of 25 kPa, the shear strength resulting from the composition of timber and Klipheuwel sand was larger than the internal shear strength of the soil. However, as the normal stress increased the shear strength between the two materials became lower than the soil shear strength (Figure 5).

The shear resistance between Klipheuwel sand and steel was lower than that exhibited by timber and sand. The shear stress between the two materials did not at tain a peak value for all normal stresses. Contrary to the control test results, the interface tests for smooth and rough concrete yielded results in which the shear strengths reached a peak and then gradually decreased up to the residual shear strength(Figure 6).

The peak shear strength from the interface tests was generally larger than that of the sand. However, the residual shear strength of the materials in contact with Klipheuwel sand was lower than the value for sand

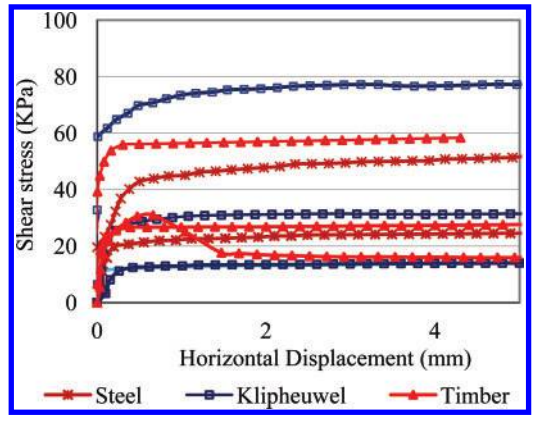

Figure 5. Klipheuwel sand, steel and timber shear stress and horizontal displacement relationship.

Table 5. Klipheuwel sand interface residual shear strength.

Normal stress (kPa)	Shear strength (kPa)					
	Sand	Timber	Steel	CS*	CM *	CR*
25	14.0	15.4	14.7	13.9	20.0	18.9
50	31.9	27.8	25.5	26.1	32.5	33.2
100	76.7	58.2	53.8	64.6	69.6	74.1

*Where CS = Smooth concrete, CM = Medium-rough concrete, CR = Rough concrete, Sand = Klipheuwel sand.

alone. The residual shear strengths results are as listed in Table 5.

4.3 *Angle of interface friction*

Klipheuwel sand yielded the higher angle of internal friction of 40.2° : It was better graded than the Cape Flat sand with more particles of varying sizes which interlock resulting in a greater resistance against sliding. Cape Flats sand had a peak angle of internal

Table 6. Interface friction angles.

	Sand	Timber	Steel	CS*	CM*	CR*
Cape Flats sand						
Peak	41.0°	37.9°	33.2°	31.1°	31.9°	34.6°
Residual	37.1°	31.7°	33.2°	31.1°	33.4°	36.1°
Klipheuwel sand						
Peak/Residual	40.2°	29.9°	28.8°	34.6°	33.9°	36.8°

*Where CS = Smooth concrete, CM = Medium-rough concrete, CR = Rough concrete, Sand = Klipheuwel sand.

friction of 41.0° , and a residual angle of internal friction of 37.1° . The interface friction resulting from the interaction between Cape Flats sand and the construction materials generally yielded lower values than that of the internal friction of sand only. Timber tests yielded the greatest value of interface friction while the smooth concrete had the lowest value which, however increased as the surface finish became rougher. The angle of interface friction at peak and at residual shear strength did not differ considerably; generally this angle was greater at residual strength than at peak shear strength, with the exception of timber where the angle was 37.9° at peak and 31.7° at the residual strength. The friction parameters are presented in Table 6. The interface shear strengths for all the construction materials and Klipheuwel sand were lower than the internal shear strength of the sand. It was observed that the angle of interface friction increased as the surface became rougher. Steel yielded the lowest interface friction with an angle of 28.8°, followed by timber at 29.9° .

4.4 *Relationship between the angle of internal and interface friction*

The relationship between interface friction and internal friction is commonly quantified using the ratio: δ/φ. Strength the ratios δ_r/φ_r and δ_p/φ_p were used to determine the relationship for the residual and peak shear parameters respectively. For Cape Flats sand, the lowest interface friction ratio was obtained from tests involving smooth concrete. At peak shear strength, the timber interface yielded the highest ratio, however at residual shear strength rough concrete yielded the highest with the ratio tending towards the internal angle of friction as the foundation material became rougher. The ratios foreach material are presented in Figure 7 and 8.

The highest strength ratio was achieved for tests ona rough concrete surface with Klipheuwel sand while the steel material yielded the lowest ratio(Figure 9). From the results, it can be deduced that the angle of interface friction tends towards the angle of internal friction with increasing surface roughness.

4.5 *Angle of interface friction ratios*

The interface friction ratios commonly used in design were compared with the ratios obtained from this

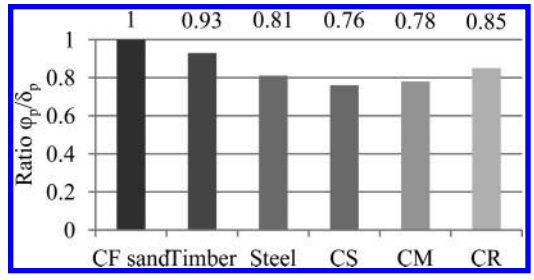

Figure 7. Bar chart of interface friction angle ratios for Cape Flats sand at peak shear strength.

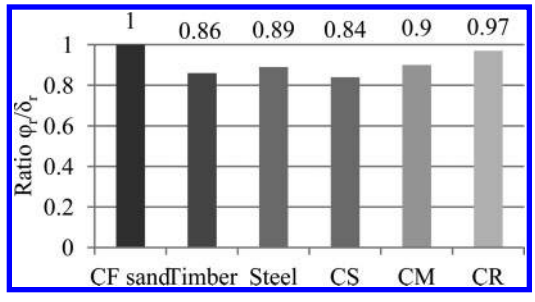

Figure 8. Bar chart of interface friction angle ratios for Cape Flats sand at residual shear strength.

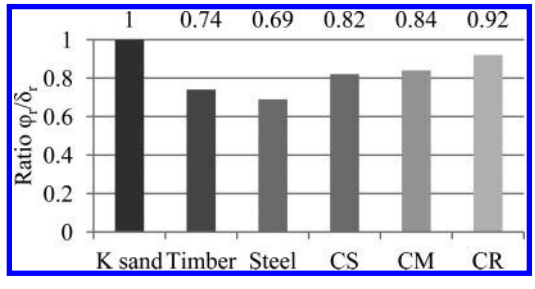

Figure 9. Bar chart of interface friction angle ratios for Klipheuwel sand.

study (Table 7). The values from the study were all found to be greater than the typical interface friction angles used in design (i.e. $2/3\varphi$), which are relatively more conservative estimations of the actual interface friction. The interface friction angles obtained from Klipheuwel sand tests were generally greater than $3/4\varphi$, and greater than $4/5\varphi$ for Cape Flats sand tests.

Overall, from the results obtained in the study, the internal friction angle of Klipheuwel sand was found to be 40° and the interface friction angles ranged between 29°–37° for the construction materials tested and while for Cape Flats sand the value of the internal friction angle was determined as 37° and the interface friction values were between 31°–36° . The various concrete finishes exhibited increasing angles of interface friction as the contact surface with the soils became rougher. A coarser texture achieved a larger shear resistance than a smooth surface due to the increased contact and interlocking of particles. The

Table 7. Comparison of angle interface friction ratios at shear strength.

Material	Cape FlatsSand		Klipheuwelsand	Typical
	Peak	Residual	Peak/Residual	value*
Timber	0.92ϕ	0.85ϕ	0.74 ϕ	0.67 ϕ
Steel	0.81 (41°)	0.89 (33°)	0.69 (29°)	20°
Smooth concrete	0.76ϕ	0.84 ϕ	0.82 ϕ	0.67–0.75 ϕ
Medium-rough concrete	0.78ϕ	0.90 ϕ	0.81 ϕ	0.67–0.75 ϕ
Rough concrete	0.85ϕ	0.97 ϕ	0.92 ϕ	0.67–0.75 ϕ

*see Table 1 for references.

rough concrete surface had the highest shear strength, and therefore the highest angle of interface friction for both sands.

5 CONCLUSION

A series of direct shear interface tests were undertaken on two locally sourced sands (Klipheuwel and Cape Flats sand) and three typical foundation materials (timber, steel and concrete)in order to examine and review the soil-construction material interfacial frictional properties. The values of interface friction determined from the study were found to be greater than the ratios currently used in practice which are conservative estimates possibly with an inherent factor of safety. The angle of interface friction obtained for Cape Flats sand and the construction materials ranged from 0.76φ–0.97φ and for Klipheuwel sand, from 0.69φ–0.92φ. The results of this study suggest that the design values of interface friction in common use approximated between0.67φ–0.75φ are not an accurate representation of the actual angle of friction at a soil-foundation interface. It is essential to establish the true values of interfacial interaction between the soils and the structures in order to avoid instances of over design based on ultra conservative estimates.

ABSTRACT: The soil flexibility effect is generally ignored in seismic design of building frames and the design is carried out based on results of dynamic analysis considering fixed base condition. Flexibility of soil causes lengthening of lateral natural period due to overall decrease in lateral stiffness of the structure. Such lengthening of lateral natural period(T) may considerably alter the seismic response of the building frames resting on Raft foundation. Hence it is necessary to incorporate the flexibility of soil on which the foundation rests during analysis, such study being termed as Soil Structure Interaction.

The present paper deals with dynamic behaviour of building frames asymmetric in plan with Raft footings under seismic forces incorporating soil-structure interaction. The analysis is carried out using FEM software SAP 2000*V14. The structure is idealized as 3D space frame where in beam and column are modeled as 2 noded line elements with six degrees of freedom at each node and slabs are modeled as thin shell with four noded plate elements having six degrees of freedom at each node. The soil is modeled as equivalent springs with single(Winkler) and six degrees of freedom(Modified winkler) the stiffness of which varies with type of soil based on the properties, viz., dynamic shear modulus and poissons ratio of soil.The raft foundation for winkler and Modified Winkler are modeled as thin shells with four noded plate elements having 6 degrees of freedom at each node and is discritised, such that the aspect ratio of the elements are equal to one.

The response in terms of fundamental Natural Period, Seismic Base Shear and Max. Lateral Displacement, for a variety of building frames with and without consideration of soil flexibility is compared to evaluate the contribution of soil structure interaction on building frames. Influence of of parameters such as different soil types(i.e, Soft, Medium and Stiff), different span lengths, number of bays and number of stories are considered in the parametric study for Zone V.

It is found that the effect of soil flexibility on building frames appreciably alters the fundamental lateral natural period and seismic base shear of the system. Due to the effect of soil flexibility, the lateral natural period and seismic base shear increase with the decreasing stiffness of soil. It is also observed that the lateral period and base shear of the building increases with increase in number of bays. The Maximum lateral displacement increases with increase in number bays and stories.

Keywords: Soil structure interaction, Natural period, Base shear, Max. Lateral displacement, Raft footing.

1 INTRODUCTION

When any structure is subjected to seismic force during an earthquake, the waves that reach produce motions in the structure itself. These motions depend on the structure's vibrational characteristics and the building or structural layout. For the structure to react to the motion, it needs to overcome its own inertia, which results in an interaction between the structure and the soil. Such an interdependent behaviour between soil and structure regulating the overall response is referred as Interaction behaviour in the present context.

It has been a common practice to consider the analysis of structure and foundation separately. Typical load distributions within the building frames are calculated based on the assumption that the base of structure is fixed i.e., assumption made that the base of the foundations transfer the load by direct bearing on solid rocky stratum.There is no doubt that, this assumption is generally applicable if the superstructure is much

Figure 1.

Figure 2.

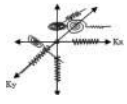

Figure 3.

more flexible/compliant than the underlying soil stratum upon which the foundations rest. However, when the reverse is true i.e., assuming that the structure is much stiffer than the soil medium, then the response of structure can be significantly influenced by the flexibility of soil.

Analyzing the structure with fixed base condition proves to be lower estimation of certain response quantities as highlighted in few earlier researches (Sekhar Chandra Dutta,et.al, Chandrashekar et.al). Soil flexibility may decrease the overall stiffness of the structural systems and hence may increase in natural period of system. So such increase in lateral natural period may considerably alters the response of building frames under the seismic forces. Hence present study has been carried out for dynamic response of building frames resting over Raft foundation incorporating soil flexibility (equivalent springs) with that of a fixed base under the influence of various parameters.

2 MODELING AND ANALYSIS METHOD

For the interaction analysis, the superstructure(3D frame), Raft foundation and soil are considered as single interactive unit and is modeled using SAP2000 V14 FEM structural analysis software package.

Superstructure of building frame is idealized as 3 dimensional space frame consisting of columns in each storey and beams and slabs at each floor level (fig. 1). Two noded line elements with six degrees of freedom at each node represent beams and columns in each storey. Flexible floor diaphragm for slab at each floor level is discretized and is modeled as thin shells with four noded plate elements having six degrees-of-freedom at each node(three translations and three rotations in their respective coordinate directions).

Raft foundation is discretized and modeled as thin shells with four noded plate elements having six degrees-of-freedom at each node.

The soil considered is sandy clay and is idealized using two types of soil models, namely, Winkler Model(WM) as per which one translational spring at each node of foundation along vertical(Z) direction is considered to simulate the effect of soil flexibility (fig.2) and Modified Winkler Model(MWM) as per which three translational and three rotational springs about three mutually perpendicular directions are considered to simulate the effect of soil flexibility (fig.3).

Any torsional effects are automatically considered in the model. The ground motions can be applied in 1, 2 or 3 directions individually or simultaneously. In the present study earthquake load is applied individually along horizontal X and Y directions.

Dynamic analyses (Response Spectrum Method) is carried out as per IS 1893-2002 (part 1) for structure modeled with fixed base(Non Interaction Analysis) and flexible base (Interaction Analysis)using SAP2000 V14.

3 SCOPE OF THE PRESENT STUDY

3.1 *Description of Building Model with Raft Foundation*

For the present study, Two bay Two bay – one, two and four storied reinforced concrete moment resisting frame buildings are chosen (without considering stiffness of infill). The storey height of base story is 4.5m (termed Ratio of Base storey to higher stories Hr=1.5 henceforth) and is kept at 3m for all the other stories in the model. In order to introduce certain amount of unsymmetry in the structures considered, the independent spans of the 2bay 2 bay structure is taken as 6m and 3m (henceforth referred as Ratio of higher to lower span Sr=2). No parapets on the roof storey but all-round brick infill masonry wall (230 mm thick) in the intermediate stories, is considered in the structure. The building is modeled as bare frame; however masses of the walls are included. To study the effect of soil flexibility, lumped mass spring model is used. The stiffness of the springs is used to represent soil flexibility.

3.2 *Input design data for building models with raft foundations*

The material properties considered are: Young's modulus of M25 concrete, E= 25×10^6 kN/m2,Density of Reinforced Concrete = 25 kN/m^3, Density of brick masonry = 20 kN/m^3, Dead load intensities like Floor finishes = 1.0 kN/m^2, Roof finishes = 2.0 kN/m^2, Live load intensities on Roof = 1.5 kN/m^2 and on Floor = 3.0 kN/m^2,Member properties taken are: Thickness of Slab=150 mm,Column size =350 mm × 500 mm, Beam size=250 mm × 600 mm, Thickness of wall=230 mm, Earthquake live load on slab as per clause 7.3.1 and 7.3.2 of IS: 1893-2002 (Part 1) is calculated as: Roof= 0.25 × 1.5 =0.375 KN/m^2,Floor=0.25 × 3.0 = 0.75 KN/m^2.

Seismic data: Seismic Zone V, Response spectra = As per 1893(part 1)2002, Importance factor =1, Response reduction factor = 5.

The foundation dimensions were designed for gravity load and all its load combinations, using STAAD ETC software package, The raft with plan dimensions 11 m × 11 m is adopted for all building models with the thickness of raft being 300 mm,400 mm and 500 mm for Single storey,two storey and four storey building frames respectively.

3.3 *Soil Parameters Considered*

The type of soil considered is sandy clay **(Bowles, 1996)** classified as soft, medium and stiff soil based on Dynamic shear modulus(G). Properties of soil types considered in this study are Stiff(Type-I with μ =0.2 and G=30000 KN/m^2); Medium(Type-II with μ =0.25 and G=20000 KN/m^2)and Soft (Type-IIIwith - μ =0.3 and G=10000 KN/m^2).

4 CALCULATION OF STIFFNESS OF ELASTIC SPRINGS FOR RAFT FOUNDATION-SOIL MODELS

The Raft foundation is discretized such that the aspect ratio of each element is equal to 1.0 and the soil system is idealized by one translational spring at each node for Winkler Model and six springs at each node(three translations and three rotations)for Modified Winkler Model. The area of element of footing influencing each node is considered for calculating stiffness of the spring at that node.

4.1 *Winkler Model*

The stiffness of the spring represented by subgrade modulus of soil (*ks′*)is calculated using Vesic's equation (1961a, 1961b), adopted from Bowles (1996).

$$ks^{I} = 0.65 * \sqrt[12]{\frac{E_s B^4}{E_f I_f}} * \frac{E_s}{1-\mu^2}, \quad kN/m^2$$

$$ks = \frac{ks^{I}}{B}, \quad kN/m^3$$

Where, ks = modulus of Unit subgrade modulus reaction, kN/m^3;E_s,E_f =Elastic Modulus of soil and footing, respect tively, kN/m^2; B=Width of each dicretized element of the Footing, (m); I_f =moment of inertia (m^4) based on cross section (not in Plan); μ = Poisson's ratio and

$$E_s = \frac{2G}{(1+\mu)}$$

Fig.4 shows the global axes direction considered in SAP2000V14.

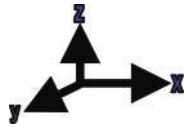

Figure 4. Global axes direction considered in SAP

Table 1. Stiffness of equivalent soil springs along various degrees of freedom (ATC40, adopted from George Gazetas, 1991)

Degrees of freedom	Stiffness of equivalent soil springs
Vertical (Kz) in kN/m	$\frac{GL}{1-\mu}\left[0.73+1.54\left(\frac{B}{L}\right)^{0.75}\right]$
Horizontal (Ky) (Lateral direction) in kN/m	$\frac{GL}{2-\mu}\left[2+2.5\left(B/L\right)^{0.85}\right]$
Horizontal (Kx) (Longitudinal direction) in kN/m	$\frac{GL}{2-\mu}\left[2+2.5\left(B/L\right)^{0.85}\right]-\frac{GL}{0.75-\mu}\left[0.1\left(1-\frac{B}{L}\right)\right]$
Rocking(Krx) (About the longitudinal,x-axis) in kN-m	$\frac{G}{1-\mu}I_x^{0.75}\left(L/B\right)^{0.25}\left[2.4+0.5\left(B/L\right)\right]$
Rocking(Kry) (About the lateral,y- axis) in kN-m	$\frac{G}{1-\mu}I_y^{0.75}\left[3\left(L/B\right)^{0.15}\right]$
Torsion (Krz) in kN-m	$3.5GI_{bz}^{0.75}\left(B/L\right)^{0.4}\left(I_{bz}/B^4\right)^{0.2}$

μ - Poisson's ratio
B, L – width and length of a rectangular foundation respectively, in m.
I_x, I_y, and I_{bz}, Moment of inertia, in m^4 of the foundation area with respect to longitudinal, lateral and vertical axes respectively.
G = Dynamic shear modulus in kN/m^2 , which depends on type of soil.

4.2 *Modified Winkler Model.*

The stiffness of springs in each translational and rotational directions are calculated as suggested by Gazetas(1991) and recommended by ATC-40 and tabulated in Table 1.

Fig. 5 and Fig. 6 show the finite element idealization of the building frame - raft foundation -soil interactive system for WM and MWM respectively.

5 RESULTS AND DISCUSSION

Here, only Fundamental natural period, Base shear and Maximum lateral displacements obtained from

Interaction Analysis(IA) are compared with Non Interaction Analysis (NIA).

5.1 *Lateral Natural Period*

Variation of Fundamental natural period, Tn with shear modulus of three types of soil for Zone V are plotted for the two types of soil models and frame type of 2bay 2bay 1storey,2 storey and 4 storeies with Sr=2 and Hr=1.5 in Figure 7 and shown in Table 1.

For any frame type and soil model considered, there is similar variation in Tn with shear modulus of soil, i.e. it slightly decreases with increase in shear modulus.

In comparison to NIA, Tn substantially increases in the interaction analysis as the structure foundation soil system is rendered flexible. The degree of variation depends on type of soil model and soil type.

Story- wise variation of natural period is as shown in Table 1, and Fig. 10. It is evident that the natural period is relatively higher as number of stories is increased. Tn of all the models are greater than the values of NIA in all types of soils. Between the soil models, WM is observed to predict maximum variation with respect to NIA.

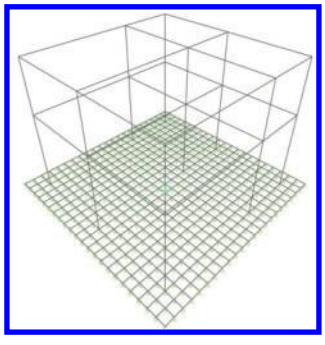

Figure 5. Finite Element idealizations of the building foundation soil interactive system for Winkler model.

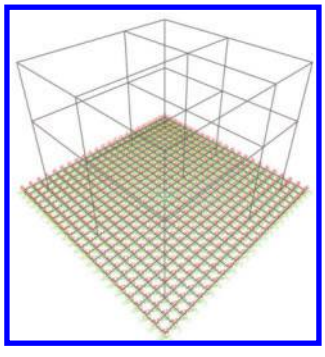

Figure 6. Finite Element idealizations of the building foundation soil interactive system for Modified Winkler Model.

5.2 *Change in Base Shear*

Table 2, Fig.8 and Fig.11 show the resulting base shear(V_B) for different number of stories of the frame and types of soil. It is seen that increase in number of stories increases the base shear. Also observed is the decrease in base shear values from soil type soft to stiff which is more effective for 4 storey than one and two storied structures.

Comparing V_B values of both soil models and also NIA, MWM shows higher values of V_B followed by WM upto 2 storey, where as for 4 storey frame NIA shows higher values of V_B followed by MWM and WM.

5.3 *Maximum Lateral Displacement*

The lateral displacement(Δ) values in the table 3 are those which are obtained as maximum values out of different modes of deformation. As Moment of Inertia along X-direction is high, displacements along Y-direction are relatively higher.

In comparison to Non interaction analysis Fig.9 and Fig.12, Δ substantially increases in the interaction

analysis as the structure foundation-soil-system is more flexible than that with fixed ends.

Trend of variation of Maximum lateral displacement with type of soil is almost same for all soil models i.e. it decreases with increase in stiffness of soil. Δ values for NIA are relatively higher than other two models followed by WM and MWM for 2 and 4storey frames where as WM shows higher values in 1 storey frames followed by WM and MWM.

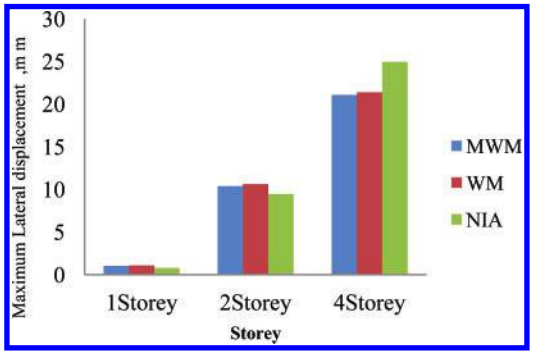

Figure 12. Variation of Max. Lateral Displacement with Storey variation for Medium soil (Type II Soil)

6 CONCLUSIONS

The present study makes an effort to evaluate the effect of soil flexibility on dynamic characteristics of building frames resting on Raft foundation, namely the Lateral natural period , Seismic base shear and Maximum lateral displacement.The study leads to the following conclusions.

The behavior of the structure is rendered flexible due to IA , as a result of which substantial increase in Tn and Δ and moderate increase in V_B, occur. For the sandy clay soil considered, the fundamental natural period of 3D-frames is maximum for type III(soft soil) and decreases as the shear modulus of soil increases. Effect of increase in number of storeys from 1 to 2 and 2 to 4 results in substantial increase in Tn in both IA and NIA.

Base shear values due to Interaction analysis are found to be higher than that of Non-Interaction analysis which is more predominant in longitudinal direction of the 3D frame. As number of storeys increases from 1 to 2 and 2 to 4 base shear increases.

The top storey sway(Δ) values along any of the horizontal directions decreases as the shear modulus of soil increases. For the frame 2bayx2bay-4 storey, as soil changes from soft to hard Δ reduces by 70.62%(MWM) and 72.73%(WM). As number of storeys increases from 1 to 2 and 2 to 4, Δ increases by about 10 & 2.03 times in MWM, 9.78&2.012 times in WM and 11.88 & 2.64 times in NIA.

Using the shear strength reduction method to assess the stability of retaining structures adjacent to excavations for the University of Cape Town's New Engineering Building

C.J. Warren-Codrington & D. Kalumba
University of Cape Town, Cape Town, South Africa

ABSTRACT: The construction of the New Engineering Building (NEB) on the University of Cape Town's (UCT) Upper Campus raised concerns about the stability of the adjacent Ring Road. This busy internal road ran along the western boundary of the site, and was supported by a tapered retaining wall which was 6.3 m at its highest point. Hence, a slope stability analysis was conducted on the critical section of the wall using conventional limit equilibrium (LE) techniques as well as the shear strength reduction (SSR) finite element (FE) method. The results of these analyses were compared and deemed the retaining wall to be safe against a global failure. The benefit of combining the LE and SSR FE methods was highlighted by the correlation between the LE failure surfaces and the development of shear strain behind the wall. Furthermore, the SSR FE analysis yielded a distinct band of shear strain behind the wall which further exemplified the usefulness of the SSR FE technique in modelling the deformation behaviour of the system.

1 INTRODUCTION

1.1 *Background*

Geotechnical engineers are often faced with the problem of assessing the stability of structures adjacent to open excavations. The Finite Element Method, since its first application to geotechnical engineering in 1966, has become very popular in assisting in this regard (Hammah *et al.*, 2005). This is based on the method's ability to predict stresses and deformations, which fall outside of the capabilities of conventional limit equilibrium (LE) techniques.

The University of Cape Town (UCT) in 2010 was faced with the problem of evaluating the response of structures to basement excavations for the New Engineering Building (NEB). The NEB formed part of UCTs three year capital expenditure programme, and required the multi-staged demolition of the former structure in conjunction with the initiation of the construction.

It was established that the proposed basement excavations may undermine the structural integrity of a retaining wall that extended along the western boundary of the site and supported Ring Road – an internal road which serviced vital amenities of UCT. The retaining wall supported 6.3 m of backfill at its highest point. A failure of this system would have had detrimental consequences for Ring Road and possibly the Chemical Engineering Building, which joined the existing wall at its highest point.

Hence, an additional lateral support system was designed and constructed by Esorfranki prior to excavations taking place. This was to provide the required stability to the slope once excavations commenced as well as transfer column loads of the NEB to underlying strata.

These slope stability concerns led to an independent investigation, undertaken by the University of Cape Town's Geotechnical Research Group and centred on good excavation practice, to assess the performance of the Ring Road lateral support system in stabilising the western boundary. This was carried out in light of extensive research into excavation failures, especially by Sowers & Sowers (2004), Chen, Hiew, & Sofianaa, (2000) and Gue & Tan, (2002), which found that inadequacy in design was the main contributing factor to many excavation failures around the world.

1.2 *Aims and objectives*

This study aimed to assess the stability of the western boundary of the NEB site by performing a slope stability analysis. This was done by employing (1) conventional limit equilibrium (LE) techniques, and (2) the Shear Strength Reduction Method (SSRM). In doing so, the study aimed to explore the advantages of combining LE techniques and the SSRM for future slope stability and support structure analyses.

1.3 *Modelling methodology*

Once the site was characterised a cross-section through the site at the highest point of the respective retaining wall was formed. This formed the basis upon which the following modelling was carried out.

The LE techniques adopted included the Fellenius Simplified, Bishop Simplified, Janbu Corrected, Janbu

and Spencer methods. A wide array of LE methods was selected to account for the respective errors accompanying each method as a result of the respective assumptions required to perform each LE analysis. A full description of these methods can be found in texts such as (Gedeon 2003). The LE slope stability analysis was carried out in *Slide*. *Slide* was a comprehensive slope stability package, capable of FE groundwater seepage modelling, rapid drawdown, sensitivity and probabilistic analyses and support design. The average of the results of the LE analysis was calculated and then compared to the output of the SSRM investigation, which was done using *Phase*^{2}. *Phase*^{2} is a powerful two dimensional elasto-plastic FE stress analysis program for underground or surface excavations in rock or soil. Both software packages were developed by *Rocscience*.

The SSRM analysis involved the systematic use of the Finite Element method (FEM) to determine a Shear Strength Reduction Factor (SSRF), or factor of safety which brings the slope to the verge of failure (Hammah *et al.*, 2005). This was done by reducing the strength of respective materials of the slope by the SSRF until the FE analysis did not converge. For a Mohr Coulomb failure criterion, the SSR factor, SSRF, was used as follows to give the reduced material strength parameters, c'^* and φ'^*:

$$\frac{\tau}{SSRF} = \frac{c'}{SSRF} + \frac{\sigma_n tan\phi'}{SSRF} \quad (1)$$

where,

$$\frac{\tau}{SSRF} = c'^* + \sigma_n \tan(\phi'^*) \quad (2)$$

and,

$$c'^* = \frac{c'}{SSRF};\ \phi'^* = \arctan\left(\frac{tan\phi'}{SSRF}\right) \quad (3)$$

2 SITE CHARACTERISATION

2.1 *Material parameters*

The geotechnical report, compiled by Kantey & Templer Consulting Engineers, found the site to be underlain by three distinct material profiles: (1) transported material, (2) reworked residual Malmesbury Group material and (3) intact residual Malmesbury Group material. The bulk unit weights (γ) of the respective materials were determined by a set of laboratory results and are given in table 1, along with the soil strength and stiffness parameters.

This confirmed published geological data that depicted the area to consist of varying thicknesses of transported material emanating from the slope to the west, followed by residual Malmsbury Group shales of the Tygerburg Formation (Brink 1985).

For the colluvial material The Mohr-Coulomb shear strength parameters, cohesion (c′) and internal angle of friction (φ'), were approximated from a back analysis conducted on an exposed cutting on the site. The Mohr

Table 1. Material parameters.

Parameter	Soil Layer (1)	(2)	(3)
γ (kN/m^3)	18	18	18.5
φ' (°)	36	28	28
c′ (kPa)	2	15	25
E (kPa)	25000	20000	20000
υ	0.35	0.3	0.3

Coulomb shear strength parameters for the reworked and intact weathered Malmesbury Group material were determined from relevant literature and case studies, with considerable reference to Brink, (1985) and (Du Plessis and Parrock 2010). The elastic material parameters, Young's Modulus (E) and Poisson's Ratio (υ) were derived from relevant literature, with special reference to Sabatini *et al.*, (2002). The grwound water table profile was determined from a series of boreholes drilled on the site perimeter during the geotechnical investigation. These results were linearly extrapolated across the site.

2.2 *Lateral support*

An anchored soldier pile wall was deemed the most appropriate retaining system for the NEB site, by the design consultants, the construction of which was to last 3 months and began in June 2011. This tied back pile wall included the following components: (1) 750 mm diameter, 17.0–20.0 m long cased auger piles; (2) 300 mm diameter, 7.75 m rotary percussion piles; (3) 1 m wide, 1.2 m deep capping beam; (4) 16.5 m Titan 52/26 permanent ground anchors; (5) steel mesh and gunite arch system.

The piles were arranged with sets of three 300 mm diameter piles in between pairs of 750 mm diameter piles. The 750 mm diameter piles were used to support 5 MN column working loads. The 750 mm diameter piles provided considerable stiffness to the lateral support system.

Once the installation of the piles was complete the capping beam was constructed to provide extra rigidity to the soldier pile wall, and it provided a base upon which ground anchors could be stressed (Figure 1). The primary purpose of the ground anchors was to minimise the deflections of the pile wall and hence to minimise the development of eccentric loads forming at the interface between the capping beam and the columns. The ground anchors also served to reduce the bending stresses in in the soldier piles. Steel mesh gunite arches were adopted to retain the soil between the piles. Wick drains were installed behind these arches to carry seepage to a drain at the basement floor slab level. The arrangement of the support system is illustrated by figure 1 and an overview of the site with the completed bulk excavations and additional lateral support system installed is given by figure 2. Critically, the placement of a crane behind the lateral support structure can be viewed in figure 2. The

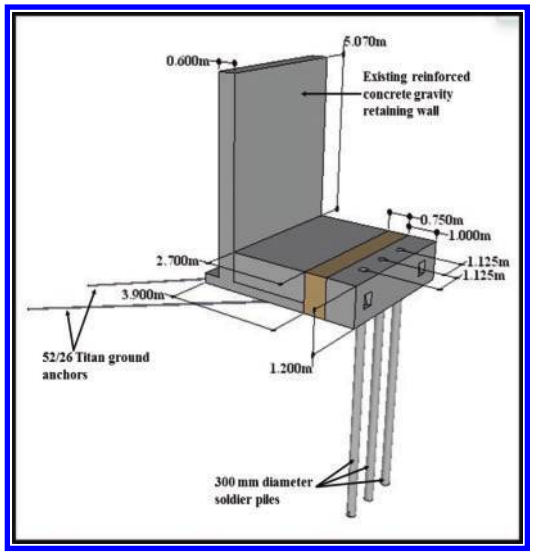

Figure 1. View of the Anchored Soldier Pile Wall.

Figure 2. Completed bulk excavations with pile wall and crane loading visible.

additional loads emanating from this temporary structure were modelled to determine the respective effects on the lateral support.

3 RESULTS

Table 2 gives the slope stability results from the different methods of analysis conducted on the Ring

‡ Circular Shear Failure Analysis
† Non-circular Shear Failure Analysis

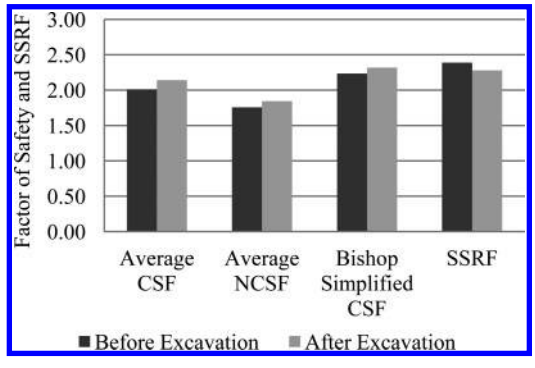

Figure 3. Slope stability analysis results.

Road lateral support. These results are summarised and shown graphically in Figure 3. It is evident from these results that the system was adequately safe both before and after excavation. This conclusion is based on factor of safety and SSRF values greater than 1.50. Furthermore, as anticipated, the stability of the system generally improved with the construction of the anchored pile wall. The SSRF was the only stability proxy to decrease after the excavation process.

On a qualitative level, the importance of the pile wall was illustrated by this analysis. The circular shear failure results (Figure 4) indicate that an overall failure of the system was the most critical mode, whereas, the analyses conducted using non-circular shear surfaces show that the most likely mode of failure was by failure of the ground anchors (Figure 5). An important observation of this was the shear surfaces extending below the pile wall despite breaching the ground anchor. This emphasised the importance of the pile wall in maintaining the stability of the slope.

The FEM SSRM results were compared to the LE analysis by superimposing the circular and non-circular failure surfaces yielded by the LE analysis onto the FEM SSRM results, illustrated by figures 6 and 7. A red and orange dashed line represented the circular and non-circular slip surfaces, respectively.

Figure 7 shows the development of two distinct zones of shear strain behind the tied back wall following excavations. The most prominent shear strain

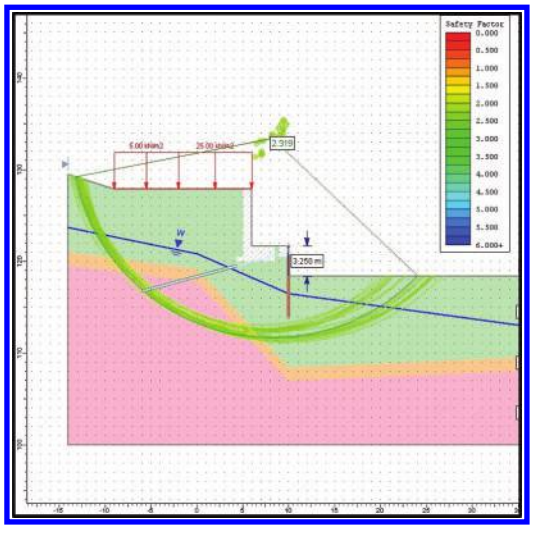

Figure 4. CSFS Slope Stability Results.

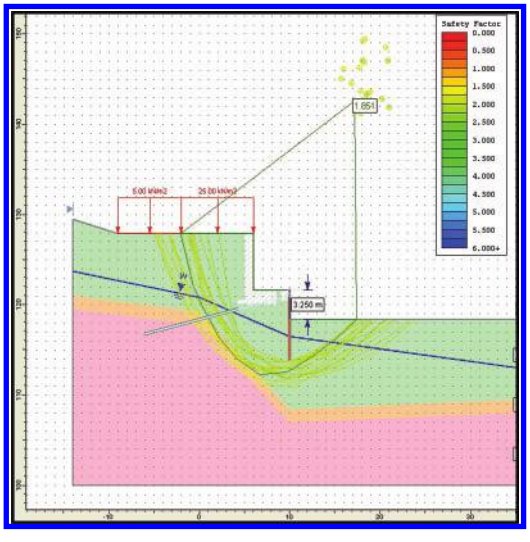

Figure 5. NCSFS Slope stability results.

zone correlated closely to the non-circular slip surface yielded by the LE analysis. The circular shear surface also followed a band of shear strain recognised by the FEM SSRM analysis, but this was less noticeable. Furthermore, Figure 6 depicts the effect of the pile with significant shear strain in front of the pile wall, but a reduced area of shear strain behind the toe of the wall. This demonstrates the mobilisation of the shear stress by the pile wall and how this stress is transferred to the soil in front of the wall.

Superimposing the LE analysis result onto the FE SSR results illustrated the effectiveness of the FE SSRM. Not only does the FE SSRM allow an assessment of the stresses and deformations of the lateral support system, but in doing so provides insight into the material behaviour under different loading

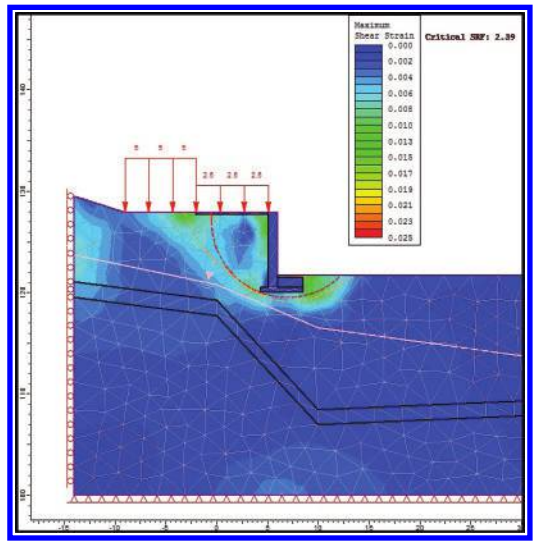

Figure 6. FEM SSR Slope Stability Results – After Demolition, but Before Excavation.

conditions and geometry. With reference to Figure 2, the LE result showed an improved factor of safety with the construction of the pile wall, but the FEM SSR results did not. The difference between the two cases is likely to be due to the increased surcharge loading behind the wall as a result of a construction crane. This was important as it illustrated the system's stability as a function of its geometry, strength parameters and loading, in terms of the material's response to stress. The FEM SSR technique essentially modelled the progressive response of the lateral support to the excavation and modified loading. This is opposed the the LE techniques assessing the likelihood of the entire system failing. In doing so, the FE SSRM highlighted key weaknesses in the material which arose from the system's geometry and loading. Such an analysis is not possible to model using LE techniques, as inter-particle material interactions are not assessed (Hammah *et al.* 2005). Furthermore, LE methods are unable to model the interaction between structural elements, such as the anchored soldier pile wall and the supported soil. FEM techniques, such as the SSRM are capable of doing this, and are able to accurately predict the soil-structure-interaction between the retained material and anchor forces, deformation, shear, sbending and axial stresses.

4 CONCLUSION

The analyses conduced on the western boundary of the NEB bulk excavations found the Ring Road lateral support system to be stable. This conclusion was derived from slope stability analyses, using numerical methods, conducted on the Ring Road lateral support system. The Ring Road lateral support system formed the western boundary to the NEB site.

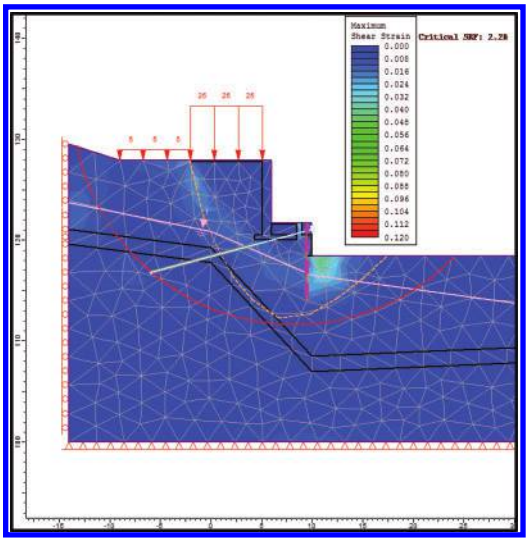

Figure 7. FEM SSR Slope Stability Results – After Excavation.

The slope stability analysis conducted on the Ring Road lateral support system showed that the system was stable based on the factor of safety and SSRF values produced from the LE and FEM SSR analyses, respectively. The section of the Ring Road lateral support that was modelled yielded factor of safety and SSRF values greater than 1.50. Although the SSRF values were found to be adequately high to assure the safety of the system, the development of a zone of increased shear strain was found in the FEM SSR analyses conducted on the Ring Road lateral support system. It is likely that this shear zone was influenced by the surcharge loading behind the wall.

This highlighted the usefulness of combining LE methods with the FEM SSR method in assessing slope stability. Furthermore, this investigation emphasized the effectiveness of using FE methods in the design of lateral support systems. This was based on FE methods being able to model the response of the materials to stress as well as the interaction between the retained soil and the support system.

Efforts to reduce the drop-out rate in civil and structural engineering programs

U. Quapp & K. Holschemacher
Faculty of Civil Engineering and Architecture, Leipzig University of Applied Sciences, Germany

ABSTRACT: Usually, drop-out rates in engineering courses of studies are higher than in other programs. There are various reasons for this. Because of the already existing lack of well educated civil and structural engineers worldwide, universities and industry are interested in finding out the reasons and developing ideas to reduce the civil and structural engineering students' drop-out. And also a lot of money is at stake. Each student not completing the program costs the taxpayers a lot of money without providing any benefit to society in future. This paper investigates reasons for the high drop-out rate in civil and structural engineering study courses and offers solutions for the problem.

1 INTRODUCTION

Usually, drop-out rates in civil and structural engineering courses of studies are higher than in other programs (Heublein *et al.* 2010). At German universities normally about 50 percent of students withdraw from their civil and structural engineering degree courses (Heublein *et al.* 2010). Currently, there already exists a lack of well educated civil engineers worldwide. In Germany alone, the engineers' unemployment rate is now around 2.4 percent, which means nearly full employment (The Association of German Engineers 2011). Additionally, in the next years more civil and structural engineers will retire than universities are able to graduate. Therefore, universities and industry are interested in finding out the reasons and developing ideas to reduce the civil and structural engineering students' drop-out (The Association of German Engineers 2011).

And also a lot of money is at stake. In Germany, higher education financing is mainly matter of the state. In some Federal States of Germany, the *Länder*, studying to the first cycle degree is for free. In other Federal States students have to pay only up to 1.000 Euros (1.300 US-Dollars) per year. But, every year of civil or structural engineering studying cost the German taxpayer approximately 8.000 Euros (11.000 US-Dollars) per each student (German Federal Statistical Office 2012). Of course, there is an interest that students do not leave the universities without a degree. Further, because of the existing lack of engineers, the ensued financial damage for German economy is around 3 billion Euros (4 billion US-Dollars) which will increase with extension of the lack (The Association of German Engineers 2011).

Not every student leaving university without a degree is unsuitable to become a civil or structural engineer. For some students the conditions are not ideal to complete their studies. That's why universities must work out the reasons for drop-out and try to optimize the study conditions to reduce the number of students not graduating in civil and structural engineering programs without losing education quality.

2 CURRENT STUDY SITUATION IN GERMANY

2.1 *Bologna Process*

As a consequence of the Bologna Process bachelor and master programs were implemented all over Europe during the last years. In Germany the former first cycle degrees leading to the degree *Diplom-Ingenieur* with duration of 4 or 5 years had to be replaced by bachelor programs with duration of 3 or 4 years and master programs of 1 or 2 years (Standing Conference of the Ministers of Education and Cultural Affairs of the *Länder* in the Federal Republic of Germany 2010). Most of the German universities decided for 3 years' bachelor with 2 years' master programs or 3.5 years' bachelor with 1.5 years' master programs. It is worth pointing out that the bachelor degree is the first cycle degree what means that the degree has to qualify the graduates to work professionally. That's why many universities tried to bring all comprehensive contents from the former national programs in the curricula of the new bachelor courses of studies to allow the students to work professionally after graduating (Quapp & Holschemacher 2010).

2.2 *University Admission Law*

German educational policy regarding schools and universities is matter of the German Federal States, the *Länder*. The disadvantage of a federal system is the difference between educational requirements and

school curricula of the various Federal States. Additionally, one out of every seven first year students is a non-national who acquired his or her higher education entrance qualification outside Germany (Federal Ministry of Education and Research Germany 2012). These differences in educational background result in various pupils' knowledge and skills after earning a higher education entrance qualification.

German University Admission Law can be recognized as difficult. Especially for admission to universities of applied sciences, which are higher education institutions with the same rights and tasks just like regular universities, there are several entrance qualifications. These regulations result in a high heterogeneity of first year students regarding knowledge and skills as well.

Currently, by change in the German University Law, additionally to candidates with school diploma corresponding to university entrance level, people without any higher education entrance qualification can be enrolled in study courses under special conditions. These candidates must hold a master craftsman's certificate and must apply for a field of study which relates to his or her profession. Reason for this change in university admission regulations is the worry about the looming shortage of engineers. In consequence, by reducing the admission requirements, it is intended to motivate more people to study engineering sciences to counter the lack of engineers in the long-term and to promote the idea of lifelong learning. In 2012, 12.000 students without higher education entrance qualification were enrolled in study courses at universities and universities of applied sciences in Germany (German Centre for Higher Education 2012).

Some of the students beginning a civil engineering course of studies completed a professional training in the building industry additionally to the higher education entrance qualification. At Faculty of Civil Engineering and Architecture at Leipzig University of Applied Sciences around 20 percent of students with these qualifications are enrolled in the first year. These students combine the knowledge in sciences and technology with experiences from the construction site. For this reason they have fewer problems in the civil engineering bachelor program than students without experience in the building industry.

2.3 *Finance of studies*

Furthermore, a students' survey by the German Federal Ministry of Education shows that 75 percent of the German students must work beside their studies (German Federal Ministry of Education 2010). German engineering students work by an average of 13 hours per week, students of economics or social sciences even more (German Federal Ministry of Education 2010). Students from financially disadvantaged families or which are in need of social support can apply for student loans granted under Germany's Federal Education Assistance Act (Germany's Federal Education Assistance Act – BaföG 2010). Depending from the financial situation of the student he or she have the possibility to receive between 400 and 600 Euros (530 to 800 US-Dollars) monthly. But students associations always complain that this amount of money is not enough for the costs of living. That's why many students are obliged to work while studying.

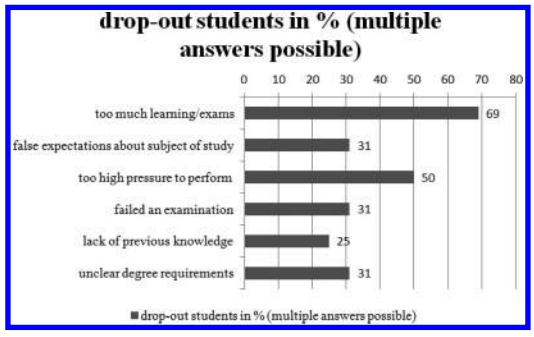

Figure 1. Reasons for drop-out at Faculty of Civil Engineering and Architecture (survey at Leipzig University of Applied Sciences 2010).

3 REASONS FOR DROP-OUT

3.1 *High workload*

One of the reasons for the large number of students not finishing their civil and structural engineering studies in Germany may be the high workload which is often higher than in other programs (Fig. 1). An explanation for the high workload can be the changes caused by the Bologna Process. So many universities overburden programs to optimize the graduates' opportunities for getting a good and well paid job. Anyway, the drop-out rates in the new bachelor programs in civil and structural engineering are higher than in former first cycle degree programs (Heublein *et al.* 2010).

Another difficulty is that at many German universities basic first year classes such as engineering mathematics, physics and chemistry are given by non-engineering lecturers. That is a problem for students because the lecturers' interests and requirements often do not meet the demands of a civil engineering education. So, students complain about theoretical course contents without any practical relevance in civil and structural engineering and high requirements, which are the same for students in sciences and engineering programs.

3.2 *New university admission regulations*

In Germany, there is a high heterogeneity among first year students. The fact that candidates without school diploma corresponding to university entrance level can be enrolled in study courses under special conditions does not make the universities' first year situation easier. This development leads to problems in the study entrance phase because of freshmen's heterogeneity regarding prior knowledge and skills, especially on the field of science and technology. The study programs in civil and structural engineering

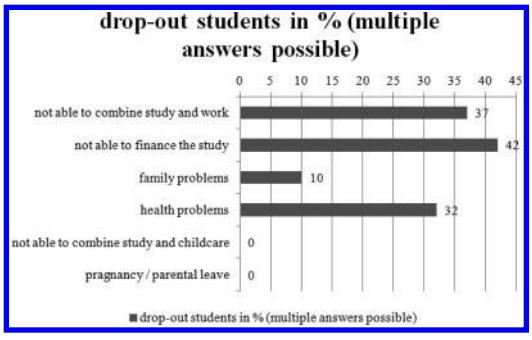

Figure 2. Reasons for drop-out at Faculty of Civil Engineering and Architecture (survey at Leipzig University of Applied Sciences 2010).

fields often require detailed knowledge in mathematics, physics and chemistry which the first year students without school diploma corresponding to university entrance level often do not possess. This causes a feeling of being overburdened among these students and results in a high drop-out rate.

It is understandable that civil and structural engineering fields of study seem very difficult and demanding to many students, containing courses like mathematics, physics, statics and technical mechanics. So, students argue, earning a university degree in social sciences and humanities would be more comfortable and easy than working so hard in engineering programs. Some students begin a civil or structural engineering study without any information about the course contents. While studying, they are surprised about the percentage of science in curriculum. Some students have no interest in science and technology and choose the civil or structural engineering field of study for some other reasons. But it is nearly impossible to complete the difficult and demanding studies if there is no passion for the science and technology which brings the students through some hard times in students' life.

3.3 *Working beside studying*

As mentioned before many students work while studying. One of the reasons why some students must leave university without a degree is that they are not able to combine study and work. Some Students give up their courses voluntarily, for others the lack of time for preparing test and examinations lead to failing definitively and getting expelled by the university administration. Determined through a detailed questionnaire, 37 percent of students leaving Leipzig University of Applied Sciences without a degree gave as the reason not to be able to combine study and work. Over 40 percent could not finance their study (Fig. 2).

4 SOLUTIONS

4.1 *StudiFIT program*

Since 2011 Leipzig University of Applied Sciences offers a program to the first year students specially developed to reduce their orientation problems in the first weeks at university. Another aim of the program is the more successful management of freshmen's heterogeneity regarding prior knowledge and skills, especially on the field of science and technology.

The Program is financed by the German Federal Government until 2016 with more than 3.7 million Euros (4.8 million US-Dollars). With the money coming from the program 12 new jobs are financed. So, 1 Program Leader, 3 Assistants, 1 e-learning consultant and 6 department consultants are responsible for the success of the program. In the first year of the program the StudiFIT team evaluated the reasons for drop-out in the first weeks of the study time. On the basis of the results a package of measures has been developed which contains e.g. extra coaching in courses like mathematics, physics and chemistry given by master students or young civil or structural engineers. Additionally, the program tries to improve the social cohesion between the students by organizing excursions, challenges and parties. The first week at university the freshmen spent together with presentations, parties, challenges and little tests in sciences. The aim is to stimulate the social responsibility under students and to create an atmosphere in which students help each other and look at each other to motivate fellow students not to give up in the early phase of study.

Furthermore the e-learning offers will be improved by the program. Learning management systems can be a valuable support for students who can't attend the classes for various reasons such like illness, work and so on. Online consultation offers, communication platforms or online access to teaching materials may help to manage students' life and reduce the drop-out rate.

A prolongation of the program after 2016 is possible if the efforts had a measurable success.

4.2 *Information*

Detailed information about contents of lessons in civil and structural engineering before starting a study in this field is extremely important in order to avoid surprises in the first year of study. Also information about help and support in sciences and basic subjects can positively influence the decision about starting a civil or structural engineering study and reduce the drop-out rate. Also comprehensive information about the different branches of work, work tasks and the daily routine of a civil or structural engineer may be helpful to introduce the applicants to the civil and structural engineering programs.

4.3 *Entrance examination*

Additionally to the StudiFIT program the selection of candidates suited for a civil or structural engineering program should be improved. Not every person with a good higher education entrance qualification will become a good civil or structural engineering student. Comparable with artistic entrance exams in

architecture there could be an entrance test for civil or structural engineering candidates. Of course, if selecting the candidates the number of freshmen will not be as high as without an entrance test. But it is much wiser to enroll fewer, but good students and reduce the drop-out rate by that measure.

4.4 *Pre-study internship*

As explained before, students with experience in building industry know what they have to expect from a civil or structural engineering program. That's why the Leipzig University of Applied Sciences requires from every undergraduate civil engineering student to prove an 8 weeks pre-study internship before enrollment.

4.5 *Competence center for engineering mathematics, physics and chemistry*

The students' problems with first year courses such as engineering mathematics, physics and chemistry are one more reason for high drop-out rates. Classes given by non-engineering lecturers have been identified as not ideal for students' understanding of the subjects. So, Leipzig University of Applied Sciences decided to establish a competence center for engineering mathematics, physics and chemistry. Lecturers which are engineers themselves should teach subject-related knowledge in sciences to enable students to apply this knowledge in solving subject-specific problems. If the center will be successful to reduce the drop-out rates we will see in the next years.

4.6 *Increase student loans*

As students' associations always complain student loans should be increased. So, students from financially disadvantaged families or who are in need of social support can concentrate on studying and are not or only some hours obliged to work while studying.

5 CONCLUSION

Not everyone who is starting in civil or structural engineering program is good enough to graduate as a civil or structural engineer. Some of them only realize this fact while studying. This means that drop-out can't be eliminated totally. But, in the interests of students who are able to finish their civil or structural engineering studies, it can be reduced.

To reduce the drop-out rate different potential solutions can be found. One of them is the improvement of the students' introductory phase (first year of study) and the offer of natural science classes given by civil and structural engineers. Also the increase of student loans would be helpful to provide students more time for learning and support them to finish their studies.

Of course, it is extremely important to guarantee the quality of the engineering graduates leaving higher education institutions by sorting out these students who are not talented enough to become a civil or structural engineer. For the future and good reputation of Germany as a country of engineering sciences, a few good engineers are better than a lot of bad ones. But regarding the already existing lack of civil and structural engineers, universities should do their best to bring every hard working and talented students to a degree.

The future will show if the efforts and the money invested in the future of the civil and structural engineering education will quickly bear fruit.

Teaching and learning of fundamentals of structural engineering in undergraduate level

M.R. Karim
Faculty of Engineering and Information Technology, University of Technology, Sydney

ABSTRACT: This paper describes some common problems that students face in grasping the concepts in fundamental engineering subjects such as Engineering Mechanics (Statics and Dynamics), Mechanics of Solids and Structural Analysis. These subjects are taught in the initial years of a student's life. New students might be able to receive information about fundamental principles and concepts, but if they are not exposed to real-world situations it can be hard for them to see their relevance. Thus these subjects can be dry and boring to students or they can be interesting and enjoyable to learn, depending on the teaching methods and strategies used by the lecturer. The author describes in this paper some simple methods and strategies that he has adopted which increase student understanding greatly, thus making learning more effective and enjoyable.

1 INTRODUCTION

In all branches of engineering, there are core subjects, which focus on fundamental principles, concepts and ideas. These are taught in the initial years of students' academic life. Conceptual and practical understanding of each topic in the subjects such as Engineering Mechanics, Mechanics of Solids and Structural Analysis are of utmost importance to almost all engineering disciplines (civil, mechanical, aeronautical, marine, mining engineering and etc.). Application subjects such as Structural Design and Structural Construction require a sound knowledge and skill of a student in the fundamentals of structural engineering. It can thus rightly be said that these fundamental subjects are the building blocks of structural engineering knowledge. A student with poor foundations in these subjects will not only face appreciable difficulty in the subsequent years of his/her studies, but also later in his/her professional life. As such the standard of assessment in these subjects should be high and the academics, who are in-charge of teaching these subjects ought not to contemplate lowering the standard.

The failure rates in Engineering Mechanics, Mechanics of Solids and Structural Analysis in all faculties in Australia and overseas is considerably high. In some faculties failure rates were found to be as high as 35%. Considerable research has been done on why failure rate is so high and how to improve learning in these subjects and many papers were published and presented in engineering education conferences. Goldfinch, Carew and & McCarthy (2008) and Dwight & Carew (2006) did extensive research and presented a very informative table where they summarized the causes of failures and the degree of success of various strategies and methods adopted by many academicians. They could not conclude with any concrete measure how to deal with the problems of students' poor performance in these subjects.

2 PROBLEMS IN LEARNING FUNDAMENTAL PRINCIPLE AND CONCEPTS

In the author's experience, a student has real problems in understanding some fundamental concepts and principles which are abstract in nature. These problems arise from the way in which information is commonly presented in lectures and engineering textbooks. The author describes a few causes that generally create barrier to learning and the measures that he took to improve students' understanding and learning.

2.1 *The Idealized Diagrams*

Subjects like Engineering Mechanics, Mechanics of Solids and Structural Analysis contain numerous abstract concepts, principles and ideas which students need to use to solve problems related to real-world structures. The theory for the subjects can be found in a large number of text books, but it is difficult for students who are generally beginners in gathering knowledge in engineering to connect the idealized diagrams and examples given in the text books to more complex situations found in real-world. To an experienced lecturer and to an experienced professional engineer connecting the real-world structure or structural member with its idealized model may appear very simple. But it can be a barrier to learning to an inexperienced student. If during a lecture a student cannot make the connection, he/she may see little relevance in the model and may lose the motivation to learn deeply and rote learning does occur.

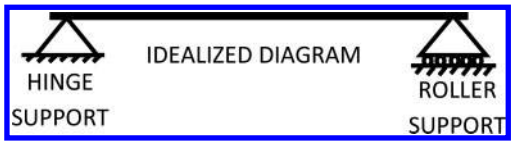

Figure 1. Simply supported beam.

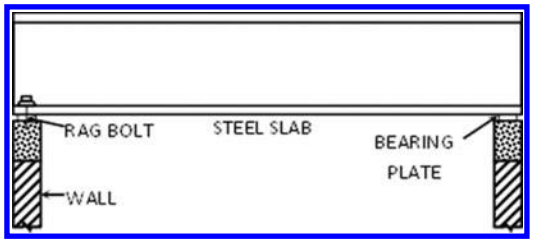

Figure 2. Structural steel beam.

Let us take an example of an idealized diagram of a simply supported beam (Figure 1). Support A is a hinge, support B is a roller. An inquisitive mind of a student would ask where in practice am I going to see such a peculiar supports (a triangle with hatched line, a triangle with circles with hatched line). If the student is not shown the steps before actually arriving at this line with peculiar triangles at the ends, he/she may have difficulty in connecting the idealized models with the real structural member (Figure 2). Such a student may simply rote learn the model, without real understanding. Making the steps explicit is very often ignored by lecturers, because it is not done in conventional engineering mechanics books.

2.2 *The use of assumptions*

Many engineering problems are solved using assumptions which are valid within certain limits. In author's experience he noticed that almost all students had difficulty in understanding what these assumptions mean. They appear to have misconceptions that they can make any assumption rather than use assumptions within defined limits. Let us take a case of one of the valid assumptions that we make in determining the bending stresses in a beam: A plane section remains plane before and after bending. No matter how much the lecturer may talk about this, students find it difficult to grasp this phenomenon. This is a relatively easy concept to demonstrate using three dimensional model beam made of sponge with vertical and horizontal lines drawn on it (Figure 3). Lecturer can explain by showing this to students and students can see that vertical lines remain straight and they do not warp which proves that the assumption is valid.

2.3 *Various names and nomenclatures used in the subjects*

In structural engineering we use many technical names and terms and many students find it difficult to visualise what exactly the members look like. As for example a beam has many names such as girder, joist, rafter, purlin and so on. The non-English speaking students face serious problem to connect the name of the structural members with the concept and principle of the topic. The author prepared a list of such commonly used names of the structural parts with sketches and hand these on to the students. Students are encouraged to buy a dictionary of engineering terms.

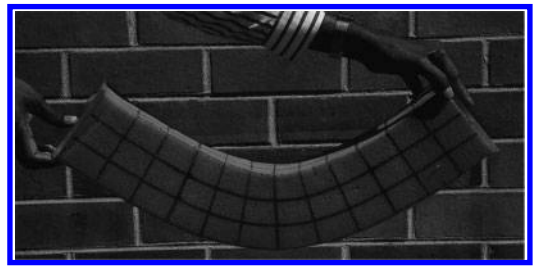

Figure 3. A plane section remains plane before and after bending.

2.4 *Clear understanding of units and to connect with real world situation*

The SI units are scientifically correct but it is difficult to visualize the effect in the context of real structure. As for example, what mental picture a student would form if we tell a student that the crushing strength of engineering brick and concrete is 20 MPa (N/mm^2) and 50 MPa (N/mm^2) respectively. The student would think that the particular concrete block is two and half times stronger than the brick. But question is how strong the brick is. The author poses a question to students to calculate: if the density of bricks is 20 kN/m^3 and if the crushing strength is 20 N/mm^2, how high you can make a brick wall neglecting wind load.

They determine the height to be 1000 m that is 1 km. The students then can comprehend that 20 MPa is a very high stress.

It is quite difficult to comprehend the weight such as N, kN and GN. It was easy with Imperial Units such as pound (lb) and Metric Units such as kg. But in SI units it may be difficult to visualize. The author advises the students that 1 N is approximately weight of an average apple and thus 1 kN is equal to weight of 1000 apple. He also advises students that 1 N/mm^2 is like holding an apple on a tooth-pick of cross sectional area of 1 mm^2 and it is exactly equal to carrying 1 million apple on a surface area of 1 m × 1 m (1 MN/m^2). Figure 4 illustrates this clearly.

2.5 *Responsibility on the part of the faculty*

Engineering Mechanics, Mechanics of Solids and Structural Analysis are the building blocks of engineering knowledge and it is taught in the early years (first year and second year) of any undergraduate degree. Its importance makes it critical that Faculty/Schools are careful in dealing with all aspects of managing these subjects. Very often newly appointed academic staff with no or very little practical knowledge in structural

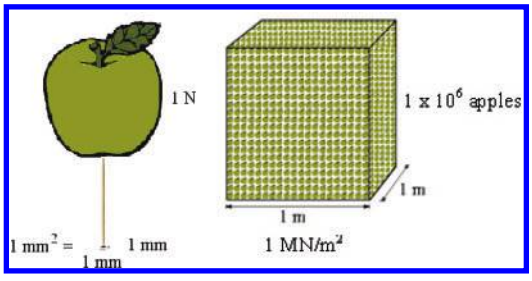

Figure 4. 1 N/mm^2 (1 MN/m^2).

design are assigned to teach these subjects and often it is found that he/she is not an effective teacher for students' learning. To become an effective teacher in these subjects one has to have knowledge and skill in design and construction of structures. These subjects should be taught and managed by senior academician who has practical experience in design and construction of structures.

In many Faculties in Australia lecture classes are very big and typically they are three hours in duration. This long duration, even with break, is not conducive to learning due to the fact that students' concentration decreases with time. Recently (Autumn 2010) in the Faculty of Engineering of UTS Engineering Mechanics (Statics), lecture duration time has been amended from one three hours class to two-two hours classes each week. There has been a marked improvement in students' learning and their performance. Number of failure has been reduced markedly from average 35% per semester previously to 21% in Autumn 2010 when the amendment has been introduced.

2.6 *Effective teaching of fundamental principles*

Lecturers teaching fundamental principles need to consider their goals very carefully in relation to student learning. A lecturer in these fundamental subjects should take into consideration of the fact that the concepts, principles and laws were developed over many centuries by scientists and engineers like Galileo, Verignon, Euler, Columbs, Newton and *et al* and it is hard for a student to grasp all those theories within one semester. Author sees his role:

- To be aware of and help students to overcome the common barriers to learning in fundamental subjects, such as engineering mechanics, mechanics of materials and structural analysis
- To motivate the students to learn the subject and to create enthusiasm and curiosity by bringing examples from real-world structures and structural members;
- To facilitate students' learning by adopting improved methods of teaching and learning: inventing, creating and devising teaching resource materials which illustrate and reinforce concepts;
- To foster students' critical thinking regarding engineering problems by providing choices based on critical assessment of alternatives;
- To create an environment in the tutorial class which is conducive to learning where students are encouraged to participate actively in the class.
- To urge students to form a positive attitude to their studies and future profession and make aware of their social responsibility in designing a structure.

2.7 *Transparencies and use of doc-camera*

The author has experience in teaching fundamental subjects with the help of chalk/markers and black/white board. It has been a successful approach for small classes for many years but it has got limitations for a large class. He has found that teaching with transparencies with the help of two over-head projectors (OHP) or using one OHP and one doc-camera is very effective. In the fundamental subjects there are many machine parts and structural elements which need to be drawn and it is time consuming to draw on the board. The structural elements and machine parts can be drawn beforehand and in the class it is placed on one OHP. The solution of the problem can be done step by step and with ease on another OHP/doc-camera. When compared to Power Point presentation, drawing and solving of problems related to parts of structure and machine on transparencies are more effective for students' learning. Thus using Power Point for these subjects should be discouraged.

2.8 *Handouts*

For conceptually difficult topics in these subjects, handouts which illustrate underlying principles with diagrams and graphics greatly enhance the learning ability of students. Handouts should not be long winded and writing should not be descriptive. In fact it is more effective if you use as little writing as possible and make sure that the topic is not fully discussed in the handout. Handouts should have blank spaces where student can write on the diagrams, sketches and photographs during the lecture.

2.9 *Models*

The usefulness of small physical models in explaining the conceptually difficult principles in Engineering Mechanics, Mechanic of Solids and Structural Analysis cannot be under estimated (Karim 1993). The author believes that these are probably the most effective teaching aids one can use to explain abstract concepts, principles and ideas. A lecturer can easily design, devise and fabricate physical models such as truss models with balsa wood and drinking straw; models of beams made of sponge; plastic rod to explain buckling of columns. A few diagrams of such models are given below (Figure 5, 6, 7 & 8).

2.10 *Practice problems*

To link the foundational learning in the classroom with the application in the real world the Author developed a number of problems (questions) which are directly related to practical engineering problems. A UNESCO

Figure 5. Eccentrically loaded member.

Figure 6. Shear in steel bolt and timber.

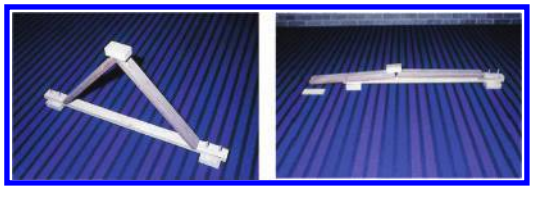

Figure 7. Horizontal and vertical shear in timber.

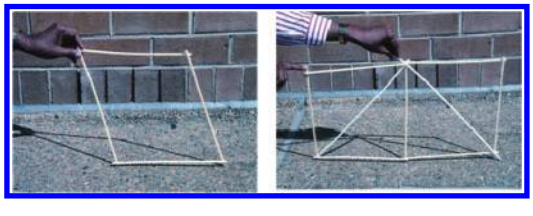

Figure 8. Construction of trusses with straw.

study (Grayson 1977) on the design of curricula has this to say:

" ..One series of studies conducted at the college level reported that 50 percent of the material known when a student finished a certain college course is forgotten within one year, and 80 percent is forgotten in two years. These students also have suggested certain conditions which can greatly reduce the amount that is forgotten. One such condition is the opportunity to use the new knowledge in daily life. This suggests that objectives concentrating on specific knowledge are more attainable, and the results are more permanent, when there are opportunities for the students to use this knowledge in their daily activities"

Figure 9. Vertical Cantilever.

Figure 10. Tension Structures (Outside class room).

Figure 11. Pedestrian Bridge: Member in tension and bending.

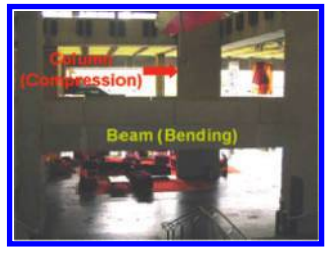

Figure 12. Frame structure (Outside class room).

The author developed some practice problems from structures in and around students' immediate environment (in and around UTS City campus). Some of these structures and structural members from the surrounding environment are given below (Figures 9, 10, 11 & 12)

3 CONCLUSION

It is important that Faculty/School of Engineering does recognize that these subjects like Engineering Mechanics, Mechanics of Solids and Structural Analysis are great important to one to become good professional engineers and senior experienced academicians should teach these subjects. Lecturers who are in charge of these fundamental subjects are to accept the fact that students experience problems in learning these subjects. Once this is recognized, the lecturer can adopt a variety of teaching strategies which make these subjects interesting and comprehensible so that learning can be effective and enjoyable. Experience has shown use of the methods and strategies described in this paper have proved successful in creating interest and enthusiasm, and the author has received consistently positive feedback from students.

Structural stability, and the complement to the differential equation

R.D. Ziemian
Bucknell University, Lewisburg, PA, USA

ABSTRACT: A fundamental understanding of structural stability is a requirement for engineers who design metal structures. Given that sophisticated computer analysis software tools are only now becoming more readily available, the teaching and learning of structural stability has been and continues to be heavily rooted in the development and solution of the related differential equations. For many structural engineering students, who may not be well versed or interested in this level of math, basic structural stability concepts are not being learned because of their perception that an understanding of structural stability requires the ability to be proficient in solving differential equations. To compensate for this and given that in-class physical laboratory testing is often impractical, faculty often resort to descriptions of experimental tests and the results obtained. Although this is a significant step in the right direction, this passive learning approach is not ideal. With this in mind, the author has developed a series of nine stability learning modules that employ readily available and relatively easy to use nonlinear analysis software. Although no statistical data has been gathered, this "virtual" laboratory experience has been in use for the past year at many universities in the U.S. and the results are very encouraging. This paper will provide an overview of these modules, including their consistent format, dissemination, and related instructional YouTube videos. A detailed description of one of the modules, including the simple finite element model employed, is also provided.

1 INTRODUCTION

With high strength-to-weight and stiffness-to-weight ratios, structural metals such as steel and aluminum continue to provide architects with unique opportunities to design elegant systems that are often distinguished by their slender form. This slenderness, however, comes with the need for designers to learn and understand essential topics in structural stability. Unfortunately, many engineering students and practitioners have linked a comprehension of stability concepts to their abilities to solve the differential equations that are often used to describe the related behavior. In cases for which a student's interest in such mathematics is not prominent, important concepts of structural stability are often deemed too difficult to learn and an inherent weakness develops in their abilities and confidence to design metal structures. In response to this, and with the overarching goal of providing students and engineers the opportunity to *see the forest for the trees* when it comes to this topic, the author has developed a series of nine learning modules in which nonlinear computational analysis is used as a virtual laboratory for learning many of the important concepts related to designing for stability. This paper will present an overview of these modules, which include topics such as elastic and inelastic flexural and lateral-torsional buckling, inelastic force redistribution, local buckling, bracing, and second-order effects. The modules have been prepared in a generic form so that many nonlinear analysis software packages could be employed. For those without access to such software or who are unsure as to whether or not their software will suffice, the author has made a nonlinear analysis program available at no cost. This software MASTAN2 (2012) is described below. Having employed these learning modules in undergraduate steel design courses, the author is convinced that the use of a virtual laboratory can significantly compliment current methods for teaching and learning important structural stability concepts.

2 BACKGROUND

The stability learning modules are intended for use in undergraduate and/or graduate level steel design, aluminum design, and/or structural stability courses. Of course, practicing engineers are also encouraged to continue their education by completing these exercises. The modules are independent of one another, and hence, faculty may employ any number of the modules depending on the objectives of their courses.

Although all of the modules can be completed with the nonlinear analysis software MASTAN2, they have been prepared in generic form so that alternative nonlinear analysis software could be employed. Each module is provided as PDF and Microsoft Word files along with accompanying Microsoft Excel spreadsheets. In addition to instructions, questions, and suggestions for further study, these files include links to YouTube videos that demonstrate the use of MASTAN2.

2.1 *Nonlinear analysis software requirements*

Understandably, the key component in this virtual laboratory approach is the structural analysis software. The analytical requirements for modeling structural stability topics may be defined in the following four general categories, with each including specific attributes.

1. Stiffness contributions:
   axial, flexural, and shear deformations
   torsion, including St. Venant and warping resistances
   connection restraint
2. Destabilizing effects:
   second-order effects, including system P-Δ and member P-δ contributions
   imperfections, including frame out-of-plumbness and member out-of-straightness
   partial yielding accentuated by the presence of residual stresses
   plastic hinges based on axial force and major- and minor-axis bending contributions
3. Solution procedures:
   two- and three-dimensional incremental and/or iterative schemes
   critical load (eigenvalue) analysis
4. Stability limit states:
   in/elastic flexural buckling
   in/elastic lateral torsional buckling
   combined in/elastic flexural and lateral torsional buckling
   in/elastic frame buckling
   plastic mechanism(s)

Several software packages are currently available that can handle most, if not all, of the above requirements. Examples of commercial programs available in the U.S. include ABAQUS, ADINA, ANSYS, PERFORM3D, LARSA4D, and SAP2000. There are also several educational programs that meet most of the above criteria, including, OpenSees, FE++2012, GTSABRE, BASP, Arcade, Dr. Frame, GBTUL, and MASTAN2. The author is confident that similar programs have been developed in other parts of the world, including Europe, Asia, and Australia. Factors to consider in deciding which software to employ include, price and availability to students, ease of use and steepness of original learning curve, experiences from other courses that may also make use of analysis software, and which of the stability learning modules are to be accomplished.

2.2 *MASTAN2*

To assure that the stability learning modules can be completed with a minimum amount of overhead to the faculty member and his/her students, the author has made the nonlinear analysis software MASTAN2 available via a web download at no cost. This software is PC and Mac compatible and does not require any third-party software; although it can also be executed on any computing platform in which MATLAB (2013) is available.

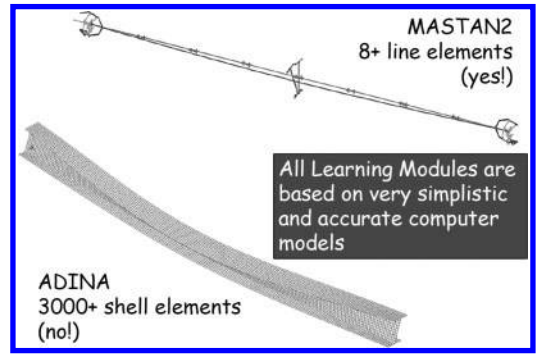

Figure 1. Example of a MASTAN2 model used to learn about in/elastic lateral torsional buckling.

The MASTAN2 software provides an easy to use graphical user interface and all of the analysis capabilities defined in the previous section. To do so, the program employs 14 d.o.f. line elements that include axial, bending, shear, and torsion (both St. Venant and warping) resistances. Second-order effects are modeled through the use of element geometric stiffness matrices and an incremental/iterative solution scheme based on an updated Lagrangian formulation (McGuire *et al.* 2000). A concentrated plasticity model, with a yield criterion that is a function of axial force and major- and minor-axis bending, is used to model material nonlinearity. An additional analysis parameter may be set to invoke a modified tangent modulus approach (Ziemian & McGuire 2004) that will closely approximate partial yielding accentuated by the presence of residual stresses.

To the best of the author's knowledge, all of the universities currently assigning the stability learning modules employ MASTAN2, although its use is not a requirement. It is important to note that very simple finite element models are needed when using MASTAN2 to complete the learning modules (Figure 1).

2.3 *Format of modules*

All of the learning modules are presented in a consistent format. An overview of each module is first provided followed by the learning objectives. The general method for which the objectives will be attained is presented followed by details specific to the use of MASTAN2. A series of questions is then provided to guide the students in thinking critically about what should have been observed in the analytical study. All modules conclude with a section titled *More Fun with Computational Analysis!*. This component provides the student direction for additional studies that can be used for more breadth and/or in-depth understanding of the concepts being learned. All modules also include references to instructional YouTube videos, related literature, and prepared Microsoft Excel spreadsheets to assist with data recording.

All of the modules reference the American Institute of Steel Construction's (AISC) *Specification for Structural Steel Buildings* (2010). Original Microsoft Word and Excel documents are provided for all learning modules thereby allowing them to be easily modified for other non-U.S. steel building codes.

3 OVERVIEW OF LEARNING MODULES

The following nine modules are currently available at the MASTAN2 website or through the American Institute of Steel Construction's Partners in Education website (www.aisc.org). Faculty members may obtain solutions to the learning modules by contacting the author.

3.1 *LM1: Elastic column buckling and the effect of end restraint*

Using critical load (eigenvalue) analyses, the elastic flexural buckling strength of a system of parallel columns with various degrees of end restraint is investigated. By creating an analysis model of six parallel columns that only differ in end restraint (Figure 2), students experience first-hand the changes in column capacities and respective buckling modes that result from varying the support conditions. Students confirm the theoretical effective length K-factors that are given in the literature, including Table C-A-7.1 of the Commentary on the AISC *Specification for Structural Steel Buildings* (2010).

3.2 *LM 2: Factors influencing the flexural buckling strength of compression members*

Using computational analysis as a virtual laboratory, the main factors that impact the in/elastic flexural buckling strength of steel wide-flange sections with nonslender elements are investigated. These factors include member slenderness, material nonlinearity, initial imperfections in geometry (out-of-straightness), and partial yielding accentuated by the presence of residual stresses. Computed strengths are presented in the form of column curves (Figure 3), which are further compared with the corresponding nominal strength curve defined in Chapter E of the AISC *Specification for Structural Steel Buildings* (2010). In completing this study, students further recognize the limitations of the theoretical Euler buckling solution and gain an appreciation of the impact that initial imperfections and partial yielding/residual stresses have separately and collectively on the flexural buckling strength of a column.

3.3 *LM3: Effective length K-factors for frame members*

By preparing and investigating a computational model of a one-story, one-bay planar frame, effective length K-factors for compression members in structural systems are investigated. In addition to studying cases of sidesway inhibited and not inhibited, elastic and inelastic buckling is explored. The computational results are compared with alignment chart methods, thereby allowing the student to assess the applicability of the assumptions made in developing the alignment charts.

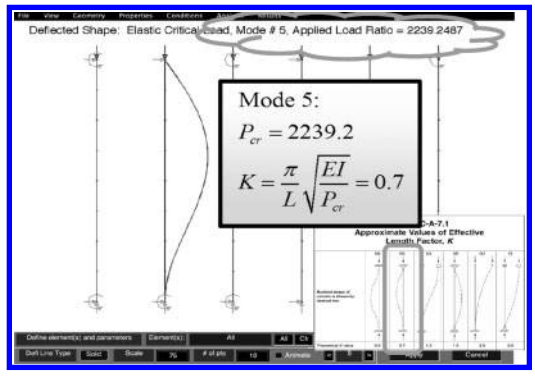

Figure 2. Example results from LM1.

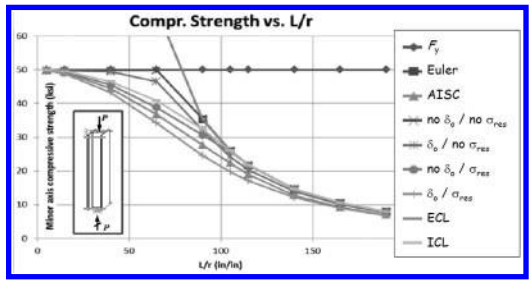

Figure 3. Column capacity curves obtained as part of LM2.

3.4 *LM4: Factors influencing the strength of flexural members*

Using an approach very similar to LM2 and the computational model shown in the upper right portion of Figure 1, the main factors that impact the major-axis flexural strength of an unbraced steel wide-flange section with compact elements are investigated. These factors include unbraced length, partial yielding accentuated by the presence of residual stresses, and initial imperfections in geometry (out-of-plane out-of-straightness). Strength limit states defined by full yielding of the cross-section (plastic hinge) and in/elastic lateral torsional buckling are studied. Computed strengths are presented in the form of beam strength curves (Figure 4), which are further compared with the corresponding nominal strength curve defined in Chapter F of the AISC *Specification for Structural Steel Buildings* (2010).

3.5 *LM5: Lateral-torsional buckling of beams with moment gradient*

The influence of a non-uniform moment distribution on the lateral-torsional buckling capacity of compact wide-flange beams is studied. Equivalent uniform

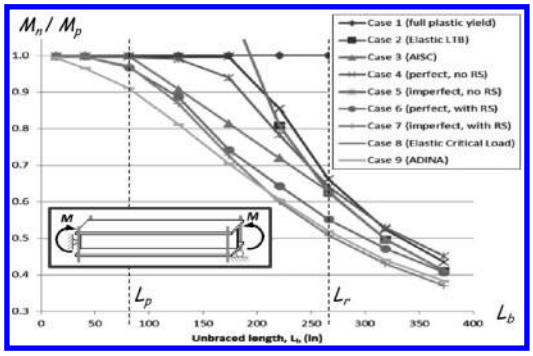

Figure 4. Beam capacity curves obtained as part of LM4.

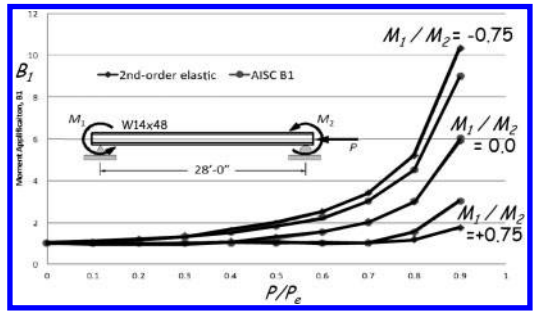

Figure 5. Moment amplification curves obtained in LM7.

moment C_b factors back-calculated from computational analyses are compared with values computed using two longstanding equations, one appearing in Chapter F of the AISC *Specification for Structural Steel Buildings* (2010) and the other in the commentary to the Specification. In addition to investigating several different possibilities of moment gradient, including linear, bi-linear, and parabolic, the impact of providing an interior brace point is also studied.

3.6 *LM6: Continuous beam design by elastic and inelastic analyses*

The design of a three-span laterally braced beam of compact section is investigated using elastic and inelastic analyses. In addition to observing differences in load carrying capacity and efficiency, force and moment redistribution as a result of member yielding is explored. In this learning module, students "compete" against one another in two categories to see who can provide the least weight design for a given load condition. The categories are (1) same section size for all three spans of the continuous beam, and (2) different section sizes may be used in each of the three spans.

3.7 *LM7: Second-order (P-Δ and P-δ) effects*

In this learning module, second-order effects in members subject to the combined effect of compression and flexure (beam-columns) are investigated. Results obtained using rigorous second-order elastic analyses are compared with approximate moment amplification factors given in Appendix 8 of the AISC *Specification for Structural Steel Buildings* (2010) and recommended in the literature. Both frame sway P-Δ and member deforming P-*δ* effects are studied.

Emphasis is placed on the relationship between the amount of moment amplification B_1 in a member and the ratio of axial force resisted to elastic critical load, P/P_e. Students also investigate the impact that single or double (reverse) curvature bending has on the degree of moment amplification (Figure 5).

3.8 *LM8: Strength of Beam-Columns*

Students employ second-order inelastic analyses to study the capacity of beam-columns subject to various

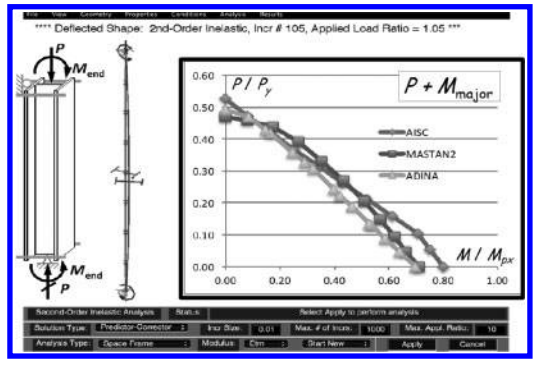

Figure 6. Beam-column capacity curves obtained in LM8.

combinations of axial force and bending moment. Both major- and minor-axis flexure of steel wide-flange sections with compact elements are investigated. Nominal strength interaction curves per the requirements of Chapter H of the AISC *Specification for Structural Steel Buildings* (2010) are compared with equivalent curves based on finite element analysis results (Figure 6). Strength limit states defined by in/elastic flexural and lateral torsional buckling as well as full yielding of the cross-section (plastic hinge) are observed. In all cases, computational analyses account for partial yielding (accentuated by the presence of residual stresses) and initial imperfections in geometry. LM8 is the logical extension of LM2, which studies the strength of compression members, and LM4, which explores the strength of flexural members.

3.9 *LM9: Design by the direct analysis method*

This learning module guides the student through the design of a simple portal frame using a relatively new approach termed the Direct Analysis Method, which is defined in Chapter C of the AISC *Specification for Structural Steel Buildings* (2010). Rigorous second-order analyses are employed to check the adequacy of compact doubly symmetric members subject to axial force and flexure.

The module includes two methods for accounting for initial frame sway imperfections and stiffness reduction due to partial yielding. These methods

include explicit modeling and the use of equivalent notional loads. Students gain competency in using code-based interaction equations to check the adequacy of beam-column members. The use of second-order to first-order drift ratios is also assessed as an indicator of a system's sensitivity to second-order effects.

4 EXAMPLE

The specific details for Learning Module 7 – *Second-order (P-Δ and P-δ) Effects* are provided below. Due to space limitations, the tables and figures are not included herein. Similar details are provided for all of the stability learning modules described above.

4.1 *Overview*

The design of a laterally braced beam of compact section is investigated using elastic and inelastic analyses. In addition to observing differences in load carrying capacity and efficiency, force and moment redistribution as a result of member yielding is explored.

4.2 *Learning Objectives*

- Employ rigorous second-order elastic analysis to determine required strengths in beam-columns.
- Observe the relationship between the amount of moment amplification in a member and its ratio of axial force to elastic critical load.
- Investigate the impact single or double (reverse) curvature bending has on the degree of moment amplification.
- Compute and assess the moment amplification factor B_1 defined in Appendix 8 of the AISC *Specification for Structural Steel Buildings* (2010).

4.3 *Method*

Part 1: Prepare a computational model of the beam-column, assuming the member is a W14x48 (A992) oriented for major-axis bending and fully braced out-of-plane. Varying the amount of axial force P, employ rigorous second-order elastic analysis to complete the provided tables for the three M_1/M_2 ratios given in the header of each table. In addition to computing the amount of amplification observed $|M_{max}|_{span}/|M_{max}|_{end}$, calculate the corresponding moment amplification factor B_1 defined in Appendix 8 of the AISC *Specification for Structural Steel Buildings* (2010).

Part 2: Prepare computational models of a second set of beam-columns, assuming once again that the members are W14x48 (A992) oriented for major-axis bending and fully braced out-of-plane. Perform the rigorous second-order elastic analyses required to complete the tables provided at the end of the module.

Hints:

- Suggested units are kips, inches, and ksi.
- Do not include initial imperfections such as member-of-straightness.
- Do not include the self-weight of the member.

4.4 *MASTAN2 details*

Per a figure provided in the module, the following suggestions are for those employing MASTAN2 to complete the above studies:

- In several cases, the maximum moment may occur at any point along the member span. Thus, it would be ideal to have an element end (node) at every location. Given that this is impossible, subdividing the member into 10 elements should provide adequate sampling points.
- By leaving $A_{yy} = \text{inf}$ and $A_{zz} = \text{inf}$ when defining the section properties, shear deformations are neglected.
- For the second-order elastic analyses, use the following options:
  - Planar frame analysis type
  - Solution type: Predictor-Corrector for $P/P_e < 0.6$ and Work-Control for $P/P_e > 0.6$
  - Load increment size of 0.1
  - Maximum number of increments set to 100
  - Maximum applied load ratio set to 1.0

4.5 *Questions*

Samples of the seven questions provided in Learning Module 7 are provided below.

1. Prepare a single plot that illustrates the relationship between P/P_e (abscissa) and the amount of moment amplification (ordinate) recorded in the data tables. For each of the three moment gradient M_1/M_2 cases, provide two curves; one for the computational ratio $|M_{max}|_{span}/|M_{max}|_{end}$ and the other based on the B_1 factor. *Note to reader – the solution is provided previously in Figure 5*. Comment on the accuracy of the approximate moment amplification B_1 factor. For which moment gradient M_1/M_2 case does the approximate B_1 factor provide the most accurate results? With this in mind, which term in the B_1 equation is most likely the greatest source of error?
2. To confirm the accuracy of the analysis software you employed, please compare the data recorded in the tables with those presented in Figs. C-C2.2 and C-C2.3 of the Commentary to the AISC *Specification for Structural Steel Buildings* (2010). Did your analyses include or neglect shear deformations? Why does AISC provide two sets of results (including and excluding shear deformations)? With this in mind, does the analysis software you employed provide an adequate degree of accuracy to meet the requirements defined by the benchmark problems and solutions given in the AISC Commentary?

4.6 *Additional resources*

This section contains electronic links to (1) a Microsoft Excel spreadsheet to assist with data recording; (2) a

six-minute YouTube video demonstrating the module; (3) the AISC *Specification for Structural Steel Buildings and Commentary* (2010); and (4) the MASTAN2 website.

5 FUTURE DIRECTIONS

There are currently three additional stability learning modules under development. Two of these will be based on frame analysis software such as MASTAN2 and will include investigations of leaning columns and exercises for understanding column and beam bracing. The third module will investigate the stability of cross sections with slender elements (flanges and webs) and will be based on CUFSM, which is computational software based on the finite strip method (Schafer & Ádány 2006) and is also available for download at no cost.

6 SUMMARY

Over the past twenty-five years, the author has learned, both first hand and from many other steel design educators worldwide, that students are not learning (and in some cases not being taught) basic structural stability concepts because of what is perceived as a dual requirement of being proficient in formulating and solving differential equations. In response to this misconception, this paper presents an overview of a series of nine learning modules on structural stability that are based on readily available and easy to use nonlinear finite element analysis software. An additional focus of the modules is to provide a "virtual" laboratory in addition to or as an alternative to more costly (both financially and setup time) physical experiments. The modules have been in use for the past year in undergraduate and graduate school course at many universities in North and South America. Although no statistical data has been formally gathered, the general response to the use of these "hands-on, learn by doing" modules has been very positive in regard to comprehension and retention of fundamental structural stability concepts. In all regards, the author encourages the reader to contact him with comments or to make suggestions for other stability related modules.

International master program in structural engineering at Leipzig University of Applied Sciences (HTWK Leipzig)

K. Holschemacher & U. Quapp
Faculty of Civil Engineering and Architecture, Leipzig University of Applied Sciences, Germany

ABSTRACT: Internationalization has become an increasingly important topic in higher education systems. However, academic globalization can only be achieved by offering courses of studies in English language. The Faculty of Civil Engineering and Architecture at Leipzig University of Applied Sciences took the initiative and created an International Master Program in Structural Engineering. Intention was to generate a course of studies which brings students together from all over the world to study structural engineering in English language. This paper provides information about the International Master Program in Structural Engineering at Leipzig University of Applied Sciences. It informs about development, structure, curriculum and partners.

1 INTRODUCTION

Academic Globalization in Europe has been under way since the Declaration of Bologna in 1999 whose objectives were permeability, higher transparency and acceptance of university degrees across Europe (German Rectors' Conference 2004). But also students from outside of Europe are of interest for German universities. This has been driven by the desire to get a larger share of the academic cake which the major receiving countries of academic mobility, namely the USA and Great Britain, divide up among themselves (Michel-Quapp & Holschemacher 2009).

The most important reason for many students using the chance of academic mobility is to improve their language skills, mostly English language skill. Therefore, a university which is not offering programs in English language is less attractive for foreign students. This was the motivation for the Faculty of Civil Engineering and Architecture at Leipzig University of Applied Sciences to offer an International Master Program in Structural Engineering to students from all over the world.

2 INTERNATIONALIZATION AT GERMAN UNIVERSITIES

One important measure in universities' internationalization strategies is to increase the percentage of foreign students. In the last years, the number of foreign students at Faculty of Civil Engineering and Architecture continuously increased. Now, the Faculty has more than 20 percent foreign students. The main reason for this is a part-time study course in civil engineering which is running in the neighbored country Austria. Its advantage is a high number of foreign but German speaking students. Students from other foreign countries are rather rare. This is caused by universities' high language requirements and the bad students' German language skill. Fewer and fewer students are speaking German language as the first foreign language. Even in countries in which traditionally German language was taught in school such as Eastern Europe or Vietnam, the importance of the German language is decreasing.

Regarding the degree structure, Germany is well prepared for students from all over the world. As a consequence of the Bologna Process, comparable degrees like bachelor and master were implemented during the last years. In Germany, the former first cycle degrees leading to the degree *Diplom-Ingenieur* with duration of four or five years was replaced by bachelor programs with duration of three or four years and master programs of one or two years (Standing Conference of the Ministers of Education and Cultural Affairs of the Länder in the Federal Republic of Germany 2010). Most of the German universities decided for three years' bachelor and two years' master programs or 3.5 years' bachelor and 1.5 years' master programs.

One of the problems German universities have regarding internationalization is the lack of English-speaking lecturers. So, it was not a matter of course that language skills played a role in appointment procedures for professorships or lectureships in the last years. Although universities now pay more attention on language skills of applicants there is still a high number of lecturers who are not able to give courses in English language. This fact leads to difficulties for

a higher education institution to develop a course offer for English-speaking foreign students.

3 PROGRAM INFORMATION

3.1 *Development*

The intention of the Faculty of Civil Engineering and Architecture of Leipzig University of Applied Sciences was to create a program which is not too specialized to be attractive to plenty of students worldwide. Thus, a master in structural engineering seemed to be the right decision. Beside the long faculty's tradition in structural engineering, one of the reasons for creating a master in the field of structural engineering was the great similarity of structural engineering standards used all over the world. Thus, students will be able to apply their new acquired knowledge in all fields of building industry worldwide.

One difficulty in creating an English-speaking structural engineering master program was the small number of structural engineering professors with sufficient English language skills to give courses with. Finally, five professors and the same number of scientific staff members have been willing to engage in this course of studies.

As mentioned before, in Germany a master program lasts from one to two years. In each academic year, students must have the possibility to award 60 credit points according to the European Credit Transfer and Accumulation System (ECTS), while credit points will be awarded for each successful completed course. 60 credit points correspond to 1800 students' working hours (Standing Conference of the Ministers of Education and Cultural Affairs of the Länder in the Federal Republic of Germany 2010). This is plenty of work for the faculty as well as for the students.

The program started in 2010 in cooperation with the first partner which was a partner university in China. In October 2012, the HTWK Leipzig welcomed already students from two nationalities in Leipzig. The study course is supported by an institute for international higher education cooperation that takes care of all organizational issues.

3.2 *General information*

The master course in structural engineering is a two-year's master program offered to students pursuing a specialization in structural engineering. In close cooperation with partner universities the academic education is organized in a 1 year plus 1 year model. The first year must be completed at the home university of the students in accordance with the curriculum of the program. After passing all courses of the first year, students spend the second year at Faculty of Civil Engineering and Architecture at Leipzig University of Applied Sciences. There, all remaining courses must be finished and the master thesis must be elaborated. After successful completion of all courses, the academic degree Master of Science "M.Sc." of Leipzig University of Applied Sciences is granted.

The program is offered only in cooperation with partner universities. These universities teach all first year courses in accordance with the curriculum developed by Leipzig University of Applied Sciences. This is necessary because the second year courses base on the knowledge students gained in the first year at home.

3.3 *Curriculum*

The course content of International Master Program in Structural Engineering covers advanced topics of civil engineering with the focus on structural engineering. It consists of two different kinds of courses, compulsory and elective courses. Both were executed as lectures, tutorials, seminars or practical trainings including computer work and accompanied by individual studies, tutorial tasks and course works. The program contents base on regular civil or structural bachelor programs, for this reason only few scientific basics such as mathematics, material sciences and building physics are taught. Teaching materials will be of course offered in English language.

While the first year, students follow the courses at their home university. There, subjects like numerical methods, Finite Element method and surface structures I, prestressed concrete construction, spread foundation, bridge design, composite structures and structural dynamics are taught. Within this year, students must select five elective courses from the elective subject pool including modern and historical building materials, construction materials and environment, energy efficient and environmentally compatible building, glass and plastic materials for structural engineering, selected topics in steel structures, selected topics in reinforced concrete, three dimensional concrete structures and precast concrete structures.

The second year students spend at Faculty of Civil Engineering and Architecture at Leipzig University of Applied Sciences. Students have to attend courses in Finite Element method and surface structures II, selected topics of structural mechanics, experimental mechanics, reinforced concrete structures and fire protection in structural engineering. Courses completed at the home universities and marks of the first year are recognized at Leipzig University of Applied Sciences.

The improvement of the students' English language proficiencies is one of the aims of the program. That's why students must attend English lessons for the first 1.5 years. While the English courses the focus is on academic English, with the intention to train students in various subject-specific terms in the field of civil and structural engineering as well as in academic writing in the foreign language.

The study program will be completed by passing the final examination, which means a master thesis and a colloquium. For preparing the master thesis 675 students' working hours are necessary, for preparing the colloquium 225 hours. That's why in the fourth

semester no other courses are offered. The intention is that students focus on their master thesis. While preparing the master thesis, students are part of a professor's research team with the possibility to do experiments by their own, to produce specimens made of concrete and so on. In this way students gain research experience and work scientifically as well as practically.

Small groups, currently 15 students, allow the lecturers to work individually with the students. Problems of understanding can be solved quickly and directly. So, students have more benefit from the classes.

Between the arrival in Leipzig and the start of the lessons, a free two-week's German language and regional cultural studies course is offered to the students by the Leipzig University of Applied Sciences. Most of the students are enthusiastic about the German language and continue their German language training at their own expense.

3.4 *Admission regulations*

The program is offered only in cooperation with partner universities. That's why only students from partner universities can apply for the program.

To study the program, applicants must hold a bachelor degree or higher in civil or structural engineering after studying at least three years on university level (Leipzig University of Applied Sciences 2011). For students from various countries like China there is a requirement for a bachelor degree with at least four years study time. This requirement results from the specialty of Chinese Curricula to include interdisciplinary courses such as politics, sports etc. with the consequence of less time for subject-specific courses.

If foreign partner universities award a degree higher than a bachelor degree, some courses can be recognized on the master curriculum. If all courses of the first master's year will be offered in this degree higher than a bachelor degree, students can get recognized the completed courses. The advantage for students is the possibility to be enrolled directly to the second master's year in Leipzig without spending the first master's year at the home university. In this case the recognition of courses is concluded in a written equivalency agreement between the foreign partner university and the Leipzig University of Applied Sciences. For this reason, the program manager of Faculty of Civil Engineering of Leipzig University of Applied Sciences compares the program contents and decides about courses to recognize.

Additionally to the subject-specific qualification, students must prove sufficient English language skills. Non-native English speakers have to verify the level of their language proficiency by TOEFL Test (Test of English as a Foreign Language) or by an equivalent recognized English language test. These language requirements are necessary to guarantee ideal conditions for a successful completion of the degree. Without sufficient language proficiency students can't follow the lectures and are not able to deliver their best performance in examinations.

3.5 *Organizational information*

The program is offered in cooperation with a university institute for international education cooperation. The institute provides support for universities interested in offering international courses of studies.

Important in an international program is, aside from the academic service, also a comprehensive service in all administrative and organizational issues for the international students.

The international students studying in this program often haven't got any or very limited German language proficiency. Therefore, they need support in all organizational things like visa application, insurances, accommodation, transport from the airport and bureaucratic procedures. The institute cares about all students' matters not connected with academic issues. Its stuff accompanies them to the doctor, to the foreigner's registration office, to the bank and so on.

3.6 *Fees*

The academic as well as the full students' service provided by Leipzig University of Applied Sciences and the University Institute for International Education Cooperation is subjected to charges. Currently, the service fee is about 13.200 Euros (18.000 US-Dollars). Included in this fee are all courses and examinations, experiments, the master thesis, the colloquium etc. Furthermore, organizational support such like transport from airport to the dormitory and first equipment package containing food and beverages and so on in the rooms of the dormitory are covered. Additionally, all foreign students must prove to the foreigner's registration office that they can cover living costs of one year. This will be done by a bank deposit. From the bank deposit the rent for the dormitory rooms, the rent deposit, health and liability insurance, fees for residence permit and membership fees for student organization will be paid. From the remaining amount of money on the bank account the student can withdraw money for covering all other personal living costs. After leaving Germany, students will get back the rent deposit.

3.7 *First experience*

In the year 2010, the first group of this program started at the first partner university in China. One year later, these 15 students were welcomed at Faculty of Civil Engineering and Architecture in Leipzig to their program's second year.

Very quickly the first group became familiar with the German life and the procedures at the university. The entire program's staff was surprised about the high activity and independence of the international students. In their free time they traveled around Germany and Europe, continued learning the German language at their own expense and came in contact with other students.

The marks of the examinations after one term were better than expected. Only two students had to repeat an examination. From the first group of 15 students 6 students graduated in 2012. The other students decided to take more time to prepare the master thesis. They will graduate some weeks later.

Also, some leisure time activities were offered to the International students. One of the highlights was a table tennis championship with students, lecturers and academic staff.

In 2012, a Syrian university joined the program and sent some students for the second group. The relationship between Chinese students and Syrian students is friendly and relaxed.

Currently, the faculty is in negotiation with some more interested universities of cooperating in this program.

4 CONCLUSION

Internationalization can work, even if universities do not have a plenty of human or financial resources. Necessary are good concepts, experienced partners and much enthusiasm. The majority of universities already discovered the potential of and the need for internationalization in a globalized academic world.

The future lies in international programs in English language. There is no better and easier way to bring foreign students to universities than International programs. The organizational and academic efforts-benefits-ratio is much higher in the International course of studies than for each individual foreign student coming e.g. with Erasmus program.

With English speaking staff, motivated lectures and intercultural openness everybody, students as well as university staff, will benefit from such a program.
